Lithium alloys with heavy metals (such as the Wood's alloy) change their specific volumes during cycling to a lesser extent as compared with lithium–aluminium alloys. Matsushita Electric Industrial Co. has developed several versions of secondary cells with electrodes based on lithium alloys with heavy metals. Specific characteristics of these batteries were very low, and these alloys were considered to be of little promise.

V. Lithium-ion rechargeable batteries

1. General information

The publications reporting the secondary cells with negative electrodes of carbon materials developed in Japan marked a revolution in the field of rechargeable lithium batteries.^{14–17} Carbon was shown to be a very convenient matrix for intercalation of lithium. The specific volumes of many graphitised materials changed by no more than 10% upon insertion of sufficiently large amounts of lithium.¹⁸

The potential of carbon electrodes which contain moderate amounts of intercalated lithium can be 0.5–0.8 V more positive than the lithium electrode potential. To make the cell's voltage sufficiently high, Japanese researchers used cobalt oxide as the active material for positive electrodes. The potential of lithiated cobalt oxide was ~4 V vs. lithium electrode; the working voltage of the cell was 3 V.

During the discharge of this cell, lithium is deintercalated from the carbon material (on the negative electrode) and is intercalated into the oxide (on the positive electrode). The charge involves the reverse processes. Thus, the system contains no metallic (zero-valent) lithium, and its charge and discharge processes simply involve the transfer of lithium ions from one electrode to another. These rechargeable batteries were named lithium-ion,¹⁴ 'rocking-chair'¹⁹ and 'swing'²⁰ cells.

Figure 1 shows the scheme of performance of a lithium-ion battery. On the left, a negative graphite electrode is shown. Its structure is characterised by the presence of layers (conditionally shown as hexagonal fragments) between which lithium ions (black points) can be inserted. On the right, the positive electrode of lithium manganese spinel with a structure that can intercalate lithium ions is shown. Lithium salts in non-aqueous solvents are used as the electrolyte. During the charging of the cell, in the external circuit, an electronic current flows from the positive electrode to the negative one, whereas inside the cell, an ionic current flows also from the positive electrode to the negative one.

Since the appearance of first publications on the development of lithium ion batteries,^{14–17} active research into the intercalation of lithium into carbon and the other materials commonly used for the positive electrodes has started. To date, the publications on

this subject number in the hundreds and involve several reviews.^{19, 21–28}

2. Examples of lithium-ion batteries

In 1991, Moli Energy Ltd elaborated the specimen of lithium-ion batteries shaped as disks (coins).²⁹ A cell of the 1225 size⁸ had a capacity of ~7 mA h and a cycle life of ~300 charge–discharge cycles at a discharge current of 1 mA and a charge current of 0.5 mA.

Of Japanese firms, the leading position in the production of lithium-ion cells belongs to Sony which produces lithium-ion cells of various types, not only coin cells but also cylindrical ones of a spiral design and prismatic cells. Its annual production exceeds 10 million cells.³⁰ Sanyo Electric Co. holds the second position. Matsushita Electric Industrial Co. also has a large-scale production. In addition, six to eight other Japanese firms have just entered the market of lithium-ion batteries.

Since 1994, Sony has arranged the production of rechargeable batteries with sufficiently stable characteristics. The cells of AA size (according to Japanese nomenclature, US 14500) with a weight of 19 g, a rated capacity of 500 mA h at a voltage of 3.6 V are most representative. The manufacturer guarantees their performance in temperature ranges from –20 to +60 °C (discharge) and from 0 to +45 °C (charge). The energy density of these cells was ~95 W h kg^{–1} or 222 W h dm^{–3}. Cells of larger sizes had somewhat higher energy densities: *e.g.*, for cells of size 16 630 and 18 650 the energy densities were 105 and 126 W h kg^{–1} (or 250 and 290 W h dm^{–3}), respectively. Under the usual storage conditions, the self-discharge of the cells was ~10% in three months.²¹

The greatest rated capacity equal to 2800 mA h was demonstrated by a cylindrical cell of the size 26 650 weighing 83 g.

A discharge under a 1 h high-current mode reduced the capacity of Sony cells only insignificantly. The manufacturer guarantees cycle life of 500 charge–discharge cycles at only a 20% capacity fade.

In Japan, in addition to the development of lithium-ion cells of small sizes, attention has focused on elaboration of large-size rechargeable batteries, which can be used for both electrical vehicles and load distribution between autonomic nets. Since 1992, the studies have been carried out in accordance with the 'New Sunshine' program, which was intended to be accomplished in ~10 years with a total financing of ~\$140 mln (USA). This programme scheduled the development of two versions of rechargeable cells, *viz.*, batteries with medium energy densities (up to 140 W h kg^{–1}) designed for long-term service (the cycle life of 3500 charge–discharge cycles) and batteries intended for a short cycle life (500 charge–discharge cycles) but displaying enhanced energy densities (up to 180 W h kg^{–1}).^{31, 32}

In other countries, the industrial output of lithium-ion batteries ranks far below that in Japan; however, certain companies intend to substantially increase the production of these secondary cells.

In the USA, the engineers of Rayovac Corp. have developed specimens of both coin and cylindrical cells.²² Coin cells of the 1225 size were characterised by energy density of 35 W h kg^{–1} or 115 W h dm^{–3}. These characteristics rank substantially below those of the cylindrical cells produced by Sony, which is explained by the fact that the effectiveness of using the cell's mass and volume are different for small and large batteries (the share of casings and other structural elements in the cell's total weight is higher in coin cells as compared with cylindrical cells). The monthly self-discharge in these cells is ~5%, which is comparable with the characteristics of Japanese cells. Engineers of Rayovac

Figure 1. A scheme of performance of lithium-ion rechargeable batteries.

§ The designations of sizes of coin cells comprise the numbers that signify their diameters (in millimetres) and heights (thickness, in tenths of a millimetre). For instance, a cell of the 1225 size has a diameter of 12 mm and a thickness of 2.5 mm.

Corp. intend to organise the production of prismatic cells with an energy density approaching $\sim 130 \text{ W h kg}^{-1}$. Being designed for a long-term discharge (and charge) by small currents, the first version of these cells should demonstrate an enhanced capacity. The second version is designed to have a lower capacity and withstand high-current discharges and charges.

Bellcore (USA) has undertaken great efforts in the development of lithium-ion batteries.^{33,34} Their cell prototypes of the AA size with a capacity of 380 mA h (*i.e.*, lower as compared with similar batteries made by Sony) were, however, capable of discharging in a 20-min mode[¶] without substantial capacity loss ($< 20\%$).

Prismatic lithium-ion batteries developed by Yardney Corp. (USA)³⁵ exhibited capacities of 3 A h and energy densities of 87 W h kg^{-1} or 225 W h dm^{-3} .

SAFT (France) have completed the preliminary stage in the production of lithium-ion batteries to be used in both communication facilities and electric vehicles.^{36,37} The energy density of such a battery was $125\text{--}150 \text{ W h kg}^{-1}$ with discharge by low currents and $90\text{--}135 \text{ W h kg}^{-1}$ at a high-current discharge. In the latter case, the power density was $190\text{--}200 \text{ W h kg}^{-1}$. A decrease in the temperature to -30°C resulted in a $20\%\text{--}25\%$ decrease in the capacity, the cycle life was assessed to be ~ 400 charge–discharge cycles.

Large-size lithium-ion batteries (capacity from 40 to 100 A h) are being elaborated by engineers of VARTA (Germany).³⁸ The characteristics of the developed prototypes are still not too high: the energy density of a cell with a capacity of 100 A h was $50\text{--}70 \text{ W h kg}^{-1}$ for a 2 h discharge mode and $\sim 30 \text{ W h kg}^{-1}$ for a 30 min discharge mode. The capacity of the cells substantially decreased with cycling, which, apparently, is associated with the scale factor.

VI. The main problems in the development of lithium-ion batteries.

1. Materials for negative electrodes

The lithium-into-graphite intercalation compounds (layered graphite compounds) have been known for a long time (see, *e.g.*, Ref. 39). In the 1970–1980s, the reversible intercalation of lithium into graphite and certain other materials from lithium salt solutions in aprotic solvents was extensively studied.^{40–46} The very first studies on the reversible lithium intercalation have shown that lithium intercalation into carbon materials is a complex process with the mechanism and kinetics largely dependent on the choice of carbon material and the electrolyte. Whereas the effect itself was quite evident, however, the results of different authors on its mechanism appear to be extremely contradictory. Even now, an important question remains open as to which properties (structure, electronic structure, the presence of impurities, *etc.*) of carbon materials determine the intercalation and deintercalation processes.

Despite the uncertainty mentioned above, certain simple relationships and phenomena have been established unambiguously. Thus it was found that, upon the first contact of an aprotic electrolyte with a carbon material (irrespective of its structure), the latter acquires a potential in the range from 2.5 to 3.5 V *vs.* lithium electrode, the value being determined by the presence of compounds with certain chemical groups (first of all, oxygen-containing groups) in the electrolyte. At a cathodic polarisation, the potential shifts to negative values, and slow intercalation of lithium begins. Simultaneously, the electrolyte is reduced (both the solvent and different impurities), and this reaction proceeds much more easily (at less negative potentials) on the surface of carbon material as compared with the metallic lithium surface.

Being partially insoluble, the reduction products form a film of the carbon material surface. This film is similar in composition and properties to the passive film formed on the lithium surface. Thus, during the first charge, electricity is consumed in both lithium intercalation and passive-film formation. A completely formed film prevents direct contact between the electrolyte and carbon, thus virtually eliminating further reduction of the electrolyte.

The second undeniable fact is that the carbon material structure affects the mechanism of lithium intercalation. As a rule, intercalation of lithium into well pronounced graphite structures results in the formation of a thermodynamically stable compound, namely, LiC_6 . In this compound, the lithium activity is equal to unity, *i.e.*, the potential of such a compound is equal to that of a lithium electrode. The majority of authors represent intercalation–deintercalation by the following equation:

The dependence of the Li_xC_6 potential on the degree of intercalation x (*i.e.*, the charge curve of a graphite electrode) was shown to have several almost horizontal steps corresponding to the following compounds: LiC_6 , $\text{Li}_{0.5}\text{C}_6$, $\text{Li}_{0.33}\text{C}_6$, *etc.*⁴⁵ Intercalation of lithium into graphite structures occurs at negative potentials (the main part of lithium is intercalated at a potential more negative than 0.5 V), *i.e.*, the activity of lithium in such intercalates is sufficiently high. On the one hand, this is an advantage, because the cell voltage increases; however, on the other hand, this is a drawback, because the reduction of electrolytes on these intercalates proceeds more actively than on non-graphitised samples. Moreover, intercalation of lithium into graphite structures is often accompanied by co-intercalation of the solvent, which leads to swelling and exfoliation of graphite.

Intercalation of lithium into amorphous structures occurs at more positive potentials, as a rule, in the range from 0.9 to 0.0 V. In this case, x *vs.* potential plots represent smooth curves typical of uniform systems. Nongraphitised structures do not exfoliate during intercalation of lithium.

Numerous studies were devoted to elucidation of how the potential variation depends on the degree of intercalation x (thermodynamics of the intercalation process) (see, *e.g.*, Refs 18, 29, 45–48). It was shown that the dependence of the activity of intercalated lithium on its content has a complex form, its mechanism still being a subject of speculation.

Different scientists tried to find a correlation between the structure of carbon materials and their abilities to intercalate lithium reversibly. This correlation is still not established conclusively. Controversial assumptions have been drawn on this subject. For instance, it was supposed⁴⁹ that reversible intercalation is possible exclusively into materials with the well pronounced graphite-type crystal structure and is unfeasible for amorphous materials. In contrast, it was also proposed⁵⁰ that lithium is intercalated only into amorphous materials. Probably, the optimum materials should possess amorphous matrices with mesophase inclusions, *viz.*, nuclei of graphite crystals. These materials are represented by various cokes, pyrographite and pyrolysis (carbonisation) products of different polymers. This assumption was confirmed by the results of studying the possibility of lithium intercalation into the same substances preliminarily pyrolysed at different temperatures. The optimal pyrolysis temperature was found to correspond exactly to the formation of the hypothesised mesophase materials.^{51,52}

The research practice employs various carbon materials, whereas in the industry only certain specific materials which ensure adequate characteristics of negative electrodes for lithium-ion cells are used. Of the latter, a material produced by Osaka Gas Co. (Japan) which is called mesocarbon microbeads (MCMB) was employed most extensively. This material is the product of pitch carbonisation carried out under certain temperature conditions.^{53,54} It was assumed that fibrous materials are also promising for fabrication of anodes.^{55–59}

¶ A discharge with such a current that the total designed capacity is realised in 20 min.

Carbon materials (obtained by pyrolysis of certain organic substances, *e.g.*, poly(*p*-phenylene), phenol–formaldehyde resin, soluble phenol–formaldehyde resin and even sucrose) with the intercalation capacity exceeding 372 mA h g^{-1} , which corresponds to the LiC_6 limiting composition, have been described. Their real intercalation capacity could reach $600\text{--}700 \text{ mA h g}^{-1}$ (see Refs 60–71).

Naturally, elucidation of the reason for such an enhanced capacity became a challenge for scientists. It was found that lithium ions intercalated into graphite can occupy different sites in the graphite lattice, *viz.*, in interstitials (proper intercalation), at the edges and on surfaces of graphite crystals.⁷² These sites differ in the types of bonds formed between the lithium ions and carbon. In amorphous matrices, lithium appears to be dissolved and uniformly distributed. Materials of the MCMB type are considered as the mixtures of pure graphite and a certain amorphous (turbostratic) material.^{67,73} Furthermore, it was assumed that excessive lithium ions can be incorporated into nanosize microcavities.^{56,65,74} Strongly disordered structures contain isolated graphite sheets (a ‘house of cards’ structure) both sides of which can adsorb the incorporated lithium. Such an intercalation mechanism doubles the intercalation capacity. Moreover, a definite correlation has been found between the intercalation capacity and the content of residual hydrogen in the carbon material.^{75,76} The formation of hydrogen–lithium bonds was hypothesised.⁶⁵ Further studies have shown that the characteristics of disordered materials gradually deteriorate so that their enhanced intercalation capacity is observed only at the beginning of their operation. These studies are being continued, however, without any definite hopes for success.^{77–80}

Passive films formed on the carbon material surface during the first cathodic charge have a great effect on intercalation–deintercalation processes. The problem of formation of passive films on carbonaceous materials has been extensively studied, being probably the central question in the development of lithium-ion cells. A vast number of studies were devoted to the elucidation of the formation mechanism, composition, structure and properties of these films. As was stressed above, the passive films on carbon material resemble those formed on the surface of pure lithium with respect to their composition and properties (see, *e.g.*, Refs 21, 81–89). They result from irreversible reduction of electrolyte components and serve as a natural barrier that prevents the further process. Thus, the carbon material surface catalyses the electrolyte reduction. The data on the kinetics of this process are contradictory.

Propylene carbonate is reduced most actively, hence, it is recommended not to use propylene carbonate-containing electrolytes in lithium-ion batteries. The electrolyte reduction during the first discharge consumes a charge which is comparable with the specific capacity of the material and represents the irreversible capacity of the negative electrode. To reduce this quantity, it is desirable to add different substances to the electrolyte, *e.g.*, carbon dioxide, crown ethers, sulfur dioxide, ethylene sulfite, nitrogen dioxide, vinylene carbonate, *etc.*^{83,90–96} Later, different procedures of surface treatment were proposed for carbon materials themselves, which includes deposition of certain protective coatings. For instance, it was proposed to oxidise^{65,97} the graphite material surface, silver-plate its particles⁹⁸ and vacuum spray fine tin films.⁹⁹ Coating of fine graphite particles with still finer nickel particles (in essence, coating of graphite with a porous nickel film) seems more practicable.¹⁰⁰ Such a treatment favours a decrease in the irreversible capacity from 310 to 40 mA h g^{-1} and a simultaneous increase in the reversible capacity. A similar result was achieved by applying a thin layer of non-graphitised carbon on the surface of graphite particles.^{101,102} Judging from the deposition method used, *viz.*, a fluidised bed treatment of graphite with a mixture of nitrogen and toluene vapour at 1000°C , the resulting coating represented pyrolytic carbon. It was shown¹⁰² that such a coating eliminates completely the irreversible capacity in such electrolytes as propylene carbonate (PC) and ethylene

carbonate (EC). Finally, an original proposal to precoat the surfaces of graphite materials with protective films which resemble the film usually formed during the first cathodic polarisation in the working electrolyte deserves mentioning. Such protective films can be formed using chemical (treatment with butyllithium)¹⁰³ and electrochemical¹⁰⁴ procedures.

It follows from above that in the elaboration of negative electrodes, attention is mainly focused on carbon materials; however, attempts have been made to study different substances. At one time, carbon compounds with nitrogen and boron were assumed to be promising.^{105–109} It was found that although their starting capacities (the capacity in the first cycles) are comparable with those of carbon materials, these decreased substantially during the cycling. The most promising results looked with carbon–silicon compositions.^{110–112}

In the late 1990s, the attention of many researchers has been attracted by the materials based on tin oxides.^{113–128} When negative electrodes made of such materials were used, lithium was intercalated into metallic tin formed during the initial cathodic polarisation of the electrode

rather than into the tin oxide.

Subsequent insertion of lithium into tin formally proceeds in the same fashion as its intercalation into carbon

but, for tin, the coefficient x can be sufficiently high, *i.e.*, reach 4.4 (for intercalation into graphite, $x = 1/6$). For $x = 4.4$, the theoretical specific capacity of a tin electrode is 991 mA h g^{-1} or $7234 \text{ mA h cm}^{-3}$. Such high values of specific capacity (especially the volumetric one) are responsible for the keen interest paid to these materials. Even being calculated with respect to the initial oxide SnO_2 rather than to tin (into which lithium is intercalated), the resulting values of specific capacity still remain sufficiently high, *viz.*, 781 mA h g^{-1} and $5428 \text{ mA h cm}^{-3}$. However, the use of tin oxides and other tin compounds entails a number of problems.

The common (and the main) drawback of all metal electrodes is the substantial change in their specific volumes upon lithium intercalation. During lithium intercalation, the specific volume of an alloy formed (or, more precisely, a binary system) substantially increases, which results in high internal stresses and, as a consequence, the electrode cracking. In turn, this results in the appearance of a high ohmic resistance at the boundaries of individual metal particles and a sharp polarisation rise. While, for primary cells, this factor cannot play any significant role, for a secondary cell (rechargeable battery), it is the determining factor. (It should be borne in mind that the specific volume changes induced by cycling were the reason for the failure of numerous attempts to create a negative electrode based on aluminium and certain alloys like the Wood alloy.)

Tin is a remarkable material because it can be obtained in a fine-grain form with a characteristic particle size of several nanometres using different technological procedures. Dispersion of tin occurs in particular owing to its formation in the lithium oxide matrix by Eqn (2). In several studies,^{115–190} this was considered to be the key factor.

Yet another principle for the preparation of highly dispersed particles is the use of tin alloys and intermetallic compounds.^{121–130} However, in this method too, the stability of a finely dispersed phase of either tin or its intermetallic compound is favoured by the presence of another (inactive) phase. A relatively complex procedure of fabrication of negative electrodes based on tin, *viz.*, chemical deposition of tin into pores of a polymeric membrane has been proposed.¹²⁷ Such a membrane (a polycarbonate filter) has a system of monodispersed cylindrical pores with diameters of 50 nm . Prior to deposition of tin, the membrane was applied on a current collector made of foil. In the end, the membrane was burnt out to give a brush of tin hairs, which are

oxidised in air to give crystalline SnO_2 . The electrodes thus prepared exhibited highly stable characteristics and were capable of discharging by huge currents (a complete discharge in 1 min!).

A two-phase system consisting of mixed powders of tin and a tin–antimony intermetallic compound (SnSb) was suggested¹²⁸ for the fabrication of negative electrodes. The ultradispersed powders can be obtained by chemical reduction using borohydride. Being inserted into such a two-phase system, lithium occurs first in the intermetallic compound, the tin phase playing the role of a stabilising matrix. Following completion of this process, intercalation of lithium into tin begins. Thus, the tin ‘matrix’ is not inert (in contrast to Li_2O) but makes an additional contribution to the capacity. The use of these electrodes allowed a specific capacity of 360 mA h g^{-1} to be maintained for 200 charge–discharge cycles. It was proposed¹²⁶ to prepare a Ni_3Sn_2 intermetallic compound by a mechanochemical method, *viz.*, by processing nickel and tin powders in a ball mill. Electrodes based on such an intermetallic compound exhibited specific capacities up to 327 mA h g^{-1} or $2740 \text{ mA h cm}^{-3}$. The same method was proposed for fabricating an intermetallic compound of indium with antimony (InSb).¹²⁹ Despite their adequate characteristics, the electrodes made of this compound have several drawbacks, *viz.*, the high cost of indium and the toxicity of antimony. Later, copper was substituted for indium and tin was substituted for antimony.^{130, 131}

A Cu_6Sn_5 intermetallic compound was also shown to be quite plausible as a matrix for intercalation of lithium. In the potential range from 2.0 to 0.2 V, lithium intercalated successfully to give a $\text{Li}_{13}\text{Cu}_6\text{Sn}_5$ compound. True enough, such an intercalation was accompanied by a noticeable increase in the specific volume; however, this effect can be eliminated by decreasing the size of intermetallic compound particles. A proposal¹³² to prepare a microcomposite material from the Cu_6Sn_5 intermetallic compound and metallic copper was more successful. This material was prepared by the so-called mechanical alloying of an equi-atomic mixture of copper and tin powders in a high-speed planetary mill in an argon atmosphere. The electrodes made of this material withstand more than 80 charge–discharge cycles with a specific capacity of 200 mA h g^{-1} .

An interesting approach was suggested¹³³ for the preparation of a Sn–LiO_2 nanocomposite by a reaction of tin oxide with lithium nitride in a ball mill in an argon atmosphere. This reaction

was carried out for 5 days. However, in reward, this method produced a ready-for-use composite; hence, there was no need to spend the charge in the primary reduction of tin by reaction (2).

Amorphous oxides of silicon and tin $\text{SiO} \cdot \text{SnO}$ (see Ref. 134) are also considered as promising materials for negative electrodes. Powders of these oxides were also obtained in a planetary ball mill from the starting monoxides. Electrodes of these materials had the initial capacity of $\sim 600 \text{ mA h g}^{-1}$ which decreased to 350 mA h g^{-1} during the initial 20 charge–discharge cycles.

Recently, in addition to most popular tin-containing compounds, other materials were proposed for use as negative electrodes in lithium-ion batteries. The following examples may be mentioned: the KC_8 intercalation compound;¹³⁵ magnesium silicide Mg_2Si (the starting capacity of 1370 mA h g^{-1} which, however, smoothly decreased to 100 mA h g^{-1} in the initial 10 charge–discharge cycles);¹³⁶ a complex nitride $\text{Li}_{2.6}\text{Co}_{0.4}\text{N}$ (the starting capacity was 760 mA h g^{-1} and also decreased with time);¹³⁷ a sodium–molybdenum bronze of the $\text{Na}_{0.25}\text{MoO}_3$ composition which exhibited an intercalation capacity in lithium of 940 A h kg^{-1} (or $4000 \text{ mA h cm}^{-3}$).¹³⁸ However, the application field of lithium-ion batteries with electrodes of this bronze is rather narrow, because their potential changes within a very wide range, *viz.*, from 3 to 0.005 V during the discharge. It was proposed to use a material based on $\text{Li}_4\text{Ti}_5\text{O}_{12}$ (Refs 139, 140) and a lithium–zinc alloy¹⁴¹ for negative electrodes. The latter material can be obtained by controlled vapour codeposition of

individual metals, the vapour mixture being condensed on a titanium current collector cooled by dry ice. The microstructure formed makes it possible to carry out cycling at high current densities.

Lithium is known to form alloys with silicon up to the $\text{Li}_{4.4}\text{Si}$ composition, which corresponds to a theoretical specific capacity of 4000 mA h g^{-1} . However, intercalation of lithium into silicon is accompanied by great changes in the specific volume. A laser-induced method was applied for the preparation of silicon powder from silane.¹⁴² The particles measuring only $\sim 80 \text{ nm}$ did not destroy during cycling. Electrodes fabricated from a mixture of such a silicon powder with carbon black demonstrated the capacity values of 1700 mA h g^{-1} after the tenth cycle and 1300 mA h g^{-1} after the twentieth cycle.

Nanocomposites of silicon microparticles in a titanium nitride matrix were also used for negative electrodes.¹⁴³ In this case, lithium gets intercalated into silicon. For a 33% silicon content, the composite capacity reached 300 mA h g^{-1} and remained unchanged for 20 cycles (no data on long-term cycling is available). The Si/TiN nanocomposites were also fabricated in a high-speed ball mill.

Mention should be made of important problems of the technology of negative electrodes such as the difficulties in the development of binding materials and current collectors, the imperfect technology for the fabrication of the electrodes themselves that gives no way of providing their uniform (small) thickness, the questions associated with corrosion of electrodes, *etc.*

2. Materials for positive electrodes

The choice of the material for the positive electrode in rechargeable lithium-ion batteries is restricted to lithiated cobalt, nickel and manganese oxides. Electrodes based on lithiated cobalt oxide are characterised by the lowest polarisation and the highest specific capacity. The performance of a positive electrode is reduced to deintercalation of lithium during the cell discharge and intercalation of lithium during the charge

The operational characteristics of high-potential electrodes (*i.e.*, the electrodes with open-circuit potentials of $\sim 4 \text{ V}$ *vs.* lithium electrode, which maintains the discharge voltage at a level above 3 V) are approximately the same. The choice of the active substance for positive electrodes was arbitrary to a certain extent. Japanese scientists prefer cobalt oxides which are much more expensive than other materials; however, their industrial synthesis is relatively simple and reproducible.

In France and Canada, preference is given to cheaper nickel oxide. Lithiated nickel oxides operate at a less positive potential than cobalt oxide. This mitigates to a certain degree the requirements of the stability of the electrolyte to oxidation during charging. At the same time, the discharge curve of a nickel-oxide electrode is steeper, *i.e.*, the voltage variations during the discharge in a cell with nickel-oxide electrodes are greater as compared with cells equipped with electrodes of manganese and cobalt oxides. The USA industry mainly uses the materials based on manganese oxides (lithium–manganese spinels) which seem to be more attractive economically and environmentally safe (see, *e.g.*, Ref. 144).

Electrochemical characteristics of positive electrodes depend to a great extent on the technology used in their synthesis. Most publications were largely devoted to technological problems, and the questions of mechanisms of processes on these electrodes have received less attention. The technology of synthesis of lithiated oxides is based on the use of various high-temperature (sintering) and low-temperature (sol–gel, ion exchange, deposition from solutions) processes. Lithiated cobalt oxide was mainly prepared by a low-temperature technology,¹⁴⁵ whereas lithiated nickel oxide was fabricated by sintering.^{146, 147}

Numerous studies aimed at the perfection of positive electrodes for lithium-ion cells are largely limited to improvement of their

structures. This is achieved by both technological methods and the introduction of different modifiers.

For example, it was shown that lithium cobaltate with the $O2$ structure has a more pronounced layered structure (suitable for reversible intercalation of lithium) as compared with conventional lithium cobaltate with the $O3$ structure.¹⁴⁸ The modification with the $O2$ structure can be prepared, for instance, by ion exchange from a solution of sodium cobaltate ($\text{Na}_{2/3}\text{CoO}_2$) and lithium bromide in hexanol. Although the materials with the $O2$ and $O3$ structures hardly differ in many parameters, the former material is more cycling-stable. Yet another technology used in the preparation of lithium cobaltate with a good texture (preferential crystal orientation along a lithium intercalation direction) consists in radiofrequency magnetron sputtering of thin films on various conductive supports,¹⁴⁹ which also facilitates the reversible cycling, *i.e.*, increases the battery life. To obtain highly dispersed LiCoO_2 powders with enhanced reversibility degrees, an original method of supercritical aqueous synthesis was put forward.¹⁵⁰ For this purpose, the aqueous solutions of LiOH , $\text{Co}(\text{NO}_3)_2$ and H_2O_2 were fed under a pressure of 30 MPa to an electric furnace at 400 °C, where the synthesis was completed in 30 s.

A method of emulsion drying was used for the preparation of highly dispersed LiCoO_2 powders.¹⁵¹

As was mentioned above, a sufficiently high discharge potential of a positive electrode at which the lithiation occurs is one of the merits of lithium cobaltate. However, this property is simultaneously a drawback, because the charging of a positive electrode occurs at still higher positive potentials at which the electrolyte can be oxidised on the catalytically active surface of cobaltate (or on a carbon additive used for increasing the active-layer conductivity). To overcome this disadvantage, an original method for modifying the electrode surface by applying a very thin (no thicker than 0.1 μm) layer of diamond-like carbon by plasma spraying from ethylene has been proposed.¹⁵² The resulting electrodes could be cycled in the potential range from 3.0 to 4.2 V with a specific capacity above 200 mA h g^{-1} .

It is known that, being heated, lithium cobaltate decomposes to evolve oxygen. This reaction is especially fast for highly dispersed powders. To enhance the cycling stability of the lithium cobaltate structure, the latter was coated with a SnO_2 film using a sol-gel technology and then annealed.¹⁵³

A similar method was used for modifying a $\text{LiSr}_{0.002}\text{Ni}_{0.9}\text{Co}_{0.1}\text{O}_2$ mixed compound.¹⁵⁴ A powder of this compound was coated with a $\text{Mg}(\text{OH})_2$ layer and then annealed. The annealing resulted in the formation of a MgO coating which prevented electrolyte oxidation during the discharge, increased the discharge capacity from 145 to 160 mA h g^{-1} and enhanced the cycling stability (the capacity fade did not exceed 0.4 mA h g^{-1} per cycle).

A LiMn_2O_4 coating was applied on the LiCoO_2 powder to protect the electrolyte from oxidation during the charge and to enhance the thermal stability of lithium cobaltate.¹⁵⁵

The use of mixed oxides, particularly, cobalt and nickel oxides, substantially improves the characteristics of lithiated oxides. Although the materials for such compounds were proposed for this use long ago, they are still being refined.^{156–159} Complex mixed oxides are also of great interest. Thus in addition to $\text{LiSr}_{0.002}\text{Ni}_{0.9}\text{Co}_{0.1}\text{O}_2$ mentioned above, a material with the composition $\text{Li}_8(\text{Ni}_5\text{Co}_2\text{Mn})\text{O}_{16}$ remarkable for its sufficiently high specific capacity ($\sim 150 \text{ mA h g}^{-1}$) and cycling stability (a capacity fade was $\sim 0.4 \text{ mA h g}^{-1}$ per cycle) deserves mention.¹⁶⁰ This material can be obtained by fine synthesis from solutions of salts of the corresponding metals in methanol and tetrahydrofuran, which is followed by controlled annealing.

Materials of the compositions $\text{LiAl}_y\text{Co}_{1-y}\text{O}_2$ have also attracted attention of scientists.^{161, 162}

The promising mixed materials with a composition described by the general formula $\text{LiCo}_{1-y}\text{Fe}_y\text{O}_2$ should be also mentioned. The cost of lithium-ion batteries based on these materials could be substantially decreased by partial substitution of cheap iron for

extremely expensive cobalt.^{163, 164} First specimens contained low ($y < 0.1$) iron fractions; however, later, materials with $y = 0.24$ were developed. Unfortunately, the resulting materials were characterised by too fast a capacity fade during cycling.

The main drawback of lithium nickelates used as the materials for positive electrodes is the impossibility of complete deintercalation of lithium. As a rule, compounds Li_xNiO_2 are cycled only in the range of $0.5 < x < 1.0$. A deeper deintercalation results in irreversible structural changes. At the same time, it was found that a material with a violated stoichiometry with the composition $\text{Li}_x\text{Ni}_{1.02}\text{O}_2$ can be cycled reversibly in the whole range of x (*i.e.*, $0 < x < 1$).¹⁶⁵

An extension of the cycle range for nickelates can be also achieved by using mixed oxides. Lithiated nickel and cobalt mixed oxides (at a small content of the latter, see, *e.g.*, Refs 166–168) are gaining in acceptance. A mixed oxide material with a layered $O2$ structure and a composition described by the formula $\text{Li}_{2/3}(\text{Ni}_{1/3}\text{Mn}_{2/3})\text{O}_2$ has been proposed.¹⁶⁹ In the structural aspect, this material resembled the layered cobaltate modification¹⁴⁸ and was also obtained by ion exchange from a sodium bronze $\text{Na}_{2/3}(\text{Ni}_{1/3}\text{Mn}_{2/3})\text{O}_2$ [or, more generally, from $\text{Na}_{2/3}(\text{Ni}_y\text{Mn}_{1-y})\text{O}_2$]. The discharge capacity of this material was $\sim 180 \text{ mA h g}^{-1}$ but the discharge curve demonstrated two steps: at a potential of $\sim 3.9 \text{ V}$, which corresponded to electron transfer to the $3d$ level of nickel, and at 2.9 V where manganese changes its valence from +4 to +3.

A series of magnesium-modified lithium nickelates with the general composition $\text{Li}_{1+x}\text{NiMg}_y\text{O}_{2+2y}$ has been described.¹⁷⁰ An introduction of magnesium resulted in stabilisation of the nickelate structure, which, on the one hand, allows its deeper delithiation, *i.e.*, increases the specific capacity and, on the other hand, reduces the capacity fade during cycling. A material with $x = 0.15$ had a specific capacity of $\sim 145 \text{ mA h g}^{-1}$, which even increased a little during the first 30 cycles. Lithiated nickel–magnesium oxides with layered structures (and approximately the same characteristics) have been described.^{171, 172}

Lithiated nickel oxides are much cheaper than lithiated cobalt oxides; however, partial substitution of iron for nickel is believed to be economically warranted. Attempts^{173, 174} for such a substitution were made, which, however, were not too successful: only the materials with the $\text{Li}_x\text{Ni}_{1-y}\text{Fe}_y\text{O}_2$ composition, where $y < 0.1$, could be cycled reversibly.

Among lithiated manganese oxides, spinels with compositions similar to LiMn_2O_4 were used most often for fabrication of positive electrodes. Intercalation of lithium into such a material (*i.e.*, during a discharge of the lithium-ion battery) resulted in formation of compound $\text{Li}_{1+x}\text{Mn}_2\text{O}_4$. Such electrodes had a rated potential value of $\sim 3 \text{ V}$. In the lithium deintercalation (the formation of $\text{Li}_{1-x}\text{Mn}_2\text{O}_4$), the potential value approached $\sim 4 \text{ V}$. Various technologies for the preparation of spinels of different compositions (LiMn_2O_4 , $\text{Li}_2\text{Mn}_4\text{O}_9$, $\text{Li}_4\text{Mn}_5\text{O}_{12}$, *etc.*) were described.^{175–184} The best results were obtained using low-temperature ‘wet’ technologies which allow finely dispersed materials to be obtained,^{177, 183, 184} although plausible high-temperature versions are known.¹⁷⁹

In studying spinels, the main attention was paid to their lattice parameters. Intercalation of lithium into a spinel was accompanied by a decrease in the a_0 parameter of the cubic lattice^{180, 182, 185} and a linear decrease in the phase-transition temperature, which was attributed to disproportionation of the spinel and a loss of a certain amount of oxygen.

A substantial decrease in the capacity during cycling, especially at high temperatures, is a drawback of lithium–manganese spinels (as well as their low specific capacity as compared with cobaltates and nickelates). The reasons for deterioration of characteristics of spinel electrodes were discussed in Ref. 186. Fourier-transform IR spectroscopic studies¹⁸⁷ have shown that self-discharge of spinel electrodes is accompanied by simultaneous oxidation of the solvent on particles of a carbon conducting additive.

Recently, attention of researchers has been attracted to non-spinel metastable and disordered lithium–magnesium structures including their monoclinic and orthorhombic modifications.^{188–195} Good characteristics of these materials are associated particularly with the high defect densities at their grain boundaries and the small sizes of grains themselves (5–20 nm). Doping spinels with small amounts of other elements, such as aluminium^{192–195} and potassium was recommended¹⁹⁶ to obtain such structures. For example, a monoclinic modification of $\text{LiAl}_{0.25}\text{Mn}_{0.75}\text{O}_2$ had a capacity of 130–150 mA h g⁻¹, being cycled in a potential range from 2.0 to 4.4 V.¹⁹² A material of the composition $\text{LiAl}_{0.05}\text{Mn}_{0.95}\text{O}_2$ had a specific capacity of 150 mA h g⁻¹ for its orthorhombic modification and ~200 mA h g⁻¹ for the monoclinic modification.¹⁹⁴ Moreover, for these materials, the capacity faded by ~0.05% per cycle, whereas for common spinels this value exceeds ~0.5% per cycle.

Yet another way of enhancing the cycling stability of positive-electrode materials is the synthesis of amorphous (or amorphised) materials, *e.g.*, complex compounds such as $\text{Li}_{1.5}\text{Na}_{0.5}\text{MnO}_{2.85}\text{I}_{0.12}$ (see Refs 197–199). Its first 40 cycles not only showed no sign for the capacity fade but also resulted in its increase from 120 to 125 mA h g⁻¹. It was suggested²⁰⁰ to use an amorphous modification of manganese dioxide Li_xMnO_2 as a starting material that can be cycled to the depth of over 400 mA h g⁻¹, which corresponds to a change in x from 0 to 1.6. It is evident that the capacity of these electrodes should be lower but are quite acceptable (260 mA h g⁻¹ in a range from 4.0 to 2.5 V).

Yet another approach to the preparation of stable materials is the use of sol–gel technology. Its version using supercritical drying is the most interesting. For example, a technology was described²⁰¹ in which, first, a hydrogel was obtained from an aqueous solution of potassium permanganate and lithium fumarate, after which water was exchanged for acetone and then hexane. The hexanogel thus obtained was dried under conditions close to critical ones. In the process, the surface tension was eliminated, and an extremely fine-grain structure retained. An electrode made of this material with the composition $\text{Li}_{0.9}\text{MnO}_{2.5}$ had a capacity of ~440 mA h g⁻¹ at a discharge up to 2.9 V. It should be noted that such electrodes could be discharged by very high currents. Thus a discharge with a current of 270 mA g⁻¹ gave a capacity of 200 mA h g⁻¹ and a discharge at 100 mA g⁻¹, *i.e.*, in a 2.5C mode,[†] resulting in a capacity of 150 mA h g⁻¹ (the maximum load tested for these electrodes corresponded to the 7.5C mode, *i.e.*, a total discharge took 8 min). A material with the composition $\text{LiAl}_{0.24}\text{Mn}_{1.76}\text{O}_{3.98}\text{S}_{0.02}$ was obtained²⁰² using the sol–gel method. Having a well defined spinel structure, this material could be cycled without any noticeable capacity loss; its capacity was 230 mA h g⁻¹. A similar material (with sulfur partially substituted for oxygen) has been described.²⁰³ A $\text{LiAl}_x\text{Mn}_{2-y}\text{O}_{4-z}\text{F}_z$ material²⁰⁴ exhibited a high cycling stability; this was attributed to the presence of a small amount of fluorine in the oxygen sublattice.

In addition to lithium–manganese spinels doped with aluminium, materials with chromium atoms partly substituted for manganese were reported to show promise for using them in lithium-ion batteries.^{205–207}

A sample of lithium–manganese spinel with a well pronounced crystalline structure (with coarse crystals) was synthesised.²⁰⁸ This material exhibited cycling stability, although its capacity was not too high (less than 80 mA h g⁻¹).

As was noted above, cobaltate particles were coated with a thin layer of manganese oxides to protect electrolytes from oxidation and enhance the thermal resistance of electrode materials.¹⁵⁵ The same group of authors have proposed a ‘reverse’

version, *viz.*, deposition of lithium cobaltate on the particles of a lithium–manganese spinel.²⁰⁹ Such a coating was applied as a gel consisting of lithium and cobalt acetates, which was followed by annealing of the specimen. This procedure allowed the authors to reduce the capacity fade from 1.1 to 0.06 mA h g⁻¹ per cycle.

The use of certain cobalt–manganese mixed spinels provides a discharge at very high potential ratings, *viz.*, ~5 V. The use of such material poses very severe requirements to the electrolyte (which should not be oxidised at a potential of ~5.3 V). In principle, the possibility of enhancing the battery voltage is a challenge. ‘Five-volt’ materials are being elaborated for several years.^{210–212} To date, two of these materials have been described, *viz.*, $\text{Li}_2\text{CoMn}_3\text{O}_8$ and LiCoMnO_4 .

In addition to lithiated cobalt, nickel and manganese oxides, other materials were suggested for use as positive electrodes, *e.g.*, lithiated chromium oxides (the capacity of ~200 mA h g⁻¹),²¹³ $\text{LiCo}_y\text{Ni}_{1-y}\text{VO}_4$,²¹⁴ LiVOPO_4 ²¹⁵ and LiFePO_4 .^{216–219} The latter compound exhibits a theoretical specific capacity of 170 mA h g⁻¹. The prospects of using these materials are still unclear, although the use of such a cheap compound as LiFePO_4 as the active material for positive electrodes seems to be challenging.

The materials based on vanadium oxides exhibited sufficiently high specific capacities; however, their voltage changed with the discharge in a very wide range, which cannot be tolerated in chemical cells designed for power supply of electronic equipment.

3. Electrolytes for lithium and lithium-ion rechargeable batteries

In lithium-ion rechargeable batteries, liquid electrolytes, which represent solutions of lithium salts in aprotic organic solvents, were used.^{220, 221} As was mentioned above, in rechargeable batteries with metallic lithium electrodes, the use of liquid electrolytes poses certain problems; hence, the efforts of researchers were focused on the search for solid polymeric electrolytes (SPE). The processes of dendrite formation and encapsulation were assumed to be eliminated at the metal lithium/SPE interface. At the same time, the possibility of using polymeric electrolytes in lithium-ion batteries was also widely discussed.

An electrolyte for a lithium-ion rechargeable battery should exhibit high conductivity. As a rule, liquid electrolytes have a conductivity in the range from 0.001 to 0.01 S cm⁻¹. The electrolyte should be resistant toward oxidation and reduction, in other words, have a wide ‘electrochemical window’.[‡] The potential range of electrolyte stability is ~5 V. As was mentioned above, the stability of electrolytes largely depends on the formation of passive films on the electrode surface. These films are conductive with respect to lithium ions and do not prevent their intercalation and deintercalation. At the same time, the films should exhibit a minimum electronic conductivity to avoid corrosion (self-discharge) of the electrode. For this very reason, the film material should not dissolve in the electrolyte. Moreover, these films should be sufficiently elastic to avoid destruction during electrode volume changes in the discharge and charge processes.

Various combinations of solvents (both individual and mixed) and lithium salts intended for use as the electrolytes were described; however, only some of them are applied in practice.

Propylene and ethylene carbonates (PC and EC) are commonly used as the solvents. Solvents based on PC are reduced on graphite negative electrodes; hence, EC was proposed as the substitute for PC. At the same time, PC has a number of advantages over EC: the solubility of lithium salts is higher in PC, its freezing point (–54 °C) is substantially lower than the freezing point of EC (+36 °C). Moreover, in certain cases, the use of PC is preferential for improvement of positive electrode characteristics. As a rule, PC and EC are used as their mixtures

[†] If a cell is completely discharged in 1 h, this mode is designated as 1C; if a cell is discharged in 2 h, the mode is designated as 0.5C or C/2; if the total discharge takes 0.5 h, then the mode is 2C, *etc.*

[‡] The difference between the potential of the beginning of anodic oxidation and the potential of the beginning of cathodic reduction.

with less viscous, although less polar, solvents such as 1,2-dimethoxyethane, dimethyl carbonate and diethyl carbonate.

Lithium hexafluorophosphate and tetrafluoroborate are used most often as lithium salts; the possibilities of using lithium hexafluoroarsenate and perchlorate were also examined. Merck (Germany) produces ready-for-use electrolytes for lithium-ion batteries of the following types: LP20, LP30 and LP40, where electrolytes represent 1 M LiPF₆ solutions in the following solvent mixtures: PC–diethyl carbonate (1 : 4), EC–dimethyl carbonate (1 : 1) and EC–diethyl carbonate (1 : 1), respectively.

In recent years, the following lithium salts were proposed for use as lithium-ion batteries, *viz.*, lithium trifluoromethanesulfonate (triflate), bis(trifluoromethylsulfonyl)imide and tris(trifluoromethylsulfonyl)methanide and their derivatives. The derivatives involved such compounds as cyclic imides Li[N(SO₂)(CF₃)_n(SO₂)], where $1 < n < 4$,^{222, 223} an asymmetrical methanide Li[C(SO₂CF₃)₂(SO₂C₄F₉)] and bismethanide Li₂[(C₂(SO₂CF₃)₄(S₂O₄C₃F₆))₂],²²⁴ imides with long fluoroalkyl chains,²²⁵ lithium hexafluorotrimethylenebis(sulfonyl)di[bis(trifluoromethylsulfonyl)methanide],²²⁶ *etc.*

Boron-containing compounds, particularly, different borates and chelatoborates were used in lithium-ion batteries as the additives that extend the potential range of electrolyte stability, increase the solubility of salts and decrease the corrosive action of the electrolyte on the current lead material (*e.g.*, aluminium).^{227–235} Of great interest is the hexamethoxycyclotriphosphazene [NP(OCH₃)₂]₃ additive, which favours a decrease in the inflammability of lithium-ion batteries.²³⁶

VII. Polymeric electrolytes for lithium-ion batteries

Among solid ionic conductors which can be used at ambient temperature, the SPE with a relatively fast ion transfer are most promising. Thin films fabricated of these polymeric electrolytes are characterised by elasticity (mobility), adequate mechanical properties, a low electronic conductivity (10^{-14} S cm⁻¹ at room temperature), a wide electrochemical window of stability (3–4 V) and are compatible with the electrodes of alkali metals.

At the same time, the use of SPE is limited due to the following reasons: first, they have a low ionic conductivity at ordinary temperatures (from 10^{-5} to 10^{-8} S cm⁻¹); second, not only lithium ions, but also anions take part in the charge transfer, which can give rise to concentration polarisation; third, like liquid electrolytes, they can form a transition layer with a high resistance upon contact with the electrode (both positive and negative) material.

Armand *et al.*²³⁷ were the first to propose the use in lithium cells of a complex of a lithium salt with a polymer [poly(ethylene oxide), PEO]. The conductivity of such a PEO–LiSCN complex system at room temperature was 10^{-8} S cm⁻¹.^{237, 238} These rechargeable batteries could operate only at temperatures above 60 °C, because it was only under these conditions that the conductivity of the electrolyte solution had acceptable values for practice. Nonetheless, the interest in these electrodes was so high that the extensive research undertaken has soon produced polymeric electrolytes with conductivities of $\sim 10^{-3}$ S cm⁻¹ at room temperature, which is comparable with the conductivity of liquid electrolytes.

An important requirement to SPE is their mechanical strength, because, to decrease the resistance, these electrodes are mainly used as thin films with thicknesses of 0.0025–0.005 cm commensurable with the thicknesses of porous separators based on polypropylene and polyethylene, which divide the electrodes in lithium batteries with liquid electrolytes. A solid polymeric electrolyte should also withstand the pressures induced by morphological changes in the electrode material during the lithium cell cycling. Thus, SPE, on the one hand, should provide ionic conduction typical of liquid electrolytes and, on the other hand,

should be spatially stable, *i.e.*, retain their solid shapes. Modern SPE fulfil all these requirements.

We can single out two large classes of polymeric electrolytes with conductivities above 10^{-5} S cm⁻¹ at room temperature. The first class involves ‘solution-free’ SPE. In addition to polymers, these SPE contain lithium salts. The second class comprises SPE ‘with solvents’, which, in addition to polymers and lithium salts, contain liquid solvents called plasticisers. These two SPE classes may have polymeric matrices with different structures.

1. Solid electrolytes with the polymer–lithium salt composition

Solid electrolytes based on crystalline polymers have low conductivities, whereas those based on amorphous polymers exhibit higher conductivities. Thus, the SPE conductivity can be increased by decreasing the degree of crystallinity of a polymer by changing its structure. Table 1 lists the characteristics of certain polymers; Table 2 lists the SPE conductivities.

Table 1. Properties of certain polymers used as the electrolyte matrices.²³⁹

Polymer ^a	Polymer unit	<i>T</i> _g / °C	m.p. / °C
PEO	–CH ₂ CH ₂ O–	–64	65
PPO	–CH(Me)CH ₂ O–	–60	see ^b
POO	–(CH ₂ O)–(CH ₂ CH ₂ O)–	–66	13
MEEP	$\begin{array}{c} \text{OCH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{OMe} \\ \\ \text{—P=N—} \\ \\ \text{OCH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{OMe} \end{array}$	–83	see ^b
PDMS	–Si(CH ₃) ₂ O–	–127	–40
PAN	–CH ₂ CH(CN)–	125	317
PMMA	–CH ₂ C(Me)(CO ₂ Me)–	105	see ^b
PVC	–CH ₂ CHCl–	82	see ^b
PVDF	–CH ₂ CF ₂ –	–40	171

^a The following abbreviations were used: PEO, poly(ethylene oxide); PPO, poly(propylene oxide); POO, poly(oxyethylene oligooxyethylene); MEEP, poly{bis[2-(2-methoxyethoxy)ethoxy]phosphazene}; PDMS, poly(dimethylsiloxane); PAN, poly(acrylonitrile); PMMA, poly(methyl methacrylate); PVC, poly(vinyl chloride); PVDF, poly(vinylidene difluoride). ^b Amorphous polymer.

Table 2. Composition and bulk conductivity with respect to Li⁺ ions for solid polymeric electrolytes.^{237, 238, 240}

Electrolyte	Conductivity at 20 °C / S cm ⁻¹
(PEO) ₈ LiClO ₄	10^{-5}
(PPO) ₈ LiClO ₄	10^{-8}
(POO) ₂₅ LiCF ₃ SO ₃	3×10^{-5}
(MEEP) ₄ LiBF ₄	2×10^{-5}

Back in 1979, it was pointed out²³⁸ that PEO exhibits good solvating ability towards those Li⁺ ions and ions of other metals located in a favourable position relative to the donor oxygen atoms of the polymeric chain. By changing the oxygen atom position in the chain, the solvating ability and the temperature transitions in the polymer can be changed. For example, PEO can form polymeric electrolytes with salts of alkali and transition metals.²⁴¹ Moreover, the existence of various PEO complexes with LiBF₄, LiPF₆ and LiB₄,²⁴² LiAsF₆,²⁴³ LiSCN,²⁴⁴ LiCF₃SO₃ and LiClO₄,²⁴⁵ LiN(CF₃SO₂)₂,^{246, 247} has been reported.

The use of inorganic additives in the form of fine powders of Al₂O₃ or LiAlO₂ was proposed to enhance the mechanical strength of an electrolyte based on PEO and a lithium salt.^{248–254} Such additives, first, prevent crystallisation of the polymer and, second, can absorb water, which allows one to

reduce the lithium electrode passivation. At room temperature, the ionic conductivity of an electrolyte with the composition $(\text{PEO})_8\text{LiClO}_4$ was $10^{-5} \text{ S cm}^{-1}$, whereas the conductivity of the $(\text{PEO})_8\text{LiClO}_4 + 10 \text{ mass \% LiAlO}_2$ composition was $10^{-4} \text{ S cm}^{-1}$.

It was proposed²⁵⁵ to modify a polymeric electrolyte based on PEO and LiBF_4 using finely dispersed Al_2O_3 powders with $\sim 10 \text{ }\mu\text{m}$ particles as well as by modified particles measuring $1.3 \times 10^{-2} \text{ }\mu\text{m}$. The conductivity of the latter SPE was higher by an order of magnitude as compared with SPE modified by $10 \text{ }\mu\text{m}$ particles.

Introduction of $\gamma\text{-LiAlO}_2$ to a polymeric electrolyte based on PEO and $\text{LiN}(\text{CF}_3\text{SO}_2)_2$ resulted in a substantial decrease in the degree of crystallinity and an increase in the stability of the Li/electrolyte interface.²⁵⁶

The effect of various types of fine powders added to a polymeric electrolyte on the conductivity and mechanical strength of PEO-based SPE was also studied.^{257,258}

Using LiClO_4 complexes with a number of aliphatic polyesters (PEst) synthesised by a reaction of poly(ethylene glycol) (PEG) ($M_w = 300, 1000$) with diacid chlorides $(\text{ClOC}[\text{CH}_2]_n\text{COCl}$, $n = 3-8, 10$) as the examples, the effect of the polymer structure on its ionic conductivity was studied.²⁵⁹ The general composition of these complexes can be expressed by the formula $\text{PEst}(m,n)$, where m is the number of ethylene groups and n is the number of methylene groups; e.g., $\text{PEst}(6,8)$ is $[-(\text{OCH}_2\text{CH}_2)_6\text{O}-\text{CO}(\text{CH}_2)_8\text{CO}-]$. In contrast to the $\text{PEO}-\text{LiClO}_4$ system with a degree of crystallinity of 0.4, the $\text{PEst}(m,n)-\text{LiClO}_4$ systems are totally amorphous, and their ionic conductivity varies in the range from 2.5×10^{-5} to $4.1 \times 10^{-5} \text{ S cm}^{-1}$. The degree of crystallinity of PEO can be reduced by shortening its chain and decreasing its molecular mass;²⁶⁰ however, low-molecular PEO with short chains represent viscous liquids even after the formation of complexes with lithium salts and could not form SPE.

With the aim of decreasing the degree of crystallinity, comb-like polymers with short PEO side-chains attached to the main chain were synthesised, e.g., poly[2-(2-methoxy)ethoxy]ethyl glycidyl ether

A complex of this amorphous polymer ($T_g = -57^\circ\text{C}$) with LiClO_4 had a conductivity of an order of magnitude of $10^{-5} \text{ S cm}^{-1}$ at room temperature.

A search for amorphous polymers has produced materials with highly mobile inorganic skeletons based on polysiloxanes $(-\text{SiR}_2\text{O}-)_n$ and polyphosphazenes $(\text{P}=\text{N}-)_n$. Siloxane polymers can be exemplified by poly(dimethylsiloxaneoligoethylene oxide)

and poly{[ω -methoxyoligo(ethylene oxide)ethoxy]methylsiloxane}

A maximum conductivity achieved using electrolytes of these types (which also represent viscous liquids) is $10^{-4} \text{ S cm}^{-1}$ (Refs 261, 262). Cross-linking of polymers decreased the conductivity to $10^{-5} \text{ S cm}^{-1}$ at room temperature. The drawback of these polymers is the sensitivity of $\text{Si}-\text{O}-\text{C}$ bonds to hydrolysis and their structural degradation with time. This problem can be

solved, e.g., by synthesising copolymers with stable $\text{Si}-\text{C}$ bonds, which has been achieved by grafting PEO to polysiloxanes.²⁶³

Electrolytes based on such a polymer ($-77^\circ\text{C} < T_g < -54^\circ\text{C}$) exhibited conductivities of $10^{-5} \text{ S cm}^{-1}$ at room temperature.

A modified polymeric electrolyte based on MEEP (see Table 1) was described.²⁶⁴ Complexes of MEEP with lithium salts had a low stability. The authors proposed to add LiAlCl_4 to such an electrolyte, which allowed them to fabricate MEEP- $(\text{LiAlCl}_4)_n$ films. The mechanical properties of spatially unstable MEEP-lithium salt complex systems were substantially improved as a result of formation of complexes with such polymers as PEO, PPO, poly(ethylene glycol diacrylate) and poly(vinylpyrrolidone). An electrolyte containing 55 mass % MEEP + 45 mass % PEO- $[\text{LiN}(\text{CF}_3\text{SO}_2)_2]_{0.13}$ had a conductivity of $6.7 \times 10^{-5} \text{ S cm}^{-1}$ at room temperature. Such electrolytes remained stable up to 4.5 V. A Li/TiS₂ cell with these electrolytes had a cycle life exceeding 200 charge-discharge cycles.

Results²⁶⁵ obtained in line with these studies should be considered as less successful. The authors have obtained a number of polysilane polymers: **1a-c**, **2** and **3**

R = Me (**a**), Pr (**b**), C_8H_{17} (**c**).

Polymers **1b** and **2** with 8 oxygen atoms per lithium ion exhibited a maximum ionic conductivity equal to $1.9 \times 10^{-7} \text{ S cm}^{-1}$.

The degree of crystallinity can be reduced by cross-linking the polymers. Such polymeric nets exhibited relatively high conductivities ($1.5 \times 10^{-5} \text{ S cm}^{-1}$ at 25°C for a LiClO_4 salt) and an acceptable mechanical strength. This approach was put forward in Refs 266-268 and involved cross-linking of low-molecular PEO ($M_w = 600, 1000, 2000$) and block-copolymers PEO-PPO-PEO with urethane and cyclosiloxane. Polymeric electrolytes based on PEO with $M_w = 2000$ which contained either LiCF_3SO_3 or $\text{LiN}(\text{CF}_3\text{SO}_2)_2$ and electrolytes with the composition $\text{PEG}-\text{LiCF}_3\text{SO}_3$ with an addition of poly(ethylene glycol dimethyl ether) (PEGDME) with $M_w = 500$ were studied.²⁶⁹ The following electrochemical properties of these three electrolytes were examined: ionic conductivity, electrochemical stability window, reduction and the resistance and stability of the lithium electrode/electrolyte interface. Moreover, prototypes of lithium cells with composite cathodes based on LiMn_2O_4 were tested with the aim of studying the performance of these electrolytes in solid lithium batteries. In SPE containing $\text{LiN}(\text{CF}_3\text{SO}_3)_2$, a conductivity of $10^{-4} \text{ S cm}^{-1}$ required for their practical application was achieved only at 60°C . An addition of PEGDME decreased the resistance of the lithium electrode/electrolyte interface and trebled the specific capacity (90 mA h g^{-1}).

A new method of SPE preparation by dissolving the polymers with high glass transition temperatures ($T_g > 90^\circ\text{C}$) in a LiCF_3SO_3 melt has been described.^{270,271} Such polymers as poly(*N,N*-dimethylacrylamide), poly(acrylonitrile) (PAN), poly-

(vinylpyrrolidone) and its copolymer with vinyl acetate were studied. At 45 °C, the conductivity of a PAN–LiCF₃SO₃ (75 mass %) electrolyte did not exceed 10^{−6} S cm^{−1}.

2. Plasticised polymeric electrolytes

In contrast to SPE with the polymer–salt composition, plasticised polymeric electrolytes contain organic solvents which are confined within the swollen polymeric matrix so that these electrolytes resemble rubber in their consistency. Plasticised electrolytes are also called polymeric gel-electrolytes (PGE). They can be obtained by adding plasticisers, *viz.*, polar aprotic solvents with high boiling points and high dielectric constants to SPE. Table 3 shows typical solvents-plasticisers.

Table 3. Certain organic solvents used as plasticisers.²⁷²

Solvent-plasticiser	m.p. /°C	b.p. /°C	Dielectric constant at 25 °C	Viscosity /10 ^{−3} Pa s
Ethylene carbonate	36	248	95.3	1.9
Propylene carbonate	−70	240	65.1	2.53
γ-Butyrolactone	−43.5	204	39	1.75
Dimethylformamide	−61	153	36.7	0.8
1,2-Dimethoxyethane ^a	−70	85	5.5	0.46

^a Used only as mixtures with high-boiling plasticisers added to decrease the viscosity.

The conductivity of PGE depends on the solvent content, its viscosity and dielectric constant. Polar solvents with low viscosities such as *N*-dimethylformamide (DMF) and γ-butyrolactone (BL) substantially increase the conductivity in lithium ions. The activation energy of conductivity decreases dramatically with an increase in the solvent-to-lithium salt molar ratio. In fact, lithium ions travel in the liquid electrolyte confined by a polymeric matrix. Hence, to obtain a PGE with an acceptable conductivity, the amount of DMF required should be only a third of that required for more viscous PC.

Solvents-plasticisers solvate Li⁺ ions facilitating their transport (this phenomenon was not observed for polyethers in which an ion travels along the polymer chain). The ‘degree of assistance’ to the ionic transport probably depends on the rate at which the ions form complexes with the polymeric chain rather than with the solvents-plasticisers.

The structures of plasticised polymeric electrolytes are still not clearly understood. The PEG structure in which Li⁺ forms a complex both with the polymeric network and the solvent has been hypothesised²⁷³ for electrolytes based on PAN (Y = CN) and PVC (Y = Cl) in a mixture of propylene carbonate–ethylene carbonate (PC/EC) solvents

To date, a large number of PGE that consist of lithium salts and plasticising organic electrolytes are known. The important advantage of PGE as compared with SPE is their high ionic conductivities at room temperature, which approaches the conductivity of liquid electrolytes. However, in practical applications of PGE, a number of other characteristics should be taken into account, *e.g.*, their ability to confine electrolyte, mechanical strength and conductivity in a wide temperature range. In particular, for multicomponent PGE, solvent losses due to leakage and vaporisation can hardly be avoided.^{274, 275} This results in a decrease in the cell resistance and impairs the electrolyte–electrode contact. The main parameter that characterises the solvent

confinement in the PGE is the affinity between the polymeric matrix and the organic solvent. This parameter also affects the mechanical strength of the PGE film and its conductivity in a wide temperature range, especially in thin-film cells which contain electrodes with high surface areas. Low degrees of affinity between a polymer and an electrolyte can result in separation of PGE into predominantly polymeric and solvent-enriched microphases. As a consequence, the mechanical strength can increase due to the formation of a polymeric network. The electrolyte electrochemical stability in lithium chemical power sources can be increased if highly polar, easily freezing solvents are used (*e.g.*, ethylene carbonate with m.p. = 36 °C). It may be assumed that an increase in the degree of solvent–polymer affinity will allow one to eliminate the problem of the increase in the PGE resistance with a decrease in the temperature, because the interaction of solvent molecules with the polymer will prevent their ordering during freezing.

Properties of PGE which contained PVDF, a copolymer of vinylidene fluoride with hexafluoropropylene (PVDF–HFP), PAN (*M_w* = 150 000) and PMMA (*M_w* = 12 000) as the polymeric components were compared,²⁷⁶ which revealed the following features. The solvent-loss rate increased in the order PMMA ≤ PAN << PVDF–HFP ≤ PVDF in accordance with the increase in the solvent affinity to the polymer and the increase in the degree of crystallinity. Polymers with low degrees of crystallinity swelled more easily and better confined the solvent, the latter being uniformly distributed throughout the polymeric matrix.

In some studies,^{277, 278} PGE based on chemically cross-linked PEO and LiBF₄ and LiN(CF₃SO₂)₂ were plasticised by PC and BL, then their ionic conductivities were compared to the conductivities of liquid electrolytes without polymers. Although the degree of dissociation of salts in PGE was higher, the conductivity appeared to be lower due to specific capture of lithium ions by the polymeric matrix.

Itoh *et al.*²⁷⁹ dissolved LiN(CF₃SO₂)₂ in PEGDME (*M_w* = 400–500) and then added γ-LiAlO₂. The solution obtained was mixed with PEO (*M_w* = 4 000 000) and a liquid electrolyte was added. The compositions thus prepared contained different amounts of the following liquid components: dimethyl carbonate (DMC), diethyl carbonate (DEC), EC and PC. These reagents were used for increasing the amorphous phase fraction in the polymeric composite membrane. Impedance measurements have shown that the maximum stability with respect to Li electrodes was observed for the following compositions (mass %): 13.6 PEO + 77.3 lithium salt solution in PEGDME + 9.1 γ-LiAlO₂ (I) and 18.2 PEO + 54.5 lithium salt solution in PEGDME + 18.2 DMC + 9.1 γ-LiAlO₂ (II). At the same time, composition (II) displayed a high ionic conductivity, *viz.*, 2 × 10^{−3} S cm^{−1} (for composition I, the ionic conductivity was 0.09 × 10^{−3} S cm^{−1}).

The main disadvantage of using PC and oligomeric ethers as the plasticisers is the low stability of the resulting films due to the solubility of the linear PEO in these solvents. To solve this problem, two approaches were suggested: (1) plasticisation of cross-linked polymeric nets which involve –CH₂CH₂O– units; (2) plasticisation of polymers which do not involve such units but are either insoluble or poorly soluble in plasticisers.

It was shown²⁷⁷ that the problem of solubility of chemically linked PEO in PC can be solved using the first approach. Although the cross-linked polymer studied was amorphous and contained the –CH₂CH₂O– unit, a non-plasticised polymeric electrolyte on its basis with addition of LiCF₃SO₃ had a conductivity of 1.4 × 10^{−6} S cm^{−1} at 25 °C. Addition of 50 mass % PC increased the conductivity of the system to 8 × 10^{−4} S cm^{−1}, while the mechanical properties allowed its application as a film.

A new plasticiser, *viz.*, a modified carbonate (MC), was synthesised,²⁸⁰ by addition of three ethylene oxide groups to propylene carbonate.

The conductivity of a PEO–LiCF₃SO₃ complex rapidly increased to 5×10^{-5} S cm⁻¹ at room temperature upon introduction of 50 mass % MC. It was assumed that this plasticiser increases the conductivity throughout the complex system bulk, in contrast to common plasticisers that provide conduction only in the liquid phase. It was assumed that MC favours a deeper dissociation of the salt as compared with PC.

A large number of studies were devoted to PAN-based PGE obtained by heating the polymer, plasticiser and lithium salt to 130–150 °C, which resulted in cross-linking along the C–N bonds

Although the amount of PAN did not exceed 20 mass %, the electrolyte obtained resembled rubber in its consistency.

Table 4 shows the conductivities of PGE based on PAN with additions of lithium salts such as LiClO₄, LiAsF₆, LiCF₃SO₃, LiN(CF₃SO₂)₂ and LiPF₆ (Refs 273, 281). PC, EC, BL, *N*-methylpyrrolidone (*N*-MP) and their mixtures were used as plasticisers.

Table 4. Conductivities of electrolytes based on PAN at 20 °C.

Electrolyte composition (mol. %)	Conductivity at 20 °C / S cm ⁻¹
21 PAN + 38 EC/33 PC + 8 LiClO ₄	1.7×10^{-3}
21 PAN + 38 EC/33 PC + 8 LiAsF ₆	2.1×10^{-3}
16 PAN + 68 PC + 16 LiClO ₄	8.6×10^{-4}
21 PAN + 18 BL/20 EC/33 PC + 8 LiClO ₄	2.3×10^{-3}
21 PAN + 40 EC/36 PC + 3 LiN(CF ₃ SO ₂) ₂	1.5×10^{-3}
21 PAN + 61 EC/13 PC + 5 LiCF ₃ SO ₃	1.1×10^{-3}
21 PAN + 61 EC/13 PC + 5 LiBF ₄	3.5×10^{-4}
21 PAN + 33 PC/30 BL/8 <i>N</i> -MP + 8 LiPF ₆	2.2×10^{-3}

Polymeric gel-electrolytes based on PAN were also modified by introducing crown ethers such as 15-crown-5 and benzo-15-crown-5.²⁸² Earlier, the effect of these crown ethers as well as 2,4-dioxo-16-crown-5 on the conductivity of PEO-based solid electrolytes was studied.²⁸³ It was found that the introduction of 15-crown-5 and 2,4-dioxo-16-crown-5 increases the ionic conductivity of a film electrolyte approximately by an order of magnitude, whereas the addition of benzo-15-crown-5 does not affect this electrolyte characteristic. A gel-electrolyte with the following composition: 8.5 mass % PAN + 81 mass % PC + 3 mass % LiClO₄ + 7.5 mass % 15-crown-5 had a conductivity of 10^{-3} S cm⁻¹ at 20 °C.²⁸²

Films prepared of a composite polymeric electrolyte involving zeolite powder dispersed in a PAN-based gel with an addition of LiAsF₆ were studied.²⁸⁴ Gel-electrolytes based on a mixture of PC/EC and PAN with addition of LiAsF₆ had ionic conductivities exceeding 10^{-3} S cm⁻¹ at room temperature. The addition of zeolite powder increased the ionic conductivity at low temperatures due to high degrees of amorphousness of the composites. The lithium electrode/electrolyte interface was studied using the impedance spectroscopy technique. The resistance of charge transfer across the Li/PGE interface was found to decrease, which indicates a decrease in the area occupied by the passive film on the surface of lithium. According to results of cyclic voltammetry, for Li/LiCoO₂ cells, an introduction of PAN and zeolite powder into a PC/EC electrolyte containing LiAsF₆ did

not change the window of electrochemical stability, and, at a current density of 0.5 mA cm⁻², the capacity loss during cycling did not exceed the corresponding values for liquid electrolytes.

A highly conducting PAN-based PGE was prepared²⁸⁵ using EC/DMC solutions of either LiPF₆ or LiC(CH₃SO₂)₃ as the plasticisers. The PGE preparation involved the following stages:

- (1) dissolution of a lithium salt in EC/DMC;
- (2) addition of PAN to the solution obtained and stirring for several hours at room temperature;
- (3) casting of the resulting liquid solution on an aluminium support preheated to 90 °C for no longer than 30 s for cross-linking of PAN;
- (4) cooling of the gel obtained to room temperature.

A LiPF₆ + EC + DMC + PAN composition with a molar ratio of 4 : 60 : 20 : 16 had a conductivity of 5.9×10^{-3} S cm⁻¹ and a break-down voltage of 4.5 V.

Ionic conductivity of a polymeric electrolyte based on PAN and lithium methacrylate (PAN–LiMA) with an addition of EC-dissolved LiClO₄ was 2.4×10^{-4} at 10 °C and 1.9×10^{-3} S cm⁻¹ at 25 °C.²⁸⁶

A copolymer of acrylonitrile with butadiene had an ultimate strength of 3.0 MPa and a conductivity of 10^{-3} S cm⁻¹.²⁸⁷

A new copolymer of PAN with bis[2-(2-methoxyethoxy)-ethyl]itaconate (PANI) was synthesised.²⁸⁸ The maximum conductivity, namely 1.9×10^{-3} S cm⁻¹, was found for a gel-electrolyte of the following composition: 25 mass % PAN + 10 mass % PANI + 50 mass % EC/BL + 15 mass % LiClO₄.

Polymeric electrolytes were also prepared based on PVC.²⁸⁹ They were obtained by dissolution of PVC in THF and subsequent addition of plasticisers with lithium salts. Then, the solution was cast on a support and dried at room temperature up to complete evaporation of THF. For an electrolyte of the following composition: 15 mass % PVC + 40 mass % PC + 40 mass % EC + 5 mass % LiClO₄, the conductivity of 1.2×10^{-3} S cm⁻¹ was reached at room temperature. Attempts to prepare an electrolyte by dissolving PVC directly in PC and EC have failed,²⁹⁰ because these polymers do not dissolve PVC even at elevated temperatures. This obstacle was bypassed using THF which dissolves all the electrolyte components.

The use of PVDF and PC-solutions of LiClO₄ as the polymeric matrix and the plasticiser, respectively, made it possible to obtain PGE with a conductivity in the range from 10^{-5} to 10^{-3} S cm⁻¹ at room temperature.²⁹¹

In recent years, the active search for polymeric composites as well as binary and ternary copolymers which can be used as polymeric matrices for electrolytes has been in progress.^{292–299}

It was shown^{282, 300, 301} that, being used as effective protective coatings for lithium electrodes, the polyacetylene (PA)/porous polyethylene (PE) and PA/polypropylene composites play the additional role of electrolyte carriers and conductors, because PA present in their compositions exhibit both ionic and electronic conductivity.

A constantly increasing number of publications devoted to synthesis of new PGE using photopolymerisation have appeared in recent years.^{302, 303} For example, this method was used for the synthesis of poly(ethylene glycol diacrylate). Synthesis of a gel-electrolyte by UV-irradiation of a mixture of oligo(urethane methacrylate) and poly(ethylene glycol monomethacrylate) has been reported;^{304, 305} the PGE conductivity was of an order of magnitude of 10^{-3} S cm⁻¹.

An ethylene oxide/propylene oxide (80 : 20) copolymer with acrylate groups at the macromonomer's termini that could be cross-linked under the action of UV-radiation was synthesised.³⁰⁶ EC/PC (1 : 1, by volume); EC/BL (1 : 1, by volume); PC; PC/BL (1 : 1, by volume); BL and LiBF₄ (1 M) were used as the plasticisers. The polymeric films obtained exhibited good mechanical properties in a wide range of concentrations of additives to liquid electrolytes. Their shear moduli decreased with an increase in the liquid component content, however, remaining sufficiently high, viz., 10 MPa even for a liquid content of 90 mass %. The ionic

conductivity of a composition with 1 M LiBF₄/BL decreased from 3 to 1×10^{-3} S cm⁻¹ with a decrease in the temperature from +20 to -20 °C.

Recently, it was proposed to use ternary copolymers as the polymeric gel-electrolytes.³⁰⁷ For example, ternary polymeric electrolytes were prepared by casting from a solution of a homogeneous mixture containing 18 mass % poly[(acrylonitrile)(methyl methacrylate)styrene] [poly(AMS)], 73 mass % 1 M LiClO₄ solution in EC/DMC (1:1, by volume) and 9 mass % silica. The Li/PGE/carbon cell had a reversible capacitance of 305 mA h g⁻¹ in a voltage range of 0.01–1.5 V and a cycling efficiency of 99%.

The next work by the same authors³⁰⁸ dealt with a PGE which contained 12 mass % poly(AMS), 75 mass % plasticiser and 13 mass % SiO₂. The plasticiser represented a 1 M solution of LiBF₄ in either EC/DMC (1:1, by volume) or EC/DMC/BL (5:4:1, by volume) (BL was added to increase the ionic conductivity). LiCoO₂ was used as the cathodic material. Indeed, the LiBF₄ + EC + DMC + γ -BL electrolyte added to the polymer has demonstrated a somewhat higher ionic conductivity (6.1×10^{-3} S cm⁻¹) as compared with the LiBF₄ + EC + DMC electrolyte (5.2×10^{-3} S cm⁻¹). The PGE films obtained were 60–80 μ m thick and had satisfactory mechanical properties.

Composite electrolytes based on a mixture of lithium-ion-conducting ceramics Li_{1.3}Al_{0.3}Ti_{1.7}(PO₄)₃ and a poly(ether urethane) electrolyte have been proposed.³⁰⁹ Electron microscopy studies have shown the ceramic and polymeric phases to be divided by ~ 1 μ m interlayers. The conductivity of a dry composite did not exceed that of the initial polymeric electrolyte. Under the action of solvent vapour (DMF, acetonitrile, water), the conductivity increased substantially as compared with a polymer subjected to a simpler plasticisation procedure. Treatment of the ceramics with a compatibilising agent

improved the adhesion on the polymer–ceramics interface but decreased the total conductivity of the specimen studied.

A polymeric matrix has a strong effect on the dendrite formation in PGE. Inhibition of lithium dendrite formation in a PAN-based electrolyte was studied.³¹⁰ The electrolytes used were obtained by dissolving PAN (up to 17 mass %) in a PC/EC solvent mixture (1:1, by volume) containing LiClO₄ (1 M) at 120–140 °C with subsequent cooling to -15 °C for 16 h. Upon electrodeposition of lithium for 1 h from liquid electrolytes containing up to 3 mass % PAN, dendrites were observed to be formed on the lithium/electrolyte interface, whereas in a gel-electrolyte (5 mass %–17 mass % PAN) their formation was suppressed. Taking into account the increase in the bulk resistance with an increase in the PAN content, its optimal concentration in the electrolyte was found to be 5 mass %–10 mass %.

A metallic lithium electrode in contact with a gel-like PAN-based electrolyte which contained two lithium salts (LiBF₄ and LiPF₆) was precycled to decrease the bulk resistance.³¹¹ The cycling was carried out in the range from +0.5 to -0.5 V at 20 °C immediately after the Li/PGE/Li cell was assembled. For cells with LiBF₄-containing PGE, the impedance values measured after storage for 230 days at 20 °C were below 100 Ω . Cells with LiPF₆ needed to be precycled at the potentials > 0.5 V and at 60 °C. The impedance values at 10 kHz that determine the bulk resistance of the gel-electrolyte were the same for both types of cells and remained unchanged during storage. This was also confirmed by the example of a Li/PGE/(1,3,4-thiadiazole-2,5-dithiol + polyaniline-based composite cathode) cell. According to XPS data, only a LiF–LiOH layer was retained upon cycling in a gel-electrolyte containing LiBF₄, whereas, in a gel-electrolyte containing LiPF₆, a dense and thin LiF interlayer was ‘incorporated’

into the LiF–LiOH mixed layer. It was assumed that the layer containing LiF and LiOH formed during preliminary cycling stabilises the Li/PGE interface.

Electrolyte based on the following polymers were studied:³¹² dimethyl ether of tetra(ethylene glycol) (tetraglyme), dimethyl ether of poly(ethylene glycol) ($M_w = 400$) and poly(methylene ethylene oxide). The study was aimed at elucidation of the kinetics of decomposition of liquid and solid polyether electrolytes, which contained either LiPF₆ or complexes based on this salt and exhibited high thermal stability and advanced electrochemical properties resembling those of a pure salt. Lithium bis(diglyme) hexafluorophosphate³¹³ and lithium (pentamethyldiethylenetriamine) hexafluorophosphate³¹⁴ were shown to exhibit advanced thermal stability and conductivity in nonaqueous media.³¹⁵

In recent years, attention is focused on electrolytes based on the PVDF–HFP copolymer called Kynar in the industry. Using LiClO₄, LiPF₆³¹⁶ and LiN(CF₃SO₂)₂,³¹⁷ as well as the EC/ethyl methyl carbonate plasticising mixtures, the PVDF–HFP electrolyte films with advanced mechanical and electrochemical properties were obtained. In another study,³¹⁸ PVDF–HFP membranes were first cast using such solvents as acetone, THF, ethyl methyl ketone and *N*-MP and then impregnated with a 1 M solution of LiBF₄ in PC. The polymeric electrolytes obtained had a conductivity of an order of magnitude of 10^{-3} S cm⁻¹.

Syntheses of new gel-electrolytes based on PVDF^{319–321} and PVDF–HFP^{322–327} have been reported.

The search for new polymeric electrolyte compositions for lithium-ion cells is in progress. About 100 publications on this subject appear annually. For a deeper insight into the state-of-the-art of this field, the readers are directed to the reviews^{239, 328, 329} and the book.²⁴²

VIII. Conclusion

In the past decade, lithium-ion rechargeable batteries have occupied a significant place in the power source market. They are extensively used in portable electronic devices. At present, active research on the development of large batteries, particularly, for electric vehicles is in progress. Success achieved in elaboration of lithium-ion cells is determined by the progress in the research fields of intercalation processes and development of high-performance intercalation materials. Despite the evident achievements, many problems remain to be solved.

While this review was in the stage of preparation, interesting publications devoted to lithium rechargeable batteries have appeared. For example, interesting information can be found in the Proceedings of the 10th International Meeting on Lithium Batteries which took place in Como (Italy) in 2000 (see Refs 330–353) as well as from the materials of the Joint Meeting of the International Society of Electrochemistry and the Electrochemical Society (USA) held in San-Francisco (USA) in 2001.^{354–390} The studies that deal with nanomaterials (such as fullerenes and nanotubes) used for negative electrodes in lithium-ion cells³⁸⁴ and, as a consequence, the new developments in the technology of nanosize materials^{341, 346, 354, 373, 390} deserve attention.³⁸⁴ The research aimed at the development of new materials for both negative^{347, 349, 350, 364, 382, 386, 387} and positive electrodes^{332, 360–362, 368, 370} as well as for electrolytes^{330, 345, 362, 375} is noteworthy. Finally, generalising reviews^{329, 335, 340, 376} should be mentioned.

Abstract. The results of the X-ray photoelectron spectroscopy studies of the electronic structures of trifluorides, oxides and other compounds of Sc, Y and lanthanides (Ln) from La to Lu, except for Pm, in the binding energy range from 0 to 1350 eV are generalised. The established dependences of the Ln4f binding energies and the relative intensities of lines on the atomic number Z do not contradict the theoretical data stating that the Ln4f atomic orbitals (AO) participate markedly in the formation of molecular orbitals (MO) in the lanthanide compounds. It is established that inner valence molecular orbitals (IVMO) composed of the metal Sc3p, Y4p, Ln5p AO and the ligand L(O,F)2s AO are formed in these systems in addition to the outer valence molecular orbitals (OVMO). It is shown that the spectral fine structure caused by multiplet splitting, many-body perturbation and dynamic effects is correlated with the lanthanide oxidation state, the spin state of ions and the mechanisms of the secondary electronic processes accompanying the photoemission and can serve as a characteristic for identification of lanthanide compounds. Charge induction is discussed using titanium and niobium double oxides as examples. The bibliography includes 206 references.

I. Introduction

The lanthanide (Ln) group includes elements with atomic numbers (Z) in the $58 \leq Z \leq 71$ range. Together with scandium, yttrium, and lanthanum, they form the class of rare earth elements (REE) and can be divided into two subgroups, namely, cerium [(La), Ce, Pr, Nd, Pm, Sm, Eu] and yttrium (Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu) subgroups. The electronic configurations of lanthanide atoms can be expressed by the general formula $\{Xe\}4f^n5d^m6s^2$, where $0 \leq n \leq 14$, $m = 0, 1$. In the ground state, lanthanides, except for lanthanum, gadolinium, lutetium and, possibly, terbium, contain no Ln5d electrons ($m = 0$); however, transition of one or two electrons from the Ln4f to the Ln5d shell does not require much energy. In compounds, lanthanides can

exhibit different valences, II, III and IV, the trivalent state being the most typical.^{1–4}

Metallic lanthanides, their chemical compounds and alloys are extensively used in various branches of science and engineering. Thus the rare earth element alloys of the SmCo₅ type are used to produce permanent magnets possessing tremendous energy.^{5,6} Samarium, europium and gadolinium, characterised by high absorption ratios for thermal neutrons, and their compounds are used in nuclear industry. Oxides of these lanthanides are parts of protective ceramic coatings of nuclear reactors; they are suitable for the manufacture of control rods.⁵ Lanthanide additives are used in catalysis.^{7,8} Yttrium, lanthanum and other lanthanides are employed to produce high-temperature superconductors. The development of efficient processes for the isolation of pure lanthanides and for the preparation of their compounds possessing specified physicochemical properties requires the knowledge of their electronic structures and types of chemical bonding. For this purpose, rare earth metals are actively studied by X-ray photoelectron spectroscopy (XPS).^{9–17}

Currently, XPS studies of the electronic structures of substances are performed using expensive spectrometers operating with both X-ray and synchrotron exciting radiations. However, the use of these spectrometers for the investigation of lanthanide compounds is associated with a number of problems because, due to the presence of unpaired Ln4f electrons and specific features of chemical bonding in these compounds and to secondary electronic processes which accompany electron photoemission, the X-ray photoelectron (XPS) spectra of these compounds in the binding energy (E_b) range from 0 to 1350 eV (in which the XPS spectra are normally recorded) contain complex fine structures. This hampers the quantitative elemental analysis of lanthanide compounds and makes difficult the determination of their oxidation states on the basis of the traditional characteristics of the XPS spectra (line intensities and chemical shifts). Therefore, the efforts of researchers are concentrated on the interpretation of the fine structure of the spectra of lanthanide compounds, elucidation of the reasons for its appearance and identification of the relationship between the spectral structure characteristics and the physicochemical properties of compounds.^{5,18}

Thus the effect of the degree of occupancy of the Ln4f shell of lanthanide compounds on the structure of their spectra and the giant Coster-Kronig electron transition phenomenon (dynamic effect) within the core and valence electron shells have been studied by XPS.^{19,20} In addition, the degree of participation of relatively low-lying occupied orbitals of neighbouring atoms in

the formation of inner valence molecular orbitals (IVMO) has been determined.¹⁸ Since an increase in the atomic number (Z) of lanthanides in the range of $57 \leq Z \leq 71$ entails an increase in the $\text{Ln}5p_{3/2}$ electron binding energy [$E_b(\text{Ln}5p_{3/2})$] in their oxides from 17.7 to 27.5 eV, while the oxygen $\text{O}2s$ electron binding energy [$E_b(\text{O}2s)$] is an intermediate value, these compounds are convenient objects for investigating the influence of the difference between the energies of the $\text{Ln}5p$ and $\text{O}2s$ atomic orbitals (AO) on the efficiency of their participation in the IVMO.¹⁸ For example, the $\text{Ln}-\text{O}$ bond lengths (R) in the lanthanide oxides Ln_2O_3 are rather great (~ 0.240 nm); therefore, the formation of IVMO for lanthanide oxides of the beginning of the row is not very efficient. However, in the case of LnO oxides in the gas phase, the $\text{Ln}-\text{O}$ distance is rather short (~ 0.180 nm);²¹ therefore, participation of the $\text{Ln}5p$ and $\text{O}2s$ AO in the formation of IVMO can be substantial; this should be taken into account when investigating the interaction between the atoms contained in the monoxides.

Analysis of the fine spectral structure (besides line intensities and chemical shifts) extends substantially the scope of XPS in the study of lanthanides and their compounds. This is the most adequate technique for determination of the lanthanide oxidation states in compounds, which is widely used in practice.^{6, 7, 12–17, 22–33} Considerable attention is also devoted to the theoretical examination of the multielectron processes which accompany the photoemission of electrons and account for the fine structure observed in the XPS spectra.^{34–41}

In this review, we present the results of XPS investigations of the electronic structures of several series of stable compounds of lanthanides (except for Pm, which is difficult to obtain), Sc, Y and La. The correlations between characteristics of the XPS spectra, physicochemical properties of these compounds and the nature of chemical bonding in them are discussed. Attention is focused on lanthanide trifluorides and oxides. The lanthanide compounds under consideration are rather stable against oxidation in air, high vacuum and X-radiation. Since some of lanthanide oxides have a variable stoichiometric composition inconsistent with the general formula Ln_2O_3 , analysis of the structures of the XPS spectra of these compounds is accompanied by comparison with analogous spectra of some LnL_3 complexes containing Ln^{3+} ions and organic ligands (L). These compounds can be regarded as clusters consisting of condensed molecules rather than as solids with a band electronic structure. Conversely, lanthanide oxides and niobates are solids in which the lanthanide ions occupy the crystal lattice points and are surrounded by oxygen atoms.

II. Lanthanide trifluorides

The lanthanide trifluorides LnF_3 ($\text{Ln} = \text{La}-\text{Lu}$, except for Pm) are relatively stable compounds; the metal ions Ln^{3+} in them are formally trivalent.^{1–4} No noticeable changes were detected in the XPS spectra of these compounds during recording of the spectra using the sample preparation procedure proposed by Teterin *et al.*⁴² In addition to this study,⁴² data on the XPS spectra of some lanthanide fluorides can be found in other publications.^{43–54}

The X-ray photoelectron spectra of lanthanide trifluorides in the binding energy range from 0 to 1350 eV exhibit fine structure for virtually all electron levels.^{42, 52, 55} To analyse XPS spectra and elucidate the relationship between the structural characteristics and the properties of substances, it is convenient to distinguish three conventional spectral ranges.

1. Electron binding energy in the range from 0 to ~ 15 eV. For lanthanide trifluorides, this range of XPS spectra exhibits a poorly resolved structure related to the electrons of outer valence molecule orbitals (OVMO), which are largely formed from the partially filled $\text{Ln}5d$, $\text{Ln}6s$ and $\text{F}2p$ AO. A structure caused by $\text{Ln}4f$ electrons also arises in this region. Theoretical calculations suggest^{54–59} significant participation of the $\text{Ln}4f$ AO in the formation of the OVMO in lanthanide compounds. In this case, in analysis of the chemical bond, the $\text{Ln}4f$ electrons cannot,

generally speaking, be classified as core electrons (as was traditionally considered before).

2. Electron binding energy in the range from ~ 15 to 50 eV. In this region, XPS spectra show relatively well resolved structure due to the electrons of the inner valence MO (IVMO),^{18, 42, 52, 55, 60–63} which are mainly composed of low-energy occupied $\text{Ln}5p$, $\text{Ln}5s$ and $\text{F}2s$ AO of neighbouring atoms. The structure of the IVMO spectra can be used to characterise the structures of the compounds under study and even to estimate the bond lengths in them.

3. Electron binding energy of > 50 eV. This XPS range is typical of electrons of inner (core) MO; specifically, for lanthanide trifluorides, the spectra of the core AO are mainly recorded. These include the $\text{Ln}3p_{3/2}$, $\text{Ln}3d$, $\text{Ln}4s$, $\text{Ln}4p$, $\text{Ln}4d$ and $\text{F}1s$ AO. Both the energy region of the binding energies of these electrons and the low-energy part of the XPS spectra of the compounds in question can be subject to various effects resulting in a more complex spectral structure.^{18, 38–40} Since these effects can arise simultaneously in any binding energy region, when interpreting spectral structure corresponding to individual shells, one should also take into account the structure displayed in other spectral regions. Therefore, when investigating lanthanide compounds by the XPS method, it is expedient to measure the spectrum over the whole experimentally accessible range (Table 1). It should be noted that one or another mechanism giving rise to the fine structure shows itself with variable probability in the spectra of electrons of different shells; this markedly facilitates interpretation of the spectra.

To identify the structural features of the low-energy XPS spectra of lanthanide fluorides, the spectra of scandium and yttrium fluorides have also been studied.^{52, 55}

1. The spectral region of electrons of the outer valence molecular orbitals

The spectra of the outer valence MO of scandium, yttrium and lanthanum trifluorides,^{52, 55} which contain no $4f$ electrons, are largely due to the $\text{M}nd$, $\text{M}(n+1)s^2$ and $\text{F}2p$ electrons of the neighbouring metal (M) and fluorine atoms, respectively (Fig. 1). They are displayed as 3.7-, 3.3- and 2.9-eV wide bell-shaped lines with smeared structures characterised by weighted-mean electron binding energies of 8.9, 8.9 and 8.4 eV, respectively. Comparison of these values with the positions of the maxima of these broadened lines (see Table 1) shows that the line in the spectrum of YF_3 is the most symmetrical. The lines related to the $\text{F}2p$ and $\text{F}2s$ electrons are approximately 21 eV apart (see Table 1). In the spectra of lanthanide trifluorides containing $\text{Ln}4f$ electrons, the line intensity markedly increases with an increase in the metal nuclear charge (Z) due to the increase in the number of these electrons (n_{4f}) (Fig. 2). With the assumption that the $\text{Ln}4f$ electrons do not participate in the formation of chemical bonds in the trifluorides, the spectral structure should be mainly governed by the final state of the ion which arises after photoemission of an $\text{Ln}4f$ electron.^{43, 51, 53, 54, 64–67}

In the XPS spectra of LnF_3 for lanthanides at the beginning of the row, the $\text{Ln}4f$ lines are located at lower binding energies than the OVMO lines (Fig. 3, see also Fig. 2). As the atomic number (Z) of lanthanides and, correspondingly, the n_{4f} number increase (the relationship between these values is considered below), the binding energy of the $\text{Ln}4f$ electrons noticeably increases, and their spectrum overlaps with the line of the OVMO electrons.^{37, 67, 68}

Starting from terbium, the spectrum of $\text{Ln}4f$ electrons starts exhibiting an extra line located at a lower binding energy than the most intense component. As the $\text{Ln}4f$ shell is being filled, this line grows approaching in intensity the high-energy component (see Fig. 2). In the $\text{Tb}4f$ spectrum of TbF_3 , this line is located at a distance of 5.2 eV from the second component. The observed splitting can be qualitatively considered using Tb^{3+} as an example.⁴³ The Tb^{3+} ion occurs in the $(4f^7)(4f^1)^1$ state, which implies the $^7F_6$ term, i.e., the $\text{Tb}4f$ shell is occupied by more than half. Photoemission of one $\text{Tb}4f$ electron gives rise to two final states: $(4f^7) - ^8S$ term and $(4f^7)(4f^1)^1 - ^{2s+1}L_J$ term. Since the former can be attained in only one way and the latter, in seven ways, the intensity ratio of the two components arising in the $\text{Tb}4f$ spectrum is expected to be 1 : 7; this is close to the experimental value (see Fig. 2).

The photoemission of an electron with the $\beta(\downarrow)$ spin is known^{43,69} to require less energy than the removal of an electron with the $\alpha(\uparrow)$ spin. The results of SCF X_α -DV (discrete variation) calculations (with allowance for spin polarisation)⁶⁹ for exchange splitting in the $\text{Ln}4f$ spectra of REE compounds for the second half of the lanthanide row are in qualitative agreement with the corresponding experimental values (Fig. 4); for LnF_3 , they are in accord with published data.⁴³

Indeed, photoemission of an $\text{Ln}4f$ electron gives rise to a more complex final state, resulting in a further complication of the spectra of the $\text{Ln}4f$ electrons. The structure of these spectra is in satisfactory agreement with the set of levels derived from theoretical considerations of the multiplet splitting of the $\text{Ln}4f$ line for the Ln^{3+} cations.^{66,70} The results of these calculations are reflected in Fig. 2 as vertical segments below the $\text{Ln}4f$ spectra. The structure

of the spectra of these electrons can characterise the lanthanide oxidation state in the compounds. As was to be expected, in the case of Lu^{3+} in LuF_3 , the line of $\text{Lu}4f$ electrons is split due to the

spin-orbit coupling into only two components, the difference between their binding energies (ΔE_{so}) being 1.2 eV in magnitude. A similar effect could be expected for the $\text{Yb}4f$ spectrum of Yb^{2+} in YbX_2 (the electronic configuration of Yb^{2+} , like that of lutetium, is $4f^{14}$); this is the case for the Yb atom⁷¹ and for the Yb metal.^{72,73} However, the structure of the spectrum of these electrons in the ytterbium fluoride (see Fig. 2) corresponds to the Yb^{3+} electronic configuration ($4f^{13}$). The structures of the spectra of the Ln4f electrons of other lanthanide ions are also unique and characterise the particular metal ion. When the energy of the exciting X-radiation increases, the intensities of the lines for the metal Ln4f electrons grow.^{74,75} Figure 5 shows the experimental values for the total relative intensity (I_{exp}) of the OVMO and the Ln4f line, found as the ratio of the total area of these spectral lines to the total area of the Ln5p and F2s lines, depending on the

number of Ln4f electrons (n_{4f}) in lanthanide fluorides. The I_{exp} values are described approximately by the linear relation

$$I_{\text{exp}} = 0.128n_{4f} + 0.20, \quad (1)$$

derived using the least-squares method. Equation (1) reflects the experimental dependence of the relative intensity of the Ln4f spectral line on the number of these electrons in the LnF_3 molecules. The absolute term in Eqn (1), equal to 0.20, characterises the relative intensity of lines for the OVMO electrons, which are partially due to Ln5d and F2p AO. It is noteworthy that this value is somewhat greater than the corresponding theoretical value calculated without allowance for the contribution of occupied Ln4f states. This suggests that an Ln4f electron involved in the chemical bond does not lose the *f* nature (traditionally, it has been considered that the Ln4f electron passes preliminarily to the Ln5d orbital), and in the case of LaF_3 , La4f states are formed in its outer valence shell. However, verification of this hypothesis requires a more accurate experimental determination of the relative line intensities than that performed by Teterin *et al.*^{37,67,68} It is significant that such data can, in principle, provide an answer to the question discussed. The difference between the relative intensities for LnF_3 containing Ln4f electrons and the absolute term in Eqn (1) (0.20) is proportional to the number of Ln4f electrons, which slightly participate in the chemical bond, and can be used to estimate the oxidation state of lanthanides in fluorides.

The theoretical dependence of the relative intensity (I_{theor}) of the Ln4f line in the spectra of LnF_3 on the number of electrons (n_{4f}) can be derived using the data on photoionisation cross-sections for low-energy subshells.^{76,77} In this case, the expression for I_{theor} can be written in the form

$$I_{\text{theor}} = \frac{\sigma(4f)n_{4f} + \sum_i \sigma_i(\text{OVMO})n_i}{\sigma(5p)n_{5p} + 3\sigma(\text{F}2s)n_{\text{F}2s}} = \frac{\sigma(4f)n_{4f}}{\sigma(5p)n_{5p} + 3\sigma(\text{F}2s)n_{\text{F}2s}} + \frac{\sum_i \sigma_i(\text{OVMO})n_i}{\sigma(5p)n_{5p} + 3\sigma(\text{F}2s)n_{\text{F}2s}}, \quad (2)$$

where $\sigma(nl)$ is the photoionisation cross-section of the *nl* shell (*n* and *l* are the principal and orbital quantum numbers, respectively); n_{nl} is the number of electrons; the summation involves

occupied OVMO.^{37, 67, 68} The first term in this expression was found under the assumption that the Ln4*f* electrons do not participate directly in the chemical bond. To estimate the second term, the expression in the numerator was replaced by the sum of terms characterising valence AO,

$$\sum_i \sigma_i(\text{OVMO})n_i \approx \sigma(5d)n_{5d} + \sigma(6s)n_{6s} + 3\sigma(\text{F}2p)n_{\text{F}2p}. \quad (3)$$

In this rather rough approximation, the second term of Eqn (2) for LaF₃ was found to be 0.17, which is smaller than the absolute term (0.20) in Eqn (1). The corresponding values for GdF₃ and LuF₃ are 0.16 and 0.15, respectively. In particular, relation (2) can be written in the form

$$I_{\text{theor}} = \frac{\sigma(4f)n_{4f}}{\sigma(5p)n_{5p} + 3\sigma(\text{F}2s)n_{\text{F}2s}} + 0.17. \quad (4)$$

Assuming that the Ln atoms involved in the chemical bonds in LnF₃ have the configuration 4*fⁿ*5*d*¹6*s*², using the atomic photoionisation cross-sections of the Ln4*f* shell⁵² and taking into account Eqn (4), one can obtain the following expression for I_{theor} :

$$I_{\text{theor}} = 0.01 n_{4f}^{2.24} + 0.17. \quad (5)$$

The plotted function I_{theor} and the corresponding experimental data are presented in Fig. 5.

The substantial difference between the theoretical and experimental values considered can hardly be explained by errors brought about by rough calculations of some terms of Eqn (5) or by the change in the Ln4*f* line intensity caused by different scattering of low-energy electrons upon photoemission. Note that the use of the photoionisation cross-sections of the outer 3*d* electrons for Period 4 elements and various low-lying inner electron levels for any other elements reported in Refs 76 and 77 to determine the relative intensities of their lines provides, as a rule, satisfactory agreement between theoretical and experimental data within the experimental error. Among other reasons, the

observed discrepancy may be due to participation of the Ln4*f* electrons in the chemical bonds.

2. The energy region of Ln5*p* and F2*s* electrons

When investigating the structures of XPS spectra of low-energy electrons in the binding energy range from 0 to 50 eV, in particular, in the spectra of lanthanide compounds, researchers noted that some lines in this range are often substantially broader than the corresponding lines for the core electrons.^{78, 79} Indeed, it follows from the uncertainty relation $\Delta E \Delta \tau \approx h/2\pi$ (ΔE is the atomic level width, $\Delta \tau$ is the lifetime of the 'hole' formed upon photoemission of an electron, and h is Planck's constant) that the lines for the low-lying electrons should be the broadest because the parameter $\Delta \tau$ decreases with an increase in the magnitude of the atomic level energy. However, for example, in LaF₃, the width (Γ) of the F2*s* line is 3.5 eV (see Fig. 1), whereas the low-lying F1*s* electrons account for $\Gamma(\text{F}1s) = 1.6 \text{ eV}$ ⁵ (Table 2).

Whereas line broadening in the binding energy range from 0 to ~15 eV can be due to the MO formation and solid-state effects, the broadening of lines in the energy range from ~15 to 50 eV cannot be interpreted in terms of the well-known classical mechanisms of fine structure origination alone. Moreover, the XPS spectra in the Ln5*p* and F2*s* binding energy range have a more complex structure than that expected upon simple superposition of the lines due to the corresponding lanthanide and fluorine atomic shells (see Fig. 2).⁵² Therefore, it has been suggested that this structure could arise due to the formation of the inner valence molecular orbitals largely composed of the Ln5*p* and F2*s* AO of neighbouring atoms.^{18, 42} In addition, it was found that separate maxima can be distinguished in the spectra and attributed, in a certain approximation, to the Ln5*p*_{3/2} and Ln5*p*_{1/2} components of the doublet (see Fig. 2).

The overall atomic spectra of this region obtained by summation of the Sc3*p*, Y4*p*, Ln5*p*_{3/2, 1/2} and F2*s* lines for scandium, yttrium, and some lanthanide trifluorides are presented in Fig. 6. In the simulation of these spectra, the spin-orbit splitting $\Delta E_{\text{so}}(\text{Mnp})$ was varied around the corresponding value for the metal,⁸⁰ and the FWHM (full line width at half maximum) Γ and

Table 2. Spectral parameters found by comparison of the approximate atomic (calculation) and experimental XPS spectra of metal fluorides: electron binding energies (E_b , eV), spin-orbit splitting [$\Delta E_{\text{so}}(\text{M}5p)$, eV], binding energy difference between the F2*s* and F1*s* electrons [$\Delta E_b(\text{F}2s - \text{F}1s)$, eV], line widths (Γ , eV)⁵⁵ and photoionisation cross-sections (σ) at 1487 eV.⁷⁶

^a For the F2*s* electrons, $\sigma = 0.210$. ^b The $\Delta E(\text{F}2s - \text{F}1s)$ values for MnF₂ and MnF₃ are 655.4 and 655.2 eV, respectively. ^c Comparison of the approximate atomic spectra of Ln, Y, Sc and F with experimental spectra of the fluorides was carried out for La–Er, Y and Sc relative to the Ln5*p*_{3/2}, Y3*p*_{3/2} and Sc3*p*_{3/2} energies, and for Tm–Lu, relative to the Ln5*p*_{1/2} energies. ^d In relative units, 1 rel.u. = 13.600 barn. ^e The values for individual metals are given.⁸⁰ ^f The Y4*p*_{3/2, 1/2} energies are presented. ^g The Sc3*p*_{3/2, 1/2} energies are presented.

Figure 6. XPS spectra of the MF_3 fluorides in the $\text{Sc}3p$ (a), $\text{Y}4p$ (b), $\text{La}5p$ (c), $\text{Tb}5p$ (d), $\text{Er}5p$ (e), $\text{Lu}5p$ (f) and $\text{F}2s$ binding energy ranges.⁴² The continuous lines show the experimental spectra, the vertical dashed segments correspond to atomic spectra; the dots show the summarised spectra; and the dashed lines are the differences between the experimental and simulated spectra.

the $\text{F}2s$ binding energies with allowance for photoionisation cross-sections^{76,77} were varied until the best agreement with the experimental spectra was attained. It was assumed that the composition of the compounds considered corresponds to the stoichiometric formula MF_3 , and the spectral lines for their electrons have a Lorentzian form. The spectral parameters found in this way and the corresponding experimental values are presented in Table 2 and in Fig. 7. These values characterise the main features of the considered spectra and barely reflect the complex structure of the spectra. Therefore, one should not expect too large a difference between the theoretical and experimental values (see Fig. 6, Table 2). Thus the general trend for the increase in the spin-orbit splitting [$\Delta E_{\text{so}}(\text{M}5p)$] and FWHM (Γ) for $\text{Ln}5p$ electrons can be followed, but the FWHM values for the $\text{F}2s$ lines are markedly different (see Table 2).

The binding energy differences between the $\text{F}2s$ and $\text{F}1s$ electrons [$\Delta E_b(\text{F}2s - \text{F}1s)$] for the metal fluorides studied differ somewhat from the corresponding values for $3d$ -metal compounds, in particular MnF_2 and MnF_3 , in which the conditions for IVMO formation from the $\text{F}2s$ and $\text{Mn}3p$ AO are much less advantageous than those in LnF_3 . It really follows from this comparison (see Table 2, Fig. 2) that the experimental spectra in the considered energy range do not consist of separate lines but have a more complex structure. The dependence of the $\text{Ln}5p$ binding energy on the atomic number (Z) is relatively weak and is nearly linear for the whole lanthanide series (see Fig. 7). This pattern of the $E_b - Z$ curve is not typical of the core shells the energy of which follows a quadratic dependence on Z .

The $\text{F}2s$ XPS spectra for LaF_3 , CeF_3 , PrF_3 , NdF_3 and SmF_3 exhibit a clear-cut shoulder removed from the basic line by ~ 2.2 eV towards higher electron binding energies. In the spectra of other lanthanide trifluorides, this region is superimposed by the

Figure 7. Binding energies (E_b) of the $\text{Ln}4p_{3/2}$ (1), $\text{Ln}5p_{1/2}$ (2) and $\text{Ln}5p_{3/2}$ electrons (3) of lanthanide trifluorides vs. the metal atomic number in the La–Lu series. The error in determination of the electron binding energies from the maxima of the corresponding lines is ± 0.2 eV.⁵

$\text{Ln}5p_{1/2}$ line, which complicates the observation of this shoulder. This extra structure cannot be due to fluorine atoms having different oxidation states because the $\text{F}1s$ line in the spectra of these compounds is rather narrow and symmetric. On passing from La to Sm, the $\text{Ln}5p_{3/2}$ and $\text{Ln}5p_{1/2}$ binding energies increase by 3.5 and 5.1 eV, respectively. Simultaneously, the shoulder at the basic $\text{F}2s$ line shifts to a much lesser extent. The absence of the corresponding shoulder at the $\text{F}1s$ line suggests that this shoulder is not due to many-body perturbation, i.e., to the so-called shake-up (or shake-down) process, which implies transition of a valence electron to a higher (or lower) excited state simultaneously with photoemission of a core electron and gives rise to shake-up (or shake-down) satellites on the side of higher (or lower) electron binding energies of the basic spectral line. In other words, the observed shoulder is not a shake-up (shake-down) satellite.^{5,42}

The same conclusion can be drawn by analysing and comparing the relative electron binding energies of satellites in the spectra of various core electrons of the fluorides studied. Complication of the structure of LnF_3 spectra in the $\text{Ln}5p$ and $\text{F}2s$ electron binding energy ranges in, for example, the spectra of LaF_3 and LuF_3 cannot be due to the multiplet splitting either, as these fluorides contain no unpaired $\text{Ln}4f$ electrons and they are diamagnetic. This splitting should result, apparently, in some broadening of the $\text{Ln}5p$ doublet lines for lanthanide trifluorides that contain unpaired $\text{Ln}4f$ electrons, which is actually observed in the spectra of fluorides of light lanthanides (see Fig. 2). This is not at variance with the results of the estimation of the influence of this factor on the $\text{Ln}5p$ spectra performed in the approximations of isolated Ln^{3+} ions⁸¹ and atoms in the metals.⁸²

On the basis of the foregoing data and with allowance for similar results for oxygen-containing lanthanide compounds,^{57–59, 78, 79, 83, 84} it was suggested that one reason for structure complication in the $\text{Ln}5p$ and $\text{F}2s$ spectral range is the formation of IVMO, mainly from the $\text{Ln}5p$ and $\text{F}2s$ AO.^{5, 18, 42, 52} The spectral structure in this energy range can be qualitatively described by considering the diagram of the IVMO levels for the clusters that reflect the surrounding of the metal atoms by the ligands in the MF_3 trifluorides (Fig. 8).

Lanthanide (La to Sm) trifluorides form a tysonite hexagonal layered lattice characterised by the D_{6h}^3 ($C6/mcm$) point group of symmetry.^{2, 85} The wavy layers of F atoms alternate in the lattice with the flat layers composed of Ln and F atoms, which form six-membered rings. The lanthanide atoms are surrounded by three fluorines. Therefore, a calculation of the electronic structure of the lanthanide trifluorides has been carried out for LnF_3 clusters with D_{3h} symmetry.⁴⁷ It has been noted² that the structures of

Figure 8. Diagram of IVMO formed by the metal Mnp and Mns AO and the ligand $L2s$ AO of model clusters. (a) ML_3^{n1-} (D_{3h} symmetry); (b) ML_6^{n2-} ; (c) ML_8^{n3-} (O_h symmetry).⁴²

lanthanide trifluorides from La to Ho can be regarded as a hexagonal LaF_3 (tysonite) structure, space group D_{3d}^4 ($P\bar{3}c1$). In this structure, each lanthanum atom is surrounded by nine fluorine atoms located at distances of 0.2416 to 0.2640 nm. At room temperature, lanthanide (Sm to Lu) trifluorides can also have the YF_3 structure² with an orthorhombic lattice, space group D_{2h}^{16} ($Pnma$). Each yttrium atom in the structure is surrounded by eight fluorine atoms located at distances of 0.225 to 0.232 nm. One more (ninth) fluorine is located at a distance of 0.260 nm.

To discuss qualitatively the spectral patterns in the $Ln5p$, $Y4p$, $Sc3p$ and $F2s$ energy ranges in terms of the IVMO concept, Teterin *et al.*⁴² used, instead of the real structures, structural models of the local environment of the metal atoms in fluorides resembling most closely the real structures but which are more symmetrical.⁴² Using group theory in a non-relativistic (NR) approximation for the chosen model clusters, one can describe schematically the structure and energy of the IVMO consisting of the Mns , Mnp and $L2s$ AO of the neighbouring metal and ligand atoms (see Fig. 8). The IVMO structures corresponding to different local environments of the metal are significantly different. Thus, for the ML_3^{n1-} cluster (D_{3h} symmetry), two energy levels representing the a_2' and e'^* IVMO are observed instead of one level representing the Mnp AO. In the case of ML_6^{n2-} and ML_8^{n3-} clusters (O_h symmetry), as for the metal atom, this energy range contains one level whose position can vary (see Fig. 8). The relative intensities of lines of the theoretical IVMO spectra for clusters of different symmetries are proportional to the electron photoemission cross-sections and degeneration factors for different levels (a_1' , a_{1g} , a_{2u} are non-degenerate, e' are doubly degenerate, and t_{2g} and t_{1u} are triply degenerate IVMO); thus, they should be typical and substantially different.

In the clusters in question, the interaction of the filled Mnp and $L2s$ AO gives rise to bonding (e' , t_{1u}) and antibonding (e'^* , t_{1u}^*) IVMO. If the admixtures of the vacant valence $Ln4f$, $Ln5d$ and $Ln6s$ AO in these IVMO are small, the electrons of these MO should influence only slightly the energy of the chemical bond in the cluster. A significant admixture of these AO in IVMO would weaken the antibonding nature of the e'^* (t_{1u}^*) MO and enhance the bonding nature of the e' (t_{1u}) MO. Thus, the formation of these IVMO would result in stronger binding between the neighbouring atoms.^{18, 55, 60, 86, 87} The interaction of the Mns AO with the $L2s$ AO can also give rise to couples of bonding a_1' and a_{1g} and the corresponding antibonding $a_1'^*$ and a_{1g}^* IVMO. Analogous con-

siderations concerning the influence of IVMO electrons on the chemical bonding in clusters are also applicable to these IVMO. Some IVMO such as a_2' , e_g , a_{2u} and t_{2g} are mainly formed by the Mnp and $L2s$ AO. However, vacant valence AO can also be admixed to them. If these admixtures are small, the IVMO would be of the quasi-atomic nature.

The limited resolving power of X-ray photoelectron spectrometers and line broadening caused by solid-state effects in the spectral range considered preclude elucidation of all structural details of the IVMO in lanthanide trifluorides. Nevertheless, the most clear-cut changes in the structure of the IVMO spectra compared to the structure of the spectra of the AO of neighbouring atoms are experimentally measurable. It is noteworthy that in a more rigorous approach, the real experimental spectra of lanthanide compounds should be compared with the theoretical spectra calculated using the relativistic approximations taking into account many-body processes that take place during the electron photoemission. However, no calculations of this type are available to date.

When discussing the low-binding energy spectral structure in MF_3 which are characterised by relatively low spin-orbit coupling between the low-energy filled Mnp shells, one can use the data of non-relativistic calculations. This is true for compounds such as, for example, ScF_3 , YF_3 and LaF_3 ; the spin-orbit splittings (ΔE_{so}) for the $Sc3p$, $Y4p$ and $La5p$ levels are equal to 0.7, 1.3 and 2.3 eV, respectively (see Table 2). The results of non-relativistic SCF X_α DVM calculations of the electronic structures of the ScF_6^{3-} (C_3 symmetry), non-symmetrical YF_9^{6-} and LaF_{11}^{8-} (D_{3h} symmetry) clusters (Fig. 9)⁶³ are given schematically in Figs 10, 11, 12. The structures of these clusters simulate most closely the environment of scandium, yttrium and lanthanum in ScF_3 , YF_3 and LaF_3 , respectively.

Figure 9. Structure of the ScF_6^{3-} (C_3 symmetry) (a) and LaF_{11}^{8-} (D_{3h} symmetry) clusters (b). The $Sc-F$ bond length in ScF_6^{3-} is 0.202 nm; in the LaF_{11}^{8-} cluster, the average value over five distances $\bar{R}(La-F) = 0.239$ nm, and that for the other six distances, $\bar{R}(La-F) = 0.272$ nm.⁶³

The calculations for the electronic structure of the ScF_6^{3-} cluster (C_3 symmetry) were performed using structural data² of ScF_3 , which indicate that the fluorine atoms are located at approximately equal distances from scandium; the average $\bar{R}(Sc-F)$ value is 0.202 nm, and no inversion centre is present (see Fig. 9).

According to these calculations, the broadened line near the Fermi level in the spectrum of ScF_3 is attributed to OVMO electrons (see Figs 1, 10). The spectral structure in the $Sc3p$ and $F2s$ binding energy range is due to the IVMO electrons. For the considered $Sc-F$ bond lengths in the ScF_6^{3-} cluster, noticeable mixing of the $Sc3p$ and $F2s$ AO takes place, resulting in the formation of the $1a_1$ and $3a_1$ IVMO. Therefore, the fine structure in the spectrum of the $Sc3p$ and $F2s$ electrons is attributable to the formation of these IVMO (see Figs 1, 6).

The resonance energy values $E_x^R(Sc-F)$,¹⁸ which characterise the covalent bonding between scandium and fluorine in ScF_3 imply that the greatest contribution to the stability of ScF_3 is made by the $5a_1$ OVMO and $2a_1$ and $1a_1$ IVMO electrons. Due to mixing

Figure 10. Diagram of the MO in the ScF_6^{3-} cluster [C_3 symmetry, $\bar{R}(\text{Sc}-\text{F}) = 0.202$ nm] calculated in the SCF X_α -DVM approximation.⁶³ The MO energies are expressed in eV (the diagram is not scaled). The values in parentheses are the resonance energies $E_\alpha^R(\text{Sc}-\text{F})$ in a.u.

of the outer and inner valence AO, as noted in a number of publications,^{18, 52, 55, 85, 86} the contribution of the bonding $1a_1$ IVMO prevails over the contribution of the antibonding $3a_1$ IVMO, and, in total, the electrons of these MO strengthen the bond. If the contribution of the $2a_1$ IVMO is taken into account, the total covalent contribution of the IVMO electrons to the chemical bond energy in the ScF_6^{3-} cluster (C_3 symmetry) would be $\sim 43\%$. Comparison of the calculated energy levels with the experimental spectra should be done using the data for the so-called transition state rather than for the ground state.⁸⁸ However, the energy levels calculated for the transition state in a narrow range of MO energies are known to be shifted relative to those found for the cluster ground state towards greater (in magnitude) E_b by a virtually constant value equal to several electron-volts (see, for example, Ref. 89). For comparison, MO energies for the ScF_6^{3-} cluster (C_3 symmetry) increased (in magnitude) by 2 eV are shown in Fig. 1 as vertical segments below the experimental XPS spectrum of scandium trifluoride. A satisfactory qualitative agreement between the experimental and theoretical results can be noted.

The structure of the yttrium local environment in YF_3 is rather complicated. Therefore, the YF_9^{6-} cluster, which has no symmetry elements and in which the metal environment resembles most

Figure 11. Diagram of MO of the asymmetrical YF_9^{6-} cluster (SCF X_α -DVM) in which the average value over eight bond lengths, $\bar{R}(\text{Y}-\text{F}) = 0.229$ nm, and for the ninth bond length, $R(\text{Y}-\text{F}) = 0.260$ nm.⁶³ The MO energies are expressed in eV (the diagram is not scaled).

closely the yttrium environment in the trifluoride, can be chosen for the electronic structure calculations. In this case, the yttrium atom is surrounded by eight fluorine atoms located at distances $\bar{R}(\text{Y}-\text{F}) = 0.229$ nm and one fluorine atom located at the distance $R(\text{Y}-\text{F}) = 0.260$ nm.^{2, 63, 90} The calculation results indicate that the higher occupied OVMO are mainly formed by the $\text{F}2p$ AO, while the lower OVMO involve the $\text{F}2p$ and $\text{Y}4d$ AO (see Fig. 11). The IVMO formation is associated with substantial mixing of the $\text{Y}4p$ and $\text{F}2s$ AO, which may be as great as 50%.

For comparison of the theoretical results of the electronic structure of the YF_9^{6-} cluster with the structure of the XPS spectrum of YF_3 , the magnitudes of the MO energy were increased by 10 eV. These results are given under the XPS spectra of yttrium trifluoride in Fig. 1 as vertical segments. The considered calculation results suggest that the spectrum in the $\text{Y}4p$ and $\text{F}2s$ binding energy range reflects the IVMO system in YF_3 . The appearance of these MO can also account for the additional structure observed in this range of the spectrum of YF_3 as shoulders next to the expected atomic lines.

Figure 12. Diagram of MO of the LaF_{11}^{8-} cluster (D_{3h} symmetry) (SCF X_α -DVM) in which the average value over five bond lengths, $\bar{R}(\text{La}-\text{F}) = 0.239$ nm, and for the other six lengths, $\bar{R}(\text{La}-\text{F}) = 0.272$ nm.⁶³ The MO energies are expressed in eV (the diagram is not scaled).

The structure of the low binding energy XPS spectra of lanthanum trifluoride was interpreted using theoretical data for the electronic structures of the LaF_{11}^{8-} cluster (D_{3h} symmetry) obtained by non-relativistic SCF X_α -DV calculations.^{5,63} The calculations were based on the crystallographic data for LaF_3 ,^{2,63} which imply that five fluorine atoms in the LaF_{11}^{8-} cluster are located at an average distance $\bar{R}(\text{La}-\text{F}) = 0.239$ nm away from the lanthanum atom, while the other six fluorines are located at a distance $\bar{R}(\text{La}-\text{F}) = 0.272$ nm (see Fig. 9). The results of calculations are presented in Fig. 12, which shows that the overlap of the $\text{La}5s$, $\text{La}5p$ and $\text{F}2s$ AO results in the formation

of the $1a_1' - 3a_2''$ IVMO system. Due to the substantial difference between the $\text{La}5p$ and $\text{F}2s$ binding energies [the experimental $\Delta E_b(\text{La}5p_{3/2} - \text{F}2s)$ value is 10.7 eV] and long $\text{La}-\text{F}$ bonds, the degree of mixing of the $\text{La}5p$ and $\text{F}2s$ AO is not large.

To compare the results of calculations for the electronic structure of the LaF_{11}^{8-} cluster (D_{3h} symmetry) with the structure of the experimental X-ray photoelectron spectrum of LaF_3 , the absolute MO energies were increased by 14 eV (see Fig. 1).

As the chemical bond in LaF_3 is formed, the difference between the $\text{La}5p_{3/2}$ and $\text{La}3d_{5/2}$ binding energies does not change within the error of measurements. For instance, for metallic lanthanum, $\Delta E_b(\text{La}5p_{3/2} - \text{La}3d_{5/2}) = 818.6$ eV⁹¹ or 818.2 eV,⁵ and for LaF_3 , this value is 818.7 eV⁴² (see Table 1). However, the formation of IVMO of the $3e'$ and $3a_2''$ type is not expected to cause necessarily a significant increase in this energy difference (see Fig. 12) because the mixing of outer and inner valence AO during the IVMO formation may be accompanied by a substantial decrease in the antibonding type of these orbitals.¹⁸ Unfortunately, no theoretical results for the trifluorides of heavier lanthanides using either the non-relativistic or relativistic approximation are currently available. Nevertheless, it follows from the given examples that the results of theoretical calculations agree qualitatively with experimental data. This suggests that the complication of the XPS spectral structure for REE trifluorides in the region of the Mnp and $\text{F}2s$ binding energies is due to the formation of IVMO.

3. The spectra of core electrons

a. The structures of the spectra of the $\text{Ln}5s$ and $\text{Ln}4s$ electrons

It follows from theoretical calculations⁵⁶⁻⁵⁹ that the $\text{Ln}5s$ AO in lanthanide compounds can be involved in the IVMO formation. However, the concomitant changes in the $\text{Ln}5s$ spectra observed on passing from metals to compounds are difficult to detect because various effects determining the structure of the XPS spectra can show themselves in this spectral range (Fig. 13). Complication of the spectral structure in the $\text{Ln}5s$ binding energy range for the compounds considered can be related to the appearance of additional broadened lines caused by electronic Auger transitions. Thus the lines at 63 and 46 eV in the spectra of ErF_3 and TmF_3 , respectively, have been attributed⁵ to the electronic Auger transitions of the M_5NN type.⁹² Nevertheless, in many cases, the basic line for the $\text{Ln}5s$ electrons, which also has a complex structure, can be distinguished in these spectra. On the side of higher (by 14–16 eV) binding energies, a relatively intense additional structure is observed. A similar, though less intense structure is found in the spectra of electrons of other deep core shells. Therefore, many-body perturbation giving rise to shake-up satellites in the spectra might be a reason for this additional structure (see Fig. 13).

Comparison of the $\text{Ln}5p$ and $\text{Ln}5s$ binding energies (see Table 1) shows that the approximate equality $E_b(\text{Ln}5s) \approx 2E_b(\text{Ln}5p)$ holds for the lanthanide trifluorides considered. It allows the suggestion that a significant complication of the $\text{Ln}5s$ spectral structure may be caused by the dynamic effect related to the giant Coster-Kronig transitions within the $\text{Ln}5s$, $\text{Ln}5p$ and $\text{Ln}4f$ shells. As a consequence, photoemission of an $\text{Ln}5s$ electron gives rise to not only the ground final state ($\text{Ln}5s^1 5p^6 4f^n$) but also an excited final state ($\text{Ln}5s^2 5p^4 4f^{n+1}$) with an energy close to that of the ground state. This situation is sometimes considered as the interaction of the configurations of the final states, $\text{Ln}5s^1 5p^6 4f^n \leftrightarrow \text{Ln}5s^2 5p^4 4f^{n+1}$. In particular, this might be the reason for some extra peaks in the $\text{Ln}5s$ spectra (see Fig. 13).

The $\text{Ln}5s$ spectra of lanthanide compounds exhibit, in the simplest case, a structure related to multiplet splitting (ΔE_{ms}).^{44,93,94} In this case, two components arise instead of the expected single line; the splitting is proportional to the number of unpaired $\text{Ln}4f$ electrons. The greatest multiplet splitting was observed for the lanthanide trifluorides of the middle of the lanthanide row, the maximum value being found for GdF_3 : $\Delta E_{\text{ms}}(\text{Gd}^{3+}) = 3.2$ eV (see Fig. 13). The dependence of the elec-

Figure 13. XPS spectra of lanthanide trifluorides in the Ln5s binding energy range.⁴² (a) LaF₃, (b) CeF₃, (c) PrF₃, (d) NdF₃, (e) SmF₃, (f) EuF₃, (g) GdF₃, (h) TbF₃, (i) DyF₃, (j) HoF₃, (k) ErF₃, (l) TmF₃, (m) YbF₃, (n) LuF₃.

tron binding energies corresponding to these two components on the lanthanide atomic number is presented in Fig. 14.

A similar structure was observed in the Ln4s spectra of lanthanide trifluorides (Fig. 15). In the case of TbF₃, DyF₃, HoF₃ and ErF₃, intense lines caused by the electronic Auger transitions of the $M_5N_{45}O_3$, $M_5N_{45}O_1$, $M_5N_4N_{45}$ and $M_4N_4N_{45}$ types, respectively, appear in the Ln4s binding energy range.⁹² In the Ln4s spectra of these compounds recorded on a spectrometer

Figure 14. Binding energies (E_b) of the Ln4s (1) and Ln5s electrons (2) of lanthanide trifluorides vs. the metal atomic number in the La–Lu series.⁵ The error of determination of the electron binding energy is ± 0.2 eV.

with X-ray $MgK_{\alpha 1.2}$ excitation (1253.6 eV) instead of $AlK_{\alpha 1.2}$ excitation (1486.6 eV), as was to be expected, no Auger lines are observed around the Ln4s XPS lines.⁴⁴ In this case, the Auger lines are shifted towards the lower binding energy range by the value

$$\Delta E = E(AlK_{\alpha 1.2}) - E(MgK_{\alpha 1.2}) = 233 \text{ eV}.$$

The parameters of the Ln4s spectra of TbF₃, DyF₃, HoF₃ and ErF₃ found by Cohen *et al.*⁴⁴ allowed interpretation of some of the lines in the previously recorded spectra of these electrons⁵ (see Table 1, Fig. 13). The use of $AlK_{\alpha 1.2}$ X-ray excitation provided the possibility of recording the Ln4s spectra for the trifluorides of light lanthanides.^{42, 52}

Like the spectra of the Ln5s electrons, the spectra of the Ln4s electrons contain a structure attributable to many-body perturbation on the higher (by ~ 14 – 16 eV) binding energy side of the basic lines (see Fig. 15). Since the approximate equality

$$E_b(Ln4s) \approx E_b(Ln4p) + 2 E_b(Ln5p),$$

holds for the whole lanthanide row, the Ln4s spectra are expected to exhibit a structure caused by the dynamic effect, which results in the formation of two final states, $Ln4s^1 4p^6 5p^6 4f^n \leftrightarrow Ln4s^2 4p^5 5p^4 4f^{n+2}$.

The above rule holds worst for heavy lanthanides; therefore, the configuration interaction should be manifested in the Ln4s spectra of these metals to a lesser extent than in the case of light lanthanides (see Table 1, Fig. 15). This interaction can lead to broadening of the Ln4s lines in the spectra of lanthanide trifluorides. For Gd³⁺, this agrees with the results of theoretical calculations.⁹⁵

In the Ln4s spectra of LnF₃, as in the spectra of lanthanide metals,⁹³ multiplet splitting is about twice as effective as in the Ln5s spectra (Fig. 16, see also Fig. 15). The maximum value is reached for GdF₃, in which the Gd³⁺ ion contains the greatest number of unpaired Gd4f electrons and occurs in an energy state with the multiplicity $2S + 1 = 8$. The dependence of the multiplet splitting for the Ln4s and Ln5s lines on the multiplicity ($2S + 1$) of the state of the lanthanide ion in the trifluorides is reflected in Fig. 16, which shows the data of different researchers obtained using both $AlK_{\alpha 1.2}$ and $MgK_{\alpha 1.2}$ excitation types (The data gained with different types of excitation supplement each other.)

The multiplet splitting values (ΔE_{ms}) found by Teterin *et al.*^{5, 42} are somewhat lower than the corresponding values determined by Cohen *et al.*⁴⁴ Apparently, this is due to the fact that in determining the ΔE_{ms} values, Teterin *et al.*^{5, 42} used, whenever possible, the binding energies for the 4s and 5s electrons found

Figure 15. XPS spectra of lanthanide trifluorides in the Ln4s binding energy range.⁴² (a) LaF₃, (b) CeF₃, (c) PrF₃, (d) NdF₃, (e) SmF₃, (f) EuF₃, (g) GdF₃, (h) TbF₃, (i) DyF₃, (j) HoF₃, (k) ErF₃, (l) TmF₃, (m) YbF₃, (n) LuF₃.

from experimental positions of the peaks rather than from the resolution of lines into two components, as was done in the other publication.⁴⁴

The experimental estimates of the ΔE_{ms} values for the Ln5s electrons are consistent with the results of calculations carried out in various approximations.^{44, 69, 87, 93} In the case of Ln4s electrons, to attain agreement with the experimental data, the researchers⁹³ multiplied the determined ΔE_{ms} values by 0.55 (see Fig. 16). The

Figure 16. Multiplet splitting (ΔE_{ms}) of the Ln4s (a) and Ln5s (b) lines in the XPS spectra of lanthanide trifluorides. (1) Data of Ref. 44 (MgK_{α1,2} excitation); (2) data of Ref. 52 (AlK_{α1,2} excitation); the continuous line shows the results of the SCF X_α-DVM calculations;⁶⁹ the dashed line shows the results of *ab initio* calculations;^{44, 93} the dependence of $\Delta E_{ms}(\text{Ln}4s)$ on the multiplicity ($2S+1$) has been multiplied by 0.55.⁹³

symmetrical pattern of the calculated E_{ms} – multiplicity plots can be explained by the fact that, as the Ln4f shell of the Ln³⁺ ions is being occupied by electrons, the total spin (S) initially increases (from La³⁺ to Gd³⁺) and then gradually decreases to zero. Thus, it can be seen from Fig. 16 that the magnitude of splitting of the Ln4s and Ln5s lines characterises the number of unpaired electrons in the lanthanide ions and, as a consequence, the lanthanide oxidation state in the compound. For example, splitting of the Ce4s line, $\Delta E_{ms}(\text{Ce}4s) = 1.5$ eV, in the XPS spectrum points unambiguously to the trivalent state of the cerium ion in the fluoride. The maximum splitting of the Gd5s and Gd4s lines is also consistent with the fact that gadolinium is trivalent in the fluoride considered (see Fig. 16). In this connection, it should be noted that the structure of the Ln4s and Ln5s spectra can be useful in the determination of the oxidation and spin states of lanthanides in compounds.

b. The structures of the spectra of the Ln4d electrons

The spectra of Ln4d electrons in lanthanide fluorides exhibit a complex fine structure in an energy range of ~40 eV (Fig. 17, see also Table 1). It is noteworthy that the greatest spin–orbit splitting $\Delta E_{so}(\text{Ln}4d)$ over the lanthanide row was found for Lu and was as low as 10 eV. For other lanthanides, the corresponding $\Delta E_{so}(\text{Ln}4d)$ values cannot be determined experimentally due to the complicated structure of the Ln4d XPS spectra. In the region of the Dy4d, Ho4d, and Tm4d spectra at 231, 163 and 235 eV, the lines for Auger electrons can arise, caused by L_1MN , L_1MN and $M_5N_5O_3$ type transitions, respectively.⁹² The lines observed at 187 and 207 eV in the Yb4d spectrum might also be Auger lines caused by the $M_5N_5O_1$ and $M_5N_4O_2$ electronic transitions (see Fig. 17). The spectra can also become complicated due to many-body perturbation accompanied by the formation of shake-up satellites on the higher binding energy side of the basic lines, for example, at $\Delta E_b = 14–16$ eV. As has already been noted with regard to the Ln4s and Ln5s spectra (see Fig. 13, 15), the

Figure 17. XPS spectra of lanthanide trifluorides in the Ln4d binding energy range.⁵² (a) LaF₃, (b) CeF₃, (c) PrF₃, (d) NdF₃, (e) SmF₃, (f) EuF₃, (g) GdF₃, (h) TbF₃, (i) DyF₃, (j) HoF₃, (k) ErF₃, (l) TmF₃, (m) YbF₃, (n) LuF₃. Vertical segments show the calculation results for the spectra of these electrons in the Ln³⁺ ions with allowance for the multiplet splitting.⁶⁶

intensity of these satellites should not be high. Among the lanthanide electronic configurations that can arise after photoemission of the Ln4d electrons upon the giant Coster-Kronig transitions between the core and valence shells, the

$\text{Ln}4d^9 5s^2 5p^6 4f^n \leftrightarrow \text{Ln}4d^{10} 5s^0 5p^5 4f^{n+2}$ configurations are the most probable. However, since the approximate equality

$$E_b(\text{Ln}4d) \approx 2 E_b(\text{Ln}5s) + E_b(\text{Ln}5p)$$

scarcely holds for lanthanides (see Table 1), it has been suggested⁴² that the structure related to the dynamic effect would not be pronounced in the Ln4d spectra.

The structure of the Ln4d spectra depends on the atomic number of the lanthanide (Z), the simplest structures being observed for LaF₃^{50, 52} and LuF₃. These fluorides contain no unpaired Ln4f electrons, and their Ln4d spectra exhibit sharp doublets related to the spin-orbit coupling. The spin-orbit splitting markedly increases by the end of the lanthanide row; indeed, it amounts to 3.1 and 10.0 eV for LaF₃ and LuF₃, respectively (see Fig. 17). The extra structure detected in the Ln4d spectra of these compounds may also be due to both the many-body perturbation and (to a lesser degree) the dynamic effect.

The Ln4d spectra of lanthanides containing the unpaired Ln4f electrons are expected to manifest multiplet splitting.^{38, 45, 96} The multiplet splitting was first observed in the spectra of 3d elements and europium.^{97, 98} Unlike the Ln5s spectra in which the line is split into two components, in the case of Ln4d spectra, the final state of the ion after photoemission of these electrons can be rather complicated. In particular, in the Ln4d spectra of most lanthanide trifluorides, the multiplet splitting gives rise to a more complicated structure in a binding energy range of ~40 eV (see Fig. 17). The results of calculations^{45, 66} of the multiplet structure of the Ln4d spectra of Ln³⁺ ions are presented in Fig. 17 as vertical segments under the experimental spectra. Qualitative agreement between the theoretical and experimental data can be noted. For example, the Gd4d spectra exhibit two most intense lines that seem to resemble in shape a doublet caused by the spin-orbit coupling of these electrons (see Fig. 17). Therefore, in the study,⁹⁹ these components in the Gd4d spectrum of metallic gadolinium and Gd₂O₃ were misattributed to the Gd3d_{5/2, 3/2} components of the doublet. In reality, these are two components of the multiplet structure largely associated with the ⁹D and ⁷D final states.⁹⁶ For the Eu atom⁹⁸ and EuO₂ (see Ref. 44), the corresponding peaks in the Eu4d spectrum were also unreasonably ascribed to a doublet. This multiplet spectral structure is typical of particular lanthanide fluorides and in some cases, it can be used to determine the oxidation and spin states of lanthanide ions.

Figure 18. Binding energies (E_b) of the Ln3p_{3/2} (1), Ln3d_{3/2} (2), Ln3d_{5/2} (3) and Ln4d_{5/2} electrons (4) of lanthanide trifluorides vs. the metal atomic number in the La–Lu series.⁵ The Ln4d_{5/2} binding energies were determined for the most intense peaks; the error in the determination of the electron binding energies is ± 0.2 eV.

As the lanthanide atomic number increases, the most intense component in the $\text{Ln}4d$ spectrum shifts regularly towards higher binding energies. This component can formally be matched to the $\text{Ln}4d_{5/2}$ electrons. Figure 18 shows the variation of the binding energies of these components vs. the lanthanide atomic number; the pattern of variation is the same as observed for the core electrons.²² The energies of the $\text{Ln}4d_{3/2}$ electrons can be estimated taking into account the fact that the spin–orbit splitting $\Delta E_{\text{so}}(\text{Ln}4d)$ gradually increases, as noted above, along the lanthanide row (La to Lu) from 3.1 to 10.0 eV.

c. The spectra of the $\text{Ln}4p$ and $\text{Ln}3p$ electrons

The binding energy range corresponding to the $\text{Ln}4p$ electrons in the spectra of lanthanide trifluorides may contain, besides the $\text{Cl}1s$ line caused by the hydrocarbon molecules absorbed on the sample surface, lines related to the Auger electrons.²⁰ These lines are broad and often reflect a whole series of Auger transitions (Fig. 19). For example, the increase in the intensity which starts at 350 eV in the $\text{Dy}4p$ spectrum of dysprosium trifluoride may be due, to an extent, to the electrons of the M_5NO type Auger transitions.⁹² In the $\text{Ho}4p$ spectrum, the Auger lines caused by the M_5NO transitions at $E_b > 310$ eV are so intense that the electronic structure of the XPS spectrum can hardly be observed. The broad band at 400 eV occurring in the $\text{Tm}4p$ spectrum is attributable to the $M_5N_3O_3$ (395.2 eV), $M_5N_4N_5$ (391.1 eV) and $M_5N_4N_4$ (403.2 eV) Auger transitions. The Auger electrons of the $M_5N_2O_2$ (385.8 eV) and $M_5N_1N_7$ (421.7 eV) transitions can be manifested in the $\text{Yb}4p$ and $\text{Lu}4p$ spectra, respectively.

Apart from the lines of the Auger electrons, low-intensity shake-up satellites occur at higher binding energies (by 4–16 eV) than the basic spin doublet lines. In this range of the electron binding energies of lanthanide trifluorides containing unpaired $\text{Ln}4f$ electrons, multiplet splitting can also be observed. Since the LaF_3 and LuF_3 molecules contain no unpaired $\text{Ln}4f$ electrons, the complex structure arising in the spectra of their $\text{Ln}4p$ electrons cannot be attributed to this splitting. The $\text{Ln}4p_{1/2}$ component in these spectra is diffuse; in the case of the $\text{La}4p_{1/2}$ line, the diffusion is pronounced, whereas the $\text{Lu}4p_{1/2}$ spectrum deviates to a lesser extent from the expected one.

Comparison of the $\text{Ln}4p$ and $\text{Ln}4d$ binding energies (see Table 1) shows that the approximate equality $E_b(\text{Ln}4p) \approx 2E_b(\text{Ln}4d)$ holds satisfactorily for the whole lanthanide row. This fact and the presence of a complex structure in the $\text{Ln}4p$ spectrum of lanthanum trifluoride suggest that the significant complication of the $\text{Ln}4p$ spectra for LnF_3 is due to the dynamic effect, which leads to the formation of several final states, $\text{Ln}4p^54d^{10}4f^n \leftrightarrow \text{Ln}4p^64d^84f^{n+1}$ (see Ref. 20). In the case of LuF_3 in which $\text{Lu}4f$ is fully occupied, the giant Coster-Kronig transition of an electron from the $\text{Lu}4d$ shell to the vacant shell next in energy can take place. The probability of such a transition is lower than that of the transition to the $\text{Ln}4f$ shell; therefore, the structural changes in the $\text{Lu}4p$ spectrum caused by the dynamic effect are less pronounced than those in the case of the $\text{La}4p$ spectrum.

The $\text{Ln}3p_{3/2}$ spectra for lanthanum, cerium and praseodymium can be analysed in a similar way (Fig. 20). In these spectral ranges, Auger lines can show up.⁹² Thus, the $\text{Ln}3p_{3/2}$ spectra can be superimposed by the Auger lines of the $M_5N_1N_3$ transitions (1125.6, 1132.0 eV). The Auger transitions of the M_3NO (1184.5 eV), M_3NN (1184.5 eV) and $M_5N_1N_1$ (1202.3 eV) types may be manifested in the $\text{Ce}3p_{3/2}$ range in the spectrum of cerium trifluoride; among other factors, this can be responsible for the intense peak observed at 1200 eV in its XPS spectrum. The Auger electrons of the M_3NN (1175.4 eV) and M_5NN_1 transitions (1184.6 eV) may be a reason for the appearance of the intense broad band at 1226 eV in the $\text{Pr}3p_{3/2}$ spectrum of praseodymium trifluoride.

Figure 19. XPS spectra of lanthanide trifluorides in the $\text{Ln}4p$ binding energy range. (a) LaF_3 , (b) CeF_3 , (c) PrF_3 , (d) NdF_3 , (e) SmF_3 , (f) EuF_3 , (g) GdF_3 , (h) TbF_3 , (i) DyF_3 , (j) HoF_3 , (k) ErF_3 , (l) TmF_3 , (m) YbF_3 , (n) LuF_3 .²⁰ Vertical segments show the expected energies for the atomic components of the $\text{Ln}4p_{3/2, 1/2}$ electrons;²² sat is satellite.

Figure 20. XPS spectra of lanthanum (a), cerium (b), and praseodymium (c) trifluorides in the $\text{Ln}3p_{3/2}$ binding energy range.⁵²

In these spectra, the peaks located at higher (by 14–16 eV) binding energies than the basic lines may be due to many-body perturbation. Since the approximate equality

$$E_b(\text{Ln}3p) \approx E_b(\text{Ln}3d) + E_b(\text{Ln}4s),$$

is obeyed, a structure related to the dynamic effect, giving rise to the $\text{Ln}3p^5 3d^{10} 4s^2 4f^n \leftrightarrow \text{Ln}3p^6 3d^9 4s^1 4f^{n+1}$ final states, should be expected in the $\text{Ln}3p$ spectra. By using a different excitation source, the structure due to a dynamic effect can be separated from the Auger lines. However, apart from $\text{AlK}_{\alpha 1,2}$ radiation (1486.6 eV), only $\text{MgK}_{\alpha 1,2}$ radiation (1253.6 eV) is currently available but its energy is not sufficient for recording these spectra. In this case, a synchrotron radiation source with variable energy is required. The dependence of the $\text{Ln}3p_{3/2}$ binding energy on the lanthanide atomic number for three fluorides is shown in Fig. 18 (curve 1). The $\text{Ln}4p$ and $\text{Ln}3p$ spectra of lanthanide trifluorides are typical of individual compounds and can be used for identification.

d. The structure of the spectra of the $\text{Ln}3d$ electrons

In X-ray photoelectron spectroscopy, determination of the oxidation states of elements from the chemical shifts of their core energy levels is normally done using the most intense single lines corresponding to the ground final state of the ion resulting from electron photoemission. In the case of lanthanide compounds, this procedure is faced with problems, because, as noted above, virtually all the spectral lines situated in the binding energy range normally employed in XPS are structured. As a rule, $\text{Ln}3d$ lines are used for this purpose whenever possible. However, the spectra of these electrons for light lanthanides also have a clear-cut fine structure, while in the case of heavier REE, due to high $\text{Ln}3d$ binding energies, the relevant lines are highly broadened or cannot be observed at all without using the synchrotron radiation (Fig. 21). The structure of the $\text{Ln}3d$ spectra of REE related to the spin–orbit splitting has been considered theoretically.¹⁰⁰

Figure 21. XPS spectra of lanthanide trifluorides in the $\text{Ln}3d$ binding energy range.⁴² (a) LaF_3 , (b) CeF_3 , (c) PrF_3 , (d) NdF_3 , (e) SmF_3 , (f) EuF_3 , (g) GdF_3 , (h) TbF_3 , (i) DyF_3 , (j) HoF_3 . Vertical segments show the lines of the lanthanide atomic spectra.²²

The need for determination of the $\text{Ln}3d$ binding energies in lanthanide compounds has stimulated investigations into the nature of the fine structure observed in these spectra.^{41, 46, 75, 101–109} It is worth noting that some Auger electron lines can also occur in this spectral region.⁹² Thus the $\text{Ln}3d$ spectra for lanthanum and cerium exhibit peaks associated with Auger electrons of the $M_5N_3O_3$ (865.6 eV) and $M_5N_1O_2$ (918.3 eV) transitions, respectively (see Fig. 21). The shoulder on the higher binding energy side with respect to the $\text{Nd}3d_{3/2}$ line can be partly due to the Auger electrons of the $M_2N_2N_2$ transition (1012.1 eV). Broadening of the $\text{Sm}3d_{3/2}$ line can also be related to the superimposition of the Auger line of the M_5N_1N transition (1118.6 eV) onto this spectrum. Due to the Auger N_3OO transition (1341.0 eV), the $\text{Ho}3d_{5/2}$ spectrum virtually cannot be observed. A similar complex structure, except for the Auger lines, shows

itself in the binding energy range of Ln3d electrons in the spectra of LaF₃ and CeF₃ recorded with MgK_{α1,2} excitation (1253.6 eV).⁴⁶ Hence, the intense extra structure in the spectra of these electrons is not related to Auger transitions.

Comparison of the binding energy of low-energy electrons [$E_b \leq E_b(\text{Ln}3d)$] suggests that the structure caused by the dynamic effect is unlikely in the Ln3d spectra. The dependence of the FWHM value (Γ) in the Ln3d_{5/2} spectra on the lanthanide atomic number ($58 \leq Z \leq 66$) suggests that the multiplet splitting does not play a crucial role in the appearance of the extra structure or line broadening (Fig. 22). If this broadening were largely related to the multiplet splitting, as has been noted in some publications,^{101–103} the maximum line width over the Ce³⁺–Gd³⁺ series would be expected for the Gd3d_{5/2} electrons; this does not agree with the $\Gamma(Z)$ dependence found experimentally (see Fig. 22).

Figure 22. Dependence of the width (Γ) of the Ln3d_{5/2} line on the lanthanide atomic number in the La–Lu series.⁴² (1) LnF₃, (2) Ln₂O₃. The Γ values are referred to $\Gamma(\text{Cl}1s) = 1.3$ eV.

The Ln3d spectra of lanthanide trifluorides exhibit low-intensity shake-up satellites located at a higher binding energy (by 14–16 eV) than the most intense Ln3d_{5/2} lines. The researchers' opinions concerning the nature of the low-energy spectral structure in the vicinity of the basic lines vary. While admitting that for light lanthanides such as La, Ce and so on, the spectral structure in the Ln3d binding energy range is mainly due to many-body perturbation, some researchers believe that these extra lines are shake-up satellites,^{45, 104–107} while others consider them to be shake-down satellites.^{75, 108, 109} A fundamental difference between the two above standpoints is that the line located at a lower binding energy, in the Ln3d_{5/2} range is interpreted as either the basic line or a satellite caused by the many-body perturbation. It is noteworthy that the binding energy of the Ln3d electrons of the ground state has to be known for the solution of many problems.

The presumptive mechanism of the appearance of the Ln3d satellites in the XPS spectra can be illustrated by means of diagrams shown in Fig. 23. They are based on the results of X_α-SW (scattered wave) calculations for the LaF₃, CeF₃, CeF₃⁺ and YbF₃ (D_{3h} symmetry) clusters in which $R(\text{La}–\text{F}) = 0.246$ nm, $R(\text{Ce}–\text{F}) = 0.241$ nm and $R(\text{Yb}–\text{F}) = 0.226$ nm.^{47, 48} The calculations of the electronic structures of these clusters before and after photoemission of an Ln3d electron were performed and MO occupancies in these clusters were analysed. On the basis of these data and using the two-level Larsson's model (see Refs 47 and 110 and references therein), the satellite intensities and energies were estimated with respect to the basic spectral lines in the sudden approximation.^{111, 112} These results have enabled some qualitative conclusions.⁴⁷

For example, for the LaF₃ cluster (D_{3h} symmetry), the removal of an Ln3d electron was found to reduce substantially the energy difference between the system of occupied bonding a'_1 , e' , e'' , a'_2 , a'_2 and e' OVMO, which mainly consist of F2p AO, and

Figure 23. Diagrams illustrating the mechanisms of formation of shake-up (a) and shake-down satellites (b) in the XPS spectra of Ln3d electrons constructed with allowance for the results of X_α-SW calculations for the LnF₃ clusters (D_{3h} symmetry).⁴⁷ The left-hand part of the figure presents the initial states of the systems, while the right-hand part shows the final states after electron photoemission.

the system of vacant antibonding e'' , a'_2 , e'^* , a'_2 and a'_1 OVMO, which include the Ln4f AO. This is due to the fact that the OVMO containing the Ln4f AO respond more efficiently to the appearance of a hole in the lanthanum atom than the OVMO containing the F2p AO. This is reflected in the diagram for the e' and e'^* OVMO couple in lanthanide trifluorides (see Fig. 23 a). In this case, the energy difference (Δ) between these MO decreases from 1.97 to 0.77 eV. Therefore, photoemission of an Ln3d electron can induce electron subexcitation within the considered OVMO, reflecting transition from the e' to e'^* OVMO. Since the e' OVMO energy is greater in magnitude than the e'^* OVMO energy, this transition corresponds to a shake-up process. In the Ln3d spectrum, the corresponding satellites should occur at higher energies than the basic lines. These results show that most intense low-energy lines observed in the La3d spectrum of lanthanum trifluoride should be assigned to the ground final state with a hole in the La3d level. The theoretical values for the satellite energy and its intensity with respect to the basic lines $\Delta E_{\text{sat}} = 1.1$ eV and $I_{\text{sat}}/I_0 = 0.42$ (I_{sat} and I_0 are the satellite and basic line intensities, respectively) differ substantially from the experimental values (4.3 eV and 0.30).⁴² Similar results were obtained for the CeF₃⁺ ($\Delta E_{\text{sat}} = 1.1$ eV, $I_{\text{sat}}/I_0 = 0.23$) and CeF₃ (1.1 eV and 0.37, respectively) clusters. The experimental ΔE_{sat} and I_{sat}/I_0 values for CeF₃ are 3.5 eV and 0.58.⁴²

For the YbF₃ cluster (D_{3h} symmetry), the calculations imply that the MO related to the Yb4f/AO are comparable in energy with

the OVMO caused by the F2p AO.⁴⁷ The removal of two Yb3d electrons entails a very pronounced increase in the energies of these two groups of MO; the energies of the OVMO composed of the Yb4f AO are appreciably increased, and the energy levels of these MO become lower than those of the OVMO formed by the F2p AO. For instance, for the e'^* and e' OVMO couple shown in Fig. 23 b, the energy difference reaches 10.98 eV in magnitude. In this case, transition of an electron from a higher OVMO, for example, e' , to the lower e'^* MO can occur simultaneously with the Yb3d photoemission. Since the e' MO energy is lower than the e'^* MO energy, this transition, as noted above, is referred to as a shake-down process and the spectral structure caused by this transition is a shake-down satellite. In particular, it follows from the results of calculations⁴⁷ that the shake-down satellites in the Yb3d spectrum are expected to occur at lower binding energies than the basic lines ($\Delta E_{\text{sat}} = -16.0$ eV), their intensity being about 5 times as high as the basic line intensity ($I_{\text{sat}}/I_0 = 4.81$). It is noteworthy that no experimental data for this electron energy range for ytterbium compounds are available to date for the reasons noted above.

On the basis of the calculation results, it was concluded⁴⁷ that an increase in the number of Ln4f electrons in the lanthanide fluoride brings about displacement of the satellites in the Ln3d spectra from left to right with respect to the basic doublet components. It remains unknown in which lanthanide spectrum in the La–Lu series the sign of the ΔE_{sat} changes.

It is noteworthy that some suggestions concerning the reasons for the appearance of satellites in the Ln3d spectra based on the results of theoretical calculations do not contradict the available experimental data. Thus an insignificant shift should be expected for the line of the OVMO formed mainly by the F2p AO of fluorides (see Fig. 3) because the F1s binding energy (E_b) changes slightly with an increase in the lanthanide number (Z). In the case of LaF₃, the OVMO line is observed at 8.1 eV (see Table 1, Fig. 1). In the LnF₃ spectra, the centre of gravity of the structure caused by the Ln4f electrons shifts from the level taken as the reference point toward higher binding energies. Due to this shift, the OVMO related to the Ln4f AO and those related to the F2p AO can become equal in energy at some Z , which agrees with the theoretical results (see Fig. 3). Hence, on photoemission of an Ln3d electron, the Ln4f electronic level is expected to be located lower than the corresponding F2p electronic levels. This should favour a shake-down electronic transition (see Fig. 23).

As the atomic number of lanthanide increases, at least, in the case of transition from LaF₃ to PrF₃, the Ln3d spectra show a decrease in the difference between the electron binding energies of the basic and satellite lines (ΔE_{sat}). Furthermore, with the assumption that one reason for the substantial broadening of the Ln3d spectral components is the formation of satellites, the change in the Ln3d_{5/2} FWHM upon an increase in Z (see Fig. 22) can be attributed to migration of the satellite from left to right on passing from La to Lu, as has been suggested on the basis of calculations. In this case, the change in the sign of ΔE_{sat} is to be expected at about $Z = 63$ (Eu) (see Fig. 22).

For identification of lines in the Ln3d spectra of the trifluorides of light lanthanides, Teterin and Baev⁵ have proposed comparing the differences between the electron binding energies of different shells found for metallic lanthanides and for lanthanide compounds. The following values were found for LaF₃: $\Delta E_b(\text{La}5p_{3/2} - \text{Ln}3d_{5/2}) = 818.4$ (823.0) eV, $\Delta E_b(\text{La}5p_{3/2} - \text{La}4d_{5/2}) = 85.8$ eV and $\Delta E_b(\text{La}4d_{5/2} - \text{La}3d_{5/2}) = 732.6$ (737.2) eV (the energies for weaker lines or shoulders are given in parentheses; see Table 1). The corresponding differences between the electron binding energies for metallic lanthanum are 818.2, 86.0 and 732.2 eV. The value $\Delta E_b(\text{La}5p_{3/2} - \text{La}3d_{5/2}) = 818.2$ eV coincides within the error of measurement with a value of 818.6 eV, found by Schlappach and Scherrer.⁹¹

If one assumes that after the IVMO formation from the La5p and F2s AO in lanthanum trifluoride, the spectrum in the La5p_{3/2} region does not differ much from the atomic spectrum (see

Table 1), the comparison of the ΔE_b values leads to the conclusion that the basic La3d line in the spectrum of LaF₃ is located at lower electron binding energies. The satellites recorded at higher (by 4.3 eV) binding energies with respect to the basic lines are due to the shake-up process.

The results of comparison of the binding energy differences $\Delta E_b(\text{Ce}5p_{3/2} - \text{Ce}3d_{5/2})$ for CeF₃ (865.3, 868.8 eV) (see Table 1) and for metallic cerium (866.3 eV),¹¹³ at least, do not contradict the statement that the satellites in the Ce3d spectra are shake-up satellites observed at higher binding energies than the basic lines. The theoretical data do not disprove this either.¹¹⁴ Comparison of the results of calculations for YbF₃ with the experimental spectra is difficult due to the fact that the Yb3d_{5/2} binding energy ($E_b = 1527$ eV) is beyond the range accessible for measurements as long as X-ray AlK _{α} 1,2 excitation is used (1486.6 eV).

The dependence of the Ln3d binding energy on the lanthanide atomic number is shown in Fig. 18. On the basis of the binding energies of these electrons, one can draw conclusions concerning the oxidation state of lanthanides from La to Ho. Note that the use of synchrotron radiation provides the possibility of an XPS study of the Ln3d electrons and compounds of heavier lanthanides.

III. Lanthanide oxides

Lanthanide oxides are the REE compounds most abundant in nature. They serve as the main raw materials for the production of various technologically important lanthanide compounds. Therefore, despite difficulties associated with experimental and theoretical investigations of the electronic structures of lanthanide oxides, this problem attracts increasing attention. These difficulties are related to the complexity of the lanthanide electronic configurations, low symmetry of the close environment of metal atoms in the crystal lattices, and to the presence of Ln ions in different oxidation states in some oxides. Thus praseodymium and terbium oxides are known¹ to have complex stoichiometric compositions (Pr₂O₃·4PrO₂ and Tb₄O₇). The oxidation state of cerium in the cerium oxide is still open to question. According to data obtained by different researchers, this oxide is either described by the general formula CeO₂ (see Ref. 1), or contains a CeO₂· n Ce₂O₃ mixture on the surface,¹¹⁵ or contains variable-valence cerium.¹¹⁶ The other lanthanide oxides may have a stoichiometric composition corresponding to Ln₂O₃.

In recent years, the XPS method has been widely used in the study of REE oxides^{27, 39, 41, 42, 50, 80, 99, 108, 115, 117–127} and some other oxygen-containing compounds.^{19, 28–30, 41, 53, 78, 79, 84, 128} Important information concerning the electronic structures of these oxides can also be drawn from X-ray emission spectra,^{129, 130} however, in most cases, studies are carried out for oxide films and separate electronic shells of metals. In a number of publications,^{5, 18, 20, 37, 68} lanthanide (except for Pm) oxides were studied as bulk samples (pressed powders). Attention was concentrated on elucidation of the mechanisms of formation of fine structure in the spectra of these compounds and the dependence of the spectral structure on the physicochemical properties and on the nature of chemical bonding in lanthanide oxides. For this purpose, the spectra over the whole energy range accessible for measurements were analysed. The binding energies of various electron shells in the ~0–1350 eV range for the oxides under study are presented in Table 3. In all cases, two lines of O1s electrons were observed. The component located at a lower binding energy is attributable to the oxide oxygen,^{33, 41} while the less intense line at higher binding energies should be ascribed to impurities containing carbonate or hydroxy groups.^{19, 131} It has been noted^{5, 42} that successful interpretation of the mechanism of appearance of the fine spectral structure requires that the data for the whole REE row be obtained using the same XPS spectrometer under the same conditions. The results of experimental studies that comply with this requirement^{20, 37, 68, 79, 132–136} are of special interest.

Note. The E_b values are presented for the peaks relative to the C1*s* binding energy for hydrocarbons on the sample surface [$E_b(\text{C1s}) = 285.0$ eV]. ^a The given energies correspond to IVMO electrons exhibited in the spectral ranges of the valence AO electrons. ^b The values in parentheses are the electron energies for less intense lines or shoulders. ^c The E_b values are given for Ln³⁺ in complex oxides (Ln₂O₃ · *n* LnO₂). ^d The Y4*p* line. ^e The Y4*s* lines. ^f The Y3*d*_{5/2, 3/2} lines. ^g The Y3*p*_{3/2, 1/2} lines. ^h The Y3*s* line. ⁱ The Sc3*p* line. ^j The Sc3*s* line. ^k The Sc2*p*_{3/2, 1/2} lines. ^l The Sc2*s* line.

1. Structure of the spectra of low binding energy electrons

The spectra of low binding energy electrons of lanthanide oxides exhibit two groups of lines with binding energies of ~ 0 –15 and ~ 15 –50 eV, attributable to the OVMO and IVMO electrons, respectively (Fig. 24, see Table 3). In the case of lanthanum oxide, the OVMO binding energy range, besides the line at 5.6 eV, mainly due to the $\text{La}5d$, $\text{La}6s$ and $\text{O}2p$ electrons, can display two weak maxima at $E_b = 11$ eV; these are due to some impurities containing presumably the CO_3^{2-} group (this is also valid for other Ln_2O_3). The corresponding $\text{C}1s$ line is located at $E_b = 290.8$ eV. In the spectra of lanthanide oxides containing $\text{Ln}4f$ electrons, the intensity of the corresponding lines gradually increases with an increase in the atomic number (Z) of the metal. The pattern of $\text{Ln}4f$ spectra of lanthanide oxides generally resembles the corresponding structure of the spectra of $\text{Ln}4f$ electrons in lanthanide trifluorides (see Fig. 2). The difference lies in the fact that the OVMO line reflecting mainly the $\text{O}2p$ AO in the XPS spectra of REE oxides is located at binding energies lower in magnitude than the $\text{F}2p$ line in the lanthanide fluoride spectra. For convenience of the comparison of the OVMO and $\text{Ln}4f$ binding energies in REE oxides with the corresponding characteristics of lanthanide fluorides, the absolute E_b values for lanthanide oxides were increased by 1.6 eV (see Fig. 3). This is the shift of the XPS lines of lanthanum trifluoride with respect to the lines of La_2O_3 (see Tables 1, 3). Considerations concerning the origin of the structure of the $\text{Ln}4f$ lines presented above for REE fluorides are also valid for the spectra of these electrons in lanthanide oxides (see Section II). However, the overlap of the OVMO and $\text{Ln}4f$ lines in the XPS spectra of lanthanide oxides starts at a smaller Z than in the case of LnF_3 (see Fig. 3).

The experimental dependence of the $\text{Ln}4f$ line intensity (I_{exp}) on the number n_{4f} of electrons in the Ln^{3+} ion found as the ratio of the total intensity $I[(\text{Ln}4f) + (\sum \text{OVMO})]$ in the binding energy range of 0–15.5 eV to the total intensity $I(\sum \text{IVMO})$, except for the $\text{Ln}5s$ lines, is shown in Fig. 25. Using the least-squares method, this dependence for lanthanide oxides was shown to be linear

$$I_{\text{exp}} = 0.12n_{4f} + 0.25. \quad (6)$$

By analogy with expression (5) corresponding to LnF_3 , the following theoretical dependence was derived for Ln_2O_3 :

$$I_{\text{theor}} = 0.01n_{4f}^{2.24} + 0.18. \quad (7)$$

It can be seen that, as for lanthanide trifluorides (see Fig. 5), in this case, too, the experimental and theoretical plots for the intensity vs. n_{4f} [see Eqns (6), (7) and Fig. 25] are appreciably different.

On passing from Lu_2O_3 to HfO_2 , the metal atomic number increases by unity, the number of the $\text{M}4f$ electrons (14) remains the same, and the intensity of the line under consideration increases jumpwise tending to the corresponding theoretical value (see Fig. 25). The $\text{Hf}4f_{7/2}$ -electron binding energy, equal to 17.4 eV, also markedly (by 9.6 eV) exceeds the binding energy of the OVMO electrons in lutetium (see Table 3). It follows from these data that the $\text{Lu}4f$ electrons, which can be regarded in a certain approximation as inner valence electrons, differ markedly in spectral characteristics from the $\text{Hf}4f$ electrons, which acquire some features of core electrons.

In the $\text{Ln}5p$ and $\text{O}2s$ spectral range, fine structure is observed. The structure becomes most intricate by the middle of the row of lanthanide oxides (see Fig. 24). Among other reasons, complication of the spectral structure may be due to the presence of lanthanide ions in different oxidation states in some lanthanide oxides. In this connection it should be noted that, as shown on the basis of analysis of the spectral structure of core electrons, REE oxides, except for cerium, praseodymium and terbium, contain Ln^{3+} ions. In praseodymium and terbium oxides, Pr and Tb in higher oxidation states occur as impurities, their concentrations being not higher than 5%.⁵ The spectral structure observed for cerium oxide is more complicated. If one assumes that the additional lines in the $\text{Ce}3d$ spectrum (36%) are due to Ce^{4+} ions, the

Figure 24. XPS spectra of low binding energy electrons in lanthanide oxides.¹³² (a) La_2O_3 , (b) CeO_2 , (c) Pr_2O_3 , (d) Nd_2O_3 , (e) Sm_2O_3 , (f) Eu_2O_3 , (g) Gd_2O_3 , (h) Tb_2O_3 , (i) Dy_2O_3 , (j) Ho_2O_3 , (k) Er_2O_3 , (l) Tm_2O_3 , (m) Yb_2O_3 , (n) Lu_2O_3 . Vertical segments show the results of calculations (SCF NR X_a -DVM) of the electronic structure of CeO_8^{12-} (O_h symmetry), PrO_7^{11-} and NdO_7^{11-} (C_2 symmetry), and LnO_6^{3-} (D_{3d} symmetry) for other oxides.^{57, 58}

contents of Ce^{4+} and Ce^{3+} ions on the surface of the cerium oxide studied should be 36% and 64%, respectively; this would complicate significantly the considered spectral structure (see Fig. 24). Teterin *et al.*^{137, 138} believe that the additional structure (36%) is caused by many-body perturbation involving the $\text{Ce}5s$ electrons and does not complicate the structures of the $\text{Ce}5p$ and $\text{O}2s$ spectra. Since the $\text{O}1s$ spectra of the studied REE oxides exhibit in

Figure 25. Relative intensity of the XPS lines of the $\text{Ln}4f$ electrons vs. the number of these electrons in lanthanide oxides (1, 2)¹³⁴ and orthoniobates LnNbO_4 (3)¹³³ and the corresponding theoretical dependence (4) [see Eqn (7)]. Two series of oxide samples were used, one provided by the Russian Research Centre ‘Kurchatov Institute’ (1) and one by the Saratov State University (2). For comparison, data for HfO_2 are given ($n_{4f} = 14$).

some cases two lines for oxygen, the $\text{O}2s$ spectrum should also contain two lines. This would complicate the spectral structure in the $\text{Ln}5p$ and $\text{O}2s$ binding energy range.

In the $\text{Ln}5p$ spectra of the oxides of light lanthanides, in particular, lanthanum, the many-body perturbation should be more pronounced than in the spectra of the corresponding fluorides. This suggestion relies on the fact that the $\text{Ln}3d$ spectra recorded for oxides exhibit more intense satellites than the corresponding spectra of fluorides. The influence of the multiplet splitting and the dynamic effect on the $\text{Ln}5p$ spectral structure should not be more pronounced in the case of REE oxides than in the case of REE fluorides and should not result in substantial complication of the spectral structure.

Since the E_b value for the $\text{O}2s$ spectra falls in the middle of the range in which the $\text{Ln}5p$ binding energy varies with an increase in the lanthanide atomic number, the formation of the inner valence MO may be a reason for the appearance of the fine spectral structure in the $\text{Ln}5p$ and $\text{O}2s$ binding energy ranges.^{55–59, 61, 62, 78, 79, 83, 84} These IVMO are largely composed of the $\text{Ln}5p$ and $\text{O}2s$ AO.^{18, 133, 135}

Lanthanide oxides have a complex geometric structure (Fig. 26),^{57–59} which accounts for complication of their electronic structures and, hence, of the XPS spectral structure for low-energy electrons and also complicates the corresponding theoretical calculations. The XPS spectra are often interpreted by referring to the results of quantum-chemical calculations for the electronic structures of lanthanide oxides.^{55, 59, 79, 84} In particular, theoretical

Figure 26. Model clusters of lanthanide oxides in which the structure of the local environment is taken into account.⁵⁹ (a) LnO_7^{11-} (C_2 symmetry) for La–Nd oxides; (b) LnO_6^{9-} (D_{3d} symmetry); (c) LnO_6^{9-} (C_2 symmetry) for Sm–Lu oxides.

investigation of the PrO_7^{11-} and NdO_7^{11-} clusters (C_2 symmetry), two series of LnO_6^{9-} clusters ($\text{Ln} = \text{Sm}–\text{Lu}$) (D_{3d} and C_2 groups of symmetry) and the CeO_8^{12-} complex (O_h symmetry) have been carried out in the spin-polarised approximation of the NR X_α -DV method.^{57–59} The energy levels found by these calculations are shown in Fig. 24 as vertical segments in the low-energy spectral range. Figures 27, 28 show the MO diagrams for the PrO_7^{11-} (C_2 symmetry) and TbO_6^{9-} (D_{3d} symmetry) clusters.

Figure 27. Diagram of the MO of the PrO_7^{11-} cluster [C_2 symmetry, $R(\text{Pr}–\text{O}) = 0.237$ nm, $R'(\text{Pr}–\text{O}) = 0.262$ nm] determined by the SCF NR X_α -DVM calculations for $\alpha(\uparrow)$.⁵⁷ MO energies (eV) and compositions (%) are given (the diagram is not scaled). Unoccupied energy levels are shown by dashed lines.

Figure 28. Diagram of the MO for the TbO_6^{9-} cluster [D_{3d} symmetry, $R(\text{Tb}-\text{O}) = 0.230 \text{ nm}$] determined by the SCF NR X_α -DVM calculations for $\alpha(\uparrow)$.⁵⁸ MO energies (eV) and compositions (%) are given (the diagram is not scaled). Unoccupied energy levels are shown by dashed lines.

As follows from the results of calculations, the PrO_7^{11-} cluster (C_2) has two groups of MO consisting of 4e–15e OVMO and 1a₁–5a₁ IVMO type orbitals (see Fig. 27). On the basis of calculations and the relevant XPS parameters, the conclusion concerning the involvement of the Ln4f AO in the formation of OVMO in the lanthanide compounds has been drawn in a number of publications.^{56–59, 68, 78, 79, 83, 84, 132}

The inner valence MO (1a₁–5a₁) of the PrO_7^{11-} cluster (C_2 symmetry) mainly consist of low-energy occupied AO of the neighbouring praseodymium and oxygen atoms. The greatest mixing of the Pr5p and O2s AO is found for the 1e, 2a₁, 3e and

5a₁ IVMO (see Fig. 27). The inner valence Pr5s AO do not participate significantly in the IVMO formation. These results indicate that a substantial overlap of the Pr5p and O2s AO, favourable for the IVMO formation, takes place in the PrO_7^{11-} cluster.

As the lanthanide atomic number increases, the energy of the Ln5p electrons approaches the O2s energy or becomes even higher for relatively large Z values; therefore, for the first half of the lanthanide row, the degree of mixing of the Ln5p and O2s AO increases upon IVMO formation, while on further increase in Z, this degree of mixing gradually decreases.

To illustrate the arrangement of the MO energy levels and the MO composition, the local environments found in the oxides formed by elements of the second half of the lanthanide row were taken into account in the simulation of the structure of the LnO_6^{9-} clusters (D_{3d} symmetry). Figure 28 shows the MO diagram based on the results of the spin-polarised NR X_α -DV calculations of the electronic structure of the TbO_6^{9-} cluster (D_{3d} symmetry).^{58, 59} The occupied 3e_u–6a_{2u} OVMO of this cluster, like those in PrO_7^{11-} , are formed by participation of the 4f AO. However, in this case, unlike PrO_7^{11-} , the molecular orbitals containing the Tb4f AO are lower in energy than the OVMO consisting mostly of the O2p AO. This is a consequence of the lower position of the Tb4f energy level compared to the Pr4f level with respect to O2p (see Fig. 3).

The IVMO in the TbO_6^{9-} cluster (D_{3d} symmetry) differ in structure from the IVMO of the PrO_7^{11-} cluster (C_2 symmetry). This is due to the different structures of these two clusters. However, in the terbium cluster, as in the praseodymium one, substantial mixing of the Tb5p and O2s AO takes place in the IVMO formation (see Fig. 28). As the lanthanide atomic number increases, the degree of participation of the Ln5p AO in, for example, the 2e_u IVMO of these clusters decreases; for LuO_6^{9-} (D_{3d} symmetry), it is as low as 4%.

According to calculations, an increase in the atomic number (Z) of lanthanides in the oxides should entail the displacement of MO energy levels caused by Ln4f electrons towards higher values, which is observed in experimental spectra (see Figs 3, 24). Indeed, the structure of the experimental spectra of Ln_2O_3 in the Ln5p and O2s binding energy ranges becomes much more complicated on approaching the center of the lanthanide row, while the spectral pattern observed for the oxides of elements situated at either the beginning or the end of the row, for example, La_2O_3 and Lu_2O_3 , is close to the sum of the atomic spectra of lanthanides and oxygen (see Fig. 24).

The similar energies of the Ln4f and O2p levels and the relatively short distances between the neighbouring lanthanide and oxygen atoms in the considered oxides may promote an increase in the degree of mixing of the Ln4f and O2p AO giving the OVMO. It is noteworthy that the involvement of the Ln5p and O2s AO in the formation of the IVMO is one of the reasons for the appearance of the fine structure in the Ln5p and O2s spectral range for lanthanide oxides.

2. The core electron spectra of lanthanide oxides

a. The Ln_2O_3 oxides

The spectral structure of the core electrons of lanthanide oxides has much in common with the spectra of the same electrons in lanthanide trifluorides provided that the lanthanide oxidation states in these compounds are equal. The formation mechanisms for the fine structure of these oxides can also be considered in the ionic approximation. Thus the spectra of the Ln5s and Ln4s electrons in Ln_2O_3 , like the spectra of the corresponding electrons in LnF_3 , exhibit multiplet splitting characterising the lanthanide spin state in oxides and fluorides (Fig. 29, see also Fig. 16). In some cases, these data can be used to determine the lanthanide oxidation state. For example, comparison of the multiplet splittings for Ln4s and Ln5s electrons in individual lanthanides and in the oxides indicates that the most pronounced discrepancy is observed between europium and Eu_2O_3 (see Fig. 29). The multiplet splitting ΔE_{ms} for the Eu4s electrons in the XPS spectra of

Figure 29. Multiplet splitting (ΔE_{ms}) of the $Ln4s$ (a) and $Ln5s$ lines (b) in the XPS spectra of oxygen-containing compounds of lanthanides and individual metals; (1) surface oxides;⁸⁰ (2) Ln_2O_3 oxides; (3) LnL_3 (L is the *o*-methoxybenzoic acid residue);⁵ (4) individual metals;⁹³ the continuous line shows the results of SCF NR X_α -DVM calculations;⁶⁹ the dashed line corresponds to the results of *ab initio* calculations;^{44,93} the dependence of ΔE_{ms} on the multiplicity ($2S+1$) of the $Ln4s$ electrons was multiplied by 0.55.⁹³

europium metal [$\Delta E_{ms}(Eu) = 7.4 \pm 0.2$ eV] differs considerably from the corresponding value for the oxide [$\Delta E_{ms}(Eu_2O_3) = 5.5 \pm 0.2$ eV] and is approximately equal to the multiplet splitting observed in the spectrum of gadolinium oxide [$\Delta E_{ms}(Gd_2O_3) = 7.8 \pm 0.2$ eV]. These results are attributable to the fact that the number n_{4f} of unpaired $Eu4f$ electrons in europium atoms is greater in the metal than in the oxide and is equal to the number of these electrons in the gadolinium contained in the oxide. In terms of the ionic approximation, this implies that europium metal contains Eu^{2+} ions, which is a known fact, while the oxide contains Eu^{3+} atoms.

The multiplet splitting in the $Ln4d$ spectra of the Ln_2O_3 oxides for $58 \leq Z \leq 70$ has a more complicated pattern than that in the $Ln4s$ and $Ln5s$ spectra of the same compounds, the structure caused by this splitting being mainly consistent with the corresponding structure observed in the spectra of the $Ln4d$ electrons in LnF_3 (Fig. 30, see also Fig. 17). As an example, Fig. 30 shows the spectrum of the $Tm4d$ electrons in Tm_2O_3 . Whereas the complex structure in the spectrum of Tm_2O_3 is mainly related to the multiplet splitting, this splitting is missing from the $Ln4d$ spectra of La_2O_3 and Lu_2O_3 , because La^{3+} and Lu^{3+} ions in the oxides contain no unpaired $Ln4f$ electrons. Indeed, the spectra of these electrons in lanthanum and lutetium oxides contain mainly doublets caused by the spin-orbit splitting: $\Delta E_{so}(La4d) = 3.0 \pm 0.1$ eV and $\Delta E_{so}(Lu4d) = 9.8 \pm 0.1$ eV. These values are in good agreement with analogous values for LaF_3 and LuF_3 (3.1 ± 0.1 and 10.0 ± 0.1 eV, respectively; see Figs 17, 30 and Tables 1, 3). The observed violation of the intensity ratio of the $La4d_{5/2}$ and $La4d_{3/2}$ doublet components in La_2O_3 can be related, as has been noted, for example for $La(OH)_3$ ^{139,140} and La_2O_3 ,⁵⁰ to the superposition of the shake-up satellite from the $La4d_{5/2}$ line on the $La4d_{3/2}$ doublet component. The structures of the $Ln4d$ spectra for other Ln_2O_3 oxides in which the lanthanide ions have

Figure 30. XPS of lanthanum (a), tulium (b), and lutetium (c) oxides in the $Ln4d$ binding energy range. The intensity of the $La4d_{3/2}$ component is increased due to the superposition of the shake-up satellite from the $La4d_{5/2}$ line.⁸³ The vertical segments below the Tm_2O_3 spectrum show the results of calculations with allowance for the multiplet splitting.⁶⁶

electronic configurations with $Ln4f$ electrons are much more complicated than the spin doublet (see Fig. 30). The spectral structures observed for the bulk samples of lanthanide oxides^{5,123} are similar to those in the spectra of surface oxides.^{73,80,118,122}

These results can serve as experimental evidence for the fact that the multiplet splitting in the spectra of $Ln4d$ electrons of lanthanide oxides gives rise to a complex fine structure the main features of which can be considered in the ionic approximation.^{45,66} Replacement of the ligands surrounding the Ln^{3+} ions induces changes in the fine spectral structure, which can be partially due to the many-body perturbation and the dynamic effect in the spectra of these electrons. In other words, fine structure parameters depend on the nature of ligands in lanthanide compounds, *i.e.*, on the type of chemical bonds in them. As a consequence, despite its complexity, the fine structure of the $Ln4d$ spectra is characteristic of a given lanthanide compound and can be used as a 'fingerprint' for compound identification.

The fine structure observed in the spectra of the $Ln4p$ electrons of lanthanide oxides generally resembles the corresponding spectral structure of lanthanide trifluorides (Fig. 31). Instead of the expected doublet related to the spin-orbit splitting, the $Ln4p$ spectra of REE oxides in the series from La to Yb exhibit a structure around the $Ln4p_{3/2}$ line and the component corresponding to the $Ln4p_{1/2}$ electrons is highly smeared.^{20,83} Note that for oxides of elements situated at the end of the lanthanide row, in particular, for Yb_2O_3 , the structure of the $Ln4p$ spectrum is similar to a doublet in shape, while the spectrum of the corresponding electrons of Lu_2O_3 is already mainly a spin doublet (see Fig. 31).

On the basis of the XPS data for lanthanide fluorides, the structure of the $Ln4p$ spectra was suggested to be due to the

Figure 31. XPS spectra of lanthanum (a), erbium (b) and lutetium (c) oxides in the Ln4*p* binding energy range.²⁰ Vertical segments show the expected atomic spectra without allowance for the dynamic effect.²²

dynamic effect, inducing the formation of the $\text{Ln}4p^5 4d^{10} 4f^n \leftrightarrow \text{Ln}4p^6 4d^8 4f^{n+1}$ type final states after photoemission of the Ln4*p* electron.⁴² The appearance of an additional final state $\text{Ln}4p^6 4d^8 4f^{n+1}$ is possible only in the case where the Ln4*f* shell is not fully occupied. This assumption is in good agreement with the experimental data for REE oxides (see Fig. 31). Indeed, since the electronic configurations of the La^{3+} and Er^{3+} ions are $\text{La}4f^0$ and $\text{Er}4f^{11}$, respectively, the photoemission of an Ln4*p* electron from La_2O_3 and Er_2O_3 may give, in addition to the ground state, $\text{Ln}4p^5 4d^{10} 4f^n$, one more two-hole final state, $\text{Ln}4p^6 4d^8 4f^{n+1}$, which would result in the formation of the fine structure in the La4*p* and Er4*p* spectra of these oxides (see Fig. 31). Photoemission of an Lu4*p* electron from Lu_2O_3 cannot produce this additional final state, and the spectrum of the Lu4*p* electrons exhibits a spin doublet and satellites associated with many-body perturbation. These results can serve as yet further proof of the fact that the XPS fine structure in the spectra of the Ln4*p* electrons of REE compounds is mainly due to the dynamic effect. The considered data²⁰ are at variance with the suggestion⁸⁰ that the Ln4*p* spectral structure of REE oxides is mainly determined by multiplet splitting.

The spectra of the Ln3*d* electrons for light lanthanide oxides exhibit a fine structure the characteristics of which differ appreciably from those of the fine structure of other REE compounds (Fig. 32, see also Fig. 21). As noted above in the discussion of the spectra of the Ln3*d* electrons in lanthanide trifluorides, the spectral fine structure is due to the many-body perturbation. The dependence of the FWHM (Γ) of the Ln3*d*_{5/2} line on the atomic number (*Z*) for lanthanide oxides resembles a similar dependence for LnF_3 (see Fig. 22). As noted previously, the observed change in the line width cannot be explained by multiplet splitting. The

Figure 32. XPS spectra of lanthanum (a), praseodymium (b) and neodymium (c) oxides in the Ln3*d* binding energy range in which many-body perturbation effects are visible.⁸³

decrease in the Γ value (Ln3*d*_{5/2}) for REE oxides for the beginning of the lanthanide row is due, as indicated by the spectra, to a decrease in the intensity of the low-energy component of the structure containing satellites.

It has been shown for 3*d*-metal compounds^{24, 141} that the intensity of satellites in the spectra of electrons of various shells decreases with a decrease in the binding energy. A similar regularity is found in the spectra of La3*d* and La4*d* electrons for LaNbO_4 .¹³³ Therefore, a similar pattern could be expected in the spectra of lanthanide compounds, in particular, oxides. In other words, if the fine structure of the Ln3*d* spectra is caused by many-body perturbation, satellites, although less intense, should also appear in the spectra of other, lower binding energy electrons. Their positions with respect to basic lines are expected to be approximately the same as those in the spectra of Ln3*d* electrons. Indeed, the most clear-cut satellites of this type (with an intensity of 43%) are found in the La4*d* spectrum of La_2O_3 (see Fig. 30); they occur on the higher binding energy side of the basic lines and can be classified as shake-up satellites. A similar satellite is recorded in the La4*p*_{3/2} spectrum (intensity 30%). This serves as experimental evidence for the fact that in the spectra of La3*d* electrons, satellites are located at a higher binding energy than the basic lines.

Comparison of the difference between the core level binding energies for LaF_3 , La_2O_3 and metallic lanthanum also leads to the conclusion that the components located at lower binding energies in the spectrum of La3*d* electrons of lanthanum oxide should be identified as the basic lines. The binding energy differences between the La4*d*_{5/2} and La3*d*_{5/2} electrons $\Delta E_b(\text{La}4d_{5/2} - \text{La}3d_{5/2})$ for metallic lanthanum and its oxide and fluoride found with allowance for the low-energy components of the La3*d*_{5/2}

spectra are equal to 732.2 ± 0.4 ,⁵ 732.3 ± 0.4 and 732.9 ± 0.4 eV, respectively (see Tables 1, 3). These values are in satisfactory agreement with one another within the determined error; meanwhile, the $\Delta E_b(\text{La}4d_{5/2} - \text{La}3d_{5/2})$ values for the $\text{La}3d_{5/2}$ high-energy components for La_2O_3 and LaF_3 are equal to 735.8 ± 0.4 and 737.2 ± 0.4 eV, *i.e.*, they markedly exceed the corresponding energy difference (732.2 ± 0.4 eV) for metallic lanthanum (see Tables 1, 3). It is also worth noting that the spectrum of $\text{La}3d$ electrons for metallic lanthanum exhibits no extra lines^{91, 142–144} comparable to the basic lines in intensity; this contradicts the data of another study¹⁴⁵ in which an intense extra structure has been detected in the spectrum of metallic lanthanum.

The data considered above convincingly demonstrate that the satellites observed in the $\text{La}3d$ spectra of the lanthanum compounds in question are due to a shake-up process which accompanies photoemission of $\text{La}3d$ electron; this is consistent with the results of other publications.^{50, 105, 140}

As noted above, praseodymium and terbium oxides may have a complex stoichiometric composition other than Ln_2O_3 . These oxides are supposed¹ to contain lanthanide ions in different oxidation states, for example, Ln^{3+} and Ln^{4+} . The intensity of the extra structure in the spectra of $\text{Pr}3d$ and $\text{Tb}3d$ electrons, which can be attributed to Pr^{4+} and Tb^{4+} ions, does not exceed 3%–5% of the basic line intensity corresponding to Pr^{3+} and Tb^{3+} ions.⁵ It has been noted¹¹⁷ that on passing from the Eu^{2+} in the metal to the Eu^{3+} in the Eu_2O_3 oxide, the energy levels of the core electrons shift by about 10 eV. Significant changes in the spectral structure of complex lanthanide oxides with respect to the spectra of Ln^{3+} compounds are also found for cerium oxide.^{116, 137}

b. Cerium oxide

In recent years, considerable attention has been devoted to the study of variable valence in lanthanides and their compounds,^{146–148} which may be responsible for the fine structure in the XPS spectra. The extra structure in the spectra of the valence and core electrons of rare earth metals,^{101, 149, 150} intermetallics^{119, 151–156} and lanthanide compounds^{157–165} has been attributed to the presence of lanthanide atoms in variable oxidation states. Theoretical calculations of the XPS spectra of rare earth metals^{166, 167} and their compounds^{116, 168–170} are often carried out using so-called Andersson's impurity model^{38, 39, 171} and its various modifications. In particular, this model has been used to interpret the complex structure of the XPS spectra of core electrons in CeO_2 .^{116, 170}

The structure of the spectrum of the $\text{Ce}3d$ electrons in cerium oxide contains a number of additional lines that are missing from the corresponding spectra of other oxygen-containing compounds and cerium fluoride (Fig. 33, see also Fig. 21).^{137, 138} This extra structure is a doublet the splitting of which ($\Delta E_b = 18.3$ eV) is in good agreement with the spin–orbit splitting of the $\text{Ce}3d$ line [$\Delta E_{so}(\text{Ce}3d) = 18.3$ eV]¹³⁸ and with the data of one more study.¹¹⁹ For example, it was assumed on the basis of the analysis of cerium spectra in intermetallic compounds^{172–174} that the two intense extra lines with $E_b \approx 898.0$ and 916.3 eV are components of a spin doublet corresponding to Ce^{4+} ions, while the low-energy doublet containing a complex structure corresponds to the $\text{Ce}3d$ electrons of the Ce^{3+} ion. It has been suggested that the presence of two types of cerium ions in the oxide may be due either to variable valence exhibited by cerium in chemical¹⁷⁵ and intermetallic compounds,¹⁵⁵ or to the formation of a mixture of oxides on the sample surface.

Thus on the basis of X-ray CeL_{III} absorption spectra and the $\text{Ce}4d$ XPS spectra it was concluded¹⁷⁶ that Ce^{3+} and Ce^{4+} ions are formed on the CeCo_2 surface. The XPS spectra of the CeO_2 oxide and the theoretical data¹⁷⁷ indicate that a variable valence of cerium in the oxide is impossible, the structure observed in the $\text{Ce}3d$ spectrum being due to the $\text{Ce}3d^9 4f^0$ and $\text{Ce}3d^9 4f^1$ configurations of the final state. The results of NR X α -SW calculations suggest¹⁷⁸ that the extra structure in the $\text{Ce}3d$ and $\text{Ce}4d$ spectra of

Figure 33. XPS spectra of the $\text{Ce}_2\text{O}_3 \cdot n\text{CeO}_2$ oxide (a) and the CeL_3 (b) and $\text{CeL}_3 \cdot 1.5 \text{H}_2\text{O}$ (c) cerium complexes in the $\text{Ce}3d$ binding energy range (L^1 and L^2 are the residues of *o*-methoxybenzoic and diphenylacetic acids, respectively).¹³⁷

CeO_2 is due to shake-up satellites. These satellites in the spectra of the $\text{Ce}3d$ electrons correspond to the $\text{Ce}3d^9 4f^0$, $\text{Ce}3d^9 4f^1$ and $\text{Ce}3d^9 5p^5(np)$ final states of the cerium ion.

X-Ray photoelectron spectra provide an unambiguous answer to the question as to whether or not the structure of the $\text{Ce}3d$ spectra is related to a complex initial or final state of the cerium ion in compounds.^{137, 138} One of the main suggestions is that the observed spectra of the core electrons of cerium in the oxide result from superposition of the structures related to the $\text{Ce}3d^9 4f^0$, $\text{Ce}3d^9 4f^1$ and $\text{Ce}3d^9 5p^5(np)$ type final states of the cerium ion. [The formation of the unusual final state $\text{Ce}3d^9 5p^5(np)$ is confirmed by the fact that the spectra of the $\text{Ce}5p$ and OVMO electrons do not exhibit the extra structure characteristic of the $\text{Ce}3d$, $\text{Ce}4d$ and $\text{Ce}4p$ spectra.] Indeed, comparison of the spectra of the $\text{Ce}4d$ and $\text{Ce}4p$ electrons for cerium oxide and the CeL_3 complex (L is the *o*-methoxybenzoic acid residue) shows that three groups of lines corresponding to cerium ions in different final states can be distinguished in these spectra as well as in the spectra of the $\text{Ce}3d$ electrons of cerium oxide (Fig. 34). In these spectra, the line corresponding to the Ce^{4+} ion is located 13.2 eV away from the corresponding Ce^{3+} line, which is consistent with the calculation results.¹⁷⁹ The intensity ratio of the lines corresponding to the $\text{Ce}3d$ electrons of cerium ions in different oxidation states indicates that the near-surface layer of the sample studied contained 36% of Ce^{4+} and 64% of Ce^{3+} in the final state.

As expected, the spectrum of $4d$ electrons of the Ce^{4+} ion is a doublet caused by the spin–orbit splitting; $\Delta E_{so}(\text{Ce}4d) = 3.4$ eV (see Fig. 34a,b). This proves experimentally the fact that the complex structure of the $4d$ spectrum of the Ce^{3+} ions with the $\text{Ce}5s^2 5p^6 4f^1$ final state is due to multiplet splitting.

Figure 34. XPS spectra of the $\text{Ce}_2\text{O}_3 \cdot n\text{CeO}_2$ oxide and the CeL_3 complex in the $\text{Ce}4d$ (a,b) and $\text{Ce}4p$ (c,d) binding energy ranges (L is the *o*-methoxybenzoic acid residue).¹³⁸ (a,c) $\text{Ce}_2\text{O}_3 \cdot n\text{CeO}_2$; (b,d) CeL_3 .

The structures of the $\text{Ce}4p$ spectra for Ce^{4+} and Ce^{3+} ions have much in common (see Fig. 34 c,d). Thus in both cases, the component due to the $\text{Ce}4p_{1/2}$ electrons virtually cannot be detected, despite the fact that the electronic configuration of Ce^{4+} is $\text{Ce}4p^5 5s^2 5p^6 4f^0$, i.e., cerium contains no unpaired $4f$ electrons. This proves experimentally the fact that the complex structure in the spectrum of $\text{Ce}4p$ electrons is mainly due to the dynamic effect.

The spectra of the $3d$ and $4d$ electrons of the Ce^{4+} ion consist of two components of a doublet and contain no complex structure, in particular, no satellites (see Figs 33, 34). This allows one to determine the binding energy difference, $\Delta E_b(4d_{5/2} - 3d_{5/2}) = 776.3$ eV. This value is close to the energy difference between the corresponding low-energy components in the $3d_{5/2}$ and $4d_{5/2}$ spectra of the Ce^{3+} ions ($\Delta E_b = 882.3 - 108.5 = 773.8$ eV, see

Table 3). The observed difference between these values ($776.3 - 773.8 = 2.5$ eV) can be due to various reasons. First, the multiplet splitting changes the structure of the $4d$ spectrum of Ce^{3+} ; this may displace the most intense peak with respect to the Ce^{3+} $4d_{5/2}$ component. However, the same difference (2.5 eV) is found between the most intense components of the $\text{Ce}4p$ doublet the structures of which for Ce^{3+} and Ce^{4+} are similar. Second, the chemical shifts of metal ions in different oxidation states are well-known³³ to be different for different energy levels. Comparison of the spectra for the $\text{Ce}3d$ (~ 900 eV), $\text{Ce}4p$ (~ 220 eV) and $\text{Ce}4d$ (~ 120 eV) shells demonstrates that the differences between the electron binding energies corresponding to the most intense lines for individual shells in Ce^{3+} and Ce^{4+} amount to 15.7, 13.2 and 13.2 eV, respectively (see Fig. 33, 34). These data suggest that upon increasing the electron binding energy from 100 to 900 eV, the difference between the chemical shifts of separate levels does not exceed 16%.^{137, 138}

It follows from the results obtained that the most intense low-energy component in the $3d_{5/2}$ spectra of Ce^{3+} may be identified as the basic line and the components next in energy may be considered as shake-up satellites. The most intense satellites are due to the many-body perturbation involving the $\text{Ce}5p$ electrons, which gives rise to an ion with a poorly shielded hole at the $\text{Ce}5p$ level.

The spectra of core electrons also allow the conclusion that the stoichiometric compositions of praseodymium and terbium oxides basically correspond to Ln_2O_3 .

IV. General rules for the formation of the XPS spectral structure of lanthanide compounds

The XPS spectral structures observed for different lanthanide compounds are rather similar if the metal ions contained in them all have the same formal oxidation state equal to three. When the lanthanide oxidation state in a compound differs from three, the structure of their XPS spectra substantially changes.

1. Spectral region of low-energy electrons

In the spectral region corresponding to low-energy electrons of various lanthanide compounds, an increase in the atomic number (Z) and the number of $\text{Ln}4f$ electrons (n_{4f}) entail an increase in line intensity near the Fermi level (see Figs 2, 24). The structure observed in this spectral region for compounds formed by elements of the middle and the end of the lanthanide row is mainly due to $\text{Ln}4f$ electrons because photoionisation cross-sections of these electrons exceed appreciably the corresponding values of the electrons of the outer valence $\text{Ln}5d$, $\text{Ln}6s$ and $\text{L}2p$ AO of the lanthanide and the ligand.⁷⁶ As noted above, the data obtained in recent years using the SCF NR X_α -DV and X_α -SW calculations for the electronic structures of clusters^{56–59} confirm the substantial participation of the $\text{Ln}4f$ AO in the formation of OVMO. Therefore, attempts have been made^{37, 68, 132} to estimate the degree of participation of the $\text{Ln}4f$ electrons in the chemical bond on the basis of spectral parameters or, at least, to estimate the degree to which the $\text{Ln}4f$ electrons can be regarded as outer valence electrons.

On passing from lanthanide oxides to fluorides, the weighted-mean $\text{Ln}4f$ electron binding energies increase. The chemical shifts of these electron levels observed on passing from one compound to another are comparable to the corresponding values for the core levels.

For example, the chemical shift (ΔE_b) of the $\text{Lu}4p_{3/2}$ electron levels in LuF_3 (relative to Lu_2O_3) in which the lutetium ion is formally in the trivalent state amounts to 1.8 eV, and the weighted-mean value for the $\text{Lu}4f$ level, $\Delta \bar{E}_b(\text{Lu}4f)$, equals 1.7 eV. The binding energy differences $\Delta E_b(\text{Lu}4f - \text{Lu}4p_{3/2})$ for lutetium oxide and fluoride coincide within the experimental error and are 350.8 and 350.9 eV for Lu_2O_3 and LuF_3 , respectively. It should be noted that the $\text{Ln}4f$ electrons respond to minor changes in the effective charge of lanthanide nuclei to approximately the

Figure 35. Binding energy of the Mnl electrons [$E_b(Mnl)$] for metal oxides, except for metallic Au and Pt, vs. the metal atomic number in the La–Hg series. (1) The results from Ref. 132; (2) the data from Ref. 22. For $M4f$ and $M5s$ electrons, the weighted-mean values of the binding energy are given, and for the Hf–Hg oxides ($Z > 71$), only the energies of the $M4f_{7/2}$ electrons are given.

same extent as the core electrons. For a separate series of lanthanide compounds, a substantial increase in the metal atomic number in the $58 \leq Z \leq 71$ range causes insignificant variation of the weighted-mean value of the $Ln4f$ binding energy. The increase in the binding energy of these electrons over the lanthanide row is 6.8 eV for fluorides and 4.5 eV for oxides (Fig. 35). On further increase in the atomic number, *i.e.*, on passing from Lu to Hg ($Z = 72$), the binding energy of the $M4f$ electrons sharply increases. The $M5p_{3/2}$ -electron binding energy varies in a similar way, although to a lesser extent. The same trend, even less pronounced, can also be followed for the $M5s$ electrons (see Fig. 35).

The dependence of the $M4f$ binding energy on Z for compounds of lanthanides and heavier metals (see Fig. 35) resembles the corresponding dependences of the Mnd electrons in transition metals and in the subsequent elements.^{22, 132} For example, the weighted-mean binding energy for the $M3d$ electrons in $3d$ -metal oxides, as in the lanthanide oxides, depends only slightly on Z over the $21 < Z \leq 29$ range but starting with zinc, it sharply increases (Fig. 36).

The relative intensity of the $Ln4f$ line in the lanthanide compounds studied follows an almost linear dependence on the metal atomic number in the $57 < Z \leq 71$ range (see Figs 5, 25). A further increase in Z results in a sharp change in the pattern of dependence (Fig. 37). For comparison with the experimental dependence,¹³² Fig. 37 also shows the relevant data obtained using photoionisation cross-sections.⁷⁶ The fundamental qualitative difference between the experimental and theoretical curves cannot be interpreted, for example, by assuming that after photoemission from a substance, the electrons are highly scattered. The extrapolation of the straight section of the theoretical curve to $Z = 57$ (La) shows that the plot for the relative intensity of the $M4f$ line vs. Z is a straight line in the case where all the $Ln4f$ shells are fully occupied. The deviation of the $Ln4f$ line intensity from a linear dependence occurs for Hf and Ta due to the fact that the outer valence $Ln4f$ electrons in these metals become inner electrons. It follows from experimental data that the relative intensity of the $M4f$ line for lanthanide oxides increases in proportion with Z . For the latter half of the lanthanide row, these values remain lower than the theoretical values but in the $71 < Z \leq 78$ range, they rapidly increase and subsequently, they exceed the theoretical values by, on average, 25%–27%; like theoretical values, they also increase with an increase in Z . Thus for Hg ($Z = 82$) in HgO,

Figure 36. Binding energy (E_b) of the Mnl electrons of CaO , Sc_2O_3 , TiO_2 , V_2O_5 , Cr_2O_3 , MnO , FeO , CoO , NiO , CuO , ZnO , Ga_2O_3 , GeO_2 , and $FeAs_2$, Se, KBr, Kr vs. the element (E) atomic number in the Ca–Kr series. (1) the results from Ref. 5; (2) the data from Ref. 22. For $M3d$ electrons, the weighted-mean values for these OVMO electrons are given, and for Zn, Ga, Ge oxides and for As^{n-} , Se, Br[−] and Kr ($Z \geq 30$), the $M3d$ energies are presented.

Figure 37. Experimental (1) and theoretical (2) dependences of the relative intensities of the $M4f$ lines for REE and heavier metal oxides, except for metallic Pt and Au, vs. the metal atomic number in the La–Hg series.¹³²

$I_{exp} = 15.6$, $I_{theor} = 11.4$ and $\Delta(I_{theor} - I_{exp}) = 4.2$, while for uranium ($Z = 92$) in $K_4UO_2(CO_3)_3$, $I_{exp} = 22.3$, $I_{theor} = 16.9$ and $\Delta I = 5.4$.

This is exemplified in Fig. 38 which shows for comparison the variations of the relative intensities of the OVMO and $E3d$ lines in the oxides of Period 4 elements (E). The corresponding theoretical intensities were calculated for atoms E using the data obtained by Scofield.⁷⁶ For elements with $Z > 30$, the experimental and theoretical values are presented as the intensity ratios for the lines of $3d$ and $3p$ electrons. This does not introduce a substantial error because the photoionisation cross-sections of the $E3d$ and $E3p$ shells are much greater than those of the $E4s$, $E4p$ or $O2p$ shells. If one takes into account the contribution to the intensity of the $O2p$ electrons of the oxide oxygen atoms for elements with $20 \leq Z \leq 29$, the theoretical intensity value would increase by approximately 10%, which provides a better qualitative agreement with the experimental data (see Fig. 38).

It follows from the obtained results that spectral characteristics of the $Ln4f$ electrons have much in common with those of the Mnd electrons in compounds of nd transition metals, which can

Figure 38. Experimental¹³² (1) and theoretical⁷⁶ (2) dependences of the relative intensities of the E3d and OVMO lines for CaO, Sc₂O₃, TiO₂, V₂O₅, Cr₂O₃, MnO, FeO, CoO, NiO, CuO, ZnO, Ga₂O₃ and GeO₂ oxides and FeAs₂, Se, KBr and Kr on the element (E) atomic number in the Ca–Kr series. For the oxides of elements with $Z \leq 30$ (Ca–Zn), the intensities were found as the ratio of the total intensity of the OVMO and E3d lines to the intensity of the 3p-electron lines, and for $Z > 30$ (Ga–Kr), they were found as the ratio of the 3d to 3p lines.

efficiently participate in the MO formation. In lanthanides, Ln4f is a valence shell, it can be involved in the MO formation in Ln compounds. At least, XPS data do not contradict the assumption, based on calculations, concerning substantial participation of the Ln4f AO in the formation of MO in these compounds.^{56–59, 180} Indeed, the involvement of these electrons in the chemical bond may be the reason for the decrease in the experimental intensity of the Ln4f lines compared to the theoretical intensity for the oxides formed by elements of the second half of the lanthanide row.

2. The spectra of the inner valence MO electrons

In order to elucidate the general features of the IVMO formed from the Ln5p and O2s AO in oxygen-containing lanthanide compounds, model NR SCF X_α-SW calculations both with and without allowance for the electron spin polarisation were carried out for the LnO₃³⁻ clusters (D_{3h} symmetry).^{79, 84} The $R(\text{Ln}–\text{O})$ bond lengths were taken to be equal to the sum of the covalent radii of the lanthanide and oxygen ions.¹ The calculation results are reflected in Fig. 39 and, for the LaO₃³⁻ cluster (D_{3h} symmetry) in which $R(\text{La}–\text{O}) = 0.174$ nm, they are also presented in Table 4. The total partial charges (Q_i^j , electron charge units) for this cluster found using the MT (muffin-tin) approximation of the SCF X_α-SW technique⁷⁹ are presented below (region II is an asymmetric region within the Watson sphere, and region III is situated outside this sphere⁵⁶).

It follows from the data of Table 4 that the occupied low-energy valence Ln5p and O2s AO can participate substantially in the MO formation in the cluster in question.

Thus in the LaO₃³⁻ cluster (D_{3h} symmetry), the 1a₂^{''} IVMO can be regarded, to a certain approximation, as a quasi-atomic MO composed mainly of the La5p AO. The 1e' and 2e' (1a₁' and 2a₁') IVMO can formally be attributed to the bonding and antibonding orbitals, respectively (see Table 4). The bonding 1a₁' IVMO contains 85% of the La5s AO and 12% of the O2s AO, whereas the antibonding 2a₁' IVMO, 17% of the La5s AO and 80% of O2s AO. In addition, the contributions of the outer valence AO of lanthanum and oxygen to these IVMO couples are quite sub-

Figure 39. MO energies (E) for the LnO₃³⁻ cluster (D_{3h} symmetry) vs. the lanthanide atomic number in the La–Lu series.⁷⁹ The 4a₁' and 5e' OVMO energies are not given. The dashed lines show unoccupied MO.

stantial but different. For example, whereas the bonding 1e' MO contains only 2.5% of the O2p AO, the antibonding 2e' MO

^a The upper fully occupied orbital.

contains 14% of the $O2p$ AO. Such admixtures of the outer valence AO to the IVMO, as noted in a series of studies of molecules of light elements^{18,55,61,86,87} and in another series of studies^{18,55,181–183} of molecules of heavy elements, result in weakening of the antibonding nature of the higher MO, in particular, the $2e'$ IVMO. As a consequence, the contributions of the electrons of IVMO couples such as, for example, the $1e'$ and $2e'$, strengthens the chemical bond between the lanthanum and oxygen atoms.

As the lanthanide atomic number in the LnO_3^{3-} cluster grows, the energies and compositions of their MO change significantly. In constructing the dependence of MO energies of these clusters on Z , the energy of the quasi-atomic $2a'_1$ MO of oxygen was suggested to be constant and equal to 26.5 eV (see Fig. 39).⁷⁹ This energy was chosen as the reference value to compare the results of theoretical calculations with experimental data. Upon an increase in Z , the most pronounced changes in energy are observed for the upper $2e''-2a'_2$ OVMO and the $1a'_2$ and $1a'_1$ IVMO. The compositions of the considered MO substantially change. Thus, with an increase in the atomic number Z , the $2e''-2a'_2$ OVMO group approaches the $O2p$ AO to an increasing extent, while the $1e''-3a'_1$ orbitals become similar to the $Ln4f$ AO. The degree of mixing of $Ln5p$ and $O2p$ AO increases with an increase in Z from 57 to ~ 64 . It follows from these data that the degree of mixing of the $Ln5p$ and $O2s$ AO in the $1e'$ and $2e'$ IVMO in, for example TbO_3^{3-} , is substantially greater than that in LaO_3^{3-} , while the lower $1a'_1$ IVMO becomes a quasi-atomic MO to an increasing extent.

As noted above, the formation of IVMO from the metal $Ln5p$ AO and the ligand $L2s$ AO in lanthanide can complicate the structure of the XPS spectra of these electrons compared to the sum of the atomic spectra (see Fig. 24). The most pronounced

complication of the spectrum in the energy range of these electrons should be expected for the oxygen compounds of lanthanides situated in the middle of the row because for these oxides, the $Ln5p$ and $O2s$ energies are the closest to each other. The degree of participation of the $Ln5p$ and $L2s$ AO in the formation of IVMO can be estimated experimentally using the method of binding energy differences between the core and valence electrons.^{182,183}

The oxygen-containing lanthanide compounds have a rather complex structure. The metal atoms are surrounded by a large number of oxygen atoms. However, there is no strong anisotropy for the $R(Ln-O)$ bond lengths in these compounds. Therefore, the IVMO of the ML_8^{n-} and ML_8^{n-} type clusters (O_h group of symmetry) can be used in qualitative considerations (see Fig. 8*b,c*). The correlation schemes of these IVMO imply that upon the formation of IVMO of the t_{1u}^* type in lanthanide compounds, their energies shift to lower (in magnitude) values with respect to the core levels. In this case, the Δ_1 value (see Fig. 8), which characterises the degree of participation of the $Ln5p$ and $L2s$ AO in the formation of the t_{1u}^* IVMO, can be estimated experimentally. The $\Delta E_3(Ln5p_{3/2}-Ln3d_{5/2})$ values reflecting the difference between the $Ln3d_{5/2}$ and the t_{1u}^* MO binding energies for various lanthanide compounds are presented in Table 5. To estimate Δ_1 (see Fig. 8), the experimental values for the corresponding energy differences for metallic lanthanides are also presented. If, as has been suggested,^{50,140} the basic line in the $Ln3d$ spectra of light lanthanide compounds occurs at higher binding energies, comparison of these data indicates that the Δ_1 value for lanthanum oxygen-containing compounds reaches 2.3 eV, that for cerium, 4.5 eV, and that for praseodymium, 0.6 eV (for the oxide) (see Table 5).

^a L¹ is the diphenylacetic acid residue, L² is the *o*-methoxybenzoic acid residue, Pc is the unsubstituted diphthalocyanine residue, Pct is the 4-*tert*-butyldiphthalocyanine residue. ^b The intensities of one of the Ln3d_{5/2} lines referred to the line whose intensity is taken to be unity are given in parentheses. ^c X = O, F, N; the binding energy differences are given for those compounds for which the X1s spectrum is a single line. ^d The binding energies are referred to the electron binding energy for carbon in adsorbed hydrocarbons, $E_b(\text{C}1s) = 285.0$ eV [at $E_b(\text{Au}4f_{7/2}) = 83.8$ eV for the standard gold plate, $E_b(\text{C}1s) = 284.4$ eV]. ^e The E_b values are given for Ln³⁺. ^f The Lu4d_{5/2} binding energy. ^g The $\Delta E_3(\text{Lu}5p_{3/2} - \text{Lu}4d_{5/2})$ values.

The data considered lead to the conclusion that IVMO are actually formed in these compounds, the upper orbitals being antibonding. If the basic lines in the Ln3d spectra of light lanthanides occur at lower binding energies, as shown for the Ln compounds studied in a number of publications,^{5,50,140} the Δ_1 value (see Fig. 8) changes its sign, while its magnitude $|\Delta_1|$ for lanthanum oxygen compounds reaches 1.3 eV (see Table 5). These results confirm the formation of IVMO in these compounds. In addition, they indicate that the upper IVMO is a bonding orbital in this case.

The same conclusion can be drawn by considering the $\Delta E_b(\text{Ln}5p_{3/2} - \text{Ln}4d_{5/2})$ energy differences for lanthanide compounds. The values for LaF₃, La₂O₃, LaL₃¹, LaL₃² · 1.5 H₂O, La₂Ti₂O₇, LaNbO₄ and metallic lanthanum amount to 85.8, 85.1, 85.4, 86.0, 85.0, 85.7 and 86.1 eV, respectively. These data confirm once again the fact that in the La3d spectra of the lanthanide compounds studied, the basic lines are located in the lower binding energy region.

On passing from light to heavy lanthanides, the Ln5p_{3/2} energy level is lowered. In the case of lutetium, it is located below the O2s level; thus, the Δ_1 value for the lutetium compounds (see Fig. 8) should change the sign. In other words, the ΔE_3 difference (see Table 5) for oxygen compounds of lutetium should become smaller in magnitude than that for metallic Lu. Indeed, it follows from the data of Table 5 that in some cases, $\Delta E_3(\text{Ln}5p_{3/2} - \text{Ln}4d_{5/2})$ for atomic lutetium is 1.1 eV higher than these values for Lu in compounds ($\Delta_1 = -1.1$ eV).

It has been noted¹⁸⁴ that the emission spectra¹⁸⁵ of Eu₂O₃ and other 'sesquialteral' lanthanide oxides exhibit peaks related to the Ln5p and O2s hybrid orbitals. The X-ray SL_{II,III} emission spectra of some sesquialteral REE sulfides¹⁸⁶ and lanthanide monosulfides¹⁸⁷ also contain peaks due to the formation of IVMO consisting of the Ln5s, Ln5p and S3s AO.

3. Multiplet splitting

Multiplet splitting shows itself most clearly in the case of the Ln4s, Ln4d and Ln5s electrons in lanthanide compounds. In the XPS spectra of Ln4s and Ln5s electrons, this splitting gives rise to two components the distance between which is correlated, along the energy scale, with the number n_{4f} of unpaired Ln4f electrons (see Figs 16, 29). These results are in satisfactory agreement with theoretical data,^{44,69,93} and the multiplet splitting value can be used as a parameter in determining the spin and oxidation states of REE ions in compounds.

The XPS spectra of compounds of lanthanides containing unpaired Ln4f electrons in the Ln4d binding energy region are due to multiplet splitting and exhibit a complex structure (see Fig. 17, 30). Instead of the expected doublets characterised by a spin-orbit splitting energy not exceeding 10 eV even for heavy lanthanides, the spectrum of these electrons exhibits a fine structure in the energy range of up to ~40 eV. The results of theoretical calculations^{45,66} carried out in the ionic approximation are in satisfactory agreement with experimental data. The fine structure of the XPS spectra of the Ln4d electrons is typical of particular REE in compounds and can be used for identification and for determination of the oxidation state of the lanthanide ion. For example, this structure allows one to make the conclusion that the cerium oxidation state in all the compounds studied, except for the oxide, is close to Ce³⁺. Apparently, in the oxide, cerium forms specific clusters, photoemission of a core electron from which gives rise to three final states including the unusual two-hole Ce3d⁹5p⁵(np) state (see Figs 33, 34). The presence of one unpaired Ce4f electron in Ce³⁺ results in a pronounced disturbance of the structure of the spin doublet present in the Ce4d spectra of the Ce⁴⁺ ion, which does not contain this Ce4f electron. The structure of the Yb4d spectra leads to the conclusion that ytterbium exists as Yb³⁺ in all the compounds studied. The Yb³⁺ electronic configuration is 4f¹³, which markedly complicates the expected spectral structure. The spectrum of the Yb4d electrons of the Yb²⁺ with the 4f¹⁴ configuration (in the YbCu₂Ge₂ intermetallic com-

pound¹⁵⁶ and metallic ytterbium^{71, 96, 188}) contains a doublet caused by the spin – orbit splitting.

4. Splitting resulting from the induced charge

Charge inducing on the centres regarded previously as diamagnetic (Ti^{4+}) in the double oxides of the FeTiO_3 type was first observed by X-ray emission spectroscopy.¹⁸⁹ The excess electron density on the titanium ion contained in complex oxides of the MTiO_3 type arises in the case where the second coordination sphere contains paramagnetic metal ions (M). Analysis of the X-ray emission spectra shows^{189–191} that, for example, on passing from TiO_2 to FeTiO_3 and, possibly, to $\text{Ln}_2\text{Ti}_2\text{O}_7$,^{28, 192, 193} the titanium ions, which are expected to be diamagnetic, are actually paramagnetic. This results in splitting of the emission lines of the titanium ions. A similar situation is also found for niobium compounds. This line splitting is a specific case of multiplet splitting, which is an indirect consequence of the presence of paramagnetic ions connected to the metal ion in question *via* an oxygen bridge.

By using a procedure for recording high-resolution XPS spectra of dielectric materials, Teterin and co-workers^{133–136, 194, 195} were able to measure the relative line widths of the spectra and the electron binding energies with an accuracy higher than ~ 0.1 eV. Thus, it became possible to detect, with a relatively high accuracy, slight changes in the unpaired electron density ($\Delta\rho$) on a metal ion in a dielectric material and to estimate semi-quantitatively the $\Delta\rho$ value using the XPS method. An increase in the number of unpaired electrons in a 3d-metal or lanthanide ion in a compound by one electron ($\Delta\rho = 1e^-$) is known^{44, 93, 94, 196} to increase the splitting of the $\text{M}3s$ or $\text{Ln}4s$ line by approximately 1 eV (see, for example, Fig. 29). Since the binding energies and the line widths for core levels can be measured with an accuracy higher than ± 0.1 eV, the change in the $\Delta\rho$ value by $0.1e^-$ can be detected by XPS. Using results reported by Teterin *et al.*,¹⁹⁴ the $\Delta\rho$ value for Ti in FeTiO_3 was found to be $\sim 0.5e^-$, while that for Nb in SmNbO_4 was found to exceed $1e^-$.

This phenomenon has been studied in more detail by XPS^{133, 134, 136} in relation to lanthanide (except for Pm and Tm) orthoniobates. On passing from niobium oxide ($\alpha\text{-Nb}_2\text{O}_5$) to orthoniobates (LnNbO_4) containing Ln^{3+} paramagnetic ions, characteristics of the XPS spectra of the core electrons of niobium change. Thus the line widths in the $\text{Nb}3p_{3/2}$, $\text{Nb}4s$ and $\text{Nb}4p$ spectra for LnNbO_4 containing lanthanides of the middle of the row are much greater than the corresponding values for the $\alpha\text{-Nb}_2\text{O}_5$ oxide. The broadening of the $\text{Nb}4s$ line becomes so pronounced that at least two components of the complex structure are clearly manifested. The observed line broadening is assumed to be mainly due to charge induction ($\Delta\rho$) onto the Nb^{5+} ion, and, on passing from $\alpha\text{-Nb}_2\text{O}_5$ to LnNbO_4 (Ln are lanthanides from the medium of the row), the Nb^{5+} ion electronic configuration changes appreciably from $\{4d\}$ to $\{4d^{\Delta\rho}\}$. It has been noted^{44, 93, 94, 196} that the multiplet splitting arises with the highest probability in the spectra of core electrons having the same principal quantum number as the unpaired electrons. In this case, the most pronounced multiplet splitting should be expected in the spectra of the $\text{Nb}4s$ electrons. This was actually observed in experiments. However, Lebedev *et al.*¹³⁶ do not rule out the possibility that the dynamic effect may also be manifested in these spectra, although it is less pronounced than the multiplet splitting.

The excess unpaired electron density ($\Delta\rho$) has been estimated^{133, 134, 136} using data on the multiplet splitting of the $\text{Ln}4s$ lines for Ln_2O_3 oxides,⁸⁰ which indicate that the presence of one unpaired 4f electron in a lanthanide ion induces splitting of the $\text{Ln}4s$ line by $\Delta E_{\text{ms}}(\text{Ln}4s) \approx 1.1$ eV. In this case, for GdNbO_4 , it was found that $\Delta\rho_1 > 1e^-$. The appearance of the extra electron density $\Delta\rho$ on the niobium ion on passing from $\alpha\text{-Nb}_2\text{O}_5$ $\{4d^0\}$ to GdNbO_4 $\{4d^{\Delta\rho}\}$ results in a shift of the core electron lines towards low binding energies; for example, for the $\text{Nb}3p_{3/2}$ electrons, this

shift is $\Delta E_b(\text{Nb}3p_{3/2}) = 0.8$ eV. Since a change in the formal oxidation state of a metal in compounds by unity results in a change of the chemical shift of the core levels by approximately one electron-volt (see, for example, Ref. 33), the excess electron density ($\Delta\rho_2$) found from the chemical shift of the $\text{Nb}3p_{3/2}$ level is smaller than the $\Delta\rho_1$ value determined from splitting of the $\text{Nb}4s$ lines, and equals $\sim 0.8e^-$. This difference between the considered values may be due, in particular, to the fact that $\Delta\rho_1$ is the sum of two contributions ($\Delta\rho_1 = \Delta\rho_2 + \Delta\rho_3$), one of them ($\Delta\rho_2$) being due to the excess charge directly on the $\text{Nb}^{\Delta\rho_2}$ ion and the other ($\Delta\rho_3$) being related to polarisation (for example, polarisation of the valence-shell electrons).

The results obtained represent one of the first steps in the study of the appearance of excess unpaired electron density on the ionic centres that have previously been considered diamagnetic. Since double oxides possess ferroelectric (LnNbO_4), antiferromagnetic (FeTiO_3) and other important physical properties, further investigation of the charge induction mechanism may shed light on the nature of these phenomena and favour the development of methods for the preparation of substances with *a priori* specified useful properties. The use of characteristics of the spectral fine structure allows efficient utilisation of the XPS method in a study of charge induction caused by indirect exchange interaction between metal ions in valuable complex materials.

5. Dynamic effect

Experimental data show that the fine structure associated with the dynamic effect is manifested most clearly in the spectra of those atomic levels the energies of which are divisible by the energies of the nearest upper levels (see above). This shows itself as an individual structure in the spectra of the $\text{Ln}4p$ electrons for all lanthanide compounds that obey most closely the approximate equality $E_b(\text{Ln}4p) \approx 2 E_b(\text{Ln}4d)$ (see Figs 19, 31, 34). Common features of the spectra of these electrons in various lanthanide compounds are that the $\text{Ln}4p_{3/2}$ component has a fine structure and that the intensity of the $\text{Ln}4p_{1/2}$ component is most often substantially suppressed.

The structure of the $\text{Ln}4p$ spectra of lutetium compounds is much less complicated. This led to the suggestion that^{5, 20} one of the possible final configurations of lanthanide ions resulting from photoemission of the $\text{Ln}4p$ electron is due to the $\text{Ln}4d$ -to- $\text{Ln}4f$ electron migration: $4p^5 4d^{10} 4f^n \leftrightarrow 4p^6 4d^8 4f^{n+1}$. The resulting data contradict the suggestion made by Padalia *et al.*⁸⁰ that the structure of the $\text{Ln}4p$ spectra is due to multiplet splitting but are consistent with the results of a calculation for X-ray $\text{LnL}\gamma_{\text{II, III}}$ emission spectra¹⁹⁷ and other X-ray spectra of lanthanides.^{198, 199}

The structure caused by the dynamic effect giving rise to the final states of the type

can markedly complicate the $\text{Ln}5s$, $\text{Ln}4s$ and $\text{Ln}3p$ spectra of lanthanides in compounds.^{5, 200}

Study of the nature of generation of the XPS spectral structure associated with the dynamic effect may clarify the role of the secondary electron processes that accompany the photoemission of electrons from individual shells. In particular, analysis of the XPS spectra stimulates the theoretical investigation of these processes,^{168, 200} while the spectra can serve as a criterion for the validity of the models chosen for calculations.

6. Many-body perturbation

When manifested to a substantial extent, many-body perturbation gives rise to satellites in the spectra of electrons of various shells. As shown for 3d transition metal^{23, 122} and lanthanide^{44, 48, 135} compounds, the most intense satellites should be manifested in the spectra of low-lying electron levels because these electrons possess a relatively low kinetic energy after photoemission. For com-

pounds of light lanthanides, the problem of the mechanism of satellite formation is especially acute for several reasons.

As noted in the Introduction, in the binding energy range used normally in investigations, virtually all the XPS spectra of various electron shells in lanthanide compounds exhibit complex structures. The structure present in the spectra of core electrons hampers the measurement of binding energies, which are traditionally used to determine the relative oxidation states of lanthanides in compounds. In the case of light lanthanides, one component of the $\text{Ln}3d_{5/2, 3/2}$ spin doublet is considered to be suitable for this purpose. However, both the $\text{Ln}3d_{5/2}$ and $\text{Ln}3d_{3/2}$ spectra in lanthanide compounds can contain at least two intense lines. Study of the reasons for the appearance of complex structures in the spectra of $\text{Ln}3d$ electrons of rare earth metals²⁰¹ and light lanthanide compounds¹⁷⁷ has attracted considerable attention.

An important problem arising in the analysis of the $\text{Ln}3d$ spectral structure in lanthanide compounds is to find out which of the two lines reflects the main final state with the hole in the $\text{Ln}3d$ level formed upon photoemission of an electron. On the one hand, clarification of this item is needed for measuring the relative binding energies of these electrons and, on the other hand, this would enable the use of the method of binding energy difference between the core and valence MO when analysing the nature of individual MO.

In a number of studies,^{45, 50, 105, 178} it has been suggested that the spectral structure of the $\text{Ln}3d$ electrons in lanthanide compounds is due to many-body perturbation giving rise to shake-up satellites, which can be more intense than the basic lines. The results obtained for individual light lanthanides^{108, 109, 155, 201} indicate that the $\text{Ln}3d$ spectra do not exhibit the highly intense satellites observed by Shabanova *et al.*¹²⁶ The low-intensity extra lines ($\sim 10\text{--}2\%$) observed in the $\text{Ln}3d$ spectra of metallic lanthanides on the lower binding energy side of the basic lines may be due to a shake-down process.²⁰¹ By analogy, it has been suggested^{75, 108, 109} that the intense extra lines recorded in the $\text{Ln}3d$ spectra of light lanthanide hydrides, oxides and hydroxides are also due to many-body perturbation with the formation of shake-down satellites. In other words, the lines in the spectra of $\text{Ln}3d$ electrons that have previously^{45, 50, 178} been classified as satellites have also been proposed^{75, 108, 109} to be basic lines. These lines should occur at higher binding energies than satellites (see Figs 21, 33).

As an argument supporting the formation of shake-down satellites in the spectra of the $\text{Ln}3d$ electrons of light REE, the researchers^{108, 109} proposed the fact that the electron binding energy corresponding to the high-energy component of lanthanide compounds is greater than the $\text{Ln}3d$ energy in individual metals (see Table 5). However, to measure the $\text{Ln}3d$ binding energy in lanthanide compounds more rigorously, one should take into account the whole structure of the spectrum of these electrons.²⁰² In this case, the $\text{Ln}3d$ binding energy can be determined using the weighted-mean value found from the complex spectrum. Moreover, if the extra structure in the spectra of these electrons is due to shake-down satellites, similar satellites (although less intense) should also occur in the spectra of electrons characterised by lower binding energies than the $\text{Ln}3d$ electrons. Unfortunately, in none of the studies^{75, 108, 109} in which a shake-down process has been proposed to interpret the $\text{Ln}3d$ spectral structure, was such an analysis performed.

In elucidation of the reasons for the appearance of highly intense satellites in the $\text{Ln}3d$ spectra of light lanthanides,^{51, 64, 135} three spectral parameters have been used: (i) the chemical shift of the electronic energy level corresponding to the considered component relative to the $\text{Ln}3d$ energy level in the metal; (ii) the presence of satellites in the spectra of other electronic energy levels; (iii) binding energy differences between lanthanides in compounds and in metals for various electrons the spectra of which exhibit no intense satellites of this type.

When considering the spectral structure for the $\text{La}3d$ electrons in lanthanum compounds from this standpoint, one can detect shake-up satellites. Indeed, the weighted-mean values of the $\text{La}3d$ binding energies in lanthanum compounds are about 0.3 eV higher than the corresponding values for metallic lanthanum, $E_b(\text{La}3d_{5/2}) = 836.6$ eV (see Table 5). The spectra of other electrons of lanthanum compounds also display satellites at higher binding energies relative to the basic lines, the satellite intensity decreasing with a decrease in the binding energies of these electrons (Table 6). This statement is also in agreement with the relationship between the binding energy difference $\Delta E_3(5p_{3/2} - 3d_{5/2})$ in the lanthanum compounds and metallic La. For example, the increase in ΔE_3 for the high-energy component of the spectrum by 4.4 eV on passing from metallic lanthanum to the trifluoride can hardly be explained by the assumption that the basic line for the $\text{La}3d$ electrons occurs in the spectrum at higher electron binding energies (see Table 5). Meanwhile, the concomitant increase in ΔE_3 for the low-energy component by 0.1 eV can be easily explained by the fact that the upper IVMO in the formation of the $\text{La}-\text{F}$ bond is an antibonding orbital. The slight participation of the $\text{La}5p$ and $\text{F}2s$ AO in the formation of IVMO in LaF_3 is also confirmed by calculations (see Fig. 12). However, to estimate more rigorously the character of the IVMO on the basis of binding energy differences, it is necessary to use the $\text{La}3d$ binding energies found as the weighted-mean ΔE_b values for the electrons reflecting the whole spectral structure.

Table 6. Intensities of the shake-up satellites $I = I_{\text{sat}}/I_0$ (%) and their energies (ΔE_{sat} , eV) relative to the basic lines in the XPS spectra of various lanthanum shells in compounds.^{20, 79, 84, 135}

Compound ^a	$I(3d_{5/2})$	$\Delta E_{\text{sat}}(3d_{5/2})$	$I(4p_{3/2})$	$I(4d_{5/2})$
LaF_3	30	4.3	18	13
LaNbO_4	72	4.2	34	27
La_2O_3	83	3.5	29	22
$\text{La}_2\text{Ti}_2\text{O}_7$	91	4.2	27	—
$\text{LaL}_3^2 \cdot 1.5\text{H}_2\text{O}$	100	2.8	—	24
LaL_3^1	132	3.1	—	55

Note. The errors in the determination of I values are $\pm 10\%$, ΔE_{sat} is ± 0.2 .
^a L^1 is the diphenylacetic acid residue, L^2 is the *o*-methoxybenzoic acid residue.

This assumption is in good agreement with the results of the study¹⁴⁰ which illustrates the formation of shake-down satellites in the spectra of the $\text{La}3d$ electrons for metallic lanthanum and shake-up satellites in the spectra of these electrons in the dielectric $\text{La}(\text{OH})_3$ (Fig. 40). Upon the formation of a hole in a core level of lanthanum, the energy of the empty $\text{La}4f$ AO levels decreases. In a metal, these levels can be filled due to transition of an electron from the conduction band, which corresponds to a shake-down process. In a dielectric having the valence band rather than the conduction band at a higher binding energy, these $4f$ levels can be occupied due to transition of an electron from this band, which implies a shake-up process.

In reality, the satellite formation is a more complex process.^{41, 203, 204} The structure and intensity of these satellites are highly sensitive to the variation of a stoichiometric composition of the substance and the nature of the ligands surrounding the lanthanide. Thus it has been noted^{45, 46} that an increase in the covalent nature of the bond, for example, in the series of lanthanum halides LaF_3 , LaCl_3 , LaBr_3 , entails a decrease in the binding energies of shake-up satellites relative to the $\text{La}3d$ basic lines, while the satellite intensity markedly increases. Hence, the spectral characteristics of the satellites may allow one to estimate the degree of ionicity (covalence) of the $\text{La}-\text{L}$ chemical bonds in lanthanum compounds. For example, it follows from XPS spectra that the ionic type of the $\text{La}-\text{O}$ bond markedly increases over the series LaL_3^1 , $\text{LaL}_3^2 \cdot 1.5\text{H}_2\text{O}$, La_2O_3 (see Table 6). Similar consid-

Figure 40. Diagram representing the positions of the 4f energy level in compounds of the light lanthanides before and after photoemission of a core electron.¹⁴⁰ The conduction band in a dielectric, for example, in La_2O_3 , is empty.

erations concerning the nature of satellites are also valid for cerium compounds.^{137, 138, 205} However, it follows from the low-energy spectra in which the $\text{Ln}4f$ states are shifted relative to the OVMO energy and from the pattern of variation of the $\text{Ln}3d_{5/2}$ FWHM for lanthanide trifluorides following an increase in the Ln atomic number (see Figs 23, 22) that shake-down satellites may be expected in the spectra of compounds formed by heavier elements.²⁰⁶ This is also consistent with the results of theoretical calculations.^{47, 114}

The data considered above make it possible to draw the conclusion that determination of the lanthanide oxidation state based on the $\text{Ln}3d$ XPS spectral characteristics of lanthanide compounds should be done using the weighted-mean value for the binding energy found with allowance for the whole complex structure of the spectrum.

V. Conclusion

The variation of the binding energy and the relative line intensity for the $\text{Ln}4f$ electrons vs. the atomic number of lanthanide in lanthanide oxides shows that the $\text{Ln}4f$ electrons largely resemble in spectral characteristics the Mnd electrons of nd transition metals. These data are consistent with the results of theoretical calculations pointing to a substantial participation of the $\text{Ln}4f$ AO in the formation of MO in lanthanide compounds. In all the studied compounds of scandium, yttrium and lanthanides, IVMO are efficiently formed by participation of occupied $\text{Sc}3p$, $\text{Y}4p$, $\text{Ln}5p$ and $\text{L}2s$ AO; this is supported by the results of theoretical calculations. This allows experimental evaluation of the type (either bonding or antibonding) of some IVMO.

The dependences on the multiplet splitting (ΔE_{ms}) of the $\text{Ln}4s$ and $\text{Ln}5s$ lines of lanthanide trifluorides, oxides and other compounds on the number of unpaired $\text{Ln}4f$ electrons have been established; they make it possible to determine spin population on the Ln atom in compounds. It was found that, due to the multiplet splitting, the spectrum of $\text{Ln}4d$ electrons for lanthanide compounds extends over a range of ~ 40 eV, which is several times greater than the spin-orbit splitting of the lines of these electrons. The mechanism of satellite formation in the spectra of $\text{Ln}3d$ electrons was analysed. For LnF_3 and Ln_2O_3 , the theoretical concept concerning the change of the sign of the binding energy difference $\Delta E_{\text{sat}} = |E_{\text{sat}}| - |E_0|$ between the satellite and the basic line (from 'plus' to 'minus') with an increase in the atomic number (Z) over the lanthanide row was confirmed experimentally. It was shown that the structure of the $\text{Ln}4p$ spectra and, in

some cases, the $\text{Ln}3p$ spectra is largely determined by the dynamic effect, resulting in the $\text{Ln}4p^5 4d^{10} 4f^n \leftrightarrow \text{Ln}4p^6 4d^8 4f^{n+1}$ and $\text{Ln}3p^5 3d^{10} 4s^2 4f^n \leftrightarrow \text{Ln}3p^6 3d^9 4s^1 4f^{n+1}$ final states, respectively.

The electron density induction on ions previously considered diamagnetic has been studied by X-ray electron spectroscopy in relation to the lanthanide-containing titanium and niobium double oxides.

Interpretation of the reasons for the formation of fine structure in the XPS spectra of lanthanides and elucidation of the relationships between the structure parameters and the physico-chemical properties of these compounds markedly extends the scope of application of the XPS method for the investigations of these compounds. In this case, X-ray electron spectroscopy becomes the most adequate method for determination of the elemental and ionic composition of lanthanide compounds, electronic configurations and magnetic characteristics of lanthanide ions, for investigations into the nature of the chemical bond and secondary electronic processes that accompany photoemission of electrons, and for determining the structure of the local environment of metal ions.

This provides the possibility of more efficient use of expensive advanced equipment and synchrotron radiation in diverse investigations of compounds of lanthanides and other elements.

IV. Structures, synthesis and superconducting properties of different classes of copper oxyfluorides	387
V. Conclusion	398

Abstract. Chemical aspects of the synthesis of complex layered copper oxyfluorides possessing superconducting properties or serving as structural matrices for the preparation of new superconductors are discussed. Primary attention is given to fluorination of layered cuprates. Different ways of inserting fluorine into complex copper oxides and the corresponding synthetic approaches are surveyed. The influence of the synthesis conditions on the fluorination pathway, which involves either the incorporation of fluorine or partial replacement of oxygen with fluorine, is analysed. The advantages of xenon difluoride over other fluorinating agents are considered. Fluorination of complex copper oxides often leads to structural changes as exemplified by fluorine-containing phases obtained with the use of both XeF₂ and other fluorinating agents. The bibliography includes 104 references.

I. Introduction

Superconducting materials possess unique properties. The high practical potential of a new generation of high-temperature superconductors, *viz.*, complex copper oxides, gave impetus to comprehensive studies of their physical and chemical properties, structural characteristics and ‘chemical composition–properties–structure–synthesis conditions’ relationships.

The data on the relationships between the composition, structure and properties of numerous copper-containing high-temperature superconducting (HTSC) oxides made it possible to state the following structural and chemical criteria for the appearance of superconductivity:¹

- the existence of a layered structure composed of weakly distorted or planar superconducting CuO₂ layers, which occur as an infinite network of vertex-sharing CuO₄ squares;

- the presence of optimum interatomic Cu–O distances (ranging from 1.90 to 1.97 Å) in the plane of the conducting layer, which ensure overlapping of the 3d_{x²–y²}-orbitals of copper

and the 2p_{x,y}-orbitals of oxygen to form delocalised states in the σ* band;

- the optimum concentration of charge carriers in the conducting CuO₂ layers must correspond to the ranges of the formal oxidation state of copper from +2.05 to +2.25 and from +1.8 to +1.9 for *p*- and *n*-type superconductors, respectively.

In the structures satisfying these criteria, the negative charge of the CuO₂ layers (if these layers are considered as composed of the Cu²⁺ cations and O^{2–} anions) is compensated by the positive charge of the adjacent nonconducting cationic-anionic charge-reservoir blocks, which offer a means of changing the oxidation state of copper in the CuO₂ layers. By varying the positive charge of these blocks, for example, through either the heterovalent cation substitution or a change in the oxygen content, the required concentration of charge carriers in the conduction band can be achieved. Another way of changing the concentration of charge carriers is to replace a portion of oxygen in the anion sublattice of complex cuprate by fluorine or to insert the fluorine atoms into the structure.

The oxygen and fluorine anions have similar ionic radii (*r*_{F[–]} = 1.29 Å and *r*_{O^{2–}} = 1.35 Å; for the coordination number of 2; see Ref. 2). Many oxides have structures analogous to those of fluorides and oxyfluorides (for example, CaO and NaF, LaOF and CaF₂, La₂CuO₄ and K₂CuF₄, *etc.*). Consequently, the incorporation of fluorine into complex layered copper oxides can give rise to oxyfluorides structurally similar to these oxides. Fluorine atoms can occupy the anion vacancies or replace oxygen atoms. In both cases, the formal oxidation state of copper is changed. If this incorporation does not lead to destruction or deformation of the CuO₂ layers, the resulting complex oxyfluoride would be expected to exhibit superconducting properties. The superconducting transition critical temperatures (*T*_c) of some complex copper oxyfluorides are even higher than those of their oxygen analogues (Table 1). Hence, complex layered copper oxyfluorides can be considered as a promising class of compounds for constructing high-temperature superconductors.

Fluorination of complex cuprates not only enables one to achieve the optimum concentration of charge carriers but also offers additional possibilities of searching for new layered compounds. The requirements for the retention of the charge balance and compatibility of interatomic distances in structural fragments (commensurability) impose limitations on the choice of cations involved in nonconducting blocks, which compensate the negative charge of the CuO₂ layers. The replacement of O^{2–} with F[–],

[†] The review is dedicated to the blessed memory of Professor L M Kovba.

Low-temperature fluorination afforded fluorine derivatives of layered cuprates, *viz.*, $\text{YBa}_2\text{Cu}_3\text{O}_{6+\delta}$,^{22, 23} La_2CuO_4 ,²⁴ $\text{M}_{2-x}\text{A}_{1+x}\text{Cu}_2\text{O}_{6-\delta}$ ($\text{M} = \text{La}$ or Nd ; $\text{A} = \text{Ca}$ or Sr),²⁵ $\text{Pb}_2\text{Sr}_2\text{YCu}_3\text{O}_8$,²⁶ *etc.* Fluorine derivatives of complex cuprates decompose upon heating to form thermodynamically stable products. Their stability is determined primarily by high crystal lattice energies of fluorine-like alkaline-earth fluorides and rare-earth oxyfluorides.

3. Fluorinating agents for the synthesis of fluorine-containing high-temperature superconductors

Low-temperature syntheses of complex copper oxyfluorides were carried out with the use of various fluorinating agents, *viz.*, gaseous fluorine (pure^{22, 27} or in mixtures with other gases^{19, 24}), NF_3 ,²³ NH_4F ,^{28–31} NH_4HF_2 ,^{32, 33} transition-metal fluorides (ZnF_2 , CuF_2 , NiF_2 , AgF_2)^{34–38} and ClF_3 .^{39, 40}

Xenon difluoride, which offers promise as a fluorinating agent, was first proposed for fluorination of HTSC cuprates in the study.¹⁷ This reagent has advantages over other reagents. At room temperature, XeF_2 is a solid compound, which enables one to use it in precise amounts and, hence, to attain the required degree of fluorination and the desired oxidation state of copper. Xenon difluoride is much less aggressive than gaseous fluorine due to which no expensive bulky apparatus is required. In addition, xenon difluoride does not generate by-products that contaminate the sample synthesised.

Xenon difluoride serves as an oxidising agent, unlike ammonium fluoride, which creates reductive conditions and leads to an increase in the oxidation state of copper only in the reactions performed in the presence oxygen^{18, 30} or through disproportionation of the reaction products to form oxidised and reduced phases.²⁰

Many transition-metal fluorides $\text{M}'\text{F}_2$ ($\text{M}' = \text{Hg}$ or Ag), like XeF_2 , are oxidising fluorinating agents. However, the reactions with the use of these compounds not only lead to fluorine incorporation but can also be accompanied by anion substitution, the probability of the latter being increased as the reaction temperature is raised. Fluorination with $\text{M}'\text{F}_2$ ($\text{M}' = \text{Zn}$, Cu or Ni) proceeds predominantly according to the reaction

In this case, the oxidation state of copper remains unchanged. When the exchange reactions are performed by direct mixing of $\text{M}'\text{F}_2$ with the compound to be fluorinated rather than being carried out in the gas phase, impurities of metal oxide contaminate the resulting sample.

4. Use of XeF_2 as a fluorinating agent in the synthesis of fluorine-containing high-temperature superconductors

Trace amounts of water, which are, for example, adsorbed on the powdered starting compounds, contaminate fluorination products due to pyrohydrolysis. Hydrogen fluoride, which is evolved in the reactions of XeF_2 or oxyfluoride that formed with water, reacts with the starting oxide or oxyfluoride with elimination of water. The latter is again involved in pyrohydrolysis.¹⁷ For example,

Fluorination at high temperatures must be carried out in hermetically sealed containers resistant to fluorine because it is necessary, first, to exclude exposure to water vapour and, second, to prevent leakage of xenon difluoride that has high volatility. We developed an original procedure for fluorination. According to this procedure, the reactions are carried out in a sealed nitrogen-filled copper tube in which a nickel crucible containing a mixture of the starting compound and XeF_2 is placed. (All operations

Figure 1. Temperature dependence of the equilibrium composition of the gas mixture containing one mole of XeF_2 at 1 atm.⁴¹ (1) XeF_2 , (2) XeF_4 , (3) Xe , (4) F_2 .

associated with the preparation of samples must be performed in a dry chamber.) In the temperature range of 423–673 K, XeF_2 exists predominantly in the gas phase and reacts with complex oxides through a gas–solid mechanism. Calculations of the temperature dependence of the equilibrium composition of the gas mixture (using the database⁴¹) containing one mole of XeF_2 at 1 atm (Fig. 1) demonstrated that at temperatures below 673 K this mixture is composed of Xe , XeF_2 and XeF_4 as the major components, the last two compounds serving as fluorinating agents. Xenon tetrafluoride surpasses xenon difluoride in oxidising activity^{42, 43} but its concentration in the gas mixture at $T < 673$ K is much lower than the concentration of XeF_2 . At reaction temperature higher than 673 K, dissociation of XeF_2 into F_2 and Xe becomes noticeable.

Fluorination with xenon difluoride in different temperature ranges involves the following main reactions. It was demonstrated⁴⁴ that the incorporation of fluorine into the structure of complex cuprate was the major process in the case of fluorination of $\text{YBa}_2\text{Cu}_3\text{O}_{6.11}$ (Y123 phase) in the temperature range from 423 to 573 K

This reaction led to an increase in the formal oxidation state of copper from +1.74 in the starting strongly reduced phase $\text{YBa}_2\text{Cu}_3\text{O}_{6.11}$ to +2.03–+2.14 in the fluorinated samples. When the temperature was increased to 673 K, competitive anion exchange took place, *i.e.*, oxygen atoms were partially replaced by fluorine atoms. The anion exchange causes partial reduction of copper cations because the formation of the fluorinated phase is accompanied by the replacement of one O^{2-} anion with one F^- anion. It is impossible to distinguish unambiguously the temperature ranges in which the fluorine incorporation and anion exchange proceed autonomously. Both competitive processes occur simultaneously

It can only be noted that the anion exchange is enhanced as the temperature is increased and finally dominates over fluorine incorporation. Thus, the reaction of the oxidised phase $\text{YBa}_2\text{Cu}_3\text{O}_{6.95}$ with XeF_2 at 623 K led to a decrease in the oxidation state of copper from +2.30 to +2.22, which is indicative of the formation of a more reduced phase, *i.e.*, of the partial replacement of oxygen with fluorine. Oxygen evolved in the course of this process is absorbed by the walls of a copper tube to form Cu_2O due to which it cannot act as an oxidiser. At 603 K,

the partial pressure of oxygen in the tube [$\ln P_{O_2} = -22.2$ (atm)], which corresponds to the equilibrium pressure of oxygen over a mixture of Cu and Cu_2O at this temperature, is comparable to the partial pressure of oxygen over the strongly reduced phase $YBa_2Cu_3O_{6.1}$ [$\ln P_{O_2} = -21.1$ (atm)] at the same temperature.⁴⁴

Nevertheless, the process can be forced to occur predominantly either by fluorine incorporation or anion exchange by changing the temperature range. This can be used for choosing the method of doping to create *p*- or *n*-type superconductors. The final step of the anion exchange involves the destruction of the structure of complex copper oxide (in the temperature range of 673–773 K) under the action of xenon difluoride or fluorine generated upon decomposition of the former:

III. Structural transformations upon fluorination of complex cuprates

As mentioned above, oxygen and fluorine have similar ionic radii and the simple replacement of oxygen atoms by an equivalent amount of fluorine atoms would not lead to substantial structural changes of complex oxyfluoride copper compared to that of complex oxide but must be accompanied by a decrease in the formal oxidation state of copper. As an example, we refer to the $Nd_2CuO_{4-x}F_x$ solid solutions, which have tetragonal structures of the T' phase (Nd_2CuO_4) (Fig. 2). An increase in the degree of replacement of O atoms by F atoms is accompanied by an increase in the unit cell parameter *a* because a reduction in the formal oxidation state of copper leads to an increase in the occupancy of the antibonding σ^* band and elongation of the equatorial Cu–O_{eq} bond. Simultaneously, the structure is slightly contracted along the *c* axis, which is probably associated with the difference in the ionic radii of oxygen and fluorine.^{4, 28}

Studies of fluorinated samples by near-edge X-ray absorption fine structure (NEXAFS) spectroscopy demonstrated that fluorine atoms replace oxygen atoms in the tetrahedrally coordinated positions of the fluorite-like Nd_2O_2 block.⁴⁵ Distortions of the crystal structures of the $Nd_2CuO_{4-x}F_x$ and $Nd_{2-x}Ce_xCuO_4$ solid solutions were examined by the electron diffraction method and high-resolution transmission electron microscopy (HRTEM).⁴⁶ The observed various superstructures of fluorine-containing compounds were identical with those of cerium-substituted compounds. These superstructures resulted, apparently, from

Figure 2. Crystal structure of Nd_2CuO_4 .

ordering of the anions and anion vacancies, which were generated upon annealing of the samples at 523–1023 K *in vacuo*, rather than were associated with the replacement of oxygen by fluorine. The examination of the superconducting $Nd_2CuO_{3.8}F_{0.2}$ sample by the HRTEM method did not reveal a superstructure for this compound.⁴

The appearance of hyperstoichiometric anions in the structure due to fluorine incorporation or the replacement of O^{2-} anions with a double amount of F^- ions can lead to structural transformations involving changes in the coordination polyhedra, interatomic distances and space symmetry up to the complete rearrangement of the crystal structure. For example, strontium cuprate Sr_2CuO_3 is structurally similar to La_2CuO_4 . However, unlike the crystal structure of the latter, which consists of the CuO_2 layers, the crystal structure of Sr_2CuO_3 is composed of chains of the vertex-sharing CuO_4 squares (Fig. 3a) due to ordering of the oxygen atoms and anion vacancies. Hence, the composition of the layer can be written as $CuO\Box$. Fluorination of Sr_2CuO_3 caused the rearrangement of the oxygen atoms and their migration from the Sr_2O_2 block to the equatorial coordination environment about the copper atoms.^{19, 47} As a consequence, complex oxyfluoride $Sr_2CuO_2F_{2+\delta}$ contains the conducting CuO_2 layers (Fig. 3b). As a result of incorporation of additional fluorine atoms into the tetrahedral cavities of the Sr_2O_2 block, the concentration of holes in the conduction band became higher than the optimum value. However, the required doping level was achieved upon subsequent reductive annealing and the compound was transformed into the superconducting state at 46 K. The partial replacement of strontium with barium to form the $Sr_{2-x}Ba_xCuO_2F_{2+\delta}$ solid solution made it possible to increase T_c to 64 K ($x = 0.6$).²⁰ Calculations of the energy of Coulombic interactions^{19, 47} suggested that the driving force for the anionic rearrangement is the difference between the lattice energy of the compound which contains fluorine atoms in the axial vertices of the octahedra about the copper atoms and the lattice energy of the same compound which contains the fluorine atoms in the equatorial positions to form the $CuOF$ layers.

Figure 3. Crystal structures of Sr_2CuO_3 (a) and $Sr_2CuO_2F_{2+\delta}$ (b).

The incorporation of additional anions into vacancies of the anion sublattice of the $B_mA_2A'_{n-1}Cu_nO_{2n+2+m\delta}$ compounds leads to an increase in the coordination number of the B cations, which was initially smaller than 6. If these cations are Cu^{2+} , the completion of their coordination environment to an octahedron must lead to deformation of the crystal structure accompanied by an increase in the distance between the layer containing the copper cations and the adjacent layers containing the A cations. The $Cu(O,F)_6$ octahedron is tetrahedrally distorted due to the

Jahn–Teller effect resulting from the unsymmetrical occupancy of the e_g level ($3d_{z^2}^2 3d_{x^2-y^2}^1$). As a consequence, the Cu–O_{ax} distance becomes substantially larger than the Cu–O_{eq} distance resulting in an increase in the interlayer distances in the structure. Thus, the formation of an octahedron about the copper atoms in Sr₂CuO₂F_{2+δ} leads to a substantial increase in the unit cell parameter c ($c = 13.468$ Å)¹⁹ as compared to that observed in the initial compound Sr₂CuO₃ ($a = 12.716$ Å).⁴⁸

If the B sublattice contains cations whose stable coordination number is smaller than 6, for example, the Ga³⁺ cations in the tetrahedral environment in the Ga1201 (MACuGaO₅, M = La, Pr or Nd; A = Ca or Sr)^{49, 50} and Ga1212 (Y_{0.6}Ca_{0.4}Sr₂Cu₂GaO₇) phases,⁵¹ the crystal structures, including the CuO₂ layers, may be distorted due to ordering of the oxygen atoms and anion vacancies in the B(O,□)₂ layers. Deformation of the structure may be responsible for the absence of superconducting properties. The filling of vacancies with additional anions upon fluorination leads to a reduction in deformations up to the formation of a structure characterised by a higher space symmetry group and undeformed conducting layers. The same effect would be expected to occur when fluorination causes changes in the sizes of the structural blocks in the plane of the CuO₂ layers, which are favourable for the establishment of their commensurability and removal of structural distortions appearing upon adaptation of the structural blocks to each other. The incorporation of fluorine atoms into the interlayer cavities of the structure with the completed anion sublattice would, most probably, lead to lowering of the symmetry due to displacement of the atoms from the ideal positions, thus minimising Coulombic repulsions between the anions in the interlayer cavities and the anions in the adjacent atomic layers.

Hence, the superconducting properties of complex copper oxyfluorides are determined not only by the character of changes in the oxidation state of copper through different mechanisms of fluorination but also by possible structural transformations.

IV. Structures, synthesis and superconducting properties of different classes of copper oxyfluorides

1. Fluorination of the MBa₂Cu₃O_{6+δ} (M = Y, Dy, Ho, Tm) and Y₂Ba₄Cu₇O_{14+δ} phases

The perovskite-like anion-deficient structures of the MBa₂Cu₃O_{6+δ} phases (M123 phase) with unit cell parameters $a \approx b \approx a_p$, $c \approx 3a_p$, where a_p is the parameters of the perovskite sublattice (Fig. 4a), involve the following layer sequence

(□ is the anion vacancy).

The anion positions in the Cu□O_δ layer (Cu1 layer) can be completely vacant at $\delta = 0$, which corresponds to the structure of the tetragonal strongly reduced M123 phase. The latter does not possess superconducting properties (the formal oxidation state of copper is +1.67). The Cu1 atoms (see Fig. 4a) have a dumbbell-like coordination typical of the Cu⁺ cations. At $\delta \approx 1$, the oxygen atoms occupy half of the vacancies in the Cu1 layer in an ordered fashion thus completing the coordination environment about the copper atoms to a square. The chains of the vertex-sharing CuO₄ squares are oriented along the b axis resulting in an orthorhombic distortion of the structure. The hole concentration in the compounds with $\delta \approx 1$ is close to the optimum value and these compounds have the highest superconducting transition temperatures ($T_c = 92$ – 94 K) of all MBa₂Cu₃O_{6+δ} compounds.

The Y₂Ba₄Cu₇O_{14+δ} compound (Y247 phase) is structurally related to YBa₂Cu₃O_{6+δ} (Y123) with the difference that the former structure contains chains consisting of the doubled copper–oxygen squares (see Fig. 4b). In the structures of both phases, the fluorine atoms can occupy the anion positions of the Cu1 layer instead of the oxygen atoms. Fluorination of samples of

Figure 4. Crystal structures of YBa₂Cu₃O₆ (a) and Y₂Ba₄Cu₇O₁₄ (b).

the Y123 phase characterised by different oxygen contents was examined in numerous studies. The results of these investigations are briefly summarised below.

Fluorine is incorporated into the structures of partially reduced or completely oxidised YBa₂Cu₃O_{6+δ} samples ($\delta \geq 0.65$) and occupy vacancies in the Cu1 layer both along the a and b directions of the orthorhombic unit cell. The positions are occupied successively. In the case of a low degree of fluorination, the fluorine atoms occupy predominantly the position (0, 1/2, 0). Powder neutron-diffraction studies demonstrated⁵² that once the occupancy of this position reached 80%, the incorporation of the fluorine atoms into the position (1/2, 0, 0) started. This scheme of filling the positions is consistent with the fact that the orthorhombic distortion of the unit cell was enhanced for YBa₂Cu₃O_{6.7}F_{0.15} and was subsequently reduced for YBa₂Cu₃O_{6.7}F_{0.3}. Fluorination of YBa₂Cu₃O_{6.7} led to an increase of T_c from 65 to 90 K.

Fluorination of a strongly reduced YBa₂Cu₃O_{6.2} sample by the electrochemical method caused the orthorhombic distortion of its tetragonal structure.⁵³ The fluorine incorporation gave rise to a blurred superconducting transition with $T_c = 55$ – 60 K, which is similar to T_c for YBa₂Cu₃O_{6.5}.

In most cases, fluorination of the strongly oxidised YBa₂Cu₃O_{6+δ} phase with δ nearly-unity allows one to prepare compounds possessing T_c no higher than that achieved for the optimally oxygen-doped sample.^{22, 23, 53, 54} However, it was reported that the treatment of YBa₂Cu₃O_{6+δ} with a mixture of nitrogen and fluorine led to an increase of T_c from 92 to 96 K.⁵⁵

An increase in the degree of fluorination of the starting phase Y123 gave rise to a fluorinated phase with a tetragonal unit cell regardless of the hyperstoichiometric oxygen content.^{53, 56} Fluorination, like the oxygen incorporation, was accompanied by the contraction of the structure along the c axis. This indicates that the copper atoms in the fluorinated and oxygen-doped Y123 phases have similar coordination environments and that anion vacancies are abundant in the Cu1 layer, which is retained even in the case of a high degree of fluorination. As exemplified by the YBa₂Cu₃O_{6.65} sample treated with NF₃,⁵⁶ tetragonal symmetry occurs due to the

fact that the positions $(1/2, 0, 0)$ and $(0, 1/2, 0)$ are statistically occupied by the anions (the occupancies of the positions are 68%).

Kistenmacher predicted⁵⁷ the existence of complex oxyfluoride $\text{YBa}_2\text{Cu}_3\text{O}_6\text{F}_2$. In the structure of this compound, the anion vacancies in the Cu1 layer are completely filled with fluorine atoms. In this compound, the oxidation state of copper must be equal to +2.33, which is identical to that observed in $\text{YBa}_2\text{Cu}_3\text{O}_7$ (oxygen-doped Y123 phase). Oxyfluoride would be expected to have tetragonal symmetry (due to the replacement of the copper–oxygen chains with the two-dimensional CuF_2 layers) and exhibit superconducting properties. Evidently, the parameter c of the tetragonal unit cell of complex oxyfluoride $\text{YBa}_2\text{Cu}_3\text{O}_6\text{F}_2$ must be substantially larger than the analogous parameter of the oxide phase due to manifestation of the Jahn–Teller effect in the CuO_2F_4 octahedra.

For complex oxyfluoride $\text{YBa}_2\text{Cu}_3\text{O}_6\text{F}_2$ to be formed, the Cu1 layers in the starting compound must contain as few oxygen atoms as possible. Fluorination of the reduced nonsuperconducting $\text{YBa}_2\text{Cu}_3\text{O}_{6.11}$ compound led to substantial changes in the X-ray diffraction pattern, an increase in the oxidation state of copper to +2.14 and the manifestation of superconductivity at 94 K (the volume of the superconducting phase was ~25%). The X-ray diffraction pattern of the fluorinated compound is characterised by the presence of sharp intense reflections with the Miller indices hkl . The general reflections hkl are virtually absent. Relying on these data, only the parameter $a = 3.869 \text{ \AA}$ of the tetragonal unit cell of the fluorinated compound was determined, the existence of strong disorder was proposed and the occurrence of numerous defects along the c direction was suggested.⁴⁴

The structure of the fluorinated sample was examined by the HRTEM method in combination with electron probe X-ray analysis, which confirmed the presence of fluorine in crystallites. The electron diffraction pattern and images obtained by the HRTEM method (Fig. 5) are unambiguously indicative of the formation of a new compound with unit cell parameters $a \approx 3.87 \text{ \AA}$ and $c \approx 13 \text{ \AA}$.⁵⁸

In the crystallites, the domains of this compound (F2 phase) or extended defects alternate with the domains of the starting structure (F1 phase). Electron probe X-ray analysis demonstrated that the fluorine content in the F2 phase is much higher than that in the F1 phase (the precise fluorine content is impossible to

Figure 5. Images along the $[100]$ direction obtained by electron diffraction (a) and HRTEM (b, c) methods. The sample was prepared by the treatment of $\text{YBa}_2\text{Cu}_3\text{O}_{6.11}$ with xenon difluoride at 623 K for 50 h.

determine by this method). Substantial broadening and a decrease in the intensities of the lines with the non-zero Miller indices l in X-ray diffraction experiments are accounted for by small sizes of the domains along the $[001]$ direction. A comparison of the experimentally observed contrast in the images obtained by the HRTEM method with the results of calculations using different structural models allowed the conclusion that an increase in the parameter c for the F2 phase is associated with an increase in the distance between the BaO and Cu1 layers (but not in the distance between the CuO_2 and $\text{Y}\square$ layers). On this basis, it was suggested that the fluorine atoms are incorporated into the anion vacancies

Figure 6. Scheme of the structural transformations in the Y123 phase upon oxygen and fluorine incorporation. (a) $\text{YBa}_2\text{Cu}_3\text{O}_7$; (b) $\text{YBa}_2\text{Cu}_3\text{O}_6$; (c) $\text{YBa}_2\text{Cu}_3\text{O}_6\text{F}$; (d) $\text{YBa}_2\text{Cu}_3\text{O}_6\text{F}_2$.

in the Cu1 layer, which is accompanied by the formation of the distorted CuO_2F_4 octahedra. According to the proposed structural model, elongation of the axial Cu–O distance from 1.85 Å in the initial compound $\text{YBa}_2\text{Cu}_3\text{O}_{6.11}$ to 2.3–2.5 Å in the fluorinated sample must lead to the parameter c of 12.8–13.2 Å in the $\text{YBa}_2\text{Cu}_3\text{O}_6\text{F}_2$ structure. The results of an electron microscopic study confirmed this suggestion and provided support for the fact that new superconducting oxyfluoride with composition $\text{YBa}_2\text{Cu}_3\text{O}_6\text{F}_2$ was synthesised. The scheme of the structural transformations caused by the incorporation of the oxygen and fluorine atoms into the tetragonal $\text{YBa}_2\text{Cu}_3\text{O}_6$ structure is shown in Fig. 6.

Upon fluorination, the properties of the $\text{Y}_2\text{Ba}_4\text{Cu}_7\text{O}_{14+\delta}$ (Y247 phase) compound are changed in much the same manner. The incorporation of fluorine atoms into the structure of strongly reduced oxide $\text{Y}_2\text{Ba}_4\text{Cu}_7\text{O}_{14.09}$ led to a rise in T_c from 30 to 62 K and an increase in the unit cell parameter c from 50.6 to 53.5 Å.⁵⁹ The fluorinated Y247 phase, unlike the fluorinated Y123 phase, remains orthorhombic because fluorination has no effect on the chains formed by the doubled copper–oxygen CuO_4 squares although the degree of orthorhombic distortion is somewhat lowered.

Investigation by the HRTEM method demonstrated that the incorporation of the fluorine atoms into the Y123 and Y247 phases occurred non-homogeneously. The completely fluorinated phase with composition $\text{YBa}_2\text{Cu}_3\text{O}_6\text{F}_2$ was found as extended domains in a matrix of the partially fluorinated Y123 phase. In the fluorinated Y247 phase, the regions in which the positions in the Cu1 layer are completely occupied by the fluorine atoms occur only as local defects (Fig. 7). An analogous microstructure was found in the fluorinated $\text{MBa}_2\text{Cu}_3\text{O}_{6.12}$ phases (M = Dy, Ho or Tm).⁶⁰ Unlike the Y123 phase, the reactions of the M123 phases with XeF_2 proceed predominantly through a mechanism of anion exchange due to which it is impossible to achieve the oxidation state of copper suitable for the manifestation of superconductivity.

Figure 7. HTREM image of the [010] zone. Local defects, which are inclusions of the $\text{Y}_2\text{Ba}_4\text{Cu}_7\text{O}_{14}\text{F}_2$ phase, are indicated by arrows. The optical-diffraction image is shown in the lower inset at the right of the illustration.

2. Fluorine derivatives of mercury-containing superconducting cuprates $\text{HgBa}_2\text{CuO}_{4+\delta}$ (Hg1201) and $\text{Hg}_{0.8}\text{Ba}_2\text{Ca}_2\text{Cu}_3\text{O}_{8+\delta}$ (Hg1223)

Fluorine atoms incorporated into the Y123 structures and related phases form strong bonds with the copper cations in the Cu1 layers thus changing their coordination environment and inter-atomic distances (Fig. 8). The structures of mercury-containing cuprates are characterised by the presence of the anion position $(1/2, 1/2, 0)$ in the mercury-containing layer. This position can be

Figure 8. Scheme of incorporation of fluorine atoms into the structures of the phases Y123, Y247 (a) and Hg1201, Hg1223 (b).

partially occupied by oxygen or fluorine atoms, thus changing the hole concentration in the conduction band. The stable dumbbell-like coordination of the Hg^{2+} cations is responsible for the absence of steric hindrances as well as for weak interactions between these anions and the mercury cations. Due to the formation of the long weak Hg–O(F) bond in the plane of the layer, the incorporation of anions into this layer cannot induce substantial structural changes, which were observed in the Y123 and Y247 phases.⁶¹ A comparative analysis of the properties of samples oxidised with fluorine or oxygen (the anion contents, the formal oxidation states of copper, structural parameters and the superconducting transition temperatures were compared) allowed important conclusions about the nature of superconductivity in mercury-containing cuprates.

Early experiments on the synthesis of the fluorinated Hg1212 and Hg1223 phases were performed with the use of BaF_2 (Ref. 62) or CuF_2 (Ref. 63) as a source of fluorine. The experiments were carried out at high temperatures (923–1073 K). These syntheses afforded multiphase samples, which contained superconducting phases with unit cell parameters similar to those of the corresponding phases in oxygen-saturated samples.

The reactions of mercury-containing cuprates with xenon difluoride proceeded at rather low temperatures (423–473 K), which made it possible to perform fluorination predominantly through fluorine incorporation, the probability of anion exchange being substantially decreased. Fluorination of the strongly reduced $\text{HgBa}_2\text{CuO}_{4.01}$ phase with $T_c = 61$ K led to a change in the superconducting transition critical temperature. At low degrees of fluorination, T_c reached maximum value of 97 K and then decreased. In the case of too high oxidation states (overdoping) of copper, the superconductivity can be completely suppressed.⁶⁴ The aforesaid is illustrated by the following example:

The presence of fluorine atoms in the mercury-containing layer was unambiguously established by ^{19}F NMR spectroscopy.^{65,66} The possible distribution of the atoms over the crystallographic positions in these structures can be judged from the temperature dependences of the rates of ^{19}F spin–lattice relaxations for the optimally fluorine-doped and overdoped Hg1201 samples. In the optimally doped compound, the fluorine atoms occupy the position $(1/2, 1/2, 0)$. An increase in the fluorine content leads to the partial replacement of oxygen atoms in the position $(0, 0, \sim 0.21)$ with fluorine atoms (in the axial vertex of the CuO_6 octahedron).⁶⁷ The structures of the optimum fluorine-doped ($T_c = 97$ K) and overdoped ($T_c \approx 80$ K) compounds were

refined by the powder neutron-diffraction method. The refined occupancies of the anion position (1/2, 1/2, 0) in the mercury-containing layer are 0.24(2) and 0.32(2) for two compounds, respectively. These values are substantially larger than the occupancies found for the oxygen-oxidised Hg1201 phases with the similar temperatures T_c [0.124(9) and 0.19(1), respectively].⁶⁸ The plots of T_c versus the fluorine or oxygen content in the mercury-containing layer are dome-shaped. However, the curve for the fluorinated samples is shifted toward larger δ values (Fig. 9). As is evident from Fig. 9, twice as much fluorine as compared to that of oxygen is required for the same T_c values and the corresponding doping level to be attained, which corresponds to the difference in the formal charges of the O^{2-} and F^- anions. This fact provides support for the ionic model of doping of mercury-containing cuprates, *viz.*, an oxygen atom creates twice as many holes in the conduction band as that generated by a fluorine atom.

Figure 9. Plot of T_c vs. the excessive oxygen (1) or fluorine (2) contents in the Hg1201 phase.

The dependence of T_c on the unit cell parameter a (or on the interatomic Cu—O_{eq} distance in the plane of the CuO₂ layer) both for the fluorinated and oxygen-oxidised samples can be approximated by a single parabolic curve with a maximum at 97 K and $a = 3.882$ Å (Fig. 10). Hence, the same superconducting transition temperatures in complex mercury-containing cuprates can be achieved not only at the same doping level but also with approximately equal equatorial Cu—O_{eq} bond lengths. If the oxidation state of copper remains constant, the Cu—O_{eq} distances are virtually independent of the amount of hyperstoichiometric anions. In contrast, the Cu—O_{ax} distance changes substantially as the occupancy of the anion position in the mercury-containing layer is varied, *viz.*, the Cu—O_{ax} bond is shortened as the amount

Figure 10. Plot of T_c vs. the unit cell parameter a for oxygen-doped (1) and fluorinated (2) Hg1201 samples.

Figure 11. Interatomic Cu—O_{ax} and Hg—O distances vs. the amounts of the oxygen or fluorine atoms in the mercury-containing layer.

of the hyperstoichiometric anions is increased. Figure 11 shows the virtually linear dependence of this distance on the amount of excessive (δ) oxygen or fluorine. In the fluorinated compounds, this bond is substantially shorter than those in oxygen-containing compounds with similar T_c .

Apparently, shortening of the Cu—O_{ax} distances results from extension of the Hg—O dumbbells, which is associated with an increase in the coordination number of the mercury atoms due to incorporation of additional anions in the mercury-containing layer. This leads to the displacement of the O_{ax} atom from mercury to copper accompanied by a noticeable shortening of the Cu—O_{ax} distance, the Cu—O_{eq} bond lengths and T_c remaining virtually constant. This change in the interatomic distances can be considered to be a result of anisotropic contraction of the CuO₆ octahedra under the action of the external pressure (~ 2 GPa) applied along the c axis.⁶⁹ According to $dT_c/dP \approx 2$ K GPa⁻¹ for the optimally oxygen-doped compound,⁷⁰ T_c for the fluorinated sample with $\delta_F \approx \delta_{opt}$ would be expected to increase by ~ 4 K. The fact that the optimally fluorine- and oxygen-doped samples have identical T_c indicates that shortening of the Cu—O_{ax} bond exerts only a slight effect on the increase in T_c in mercury-containing cuprates under the influence of the applied external pressure. The increase in T_c is most probably caused by shortening of the Cu—O_{eq} distances.

This conclusion was confirmed by the results of studies of the fluorinated Hg_{0.8}Ba₂Ca₂Cu_{3.2}O_{8+δ} samples (Hg1223 phase). The reduced Hg1223 sample ($T_c = 100$ K) was divided into two portions one of which was annealed under a stream of oxygen, and the remaining portion was fluorinated. For both samples, T_c was found to be increased, but the transition temperature for the fluorinated sample was 4 K higher (138 K) than that for the oxygen-oxidised sample (134 K).^{71,72} The unit cell parameters a and c of these samples are given below:

Sample	a / Å	c / Å
Hg _{0.8} Ba ₂ Ca ₂ Cu _{3.2} O _{8+δ}	3.8524(4)	15.819(4)
Hg _{0.8} Ba ₂ Ca ₂ Cu _{3.2} O ₈ F _{2δ}	3.8501(2)	15.773(3)

The structure of the fluorinated sample was refined based on the neutron diffraction data.⁷² In this sample, two anion positions in the mercury-containing layer, *viz.*, (1/2, 1/2, 0) and (1/2, 0, 0), are occupied with occupancies of 27(1)% and 10(1)%, respectively, as distinct from the fluorinated Hg1201 sample. Apparently, the fact that the anions occupy the position (1/2, 0, 0) is associated with the partial replacement of the mercury atoms with copper atoms. The total amount of anions in the mercury-containing layer of the fluorinated sample with the maximum T_c value is substantially larger than the amount of hyperstoichiometric oxygen in the optimally oxygen-doped sample [18% and 8% for the positions (1/2, 1/2, 0) and (1/2, 0, 0), respectively].⁷³

Figure 12. Maximum T_c vs. the unit cell parameter a for oxygen-oxidised and fluorinated mercury-containing cuprates.

The maximum T_c values for the first three members of the homologous series of mercury-containing complex cuprates $\text{HgBa}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+2+\delta}$ and the fluorinated Hg1201 and Hg1223 phases depend linearly on the unit cell parameter a ; $dT_c/da \approx 1350 \text{ K } \text{\AA}^{-1}$ (Fig. 12).^{72, 74} It is believed that the T_c for these compounds depends on the degree of contraction of the CuO_2 planes induced by the modification of the chemical composition. The similar value of dT_c/da was also found upon epitaxial contraction of thin single-crystalline films of $\text{La}_{0.9}\text{Sr}_{0.1}\text{CuO}_4$.⁷⁵

For the fluorinated Hg1223 sample, the absolute value of dT_c/da is almost an order of magnitude larger than dT_c/da obtained under the applied external pressure ($dT_c/dP \approx 1.7 \text{ K GPa}^{-1}$, $dT_c/da \approx -160 \text{ K } \text{\AA}^{-1}$).⁷⁶ This difference may be attributed to the structural changes of the CuO_2 layers. In the Hg1201 phase, these layers are planar, whereas the $\text{Cu}-\text{O}-\text{Cu}$ angle in the Hg1212 phase is close to 180° .⁷⁷ High external pressure causes corrugation of the CuO_2 layers. For example, the $\text{Cu}-\text{O}-\text{Cu}$ angle in the Hg1223 structure is decreased to 175.0° at a pressure of 2 GPa, T_c being increased to 138 K. The $\text{Cu}-\text{O}-\text{Cu}$ angle in the Hg 1223 phase changes only slightly upon fluorination (178.4° and 177.3° for the oxidised⁷⁷ and fluorinated samples, respectively). The $\text{Cu}-\text{O}-\text{Cu}$ bond angle is an important parameter governing T_c . For HTSC with $T_c > 100 \text{ K}$, the deviation of this angle from 180° is no larger than 4° .

Hence, chemical modifications of the structure, which lead to a decrease in the $\text{Cu}-\text{O}$ distance without a change in the degree of corrugation of the CuO_2 layers, is a promising way of increasing T_c in complex superconducting copper oxides.

3. Fluorine incorporation into structures of non-superconducting anion-deficient perovskite-like complex cuprates

Let us discuss the effect of fluorine incorporation on the structure and properties of anion-deficient copper-containing perovskites, which do not exhibit superconducting properties but which, nevertheless, could become superconductors if the appropriate doping level is achieved and the compound attains a structure suitable for the manifestation of superconductivity.

Perovskite-like complex cuprates with structures of brownmillerite MACuGaO_5 ($M = \text{La, Pr or Nd}$; $A = \text{Ca or Sr}$), which are denoted as Ga1201,^{49, 50} belong to the orthorhombic system (Fig. 13a) with the parameters $a \approx 4a_p$, $b \approx c \approx a_p\sqrt{2}$ (a_p is the parameter of the perovskite sublattice) and consist of alternating layers

The gallium and copper cations are in the tetrahedral and octahedral coordination environments, respectively. The GaO_4 tetrahedra in the plane of the $\text{GaO}\square$ layer share vertices to form chains along the c axis of the unit cell. The ordered arrangement of

Figure 13. Crystal structures of LaSrCuGaO_5 (a) and $\text{LaSrCuGaO}_{5-x}\text{F}_{2x-y}$ (b).

the oxygen atoms and anion vacancies in these layers leads to distortion of the equatorial coordination environment about the copper atoms. In the Ga1201 compounds, two short (1.89 Å) and two long (1.96 Å) $\text{Cu}-\text{O}$ distances were found.^{78, 79} The substantial difference in the $\text{Cu}-\text{O}_{\text{eq}}$ bond lengths in the plane of the CuO_2 layers may be responsible for the fact that these compounds do not exhibit superconducting properties even if the appropriate oxidation state of copper is achieved. Actually, the $\text{La}_{1-x}\text{Sr}_{1+x}\text{CuGaO}_5$ solid solution (Ga1201 phase) ($0 \leq x \leq 1.2$, the maximum oxidation state of copper is $+2.2$) are not superconductors.⁸⁰ At the same time, homologues of the Ga1201 compounds, viz., the Ga1212 compounds, possess superconducting properties. This difference in the properties is associated with the difference in the coordination environment of the copper atoms in these compounds. In the structure of the superconductor $\text{Y}_{0.6}\text{Ca}_{0.4}\text{Sr}_2\text{Cu}_2\text{GaO}_7$ ($T_c = 44 \text{ K}$), the copper atoms occupy the centres of the square pyramids formed by the oxygen atoms, the equatorial $\text{Cu}-\text{O}$ distances being virtually equal (1.92 and 1.93 Å).⁵¹

For the Ga1201 phases to exhibit superconducting properties, not only the appropriate doping level must be achieved but also strong distortion of the structure caused by the anion ordering in the $\text{GaO}\square$ layers must be diminished. This can be attained by inserting fluorine atoms into the anion vacancies. In this case, an increase in the formal oxidation state of copper will be accompanied by the formation of the five- and six-coordinate environment about the gallium atoms, which is favourable for a depression of the orthorhombic distortion and equalisation of the equatorial $\text{Cu}-\text{O}$ distances.

The treatment of LaACuGaO_5 ($A = \text{Ca, Sr}$) with xenon difluoride led to a decrease in distortion of the unit cell up to the transition of the orthorhombic phase into the tetragonal phase (for $A = \text{Sr}$) with the parameters $a \approx a_p$, $c \approx 2a_p$.⁸¹ Upon fluorination, the oxidation state of copper depends substantially on the reaction conditions. If fluorination is carried out over a long period (150 h) in the presence of a large excess of xenon difluoride at rather low temperature (573 K), the reaction proceeds according to the combined mechanism of anion exchange and fluorine incorporation:

Upon such fluorination, the oxidation state of copper reaches $+2.16$. An elevation of the temperature to 673 K is accompanied by a slight reduction in the oxidation state of copper (to $+1.95$)

due to the fact that the anion exchange becomes the predominant process:

The result of structural transformation occurring upon fluorination is shown in Fig. 13 *b*. Excessive fluorine atoms partially occupy the vacancies in the GaO_4 layers and the coordination environment about the gallium atoms becomes nearly octahedral. The oxygen and fluorine atoms and the anion vacancies are arranged in a disordered fashion in the positions $(1/2, 0, 1/2)$. In the case of the space group $P4/mmm$ and the above-mentioned unit cell parameters, the CuO_2 layers must be planar and the $\text{Cu}-\text{O}$ distances in the plane of the layer must be equal in length. In such a situation, the structure of the fluorinated phase will meet the criteria necessary for the manifestation of superconducting properties. However, all attempts to perform the transition of fluorinated samples into the superconducting state failed whatever the doping level used.

The simplest copper oxyfluorides which can exhibit superconducting properties are hypothetical solid solutions with composition $(\text{La}, \text{Sr})\text{CuO}_2\text{F}$ based on the perovskite structure. The required oxidation state of copper can be achieved through the heterovalent replacement of La with Sr in the A sublattice. These solid solutions must have a structure of tetragonally distorted perovskite containing CuO_2 planar layers and fluorine atoms in the axial positions of the octahedra about the copper atoms. These compounds can be synthesised by soft fluorination of anion-deficient perovskites in the ratio $(\text{La}, \text{Sr})/\text{Cu} = 1$.

Various perovskite-like anion-deficient copper oxides are known whose three-dimensional structures differ primarily by the character of ordering of the oxygen atoms and anion vacancies within the ab plane of the perovskite sublattice. Thus, the columns of the oxygen atoms passing along the $[001]$ direction are removed in a certain order resulting in a decrease in the coordination number of the copper atoms from 6 to 5, 4 or 2. Among these oxides are also the $(\text{La}_{1-x}\text{Sr}_x)_8\text{Cu}_8\text{O}_{20-\delta}$ solid solutions with tetragonal structures and the unit cell parameters $a \approx a_p 2\sqrt{2}$, $c \approx a_p$ (Fig. 14).^{82, 83}

For a superconducting compound to be prepared, the character of the distribution of the oxygen atoms in the starting compound must be changed upon fluorination so as to form the CuO_2 planes. Fluorination of $\text{La}_{6.5}\text{Sr}_{1.5}\text{Cu}_8\text{O}_{19.65}$ with xenon difluoride afforded a tetragonal perovskite-like phase with the presumed composition $\text{La}_{0.813}\text{Sr}_{0.187}\text{Cu}(\text{O}, \text{F})_{3-\delta}$ and the unit cell parameters $a < c \approx a_p$.⁸⁴ In a single sample, the fluorinated phase always coexists with the starting phase within one crystallite (Fig. 15). Thermal treatment at 673 K in air led to decomposition of $\text{La}_{0.813}\text{Sr}_{0.187}\text{Cu}(\text{O}, \text{F})_{3-\delta}$ to give LaOF and SrF_2 , which indicates that this phase contains a substantial amount of fluorine. The structure of $\text{La}_{0.813}\text{Sr}_{0.187}\text{Cu}(\text{O}, \text{F})_{3-\delta}$ was refined by the Rietveld method and confirmed by HRTEM (see Fig. 14). In the structure of this compound, the anion positions in the equatorial environment about the copper atoms are completely occupied, whereas the vacancies are located in the axial positions. The Jahn–Teller effect induced by an octahedral coordination about some copper atoms causes elongation of the axial distances (2.026 Å) as compared to the equatorial distances (1.896 Å) and the tetragonal distortion of the perovskite unit cell. Oxyfluoride $\text{La}_{0.813}\text{Sr}_{0.187}\text{Cu}(\text{O}, \text{F})_{3-\delta}$ does not exhibit superconducting properties.

The two examples considered above show that filling of the anion vacancies upon fluorination diminishes structural distortions caused by the ordering of the oxygen vacancies. However, the statistical distribution of the fluorine and oxygen atoms and the anion vacancies over certain crystallographic positions [for example, in the equatorial environment about the gallium atoms in the structures of fluorinated brownmillerites or in the axial positions of the $\text{Cu}(\text{O}, \text{F})_{6-\delta}$ octahedra in the $\text{La}_{0.813}\text{Sr}_{0.187}$.

Figure 15. HRTEM images of the domains of the fluorinated $\text{La}_{0.813}\text{Sr}_{0.187}\text{Cu}(\text{O}, \text{F})_{3-\delta}$ (a) and starting $\text{La}_{6.5}\text{Sr}_{1.5}\text{Cu}_8\text{O}_{19.65}$ (b) phases. In the optical diffraction patterns, suppression of the superstructure with $a_p 2\sqrt{2}$ upon fluorination is shown.

$[\text{Cu}(\text{O},\text{F})_{3-\delta}]$ structure] may be responsible for substantial static displacements (associated with the presence of the B-type cations possessing non-completed coordination spheres) and, as a consequence, can cause local distortions of the CuO_2 layers. This fact as well as the possibility of the partial replacement of oxygen with fluorine in the CuO_2 layers may account for the fact that fluorinated anion-deficient perovskite-like cuprates do not show superconductivity.

4. Incorporation of fluorine atoms into interlayer cavities in the structures of complex cuprates

Fluorination of anion-deficient cuprates is most often accompanied by the formation of compounds with simpler high-symmetry structures, whereas fluorination of complex copper oxides with the filled anion sublattice leads most commonly to structural distortions. The $(\text{M}', \text{M}'', \text{A})_2\text{CuO}_{4-\delta}$ compounds (M' and M'' are rare-earth cations of different radii, A is an alkaline-earth cation) have structures with ordered alternation of the CuO_2 layers and the $(\text{M}, \text{A})_2\text{O}_2$ blocks. These structures contain interlayer cavities accessible to additional anions. These cuprates crystallise in three structural types, *viz.*, T , T' and T^* . In the structures of the T phases [La_2CuO_4 , $\text{La}_{2-x}\text{A}_x\text{CuO}_{4-\delta}$ (A = Sr or Ba), the K_2NiF_4 structural type], the CuO_2 layers alternate with the NaCl-type $[(\text{La}, \text{A})\text{O}][\text{O}(\text{La}, \text{A})]$ blocks (Fig. 16). Rare-earth cuprates having smaller ionic radii ($\text{M} = \text{Pr} - \text{Gd}$) crystallise in the T' type structure. The structures of the T' phases can be represented as the result of alternation of the fluorite-like $(\text{M})(\text{O}_2)(\text{M})$ fragments (see Fig. 2) and the CuO_2 layers. The T^* phases $[(\text{La}, \text{M}, \text{Sr})_2, \text{CuO}_{4-\delta}]$, $\text{M} = \text{Sm} - \text{Er}$] contain both types of blocks, *viz.*, fluorite- and NaCl-like blocks, so that the structures of these phases can be described as the following sequence of layers:

In all three structural types, the cations occupy the same positions, but these structural types differ in the distributions of the anions in the $(\text{M}, \text{A})_2\text{O}_2$ blocks. If it is considered that the cations form a close packed motif, the NaCl-type $[(\text{M}, \text{A})\text{O}][\text{O}(\text{M}, \text{A})]$ block in the T phases is formed by the arrangement of the oxygen atoms in the octahedral cavities of the close packing. In the structures of the T' phases, the fluorite-like $(\text{M})(\text{O}_2)(\text{M})$ block is formed by the arrangement of the oxygen atoms in half of the tetrahedral cavities. Hence, the anion positions in the $(\text{M}, \text{A})_2\text{O}_2$ blocks, which are occupied by the oxygen atoms in the T phase, remain vacant in the T' phase and *vice versa* (see Fig. 16). Additional anions in the structures of this

Figure 16. Scheme of formation of the intergrowth structures with alternation of CuO_2 layers and the fluorite- and/or NaCl-type $(\text{M}, \text{A})_2\text{O}_2$ blocks.

type are located in vacant interlayer tetrahedral (in the case of the NaCl-like blocks) or octahedral (in the case of the fluorite-like blocks) cavities. When both types of cavities are simultaneously occupied, the distances between the anions in the $(\text{M}, \text{A})_2\text{O}_2$ block and the anions in the interlayer cavities are no larger than 2–2.15 Å. The arrangement of like-charged ions at such short distances will destabilise the structure and it can be substantially distorted due to Coulombic repulsions between the anions.

Lanthanum cuprate La_2CuO_4 was one of the first compounds that was subjected to fluorination to obtain a superconductor.^{24, 27, 30, 85–87} Fluorination of this cuprate with various agents gave rise to oxyfluorides, which differ in the structure and properties depending on the conditions of thermal treatment. The main steps of the incorporation of fluorine into La_2CuO_4 are shown in Scheme 1.

Scheme 1

The treatment of La_2CuO_4 with fluorine or XeF_2 at a rather low temperature afforded fluorinated lanthanum cuprate with $T_c = 35 - 40$ K. The incorporation of small amounts of fluorine ($\delta \leq 0.18$) into the La_2CuO_4 structure is accompanied by an increase in the degree of orthorhombic distortion of the unit cell and an insignificant increase in the parameter c .²⁷ Neutron diffraction studies of the crystal structures of the starting and fluorinated samples demonstrated that low degrees of fluorination do not cause substantial rearrangements of the initial structure.⁸⁵ Excessive fluorine atoms are located in the interlayer cavities, which are tetrahedrally surrounded by the lanthanum atoms (NaCl-type block). The incorporation of fluorine atoms occurs analogously to that of oxygen atoms⁸⁸ and the degree of orthorhombic distortion, which depends on the amount of hyperstoichiometric anions, appeared to be similar for the oxygen-oxidised and fluorinated samples with similar anionic stoichiometry ($a = 5.332$ Å, $b = 5.423$ Å, $c = 13.222$ Å for $\text{La}_2\text{CuO}_{4.18}$).⁸⁹ Fluorination of the T phases in which lanthanum atoms are partially replaced with alkaline-earth metals gives rise to compounds exhibiting the superconducting properties at small degrees of replacement analogous to the effect of oxygen incorporation. Superconductivity was observed in the fluorinated solid solutions $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ ($x < 0.1$, $T_c = 36 - 40$ K)^{85, 90} and $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$ ($x < 0.15$, $T_c = 32 - 42$ K).^{86, 91} In the case of higher strontium or barium contents, T_c for the initial and fluorinated samples remains identical.

The treatment of La_2CuO_4 with fluorine or XeF_2 at higher temperatures (503–523 K, the second step) gives rise to non-superconducting oxyfluoride with the body-centred tetragonal unit cell, which either corresponds to the K_2NiF_4 subcell⁸⁷ or differs from this subcell only by the parameter a equal to $\sqrt{2}a_{\text{K}_2\text{NiF}_4}$ ($a_{\text{K}_2\text{NiF}_4}$ is the unit cell parameter of K_2NiF_4).⁹² In this step, the unit cell is substantially expanded in the ab plane

Figure 17. Model of the crystal structure of oxyfluoride formed upon fluorination of La_2CuO_4 at 523 K. The copper atoms are in an octahedral environment.

($a_{\text{K}_2\text{NiF}_4} = a/\sqrt{2} \approx 3.802 \text{ \AA}$ and $a_{\text{K}_2\text{NiF}_4} = 4.038 \text{ \AA}$ for the initial and fluorinated samples, respectively). Electron diffraction studies revealed a superstructure with $a = 2a_{\text{K}_2\text{NiF}_4}$, $c = 2c_{\text{K}_2\text{NiF}_4}$ (see Ref. 87) formed due to the alternation of the vacant and occupied tetrahedral cavities along the $[001]_{\text{K}_2\text{NiF}_4}$ and $[110]_{\text{K}_2\text{NiF}_4}$ directions (Fig. 17). This ordering may also be accompanied by cooperative rotation of the CuO_6 octahedra about the $[110]_{\text{K}_2\text{NiF}_4}$ direction to achieve the maximum distances between the oxygen atoms involved in the axial environment about the copper atoms and the anions in the interlayer cavities.

In the third step, the interaction with XeF_2 proceeds predominantly through a mechanism of anion exchange to give oxyfluoride with composition $\text{La}_2\text{CuO}_{3.6}\text{F}_{0.8}$ containing copper in the oxidation state +2. This compound belongs to the monoclinic system and its unit cell is determined by the following vectors:⁸⁷

$$\begin{aligned} \mathbf{a}_m &= 2(\mathbf{a}_{\text{K}_2\text{NiF}_4} + \mathbf{b}_{\text{K}_2\text{NiF}_4}) + \mathbf{c}_{\text{K}_2\text{NiF}_4}, \\ \mathbf{b}_m &= -\mathbf{a}_{\text{K}_2\text{NiF}_4} + \mathbf{b}_{\text{K}_2\text{NiF}_4}, \\ \mathbf{c}_m &= -\frac{1}{2}(3\mathbf{a}_{\text{K}_2\text{NiF}_4} + 3\mathbf{b}_{\text{K}_2\text{NiF}_4} - \mathbf{c}_{\text{K}_2\text{NiF}_4}), \\ \beta &\approx 91.5^\circ. \end{aligned}$$

The structural model established based on the results of a electron diffraction study and the HRTEM method is shown in Fig. 18. The fluorine atoms occupy 40% of the tetrahedral cavities in an ordered fashion. In this case, the oxygen atoms are partially removed from the LaO layers and a part of the CuO_6 octahedra are transformed into the CuO_5 square pyramids. The remaining octahedra are rotated about the b_m axis in such a way that the distances between the axial oxygen atoms and the fluorine atoms become lower. The blocks in which the tetrahedral positions are occupied and the axial oxygen atoms are removed (fluorite fragments) alternate with the NaCl -type fragments. However, the alternation of these blocks, unlike that observed in the T^* phases, occurs not only along the $[001]_{\text{K}_2\text{NiF}_4}$ direction but also along the $[110]_{\text{K}_2\text{NiF}_4}$ direction.

Lanthanum cuprate La_2CuO_4 can be considered as the first member of the homologous series of cuprates with structures of the Ruddlesden–Popper phases $(\text{M},\text{A})_{n+1}\text{Cu}_n\text{O}_{2n+2+\delta}$ ($\text{M} = \text{REE}$, $\text{A} = \text{Ca}$ or Sr) with $n = 1$. The structure of the

Figure 18. HRTEM images (a), the structural model (the copper atoms are in the octahedra and tetragonal pyramids) (b) and the projection displaying the directions of cooperative atomic displacements in the $\text{La}_2\text{CuO}_{3.6}\text{F}_{0.8}$ phase (c).

homologue with $n = 2$ ($\text{M}_{2-x}\text{A}_{1+x}\text{Cu}_2\text{O}_{6+\delta}$) contains doubled CuO_2 layers separated by $\text{A}\square$ layers:

the cation positions in the $\text{A}\square$ layer can be occupied simultaneously by rare-earth and alkaline-earth atoms as, for example, in the case of $\text{A} = \text{Sr}$ (Fig. 19). In this compound, the copper atoms have a square-pyramidal coordination. This structure, unlike the structure of the preceding member of the homologous series, contains two possible positions suitable for location of additional

Figure 19. Crystal structures of the members of the homologous Ruddlesden–Popper series with $n = 2$ (a), 3 (b).

anions, *viz.*, in tetrahedral cavities of the $(\text{Ln},\text{A})_2\text{O}_2$ block and in the $\text{A}\square$ layer with completion of the coordination environment about copper to an octahedron.

The behaviour of these compounds upon fluorination differs from that of La_2CuO_4 . The treatment of $\text{La}_{1.9}\text{Sr}_{1.1}\text{Cu}_2\text{O}_{6.05}$ and $\text{La}_{1.9}\text{Ca}_{1.1}\text{Cu}_2\text{O}_{5.95}$ with reagents, such as F_2 , NH_4F or CuF_2 , led initially to an increase in the parameters a and c of the tetragonal unit cell. However, further increase in the degree of fluorination caused the transformation of the Sr-containing sample into the orthorhombic phase accompanied by a decrease in the unit cell parameters in the ab plane and a substantial increase in the parameter c (from 20.048 to 21.68 Å).²⁵ The authors of the cited study²⁵ related the formation of the orthorhombic phase characterised by the larger parameter c (and, correspondingly, by the larger distance between the CuO_2 layers) to the facts that the positions in the $\text{A}\square$ layer are occupied by fluorine atoms and some copper atoms have an octahedral environment. For $\text{La}_{1.9}\text{Ca}_{1.1}\text{Cu}_2\text{O}_{5.95}$, this effect was not observed due, apparently, to the smaller distance between the CuO_2 layers because the calcium atom is smaller than the strontium atom.

Superconducting oxyfluorides of this series with $n = 2, 3$ were synthesised at high pressure. Samples with compositions $\text{Sr}_2\text{CaCu}_2\text{O}_{4.6}\text{F}_2$ and $\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{6.2}\text{F}_{3.2}$ showed bulk superconductivity ($T_c = 99$ and 111 K, respectively) in spite of the fact that they contained substantial amounts of impurity phases.¹¹ The $\text{Sr}_2\text{NdCu}_2\text{O}_5\text{F}$ compound turned out to be single-phase and did not exhibit superconducting properties because it contained copper in the oxidation state +2. However, the $\text{Sr}_2\text{Nd}_{0.2}\text{Ca}_{0.8}\text{Cu}_2\text{O}_5\text{F}$ solid solution generated upon the partial replacement of neodymium with calcium showed the superconducting transition at 85 K.⁹ It was suggested that the fluorine atoms in all these phases are located in the NaCl-type blocks and are involved in the $(\text{SrF})(\text{FSr})$ or $(\text{SrO}_{0.5}\text{F}_{0.5})(\text{F}_{0.5}\text{O}_{0.5}\text{Sr})$ layers. The crystal

structures of superconducting complex copper oxyhalides belonging to the Ruddlesden–Popper phases have been surveyed in the review.⁹³

Of complex copper oxyfluorides, fluorine derivatives of Nd_2CuO_4 have received the most study. Most of the investigations were devoted to the structures and properties of the $\text{Nd}_2\text{CuO}_{4-x}\text{F}_x$ solid solutions in which the n -type superconductivity with $T_c = 27$ K (at $x = 0.3$) was revealed.³ As mentioned above (see Section III), the partial replacement of oxygen atoms in the fluorite-like Nd_2O_2 blocks with an equivalent amount of fluorine has virtually no effect on the crystal structure of the resulting compound. Fluorine incorporation into the Nd_2CuO_4 structure afforded a new phase with composition $\text{Nd}_2\text{CuO}_3\text{F}_2$.⁹⁴ This compound was found by electron microscopy in samples prepared by fluorination of Nd_2CuO_4 with xenon difluoride at 573–673 K. This phase crystallises in the monoclinic system (the unit cell parameters $a \approx 12.96$, $b \approx 5.5$, $c \approx 5.8$ Å, $\beta \approx 92^\circ$). The model structure of this compound was constructed from images obtained by the HRTEM method. According to this model, a portion of the anions which are located in the positions tetrahedrally coordinated by the neodymium atoms form chains along the c axis alternating with chains of the vacancies along the b direction (Fig. 20). Another portion of anions occupy axial positions in the octahedral environment about the copper atoms. The presence of copper atoms possessing octahedral coordination is responsible for the increase in the parameter c from 12.167 in the starting phase to 12.96 Å in the fluorinated compound. The layers of the $\text{Cu}(\text{O},\text{F})_6$ octahedra are distorted due to the cooperative rotation required for the maximum distance between the anions to be attained.

Figure 20. Crystal structure of $\text{Nd}_2\text{CuO}_3\text{F}_2$.

The $\text{Nd}_2\text{CuO}_3\text{F}_2$ compound is structurally similar to $\text{La}_2\text{CuO}_{3.6}\text{F}_{0.8}$. The structures of these compounds are analogous to the structure of the T^* phase and can be considered as intermediate between the structures of the T and T' phases. In both structures, the NaCl- and fluorite-like blocks alternate not only along the c axis of the tetragonal subcell but also in the ab plane. In both cases, the ratios between the parameters of the tetragonal subcells $c/3a \approx 1.08$ are in the T^* -phase stable region ($c/3a \approx 1.15$ for T phases, $c/3a \approx 1.06$ – 1.08 for T^* phases and $c/3a \approx 1.02$ for T' phases⁹⁵).

Apparently, the results of fluorination of the T^* phases depend substantially on their cation composition. The refinement of the crystal structures of $\text{La}_{1.25}\text{Dy}_{0.75}\text{CuO}_{3.75}\text{F}_{0.5}$ (see Ref. 34) and $\text{LaBa}_{0.2}\text{Gd}_{0.8}\text{CuO}_{3.55}\text{F}_{0.8}$,⁹⁶ which were prepared by fluorination of the corresponding cuprates with ZnF_2 and CuF_2 , demonstrated that excessive anions were located in the tetrahedral cavities of the NaCl-type blocks, while the fluorite-like blocks remained unchanged. Repulsions between the anions and/or a

reduction in the formal oxidation state of copper lead to elongation of the equatorial Cu—O distances from 1.933 to 1.942–1.962 Å as well as to a small increase in the parameter c . However, the $\text{LaBa}_{0.2}\text{Gd}_{0.8}\text{CuO}_{3.55}\text{F}_{0.8}$ structure retains tetragonal symmetry, whereas $\text{La}_{1.25}\text{Dy}_{0.75}\text{CuO}_{3.75}\text{F}_{0.5}$ crystallises in the orthorhombic system with the unit cell parameters a and b , which are increased by a factor of $\sqrt{2}$. In both cases, the atoms occupying the axial vertices in the $\text{Cu}(\text{O},\text{F})_5$ pyramids are shifted from the ideal positions in the ab plane due, probably, to their interactions with the anions located in the interlayer cavities.

Samples prepared by fluorination of the T^* phase $\text{LaHo}_{0.75}\text{Sr}_{0.25}\text{CuO}_{3.9}$ with xenon difluoride have complex microstructures, which can be described as narrow extended domains of a phase with high fluorine content (phase I) located in a matrix of the low-fluorinated orthorhombic T^* phase (phase II) (Fig. 21).⁹⁷ The results of the HRTEM study demonstrated that the structure of the fluorite-like blocks in the low-fluorinated phase II remains

Figure 21. Electron microphotographs of the fluorinated $\text{LaHo}_{0.75}\text{Sr}_{0.25}\text{CuO}_{3.9}$ sample taken at a low magnification (a) and high resolution (b);⁹⁷ (a) the corresponding electron diffraction pattern is shown in the inset; (b) the inset presents an enlarged fragment of the image of phase I, which is superimposed on the theoretical image calculated from the proposed structural model; the $\text{La}_{0.25}\text{Ho}_{0.75}$ layers are indicated by arrows; I and II are phases with different fluorine contents.

unchanged, whereas the NaCl-type blocks acquire a structure similar to that of analogous blocks in $\text{La}_2\text{CuO}_{3.6}\text{F}_{0.8}$. Phase I belongs to the monoclinic system with the unit cell parameters $a_m \approx b_m \approx 5.5 \text{ Å} \approx a_t\sqrt{2}$, $c_m \approx 12.84 \text{ Å} \approx c_t$, $\beta \approx 91.4^\circ$ (the subscripts m and t identify the monoclinic and tetragonal unit cells, respectively). As in the case of the T' phase, an increase in the c_m parameter compared to $c_t = 12.553 \text{ Å}$ is indicative of the incorporation of additional anions into the axial positions of the coordination environment about the copper atoms. The characteristic feature of phase I is the identical distribution of the anions over the tetrahedral and octahedral positions resulting from fluorination of the initially different blocks, viz., the NaCl-type $(\text{La}_{0.75}\text{Sr}_{0.25}\text{O})(\text{OLa}_{0.75}\text{Sr}_{0.25})$ and the CaF_2 -type $(\text{La}_{0.25}\text{Ho}_{0.75})\text{O}_2(\text{La}_{0.25}\text{Ho}_{0.75})$ blocks (see Fig. 21). Consequently, not only the NaCl-type blocks but also the fluorite-like blocks undergo structural changes in the high-fluorinated samples. In the phase I, the vacant and occupied tetrahedral positions alternate in a 'staggered' fashion. The monoclinic distortion of phase I results from displacements of the A cations caused by interactions with the ordered oxygen and fluorine atoms in the tetrahedral cavities.

Hence, the fluorine incorporation upon fluorination of the T , T' and T^* phases has no direct effect on the CuO_2 planes, but these planes may be distorted due to cooperative rotation of the coordination polyhedra of the copper atoms. The $(\text{M},\text{A})_2\text{O}_2$ blocks are subjected to fluorination, the fluorine atoms first occupying the tetrahedral cavities in the NaCl-type blocks, while the fluorite-like blocks retain the initial structure under the same conditions. When two types of the anion positions are simultaneously occupied, these blocks undergo structural rearrangements, which are accompanied by the alternation of the NaCl- and fluorite-type structural fragments in directions perpendicular and parallel to the CuO_2 layers. Hence, the structures of the high-fluorinated compounds are intermediate between the structures of the T and T' phases and are structurally similar to the T^* phases. A substantial increase in the parameter c for the fluorinated T' and T^* phases occurs due to completion of the coordination polyhedron about the copper atom to a tetragonal pyramid or an octahedron.

In the fluorite- or NaCl-type $(\text{M},\text{A})_2\text{O}_2$ blocks in which the A positions are occupied by alkaline-earth and/or rare-earth cations, ionic interactions prevail. Because of this, the bonds in the $(\text{M},\text{A})\text{O}$ layers in the NaCl-type blocks are comparable in strength to the bonds between the adjacent $(\text{M},\text{A})\text{O}$ layers. The structures of Bi-containing layered cuprates $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+4+\delta}$ involve the NaCl-type Bi_2O_2 blocks. Unlike the $(\text{M},\text{A})_2\text{O}_2$ blocks containing isotropic chemical bonds, the BiO and OBi layers in the Bi_2O_2 block are linked only through van der Waals interactions, which is attributed to the crystal-chemical characteristics of the Bi^{3+} cation. Due to this structure of the Bi_2O_2 blocks, various halogen-containing agents (I_2 , Br_2 , HgBr_2 or LiI_3) can be intercalated into Bi-containing cuprates.^{98–102} The iodine atoms intercalated into the Bi2212 and Bi2223 phases form an additional layer between the BiO and OBi layers as a result of which the distance between these layers is increased and the layers are shifted with respect to each other by a vector of the perovskite-like subcell $(1/2, 1/2, 0)$ to form a primitive unit cell. After intercalation, the structural modulations of the BiO layers, which are characteristic of this family of superconductors due to the incommensurability of the Bi_2O_2 blocks and the CuO_2 layers, are retained because interactions between the intercalated atoms and the BiO and OBi layers are weak, the structures of the latter remaining virtually unchanged. In the compounds containing the intercalated F atoms, the Bi—F bond is more ionic than the bonds between the Bi atoms and other halogens and, hence, the results of incorporation of fluorine atoms into the structures of Bi-containing HTSC will be different.

Fluorination of $\text{Bi}_2\text{Sr}_{1.6}\text{La}_{0.4}\text{CuO}_{6.33}$ (Bi2201 phase, $T_c = 27 \text{ K}$) with xenon difluoride led to an increase in the unit cell parameter c and was accompanied by suppression of the

Figure 22. HRTEM images (*a*, *b*) and electron diffraction patterns (*c*, *d*) for the fluorinated Bi2201 phases of low (*a*, *c*) and high (*b*, *d*) fluorine contents.¹⁰³

It can be seen that incommensurate modulations disappear as the degree of fluorination is increased.

superstructure $\sqrt{2}a_p \times \sqrt{2}a_p$ in the *ab* plane and the disappearance of the incommensurate modulations (Fig. 22), *i.e.*, by the formation of a tetragonal primitive unit cell with $a = 3.837$, $c = 26.18$ Å.¹⁰³ Consequently, the incorporated fluorine atoms change the structure of the BiO layers. Excessive anions occupy the cavities of the Bi_2O_2 blocks tetrahedrally coordinated by the Bi atoms so that the Bi_2O_2 blocks are transformed into the $\text{Bi}_2\text{O}_{2-x}\text{F}_{2+x}$ blocks in which the Bi atoms are located in mono-capped square antiprisms to form short bonds with the F atoms and five long bonds with the O atoms (Fig. 23).

Figure 23. Crystal structure of the fluorinated Bi2201 phase.

Structurally analogous blocks were found in compounds of the homologous series of Aurivillius phases, for example, in $\text{Bi}_2\text{NbO}_5\text{F}$.¹⁰⁴ Comparison of the interlayer distances in the Bi_2O_2 blocks in the Bi2201 phase and in the $\text{Bi}_2\text{O}_2\text{F}_2$ block of the Aurivillius phase accounts for the increase in the unit cell parameter c from 24.35 to 26.18 Å upon fluorination. The distance between two bismuth-containing layers located above and below the interlayer cavities is decreased from 3.18–3.20 Å in the starting Bi2201 phase to 2.49–2.56 Å in the fluorinated Bi2201 phase. This decrease is caused by Coulombic interactions between the anions in the interlayer cavities and the Bi^{3+} cations (Fig. 24). It should be noted that the oxygen atoms in the BiO layers experience repulsions from the interlayer anions. Hence, the BiO layers in the structure of the starting Bi2201 phase are nearly planar and the distance between the bismuth- and oxygen-containing sublayers of this layer along the c axis is no higher than 0.24–0.26 Å, whereas this distance in Aurivillius phases increases to 0.92–1.07 Å. This leads to splitting of the BiO layer into two layers one of which consists of the bismuth atoms and the other is composed of the oxygen atoms. In spite of shortening of the distance between the layers containing the bismuth cations, the total increase in the size of the $\text{Bi}_2\text{O}_2\text{F}_2$ block reaches 0.7–1.0 Å, which must lead to an increase in the parameter c by 1.4–2.0 Å. An increase in the coordination number of bismuth in a fluorinated phase also leads to elongation of the Bi–O bond and an increase in the size of the block in the *ab* plane. As a result, the commensurability between the $\text{Bi}_2\text{O}_2\text{F}_2$ blocks and the CuO_2 layers is achieved thus diminishing modulations. It should be noted that the structure of the fluorinated Bi2201 phase is a hybrid combining the Bi-containing $\text{Bi}_2\text{O}_{2-x}\text{F}_{2+x}$ blocks (like in Aurivillius phases) and the perovskite-like $\text{A}_{2n}\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+2}$ blocks ($n = 1$). Such phases belong to a new homologous series $\text{Bi}_2\text{A}_2\text{Ca}_{n-1}\text{Cu}_n(\text{O},\text{F})_{2n+6}$. The third representative of this series, *viz.*, $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_8\text{F}_4$, was prepared by treating the Bi2223 phase with $\text{NH}_4\text{F} \cdot \text{HF}$ (see Ref. 33) although the superstructure $\sqrt{2}a_p \times \sqrt{2}a_p$ is retained. The distance between the bismuth- and strontium-containing layers is increased from 2.7 Å in the starting phase to 3.6 Å in the fluorinated phase, whereas the distance between two adjacent bismuth-containing layers is decreased from 3.2 to 2.5 Å in the fluorinated phase. In the plane of the layer, the Bi–Bi distances are also elongated from 3.53 Å in the starting phase to 3.76 Å in the fluorinated phase.

Figure 24. Crystal structures of the Bi2201 phase (*a*) and the Aurivillius phase $\text{Bi}_2\text{NbO}_5\text{F}$ (*b*).

Fluorination of the Bi2201 and Bi2223 phases led to degradation of their superconducting properties. The $\text{Bi}_2\text{Sr}_{1.6}\text{Ca}_{0.4}\text{CuO}_{6.33}$ compound ($T_c = 27$ K) lost superconductivity upon fluorination. In the Bi2223 phase (which is initially characterised by $T_c = 105$ K), the volume of the superconducting phase decreased and a second superconducting transition with $T_c = 75$ K was observed.

The advantage of the fluorinated Bi2201 phase over the starting compound in which the CuO_2 layers are substantially distorted is the absence of incommensurate modulations. Apparently, attainment of the optimum ratio between oxygen and fluorine with retention of these layers will allow one to prepare superconducting compounds based on oxyfluorides of a new homologous family.

V. Conclusion

Fluorination of complex cuprates can be used for the preparation of new compounds with structures necessary for superconducting properties to be manifested. In addition, fluorination of these compounds can be employed for attaining the required concentration of carriers (electrons or holes) in the conduction band. The character of the changes of the crystal structure upon fluorination is determined by the structural features of the starting compound and the amount of excessive anions. The following regularities can be noted:

- the replacement of oxygen atoms with an equivalent amount of fluorine atoms causes only slight changes to the unit-cell dimensions associated with a small difference in the ionic radii of O^{2-} and F^- and with elongation of the equatorial $\text{Cu}-\text{O}_{\text{eq}}$ bonds due to a decrease in the oxidation state of copper;

- the incorporation of excessive fluorine atoms and completion of the coordination polyhedron about the Cu^{2+} cations to an octahedron leads to substantial elongation of the axial $\text{Cu}-\text{O}$ bonds accompanied by an increase in the distances between the $\text{Cu}(\text{O},\text{F})_2$ and AO layers;

- the filling of anion vacancies in the structure with fluorine atoms diminishes structural distortions caused by ordering of the oxygen atoms and anion vacancies;

- location of fluorine atoms in the interlayer cavities induces rearrangement of the crystal structure to reduce Coulombic repulsions between the anions in the interlayer cavities and anions in the adjacent layers.

This review has been written with the financial support of the Russian State Scientific Program on Superconductivity 'Poisk', INTAS (Grant No. 99-1136), the Cooperative Research Development Foundation (Project No. 2256), and Volkswagen Stiftung (Grant No. I/75849). We thank V V Sokolov (Laboratory of Inorganic Synthesis, Institute of Applied Chemical Physics, Russian Research Centre 'Kurchatov Institute') and the research teams working at the Laboratory of Inorganic Crystal Chemistry of the Department of Chemistry of the M V Lomonosov Moscow State University and at the Laboratory of Electron Microscopy of the University of Antwerpen for helpful discussion and valuable advice. A M Abakumov and E V Antipov acknowledge the support of the Academic Council of the M V Lomonosov Moscow State University and the Charity Foundation for the Support of National Science of the Russian Academy of Sciences.

Abstract. Experimental and theoretical data on the structure and properties of compounds of tetravalent transactinides (TAn^{IV}) Rf ($Z = 104$), Db ($Z = 105$), Sg ($Z = 106$), Bh ($Z = 107$), Hs ($Z = 108$), Mt ($Z = 109$) and ^{110}TAn ($Z = 110$) are described systematically. The problem of disposition of the transactinide elements in the Periodic system is discussed and the properties of the $6d$ -, $5d$ -, $4d$ -, $3d$ - and $5f$ -elements are compared. Regularities of changes in the thermodynamic characteristics of TAn^{IV} compounds *versus* the atomic number, $Z(TAn)$, are elucidated. Peculiarities of changes in thermodynamic properties upon the formation of nitrate, fluoride and chloride TAn^{IV} complexes in solution are discussed. The bibliography includes 140 references.

I. Introduction

Theoretical investigations into the chemical properties of the heavy elements, *viz.*, actinides (An) and transactinides (TAn)^{1–10} involve assessment of the influence of relativistic effects (RE) on these properties. One of the major propositions of the relativity theory is that the velocity of a particle cannot exceed the velocity of light, as follows from the relativistic mass equation:

$$m = \frac{m_0}{\sqrt{1 - (v/c)^2}},$$

where m is the mass of the moving particle, m_0 is the mass of the particle at rest, v is the velocity of the particle and c is the velocity of light.

Since the mass appears in the denominator of the expression for the Bohr radius (a_0), the relativistic mean radius is smaller than the nonrelativistic radius:

$$a_0 = \frac{h^2}{\pi m Z^2 e^2},$$

where h is the Planck constant, Z is the charge of the atom and e is the charge of the electron.

There are three types of possible influence of RE on the electron shells of atoms.

1. Contraction and, hence, stabilisation of the s -, $p_{1/2}$ - and $p_{3/2}$ -shells. The s - and $p_{1/2}$ -shells are contracted to nearly the same extent while the $p_{3/2}$ -shells are much less contracted.

2. Expansion of the f - and d -shells. The s - and $p_{1/2}$ -electrons screen nuclear attraction more effectively than the f - and d -electrons which experience weaker nuclear attraction and the corresponding orbitals become more diffuse and energetically destabilised.

3. Spin–orbit splitting, which increases as Z increases.

In addition to RE, the s -, p -, d - and f -electrons are also affected by nonrelativistic shell effects. It is appropriate to consider three types of the influence of RE on the physicochemical properties of heavy elements.

1. Relativistic effects completely determine a particular property and regular trends of its changes along the period and down the group of the Periodic system.

2. Relativistic effects make a particular property more pronounced, but the regularities of its changes are controlled by nonrelativistic shell effects.

3. Relativistic and nonrelativistic shell effects act in opposite directions.

On going from the $3d$ -elements to the $4d$ -, $5d$ - and $6d$ -elements the atomic radii increase and the d - and s -orbitals become more diffuse due to nonrelativistic shell effects. Relativistic effects cause destabilisation of the d -orbitals and stabilisation of the s -orbitals. Thus, the RE and the shell effects exhibit a synergistic effect in the case of d -orbitals and an antagonistic effect in the case of s -AOs ($4s$, $5s$, $6s$, $7s$).

On going from the $3d$ -elements to the $4d$ -elements relativistic effects cause greater stabilisation of the $5s$ -electrons compared to the $4s$ -electrons. However, if we go from the $4d$ -elements to the $5d$ -elements, the effect of lanthanide contraction, which additionally stabilises the $6s$ -electrons, is superimposed on relativistic stabilisation of the $5s$ - and $6s$ -electrons. Assuming that relativistic stabilisation of the valence s -electrons dominates over the destabilising shell effects, one should expect a regular increase in the ionisation potentials (IPs) down the groups Ti–Zr–Hf,

[†] Dedicated to V I Spitsyn on occasion of his 100th birthday.

Cu–Ag–Au, *etc.* However, the IP values change irregularly, which reflects a complex scheme of compensation effects.

For instance, on going from the 3*d*-elements to the 4*d*-elements stronger relativistic stabilisation of the 5*s*-electrons compared to 4*s*-electrons causes a decrease rather than the expected increase in the IPs of all elements except Zr and Mo. It is impossible to differentiate the influence of the shell and relativistic effects, lanthanide contraction, *etc.*, even in the simplest case when analysing the properties of free atoms. Moreover, the contributions of these effects to the chemical properties of compounds cannot also be differentiated. This can be done only theoretically by performing calculations without and with inclusion of RE. However, calculations without inclusion of RE correspond to hypothetical systems rather than real atoms and molecules; therefore, only the experimental data can serve as a criterion for the significance of the influence of RE on the properties of heavy elements.

The actinides ($Z = 89–103$) precede the transactinide elements ($Z \geq 104$). The influence of RE on the properties of actinides, lanthanides (Ln) and transactinides has been analysed.^{1–6} Important manifestations of RE in actinides include high oxidation states of U, Np, Pu and Am and the valence of 4 or 5 in the metallic state of early actinides, which is atypical of lanthanides.

Mention was also made¹ that, despite the great importance of the contribution of RE to the properties of heavy elements, it should not be overestimated. There are numerous examples of situations where, contrary to expectations, relativistic effects do not manifest themselves in the properties of An. Of particular importance is the analysis of the influence of RE on the properties of heavy An ($Z = 98–103$) which precede the transactinides ($Z \geq 104$).

For instance, relativistic destabilisation of the 5*f*-electrons increases with $Z(\text{An})$. At first glance, this should lead to stabilisation of high oxidation states of not only the early, but also late actinides. However, the opposite effect, that is, stabilisation of the divalent state of late actinides was established experimentally. Therefore, the effect of actinide contraction appears to be much stronger than relativistic destabilisation of the 5*f*-electrons for An with $Z > 96$.

Yet another example, which has been analysed in detail⁴ using the published data, is provided by the correlations between changes in the sublimation enthalpies, $\Delta_s H^\circ$, of lanthanides and actinides and their valences V in the metallic state. Would RE affect the sublimation enthalpy, one should expect $V_{\text{An}} > V_{\text{Ln}}$ throughout the An and Ln series. However, experiments with the late An and Ln revealed another regularity, namely, $V_{\text{Ln}} > V_{\text{An}}$, which contradicts the assumption that RE have a crucial effect on the properties of the late An from Cf ($Z = 98$) to No ($Z = 102$).

Desclaux and Fricke hypothesised⁷ that strong RE will violate the logic of the Periodic system. According to calculations,⁷ the Lr atom has the $5f^{14} 7s^2 7p_{1/2} ({}^2P_{1/2}^0)$ ground-state electron configuration due to relativistic stabilisation of the $7p_{1/2}$ -electron, which means that Lr should be considered as an analogue of the Ga rather than Lu subgroup elements. Probably, calculations⁷ overestimated the influence of RE since this idea was not supported experimentally. It should be noted that the idea of relativistic stabilisation of the $7p_{1/2}$ -electron seems to be rejected. In the studies cited in review⁴ Lr was considered as an analogue of Lu and characterised by a $\Delta_s H^\circ(\text{Lr})$ value of ≈ 4 eV, which is close to the $\Delta_s H^\circ$ for Sc, Y, La, Gd, Lu, Ac and Cm, rather than ~ 2 eV for In, Ga and Tl. All estimates of the thermodynamic properties made for Lr^{III} aqua ions and for solid halides, oxides and sulfides reported in the chemical literature are close to corresponding values for Cm compounds.

According to Pyykkö's hypothesis,⁸ the most important chemical anomalies in the second half of the Periodic system are due to RE. This has been repeatedly exemplified using the difference between the chemical properties of Ag and Au, which is due

to the so-called 'relativistic maximum for gold'. However, this interpretation does not take into account specific features of the electronic structure of Ag atom (see Refs 9 and 10). Among the 3*d*-, 4*d*- and 5*d*-elements (a total of 27 elements from Sc to Au), the Ag atom has the most stable *d*-electrons: the excitation energy of the 4*d*-electron from the $\text{Ag}(4d^{10}5s)$ electron configuration is higher than for any other *d*-elements. It is the local nonrelativistic shell effect for Ag that is to a great extent responsible for distinctions between the chemical properties of Ag and Au.

Experimental data^{11–20} on the chemistry of rutherfordium (Rf), dubnium (Db), seaborgium (Sg), bohrium (Bh) and hassium (Hs) allow some generalisations and predictions. However, no measurements of the properties of TAn, which could be unambiguously interpreted as a manifestation of RE, have been reported so far.⁹ It was mentioned^{8,9,21} that interpretation of the properties of TAn required a weighed analysis of the role played by relativistic and nonrelativistic effects.

Manifestation of the spin–orbit RE can be experimentally confirmed in studies of the spectral and magnetic properties, which depend on the spin–orbit splitting energy and on the fine structure of energy levels. However, these investigations are still a long way in the future. Currently, the main avenues of research into the properties of TAn involve studies of the gas-state behaviour of TAn (first of all, volatility measurements of halides and oxides^{11,14,17}) and of the complexation of TAn in solutions.^{12,15,16,18,19}

Flerov and Zvara (Joint Institute of Nuclear Research, Dubna, Russian Federation) laid the foundation for a general strategy of studying the properties of TAn, which involves comparison of the properties of the elements in higher oxidation states in the groups Rf–Hf–Zr, Db–Ta–Nb, Sg–W–Mo, Bh–Re–Tc and Hs–Os–Ru. Currently, there are three points of view on the disposition of TAn in the Periodic table and on their relation to the 4*d*-, 5*d*- and 5*f*-elements.

1. Relativistic effects cause an inversion of the trends of changes in the properties^{14,15,19} on going from the 5*d*-elements to the 6*d*-elements, so that the properties are changed in the order 4*d*–6*d*–5*d*. Therefore the chemical properties of TAn cannot be extrapolated within particular groups. For Group IV elements, this conclusion was based on the results of quantum-chemical calculations of the effective charges q on the M atoms in gaseous molecules MCl_4 , which were found to be +1.18, +1.04 and +1.07 for Zr, Hf and Rf, respectively. Nonmonotonic change in the charges $q(\text{Zr}) > q(\text{Rf}) > q(\text{Hf})$ was used to explain the processes occurring in solutions (complexation,^{15,16} hydrolysis¹⁹) and in the crystalline state (sublimation enthalpy¹⁴).

2. Regularities typical of the *d*-elements are logically extended to the transactinides, *i.e.*, the passage 4*d*–5*d*–6*d* occurs without inversion of properties.¹⁷

3. The chemical properties of TAn are similar to those of the preceding actinide elements (Rf–Th).¹²

In this review, we analysed the thermodynamic properties of the TAn^{IV} compounds in the gas phase, aqueous solutions and in the crystalline state and compared them with the properties of compounds of the 3*d*-, 4*d*-, 5*d*- and 5*f*-elements. The subject of our study were the chlorides and bromides which are known to exist for all the TAn^{IV} , An^{IV} and *d*-transition elements M^{IV} .

When comparing the properties of TAn with those of (i) their *d*-analogues within the groups of the Periodic table and (ii) the corresponding An (Rf–Zr–Hf–Th; Db–Nb–Ta–Pa, *etc.*), researchers have to return to studying the properties of analogous compounds, since only the results obtained under the same conditions should be compared. Sometimes, the results of recent experiments with the 4*d*-, 5*d*- and 5*f*-elements are inconsistent with earlier results even at qualitative level. To appreciate the reasons for this inconsistency, in this review we considered the results of both recent (1990–2002) and earlier (1960–1975) experimental studies.

II. Structural properties: covalent and ionic radii and interatomic distances

Bokii²² pointed out that in the molecules of the A_2MX_6 ($A = K, Rb, Cs, X = Cl, Br$) compounds, e.g., K_2PtCl_6 , the measured r_{Pt-Cl} distance (2.34 Å) differs from the sum of the ionic radii of Cl^- and Pt^{4+} (1.81 Å + 0.62 Å = 2.43 Å). This allowed him to suggest that the $M-X$ bonds in these compounds are covalent rather than ionic and therefore the r_{M-X} distances cannot be calculated using the r_{ion} values. More recently,²³ the covalent radii, r_{cov} , along with the r_{ion} values were included in the set of commonly used structural parameters of the $4d$ - and $5d$ -elements.

It was found that the measured r_{M-X} distances in compounds of the $4d$ - and $5d$ -elements are linearly related to the maximum electron density radii, $r_{max}(nd)$, of the $4d$ - and $5d$ -AOs in the ground-state electron configurations of gaseous atoms

$$r_{M-X} = ar_{max}(nd) + c, \quad (1)$$

where a and c are constants and $n = 4, 5$.

Thus, if we know the $r_{max}(nd)$ values for all the $4d$ -, $5d$ - and $6d$ -elements and the r_{M-X} distances in compounds of the $4d$ - and $5d$ -elements, it is possible to estimate the corresponding distances in compounds of the $6d$ -elements. The $r_{max}(nd)$ values for the atoms of the $4d$ -, $5d$ - and $6d$ -elements were calculated using the relativistic Dirac–Fock approach.²⁴ The r_{M-Cl} values in gaseous MCl_4 ($M = Ti, V, Zr, Hf, Mo$ and W) molecules and in crystalline A_2MCl_6 ($A = K, Rb$ and $Cs; M = Ti, Zr, Mo, Tc, Pd, Hf, W, Re, Ir, Os$ and Pt) salts were measured.^{25–38} The r_{M-X} distances in compounds of the $4d$ - and $5d$ -elements were measured^{25–38} while the $r_{max}(nd)$ distances in the atoms of the $4d$ -, $5d$ -, $6d$ -elements, averaged over the degree of degeneracy of quantum numbers $j = 1 \pm 0.5$, were calculated.²⁴ Formula (1) was used to estimate the structural parameters of TAn^{IV} compounds (see Refs 4 and 21), such as r_{M-X} and $r_{cov} = r_{M-X} - r_X$ ($X = Cl, r_{Cl} = 0.99$ Å; $X = Br, r_{Br} = 1.14$ Å).

The structural data for the TAn^{IV} compounds listed in Table 1 are the r_{cov} (CN = 4) and r_{cov} (CN = 6) values, the r_{M-Cl} and r_{M-Br} values for gaseous and crystalline tetrahalides, the r_{M-Cl} values for gaseous MCl_6^{2-} anions and the lattice constants a for A_2TAnCl_6 ($A = K, Rb, Cs$) compounds.

Though the use of the r_{ion} parameters for evaluation of the $Pt-Cl$ distance in the $PtCl_6^{2-}$ anion overestimates this value by 0.09 Å (see Ref. 22), the ionic radii of the $3d$ -, $4d$ - and $5d$ -elements are listed in all crystallochemical tables, since for a particular

oxidation state and CN value they determine both the horizontal and vertical trends of changes in the structural properties. The ionic radius of Rf^{IV} was first calculated three decades ago,³⁹ more recently, this value was refined.^{40,41} For CN = 6, the estimates of $r_{ion}(Rf^{IV})$ are 0.74 (see Ref. 41), 0.75 (see Ref. 39) and 0.79 Å (see Ref. 40).

The $r_{ion}(TAn^{IV})$ values can also be estimated by extrapolating the ionic radii of the early analogues of the $4d$ -, $5d$ - and $5f$ -elements. On the one hand, the $r(M^{IV})$ values for transactinides were evaluated²¹ using the $r_{ion}(M^{IV})$ ⁴² parameters of the $4d$ - and $5d$ -elements and the calculated r_{cov} values of the $4d$ -, $5d$ - and $6d$ -elements. The estimate of $r_{ion}(Rf^{IV})$ was found to be 0.78 Å (see Table 1). On the other hand, the $r(TAn^{IV})$ parameters were evaluated using the results obtained for An . Tetravalent transactinide compounds ($Z = 104–110$) extend the series of An^{IV} compounds, which were synthesised for all actinides from Th ($Z = 90$) to Es ($Z = 99$). The ionic radii, $r_{ion}(An^{IV})$, for CN = 6 and 8 were also reported (see Ref. 43). For CN = 6, they decrease on going from Th^{IV} ($r_{ion} = 0.932$ Å) to Es^{IV} ($r_{ion} = 0.812$ Å) following a power dependence on Z . This allowed one to estimate the $r_{ion}(Rf^{IV})$ parameter, which was found to be 0.75 Å. Thus, the former value (0.78 Å) reflects the covalent character of bonding, typical of compounds of the d -elements, while the latter value (0.75 Å) reflects more ionic character of bonding, characteristic of actinides. This points to dual properties of TAn that are similar to both the $4d$ - and $5d$ -elements and the actinides. For CN = 8, the calculated $r_{ion}(Rf^{IV})$ value is 0.836 Å.²¹

Not all crystal MX_4 compounds of the $4d$ - and $5d$ -elements are isostructural,^{25–38} but for all of them the CN equals 6 rather than 4. As a rule, typical of these compounds is a distorted octahedral coordination of the M atom and the presence of both bridging and terminal X atoms. For $ZrCl_4$, the r_{Zr-Cl} distances vary between 2.307 and 2.655 Å (see Ref. 44). It is believed^{4,21} that in the crystalline tetrahalides of the $6d$ -elements the CN also equals 6. The averaged r_{M-X} distances in the crystalline (c) MX_4 ($M = Zr, Hf, Nb, Ta, Mo, W, Tc, Re$ and Os) compounds are linearly related to the $r_{max}(nd)$ values. This allowed estimation of the r_{M-X} distances in halide compounds of TAn based on the known²⁴ $r_{max}(6d)$ values (see Table 1). For both the MCl_6^{2-} anions in the gas (g) phase and $MCl_4(c)$ chlorides the CN is 6; however, unlike the crystalline chlorides, the anions contain only terminal bonds, which could be the reason for the small difference between the r_{M-Cl} distances.

Table 1. Maximum electron density radii $r_{max}(6d)$, covalent (r_{cov}) and ionic (r_{ion}) radii of TAn^{IV} for CN = 4 and CN = 6 and distances r_{M-X} in gaseous MX_4 molecules and MX_6^{2-} anions and in crystalline MCl_4 compounds (see Ref. 4). Lattice constants a of compounds A_2MCl_6 ($A = K, Rb, Cs$). All values are given in Å.

III. Standard formation enthalpies of gaseous and crystalline tetrahalides

Using the published thermodynamic^{45–66} and structural data^{25–38, 67–76} for tetrahalides of the 3*d*-, 4*d*-, 5*d*- and 5*f*-elements in the gas phase and in the crystalline state, we found some common parameters that were used for calculations of the standard formation enthalpies, $\Delta_f H^\circ(\text{MX}_4, \text{g})$, of the MX_4 compounds of all elements including TAn (see Ref. 67) and for prediction of the $\Delta_f H^\circ(\text{MX}_4, \text{g})$ values from the following equation

$$\Delta_f H^\circ(\text{MX}_4, \text{g}) = \Delta_s H^\circ(\text{M}) + 4\Delta_f H^\circ(\text{X}, \text{g}) - \left[a - \frac{b}{r(\text{M}-\text{X})} \right], \quad (2)$$

where $\Delta_s H^\circ(\text{M})$ is the standard sublimation enthalpy of M, $\Delta_f H^\circ(\text{X}, \text{g})$ is the standard formation enthalpy of gaseous atoms X, $a - b/r(\text{M}-\text{X})$ is the energy of all bonds, $D(\text{MX}_4, \text{g})$, in gaseous MX_4 molecule and a and b are constants. This approximation was used for calculating the thermodynamic properties of the An and Ln compounds (including aqua ions) and their redox potentials.^{45–48, 53, 59, 60, 67} Using the measured $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ values (M = Ti, V, Cr, Zr, Nb, Mo, Ru, Hf, Ta, W and Os),^{30, 49–55} the a and b coefficients were determined and the $D(\text{MX}_4, \text{g})$ and $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ parameters were calculated for all TAn and for Rh, Ir, Pd and Pt. The $\Delta_f H^\circ(\text{AnCl}_4, \text{g})$ values for An = Th, U and Pu were measured^{58, 61, 63, 64} while those for Am, Cm, Bk, Cf, Es were estimated.⁴⁸ The $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ parameters for TAn, calculated by the author of this review, are listed in Table 2. In Fig. 1 we compare the standard formation enthalpies of gaseous tetrachlorides of the 4*d*-, 5*d*-, 6*d*- and 5*f*-elements in graphical form.

As can be seen in Fig. 1, tetrachlorides of transactinide elements lose their thermodynamic stability as the number of antibonding electrons increases from RfCl_4 to the ^{110}TAn tetrachloride. The same trend is also observed for tetrachlorides of the 4*d*- and 5*d*-elements, namely, RuCl_4 and OsCl_4 have the highest (largest positive) formation enthalpies. A decrease in the thermodynamic stability along the TAn series was also predicted for gaseous tetrabromides. Gaseous tetrahalides of Group IV–VIII elements become thermodynamically more stable on going from the light to heavy elements; the stability sequence is $4d < 5d < 6d$, $4d \approx 5d < 6d$ and $4d > 6d > 5d$.

Theoretical aspects of comparison of the 5*f*- and 6*d*-elements have been studied for long. Zachariasen⁵⁷ proposed a thoride

Figure 1. Comparison of $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ values for actinides (1) and for the 6*d*- (2), 5*d*- (3) and 4*d*-elements (4).

theory which treated the actinides as typical 6*d*-metals. This theory was repeatedly criticised; however, it contains a grain of truth, namely, the proposition that particular chemical properties of compounds of the 5*f*-elements are similar to those of the 6*d*-elements. This also still holds.^{12, 18} In Fig. 2, we compare the bond energies, $D(\text{MCl}_4, \text{g})$, of gaseous tetrachlorides of the 4*d*-, 5*d*- and 6*d*-elements and of the actinides. Again, the $D(\text{MCl}_4, \text{g})$ values for gaseous MCl_4 (M = Zr, Nb, Mo, Ru, Hf, Ta, W, Os) molecules and the $D(\text{AnCl}_4, \text{g})$ parameters for An = Th, U and Pu were calculated using Eqn (2) in which all the values, except D , viz., $\Delta_f H^\circ(\text{MX}_4, \text{g})$, $\Delta_s H^\circ(\text{M})$ and $4\Delta_f H^\circ(\text{X}, \text{g})$ were obtained experimentally. Therefore, the D values for these compounds can be considered experimental. The bond energies of compounds for which no experimental data are available (TAn; Rh, Ir; Pd, Pt and An = Pa, Np, Am, Cm) were calculated by the author of this review. Comparison of the data presented in Figs 1 and 2 shows that the bond energies, $D(\text{AnCl}_4, \text{g})$ for the early actinides (Th–Cm) and $D(\text{MCl}_4, \text{g})$ for TAn, differ insignificantly, whereas the

^a $\Delta_h H^\circ(\text{MCl}_6^{2-}, \text{g})$ is the hydration enthalpy of gaseous MCl_6^{2-} anions.

Figure 2. Bond energies $D(\text{MCl}_4, \text{g})$ of actinides (1) and of the 6d- (2), 5d- (3) and 4d-elements (4).

formation enthalpies for the following pairs of elements: Pa–Db, U–Sg, Np–Bh, Pu–Hs and Am–Mt (except for the pair Rf–Th) differ substantially, that is, smaller $\Delta_s H^\circ(\text{An})$ values [compared to $\Delta_s H^\circ(\text{M})$] lead to the higher thermodynamic stability of AnCl_4 compared to MCl_4 .

Problems concerning monotonic (passage $4d \rightarrow 5d \rightarrow 6d$) or nonmonotonic (passage $4d \rightarrow 6d \rightarrow 5d$) changes in the properties within the groups of the Periodic table and analogies between the properties of the 5f- and 6d-elements have been the subject of a considerable literature. Nonmonotonic changes in properties are associated with RE. We believe that the chemical properties (in particular, thermodynamic properties) reflect the totality of many properties of free atoms and interactions between them. An increase or a decrease in certain parameters can lead to non-monotonic changes in the thermodynamic properties within the

Figure 3. Bond energies $D(\text{M}-\text{Cl})$ in tetrachlorides of the d-elements as functions of $r_{\text{M}-\text{Cl}}^{-1}$. Group IV elements (a), Group V elements (b), Group VI elements (c) and Group VIII elements (d).

Figure 4. Changes in the $\Delta_s H^\circ(\text{M})$ (1) and $D(\text{M}-\text{Cl})$ (2) values for tetrachlorides of Group IV, V, VI and VIII elements and for the corresponding actinide pseudohomologues.

groups of the Periodic table. From this standpoint, let us compare the properties of compounds $\text{MCl}_4(\text{g})$ and $\text{AnCl}_4(\text{g})$ within particular groups. According to Eqn (2), the main properties determining the changes in the thermodynamic stability of tetrachlorides within the groups are $\Delta_s H^\circ(\text{M})$, $r_{\text{M}-\text{Cl}}$ and $D(\text{MCl}_4, \text{g})$. The bond energies $D(\text{M}-\text{Cl})$ in tetrachlorides of the d-elements of Groups IV, V, VI and VIII including the actinide pseudohomologues are plotted in Fig. 3 as functions of the $r_{\text{M}-\text{Cl}}^{-1}$ parameter. Figure 4 presents the dependence of $\Delta_s H^\circ(\text{M})$ and $D(\text{M}-\text{Cl})$ on Z in these groups.

1. TiCl_4 , ZrCl_4 , HfCl_4 , ThCl_4 and RfCl_4

For all gaseous tetrachlorides of Group IV elements (except RfCl_4), the interatomic distances were measured to an accuracy of $\pm 0.02 \text{ \AA}$ and the $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ were determined. The interatomic distances are $r_{\text{Ti}-\text{Cl}} = 2.23 \text{ \AA}$; $r_{\text{Zr}-\text{Cl}} = 2.32 \text{ \AA}$, $r_{\text{Hf}-\text{Cl}} = 2.33 \text{ \AA}$ (see Ref. 25) and $r_{\text{Th}-\text{Cl}} = 2.58 \text{ \AA}$ (see Ref. 65).

Using the values $\Delta_f H^\circ(\text{ThCl}_4, \text{g}) = -964 \text{ kJ mol}^{-1}$ and $\Delta_s H^\circ(\text{Th}) = 597.1 \text{ kJ mol}^{-1}$ taken from Refs 61 and 66, one can obtain the $D(\text{ThCl}_4, \text{g})$ value equal to 2047 kJ mol^{-1} . Therefore, the bond energies, $D(\text{MCl}_4, \text{g})$, of tetrachlorides MCl_4 ($\text{M} = \text{Ti}, \text{Zr}, \text{Hf}, \text{Th}$ and Rf) are equal to 1720, 1965, 1997, 2047 and 2090 kJ mol^{-1} , respectively. A sharp, experimentally observed increase in $r_{\text{Th}-\text{Cl}}$ compared to $r_{\text{Hf}-\text{Cl}}$ can be considered as manifestation of RE which destabilise the 6d-AO of thorium. Compared to $D(\text{Hf}-\text{Cl})$, the $D(\text{Th}-\text{Cl})$ value increases rather than decreases (see Fig. 3). Based on the $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ values for $\text{M} = \text{Zr}, \text{Hf}, \text{Th}$ and Rf ($-870, -889, -964$ and -971 kJ mol^{-1} , respectively), Group IV elements can be divided into pairs Zr–Hf and Th–Rf with close values of the enthalpies $\Delta_f H^\circ(\text{MCl}_4, \text{g})$. From the standpoint of thermodynamic properties, ThCl_4 belongs to the group of chlorides of the d-elements, which emphasises a specific feature of the early TAn, namely, similarity of their properties to those of An and of the d-homologues. All trends of changes in the chemical properties of compounds of Group IV elements and the similarity of Rf to Zr (see Refs 15 and 19) and to Th (see Ref. 18) are considered as manifestations of RE. Stability of the compounds under consideration, i.e., the $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ value, depend on $\Delta_s H^\circ(\text{M})$, $r_{\text{M}-\text{Cl}}$ and $D(\text{M}-\text{Cl})$. Each of these quantities changes within the group in its own manner. For instance, the $\Delta_s H^\circ(\text{M})$ values increase from Th to Zr, Hf and Rf ($597, 608, 622$ and 634 kJ mol^{-1} , respectively).

$$\Delta_s H^\circ(\text{Th}) < \Delta_s H^\circ(\text{Zr}) < \Delta_s H^\circ(\text{Hf}) < \Delta_s H^\circ(\text{Rf}) \quad (3)$$

Thus, according to Eqn (2), the order of change in the sublimation enthalpies, $5f < 4d < 5d < 6d$, must correspond to the highest thermodynamic stability of ThCl_4 .

However, the $r_{\text{M}-\text{Cl}}$ values change in another manner, $4d \leq 5d < 6d < 5f$

$$r_{\text{Zr}-\text{Cl}} \leq r_{\text{Hf}-\text{Cl}} < r_{\text{Rf}-\text{Cl}} < r_{\text{Th}-\text{Cl}}, \quad (4)$$

which corresponds to the lowest thermodynamic stability of ThCl_4 . This order is due to the geometry of the molecules in question. In the gas phase, ZrCl_4 and HfCl_4 are characterised by tetrahedral coordination. This type of coordination is also assumed for RfCl_4 ; however, an electron diffraction study⁶⁵ of ThCl_4 and UCl_4 revealed a distorted C_{2v} symmetry. As a result of superimposition of the effects denoted by sequences (3) and (4), we get

$$\begin{aligned} D(\text{Zr}-\text{Cl}) &< D(\text{Hf}-\text{Cl}) < D(\text{Th}-\text{Cl}) < D(\text{Rf}-\text{Cl}) \\ \Delta_f H^\circ(\text{ZrCl}_4, \text{g}) &\geq \Delta_f H^\circ(\text{HfCl}_4, \text{g}) > \Delta_f H^\circ(\text{ThCl}_4, \text{g}) \geq \\ &\geq \Delta_f H^\circ(\text{RfCl}_4, \text{g}). \end{aligned}$$

Thus, two pairs of elements, viz., Zr–Hf and Th–Rf have similar thermodynamic properties.

Thorium is the second element of the An series. The atomic properties of Th are still not affected by the actinide contraction. Rutherfordium is the first element in the TAn series, whose properties are affected by both the actinide contraction and RE. Relativistic effects become stronger as Z increases:^{8,24} in Rf ($Z = 104$), the $6d$ -AO should experience greater relativistic destabilisation than in Th ($Z = 90$). This means that the $r_{\text{Rf}-\text{Cl}}$ distance in the RfCl_4 molecule must be at least comparable or longer than the $r_{\text{Th}-\text{Cl}}$ distance in the ThCl_4 molecule. The measured $r_{\text{Th}-\text{Cl}}$ distance (2.58 Å, see Ref. 65) and the calculated $r_{\text{Rf}-\text{Cl}}$ distance (2.417 Å, see Ref. 4) undoubtedly indicate that the effect of actinide contraction appears to be stronger than both relativistic and nonrelativistic structural-shell destabilisation of the $6d$ -AO for Rf.

2. V, Nb, Ta, Pa and Db

For compounds of Group V elements, the $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ values (determined with an accuracy of ± 15) decrease on going from the light to heavy elements.^{4,68–69}

MCl_4	VCl_4	NbCl_4	TaCl_4	DbCl_4	PaCl_4
$\Delta_f H^\circ(\text{MCl}_4, \text{g}) / \text{kJ mol}^{-1}$	–535	–567	–561	–707	–809

However, if the thermodynamic stability of RfCl_4 is close to that of ThCl_4 , DbCl_4 appears to be less stable than PaCl_4 despite the fact that $r_{\text{Pa}-\text{Cl}} > r_{\text{Db}-\text{Cl}}$ (2.543 vs. 2.379 Å, respectively). On the other hand, the bond energy, $D(\text{M}-\text{Cl})$, in gaseous MCl_4 increases from V to Db as Z increases. This trend of changes in the main parameters is due to the large difference ($\sim 200 \text{ kJ mol}^{-1}$) between the sublimation enthalpies, $\Delta_s H^\circ(\text{M})$, of Pa and Db.

Element	V	Pa	Nb	Db	Ta
$\Delta_s H^\circ(\text{M}) / \text{kJ mol}^{-1}$	513	570	722	769	782

It should be noted that for Th and Rf this difference is $\sim 40 \text{ kJ mol}^{-1}$.

Figure 4 clearly displays a nonmonotonic trend in the changes in the parameters $\Delta_s H^\circ(\text{M})$ and $\Delta_s H^\circ(\text{An})$ with an increase in Z and a nearly monotonic trend of changes in $D(\text{M}-\text{Cl})$.

We also analysed the changes in the properties determining the thermodynamics of gaseous tetrachlorides of Group V–VIII elements in order to show the disposition of the TAn and An elements relative to the $3d$ -, $4d$ - and $5d$ -elements (Table 3).

Trends in the changes of the chemical properties of d -elements down the groups of the Periodic table and their comparison with the properties of An have been the subject of a considerable amount of literature.^{9,12–19} Particular emphasis is placed on how these properties change with Z , monotonically ($4d \rightarrow 5d \rightarrow 6d$) or nonmonotonically ($4d \rightarrow 6d \rightarrow 5d$). Nonmonotonic changes in particular properties are explained by nonmonotonic changes in the effective charges of gaseous molecules, which, in turn, are interpreted as the influence of RE.^{14,15,19}

However, it was recently shown⁹ that the effective charges cannot serve as quantitative criteria for the manifestation of RE. The data presented in Figs 3 and 4 and the above-mentioned $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ and $\Delta_s H^\circ(\text{M})$ values taken from Refs 9, 10, 21, 48, 59, and 67 or calculated by the author of this review suggest that the thermodynamic properties represent a complex combination of different properties. For instance, compensation effects in the parameters $\Delta_s H^\circ(\text{M})$ and $D(\text{M}-\text{Cl})$ can cause both monotonic and nonmonotonic dependences of the $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ values within the groups. The absolute values of the parameters $\Delta_f H^\circ(\text{MCl}_4, \text{g})$ are closest for Zr, Hf, Th and Rf. For heavier analogues, that is, Nb, Ta, Db, Pa; Mo, W, Sg, U; Tc, Re, Bh and Np the difference between TAn and An increases as the number of localised f -electrons in An increases; therefore, it is beyond reason to compare the TAn and An elements. The main regularities revealed for tetrachlorides also manifest themselves to a certain extent for tetrabromides.

A method for calculating the formation enthalpies of crystalline compounds (LnX_3 , AnX_3 and AnX_4 ; $\text{X} = \text{F}, \text{Cl}, \text{Br}, \text{I}$) was proposed.^{48,59} It is based on consideration of the formation of crystalline compounds from ions. This approach was used to calculate the formation enthalpies of crystalline compounds from gaseous atoms.^{4,21,67} The formation enthalpies of crystalline compounds were calculated by the following equation

$$\Delta_f H^\circ(\text{MX}_4, \text{c}) = \Delta_s H^\circ(\text{M}) + 4\Delta_f H^\circ(\text{X}, \text{g}) - U(\text{MX}_4, \text{c}), \quad (5)$$

where $U(\text{MX}_4, \text{c})$ is the crystal lattice energy.

The lattice energies can be estimated using the lattice parameters^{30,45–48} or the $r_{\text{M}-\text{X}}$ distances. For instance, calculations with known $r_{\text{M}-\text{X}}$ and $U(\text{MX}_4, \text{c})$ values or with $r_{\text{An}-\text{X}}$ and $U(\text{AnX}_4, \text{c})$ values determined from the experimental $\Delta_f H^\circ(\text{MX}_4, \text{c})$ ($\text{M} = \text{Zr}, \text{Hf}, \text{Ta}, \text{Nb}, \text{Mo}, \text{W}, \text{Tc}, \text{Re}, \text{Ru}, \text{Os}, \text{Pt}, \text{Th}, \text{Pa}, \text{U}, \text{Np}, \text{Pu}$) parameters^{45–76} revealed correlations between $r_{\text{M}-\text{X}}$ and $U(\text{MX}_4, \text{c})$ or between $r_{\text{An}-\text{X}}$ and $U(\text{AnX}_4, \text{c})$, which allowed one to calculate the $\Delta_f H^\circ(\text{MX}_4, \text{c})$ values for all the crystalline tetrahalides of the d -elements of Rows 4–6 and for the actinides. The lattice energies of Pd, Rh, Ir and TAn were calculated^{4,21} and those of Am, Cm, Bk, Cf and Es determined.⁴⁸ The $\Delta_f H^\circ(\text{MX}_4, \text{c})$ values for TAn are listed in Table 2.

Table 3. Sequence of changes in the properties of Group V–VIII elements and their compounds.

Parameters	Sequence of changes in properties			
	Group V elements and Pa: V(3d), Nb(4d), Ta(5d), Db(6d), Pa(5f)	Group VI elements and U: Cr(3d), Mo(4d), W(5d), Sg(6d), U(5f)	Group VII elements and Np: Mn(3d), Tc(4d), Re(5d), Bh(6d), Np(5f)	Group VIII elements and Pu: Fe(3d), Ru(4d), Os(5d), Hs(6d), Pu(5f)
$\Delta_s H^\circ(\text{M})$	$3d < 5f < 4d < 6d < 5d$	$3d < 5f < 4d < 6d \leq 5d$	$3d < 5f < 4d < 6d < 5d$	$5f < 3d < 4d < 5d \approx 6d$
$r(\text{M}-\text{Cl})$	$3d < 4d < 5d < 6d < 5f$	$3d < 4d < 5d < 6d < 5f$	$3d < 4d < 5d < 6d < 5f$	$4d < 5d < 6d < 5f$
$D(\text{M}-\text{Cl})$	$3d < 4d < 5d < 5f < 6d$	$3d < 4d < 5d < 5f \leq 6d$	$4d < 5d < 6d < 5f$	$4d < 5d < 6d < 5f$
$\Delta_f H^\circ(\text{MCl}_4, \text{g})$	$3d > 5d \approx 4d > 6d > 5f$	$5d > 4d > 3d > 6d > 5f$	$4d > 5d > 6d > 5f$	$4d > 5d > 6d > 5f$

IV. Volatility of transactinide compounds as a function of their structure in the crystalline and gaseous states

1. Comparison of earlier and recently obtained results

One of the main experimental methods used for determining the sublimation enthalpies of TAn is the volatility measurements of their halides and oxyhalides.^{11, 13, 14, 17, 77–85} Volatile compounds of metals are compounds that can undergo sublimation and condensation at moderate (< 700–800 K) temperatures. However, both the experimental data and their theoretical interpretation are contradictory. It was not an occasion that the authors of monograph⁷⁷ wrote that ‘volatility belongs to such properties of chemical compounds that are hard to predict even qualitatively’. They also mentioned that, despite the existence of two experimental methods for studying the volatility properties (measurements of sublimation enthalpies and determination of the temperature dependence of the vapour pressure, $P = f(T)$), only the second approach allows one to obtain complete and reliable information on the volatility properties. For instance, the sublimation enthalpies of ZrCl_4 and HfCl_4 were reported to be equal, *viz.*, $\Delta_s H^\circ(\text{ZrCl}_4) = \Delta_s H^\circ(\text{HfCl}_4) = 100 \text{ kJ mol}^{-1}$,^{26, 86} however, measurements of the $P = f(T)$ dependence over a wide temperature range pointed to the higher volatility of HfCl_4 compared to ZrCl_4 . Theoretical predictions of volatility properties are also complicated by the need to take into account the molecular structure in the crystalline and gaseous states.

Chemical experiments with TAn are carried out using single atoms (the so-called ‘one atom-at-a-time’ technique). Since in these experiments we deal with single molecules, neither $P = f(T)$ nor $\Delta_s H^\circ$ can be measured. Therefore, TAn are studied by isothermal gas chromatography and thermochromatography. The parameter measured in gas chromatography studies²⁰ is the enthalpy of adsorption, $\Delta_a H_T^\circ$, on a chromatographic surface (usually, quartz). The sublimation enthalpies of chlorides and oxychlorides, $\Delta_s H_{298}^\circ$, are calculated from a linear correlation between these values, $\Delta_s H_{298}^\circ$ and $\Delta_a H_T^\circ$. However, the results obtained using this procedure are less reliable than those of the direct measurements of $\Delta_s H_{298}^\circ$. From the viewpoint of the reliability of the results obtained and based on conclusions drawn in monograph,⁷⁷ the experimental methods used in volatility studies can be listed in the following order

$$P = f(T) > \text{direct measurements of } \Delta_s H^\circ > \text{correlation of } \Delta_s H^\circ \text{ and } \Delta_a H_T^\circ.$$

In addition, a drawback of the experiments with TAn ‘is that the chemical composition of compounds under study cannot be identified and that possible chemical formulae are postulated based on the results of experiments with early homologues’.¹⁴ These experiments are carried out assuming a complete analogy between the chemical properties of the 4d-, 5d- and 6d-elements within the groups of the Periodic table and the same type of compounds of the same chemical composition, though it is not universally true. For instance, in Groups VI and VII almost all halide compounds of rhenium are volatile at room or higher temperatures.⁷⁰ ReO_3Cl and ReOCl_4 that are hard to separate are formed under the same conditions.⁷⁰ Even more complicated is the situation observed in the case of the identification of volatile compounds of Group VI elements.⁷⁰ For instance, pairs of compounds MoO_2Cl_2 and MoOCl_4 or WO_2Cl_2 and WOCl_4 are formed under the same conditions; MoO_2Cl_2 and MoOCl_4 can be chemically separated only by *in vacuo* sublimation at 70–80 °C; WO_2Cl_2 undergoes disproportionation resulting in WOCl_4 , which in dioxygen atmosphere adds a O_2 molecule and releases Cl_2 , thus again forming WO_2Cl_2 . Recently,⁸⁷ thermodynamic analysis was performed on all possible Mo and W compounds that can be formed in the gas phase.

Further, assuming a complete analogy between the chemical properties of the 4d-, 5d- and 6d-elements within the corresponding groups, the same adsorption mechanism is postulated for all

homologues. Clearly, adsorption depends on the character of bonding between individual molecules or their ensembles and the surface. Surface reactions are neither microscopic nor macroscopic; they belong to a broad class of ‘intermediate’ reactions which comprises both microscopic and macroscopic reactions.⁸⁸

The surface of quartz is an arena in which different chemical processes occur. Quartz possesses no strong basic or acid properties. Depending on temperature, its surface can adsorb protons, hydroxy groups, polarised siloxane groups, chlorine and dioxygen molecules, *etc.*⁸⁸ The minimum energy of the van der Waals interaction necessary for physisorption to occur is $\approx 20 \text{ kJ mol}^{-1}$. The $-\Delta_a H_T^\circ$ values measured in the experiments with TAn and their homologues lie between 50 and 250 kJ mol^{-1} . These magnitudes of the heats of adsorption suggest different adsorption mechanisms including the formation of chemical bonds $\text{M}-\text{Cl}$, $\text{M}-\text{Si}$, $\text{M}-\text{OH}$, *etc.*, between the adsorbed molecules and quartz surface irrespective of one molecule or ensemble of gaseous molecules is adsorbed on the surface. Yet another problem is the heterogeneity of the real quartz surface and possible modification of this surface by some components of the carrier gas. Therefore, taking into account the conclusions drawn in monograph⁷⁷ and the postulates proposed by the authors of other studies,^{14, 17} the results obtained from the correlation of $\Delta_s H^\circ$ with $\Delta_a H_T^\circ$ seem to be even less reliable.

Theoretical chemistry uses four approaches to volatility studies.

The first approach is based on calculations of (i) bond covalencies and effective charges in gaseous molecules or (ii) dipole moments of these molecules using the same charges. Changes in the effective charges are interpreted as a manifestation of RE. This approach ignores the mechanism of adsorption and, hence, the structure of solids. The high covalency of the $\text{M}-\text{Cl}$ bonds in gaseous molecules is assumed to correspond to high volatility of respective crystalline compounds. This model was used to rationalise the trend in the changes in the volatility of chlorides MCl_4 ($\text{M} = \text{Rf}, \text{Hf}, \text{Zr}$).¹⁴ However, experimental data showed that the covalency of the $\text{M}-\text{X}$ bonds in gaseous MX_4 molecules cannot serve as criterion for volatility. Undoubtedly, TiF_4 is a more ionic compound than TiI_4 ; nevertheless, both of them are characterised by the same volatility.⁷⁰ The volatility of the covalent compound UCl_6 is much lower than that of ionic compound UF_6 ; the ionic compounds UF_6 , NpF_6 and PuF_6 exhibit the highest volatilities among all the simple and complex An compounds.⁶¹ The results of calculations of gaseous Group VI dioxyhalides MO_2Cl_2 ($\text{M} = \text{Mo}, \text{W}, \text{Sg}$), carried out in the framework of a relativistic discrete variation approach have been reported.¹⁵ According to calculations,¹⁵ SgO_2Cl_2 is characterised by the largest contribution of covalent bonding and should be the most volatile compound within the group. However, experiments showed the opposite: SgO_2Cl_2 possesses the lowest volatility within the group of the Periodic table.¹⁴ It was then assumed¹⁵ that volatility is determined by the dipole moments of gaseous molecules, $\mu(\text{MO}_2\text{Cl}_2)$; however, experimental data revealed that neither bond covalency nor dipole moments of gaseous molecules can serve as criterion for volatility. For instance, gaseous molecules AnF_6 ($\text{An} = \text{U}, \text{Np}, \text{Pu}$) have equal dipole moments, $\mu(\text{AnF}_6)$; however, NpF_6 in the crystalline state has abnormally high vapour pressure.⁶¹ Experimental data showed that the approach based on calculations of bond covalencies and effective charges¹⁴ and dipole moments¹⁵ of gaseous molecules is incorrect and inapplicable in the case of the prediction of volatility.

The second approach was proposed by Zhuikov *et al.*⁷⁸ who assessed the volatility of the tetrachlorides RfCl_4 , HfCl_4 and ZrCl_4 from the parameters of thermodynamic cycle including the cohesive energy of the metal. In contrast to the preceding case, this model, though indirectly, takes into account two states of matter.

Eichler⁷⁹ hypothesised that the formation enthalpy of gaseous metal atoms can serve as a measure of sublimation enthalpies of

chemical compounds and suggested a correlation between these parameters (third approach).

An experimental indication of the volatility of metal compounds is the possibility of sublimation of the substance under study.⁷⁷ Therefore, in early studies^{21, 67} researchers used the difference between the standard formation enthalpies of a compound in the crystalline and gaseous states as a possible characteristic of volatility (fourth approach).

The need to take into account the distinctions between the structure of two phase states (probably, in terms of adsorption mechanism) when calculating the sublimation enthalpies of chemical compounds has been proposed^{11, 13, 67, 77, 78, 79} and can be exemplified as follows.

Group IV. Titanium tetrachloride in the gaseous and crystalline states has a monomeric structure (CN = 4), which is responsible for the small $\Delta_s H^\circ(\text{TiCl}_4)$ value (52 kJ mol⁻¹).²⁶

Similarly to TiCl₄, tetrachlorides of zirconium and hafnium in the gas phase have a tetrahedral structure (CN = 4). However, in the crystalline state these compounds are polymers with octahedral coordination (CN = 6). For the sublimation enthalpies of these compounds, we get $\Delta_s H^\circ(\text{ZrCl}_4) \approx \Delta_s H^\circ(\text{HfCl}_4) \approx 100$ kJ mol⁻¹.²⁶ An increase of 2 in the CN for the crystalline state compared to the gaseous state causes a nearly twofold increase in the parameters $\Delta_s H^\circ(\text{ZrCl}_4)$ and $\Delta_s H^\circ(\text{HfCl}_4)$ compared to $\Delta_s H^\circ(\text{TiCl}_4)$.

For thorium tetrachloride, the CN is 4 in the gaseous state and 8 in the crystalline state.^{61, 65} An increase of 4 in the CN for the crystalline state compared to the gaseous state caused a nearly fourfold increase in the parameter $\Delta_s H^\circ(\text{ThCl}_4)$ (249 ± 20 kJ mol⁻¹) compared to $\Delta_s H^\circ(\text{TiCl}_4)$. Therefore, the CN in gaseous molecules remains unchanged (CN = 4) on going from TiCl₄ to ThCl₄; however, the structure of crystalline compounds becomes more complex, which results in an increase in $\Delta_s H^\circ(\text{MCl}_4)$. If all crystal compounds were built of monomeric molecules similar to TiCl₄, they would be characterised by a small sublimation enthalpy (~50 kJ mol⁻¹). Probably, the properties of adsorbed molecules are similar to those of the molecules in the crystalline rather than the gaseous state.

The sublimation enthalpies, $\Delta_s H^\circ(\text{MCl}_4)$, correlate with the $r(\text{M}^{\text{IV}})$ of Ti, Zr, Hf and Th in the crystalline state.

M^{IV}	CN	Ionic radius $r(\text{M}^{\text{IV}})/\text{\AA}$	$\Delta_s H^\circ(\text{MCl}_4)$ /kJ mol ⁻¹
Ti	4	0.60	52
Zr	6	0.72	100
Hf	6	0.73	100
Th	8	1.048	249

The formula is as follows

$$\Delta_s H^\circ(\text{MCl}_4) \approx 442 r(\text{M}^{\text{IV}}) - 215 \text{ kJ mol}^{-1}.$$

Substituting the value $r(\text{Rf}^{\text{IV}})(\text{CN} = 6) = 0.75 - 0.78 \text{ \AA}$, we get $\Delta_s H^\circ(\text{RfCl}_4) = 117 - 130 \text{ kJ mol}^{-1}$, which is close to the experimental value $\Delta_s H^\circ(\text{RfCl}_4) = 109 \pm 10 \text{ kJ mol}^{-1}$.¹⁴ It seems logical to assume that adsorption of RfCl₄ causes expansion of its coordination sphere and an increase in CN to 6 (similarly to ZrCl₄ and HfCl₄) rather than 8 as in the case of ThCl₄.

Other values of the parameter $\Delta_s H^\circ(\text{RfCl}_4)$ reported in the literature are 90 ± 15 (see Ref. 80) and 122–138 kJ mol⁻¹ (see Ref. 83). They lie within the interval 110 ± 30 kJ mol⁻¹, which is consistent with the value reported by Türlér.¹⁴

Thus, the results of volatility studies can provide the possibility of modelling the structure of crystalline TAn compounds. The volatility of compounds of Group VI–VII elements can be analysed analogously.

Group VI. Nearly two decades ago Academician V I Spitsyn brought the attention of the author of this review to the problem¹ of analysing the chemical properties of Mo and W compounds in order to find optimum conditions for their separation. The main conclusion drawn after solving this problem was that separation

of Mo and W requires the use of their compounds in their lower oxidation states. It was found that the higher the oxidation state the less significant the distinctions between the chemical behaviour of Mo and W and that maximum similarity of the Mo and W compounds is observed for the oxidation state VI. Currently, some effort has been made to reveal distinctions between the chemical behaviour of compounds of Mo^{VI}, W^{VI} and Sg^{VI} in the gaseous state and in solution. The main problem of volatility studies of Group VI compounds is to identify the substances formed in the gas phase.^{70, 87}

The thermodynamic stability of the W and Mo compounds was also used as a criterion for identification.⁸⁷ It was concluded⁸⁷ that MoO₂Cl₂, WO₂Cl₂ and SgO₂Cl₂ have similar thermodynamic properties (their boiling points are close). The stability of MO₂Cl₂ and MOCl₄ towards thermal decomposition was determined using the energy of the charge-transfer transition, ΔE_{ct} , in the electronic spectra.¹⁵ This method was also used for estimating the redox potentials of Pu(VII)/Pu(VI), Np(VII)/Np(VI), *etc.*^{1–3, 45–47} in solutions from the measured ΔE_{ct} values for their complexes. However, these spectral transitions are by no means related to the gas-phase stability of compounds which is determined by the standard formation enthalpy. Based on the results of determination of ΔE_{ct} values, MO₂Cl₂ was suggested to be more stable towards thermal dissociation than MOCl₄ (see Ref. 15). However, the standard formation enthalpies ($\Delta_f H^\circ$) of gaseous MO₂Cl₂ and MOCl₄ (M = Mo, W) molecules changes in the order WO₂Cl₂ < MoO₂Cl₂ = WOCl₄ < MoOCl₄ (see Ref. 87). This trend is quite remarkable since it contradicts the conclusions drawn by Kratz.¹⁵ Taking into account the results of studies,^{70, 87} the theoretically predicted¹⁵ trend in changes in the volatility of oxychlorides of Mo, W and Sg seems to be doubtful; in addition, there is no proof so far that the experimental¹⁴ sublimation enthalpies [$\Delta_s H^\circ = 114 \pm 11$, 124 ± 10 and $127 \pm 10(21)$ kJ mol⁻¹] can be unambiguously attributed to the compounds MoO₂Cl₂, WO₂Cl₂ and SgO₂Cl₂, respectively. In the gas phase, MoO₂Cl₂, WO₂Cl₂, WOCl₄ and MoOCl₄ mainly have the monomeric structure; however, in the crystalline state the CN increases and these compounds have a polymeric structure. Compounds MO₂Cl₂ (M = Mo, W) readily add neutral oxygen-containing molecules to give complexes MO₂Cl₂ · 2L (L = HCONMe₂, Me₂SO, *etc.*). In the crystalline state, MoO₂Cl₂ · 2L has a monomeric structure while WO₂Cl₂ · 2L has a polymeric structure.⁷⁰ In this connection, a new problem arises since different adsorption mechanisms of Mo and W(Sg) compounds become possible. Probably, a more conservative interpretation of the chemical properties of Sg in the gas phase is required, which takes into account the accuracy of the experimental data. It cannot be ruled out that conclusions drawn by Kratz¹⁵ about the chemical behaviour of Sg should be revised since there is no proof that only one type of compounds, *viz.*, MO₂Cl₂ (M = Mo, W, Sg) is formed in the gas phase.

Group VII. In the gaseous state, the CN of oxychlorides MnO₃Cl, TcO₃Cl and ReO₃Cl equals 4. Transition to the crystalline state leads to the formation of bridging bonds and the CN value increases. This should cause an increase in volatility in the order MnO₃Cl < TcO₃Cl < ReO₃Cl < BhO₃Cl. For TcO₃Cl, ReO₃Cl and BhO₃Cl this sequence was obtained experimentally,¹⁷ which is consistent with recently reported results. For instance, MnO₃Cl undergoes sublimation at –68 °C (see Ref. 70) while the sublimation temperatures of TcO₃Cl, ReO₃Cl and BhO₃Cl are respectively –20–40, 20–80 and 80–180 °C (see Ref. 17).

Group VIII. It does not always happen that the structure of compounds changes upon transition from the gaseous to the crystalline state. Compounds HsO₄ and OsO₄ were predicted⁶⁷ to have a monomeric structure in the crystalline state.

In conclusion, let us compare the results concerning the trend in changes of the volatility of tetrahalides and its interpretations given by different authors.

Earlier results²⁶ obtained from measurements of the temperature dependence of the vapour pressure, $P = f(T)$, show that the

volatility changes in the order $\text{HfCl}_4 > \text{HfBr}_4 > \text{ZrCl}_4 > \text{ZrBr}_4$. According to Türlér,¹⁴ it changes in another manner, namely, $\text{ZrBr}_4 \geq \text{ZrCl}_4 > \text{HfCl}_4 > \text{HfBr}_4$. Some other examples of inconsistency between the results of earlier and recent studies can be given. For instance, it was established that NbBr_5 has higher volatility than TaBr_5 .⁸⁴ These results were shown⁸⁵ to contradict those obtained earlier from the $P = f(T)$ measurements [according to monograph,²⁶ all tantalum halides (TaF_5 , TaCl_5 , TaBr_5) have higher volatilities than the corresponding niobium halides (NbF_5 , NbCl_5 , NbBr_5)].

Seemingly, one can conclude that the results of volatility measurements performed by classical methods [$P = f(T)$] using macroamounts of substances always differ from those obtained in experiments with microamounts. However, sometimes the results of both types of experiments coincide. For instance, TcO_3F was reported⁸⁹ to be more volatile than ReO_3F and a similar trend was revealed for TcO_3Cl and ReO_3Cl .¹⁷ Lower volatility of NbOCl_3 compared to NbCl_5 was reported in both earlier^{26,86} and recent studies.¹⁴

Inconsistency of the results obtained seems to be due not only to the fact that the volatility is measured using macroamounts or microamounts of chemical compounds. The main reason is that the chemical composition of compounds studied in modern experiments can hardly be established, whereas in earlier studies the chemical composition of the gas phase was thoroughly investigated. Earlier, all the compounds formed as well as decomposition products were analysed when performing $P = f(T)$ measurements. For instance, studies of NbOCl_3 were carried out taking into account the presence of accompanying chloride NbCl_5 in the vapour (see Ref. 26).

It is hard to agree with the conclusion¹⁴ that 'relativistic effects are most experimentally pronounced' in the volatilities of TAn halides and oxyhalides determined using correlation with adsorption enthalpies. This conclusion is based on the results of bond covalency calculations in gaseous molecules; however, this parameter is by no means related to volatility. Türlér also stated¹⁴ that 'recent experiments demonstrated that the chemical properties of heavy elements can no longer be predicted based on simple down-the-group extrapolations because of the influence of RE'. At the same time, he postulated the same chemical composition and adsorption mechanism for all compounds of the $4d$ -, $5d$ -, $6d$ -elements within corresponding groups. Thus, these conclusions contradict the initial postulates.

The authors of studies^{14,15} pose illusive problems that are insoluble due to large experimental errors and the above-mentioned postulates. They draw definite conclusions about the influence of RE on the adsorption enthalpy without knowledge of the molecules that are formed on the surface.

Gas-state chemistry of TAn compounds has been successfully progressing in spite of great experimental problems. Probably, one can assume that the $6d$ -elements and the early $4d$ - and $5d$ -homologues can form compounds of analogous chemical composition; however, unambiguous identification of these compounds is impossible.

2. Sublimation enthalpies of TAn tetrahalides

The sublimation enthalpies, $\Delta_s H^\circ(\text{MX}_4)$, of MX_4 ($\text{X} = \text{Cl}, \text{Br}$) compounds were calculated by the author of this review for tetrahalides of the $4d$ -, $5d$ - and $6d$ -elements and actinides as the differences between the standard formation enthalpies of the corresponding compounds in the gaseous and crystalline states. The sublimation enthalpies of TAn compounds are listed in Table 2. Calculations were carried out assuming that the CN for compounds of the $4d$ -, $5d$ - and $6d$ -elements equals 4 in the gaseous state and 6 in the crystalline state. The experimental CN values for AnCl_4 compounds were reported by Brown.⁶¹ Comparison of the calculated and experimental $\Delta_s H^\circ(\text{MX}_4)$ values for compounds of

the $4d$ - and $5d$ -elements allowed us to estimate the error (uncertainty) of calculations at $\pm 15 \text{ kJ mol}^{-1}$. The $\Delta_s H^\circ(\text{MCl}_4)$ values (in kJ mol^{-1}) obtained for tetrachlorides of Group V–VIII elements are listed below:

M (Group IV)	Zr	Hf	Rf
$\Delta_s H^\circ(\text{MCl}_4) / \text{kJ mol}^{-1}$	112	102	106
M (Group V)	Nb	Ta	Db
$\Delta_s H^\circ(\text{MCl}_4) / \text{kJ mol}^{-1}$	128	144	141
M (Group VI)	Mo	W	Sg
$\Delta_s H^\circ(\text{MCl}_4) / \text{kJ mol}^{-1}$	113	160	158
M (Group VII)	Tc	Re	Bh
$\Delta_s H^\circ(\text{MCl}_4) / \text{kJ mol}^{-1}$	112	141	131
M (Group VIII)	Ru	Os	Hs
$\Delta_s H^\circ(\text{MCl}_4) / \text{kJ mol}^{-1}$	109	147	147
M (Group VIII)	Rh	Ir	Mt
$\Delta_s H^\circ(\text{MCl}_4) / \text{kJ mol}^{-1}$	83	115	112

Vertical trends in the changes of the $\Delta_s H^\circ(\text{MCl}_4)$ values are different, namely, $5d \leq 6d < 4d$ for Group IV, $4d < 6d \leq 5d$ for Group V and $4d < 6d \leq 5d$ for Group VI.

As mentioned above, many of the thermodynamic properties of Group IV elements are similar. The sublimation enthalpies of the tetrachlorides of Group IV elements are also close. The calculated sublimation enthalpies of An tetrachlorides (in kJ mol^{-1}) are listed below:

Actinide	Th	Pa	U	Np	Pu	Am	Cm	Bk	Cf
$\Delta_s H^\circ(\text{AnCl}_4)$	249	220	213	168	172	110	128	131	62

The error (uncertainty) of calculations of the $\Delta_s H^\circ(\text{AnCl}_4)$ parameters was estimated at $\pm 20 \text{ kJ mol}^{-1}$ based on their comparison with the corresponding experimental values for An = Th, U and Pu (see Refs 61 and 70).

Two different trends should be recognised when comparing the sublimation enthalpies of tetrachlorides of the d - and $5f$ -elements, namely, the volatility of early An compounds decreases while that of the d -element compounds increase as Z increases. Among the early An compounds, the volatility of tetrachlorides is much higher than that of tetrachlorides of the d -elements (the difference is $\approx 100 \text{ kJ mol}^{-1}$). This difference decreases near the middle of the actinide series and then the volatilities of the tetrachlorides differ insignificantly. The volatility of tetrachlorides of the heavy d - and f -elements decreases with an increase in Z .

The trend in the changes in the volatility of AnCl_4 compounds and tetrachlorides of d -elements (MCl_4) deserves attention. Eichler⁷⁹ suggested a correlation between the $\Delta_s H^\circ(\text{M})$ and $\Delta_s H^\circ(\text{MCl}_4)$ values. We tested this idea using An and AnCl_4 compounds as an example. Comparison of the experimental and calculated $\Delta_s H^\circ(\text{An})$ and $\Delta_s H^\circ(\text{AnCl}_4)$ values along the actinide series confirmed that changes in these parameters follow the same trend. Based on correlation between these values, one can even estimate the $\Delta_s H^\circ(\text{AnCl}_4)$ parameters to an accuracy of $\pm 40 \text{ kJ mol}^{-1}$. This is quite good accuracy for prediction of a trend that reflects a decrease in $\Delta_s H^\circ(\text{AnCl}_4)$ with a decrease in $\Delta_s H^\circ(\text{An})$. In turn, a dramatic decrease in $\Delta_s H^\circ(\text{An})$ on going from early to late An is due to the change in the valence V_{An} in the metallic state.

For the $4d$ -, $5d$ - and $6d$ -transition metals the dependence of $\Delta_s H^\circ(\text{M})$ on $Z(\text{M})$ is nearly parabolic: the $\Delta_s H^\circ(\text{M})$ values increase on going from the early to the middle of the series and then decrease towards the end of the series. It cannot be ruled out that this type of correlation⁷⁹ can be used for the first (Rf–Bh) and second (Bh–¹¹²TAn) half of the TAn series separately.

V. Standard formation enthalpies of gaseous MCl_6^{2-} anions and affinity of tetrachlorides towards chloride ions

Using the formation enthalpies of gaseous MCl_6^{2-} anions, $\Delta_f H^\circ(\text{MCl}_6^{2-}, \text{g})$, one can estimate the affinity of gaseous and crystalline tetrachlorides towards chloride ions and thus compare the trends of changes in these important parameters within the groups of the 4*d*-, 5*d*- and 6*d*-elements. In addition, this allows comparison of the thermodynamic properties of hexachlorides in aqueous solutions:

$$\Delta_f H^\circ(\text{MCl}_6^{2-}, \text{g}) = \Delta_f H^\circ(\text{MCl}_6^{2-}, \text{aq}) - \Delta_h H^\circ(\text{MCl}_6^{2-}, \text{g}) + C, \quad (6)$$

where $\Delta_h H^\circ(\text{MCl}_6^{2-}, \text{g})$ is the hydration enthalpy of the gaseous MCl_6^{2-} anion and C is a constant [$C = -2\Delta_f H^\circ(\text{H}^+, \text{g}) - 2\Delta_h H^\circ(\text{H}^+, \text{g})$].

The formation enthalpy of gaseous anions, $\Delta_f H^\circ(\text{MCl}_6^{2-}, \text{g})$, is the main parameter used for calculating the formation enthalpy of crystalline salts A_2MCl_6 . For the reaction listed below

the $\Delta_f H^\circ(\text{MCl}_6^{2-}, \text{g})$ values can be predicted using the equation

$$\Delta_f H^\circ(\text{MCl}_6^{2-}, \text{g}) = \Delta_s H^\circ(\text{M}) + 4\Delta_f H^\circ(\text{Cl}, \text{g}) + 2\Delta_f H^\circ(\text{Cl}^-, \text{g}) - \left[c - \frac{d}{r(\text{M}-\text{Cl})} \right], \quad (7)$$

where the last term,

$$c - \frac{d}{r(\text{M}-\text{Cl})} = D(\text{MCl}_6^{2-}),$$

is the bond energy in the anion, the coefficients c and d are found from experimental $\Delta_f H^\circ(\text{MCl}_6^{2-}, \text{g})$ values for the 4*d*- and 5*d*-elements; the $r(\text{M}-\text{Cl})$ values for CN = 6 are listed in Table 1.

Using Eqn (7), one can calculate the $D(\text{M}-\text{Cl})$ values for all the 4*d*-, 5*d*- and 6*d*-elements and the $\Delta_f H^\circ(\text{MCl}_6^{2-}, \text{g})$ values for TAn. These calculations were performed by the author of this review for anions of the 4*d*- and 5*d*-elements with an accuracy (uncertainty) of $\pm 15 \text{ kJ mol}^{-1}$. The formation enthalpies $\Delta_f H^\circ(\text{MCl}_6^{2-}, \text{g})$, $\Delta_f H^\circ(\text{MCl}_6^{2-}, \text{aq})$ and $\Delta_h H^\circ(\text{MCl}_6^{2-}, \text{g})$ are listed in Table 2.

It was found that the thermodynamic stability of gaseous MCl_6^{2-} anions and aqua ions ($\text{MCl}_6^{2-}, \text{aq}$) decreases with an increase in $Z(\text{TAn})$, whereas the order of changes in these values within particular groups is as follows: 4*d* < 5*d* < 6*d*. The same trends for the TAn series are also observed for MBr_6^{2-} anions.

The affinity $A(\text{Cl}^-, \text{g})$ of MCl_4 compounds in the crystalline and gaseous states towards two Cl^- ions can be calculated using the following equations

$$A(\text{Cl}^-, \text{g}) = \Delta_f H^\circ(\text{MCl}_6^{2-}, \text{g}) - \Delta_f H^\circ(\text{MCl}_4, \text{g}) - 2\Delta_f H^\circ(\text{Cl}^-, \text{g})$$

and

$$A(\text{Cl}^-, \text{c}) = \Delta_f H^\circ(\text{MCl}_6^{2-}, \text{g}) - \Delta_f H^\circ(\text{MCl}_4, \text{c}) - 2\Delta_f H^\circ(\text{Cl}^-, \text{g}).$$

Both monotonic and nonmonotonic trends in changes in the affinity towards chloride ions within groups were found experimentally for tetrachlorides of *p*- and *d*-elements⁹⁰

In the text below we compare the $A(\text{Cl}^-, \text{g})$ values for tetrachlorides of the 4*d*-, 5*d*- and 6*d*-elements²¹ and actinides.⁹¹ (The values for TiCl_4 and ThCl_4 were taken from Ref. 30).

1. Tetrachlorides of Group IV elements

MCl_4	RfCl_4	ThCl_4	HfCl_4	ZrCl_4	TiCl_4
$A(\text{Cl}^-, \text{g}) / \text{kJ mol}^{-1}$	-286	-287	-284	-190	-76

Thus, the heavy Group IV elements are characterised by nearly equal affinity towards chloride ions, which decreases on going to the early elements of this Group.

2. Tetrachlorides of Group V elements

MCl_4	TaCl_4	DbCl_4	NbCl_4
$A(\text{Cl}^-, \text{g}) / \text{kJ mol}^{-1}$	-266	-246	-169

3. Tetrachlorides of Group VI elements

Inversion of $A(\text{Cl}^-, \text{g})$ values^{30,90} for MoCl_4 and WCl_4 is observed, so that the $A(\text{Cl}^-, \text{g})$ value for UCl_4 (-270 kJ mol^{-1})³⁰ 'completes' the picture:

MCl_4	UCl_4	SgCl_4	MoCl_4	WCl_4
$A(\text{Cl}^-, \text{g}) / \text{kJ mol}^{-1}$	-270	-220	-219	-214

4. Tetrachlorides of Group VII elements

MCl_4	ReCl_4	BhCl_4	TcCl_4
$A(\text{Cl}^-, \text{g}) / \text{kJ mol}^{-1}$	-181	-171	-168

5. Tetrachlorides of Group VIII elements

MCl_4	RuCl_4	OsCl_4	HsCl_4
$A(\text{Cl}^-, \text{g}) / \text{kJ mol}^{-1}$	-223	-209	-175

For actinides NpCl_4 and PuCl_4 , the $A(\text{Cl}^-, \text{g})$ values ($\approx -270 \pm 20 \text{ kJ mol}^{-1}$) are larger than those obtained for the *d*-elements of Groups VII and VIII.

Thus, RfCl_4 , ThCl_4 and HfCl_4 are better acceptors of chloride ions than ZrCl_4 while DbCl_4 and TaCl_4 are better acceptors of chloride ions compared to NbCl_4 . From this point of view, chlorides of Group IV elements (RfCl_4 , ThCl_4 , HfCl_4 , ZrCl_4) are 'better' than the corresponding chlorides of Group V elements (DbCl_4 , PaCl_4 , TaCl_4 , NbCl_4). However, UCl_4 is a better acceptor of chloride ions than SgCl_4 , MoCl_4 and WCl_4 , while NpCl_4 and PuCl_4 are better acceptors of chloride ions compared to BhCl_4 and HsCl_4 .

Some experimental studies on the chemistry of Rf, Db and Sg revealed nonmonotonic changes in the properties in the order 4*d* > 6*d* > 5*d*. 'Prediction of an inverse trend for the properties on going from the 5*d*-elements to the 6*d*-elements' was stated¹⁵ to be a new effect in chemistry. Theoretically, inversion was rationalised by the influence of Re on TAn; however, trends observed experimentally in the chemistry of the 3*d*-, 4*d*-, 5*d*- and 5*f*-elements are not reduced only to inversion. For instance, studying the above-mentioned property, viz. the affinity of tetrahalides towards chloride ions, reveals different trends.

The affinities of crystalline TAn tetrachlorides toward chloride ions, $A(\text{Cl}^-, \text{c})$, are listed in Table 2. They are less negative than the corresponding $A(\text{Cl}^-, \text{g})$ values.

VI. Solution behaviour of transactinides

A series of earlier and more recent studies concerned with the investigation of the nitrate, fluoride and chloride complexes of the *d*-elements including An was reported.^{12, 15, 16, 18, 92-140} Recently, TAn complexes have been studied along with complexes of the 4*d*-, 5*d*- and 5*f*-elements. The behaviour of the compounds of the 4*d*- and 5*d*-elements in aqueous solutions was previously investigated by extraction in a two-phase system; this method has been used so far in studies of the 4*d*-, 5*d*- and 6*d*-elements. For as long as four or five decades, Zr and Hf have been extracted from solutions of mineral acids (HCl , HNO_3 , HClO_4) by tri-*n*-butyl phosphate (TBP), which is also used for extraction of Zr and Hf with Rf additives in order to compare the stability of neutral complexes (RfCl_4)_{aq}, (HfCl_4)_{aq} and (ZrCl_4)_{aq}. Previously, the influence of hydrolysis on the complexation and extraction of Zr^{IV} and Hf^{IV} was studied; recently, Rf^{IV} has been the subject of intensive research.

However, the conclusions drawn from the results of complexation investigations in the earlier and recent studies do not always coincide. In modern literature, the results are rationalised by the influence of RE and by specific features of single-atom experiments. We believe that there are also some other reasons for inconsistency between the recent and previously obtained results. They are discussed below.

1. Anionic chloride complexes

Quaternary ammonium salts are known to be extractants of Zr^{IV} and Hf^{IV} in the form of anions. Early studies revealed inhibition of both hydrolysis and polymerisation in the aqueous phase in the acid medium at a low concentration of cations.¹⁴⁰ These conditions are similar to those of the experiments with TAn (studies of the behaviour of single atoms) and their homologues within groups of the Periodic system. Extraction studies in the two-phase system using quaternary ammonium salts as extractants demonstrated^{92,93} that Rf, Hf and Zr form anionic MCl_6^{2-} complexes which are more stable than AnCl_6^{2-} complexes. It was also revealed⁹⁴ that the RfCl_6^{2-} anion is more stable than the HfCl_6^{2-} and ZrCl_6^{2-} anions. The stability of $\text{MCl}_6^{2-}(\text{aq})$ anions for Group IV elements was shown to increase on going from the light to heavy elements.²¹ For instance, the $\Delta_f H^\circ(\text{MCl}_6^{2-}, \text{aq})$ for Zr, Hf and Rf are -1473 , -1577 and -1637 kJ mol⁻¹, respectively. Thus, the stability of the anions increases in the order $\text{ZrCl}_6^{2-} < \text{HfCl}_6^{2-} < \text{RfCl}_6^{2-}$, which is consistent with the results of earlier studies.^{92–94} It was also found that, despite greater stability of the $\text{MCl}_6^{2-}(\text{aq})$ anions ($\text{M} = \text{TAn}$) compared to the corresponding anions containing the 4d- and 5d-elements, no monotonic increase in stability on going from the 4d-elements to the 6d-elements is observed for all groups of the Periodic table. In particular, a nonmonotonic change in the thermodynamic stability of $\text{MCl}_6^{2-}(\text{g})$ and $\text{MCl}_6^{2-}(\text{aq})$ anions in the order $\text{Sg} > \text{Mo} > \text{W}$ is predicted for the Group VI elements.

2. Neutral chloride complexes

It was pointed out^{15,19} that the results of experimental extraction studies of neutral chloride complexes of Rf from concentrated (8–12 M) HCl solutions in TBP, obtained by different authors^{12, 15, 16, 19, 116, 129–132} contradict one another. It was suggested¹² that the extraction behaviour of Rf is similar to that of Th and Pu rather than Zr and Hf. Recently reported^{19, 130} extractive power sequences corresponding to the changes in stability of neutral complexes are different, that is $\text{Zr} > \text{Rf} > \text{Hf}$ (see Ref. 19) and $\text{Zr} > \text{Hf} > \text{Rf}$ (see Ref. 130). From the standpoint of the ability of the Zr, Hf and Rf complexes to undergo hydrolysis, these elements can be ordered as follows: $\text{Hf} > \text{Rf} > \text{Zr}$ (see Ref. 19). Competition between hydrolysis and formation of inner-sphere complexes during extraction was suggested^{15,19}

It is believed¹⁵ that no extraction of the hydrolysed complexes occurs in the organic phase because of the formation of strong hydrogen bonds between OH^- and H_2O in the aqueous phase.

Generally, earlier experimental studies^{117–120, 133–136} revealed that under specific conditions hydrolysed complexes of both Zr^{IV} and Hf^{IV} are extracted along with non-hydrolysed complexes. It was also shown that hydrolysed compounds of Zr and Hf exist in weak acid solutions only at high concentrations of Zr^{IV} and Hf^{IV}.

It was postulated^{15,19} that the trend in the changes of the effective charges $q(\text{Zr}) > q(\text{Rf}) > q(\text{Hf})$ in gaseous MCl_4 molecules [$q(\text{ZrCl}_4) = 1.18$, $q(\text{RfCl}_4) = 1.07$ and $q(\text{HfCl}_4) = 1.04$] holds for all processes occurring in solution: the ability to undergo hydrolysis ($\text{Hf} > \text{Rf} > \text{Zr}$), the formation of complexes $\text{MCl}_4(\text{aq})$ ($\text{Zr} > \text{Rf} > \text{Hf}$) and extractive power ($\text{Zr} > \text{Rf} > \text{Hf}$). However, the accuracy of quantum-chemical calculations of the effective charges was shown⁹ to be by a factor of 25 to 30 lower than the difference between the charges q on Rf and Hf (± 1 vs. 0.03, respectively) which was used for the interpretation^{15,19} of proc-

esses occurring in solution. Therefore, the use of similar quantum-chemical approaches in this case is incorrect.

Previously,⁷⁰ it was found that HCl solutions contain mainly hydrolysed polymeric outer-sphere complexes $[\text{M}_4(\text{OH})_8(\text{H}_2\text{O})_{16}]\text{Cl}_8$ ($\text{M} = \text{Zr}, \text{Hf}$) stabilised due to the formation of M–M bonds and bridging M–OH–M bonds. These data contradict the hypothesis proposed by Kratz.¹⁵ Structural studies showed that in solution the metal atoms form trimeric and tetrameric clusters that also stabilise the hydrolysed complexes. Hydrolysed monomeric inner-sphere complexes are thermodynamically unstable in the absence of these stabilising factors in concentrated HCl solutions.

Specific conditions of experiments with single TAn atoms exclude the possibility of formation of hydrolysed cluster-like structures $[\text{TAn}_4(\text{OH})_8(\text{H}_2\text{O})_{16}]\text{Cl}_8$. Hydrolysed monomeric outer-sphere complexes $[\text{TAn}(\text{OH})_2(\text{H}_2\text{O})_4]\text{Cl}_2$ are unstable in this case. It should be noted that hydrolysis does not determine the extraction sequence in studies with single TAn atoms in concentrated HCl solutions.

Earlier studies^{133–136, 140} on extraction of Zr^{IV} and Hf^{IV} from concentrated acid solutions modelled modern experimental conditions. Therefore, the results obtained in these works can be used to support the idea proposed in this review that in the TAn chemistry hydrolysis does not determine the extraction sequence. In the above-mentioned studies, microamounts of Zr^{IV} and Hf^{IV} were used to inhibit both hydrolysis and formation of polymeric structures. The formation of simple adducts (MCl_4, aq) · 2 TBP in the organic phase under favourable conditions (concentrated acid solutions at low concentration of Zr^{IV} and Hf^{IV}) was revealed.^{134,135} This suggests that inner-sphere complexes $\text{RfCl}_4(\text{H}_2\text{O})_m$ are mainly formed in solution and that two H_2O molecules are replaced by two TBP molecules in extraction. Kacher *et al.*¹³⁰ studied extraction from 8 M HCl in TBP and experimentally established the extraction sequence $\text{Zr} > \text{Hf} > \text{Rf}$, which is due to the formation of more stable complexes $\text{RfCl}_4(\text{aq})$. Formation of hydrated complexes $\text{Rf}^{\text{IV}}(\text{H}_2\text{O})_x$ was postulated by Bilewicz *et al.*¹²²

One would suggest the existence of hydrated $\text{TAn}^{\text{IV}}(\text{aq})$ complexes [in particular, $\text{Rf}^{\text{IV}}(\text{aq})$] in specific conditions of single-atom experiments and estimate the $\Delta_f H^\circ(\text{TAn}^{\text{IV}}, \text{aq})$ and $\Delta_f H^\circ(\text{MCl}_4, \text{aq})$ values for TAn (see Table 2). For Group IV elements, the stability of $\text{M}^{\text{IV}}(\text{aq})$ and $\text{MCl}_4(\text{aq})$ increases nearly monotonically from Zr to Th: $\Delta_f H^\circ(\text{ZrCl}_4, \text{aq}) = -1139$, $\Delta_f H^\circ(\text{HfCl}_4, \text{aq}) = -1243$, $\Delta_f H^\circ(\text{RfCl}_4, \text{aq}) = -1303$ and $-\Delta_f H^\circ(\text{ThCl}_4, \text{aq}) = -1486$ kJ mol⁻¹.

Estimation of the hydrolysis constant for weak acid solutions seems to be of considerable interest. Gregorich¹² showed that the ability of Rf^{IV} to undergo hydrolysis is similar to that of An^{IV} rather than Hf^{IV} and Zr^{IV}. Using experimental data, it was found that the first hydrolysis constant, $\log K_H$, for the Rf^{IV} ion lies between the $\log K_H$ values of thorium and plutonium ions: $\log K_H(\text{Pu}^{\text{IV}}) > \log K_H(\text{Rf}^{\text{IV}}) > \log K_H(\text{Th}^{\text{IV}})$. A rough qualitative correlation between the ionic radii $r(\text{M}^{\text{IV}}, \text{CN} = 6)$ and $\log K_H(\text{M}^{\text{IV}})$ values, namely, a decrease in $\log K_H(\text{M}^{\text{IV}})$ with an increase in $r(\text{M}^{\text{IV}})$ can be observed:

Ion					Pu ^{IV}	Ce ^{IV}	U ^{IV}	Th ^{IV}
log <i>K</i> _H (M ^{IV})					−0.5	−0.7	−1.5	−3.2
Ion	Zr ^{IV}	Hf ^{IV}	Rf ^{IV}	Pu ^{IV}	Ce ^{IV}	U ^{IV}	Th ^{IV}	
<i>r</i> (M ^{IV})/Å	0.72	0.73	0.78	0.86	0.87	0.89	0.93	

The ionic radius of Rf lies between those of Zr–Hf and An. This reflects a qualitative similarity of Rf to An established in hydrolysis studies.¹²

3. Nitrate complexes

Recently,^{95,96} the stability of nitrate complexes of trivalent lanthanides was studied in the framework of the structural-thermodynamic model. Application of this model to stability studies of nitrate complexes of Zr^{IV}, Hf^{IV}, Rf^{IV}, Ce^{IV} and Th^{IV}

in weak acid solutions revealed that the formation of nitrate aqua complexes $[M(NO_3)_x]^{(4-x)+}$ ($M = \text{Zr, Hf, Rf, Pu, Ce, Th}$; $x = 1-3$) causes a decrease in ΔG° on going from Zr to Th.

Complexes	$\Delta G^\circ[M(NO_3)_x]^{(4-x)+}$					
	Zr	Hf	Rf	Pu	Ce	Th
$[MNO_3]^3+(\text{aq})$	1.4	+0.9	-1.4	-3.8	-4.5	-6.9
$[M(NO_3)_2]^{2+}(\text{aq})$	+6.0	+5.5	+0.4	-5.6	-6.7	-8.7

These results are consistent with those of earlier experimental studies,⁹⁷⁻¹⁰⁵ according to which Rf forms cationic outer-sphere complexes with NO_3^- anions in weak nitrate solutions more readily than Zr and Hf but with somewhat more difficulty than f-elements.

4. Fluoride complexes

In the framework of the same model the author of this review showed that the change in the free energy, ΔG° , in the formation of inner-sphere complexes $[MF]^{3+}(\text{aq})$ corresponds to an insignificant change in the ΔG° energy on going from Zr to Th. The $\Delta G^\circ\{[MF]^{3+}(\text{aq})\}$ values for $M = \text{Zr, Hf, Rf}$ and Th are -42.0 , -40.0 , -38.0 and $-36.0 \text{ kJ mol}^{-1}$, respectively. Therefore, based on the results of calculations of the stability of cationic complexes $[RfF]^{3+}(\text{aq})$, Rf is similar to its analogues and should be placed between Zr-Hf and Th, though the ΔG° values differ insignificantly. These theoretical results correlate with the $\Delta G_{\text{HF}}^\circ$ and $\Delta G_{\text{F}^-}^\circ$ values obtained in earlier experimental studies^{106-112, 139} of the formation of (i) cationic fluoride complexes of Zr, Hf and Th, *e.g.*, $\{[MF]^{3+}[\text{H}^+](\text{aq})\}$, by addition of HF molecule followed by elimination of a proton and (ii) complexes $[MF]^{3+}(\text{aq})$. In the case of formation of inner-sphere complexes $[MF]^{3+}(\text{aq})$, the fluoride ligand can be considered as an undissociated acid or an anion, which leads to different $\Delta G_{\text{HF}}^\circ$ and $\Delta G_{\text{F}^-}^\circ$ values for the same M (the difference is 5 to 10 kJ mol^{-1}). According to Tananaev,¹⁰⁶ the free energy changes by -34 kJ mol^{-1} upon the formation of the $[\text{ThF}]^{3+}(\text{aq})$ complex, whereas Ahrlund¹³⁹ reported a value of -44 kJ mol^{-1} . Based on these results, one can conclude that stabilities of the cationic complexes $[\text{ThF}]^{3+}(\text{aq})$, $[\text{HfF}]^{3+}(\text{aq})$ and $[\text{ZrF}]^{3+}(\text{aq})$ differ insignificantly. The experimental¹¹³⁻¹¹⁵ and calculated^{4, 21} stabilities (β) of the actinide complexes $[\text{AnF}]^{3+}(\text{aq})$ or $[\text{AnF}_2]^{2+}(\text{aq})$ suggest greater similarity of Rf to its analogues within the group (Hf and Zr) rather than to actinides:

$$\log \beta_2\{[\text{RfF}_2]^{2+}(\text{aq})\} = 7.7; \log \beta_2\{[\text{HfF}_2]^{2+}(\text{aq})\} = 7.8;$$

$$\log \beta_2\{[\text{PaF}_2]^{2+}(\text{aq})\} = 8.3; \log \beta_2\{[\text{UF}_2]^{2+}(\text{aq})\} = 12.4,$$

where β_2 is the stability constant of the complex containing two ligands.

Another conclusion was drawn from the sorption studies of Rf, Hf, Zr and Th in mixed HNO_3 -HF solutions on both cation and anion exchange columns.^{16, 18, 116} In the formation of fluoride complexes, Rf behaves in a different manner compared to Hf and Zr and is more similar to Th in accord with the decreasing stability of the complexes, $\text{Zr}^{\text{IV}} \approx \text{Hf}^{\text{IV}} > \text{Rf}^{\text{IV}} > \text{Th}^{\text{IV}}$. The trend was theoretically explained by the fact that F^- is a hard anion and better (stronger) interacts with small cations (Zr^{IV} and Hf^{IV}), whereas the behaviour of Rf is a direct consequence of RE.¹⁸

We believe that discussion of manifestations of RE in complexes of unknown chemical composition and type (fluoride, nitrate or mixed fluoride nitrate, inner-sphere or outer-sphere, *etc.*) is inadmissible. These statements discredit the basic idea of manifestation of relativism in chemical properties.

Based on the results of earlier studies,^{107, 117-120, 133-138} one can conclude that mixed rather than simple fluoride complexes are formed under experimental conditions reported by Shädel *et al.*^{16, 18, 116} A salient feature of the chemistry of Hf^{IV} and Zr^{IV} is a synergistic effect in the extraction of these elements from

solutions of two inorganic acids (HNO_3 -HF, HNO_3 -HCl, HNO_3 - HClO_4), that is, obtaining high separation coefficients of Zr^{IV} and Hf^{IV} as a result of the formation of mixed complexes upon addition of the second acid and variation of its concentration.^{99, 117-120, 133-139} The synergistic effect is due to the formation of the Zr^{IV} and Hf^{IV} complexes of different composition, on which lies the basis of the process of their separation by extraction from a mixture of two inorganic acids. Earlier studies of mixed complexes, *e.g.*, $\text{MF}_x(\text{NO}_3)_{4-x}$, revealed changes in the number x (*i.e.*, the F^-/NO_3^- ratio) depending on the metal (Zr^{IV} , Hf^{IV} , Th^{IV}). The existence of the complexes $\text{ZrF}(\text{NO}_3)_3$ (see Ref. 117), $\text{HfF}_2(\text{ClO}_4)_2$ (see Ref. 107), $\text{ZrCl}_{4-x}(\text{NO}_3)_x$ (see Ref. 118), $\text{M}(\text{NO}_3)_x(\text{ClO}_4)_{4-x}$ ($M = \text{Zr, Hf}$) (see Refs 119, 136-138), $\text{HfCl}_x(\text{ClO}_4)_{4-x}$ (see Refs 136-138), $\text{ZrCl}_5\text{NO}_3^{2-}$ (see Ref. 136), *etc.*, was established. Thus, comparison of earlier results on the complexation and extraction of Zr^{IV} , Hf^{IV} and Th^{IV} with recently obtained data for Rf^{IV} , Zr^{IV} , Hf^{IV} and Th^{IV} provides strong evidence that the authors of study¹⁸ did not take into account the results of earlier studies and were based on the assumptions that (i) NO_3^- anions are not involved in complexation and (ii) Zr^{IV} , Hf^{IV} , Th^{IV} and Rf^{IV} form the same type of fluoride complexes for all cations, which seems to be doubtful.¹³³⁻¹³⁹

The results of study¹⁸ were recently revised¹¹⁶ and the authors agreed that the NO_3^- anion may be involved in complex formation. However, their major conclusion that Rh is similar to Th and different from Zr and Hf in the formation of fluoride complexes remained unchanged.

The structure of neutral crystalline complexes $\text{MF}_4(\text{H}_2\text{O})_3$ ($M = \text{Hf, Zr}$) was studied by X-ray diffraction analysis.^{120, 121} Complex $\text{ZrF}_4(\text{H}_2\text{O})_3$ has a dimeric structure while complex $\text{HfF}_4(\text{H}_2\text{O})_3$ has a polymeric structure. For both complexes, the CN value equals 8 due to the formation of bridging bonds. The $\text{ZrF}_4(\text{H}_2\text{O})_3$ molecule has three $\text{Zr}-\text{OH}_2$ bonds and five $\text{Zr}-\text{F}$ bonds while the $\text{HfF}_4(\text{H}_2\text{O})_3$ molecule containing one molecule of bound water has six $\text{Hf}-\text{F}$ bonds and two $\text{Hf}-\text{OH}_2$ bonds. As can be seen, Hf exhibits higher affinity towards F^- than Zr. One can assume that this trend will be more pronounced on going to Rf. This is confirmed by the formation enthalpies, $\Delta_f H^\circ(\text{MF}_4, \text{c})$, of crystalline compounds, which decrease on going to heavier elements.

$\text{MF}_4(\text{c})$	ZrF_4	HfF_4	RfF_4
$\Delta_f H^\circ / \text{kJ mol}^{-1}$	-1912	-1930	-1997

The reliably proven¹²³⁻¹²⁷ existence of anionic form $[\text{RfF}_6]^{2-}$ is in good agreement with the chemical properties of the 4d- and 5d-elements. At the same time, it is known that, despite the predominance of the complexes $[\text{HfF}_6]^{2-}$ in acidic aqueous solutions with the HF : Hf ratio greater than 1, changes in this ratio can also result in other anionic forms. In this connection, it is pertinent to remember the study by Tananaev and Guzeva¹²⁸ who showed that the thermal stability of alkali metal salts of Zr and Hf changes in the order $[\text{MF}_7]^{3-} > [\text{MF}_6]^{2-} > [\text{MF}_5]^-$. In addition, Varga and Hume¹⁰⁷ revealed instability of $[\text{HfF}_5]^{2-}$ in solution. Taken together, these facts do not exclude the possibility of formation of not only $[\text{RfF}_6]^{2-}$, but also $[\text{RfF}_7]^{3-}$ in solution; however, this is only a hypothesis proposed by the author of this review.

VII. Standard formation enthalpies, $\Delta_f H^\circ(\text{A}_2\text{MCl}_6)$, of crystalline compounds

Standard formation enthalpies of crystalline compounds A_2MCl_6 with K^+ , Rb^+ and Cs^+ cations were obtained for many 4d- and 5d-elements.^{22, 26, 29, 30, 31, 49-55} For instance, the $\Delta_f H^\circ(\text{K}_2\text{MCl}_6, \text{c})$ values for K_2MCl_6 salts are known for all 5d-metals from Hf to Pt and for almost all 4d-metals. For the 3d-, 4d- and 5d-elements, the standard formation enthalpies of gaseous MCl_6^{2-} ions and crystalline salts K_2MCl_6 are linearly related. Knowing the standard formation enthalpies of gaseous MCl_6^{2-} ions for the 4d-, 5d- and 6d-elements and the experimental $\Delta_f H^\circ(\text{K}_2\text{MCl}_6, \text{c})$ values for the

4d- and 5d-elements, one can calculate the $\Delta_f H^\circ(\text{K}_2\text{MCl}_6, \text{c})$ parameters for TAn with an accuracy of $\pm 15 \text{ kJ mol}^{-1}$. The experimental $\Delta_f H^\circ(\text{K}_2\text{MCl}_6, \text{c})$, $\Delta_f H^\circ(\text{Rb}_2\text{MCl}_6, \text{c})$ and $\Delta_f H^\circ(\text{Cs}_2\text{MCl}_6, \text{c})$ values for compounds of the 3d-, 4d- and 5d-elements are related by simple relationships that can be used for calculating the $\Delta_f H^\circ$ values for compounds of the 6d-elements ($\Delta_f H^\circ$ are given in kJ mol^{-1})

$$\Delta_f H^\circ(\text{Rb}_2\text{MCl}_6, \text{c}) = 1.014 \Delta_f H^\circ(\text{K}_2\text{MCl}_6, \text{c}),$$

$$\Delta_f H^\circ(\text{Cs}_2\text{MCl}_6, \text{c}) = 0.983 \Delta_f H^\circ(\text{K}_2\text{MCl}_6, \text{c}) - 83.$$

The calculated formation enthalpies, $\Delta_f H^\circ(\text{K}_2\text{MCl}_6, \text{c})$, $\Delta_f H^\circ(\text{Rb}_2\text{MCl}_6, \text{c})$ and $\Delta_f H^\circ(\text{Cs}_2\text{MCl}_6, \text{c})$ of transactinide salts are listed in Table 2. The crystal lattice energies, $U(\text{A}_2\text{MCl}_6, \text{c})$, and the lattice constants, $a(\text{A}_2\text{MCl}_6, \text{c})$, are known to be linearly related.³⁰ Therefore, knowledge of the $\Delta_f H^\circ(\text{A}_2\text{MCl}_6, \text{c})$ values allows calculations of $U(\text{A}_2\text{MCl}_6, \text{c})$ and lattice constants $a(\text{A}_2\text{MCl}_6, \text{c})$ for transactinide salts with K^+ , Rb^+ and Cs^+ cations (see Table 1).

VIII. Conclusion

In this review we have shown that TAn possess dual properties, which can be similar to those of both the 4d- and 5d-elements and (in some instances) the early actinides. However, this similarity becomes less pronounced with an increase in $Z(\text{An})$ or $Z(\text{TAn})$. The volatility of the tetrahalides of early actinides becomes lower as the atomic number of An increases; however, it increases for compounds of the 4d- and 5d-elements. The greatest similarity is observed for the thermodynamic properties of Group IV elements (Zr–Hf–Rf–Th). The thermodynamic stability of halide compounds of tetravalent transactinides in the gaseous and crystalline states and in aqueous solution decreases with an increase in $Z(\text{TAn})$; however, it increases within particular groups of the Periodic table on going from the light to heavy elements.

A possible reason for the inconsistency between the results of earlier (1960–1970) and more recent (1990–2000) studies of the volatility of halides and oxyhalides of the d-elements and of extraction, hydrolysis and complexation in solution is that in transactinide chemistry the experimental data are interpreted in the framework of the hypothesis that RE cause changes in the chemical properties down the groups of the Periodic system. However, the influence of RE on the chemical properties of transactinides is to a great extent compensated by actinide contraction. It should be emphasised that no experimental data on the properties of TAn, which could be unambiguously interpreted as a manifestation of relativistic effects, have been reported so far.

Yet another reason for the above-mentioned inconsistency is the lack of methods that allow identification of the chemical composition of transactinide compounds formed. Single-atom experiments are carried out assuming complete analogy between the chemical properties of the 4d-, 5d- and 6d-elements within the groups of the Periodic system, i.e., the same type of compounds of the same composition (this is not always true). In the early studies the chemical composition of newly formed compounds of the 4d- and 5d-elements was thoroughly analysed and, as a rule, established.

Abstract. The published data on bimolecular processes of radical generation in chain degradation, polymerisation, oxidation and halogenation reactions of organic compounds are systematised and analysed within the framework of the parabolic model of homolytic bimolecular reactions. The specific features of these highly endothermic reactions are discussed with a special emphasis on their striking similarity to radical abstraction processes with identical reaction centres in the transition state. The feasibility of theoretical evaluation of the activation energies and the rate constants of bimolecular reactions in radical generation is demonstrated. The bibliography includes 86 references.

I. Introduction

Initiators, light and penetrating radiation are widely used to induce chain reactions. However, it is known that chain reactions can also be generated in the absence of initiating factors. Very often, the role of free radical sources in chain degradation, oxidation, halogenation and polymerisation reactions is played by various bimolecular processes. This idea was first suggested by N N Semenov.¹ Studies of autoinitiation mechanisms of liquid-phase oxidation of hydrocarbons have shown that various bimolecular reactions of hydroperoxides with the original hydrocarbon and its oxidation products, such as alcohols, ketones and acids occur in the reaction medium. The rates of such reactions are several orders of magnitude higher than the rate of the homolytic cleavage of the weak O–O bond in ROOH.^{2–8} In the absence of the hydroperoxide, free radicals are formed in bi- and trimolecular reactions of oxygen with hydrocarbons involving the C–H and C=C bonds.^{2, 3, 5–10}

Generation of radicals by bimolecular reactions is largely endothermic and proceeds at a very slow rate. The methods for the study of their kinetics involve the use of free radical acceptors, inhibitors (in the case of oxidation reactions) or the rate of determination of the chain reactions triggered by bimolecular processes.^{2, 7, 9} If a chain reaction does not take place in the system under study, the rate of radical generation is judged upon by the decrement of one of reaction components. Studies of such reactions present difficulties which are not always overcome. The rates of such reactions are usually low because of high activation energies. In many cases, generation of radicals occurs in parallel by several bimolecular reactions and the rate of only one of them (as a rule, the fastest reaction) can be measured. Therefore, theoretical evaluation of rate constants for such reactions is an urgent task.

As bimolecular processes of radical formation are endothermic, the determination of their activation energies E is seemingly easy. The corresponding equation may appear as:

$$E \approx \Delta H,$$

where ΔH is the enthalpy of the reaction.¹ However, this condition is not always fulfilled. Strictly speaking, for endothermic reactions:

$$E = \Delta H + \Delta E,$$

the increment ΔE can be large enough ($\sim 10 \text{ kJ mol}^{-1}$) even for highly endothermic reactions ($\Delta H \geq 150 \text{ kJ mol}^{-1}$). The determination of the coefficient A (the pre-exponential factor) in the Arrhenius equation:

$$E = RT \ln \frac{A}{k},$$

which was found to be enthalpy-dependent, also presents a problem.¹¹ These difficulties were successfully overcome in the framework of the parabolic model of a bimolecular homolytic reaction. Earlier, we used this model for determining the activation energies of radical abstraction and addition reactions.^{12, 13} In more recent experiments, we used the parabolic model for the description of a vast variety of bimolecular homolytic reactions.^{14–28} The present review is devoted to the analysis and comparison of experimental and calculated data (e.g., activation

E T Denisov, T G Denisova Institute of Problems of Chemical Physics, Russian Academy of Sciences, 142432 Chernogolovka, Moscow Region. Fax (7-096) 524 96 76. Tel. (7-096) 252 19 14. E-mail: edenisov@icp.ac.ru (E T Denisov), denisova@icp.ac.ru (T G Denisova)

energies and rate constants) for generation of radicals by homolytic bimolecular reactions.

II. Classification of bimolecular reactions in radical generation

A bimolecular initiation reaction can dominate over the monomolecular decomposition of the reagent molecule involving the weakest bond, if $\Delta H < D_{\min}$ (where $D_{\min}$ is the bond stability).

In many bimolecular reactions, the energy of cleavage of a weak bond is compensated for by the energy of formation of a rather stable bond.

All known bimolecular homolytic reactions may be divided into three types:

1. Abstraction reactions of hydrogen or halogen (X) from the RH or the YX molecule by an acceptor molecule possessing a multiple bond (C=C, C $\equiv$ N, C=O, O=O, etc.), e.g.:

In the first reaction, the cleavage of the C–H bond is partly compensated for by the formation of the O–H bond in the hydroperoxide radical formed. For example, for the reaction where RH is cumene for which $D(\text{C–H}) = 335 \text{ kJ mol}^{-1}$ (D is the bond strength), the enthalpy is equal to 135 kJ mol^{-1} .

$$\Delta H = D(\text{C–H}) - D(\text{H–O}_2) = 355 - 220 = 135 \text{ kJ mol}^{-1}.$$

At the same time, the energy of the weakest bond C–CH₃ in cumene is equal to 300 kJ mol^{-1} . Hence, $\Delta H \ll D_{\min}$.

The X–X (or Y–X) bonds in halogen molecules are weak, while the C–X bonds in halide molecules are strong. Thus the bond energies of F₂, ICl and Cl₂ molecules are equal to 159, 211 and 243 kJ mol^{-1} , respectively. The enthalpy of the reaction:

is low and is sometimes negative. Therefore, these reactions proceed rather rapidly. The role of halogen atom acceptors in such reactions is played by alkenes, alkynes, imines, nitriles and nitro compounds.

2. Dissociative abstraction reactions in which the cleavage of two bonds is accompanied by the formation of a molecule with a strong bond, e.g.:

Since the F–F bond is weak (159 kJ mol^{-1}) and the H–F bond is very strong (570 kJ mol^{-1}), for many hydrocarbons with $D(\text{C–H}) < 411 \text{ kJ mol}^{-1}$ this reaction is exothermic.

A similar situation is typical of bimolecular reactions involving hydrogen peroxide and hydroperoxides:

In these reactions, the energies of cleavage of two bonds (R–H and R'O–OH) are largely compensated for by the energy of formation of a stable O–H bond in the H₂O molecule (498 kJ mol^{-1}); in many cases, the change in the reaction enthalpy:

$$\Delta H = D(\text{O–H}) + D(\text{O–O}) - 498$$

is less pronounced than the change in the dissociation energy of the least stable O–O bond in the hydroperoxide molecule.

3. Reactions of biradical generation. The $\sigma\text{–C–C}$ bond of hydrocarbons is always stronger than the $\pi\text{–C–C}$ bond. For example, for the ethane molecule $D(\sigma\text{–C–C}) = 378 \text{ kJ mol}^{-1}$, whereas for the ethylene molecule $D(\pi\text{–C–C}) = 270 \text{ kJ mol}^{-1}$. In the presence of substituents at the double bond of a hydrocarbon molecule, a biradical is formed with relatively low energy consumption, e.g.:

Chain reactions are initiated in the presence of active reagents, such as oxygen or a monomer (e.g., in polymerisation reactions).

Thus, the bimolecular reactions in radical generation are rather diverse: they involve C–H, N–H, O–H and S–H bonds of saturated molecules, on the one hand, and O₂, O₃, F₂, Cl₂ and other halogen-containing molecules, peroxides, disulfides and molecules containing multiple bonds, on the other hand.

III. The parabolic model of a bimolecular reaction

Generation of radicals by a bimolecular homolytic reaction, such as:

is interpreted within the framework of the parabolic model^{12, 13} as a result of intersection of two parabolic potential curves plotted on the coordinates of the amplitude of the stretching vibration of atoms involved in bond formation *versus* potential energy. The main parameters of this reaction are as follows:

1. Reaction enthalpy ΔH_e which includes the difference between the zero-point vibrational energies of the reacting bonds:

$$\Delta H_e = D_i - D_f + 0.5hN_A(v_i - v_f), \quad (1)$$

where D_i and D_f are dissociation energies and v_i and v_f are the stretching vibration frequencies of the bond that is cleaved (i) and of the bond that is formed (f), respectively, h is Planck's constant and N_A is Avogadro's number.

2. Activation energy E_e which includes the zero-point vibrational energy of the bond being attacked:

$$E_e = E + 0.5(hN_A v_i - RT), \quad (2)$$

where E is the experimental activation energy.

3. Distance r_e which is equal to the sum of the amplitudes of stretching vibrations of the reacting bonds in the transition state.

4. Dynamic characteristics of the bond that is cleaved (b_i) and that is formed (b_f):

$$b_i = \pi v_i (2\mu_i)^{1/2},$$

$$b_f = \pi v_f (2\mu_f)^{1/2},$$

where μ_i and μ_f are the reduced masses of the atoms forming these bonds and $2b^2$ is the force constant of the bond.

The above parameters are related to one another by the following expression:

$$br_e = \alpha \sqrt{E_e - \Delta H_e} + \sqrt{E_e}, \quad (3)$$

where $\alpha = b_i/b_f$, $b = b_i$.

By using the parameter br_e , it is possible to calculate the activation energy of the thermally neutral reaction E_{e0} :

$$\sqrt{E_{e0}} = \frac{br_e}{1 + \alpha}, \quad (4)$$

which is characteristic of the whole class of reactions with $br_e = \text{const}$.

As a rule, the coefficient A in the Arrhenius equation (calculated in relation to one reacting bond) for the same class of reactions is the same, which makes it possible to calculate E from the rate constant k :

$$E = RT \ln \left(n \frac{A}{k} \right), \quad (5)$$

where n is the number of reacting bonds.

Since in all elementary reactions $E > 0$, relation (3) is fulfilled for $\Delta H_e > \Delta H_{e \min}$. If $\Delta H_e < \Delta H_{e \min}$, the activation energy E is very small and is equal to $0.5 RT$.¹¹

In the case of highly endothermic reactions, the activation energy and the enthalpy are very close.¹¹ According to the parabolic model, for $\Delta H_e > \Delta H_{e \max}$:

$$E = \Delta H + 0.5 RT. \quad (6)$$

The threshold value of $\Delta H_{e \max}$ is related to parameters which characterise a certain class of reactions by the following expression:¹²

$$\Delta H_{e \max} = (br_e)^2 - 2\alpha br_e \sqrt{0.5hN_A v_f} + 0.5hN_A v_f (\alpha^2 - 1). \quad (7)$$

If reactions with high enthalpy ($\Delta H_e > \Delta H_{e \max}$) belong to the same class, the pre-exponential factor A is not constant, but rather is a function of reaction enthalpy. Within the framework of the parabolic model, this dependence appears as:¹¹

$$A = A_0 \left[1 + \beta \left(\sqrt{\Delta H_e} - \sqrt{\Delta H_{e \max}} \right) \right]^2, \quad (8)$$

where $\beta = 1.3$.

If a reaction belongs to a class described by kinetic parameters (A , r_e , b , b_i , b_f , α , $1/2hN_A v_i$, $1/2hN_A v_f$), its rate constant and activation energy can be calculated from the formula:

$$k = n A_0 \exp \left(-\frac{E}{RT} \right), \quad (9)$$

as well as from the ratio given below.¹²

For reactions with $\Delta H_e < \Delta H_{e \max}$:

for $\alpha = 1$:

$$\sqrt{E_e} = \frac{br_e}{2} + \frac{\Delta H_e}{2br_e}, \quad (10)$$

for $\alpha \neq 1$:

$$\sqrt{E_e} = \frac{br_e}{1 - \alpha^2} \left[1 - \alpha \sqrt{1 - \frac{1 - \alpha^2}{(br_e)^2} \Delta H_e} \right], \quad (11)$$

for low values of α , where $\Delta H_e(1 - \alpha^2) \ll (br_e)^2$:

$$\sqrt{E_e} = \frac{br_e}{1 + \alpha} + \frac{\alpha \Delta H_e}{2br_e}. \quad (12)$$

For reactions with $\Delta H_e > \Delta H_{e \max}$, the activation energy is calculated by the formula (6) and the rate constant is calculated by the formula (13) taking into account the dependence of the pre-exponential factor on ΔH_e :

$$k = A_0 e^{-1/2} \left[1 + \beta \left(\sqrt{\Delta H_e} - \sqrt{\Delta H_{e \max}} \right) \right]^2 \exp \left(-\frac{\Delta H}{RT} \right). \quad (13)$$

The calculations of activation energies and rate constants of bimolecular homolytic reactions should take into consideration the following factors.

1. If the enthalpy of the reaction is such that $\Delta H_e < \Delta H_{e \max}$, then $E > \Delta H$ and the activation energy should be calculated by one of the formulae (10)–(12). In its turn, the threshold value of $\Delta H_{e \max}$ depends on parameters α , r_e , b and the zero-point vibrational energy of the bond that is cleaved. It should be borne in mind that the threshold value of $\Delta H_{e \max}$ varies widely for different classes of reactions. The dependencies of the difference $E - \Delta H$ on ΔH for four classes of reactions are shown in Fig. 1. As can be seen, in the range where $E > \Delta H$ on going from $\text{XCl} + \text{RH}$ to $\text{ROOH} + \text{RH}$ reactions, the enthalpies of the reactions vary from ~ 20 to 250 kJ mol^{-1} , i.e., by more than one order of magnitude. Consequently, before one uses a simple formula (6) for the calculation of activation energies, it is necessary to be sure that $\Delta H_e > \Delta H_{e \max}$. However, in this case the pre-exponential factor in the Arrhenius plot depends on ΔH (i.e., $A \neq \text{const}$) due to the intersection of potential curves of the reacting bonds at a

Figure 1. The dependence of the difference $E - \Delta H$ on the enthalpy ΔH for the reactions $\text{XCl} + \text{RH}$ (1), $\text{XF} + \text{RH}$ (2), $\text{RCH}=\text{CH}_2 + \text{RH}$ (3), $\text{ROOH} + \text{RH}$ (4).

distance exceeding r_e , and the dependence is described by the formula (8), while the rate constant is described by the formula (13).

2. Bimolecular reactions with cleavage of two bonds differ from those in which only one bond is cleaved. In the latter case, the probability of concentration of the activation energy on one bond is expressed by the exponential function $\exp(-E/RT)$. If two bonds are cleaved, the probability of simultaneous concentration of energy on the both cleavable bonds manifests a more complex dependence on E . The rate constant for such a reaction is expressed by the formula:²⁹

$$k = A_0 \left(\frac{2RT}{\pi E} \right)^{1/2} \exp \left(-\frac{E}{RT} \right). \quad (14)$$

Within the framework of the parabolic model, the activation energy for the above-described case can be presented in an alternative way. For example, the activation energy of the reaction of RH with F_2 can be characterised by the coordinate of the point of intersection of the potential curves for $\text{R}-\text{H}$ and $\text{H}-\text{F}$ or $\text{F}-\text{F}$ and $\text{H}-\text{F}$ bonds. Naturally, the kinetic characteristics of the same reaction will be different. Preference in such cases will be given to the variant where both bonds (i.e., that is cleaved and that is formed) involve a light atom.

3. The kinetic parameters, e.g., br_e , can be determined from the experimental data only for reactions where $\Delta H_e < \Delta H_{e \max}$. Unfortunately, such reactions are very few in number. It is noteworthy that bimolecular radical and molecular reactions are similar.^{25–27} If such reactions have identical reaction centres, their main characteristics (α , br_e , E_{e0} and $0.5hN_A v$) are also identical or similar. For example, the reactions:

are characterised by the same set of parameters:^{12,14} $br_e = 13.61 \text{ (kJ mol}^{-1}\text{)}^{1/2}$, $\alpha = 0.814$, $0.5hN_A v = 17.4 \text{ kJ mol}^{-1}$, $0.5hN_A(v_i - v_f) = -3.8 \text{ kJ mol}^{-1}$ and $E_{e0} = 56.3 \text{ kJ mol}^{-1}$. This makes it possible to estimate the activation energies and rate constants for homolytic reactions of the 'molecule + molecule' type by using the known parameters of reactions (with an analogous reaction centre) of the 'radical + molecule' type. Examples of generation of radicals by such bimolecular reactions and their analogues, viz., radical reactions characterised by the same set of parameters, are given below.

IV. Retrodisproportionation reactions

Disproportionation of alkyl radicals proceeds at a very fast rate which is close to the rate of molecular collisions in the gas phase and the diffusion-controlled rate in the liquid phase.³⁰ Disproportionation is a highly exothermic reaction, *e.g.*, ΔH for the disproportionation of ethyl radicals:

is equal to -270 kJ mol^{-1} . The reverse reaction, *i.e.*, retrodisproportionation:

represents an endothermic process which proceeds at a very slow rate. The retrodisproportionation reactions investigated in great detail by Ruchardt *et al.*^{10, 31–37} play a prominent role in chain processes of hydrocarbon cracking, polymerisation and oxidation. The activation energies and enthalpies of such reactions were found to be very similar. The attack of an alkene on the weak C–H bond of the hydrocarbon playing the role of a hydrogen donor is consistent with the kinetic isotope effect.³¹ The solvent polarity weakly affects the rate constant for this reaction. However, the rates of reactions in which the role of a hydrogen acceptor is played by benzoquinone strongly depend on the solvent polarity. The values of experimentally determined rate constants and activation energies for reactions of alkenes and benzoquinone with 9,10-dihydroanthracene are given in Table 1.

The structures of reaction centres of retrodisproportionation and radical abstraction reactions are similar: $\text{C}=\text{C}\cdots\text{H}\cdots\text{R}$ and $-\text{C}\cdots\text{H}\cdots\text{R}$. This circumstance was taken into consideration in the calculations based on the use of the parabolic model.¹⁵ The kinetic and thermodynamic parameters of the corresponding disproportionation reactions are given in Tables 2 and 3.[†]

[†] The alkyl, allyl and benzyl radicals in the Tables are designated as R^1 , R^2 and R^3 , respectively.

Table 1. The activation energies and rate constants for the retrodisproportionation reaction of 9,10-dihydroanthracene with alkenes (PhOPh is used as solvent).^{31–37}

Alkene	T/K	E	$\log A$	$k(550 \text{ K})$
Styrene	553–583	111.5	6.60	1.02×10^{-4}

2,3-Dichloro-5,6-dicyano-1,4-benzoquinone ^a	298–338	51.56	7.11	1.62×10^2
2,3-Dichloro-5,6-dicyano-1,4-benzoquinone ^b	298–338	37.4	5.11	36.2
2,3-Dichloro-5,6-dicyano-1,4-benzoquinone ^c	298–338	43.6	6.28	1.37×10^2

Note. Hereinafter, the dimensionalities of the activation energies, the pre-exponential factor A and the rate constants are kJ mol^{-1} , $\text{litre mol}^{-1} \text{ s}^{-1}$ and $\text{litre mol}^{-1} \text{ s}^{-1}$. ^a In dioxane; ^b in acetonitrile; ^c in acetic acid, respectively.

The enthalpies for the retrodisproportionation reactions involving hydrogen acceptors, such as ethylene, but-1-ene, cyclohexa-1,3-diene, *etc.*, are listed in Table 4; the calculated rate constants and activation energies of retrodisproportionation reactions involving styrene and benzoquinone as hydrogen acceptors are given in Tables 5 and 6. The results of these calculations are in good agreement with the experimental data. For example, the calculated and experimental values of $k(550 \text{ K})$ for the retrodisproportionation of styrene with 9,10-dihydroanthracene are equal to 9.2×10^{-5} and $1.0 \times 10^{-4} \text{ litre mol}^{-1} \text{ s}^{-1}$, respectively.³¹

V. Thermal generation of radicals in monomers

Radical polymerisation reactions are triggered by various processes. However, in some cases spontaneous polymerisation of monomers occurs without initiation.^{38,39} Using spontaneous polymerisation of styrene as an example, Mayo⁴⁰ has shown that the rate of thermal generation of radicals is directly proportional to the third power of the styrene concentration. More recent findings suggest that thermal polymerisation is initiated by mono- rather than by biradicals. Two mechanisms of thermal initiation of radical polymerisation are described below.³⁹

1. The interaction of two monomeric molecules yields a biradical, *e.g.*:

$\text{PhMeC}=\text{CH}_2 + \text{CH}_2=\text{CMePh} \rightleftharpoons \text{PhMeC}^\bullet\text{CH}_2\text{CH}_2\text{C}^\bullet\text{MePh}$, which further enters into a radical abstraction reaction with the monomeric molecule:

Each of the radicals formed initiates the growth of the macromolecule.

2. The biradical formed in the course of a reversible bimolecular reaction enters into a reaction of hydrogen transfer from the radical to the monomer:

The rate of radical generation for both reaction mechanisms is determined from the following ratio:

$$v_i = kK[\text{CH}_2=\text{CHR}]^3, \quad (15)$$

where k is the rate constant for the reaction of the biradical with the monomer and K is the equilibrium constant of the reversible reaction of biradical formation.

The values of the constant K (ΔH and ΔS values are taken from the database⁴¹) and the dissociation energies of the C–H bonds (see Ref. 42) calculated by the equation:

$$-RT \ln K = \Delta H - T\Delta S \quad (16)$$

are given in Table 7; the values of E and k for bimolecular radical reactions established with the use of the parabolic model and the parameters listed in Table 2 are given in Tables 8 and 9.

Table 7. The enthalpy, entropy, Gibbs potential (ΔG /kJ mol^{−1}) and equilibrium constant of the reaction $2\text{RCH}=\text{CH}_2 \longrightarrow \text{RC}^{\bullet}\text{HCH}_2\text{CH}_2\text{C}^{\bullet}\text{HR}$.^{41, 42}

VI. Reactions involving halogen molecules

Molecular fluorine reacts with organic molecules at very fast rates even at low (200 K and lower) temperatures.^{1, 39, 43} High reactivity of the fluorine molecule is due to the low degree of binding between the atoms [$D(\text{F}-\text{F}) = 159 \text{ kJ mol}^{-1}$], whereas the C–F and F–H bonds in the fluorination products are strong [$D(\text{F}-\text{H}) = 570 \text{ kJ mol}^{-1}$ and $D(\text{H}_3\text{C}-\text{F}) = 464 \text{ kJ mol}^{-1}$].⁴⁴ Therefore, radical generation reactions involving molecular fluorine are exothermic and proceed at fast rates. Two radical generation reactions involving fluorine were predicted by N N Semenov¹ and are widely known.

One of them includes abstraction of the hydrogen atom from the C–H bond by the fluorine molecule resulting in the formation of the HF molecule and the fluorine atom:⁴⁵

This reaction is exothermic even for isobutane [$D(\text{R}-\text{H}) = 400 \text{ kJ mol}^{-1}$]; its enthalpy is $\Delta H = 400 + 159 - 570 = -11 \text{ kJ mol}^{-1}$.

Other fluorine-containing molecules react analogously:

The values of enthalpies for such reactions are given in Table 10.

The reaction centres of the transition state ($\text{F} \cdots \text{H} \cdots \text{R}$) of the reaction indicated above and those involving $\text{F}^\cdot$:

are similar.

The kinetic parameters which characterise, in the framework of the parabolic model, the reactions involving fluorine- and chlorine-containing molecules are given in Tables 11 and 12; the results of the calculation of the activation energies and rate

Table 10. The enthalpies of reactions of hydrogen abstraction by fluorine-containing molecules $\text{RH} + \text{FY} \longrightarrow \text{R}^\cdot + \text{HF} + \text{Y}^\cdot$.

constants are given in Table 13. The calculated and experimental values are very similar. For example, the experimental rate constant for the reaction:

is equal to $2.0 \times 10^9 \exp(-47.0/RT) = 1.5 \times 10^3 \text{ litre mol}^{-1} \text{ s}^{-1}$ (400 K),⁴⁵ whereas the calculated rate constant is equal to $1.8 \times 10^{10} \exp(-51.0/RT) = 3.9 \times 10^3 \text{ litre mol}^{-1} \text{ s}^{-1}$.

Generation of radicals in yet another fluorine-induced reaction, which was also predicted by N N Semenov,¹ is the addition of fluorine to the double bond:

The activation energies and rate constants for this type of reaction were calculated within the framework of the parabolic model and using kinetic parameters of the given reaction (see Tables 11 and 12) (Table 14). The calculated rate constant for the reaction of F₂ with ethylene is equal to $1.69 \times 10^4 \text{ litre mol}^{-1} \text{ s}^{-1}$ (300 K), *i.e.*, is similar to the experimental values of *k*, *viz.*, $k = 2.04 \times 10^4$ (for 298 K),⁴⁶ 1.81×10^4 (for 298 K)⁴⁷ and $4.16 \times 10^4 \text{ litre mol}^{-1} \text{ s}^{-1}$ (for 315 K).⁴⁸

It may be assumed that analogous reactions occur with molecular chlorine:

The enthalpies of these reactions are much lower than the dissociation energy of the Cl–Cl bond, but it is these reactions that seem to be the main radical sources in chain chlorination reactions in the absence of external initiators. Among chlorine-containing molecules, nitrosyl chloride ClNO has proved to be the most active hydrogen acceptor. The abstraction of the hydrogen atom by YCl molecules occurs with an activation energy similar to the reaction enthalpy [see formula (6)]. The rate constants for some of these reactions (Tables 11 and 12) calculated within the framework of the parabolic model are given in Table 15.

Table 13. The enthalpies, activation energies and rate constants for the reactions $F_2 + RH \longrightarrow F^\bullet + HF + R^\bullet$ calculated within the framework of the parabolic model.²²

VII. Generation of radicals by ozone-induced bimolecular reactions

Ozone reacts very rapidly with alkenes and organoelement compounds without the formation of free radicals.^{49–53} However, it reacts with the C–H bonds of hydrocarbons and other organic compounds to generate free radicals.³ Evidence for this assumption can be derived from the following facts. Ozone initiates the chain oxidation of hydrocarbons in both gas and liquid phases.^{54–57} The peroxy radicals produced in the oxidation of hydrocarbons and polymers by an O_3-O_2 mixture were identified by EPR.^{58,59} The formation of peroxy radicals is confirmed by chemiluminescence induced by oxidation of hydrocarbons with the above mixture due to disproportionation of the peroxy radicals.^{55,60} Deuterated hydrocarbons are oxidised by ozone more slowly, which suggests that the ozone attack at the C–H and C–D bonds is a limiting step of the oxidation.^{53,61–65} The

oxidation of hydrocarbons by ozone in carbon tetrachloride yields alkyl chlorides:^{60,66,67}

whereas the oxidation of alcohols yields hydrogen chloride:⁶⁸

Ozone is decomposed in the gas phase at elevated temperatures to generate molecular and atomic oxygen; the latter initiates the formation of radicals:

Hydrogen abstraction concomitant with cage radical processes is the most feasible reaction in the liquid phase:

The labile compounds $ROOOH$ and $HO_3^\cdot$ are rapidly decomposed to generate the radicals:

The reactive hydroxyl radical reacts rapidly with RH :

This mechanism is consistent with the high probability (p) of the exit of radicals to the bulk:

$$p = \frac{k_i}{2k_d},$$

where k_i and k_d are the rate constants determined experimentally for radical generation and ozone consumption, respectively (Table 17).^{69–72}

The low value of p for cumene is due to the fact that ozone reacts simultaneously with the C–H bond and with the π -bonds of the benzene ring without the formation of free radicals.⁷⁰ A similar situation takes place in the reaction of ozone with carbonyl compounds. Ozone reacts with both the C–H bond with the formation of radicals and the carbonyl group to yield a labile tetraoxide. The latter is rapidly decomposed to yield singlet oxygen.⁶⁶

Since the reaction centres of the reactions $RH + O_3$ and $RO_2^* + RH$ are similar, this has been used to calculate the kinetic and thermodynamic parameters of ozone-mediated reactions (Tables 18–20).^{14, 20}

The experimental data for the reaction $RH + O_3$ can be found elsewhere.^{3, 8, 51, 52}

VIII. Chain generation in reactions with molecular oxygen

Chains are generated in the early steps of the oxidation of hydrocarbons in the absence of a hydroperoxide:³

which was proposed by Bolland and Gee.⁷³ The fact that this reaction occurs for oxidisable aldehydes was proved by Cooper and Melville.⁷⁴ The main experimental evidence in favour of this mechanism can be summarised as follows.^{7, 9}

1. The rate of the radical formation in an $RH + O_2$ system measured by the free radical acceptor method for different compounds is directly proportional to the product of the concentrations $[RH] \times [O_2]$.

2. The rate constant for the reaction $RH + O_2$ increases with the decrease in stability of the weakest C–H bond in the molecule

Table 20. The enthalpies, activation energies and rate constants for the reactions $2RH + O_3 \longrightarrow R^* + HO_3^*HR$ calculated within the framework of the parabolic model.¹⁴

to be oxidised. Substitution of deuterium for the hydrogen atom in the RH molecule lowers the reaction rate, *e.g.*, the k_H/k_D ratio for diethyl sebacate is equal to 5.2 (413 K).⁷⁵

3. In polar solvents, the reaction $RH + O_2$ proceeds more rapidly, which is consistent with the polar nature of the transition state $R(\delta^+) \cdots H \cdots (\delta^-)O_2$.⁷⁵

4. The polarity causes a multidipole effect, *viz.*, the rate constant for a reaction increases with an increase in the number of polar groups in the molecule to be oxidised.⁷⁶

The values of rate constants for the reaction $RH + O_2$ can be found in numerous reviews and reference books (see, *e.g.*, Refs. 3, 7–9).

The structures of the transition states of the reactions $RH + O_2$ and $RO_2^* + RH$ are similar. The kinetic and thermodynamic parameters of the reaction $RH + O_2$, which characterise this reaction within the framework of the parabolic model, coincide with the corresponding parameters of the reaction $RH + O_3$ (see Tables 18 and 19). As the H–O bond in the radical $H-O_2^*$ formed is weak (220 kJ mol^{-1}), the activation energy of this reaction is close to its enthalpy; the pre-exponential factor A_0 depends on enthalpy.^{7,11} The values of the activation energy and the rate constant for this reaction calculated within the framework of the parabolic model are given in Table 21.

Table 21. The enthalpies, activation energies and rate constants for the reactions $RH + O_2 \longrightarrow R^* + HO_2^*$ calculated within the framework of the parabolic model.¹⁶

For compounds with weak C–H bonds [$D(\text{C–H}) < 330 \text{ kJ mol}^{-1}$], the chain generation follows a trimolecular mechanism:^{7,9}

In the oxidation of unsaturated compounds, the chains appear in the reaction of O₂ addition to the double bond:^{5,7,9}

This process was suggested by Farmer⁷⁷ and experimentally proved for styrene by Miller and Mayo.⁷⁸ The reaction is endothermic, but its activation energy significantly exceeds ΔH .⁵

Monomer	$\Delta H / \text{kJ mol}^{-1}$	$E / \text{kJ mol}^{-1}$
CH ₂ =CH ₂	80.8	—
CH ₂ =CH ₂ Et	80.4	—
CH ₂ =CHPh	20.4	118
CH ₂ =CHC(O)OMe	84.8	117
CH ₂ =C(Me)C(O)OMe	86.9	115

With an increase in the solvent polarity, the rate of this reaction increases. For example, the reaction of O₂ addition to butyl methacrylate at 363 K is described by the rate constants equal to $8.1 \times 10^{-7} \text{ litre mol}^{-1} \text{ s}^{-1}$ in *N,N*-dimethylformamide and $3.4 \times 10^{-7} \text{ litre mol}^{-1} \text{ s}^{-1}$ in chlorobenzene.⁵ This may be preceded by the formation of a charge transfer complex:

For some unsaturated compounds, chain generation follows a trimolecular mechanism, most probably, with the simultaneous formation of a biradical containing a peroxide bridge.⁵

IX. Bimolecular reactions of hydroperoxides

The O–O bond of hydroperoxides is weak; the cleavage of this bond occurs with the formation of radicals:^{2,7}

This reaction is responsible for the autoacceleration of the gas phase oxidation of hydrocarbons. In the case of liquid-phase oxidation of organic compounds, the autoacceleration of the chain reaction is due to diverse bimolecular reactions involving ROOH which proceed much faster than the monomolecular decomposition of the hydroperoxide.

The bimolecular reaction of hydroperoxide decomposition:

was discovered by Bateman *et al.*^{79,80} in the study of kinetics of autoxidation of unsaturated acid esters. It was found that the rate of radical generation in the developed oxidation reaction is proportional to the square of the ROOH concentration. Later, this reaction was studied by the free radical acceptor method over a broad range of ROOH concentrations. The following kinetic scheme for radical generation was proposed:⁸¹

According to this scheme, the rate of radical generation is equal to:

$$v_i = k_{i1}[\text{ROOH}] + k_{i2}K[\text{ROOH}]^2(1 + K[\text{ROOH}])^{-1}$$

For Me₃COOH (see Ref. 81) and PhMe₂COOH (see Ref. 82), the following parameters were determined (363 K):

Hydroperoxide	<i>K</i> /litre mol ⁻¹	10 ⁷ <i>k</i> _{i2} /litre mol ⁻¹ s ⁻¹	10 ⁶ <i>k</i> _{i2} <i>K</i> /litre mol ⁻¹ s ⁻¹
Me ₃ COOH	1.9	8.61 (Ref. 81)	1.64
PhMe ₂ COOH	1.3	1.23 (Ref. 82)	0.16

The experimental data on bimolecular decomposition of hydroperoxides can be found in the reference books.^{3,8}

In the bimolecular ROOH decomposition reaction, the hydroxy group of one molecule attacks the O–O bond of another molecule and results in its cleavage. The reaction centres of this reaction and of the reaction of hydrogen peroxide reduction by the ketyl radical:

are similar.

The bimolecular decomposition of hydroperoxides is described well in terms of the kinetic parameters of the reaction of the ketyl radical with hydrogen peroxide,^{25,27} these parameters are given in Tables 22 and 23, and the activation energies and rate constants for these reactions calculated within the framework of the parabolic model are given in Table 24.

The formation of radicals in a bimolecular reaction of a hydroperoxide with an alkene was proved experimentally using the reaction of styrene with cumyl hydroperoxide as an example:⁸³

The rate of radical generation in this reaction is calculated by the formula:⁸⁴

$$v_i = k_i[\text{ROOH}][\text{CH}_2=\text{CHPh}],$$

where:

$$k_i = 1.2 \times 10^4 \exp\left(-\frac{72.0}{RT}\right) \text{ litre mol}^{-1} \text{ s}^{-1}.$$

This reaction is similar to the thermally neutral reaction, since $\Delta H = 9.7 \text{ kJ mol}^{-1}$.

Later, such reactions were studied for some other monomers.⁵ Thus studies of reactions with esters of polyatomic alcohols revealed the effect of the multidipole interaction.^{84,85} Presumably, this reaction is preceded by the formation of a charge transfer complex.

The reaction centres of this reaction and the substitution reaction involving alkyl radicals:⁸⁶

are similar. This circumstance can be used to calculate activation energies and rate constants of peroxides reactions. The kinetic and thermodynamic parameters are given in Tables 22, 23 and 25.

The condition $\Delta H < D(\text{O}-\text{O})$ [$D(\text{O}-\text{O}) = 175 \text{ kJ mol}^{-1}$] must be met to ensure successful competition of bimolecular reactions of the type:

with monomolecular decomposition of the hydroperoxide. This condition is fulfilled for the majority of reactions of organic compounds, since $D(\text{Y}-\text{H}) < D(\text{HO}-\text{H})$ [$D(\text{HO}-\text{H}) = 498 \text{ kJ mol}^{-1}$]. For example, the enthalpy of the reaction of a hydroperoxide with cumene is equal to 41 kJ mol^{-1} . However,

within the framework of the parabolic model^{25–27} the activation energy of this reaction is rather high (the calculated value for the reaction of *tert*-butyl hydroperoxide with cumene is $135.6 \text{ kJ mol}^{-1}$), which may be attributed to high repulsion energy in a non-linear transition state complex.

The kinetic parameters for the reactions involving C–H, N–H and O–H bonds (hydrocarbons, amines, alcohols, acids) are given in Tables 22 and 23; the results of calculations within the framework of the parabolic model are given in Table 26.

A comparison of the experimental and calculated values of the rate constants revealed that the former exceed the latter by several orders of magnitude (Table 27). Presumably, under the given experimental conditions the investigators deal with other, more efficient mechanisms of radical generation from the same reactants.

A comparison of rate constants and activation energies for the reactions $\text{ROOH} + \text{RH}$ and $\text{ROOH} + \text{C}=\text{C}$ revealed that the latter reaction proceeds faster and with lower activation energies (see Table 27). Probably, reactions of hydroperoxides with alkylaromatic hydrocarbons, *e.g.*, cumenes, of the type:

proceed faster.

The generation of radicals in the reaction of a hydroperoxide with a carboxylic acid follows, most probably, the mechanism of an acid-catalysed reaction as this takes place in an $\text{ROOH} + \text{mineral acid system}$ where the formation of radicals is preceded by the protonation of the hydroperoxide.⁷

In the reaction of alcohols with hydroperoxides

the radicals are also formed much faster (by 4–5 orders of magnitude) than in the bimolecular reaction of hydroperoxide decomposition (see Table 27).

Apparently, in these systems, too, a more rapid acid-catalysed hydroperoxide cleavage takes place.

X. Conclusion

Bimolecular reactions leading to radical generation are extremely diverse. Very often, they proceed much faster than monomolecu-

lar dissociation of molecules involving the weakest bond. Presumably, the fulfilment of the condition $E(\text{a bimolecular reaction}) < D(\text{a weak bond})$ depends on the enthalpy ratio of these reactions, *viz.*, $E(\text{a bimolecular reaction}) < D(\text{a weak bond})$, if $\Delta H(\text{a bimolecular reaction}) < D(\text{a weak bond})$. However, judging from the activation energies of individual reactions, this condition is insufficient.

First, for the dissociation reaction:

$$E_d = D + RT \approx D,$$

whereas for the bimolecular endothermic reaction:

$$E = \Delta H + \Delta E,$$

ΔE being dependent on the type of the reaction and ΔH (see Fig. 1). Therefore, a concrete analysis of the reactions that are compared is necessary.

Second, the pre-exponential factor A in the Arrhenius equation for the monomolecular decomposition reaction is $\sim 10^{13} - 10^{16} \text{ s}^{-1}$, while that for the bimolecular reaction (due to a negative activation enthalpy) is equal to $\sim 10^8 - 10^{10} \text{ litre mol}^{-1} \text{ s}^{-1}$. Moreover, proper allowance must be made for the fact that in the case of endothermic processes with $\Delta H_c > \Delta H_{e \text{ max}}$ the pre-exponential factor increases with the enthalpy of the reaction. The parabolic model takes proper account of all these factors and allows the estimation of activation energies and rate constants for any bimolecular homolytic reaction for which an analogous bimolecular radical reaction exists.

VI. Conclusion	460

Abstract. The results of experimental and theoretical investigations of the phase equilibria in the titanium–carbon system are generalised. The generalised thermodynamic characteristics of disordered titanium carbide, TiC_y , are reported. Peculiarities of the crystal structures of all the known and hypothetical compounds of titanium with carbon are considered in detail. The X-ray diffraction patterns which allow identification of all these compounds are presented. The phase diagrams of the Ti–C system constructed with allowance for atomic ordering of nonstoichiometric carbide, TiC_y , and for the existence of the molecular cluster-like compounds Ti_8C_{12} and $\text{Ti}_{13}\text{C}_{22}$ (TiC_2) are discussed. The bibliography includes 142 references.

I. Introduction

Carbides of Group IV and V transition *d*-metals belong to strongly nonstoichiometric interstitial compounds.^{1–3} A typical representative of strongly nonstoichiometric compounds is cubic titanium monocarbide TiC_y ($0.48 \leq y \leq 1.00$) with the *B1*-type structure, which has found wide practical applications and has been the subject of intensive experimental and theoretical research.

In 1823, Wollaston reported the discovery of pure crystalline titanium in metallurgic slags. However, after a lapse of 33 years Wöhler (Germany) showed that these crystals were titanium carbide containing nitrogen impurity. More recently in the 19th century contaminated titanium carbide was extracted from titanium-containing cast iron.^{4,5} Some attempts at obtaining pure titanium carbide by carbothermal reduction of titanium dioxide, TiO_2 , were also made (see Ref. 6).

The history of studies of titanium carbide and the Ti–C system can arbitrarily be divided into three periods.

In the first period (from the middle 1850s up to 1940), titanium carbide as well as the carbides and nitrides of other transition metals (zirconium, hafnium, vanadium, niobium, tantalum) were treated as ordinary chemical compounds of stoichiometric com-

position. Most studies carried out in this period were related to the establishment of the types of crystal structure and to the determination of the unit cell parameters of the titanium carbide samples obtained in one way or another. Titanium carbide was assumed to have a stoichiometric composition TiC . By the end of the first period, investigations of the thermodynamic and various physical properties of carbides and nitrides began and massive discrepancies between the results of different studies of the properties of titanium carbide were revealed. These discrepancies could not be rationalised by the measurement errors or by differences in the experimental methods. Detailed crystal-chemical studies showed that the discrepancies were due to the different content of carbon atoms in the carbide. It was found that, in contrast to other compounds, the composition of titanium carbide and, broadly, of the Group IV and V transition metal carbides and nitrides can vary over a very wide range while their crystal structure remains unchanged. In particular, the composition of titanium monocarbide TiC_y can vary from $\text{TiC}_{0.48}$ to $\text{TiC}_{1.00}$.

In the second period (from 1940 to 1970s), emphasis was mainly placed on investigations of the composition–property correlations for strongly nonstoichiometric compounds (in particular, interstitial phases). Interest in the carbides peaked in the 1960s, when thousands of communications were reported, concerning the effect of composition on the crystal-chemical, thermodynamic, thermal-physical, electrical, magnetic, optical, mechanical and other properties of these substances. By this time, the main qualitative concepts of the nature of chemical bonding in nonstoichiometric carbides have been developed. In the 1970s, the number of publications concerning basic problems relating to nonstoichiometric carbides reduced considerably; however, this time was characterised by increasing interest in applied studies. Titanium carbide had found wide use in production of hard alloys for metal-cutting tools. Most of the researchers erroneously concluded that there was almost nothing left to study in nonstoichiometric carbides. The first (tentative) variants of the phase diagram of the Ti–C system were reported,^{7,8} which reflected the existence of the only compound, *viz.*, cubic titanium monocarbide, TiC_y , with a broad homogeneity region. These phase diagrams remained nearly unchanged up to the mid-1990s.

For a long time after nonstoichiometric compounds were shown to have broad homogeneity regions, it was assumed that non-metal interstitial atoms and structural vacancies (unoccupied interstices of the metal sublattice) were randomly distributed over the lattice. However, crystallographic studies reported in 1967 (see Ref. 9) and more recently revealed that under particular condi-

tions the interstitial atoms and vacancies can be redistributed over the sites of the crystal lattice, thus forming different types of ordered structures. The ordering of carbon atoms and structural vacancies was first observed in nonstoichiometric titanium carbide.⁹

In the late 1960s, the third period began of studies of nonstoichiometric compounds, which is mainly related to investigations into the ordering and its influence on the properties of these systems. Currently, one can say with certainty that at temperatures below 1000 K nonstoichiometric carbides and nitrides exist in the thermodynamically equilibrium ordered state, whereas their disordered state is metastable in the same temperature range.

In the 1980s, research into correlations between the properties of strongly nonstoichiometric compounds and the character of distribution of the interstitial atoms and vacancies began. It was shown that the effect of atomic and vacancy ordering on changes in the properties of a nonstoichiometric compound is comparable with the effect of varying the composition of the same system within the homogeneity region of the ordered phase. Therefore, varying the composition and redistribution of the atoms and vacancies in the crystal lattice of strongly nonstoichiometric compounds are two ways of controlling the properties of these compounds that possess equal rights.

A large number of ordered phases of strongly nonstoichiometric compounds was found during the decade from 1990 to 2000. The results of experimental studies and calculations of the phase equilibria allowed construction of the phase diagrams of the M–C and M–N (M = Ti, Zr, Hf, V, Nb, Ta) systems with allowance for both the presence of strongly nonstoichiometric carbides (MC_y) and nitrides (MN_y) and their ordering at temperatures below 1300 K (see Refs 1–3 and 10–27).

In 1992, a novel class of molecular metal–carbon nanoclusters was discovered.^{28–38} Three stable molecular clusters — Ti₈C₁₂, Ti₁₃C₁₄ and Ti₁₃C₂₂ — were obtained in the Ti–C system. Some experimental and theoretical studies on titanium dicarbide, TiC₂, were also reported.

Thus, the last two decades are characterised by avalanche-like growth of the body of information on the phase equilibria and compounds in the Ti–C system. The phase diagram of this system was found to be much more intriguing and complicated than it was assumed previously. The aim of this review was to generalise the results of recent (reported between 1980 and 2000) experimental and theoretical investigations of chemical compounds and phases in the Ti–C system taking into account all available information. The emphasis is placed on the phase equilibria in this binary system and on the crystal structure of both the known and theoretically possible (model) phases and compounds of carbon and titanium.

II. Phase diagrams of the Ti–C system at temperatures above 1000 K and thermodynamic properties of disordered titanium monocarbide TiC_y

1. Phase diagrams

No phase diagrams of the Ti–C system constructed with allowance for the ordering of nonstoichiometric carbide TiC_y were reported until the mid-1990s. In the text below we will consider the principal results of investigations into the phase equilibria in the Ti–C system at temperatures above the ordering temperature of nonstoichiometric titanium carbide (*i.e.*, at $T > 1000$ K).

Detailed studies of phase equilibria in binary carbide-forming M–C (M is a transition metal) systems were mostly carried out in 1961–1965.³⁹ Up to now, the experimental results [including those for the Ti–C system at temperatures above 1800 K (see Ref. 7)] obtained at that time are the most reliable and accurate.

The phase diagram of the Ti–C system is presented in Fig. 1. In this system, cubic titanium carbide TiC_y with the B1-type

Figure 1. Experimental phase diagram of the Ti–C system at $T > 1800$ K.⁷

structure is in equilibrium with β -Ti (bcc structure) or α -Ti (hcp structure).

The melting temperature of pure metallic β -Ti is 1941 ± 8 K (see Ref. 7). The addition of carbon to titanium reduces the melting temperature of Ti down to the eutectic temperature [1918 ± 5 ,⁴⁰ 1923 ± 7 ,⁷ 1921 ± 5 ,^{41–43} 1925 K (see Ref. 44)]. The eutectic $L \rightleftharpoons \beta\text{-Ti} + \text{TiC}_y$ was reported to contain 4.4 at.% of carbon,⁴⁰ however, metallographic tests⁷ showed that the content of carbon in the eutectic is 1.5 ± 0.5 at.%. Difficulties in determination of the eutectic composition by metallographic tests have been pointed out.^{7,39}

Allotropic transformation $\alpha\text{-Ti} \rightleftharpoons \beta\text{-Ti}$ occurs at 1155 ± 5 K (see Ref. 8). The addition of carbon to titanium causes an increase in the temperature of this transformation up to the temperature of the $\beta\text{-Ti} + \text{TiC}_y \rightleftharpoons \alpha\text{-Ti}$ peritectoid transformation, which equals 1193 ± 3 K (see Refs 41–43) or 1205 K (see Ref. 44).

At temperatures above 1000 K, there is only one nonstoichiometric compound in the binary system Ti–C, *viz.*, cubic titanium carbide TiC_y with a very broad homogeneity region from TiC_{0.47} to TiC_{0.96} at $T \approx 1920$ K.^{7,39} Raising the temperature up to 3000 K causes a shift of both the lower and upper bounds of the homogeneity region of TiC_y towards a higher content of carbon. At $T \approx 3000$ K, the upper bound of the homogeneity region corresponds to a TiC_{0.998} composition (see Ref. 8). The highest melting temperature, 3340 ± 15 K (see Refs 7, 39, 41–43) or 3341 K (see Ref. 44), has carbide TiC_{0.80} which undergoes congruent melting. The temperature of the $L \rightleftharpoons \text{TiC}_y + C$ eutectic containing ~ 63 at.% of carbon is 3049 ± 12 K,⁷ 3049 ± 6 K (see Refs 39, 41, 42) or 3048 K (see Ref. 44).

Figure 2 presents the phase diagram of the Ti–C system constructed by Murray^{41,42} for $T > 800$ K. The same phase diagram was also reported in a reference guide.⁴³ Most of the phase equilibria in this diagram were shown tentatively. Murray supplemented the phase diagram shown in Fig. 1 with some essential details by indicating the regions of allotropic transformation $\alpha\text{-Ti} \rightleftharpoons \beta\text{-Ti}$ and peritectoid transformation $\beta\text{-Ti} + \text{TiC}_y \rightleftharpoons \alpha\text{-Ti}$. On the other hand, the phase diagram of this system (see Fig. 2) contained a tentatively shown existence region of ordered Ti₂C phase that was thought to exist and be stable at temperatures below 2170 K.^{9,45} However, the first report⁹ on the stability of the ordered Ti₂C phase at $T \leq 2170$ K was found to be erroneous: more recently, numerous studies of the ordering of nonstoichiometric carbide TiC_y revealed that cubic ordered Ti₂C phase (space group C_{4h}^5) is formed at temperatures below 1000 K (see, *e.g.*, Refs 12, 21, 46–56). At $T < 1000$ K,

Figure 2. Phase equilibria in the Ti–C system at $T > 800$ K.^{41–43} Ti_2C is the ordered phase of nonstoichiometric titanium carbide TiC_y .

Figure 3. Phase diagram of the Ti–C system at $T > 1000$ K calculated⁴⁴ taking into account the results of experimental studies.^{7, 8, 39}

there are several ordered phases in the homogeneity region of carbide TiC_y that are not shown in this phase diagram.

Phase equilibria in the system under study at temperatures above 1000 K have most reliably been shown in the phase diagram calculated by Jonsson⁴⁴ taking into account the experimental data reported by Rudy *et al.*^{7, 39} Jonsson's phase diagram is shown in

Table 1. Crystal structure of phases that exist in the Ti–C system at $T > 1000$ K.

Phase	Existence region [C (at.%)]	Space group	Pearson notation	Lattice type
β -Ti	0–0.6	$Im\bar{3}m (O_h^9)$	<i>cI2</i>	<i>A2</i> (W)
α -Ti	0–1.6	$P6_3/mmc (D_{6h}^4)$	<i>hP2</i>	<i>A3</i> (Mg)
TiC_y	~32.0–49.8	$Fm\bar{3}m (O_h^3)$	<i>cF8</i>	<i>B1</i> (NaCl)
C	100	$P6_3/mmc (D_{6h}^4)$	<i>hP4</i>	<i>A9</i> (graphite)

Table 2. Characteristics of special points in the phase diagram of the Ti–C system at $T > 1000$ K.

Phase transformation	Composition of phases involved in reaction [C (at.%)]			T /K	Phase transformation type
$L \rightleftharpoons \beta\text{-Ti} + \text{TiC}_y$	1.8	0.6	32	1918 ± 5	eutectic transformation
$L \rightleftharpoons \text{TiC}_y$	—	44.4	—	3340 ± 15	congruent melting
$L \rightleftharpoons \text{TiC}_y + \text{C}$	65.1	48.5	~100	3050 ± 6	eutectic transformation
$\beta\text{-Ti} + \text{TiC}_y \rightleftharpoons \alpha\text{-Ti}$	0.4	34.4	2.1	1193 ± 3	peritectoid transformation
$L \rightleftharpoons \beta\text{-Ti}$	—	0	—	1941 ± 8	melting
$\beta\text{-Ti} \rightleftharpoons \alpha\text{-Ti}$	—	0	—	1155 ± 5	allotropic transformation

Fig. 3. The results of investigations of the crystal structure of different phases and the characteristics of special points of the phase diagram of the Ti–C system at $T > 1000$ K are listed in Tables 1 and 2, respectively.

2. Structure and thermodynamic properties of disordered titanium carbide

a. Structure

Disordered cubic titanium monocarbide TiC_y with the *B1*-type structure is the most important chemical compound that exists in the Ti–C system at temperatures above 1000 K. The unit cell of TiC_y comprises two face-centred (metal and non-metal) sublattices displaced by half the lattice constant with respect to each other (Fig. 4). All sites in the metal sublattice of TiC_y are occupied by titanium atoms. The number of sites in the non-metal (carbon) sublattice is larger than that of interstitial atoms (*i.e.*, carbon atoms), which is typical of nonstoichiometric compounds. In the disordered state, which is in thermodynamic equilibrium only at $T > 1000$ K and is treated as a quenched metastable state at lower temperatures, carbon atoms are randomly distributed over the sites. The non-metal sublattice is characterised by the same site occupation probability equal to the value of y (the relative content of carbon in the carbide). This is responsible for the retention of cubic symmetry of the disordered non-metal sublattice and means that all sites in the carbon sublattice of disordered TiC_y are crystallographically equivalent. A typical X-ray diffraction pattern of homogeneous cubic titanium carbide is shown in Fig. 5. The lattice constant of TiC_y nonmonotonically increases as the content of carbon increases (Fig. 6).⁵⁷

Nonstoichiometric titanium carbide can possess quite different thermodynamic properties within the homogeneity region. Therefore, of particular value are those studies in which the

Figure 4. Unit cell of cubic disordered nonstoichiometric TiC_y with the *B1*(NaCl)-type structure. All sites in the metal sublattice are occupied by Ti atoms, while the sites in the non-metal sublattice are randomly occupied by C atoms.

Figure 5. X-Ray diffraction pattern of disordered titanium carbide $\text{TiC}_{0.52}$ with cubic $B1$ -type structure ($a_{B1} = 0.4306$ nm, $\text{CuK}\alpha_{1,2}$ radiation).

Figure 6. Lattice constant a_{B1} of the basic crystal lattice as a function of the composition of titanium carbide, TiC_y , in the quenched disordered (full circles) and annealed ordered (open circles) states.⁵⁷ Samples obtained by sintering Ti and $\text{TiC}_{0.94}$ (1, 2), by sintering Ti and C (3, 4) and by hot pressing Ti and $\text{TiC}_{0.98}$ (5). The existence regions of the ordered phases Ti_2C , Ti_3C_2 and Ti_6C_5 are labelled I, II and III, respectively.

measured thermodynamic characteristics were attributed to a certain composition of the carbide with the known (disordered or ordered) structural state. The presence of the temperature and concentration dependences of thermodynamic characteristics of disordered carbide allows quantitative description of high-temperature phase equilibria involving TiC_y ; however, of much greater importance is that using these data also provides the possibility of direct investigations into the disorder–order phase transformations. Unfortunately, the available experimental data on thermodynamic characteristics of nonstoichiometric titanium carbide are scarce.

b. Enthalpy (heat) of formation

Burning of a substance in oxygen in a calorimetric bomb is the main method of experimental determination of the formation enthalpy. Most of the data on the formation enthalpy of disordered TiC_y were obtained using this technique. The formation enthalpy can also be determined indirectly from the dependence of the partial pressure of the components of a compound on the evaporation temperature.

Calorimetric measurements of the standard formation enthalpy ($\Delta H_{f,298}^\circ$) of titanium carbide of a nearly stoichiometric

composition $\text{TiC}_{0.996}$ by burning of carbide in oxygen revealed⁵⁸ that $\Delta H_{f,298}^\circ = -183.8 \pm 1.7$ kJ mol⁻¹. Calculations using the refined value of the formation enthalpy of titanium dioxide gave a more correct value: $\Delta H_{f,298}^\circ = -184.6 \pm 1.7$ kJ mol⁻¹.⁸

Morozova *et al.*⁵⁹ determined the formation enthalpies of disordered cubic carbides of compositions $\text{TiC}_{0.79}$, $\text{TiC}_{0.91}$ and $\text{TiC}_{1.00}$ by burning them in oxygen and calorimetrically measuring the heat effect. The $\Delta H_{f,298}^\circ$ values for these carbides were found to be -183.0 ± 2.1 , -206.8 ± 0.8 and -192.6 ± 2.1 kJ mol⁻¹, respectively. The dependence of the formation enthalpy (in kJ mol⁻¹) determined by burning technique⁵⁹ on the composition of TiC_y can be described by the following formula:^{1–3,27}

$$\Delta H_{f,298}^\circ(y) = -91.07 - 186.7y + 89.0y^2.$$

The formation enthalpies of carbides $\text{TiC}_{0.63}$, $\text{TiC}_{0.72}$, $\text{TiC}_{0.80}$ and $\text{TiC}_{0.91}$ (-108.0 ± 7.0 , -135.0 ± 7.0 , -157.0 ± 7.0 and -184.0 ± 7.0 kJ mol⁻¹, respectively) were determined from the data on vacuum evaporation of TiC_y in the temperature range from 1873 to 2673 K.^{60,61} The dependence of $\Delta H_{f,298}^\circ$ (in kJ mol⁻¹) on the composition of TiC_y calculated using these values has the form⁶¹

$$\Delta H_{f,298}^\circ(y) = 135.6 - 467.8y + 128.3y^2.$$

Comparison of the $\Delta H_{f,298}^\circ(y)$ dependences obtained from calorimetric and evaporation measurements showed that these results are in satisfactory agreement for carbides with $y > 0.9$ but disagree at lower content of carbon. These dependences cannot be combined since the discrepancies between them seem to be due to the systematic errors of the methods employed. However, one can assume that the formation enthalpy of carbides TiC_y ($y < 0.9$) lies between the values found from calorimetric and evaporation measurements.

Analysis of the experimental data on the formation enthalpy of titanium monocarbide taking into account the position of the lower bound of the homogeneity region of TiC_y suggested¹⁸ that the dependence of $\Delta H_{f,298}^\circ$ (in kJ mol⁻¹) on the carbide composition has the form

$$\Delta H_{f,298}^\circ(y) = 16.75 - 304.49y + 89.04y^2. \quad (1)$$

Mention may be made that dependence (1) is close to the average between the experimental dependences $\Delta H_{f,298}^\circ(y)$ obtained from the results of calorimetric⁵⁹ and evaporation⁶¹ measurements.

c. Enthalpy (heat content)

High-temperature enthalpy ($H_T^\circ - H_{298}^\circ$) measurements are usually carried out by a mixing technique using an adiabatic-shell calorimeter. The high-temperature enthalpy of titanium carbide was measured^{62–65} and the following expressions for description of the temperature dependences of the enthalpy (in kJ mol⁻¹) were proposed.

For carbide of composition $\text{TiC}_{0.99}$ in the temperature range from 400 to 1800 K (see Ref. 62):

$$H_T^\circ - H_{298}^\circ = -19.95 + 49.53 \times 10^{-3}T + 1.67 \times 10^{-6}T^2 + 1499T^{-1}. \quad (2)$$

For carbide of composition $\text{TiC}_{0.95}$ (the measurement error was $\pm 1.4\%$) in the temperature range from 1300 to 2700 K (see Ref. 63)

$$H_T^\circ - H_{298}^\circ = -13.68 + 41.13 \times 10^{-3}T + 4.48 \times 10^{-6}T^2. \quad (3)$$

Storms⁸ found the following formula for calculating the enthalpy (in kJ mol⁻¹) of stoichiometric compound $\text{TiC}_{1.0}$ in the temperature range from 300 to 3000 K

$$H_T^\circ - H_{298}^\circ = -22.19 + 55.67 \times 10^{-3}T - 4.07 \times 10^{-6}T^2 + 1763.6T^{-1} + 16.1 \times 10^{-10}T^3. \quad (4)$$

The enthalpies of disordered carbides $\text{TiC}_{0.64}$, $\text{TiC}_{0.71}$, $\text{TiC}_{0.82}$ and $\text{TiC}_{0.99}$ were measured in the temperature range 1300–2500 K by a mixing technique.^{64,65} The authors suggested a polynomial description of the temperature dependence of the enthalpy; however, the polynomials did not fulfil the obvious normalisation condition:

$$H_T^\circ - H_{298}^\circ \equiv 0 \text{ at } T = 298 \text{ K.}$$

Because of this, we calculated the temperature dependences of the enthalpy (in kJ mol^{-1}) of these carbides taking into account the normalisation condition^{1,27} using the experimental data reported by Fesenko *et al.*⁶⁴ and the following expression

$$H_T^\circ - H_{298}^\circ = A + BT + CT^2 + DT^{-1}.$$

The corresponding formulae are as follows:
for carbide of composition $\text{TiC}_{0.64}$

$$H_T^\circ - H_{298}^\circ = -2.42 + 24.54 \times 10^{-3} T + 7.47 \times 10^{-6} T^2 - 1657.1 T^{-1}, \quad (5)$$

for carbide of composition $\text{TiC}_{0.71}$

$$H_T^\circ - H_{298}^\circ = -2.03 + 24.46 \times 10^{-3} T + 8.12 \times 10^{-6} T^2 - 1780.9 T^{-1}, \quad (6)$$

for carbide of composition $\text{TiC}_{0.82}$

$$H_T^\circ - H_{298}^\circ = -5.75 + 30.90 \times 10^{-3} T + 6.54 \times 10^{-6} T^2 - 1204.9 T^{-1} \quad (7)$$

and for carbide of composition $\text{TiC}_{0.99}$

$$H_T^\circ - H_{298}^\circ = -12.97 + 36.61 \times 10^{-3} T + 6.79 \times 10^{-6} T^2 + 431.1 T^{-1}. \quad (8)$$

These equations can be combined to derive a common function

$$\begin{aligned} (H_T^\circ - H_{298}^\circ)_{\text{TiC}_y} = & (15.86 + 12.03 \times 10^{-3} T + 9.67 \times 10^{-6} T^2 - 6051.5 T^{-1}) + \\ & (-22.80 + 6.17 \times 10^{-3} T - 3.09 \times 10^{-6} T^2 + 6328.2 T^{-1})y + \\ & (-5.680 + 19.06 \times 10^{-3} T)y^2 \quad (\text{kJ mol}^{-1}), \end{aligned} \quad (9)$$

which allows estimation of the enthalpy of disordered monocarbide TiC_y with any content of carbon in the temperature range from 300 to 2000 K.

d. Heat capacity and entropy

The heat capacity, C_p , of titanium carbides of compositions $\text{TiC}_{0.95}$ and $\text{TiC}_{0.99}$ was measured using the adiabatic technique in the temperature range from 12 to 300 K.⁶⁶ A decrease in the content of carbon in the TiC_y carbide is accompanied by a decrease in C_p . Lorenzelli *et al.*⁶⁷ measured the heat capacity of samples of disordered and ordered carbide of composition $\text{TiC}_{0.625}$ between 0.5 and 5.0 K; however, they presented only the difference between the heat capacities of the samples.

Since

$$C_p = \frac{d(H_T^\circ - H_{298}^\circ)}{dT},$$

the high-temperature heat capacity is usually determined using the results of experimental enthalpy measurements. This allows the functions (5)–(9) to be used for estimating the heat capacity of disordered TiC_y .

The entropy, S_{298}° , of stoichiometric titanium monocarbide $\text{TiC}_{1.0}$ is $24.24 \text{ J mol}^{-1} \text{ K}^{-1}$ (see Ref. 8). No experimental data on changes in entropy within the homogeneity region of cubic carbide TiC_y are available so far. To a first approximation, the dependence of entropy on the composition of carbide MC_y can be

represented by the additive sum of the entropies of the components normalised to the entropy of stoichiometric carbide $\text{MC}_{1.0}$, *i.e.*,

$$S_{298}^\circ(y) = k(S_{298}^\circ \text{M} + yS_{298}^\circ \text{C}), \quad (10)$$

where $k = S_{298}^\circ \text{MC}_{1.0} / (S_{298}^\circ \text{M} + S_{298}^\circ \text{C})$ is the normalisation constant and $S_{298}^\circ \text{M}$ and $S_{298}^\circ \text{C}$ are the entropies of the metal and carbon, respectively. The entropies of α -Ti and carbon are 30.72 (see Ref. 68) and $5.39 \text{ J mol}^{-1} \text{ K}^{-1}$ (see Ref. 69), respectively. Taking into account these values and the value $S_{298}^\circ \text{TiC}_{1.0} = 24.24 \text{ J mol}^{-1} \text{ K}^{-1}$ (see Ref. 8), the normalisation constant, k , was found to be 0.671 . To a first approximation, the dependence of entropy (in $\text{kJ mol}^{-1} \text{ K}^{-1}$) on the composition, TiC_y , has the form

$$S_{298}^\circ(y) = 20.62 + 3.62 y. \quad (11)$$

e. The free energy

The free energy of disordered carbide can be calculated using the dependences (1), (9) and (11).

Indeed, thermodynamic properties of solids are usually described assuming a constant pressure (usually, p is set to 0 or 1). Under isobaric conditions, the internal energy (configuration energy of a crystal), E , equals the enthalpy H . At 298 K, the enthalpy of a compound is equal to the formation enthalpy of this compound from corresponding elements, *i.e.*, $H_{298}^\circ \equiv \Delta H_{f,298}^\circ$. Taking into account the temperature dependence of the enthalpy of nonstoichiometric compound MX_y , from here it follows that

$$\begin{aligned} E(y, T) = H(y, T) = H_{298}^\circ(y) + (H_T^\circ - H_{298}^\circ)_{\text{MX}_y} \equiv & (12) \\ \equiv \Delta H_{f,298}^\circ(y) + (H_T^\circ - H_{298}^\circ)_{\text{MX}_y}. \end{aligned}$$

The free energy (F) of a disordered nonstoichiometric compound MX_y is given by the following expression^{1–3, 14, 17, 20, 22, 70}

$$\begin{aligned} F(y, 0, T) = E(y, T) - T[S(y, 0, T) + S_c(y, 0)] \equiv & (13) \\ \equiv F_0(T) + yF_1(T) + y^2F_2(T) - TS_c(y, 0), \end{aligned}$$

where $S(y, 0, T)$ is the non-configurational entropy, which is an explicit function of temperature; $S_c(y, 0)$ is the combinatorial (configurational) entropy, which is independent of temperature; and $F_0(T)$, $F_1(T)$ and $F_2(T)$ are the free energy parameters.

Using the standard entropy, the temperature dependence of entropy can be written as follows

$$S(T) = S_{298}^\circ + \int_{298}^T \frac{d(H_T^\circ - H_{298}^\circ)}{T}.$$

In this case

$$S(y, 0, T) = S_{298}^\circ(y) + \int_{298}^T \frac{d(H_T^\circ - H_{298}^\circ)_{\text{MX}_y}}{T}. \quad (14)$$

The free energy of a disordered compound MX_y minus the term responsible for the contribution of configuration entropy, $S_c(y, 0)$, is given by the expression

$$F_0(T) + yF_1(T) + y^2F_2(T) \equiv E(y, T) - TS(y, 0, T) \quad (15)$$

or, taking into account Eqns (12) and (14),

$$\begin{aligned} F_0(T) + yF_1(T) + y^2F_2(T) = \Delta H_{f,298}^\circ(y) + & (16) \\ + (H_T^\circ - H_{298}^\circ)_{\text{MX}_y} - T \left[S_{298}^\circ(y) + \int_{298}^T \frac{d(H_T^\circ - H_{298}^\circ)_{\text{MX}_y}}{T} \right]. \end{aligned}$$

The expression for a fraction of the free energy (in kJ mol^{-1}) of disordered carbide TiC_y was derived^{1–3, 27} from Eqn (16) using the dependences (1), (9) and (11)

$$\begin{aligned}
 F_0(T) + yF_1(T) + y^2F_2(T) = & \quad (17) \\
 = (32.61 + 31.61 \times 10^{-3} T - 9.67 \times 10^{-6} T^2 - 3026 T^{-1} - \\
 - 12.03 \times 10^{-3} T \ln T) + (-327.29 + 71.49 \times 10^{-3} T + \\
 + 3.09 \times 10^{-6} T^2 + 3164 T^{-1} - 6.17 \times 10^{-3} T \ln T)y + \\
 + (83.36 + 127.65 \times 10^{-3} T - 19.06 \times 10^{-3} T \ln T)y^2,
 \end{aligned}$$

where the parameters $F_0(T)$, $F_1(T)$ and $F_2(T)$ of the free energy $F(y, 0, T)$ [see Eqn (13)] are given in explicit form. Knowledge of these parameters allows all types of thermodynamic calculations of the phase equilibria involving nonstoichiometric titanium carbide.

3. High-temperature evaporation of titanium carbide

Thermodynamic properties of nonstoichiometric carbides are often determined using measurements of the vapour pressure above the solid compounds. Of particular interest is the case of congruent evaporation.

According to the kinetic theory of gases, the rate of evaporation from the surface that is in equilibrium with vapour equals the condensation rate, which is proportional to the equilibrium vapour pressure p . Under nonequilibrium conditions (in the case of, e.g., vacuum evaporation from the open surface) the evaporation rate is independent of the condensation rate and equals the equilibrium evaporation rate at a given temperature;⁷¹ this holds if the residual pressure in the vacuum chamber does not exceed 10 Pa. Therefore, knowledge of the rate of steady-state vacuum evaporation allows determination of the equilibrium parameter, namely, the saturated vapour pressure, and calculation of the thermodynamic characteristics. If transition from the condensed phase to the vapour phase is accompanied by dissociation of the former, the observed evaporation rate and the partial pressure are lower than the equilibrium values; this can be taken into account by introducing the evaporation coefficient $\alpha \leq 1.0$.

The kinetic and thermodynamic conditions for congruent evaporation of disordered nonstoichiometric interstitial compounds have been studied in detail in monograph.¹⁴ Thermodynamics of congruent evaporation of nonstoichiometric compounds was also developed.^{72, 73}

Evaporation of TiC_y at temperatures above 1800 K was studied by many authors. Mass spectrometric studies of the composition and the pressure measurements of the vapour above titanium carbide evaporated from a graphite effusion chamber (evaporation in the presence of excess of free carbon) at 2200–2500 K showed that the vapours contained elemental carbon and titanium and the C_2 and C_3 units; no molecular species TiC were found.^{74, 75} The vapour pressure of titanium above the titanium carbide–graphite system at 2383–2593 K measured⁷⁶ by the Knudsen effusion technique was found to be much higher than that determined by other authors. The value reported in this study seems to be overestimated, since evaporation of pure graphite through the effusion orifice was ignored. In the temperature range between 2518 and 2790 K, the vapours above the titanium carbide–carbon system contained Ti, TiC_2 , TiC_4 and C_3 units.⁷⁷ According to estimates,⁷⁸ the gas phase above this system contains elemental titanium and carbon as the major components at $T < 2500$ K and Ti, C and C_3 units at $T > 2500$ K. Titanium carbide was shown to undergo dissociation during evaporation at $2200 < T \leq 2500$ K in the presence of excess of free carbon; in this case, elemental titanium is released in the gaseous state while carbon is released in the solid state.^{74–76}

Studies of evaporation of carbide $\text{TiC}_{0.97}$ at 2773 K using Langmuir's technique revealed that under these conditions the compound undergoes congruent evaporation and that the vapours contain mostly elemental titanium and carbon.⁷⁹ The composition of carbide TiC_y affects the vapour pressure, namely, the vapour pressure of titanium monotonically increases from 1×10^{-4} Pa for $\text{TiC}_{0.91}$ to 0.2 Pa for $\text{TiC}_{0.55}$ as the content of carbon decreases (see Ref. 8). Evaporation and dissociation of

carbide $\text{TiC}_{0.91}$ in the temperature range between 1873 and 2673 K can be described by the reaction⁸⁰

where $z(T) = y$ at $T \leq 2100$ K; $z(T)$ decreases from y down to 0 as the temperature increases from 2100 to 2273 K; $z(T) = 0$ at $T \geq 2273$ K. The vapour pressure of titanium above carbide $\text{TiC}_{0.91}$ at 1900 K was found to be $\sim 6 \times 10^{-5}$ Pa,⁸⁰ which is close to the value reported by Storms.⁸

Evaporation of titanium carbide was mainly studied near the upper bound of the homogeneity region of the cubic phase taking the TiC_y samples with $y > 0.9$ as examples (see Refs 74–77, 79 and 80). The evaporation coefficient was assumed to be equal to unity, though if evaporation is accompanied by dissociation, this value is less than 1. The results of determination of the vapour pressure of titanium reported by different authors^{8, 74–77, 79, 80} are substantially different (from 2 to 40 times).

Vacuum evaporation (at 0.0013 Pa) of samples of cubic monocarbide TiC_y with different contents of carbon ($0.6 < y \leq 0.93$) was studied in the temperature range between 1873 and 2673 K.^{60, 61} The samples represented disordered titanium carbide, since only disordered nonstoichiometric carbides are in thermodynamic equilibrium at $T > 1300$ –1500 K.^{1–3, 14, 17, 70} All TiC_y samples were found to be homogeneous and contained one phase with the B1-type structure. Evaporation of titanium carbide was studied by Langmuir's technique. The evaporation rate

$$V = \frac{\Delta m}{S_{\text{ef}} t}$$

was determined from the mass loss (Δm) from the effective evaporation surface area, S_{ef} , of a vacuum heated sample over a period t . Due to the presence of the open surface pores the S_{ef} value was larger than the geometric evaporation surface area S

$$S_{\text{ef}} = S \left[1 + \left(\frac{9\pi P^2}{2} \right)^{1/3} \right],$$

where P is the relative porosity. The evaporation surface area was determined^{60, 61} with allowance for porosity which was determined as the average between the initial (before the experiment) and final (after heating) porosity. Evaporation was carried out until establishment of a constant total evaporation rate V (for a given temperature) and a constant crystal lattice parameter on the surface of the sample, i.e., until steady-state regime of the process.

The overall time of vacuum evaporation of titanium carbide samples varied from 2–8 h at 2673 K to 54 h at 1873 K. During evaporation the lattice constant on the surface of the samples remained virtually unchanged, which indicated a constant composition of TiC_y at $T < 2673$ K.

Evaporation of carbides TiC_y at $T < 2273$ K led to release of elemental carbon on the surface of the samples, whereas no elemental carbon was found on the surface of the TiC_y samples at higher evaporation temperatures ($T \geq 2273$ K). These data and the results of evaporation rate measurements suggest that at $T \leq 2273$ K evaporation of titanium carbide TiC_y is described by reaction (18). Indeed, at $T < 2100$ K the pressure and evaporation rate of metallic titanium are much higher than those of elemental carbon;⁶⁸ because of this, carbon is mainly released in the solid phase and can thus be found on the surface of the samples. As the content of carbon in TiC_y decreases (especially at $y \leq 0.8$), the amount of elemental carbon released on the surface rapidly decreases. Raising the temperature leads to an increase in the evaporation rate of carbon and no elemental carbon was found on the surface of TiC_y samples at $T > 2300$ K. At $T > 2273$ K, which corresponds to complete evaporation of carbon released on the surface, the $z(T)$ value equals zero, and the equilibrium in system (18) loses ambiguity. Since at temperatures below 2600 K (in the absence of excess elemental carbon) the vapour above titanium carbide contains mostly elemental

Table 3. ^a For carbide TiC_y , $\ln p_{\text{Ti}}^{\circ} = \ln p_{\text{Ti}}^{\circ} + \ln y$. ^b Found using the equation of the second law of thermodynamics (see below). ^c Found using the equation of the third law of thermodynamics (see below).

titanium and carbon and does not contain C_2 units and larger carbon molecular species and titanium carbide molecules,⁷⁸ one can suggest congruent evaporation of TiC_y in the temperature range between 2273 and 2673 K following the reaction

This character of evaporation of TiC_y has been confirmed experimentally.^{78–80}

An increase in the evaporation temperature causes a rapid increase in the evaporation rate: *e.g.*, the evaporation rate of $\text{TiC}_{0.92}$ increases by a factor of more than 20 000 as the temperature increases from 1873 to 2673 K. For TiC_y samples with different contents of carbon the temperature dependence of the evaporation rate has the form

$$\ln V = a - \frac{b}{T}.$$

In Table 3 we present the values of the coefficients a and b for some carbides. The evaporation rate of carbide of composition $\text{TiC}_{0.92}$ calculated using this dependence for 2773 K is $108 \times 10^{-5} \text{ kg m}^{-2} \text{s}^{-1}$. This is rather close to the estimate $(93–113) \times 10^{-5} \text{ kg m}^{-2} \text{s}^{-1}$ for the evaporation rate of $\text{TiC}_{0.97}$ at 2773 K.⁷⁹

If a compound MC_y undergoes congruent evaporation, the observed partial pressures of its components, p_{M} and p_{C} , are^{14, 71, 80}

$$p_{\text{M}} = \alpha_{\text{M}} p_{\text{M}}^{\circ} = \frac{V(2\pi RT A_{\text{M}})^{1/2}}{M}, \quad (20)$$

$$p_{\text{C}} = \alpha_{\text{C}} p_{\text{C}}^{\circ} = \frac{yV(2\pi RT A_{\text{C}})^{1/2}}{M}, \quad (21)$$

where α_{M} , α_{C} and p_{M}° , p_{C}° are the evaporation coefficients and the equilibrium partial pressures of the metal and non-metal components of condensed carbide MC_y ; V is the total evaporation rate; A_{M} and A_{C} are the atomic masses of the metal and carbon, respectively, and $M = A_{\text{M}} + yA_{\text{C}}$ is the molecular mass of carbide MC_y .

Under equilibrium congruent evaporation one gets $p_{\text{C}}^{\circ} = y p_{\text{M}}^{\circ}$; hence from Eqns (20) and (21) it follows¹⁴ that

$$\alpha_{\text{C}} = \alpha_{\text{M}} \left(\frac{A_{\text{C}}}{A_{\text{M}}} \right)^{1/2},$$

$$p_{\text{C}} = y \left(\frac{A_{\text{C}}}{A_{\text{M}}} \right)^{1/2} p_{\text{M}}.$$

In Fig. 7 we present the dependences of the partial pressure of titanium on the composition of carbide TiC_y . At any temperature, the larger the deviation of the carbide composition from the stoichiometric composition, the higher the p_{Ti} value. Earlier, an analogous type of change in p_{Ti} was reported for $T = 1900 \text{ K}$.⁸

**Figure 7.** Partial pressure of titanium, p_{Ti} , as a function of the composition of titanium carbide, TiC_y ; pressure p_{Ti} above the TiC_y carbide at 1900 K (1);⁸ data⁶¹ (2) and pressure p_{Ti} above the $\text{TiC}_{0.97}$ carbide at 2773 K (3).⁷⁹

Taking into account the relationship

$$p_{\text{C}} = y \left(\frac{A_{\text{C}}}{A_{\text{M}}} \right)^{1/2} p_{\text{M}},$$

the equilibrium constant, K , of reaction (19) is (when calculating K values, the partial pressure is given in atmospheres):

$$K = p_{\text{M}} p_{\text{C}} = p_{\text{M}}^{(1+y)} y y \left(\frac{A_{\text{C}}}{A_{\text{M}}} \right)^{y/2} = \alpha_{\text{M}}^{(1+y)} (p_{\text{M}}^{\circ})^{(1+y)} y^y \left(\frac{A_{\text{C}}}{A_{\text{M}}} \right)^{y/2}. \quad (22)$$

Knowledge of the equilibrium constant K allowed estimation of the enthalpy of process (19);⁶¹ in the case of evaporation accompanied by dissociation this is the atomisation enthalpy $\Delta_{\text{at}}H_{298}^{\circ}$. In accord with the second law of thermodynamics, the $\Delta_{\text{at}}H_{298}^{\circ}$ value was found using the available temperature dependences of K and by solving Van't Hoff's isobar equation

$$\frac{d \ln K}{dT} = \frac{\Delta_{\text{at}}H_{298}^{\circ}}{RT^2}. \quad (23)$$

Calculations of $\Delta_{\text{at}}H_{298}^{\circ}$ were carried out with inclusion of correction Δ for the temperature dependence of the enthalpy of the components of reaction (19):

$$\Delta = (H_T^\circ - H_{298}^\circ)_{\text{Ti(g)}} + y(H_T^\circ - H_{298}^\circ)_{\text{C(g)}} - (H_T^\circ - H_{298}^\circ)_{\text{TiC}_y(\text{s})}.$$

The $\Delta_{\text{at}}H_{298}^\circ$ values for carbides TiC_y under study were found by the least-squares minimisation of the expression

$$R \ln K(T) = c - \frac{\Delta_{\text{at}}H_{298}^\circ + \Delta}{T},$$

where c is a constant, using the experimental dependences $K(T)$. The heat effect of reaction (19), *i.e.*, the atomisation enthalpy of carbide TiC_y , was also determined using the equation of the third law of thermodynamics.

$$\Delta_{\text{at}}H_{298}^\circ = T\Delta\phi_T' - RT \ln K$$

with allowance for the calculated temperature and concentration dependence of the reduced potential $\Delta\phi_T'$.

The calculated standard atomisation enthalpies, $\Delta_{\text{at}}H_{298}^\circ$, of titanium carbides of different composition and the evaporation coefficients α_M and α_C are listed in Table 3. The parameters of the dependences $\ln V - T$ and $\ln p_{\text{Ti}}^\circ - T$ (see Table 3) correspond to the temperature range of congruent evaporation of TiC_y (from 2273 to 2673 K).

The dependence of the atomisation enthalpy on the composition of carbide TiC_y calculated by the least squares method using the $\Delta_{\text{at}}H_{298}^\circ$ values calculated from the equations of the second and third laws of thermodynamics has the form:

$$\Delta_{\text{at}}H_{298}^\circ(y)_{\text{TiC}_y} = 335.4 + 1177.8y - 128.3y^2 \pm 7. \quad (24)$$

For compounds MX_y , the atomisation enthalpy is given by the expression

$$\Delta_{\text{at}}H_{298}^\circ(y) = \Delta_s H_M^\circ + y\Delta_s H_X^\circ - \Delta H_{\text{f}298}^\circ(y), \quad (25)$$

where $\Delta_s H_M^\circ$ and $\Delta_s H_X^\circ$ are the evaporation enthalpies of the components M and X, respectively, and $\Delta H_{\text{f}298}^\circ(y)$ is the formation enthalpy of compound MX_y . The expression for the dependence of the heat of formation of carbide TiC_y on its composition derived using the relationships (24) and (25) and the reference data on the evaporation enthalpies of titanium and carbon, $\Delta_s H_{\text{Ti}}^\circ = 471$ and $\Delta_s H_{\text{C}}^\circ = 710 \text{ kJ mol}^{-1}$ (see Ref. 68) has the form^{60,61}

$$\Delta H_{\text{f}298}^\circ(y)_{\text{TiC}_y} = 135.6 - 467.8y + 128.3y^2 \pm 7. \quad (26)$$

The $\Delta H_{\text{f}298}^\circ$ values for carbides of compositions $\text{TiC}_{0.79}$, $\text{TiC}_{0.91}$ and $\text{TiC}_{1.00}$ were found to be -157 , -184 and -204 kJ mol^{-1} , respectively;⁶¹ this is in fairly good agreement with the results of earlier studies [*cf.* the $\Delta H_{\text{f}298}^\circ$ values of -183 , -207 (see Ref. 59) and -184 kJ mol^{-1} (see Ref. 58) for carbides of compositions $\text{TiC}_{0.79}$, $\text{TiC}_{0.91}$ and $\text{TiC}_{0.996}$, respectively]. The dissociation enthalpy of a gaseous titanium carbide molecule is $473 \pm 60 \text{ kJ mol}^{-1}$ (see Refs 68, 81). Using this value, the evaporation enthalpy of titanium carbide TiC_y was also roughly estimated^{60,61} as the difference between the atomisation and dissociation enthalpies (see Table. 3).

4. Nanocrystalline titanium carbide

Establishment of the fact that reduction of the grain or crystallite size down to and below a certain threshold value can cause substantial changes in the properties of solids^{82–86} gave a strong impetus to investigations of the nanocrystalline state of matter. Pioneering studies in this field were reported by Gleiter^{87–90} who developed a method for fabrication of compact nanomaterials from nanopowders (the so-called ‘compaction’). Ultradispersed and nanocrystalline transition metal carbides can be prepared by plasmachemical synthesis, mechanochemical synthesis, intense plastic deformation and structure ordering.^{91,92} Investigations of the nanocrystalline state of carbides are directed at making them less brittle and at improving their plasticity with simultaneous retention of high hardness typical of these compounds.

Ultradispersed transition-metal carbide powders are usually obtained by the interaction of chlorides of corresponding elements with dihydrogen and methane or other hydrocarbons in the low-temperature (4000–8000 K) argon plasma. The particles of such powders are single crystals 10 to 100–200 nm in size. Finely dispersed titanium, zirconium, niobium, tantalum, boron and silicon carbide powders were prepared by a plasmachemical technique.^{93,94}

Gas-phase synthesis involving laser heating of the mixture of reactant gases is a kind of plasmachemical synthesis.^{95–98} Laser heating allows control of homogeneous nucleation and excludes contamination. As the intensity of laser radiation increases, the size of nanoparticles decreases due to an increase in the temperature and in the heating rate of the reactant gases.

In the last decade, a mechanochemical technique has found wide use for the synthesis of nanocrystalline carbides. Mechanical milling is the most efficient method for production of large amounts of powders of different nanomaterials including carbides. Mechanochemical synthesis of nanocrystalline titanium carbide from a mixture of the metal and carbon powders was reported.⁹⁹ The mixture was ball milled. Formation of carbide occurred after pulverisation over a period of 4 to 12 h; the average particle size of the nanocrystalline powder after 48 h milling was $7 \pm 1 \text{ nm}$.

Nanocrystalline powder of cubic titanium carbide was also prepared by pulverising metallic titanium and graphite in a sapphire ball mill. The components were taken in a ratio that provided a $\text{Ti}_{44}\text{C}_{56}$ composition of the product.¹⁰⁰ The ball-to-powder mass ratio was 10:1. Milling was performed at room temperature in an argon atmosphere.

After pulverisation for 2000 s the X-ray diffraction pattern of the reactant mixture exhibited only broad reflections of elemental carbon and titanium (Fig. 8). Milling over a period of $1.1 \times 10^4 \text{ s}$ led to nearly complete disappearance of the graphite reflections. New reflections appeared after pulverisation for $1.5 \times 10^4 \text{ s}$ corresponded to a new cubic phase with the B1-type structure, *viz.*, titanium carbide. The lattice constant of titanium carbide pre-

Figure 8. Changes in the X-ray diffraction patterns of a powder mixture $\text{Ti}_{44}\text{C}_{56}$ as a function of milling duration (t) in the mechanochemical synthesis of titanium carbide ($\text{CuK}\alpha_{1,2}$ radiation).¹⁰⁰ $t = 2 \times 10^3$ (1), 6×10^3 (2), 8×10^3 (3), 1.15×10^4 (4), 1.5×10^4 (5), 2.2×10^4 (6), 4×10^4 (7), 8×10^4 (8) and $7.2 \times 10^5 \text{ s}$ (9).

pared in this manner was 0.4326 nm. Prolonged milling (4×10^4 s) led to complete disappearance of the reflections of metallic titanium and to an increase in the intensity of titanium carbide reflections. After 8×10^4 s, mechanical deformation of the powder particles developed and the grain size reduced dramatically, which was manifested in substantial broadening of reflections in the X-ray diffraction pattern. Pulverisation for 72×10^4 s resulted in the formation of titanium carbide nanocrystals. No observable changes in the state of the carbide sample were detected upon further extension of milling duration to 10^6 s.

Figure 9 illustrates the changes in the powder grain size during pulverisation according to X-ray diffraction and electron microscopy studies. The formation of nanocrystalline titanium carbide involves four stages. The first stage (milling for no longer than 1.1×10^4 s) is characterised by the formation of Ti/C composite particles with an average size of ~ 1000 nm. Metallographic tests revealed an onion-like structure of these species comprised of titanium and carbon layers. In the second stage, which takes from 1.1×10^4 to 2×10^4 s, solid-phase interaction between titanium and carbon occurs, resulting in coarse-grained titanium carbide particles 800 to 1000 nm in size. The third stage takes from 2×10^4 to 8×10^4 s and involves intense milling of titanium carbide grains followed by the formation of finely dispersed powder with a rather broad grain size distribution (from 5 to 100 nm in diameter); in this stage, titanium carbide grains form agglomerates of size 5 to 10 μm . The last, fourth, stage takes 8×10^4 to 1×10^6 s and is characterised by ‘grain size homogenisation’ of the nanocrystalline powder. Carbide powder thus obtained had a particle size of $\sim 2 \pm 1$ nm while its grains were agglomerated into spherulites of size no greater than 300 nm.

Figure 9. Grain size (d) of milled $\text{Ti}_{44}\text{C}_{56}$ powder as a function of milling duration t in the mechanochemical synthesis of titanium carbide.¹⁰⁰ The grain size was determined from broadening of X-ray diffraction reflections (1) and by electron microscopy (2).

Titanium carbide powders prepared¹⁰⁰ by milling over different periods of time (2.2×10^4 , 4×10^4 , 8×10^4 and 7.2×10^5 s) were sintered in activated plasma. This type of sintering is a kind of hot pressing. Salient features of the method are the use of pulsed voltage for plasma activation and combination of nonaxial torsion with pressure. Sintering for less than 8 min resulted in compact titanium carbide samples of high density (up to 5.2 g cm^{-3}) while the average grain size remained less than 70 nm. The microhardness of the sintered samples ($32 \pm 3 \text{ GPa}$) was no greater than that of conventional coarse-grained titanium carbide TiC_y ($0.9 \leq y \leq 1.0$).

The results obtained by El-Eskandarany *et al.*¹⁰⁰ pointed to high efficiency of mechanochemical synthesis for fabrication of nanocrystalline titanium carbide; however, no data on the chem-

ical composition of the carbide were reported in this study. The assumption¹⁰⁰ that the composition of mechanochemically synthesised titanium carbide is identical to that of the initial mixture ($\text{Ti}_{44}\text{C}_{56}$) seems to be doubtful. The reported lattice constant of titanium carbide is somewhat smaller, while the measured density is higher than the corresponding parameters of stoichiometric carbide $\text{TiC}_{1.0}$ (0.4328 nm and 4.91 g cm^{-3} , respectively). The reason for such a high density of titanium carbide obtained by El-Eskandarany *et al.*¹⁰⁰ is particularly incomprehensible. Even assuming that the synthesised carbide with the B1-type structure has the same composition as the charge [*i.e.*, $\text{Ti}_{0.44}\text{C}_{0.56}$ (or $\text{TiC}_{1.27}$?)], the metal sublattice of this carbide should contain defects, since for the B1-type structure the number of sites in the non-metal sublattice is the same as that in the metal sublattice and there are no possibilities of arranging any sort of excess atoms. If a particular sort of atom is in relative excess, the sublattice formed by the other sort of atom contains structural vacancies. In our case titanium carbide with the defect metal sublattice can have a composition $\text{Ti}_{0.79}\text{C}_{1.00}$; however, its density should be 20% lower than the calculated (theoretical) value. Noteworthy is that no vacancies were found so far in the metal sublattice of carbides; therefore, the metal sublattice of transition metal carbides is assumed to be perfect. Taking into account the aforesaid, the results obtained by El-Eskandarany *et al.*¹⁰⁰ should be thoroughly checked. We believe that titanium carbide synthesised in that study was highly contaminated with metal, which led to higher density of the material compared to the theoretical value.

A promising way of producing compact nanomaterials is to employ intense plastic deformation.^{85, 92, 101} Preparation of compact samples of nanocrystalline titanium carbide using this technique was reported.¹⁰² Milling and compacting experiments were carried out with coarse-grained ($d \approx 2\text{--}5 \mu\text{m}$) powder of nonstoichiometric carbide $\text{TiC}_{0.62}$. Intense plastic deformation was produced by applying torsion under quasi-hydrostatic pressure. X-Ray diffraction studies revealed retention of the B1-type cubic structure of all plastic deformed titanium carbide samples; however, the diffraction reflections were substantially broadened (Fig. 10). Evaluation of the grain size from the broadening magnitude showed that the compacted nanocrystalline samples of nonstoichiometric titanium carbide had an average grain size lying between ~ 30 and 50 nm. Contrary to metals, titanium carbide is very hard and brittle; therefore, it is of considerable interest that the grain size of titanium carbide was smaller than that of the metal samples after nearly identical plastic deformation.

Figure 10. Broadening of the (111)_{B1} reflection of nanocrystalline titanium carbide of composition $\text{TiC}_{0.62}$ prepared by intense plastic deformation (1) and coarse-grained (grain size $\sim 5 \mu\text{m}$) carbide $\text{TiC}_{0.62}$ (2).¹⁰² 2Δ is the total width of the reflection at half-maximum ($\text{CuK}\alpha_{1,2}$ radiation).

III. New chemical compounds in the Ti–C system

The discovery of molecular clusters of carbon and the first observations of the C_{60} fullerene molecule^{103–105} gave an impetus to investigations into the synthesis, structure and properties of fullerenes (see, *e.g.*, Refs 106–108) and to an intensive search for methods of obtaining molecular clusters of other substances. By analogy with fullerenes, molecular clusters were expected to have unique physical and chemical properties that differ from the properties of the known polymorphous modifications of the same substances.

1. Molecular cluster Ti_8C_{12}

In 1992,²⁸ search for new molecular clusters led to the discovery of unusual, stable charged cluster $Ti_8C_{12}^+$ corresponding to a pentagondodecahedral molecule of stoichiometric composition Ti_8C_{12} (Fig. 11 *a*). In an ideal dodecahedral molecule, all atoms are arranged on a sphere whose surface is obtained by linking adjacent atoms and comprises twelve regular pentagons. In this molecule, all carbon and titanium atoms are tricoordinated (similarly to fullerene C_{60}), occupy identical sites and are distributed over the vertices of the dodecahedron in such a manner that the Ti atom is linked to carbon atoms only while six C_2 units alternate with eight Ti atoms. The dodecahedral structure of Ti_8C_{12} can be represented as a cube with eight titanium atoms at the vertices and a C_2 unit in each face. The point symmetry group, T_h , of this structure includes 24 symmetry elements (rotations and reflections). High symmetry of the met-car (metallocarbohedrene) molecule implies its stability.

Figure 11. Dodecahedral structure of a Ti_8C_{12} molecular cluster of T_h symmetry (*a*) and a fragment of structure of T_d symmetry (*b*).²⁹

Yet another possible structure of the Ti_8C_{12} cluster is characterised by the point symmetry group T_d (see Fig. 11 *b*).²⁹ In this structure, titanium atoms occupy two types of lattice sites and each type of site forms a tetrahedron. The smaller tetrahedron is rotated by 90° about the larger tetrahedron. The sites in the titanium sublattice differ in arrangement with respect to the C_2 units. Indeed, six C_2 units are arranged parallel to the edges of the larger tetrahedron built of $Ti(1)$ atoms and perpendicular to the edges of the smaller tetrahedron formed by four $Ti(2)$ atoms. The $Ti(1)$ atoms are linked to three adjacent carbon atoms while the $Ti(2)$ atoms form bonds with six carbon atoms. The $Ti(1)$ –C and $Ti(2)$ –C distances are 0.193 and 0.219 nm, respectively.²⁹

The issue of which structural type is practically realised is still to be clarified since no molecular crystals of met-cars have been synthesised so far.

Clusters Ti_8C_{12} were synthesised using the gas-phase plasma-chemical technique with helium as inert gas, hydrocarbons (methane, ethylene, acetylene, propylene and benzene) and titanium vapours as reactants; the pressure of the gas mixture in the reactor was 93 Pa. A rotating metallic titanium rod was evaporated by exposing it to focussed radiation of a Nd laser operated at 532 nm, thus creating an ionised metal vapour beam. Neutral and ionised clusters were separated from other reaction products and

analysed mass spectrometrically. The mass spectra of the reaction products exhibited a sharp peak corresponding to the Ti_8C_{12} molecule. In addition to neutral molecules, the mixture of ionised gases also contained stable $Ti_8C_{12}^+$ ions.

The cluster Ti_8C_{12} was assumed²⁸ to be a member of a novel class of molecular clusters and called metallocarbohedrene or met-car (see Ref. 106). In met-cars, both the transition metal and carbon atoms form a cage-like structure. Indeed, other M_8C_{12} clusters of such transition metals as Zr, Hf, V,^{30,31} Cr, Mo and Fe³² were obtained after a short time. Met-cars have been reviewed.^{33,34}

The high stability of the cluster Ti_8C_{12} is thought to be due to peculiarities of its molecular and electronic structure; chemical bonds in the Ti_8C_{12} molecule are similar to those in the carbon fullerenes.²⁸ However, in contrast to C_{60} fullerene, both ionised and neutral M_8C_{12} molecules are comprised of five-membered rings only. The shape of the surface of stable cluster Ti_8C_{12} is similar to that of hypothetical unstable (and, hence, unfeasible) C_{20} fullerene. This fact shows that full similarity of chemical bonds in the clusters M_8C_{12} to those in carbon fullerene is hardly probable.

Indeed, calculations of the equilibrium crystal and electronic structure of the cluster Ti_8C_{12} with T_h symmetry (see Ref. 35) showed that the bonds between the titanium atoms and three adjacent carbon atoms differ from the bonds between carbon atoms in graphite or C_{60} fullerene. In particular, the Ti–C and C–C bond lengths in the Ti_8C_{12} molecule differ by nearly a factor of 1.5 and equal $3.76a_0$ and $2.63a_0$ ($a_0 = 0.052918$ nm is the radius of the first Bohr orbit), respectively. According to Reddy *et al.*,³⁶ the Ti–C bond is $\sim 30\%$ longer than the C–C bond. On the other hand, the distances from carbon and titanium atoms to the centre of the cluster are nearly equal. This means that the real dodecahedral structure of Ti_8C_{12} is strongly distorted. The bonding states of the cluster Ti_8C_{12} are thought to be composed of the Ti *d*-AOs and the C_2 MOs while the Fermi level lies between the bonding and antibonding states of titanium, thus providing stability for the cluster.³⁵ Analogous conclusions that clusters M_8C_{12} have a distorted rather than ideal pentagondodecahedron shape were obtained in calculations reported by other authors.

Comparative analysis of the electronic structure of the Ti_8C_{12} met-car of T_h and $T_d^\dagger$ symmetry showed³⁷ that in both structural types the highest occupied energy level corresponds to a sharp peak of the density of states (DOS) composed mainly of the $C2p$ - and $Ti3d$ -AOs. High chemical stability of compound Ti_8C_{12} is due to a combination of strong $Ti3d$ – $C2p$ interactions between the titanium atoms and C_2 unit on the one hand and to the C–C interactions in the carbon units on the other hand. In both structural types, Ti_8C_{12} has an open electron shell and can therefore be both electron acceptor and donor.

The atoms in met-car molecules are tightly bound. For instance, the bond energy in the Ti_8C_{12} molecule is 6.1–6.7 eV per atom.^{35,36,38} For comparison, this parameter is 7.4–7.6 eV per atom for C_{60} fullerene molecule (see Refs 109, 110) and 7.2 eV per atom for titanium carbide TiC with the *B1* (NaCl)-type fcc structure.³⁵

Modern concepts of the geometry and electronic structure of molecular clusters Ti_8C_{12} (see Refs 29, 35–38) provide good explanation for their chemical stability and specific features of the reactivity towards both polar and nonpolar compounds. Combination of high reactivity and stability of Ti_8C_{12} clusters was confirmed experimentally.¹¹¹

Molecular cluster Ti_8C_{12} has been the most detailed studied new compound in the Ti–C system; however, no macroscopic amounts of this substance were obtained so far.

[†] Calculations for T_h and T_d symmetry were carried out using the structure parameters and interatomic distances reported by Reddy *et al.*³⁶ and by Lin and Hall,²⁹ respectively.

2. Polymorphous modification of dicarbide TiC₂

Comparative analysis of the electronic structure of hypothetical metastable polymorphous modifications of carbide TiC_{1.0} with the *B2* (CsCl)-, *B8* (NiAs)-, *B3*- and *B4* (sphalerite and wurtzite ZnS)-type structures and that of the real carbide TiC_{1.0} with the *B1*-type structure showed¹¹² that search for new stable modifications of titanium carbide should be performed among those substances that are structurally similar to or derived from the *B1* type.

Titanium dicarbide, which can have several types of crystal structure, was studied as a representative of this group of substances.^{112, 113} The ThC₂-type monoclinic structure (space group *C2/c*) has a tetrahedral body-centred metal sublattice while the C₂ units occupy the octahedral interstices. In the CaC₂ (*C11a*)-type tetragonal body-centred structure [space group *I4/m* (*C*_{4h}⁵)] the C₂ units also occupy octahedral interstices. The *C11a* structural type can be derived from the *B1*-type lattice by extending it along the *c* axis; sites in the non-metal sublattice are occupied by the C₂ units oriented along the *c* axis. The unit cell of titanium dicarbide with this structural type comprises two formula units TiC₂ (Fig. 12). The atomic coordinates in the unit cell are listed in Table 4; the running coordinate of carbon atoms, *z/c* = 0.427, was determined assuming the same length of all Ti–C distances in the unit cell because each type of atom occupies sites of the same type. Figure 13 presents the X-ray diffraction pattern of tetragonal TiC₂ calculated using the atomic coordinates listed in Table 4.

Figure 12. Unit cells of body-centred tetragonal TiC₂ with the CaC₂ (*C11a*)-type structure, space group *I4/m* (*C*_{4h}⁵) (a), and with the CsCl (*B2*)-type structure, space group *P4/mmm* (*D*_{4h}¹) (b).

The non-metal sublattice of titanium dicarbide with the *B2* (CsCl)-type tetragonal structure [space group *P4/mmm* (*D*_{4h}¹)] is built of C₂ units. The unit cell of this structure comprises one

Figure 13. X-Ray diffraction pattern of tetragonal TiC₂ with the CaC₂ (*C11a*)-type structure, space group *I4/m* (*C*_{4h}⁵). Calculated for CuK_{α1,2} radiation.

formula unit TiC₂ (see Fig. 12). The atomic coordinates in the unit cell are listed in Table 4. The running coordinate, *z/c*, of carbon atoms remains unknown so far and can vary between 0 and 0.5. The C–C separation in the C₂ unit is 0.124 nm; in titanium dicarbide this distance should be somewhat longer due to titanium–carbon interatomic interactions. This suggests that the most probable *z/c* values lie between 0.25 and 0.31. Figure 14 presents the X-ray diffraction patterns of tetragonal titanium dicarbide TiC₂ (space group *P4/mmm*) calculated for several different positions of the carbon atom (*z* = 0.10, 0.25, 0.30 and 0.40). Position of the carbon atom has a strong effect on the intensity ratio of diffraction reflections, namely, an increase in *z* from 0.1 to 0.4 causes a decrease in the intensities of the (001) and (111) reflections and an increase in the intensity of the (101) reflection.

Similarly to cubic monocarbide TiC_y, in titanium dicarbide with the CaF₂ (*C1*)-type cubic structure [space group *Fm3m* (*O*_h⁵)] (Fig. 15) titanium atoms form a face-centred metal sublattice. However, carbon atoms occupy tetrahedral rather than octahedral (as in TiC_y) interstices. Naturally, the lattice constant of titanium dicarbide must be larger than that of titanium monocarbide, since only in this case is the size of the tetrahedral interstice sufficient to contain a carbon atom. Analysis of the crystal structure of cubic TiC₂ showed that it is a typical representative of interstitial phases. In the nondistorted crystal

Effect of the position of carbon atom (z) in the unit cell of tetragonal TiC_2 with the CsCl -type structure (space group $P4/mmm$, $a = 0.2594$, $c = 0.337$ nm) on the intensity ratio of diffraction reflections (calculated for $\text{CuK}\alpha_{1,2}$ radiation). $z = 0.40$ (1); 0.30 (2); 0.25 (3) and 0.10 (4).

Figure 15. Unit cell of cubic TiC_2 with the CaF_2 ($C1$)-type structure, space group $Fm\bar{3}m$ (O_h^5).

lattice of this compound each carbon atom has a regular tetrahedral environment (four titanium atoms) while each titanium atom is surrounded by eight carbon atoms arranged at the cube vertices. The unit cell of cubic titanium dicarbide comprises four TiC_2 formula units. The calculated X-ray diffraction pattern of this dicarbide is shown in Fig. 16.

The electronic energy spectrum of hypothetical titanium dicarbide TiC_2 with the ThC_2 -type monoclinic structure [space group $C2/c$ (C_{2h}^6)] was calculated.^{112,113} The lattice constants of this compound are $a = c = 0.510$ and $b = 0.310$ nm.¹¹² The unit

cell of monoclinic titanium dicarbide constructed using the atomic coordinates for monoclinic ThC_2 (see Ref. 114) is shown in Fig. 17 (the atomic coordinates in the unit cell are listed in Table 4). The unit cell comprises four formula units TiC_2 . Distorted octahedra built of six titanium atoms contain two asymmetrically arranged carbon atoms (connected by a dashed line) separated by 0.251 nm. Atoms of the C_2 units are shared by two neighbouring octahedra while the C—C bonds pass through their common edges; the C—C distance in the C_2 units is 0.097 nm (in Fig. 17, the atoms of these units are shown connected by an arrow). The X-ray diffraction pattern calculated for polycrystalline dicarbide TiC_2 with this unit cell is shown in Fig. 18.

Figure 18. X-Ray diffraction pattern of monoclinic TiC_2 with the ThC_2 -type structure, space group $C2/c$ (C_{2h}^6). Calculated for $\text{CuK}\alpha_{1,2}$ radiation.

In polymorphous modifications of TiC_2 with the CaC_2 -, CsCl -, CaF_2 - and ThC_2 -type structures the Fermi level lies in the region of delocalised d -states of titanium;^{112,113} therefore, all the four TiC_2 modifications behave as metals. The most stable is dicarbide with the ThC_2 -type monoclinic structure. In dicarbide with the CaC_2 -type structure the C—C bonds in C_2 units are the strongest, whereas the Ti—C bonds are poorly populated and, hence, weaker. Calculations for cubic TiC_2 with the CaF_2 -type structure showed the absence of C—C bonds. According to calculations of the electronic structure of titanium dicarbides with the CaC_2 - and ThC_2 -type structures, the density of electron states at the Fermi level depends on the orientation of C_2 units in the crystal lattice. This implies the possibility of modifying the

Figure 19. Arrangement of C_2 dimers in hypothetical titanium dicarbide with body-centred tetragonal structure of the CaC_2 (YC_2) type (a) and possible orientation disorder types of the carbon dimers (b–f).¹¹²

electronic structure and properties of titanium dicarbide by means of orientation ordering of the C_2 units.

Some of the possible types of orientation ordering of C_2 units are shown in Fig. 19.^{112, 113} The simplest form has the electronic spectrum of dicarbide TiC_2 with ordered CaC_2 -type structure (see Fig. 19 a). Changes in the orientation of a fraction of C_2 units are accompanied by complication of the DOS distribution profile and by the appearance of new peaks. The most probable orientation type of C_2 units is to some extent similar to the ThC_2 -type structure (Fig. 19 d).¹¹² The least probable is the orientation of a fraction of C_2 units along the edges of the unit cell (Fig. 19 c).

Experimental studies concerning the search for titanium dicarbide are scarce. A carbon–titanium compound with the concentration of bound carbon of greater than 50 at.% was first obtained in the high-temperature interaction of ethylene with titanium tetrachloride (gas-phase synthesis).¹¹⁵ The carbide thus obtained had a CsCl-type cubic lattice with a lattice constant of 0.313 nm and was thought to have a TiC_2 composition. However, attempts at reproducing these results¹¹⁵ failed.

A recent microdiffraction study¹¹⁶ on films prepared by ion sputtering of carbon and titanium followed by vapour deposition revealed the formation of a compound with a body-centred lattice and composition TiC_2 . The deposition temperature was varied from 330 to 770 K; thin films were deposited on fresh KCl cleavages, coatings 10 to 18 μm thick were obtained on glassy substrates. Films condensed at 330 K and annealed at 700 K for 3 h contained only titanium monocarbide. As the deposition (condensation) temperature increased from 330 to 620 K, the phase composition of the films remained unchanged; however, the fcc lattice constant of titanium carbide in these films reached ~ 0.455 nm at a carbon content of greater than 65 at.%. A gas-phase electron diffraction study also revealed a decrease in the intensity of reflections accompanied by an increase in the diffuse background at a carbon content of greater than 60 at.%. The electron diffraction patterns of the films containing ~ 65 at.% of carbon and deposited at 670 K exhibited three diffuse lines assigned to the body-centred lattice with a lattice constant of ~ 0.3 nm. A homogeneous film was prepared by condensation at 770 K; the partial pressure of reactants (gaseous carbon and titanium) was 8×10^{-8} Pa, the film growth rate was ~ 0.1 nm s^{-1} and the content of carbon in the vapours was ~ 66 at.%. The results obtained allowed one to suggest the formation of TiC_2 films, a body-centred lattice of this compound with a lattice constant of 0.294 nm and the structure of titanium dicarbide.

The results reported by Perekrestov and Pavlov¹¹⁶ and especially their interpretation provoke some objections. First of all, no direct determination of film composition was made (at best, the content of carbon in the gas flow was monitored indirectly). The proposed crystal lattice structure of TiC_2 is not body-centred. This is a cubic lattice [space group $F\bar{4}3m$ (T_d^2)] with a face-centred metal (titanium) sublattice and a diamond-like non-metal (carbon) sublattice [$A4$ type, *i.e.*, two face-centred lattices displaced by $(1/4, 1/4, 1/4)$ with respect to each other]. In the unit cell of this structure (Fig. 20) half of the carbon atoms occupy the octahedral interstices of the titanium sublattice, while the rest of the carbon atoms occupy half of the tetrahedral interstices of the titanium sublattice, so each of them is tetrahedrally surrounded by four titanium atoms and by four carbon atoms. This unit cell comprises four formula units TiC_2 and the lattice constant is 0.588 nm. The atomic coordinates in the cubic unit cell of TiC_2 (space group $F\bar{4}3m$) are listed in Table 4 and the calculated X-ray diffraction pattern is presented in Fig. 21.

Figure 20. Unit cell of cubic TiC_2 , space group $F\bar{4}3m$ (T_d^2), $a = 0.588$ nm.

Figure 21. X-Ray diffraction pattern of polycrystalline cubic TiC_2 , space group $F\bar{4}3m$ (T_d^2), $a = 0.588$ nm. Calculated for $CuK_{\alpha 1,2}$ radiation.

In addition to clusters M_8C_{12} (see Section III.1), laser-assisted plasmachemical synthesis led to the formation of cluster-type nanoparticles M_mC_n ($M = Ti, Zr, Hf, V$; $m:n \approx 1:2$).^{28, 30, 31} For $M = Ti$, molecular clusters of composition $Ti_{13}C_{22}$ were usually formed (*i.e.*, the titanium : carbon ratio was close to the corresponding parameter in ideal TiC_2). Preferable formation of nano-clusters with a high content of carbon ($M:C \approx 1:2$) occurred at a high concentration of hydrocarbon in the gas phase and at an increased laser power, which led to an increase in the hydrogenation degree of the hydrocarbon and, correspondingly, to an increase in the content of carbon in the plasma.

Thus, analysis of the available data suggests that titanium dicarbide TiC_2 can belong to five structural types. These are the ThC_2 -type monoclinic structure [space group $C2/c$ (C_{2h}^6)]; CaC_2 ($C11a$)- and CsCl ($B2$)-type tetragonal structures with $I4/m$ (C_{4h}^5) and $P4/mmm$ (D_{4h}^1) space groups, respectively; CaF_2 ($C1$)-type cubic structure [space group $Fm\bar{3}m$ (O_h^h)] and a cubic structure

with a diamond-like carbon sublattice and the $F\bar{4}3m$ (T_d^2) space group.

3. Endohedral fullerene $\text{Ti}@\text{C}_{28}$ and rhombohedral titanium carbide

The discovery of C_n fullerenes ($n = 60-90$) (see Refs 70–73, 117, 118) and further studies of these compounds showed that the C_n clusters containing less than 60 carbon atoms are of low stability. Fullerenes with a small number of atoms (*e.g.*, C_{28} fullerene) can be stabilised by preparing endohedral complexes $\text{M}@\text{C}_{28}$ in which the dopant atom is placed inside the carbon sphere. A $\text{Ti}@\text{C}_{28}$ endohedral complex was also synthesised.¹¹⁹

The possibility of stabilising unstable C_{28} fullerene by intercalating it with both non-metal atoms of 2*p*-elements (B, C, N and O) and metals (3*d*-elements such as Sc, Ti, V, Cr, Fe and Cu) was studied theoretically.^{112, 120} When estimating the formation probability of endohedral $\text{M}@\text{C}_{28}$ complexes with 3*d*-metals, one can take into account the geometric, chemical and kinetic factors. In the case of C_{28} fullerene the maximum radius of a metal ion that can be placed inside the carbon sphere lies between 0.09 and 0.10 nm (see Ref. 121); all 3*d*-metals fulfil this geometric criterion. The chemical factor is favourable if electron density transfer as a result of intercalation favours an increase in the bonding character of the MOs. The kinetic factor includes the formation mechanism of endohedral complexes. They are prepared by rolling a graphene sheet around the metal atom adsorbed on the graphite surface. This can occur if the interaction between the metal and the graphite surface causes strengthening of the M–C bonds and weakening of the C–C bonds (especially of the interlayer bonds). Recent studies^{112, 120} showed that intercalation of metal atoms is accompanied by electron density transfer from these atoms to the atoms of the fullerene cage, by changes in the populations of the overlapping C–AOs, by the formation of the M–C bond and by a change in the pattern of the electronic energy spectrum.

The endohedral complex $\text{Ti}@\text{C}_{28}$ with the Ti atom at the centre of the C_{28} polyhedron was shown to be the most stable (with inclusion of the chemical and kinetic factors).¹²⁰ Probably, this complex can be considered as a possible molecular cluster-like compound that can be formed in the Ti–C system.

The results of a recent study¹²² on the electronic structure of hypothetical metastable polymorphous modifications of $\text{TiC}_{1.0}$ prompted us to mention a study by Dubrovinskaia *et al.*¹²² who experimentally found a rhombohedral modification of titanium carbide. The sample of cubic titanium carbide (no composition was reported) with a lattice constant of 0.4327 nm was subjected to quasi-hydrostatic pressure (~ 10 GPa) at 300 K. This resulted in broadening of the diffraction reflections of the $B1$ -type cubic structure and in splitting of the $(111)_{B1}$ reflection into two lines corresponding to the rhombohedral structure at a pressure of 18 and 38 GPa. The authors believed that rhombohedral distortion of the cubic unit cell is due to extension of its $[111]$ diagonal, which led to splitting of the $(111)_{B1}$ reflection into the (003) and (101) rhombohedral lines and to splitting of the $(200)_{B1}$ reflection into the (104) and (110) lines. Rhombohedral titanium carbide prepared at a pressure of 38 GPa has a unit cell with the lattice constants $a = 0.29442$ and $c = 0.73354$ nm (in a hexagonal setting).

IV. Ordered phases of nonstoichiometric titanium carbide TiC_y

The ordering of interstitial atoms was experimentally found for most of the nonstoichiometric transition metal carbides, nitrides and oxides. In disordered nonstoichiometric compounds the interstitial atoms and structural vacancies form a substitution solution in the non-metal sublattice, all sites of the non-metal sublattice being crystallographically equivalent. Ordering causes redistribution of the interstitial atoms and vacancies over sites of the non-metal sublattice, thus making the lattice sites inequivalent. The crystal lattice is divided into at least two sublattices

differing in site occupation probabilities by the atoms of the same sort. Ordering is accompanied by symmetry reduction of the crystal, since some of the symmetry elements of a disordered non-metal sublattice that match the occupied and vacant sites do not belong to the group of symmetry elements of the ordered crystal in which these sites become crystallographically inequivalent.

From the aforesaid it follows that the nonstoichiometry responsible for the fact that the number of interstitial sites is larger than that of atoms occupying these sites is a prerequisite to the ordering in defect carbides.

Description of different ordered phases of nonstoichiometric carbides, nitrides, oxides and their solid solutions can be found in reviews^{1, 22, 123–127} and monographs.^{2, 3, 14, 17, 27, 70}

Compared to other carbides (except for vanadium carbide VC_y), the ordering in nonstoichiometric titanium carbide TiC_y with the $B1$ -type cubic structure has been studied in most detail; however, the mechanism of this process is still to be clarified. A great body of experimental information on the chemical composition and structure of ordered phases of titanium carbide TiC_y , published earlier has not been confirmed later. The main characteristics of both experimentally observed and theoretically calculated ordered phases of nonstoichiometric titanium carbide are listed in Table 5.

As mentioned above, disordered titanium carbide TiC_y ($\text{TiC}_y\Box_{1-y}$) is characterised by an extremely broad homogeneity region from $\text{TiC}_{0.48}$ to $\text{TiC}_{1.00}$ (see Refs 2, 3, 14). Within this region, carbon atoms and structural vacancies $\Box$ form a substitution solution in the non-metal sublattice. Depending on the composition and the synthesis and heat treatment conditions, TiC_y can exist in a disordered or ordered state. The disordered state is in thermodynamic equilibrium at $T > 1100$ K, while the ordered state is in thermodynamic equilibrium at $T < 1000$ K. Due to the low diffusive mobility of the atoms, the disordered state of nonstoichiometric titanium carbide is retained upon quenching from $T > 1100$ K to rather low temperatures (~ 300 K) and exists as a metastable state at $T < 1000$ K.

Order-parameter functional (OPF) calculations^{1–3, 18, 20, 22} showed that monocarbide TiC_y can form three ordered phases of compositions Ti_2C , Ti_3C_2 and Ti_6C_5 . According to the inverse Monte Carlo calculations performed for a narrower composition range from $\text{TiC}_{0.55}$ to $\text{TiC}_{0.70}$ (see Ref. 12), the ordered phases Ti_2C and Ti_3C_2 are in thermodynamic equilibrium at $T < 950$ K, which is in agreement with the results of the above-mentioned calculations.^{1–3, 18, 20, 22} Experimental studies of carbide TiC_y in the composition range $0.5 \leq y < 0.7$ revealed the existence of ordered phases of the Ti_2C type with cubic (space group $Fd\bar{3}m$) and trigonal (space group $R\bar{3}m$ or $P3_121$, the former being more probable) symmetry (see Table 5), orthorhombic ordered phase Ti_3C_2 (space group $C222_1$) and hexagonal ordered phase Ti_6C_5 (see Ref. 130). The trigonal ordered phase Ti_8C_5 (space group $R\bar{3}m$) was reported erroneously. Virtually no studies of the ordering of TiC_y ($y > 0.7$) were performed until the mid-1990s.

Let us consider in more detail which ordered phases of the compositions Ti_2C and Ti_3C_2 can be formed in nonstoichiometric carbide TiC_y .

According to different studies of TiC_y , an ordered phase of composition Ti_2C with cubic (space group $Fd\bar{3}m$) (see Refs 9, 46–48, 50) or trigonal (space group $R\bar{3}m$) (see Refs 12, 49) symmetry is formed in the range $0.5 \leq y \leq 0.65$ at $T < 1100$ K.[‡] Cubic Ti_2C phase is thought to be metastable. Initially,^{49, 129} the cubic phase was assumed to have a higher T_{trans}

[‡] Information on the existence of the trigonal (space group $P3_121$) Ti_2C ($\text{Ti}_6\text{C}_{3+x}$) phase is erroneous: formation of a trigonal (space group $P3_121$) M_2C -type phase with the unit cell parameters $a = b = a_{B1}/\sqrt{2}$ ($\mathbf{a} = \{1/2, 1/2, 0\}_{B1}$) and $c = 3\sqrt{2} \times a_{B1}$ ($\mathbf{c} = \{222\}_{B1}$) based on the basic $B1$ -type structure is impossible, since in this case the sites of the metal and non-metal sublattices partially match one another.

Table 5. Characteristics of ordered phases of nonstoichiometric titanium carbide TiC_y with cubic $B1$ -type structure.

Com- position	Existence region	Symmetry (lattice type)	Space group	Unit cell parameters /nm	Ref.	Note ^a
Ti_2C	$\text{TiC}_{0.52} - \text{TiC}_{0.71}$	cubic	$Fd\bar{3}m$	$a = 2a_0$	9, 48	carbon sublattice is partially ordered; $T_{\text{trans}} \approx 950 - 1030$ K

Ti_6C_5	—	hexagonal	—	$a = b = (a_0\sqrt{6})/2 = 0.529,$ $c = (4a_0\sqrt{3})/3 = 0.996$	130	phase was found in thin films
Ti_2C	$\text{TiC}_{0.47} - \text{TiC}_{0.54}$	—	—	—	18, 20, 22	calculated; $T_{\text{trans}} < 950$ K; the homogeneity region corresponds to 600 K
Ti_3C_2	$\text{TiC}_{0.62} - \text{TiC}_{0.70}$	—	—	—	18, 20, 22	calculated; $T_{\text{trans}} < 930$ K; the homogeneity region corresponds to 600 K
Ti_6C_5	$\text{TiC}_{0.80} - \text{TiC}_{0.90}$	—	—	—	18, 20, 22	calculated; $T_{\text{trans}} < 920$ K; the homogeneity region corresponds to 600 K

^a T_{trans} is the disorder–order transformation temperature.

value than the trigonal phase, thus being an intermediate ordered high-temperature phase with respect to the disordered phase and low-temperature trigonal phase of composition Ti_2C . Tashmetov *et al.*¹³¹ reported a consecutive phase transformation

However, de Novion *et al.*¹² suggested that in TiC_y ($y \geq 0.58$) the cubic phase Ti_2C can exist as a metastable phase for which T_{trans} is ~ 10 K lower than for the trigonal ordered phase.

Analysis of the results of experimental structural studies^{9, 12, 46–50, 128, 131} showed that cubic superstructure Ti_2C is usually found in annealed TiC_y samples with $y < 0.55–0.56$, whereas the samples with $0.58 \leq y \leq 0.65$ are characterised by trigonal ordering. It should be noted that the X-ray diffraction patterns of both cubic and trigonal ordered phases of composition Ti_2C exhibit identical sets of superstructure reflections and can be distinguished only given trigonal distortions in the phase with the space group $R\bar{3}m$ and taking into account the directions of static atomic displacements.¹²⁶ Probably, this is the reason for attributing the observed superstructure reflections in annealed carbide TiC_y ($y \geq 0.59$) to the cubic phase Ti_2C in the studies^{46–48, 50} concerned with the cubic model of ordering.⁹ Other authors^{12, 49, 128, 129, 131} showed that trigonal phase Ti_2C is the major ordered phase of TiC_y ($y \geq 0.6$).

The assumption of the existence of ordered phase Ti_3C_2 in the composition range $\text{TiC}_{0.60} - \text{TiC}_{0.70}$ was confirmed by some experimental studies. An elastic neutron scattering study¹²⁹ of annealed single crystal $\text{TiC}_{0.61}$ revealed the presence of the $(2/3 \ 2/3 \ 0)$ superstructure reflections. The X-ray diffraction pattern of annealed carbide $\text{TiC}_{0.70}$ exhibited weak superstructure reflections with the reduced diffraction vector $|\mathbf{q}| \approx 2.03$ characteristic of the orthorhombic phase Ti_3C_2 (space group $C222_1$).¹³² Diffuse neutron scattering maxima corresponding to the $(2/3 \ 2/3 \ 0)$ reflections and due to short-range order in $\text{TiC}_{0.76}$ were detected.¹³³ Estimation of the short-range order parameters in a

single crystal of composition $\text{TiC}_{0.64}$ ¹² using the diffuse neutron scattering data showed that agreement between the calculated and experimental data is the best when annealed carbide $\text{TiC}_{0.64}$ contained a mixture of two ordered phases Ti_2C and Ti_3C_2 . The existence of a trigonal phase Ti_3C_2 was also confirmed by the OPF^{18, 20, 22} and Monte Carlo^{10, 12} calculations. A theoretical study¹⁸ also suggested the formation of an ordered phase Ti_6C_5 in carbide TiC_y ($0.78 < y < 0.88$). The calculated disorder–order transformation temperatures for the Ti_3C_2 and Ti_6C_5 phases did not exceed 950 K.^{18, 20, 22}

The structure of the ordered phases of nonstoichiometric carbide TiC_y has been studied in detail.²¹

Samples of nonstoichiometric titanium carbide TiC_y with different carbon content ($0.52 \leq y \leq 0.98$) were synthesised by hot pressing the mixtures of $\text{TiC}_{0.98}$ and metallic titanium powders ($T = 1773–2173$ K, $p = 20–30$ MPa) in highly pure argon atmosphere for 30 min or by solid-phase vacuum sintering the $\text{TiC}_{0.94}$, carbon black and metallic titanium powders ($T = 2000$ K, $p = 0.001$ Pa) for 6 h. The ordered state of the carbides obtained was achieved by annealing the samples with gradual lowering of the temperature from 1070 down to 770 K for 340 h. Annealing resulted in the appearance of superstructure reflections in the X-ray diffraction patterns of carbides $\text{TiC}_{0.50}$, $\text{TiC}_{0.52}$, $\text{TiC}_{0.54}$, $\text{TiC}_{0.55}$, $\text{TiC}_{0.58}$ and $\text{TiC}_{0.62}$.

The X-ray diffraction patterns of the annealed carbides $\text{TiC}_{0.50}$, $\text{TiC}_{0.52}$ and $\text{TiC}_{0.54}$ exhibited identical sets of superstructure reflections. The first superstructure reflection with the reduced wave vector $|\mathbf{q}| = (2a_B \sin \theta)/\lambda \approx 0.870$ in the region $2\theta \approx 17.8–17.9^\circ$ corresponds to the vector $\{1/2 \ 1/2 \ 1/2\}$ of length $|\mathbf{q}| \approx 0.866$. The next three superstructure reflections at $2\theta \approx 34.5, 45.9$ and 55.4° correspond to the vectors $\{3/2 \ 1/2 \ 1/2\}$, $\{3/2 \ 3/2 \ 1/2\}$ and $\{3/2 \ 3/2 \ 3/2\}$. The $\{3/2 \ 3/2 \ 1/2\}$ superstructure reflection is very weak. Taking into account the positions of the observed superstructure reflections and the absence of trigonal splitting of the $(331)_{B1}$, $(420)_{B1}$ and $(422)_{B1}$ lines, one can suggest that annealing led to the formation of the ordered cubic phase Ti_2C (space group $Fd\bar{3}m$) in carbides $\text{TiC}_{0.50}$, $\text{TiC}_{0.52}$ and $\text{TiC}_{0.54}$. The channel of disorder–order structural phase transformation TiC_y (space group $Fm\bar{3}m$) $\rightleftharpoons$ Ti_2C (space group

Figure 22. Cubic unit cell (space group $Fd\bar{3}m$) of the Ti_2C superstructure in the lattice with the $B1$ -type structure (Ti atoms are not shown).^{17, 27, 126}

$Fd\bar{3}m$) includes all four arms of the $\{\mathbf{k}_9\}$ Lifshitz star: $\mathbf{k}_9^{(1)} = (\mathbf{b}_1 + \mathbf{b}_2 + \mathbf{b}_3)/2$, $\mathbf{k}_9^{(2)} = \mathbf{b}_1/2$, $\mathbf{k}_9^{(3)} = \mathbf{b}_2/2$ and $\mathbf{k}_9^{(4)} = \mathbf{b}_3/2$.[§]

The unit cell of cubic superstructure M_2C (space group $Fd\bar{3}m$) is shown in Fig. 22. The translation vectors of and the atomic and vacancy coordinates in the unit cell are listed in Table 6. In completely ordered, ideal cubic superstructure M_2C all metal atoms occupy sites of the M_3^4 type (the subscript and superscript denote the number of vacancies in the first and second coordination sphere of the metal atom, respectively). The non-metal sublattice of this superstructure is characterised by alternation of the $(111)_{B1}$ atomic planes in which $1/3$ and $2/3$ of the total number of sites are vacant.

Table 6. Characteristics of cubic [space group $Fd\bar{3}m (O_h^7)$] M_2C superstructure: $\mathbf{a}_1 = \langle 200 \rangle_{B1}$, $\mathbf{a}_2 = \langle 020 \rangle_{B1}$, $\mathbf{a}_3 = \langle 002 \rangle_{B1}$.^{16, 27, 126}

Atom	Position	Atomic coordinates in ideal ordered structure		
		x/a_1	y/a_2	z/a_3
C1 (vacancy)	16 (c)	1/8	1/8	1/8
C2	16 (d)	5/8	5/8	5/8
M1	32 (e)	3/8	3/8	3/8

The X-ray diffraction pattern of annealed carbide $\text{TiC}_{0.58}$ exhibited the $\{1/2 \ 1/2 \ 1/2\}$, $\{3/2 \ 1/2 \ 1/2\}$ and $\{3/2 \ 3/2 \ 3/2\}$ superstructure reflections at $2\theta \approx 17.9^\circ$, 34.4° and 55.4° (see Ref. 21). No $\{3/2 \ 3/2 \ 1/2\}$ reflection was observed. An important distinction of the X-ray diffraction pattern of annealed carbide $\text{TiC}_{0.58}$ from those of annealed carbides of compositions $\text{TiC}_{0.50}$, $\text{TiC}_{0.52}$ and $\text{TiC}_{0.54}$ is the presence of trigonal splitting of the $(220)_{B1}$, $(311)_{B1}$, $(222)_{B1}$, $(331)_{B1}$, $(420)_{B1}$ and $(422)_{B1}$ lines. This is an indication of the trigonal ordered phase Ti_2C (space group $R\bar{3}m$) formed in carbide $\text{TiC}_{0.58}$ upon annealing.

The unit cell of the trigonal phase is shown in Fig. 23. Its translation vectors and the atomic and vacancy coordinates in ideal trigonal structure M_2C are listed in Table 7. The TiC_y (space group $Fm\bar{3}m$) $\rightleftharpoons$ Ti_2C (space group $R\bar{3}m$) disorder – order phase transition channel involving the formation of this superstructure includes one arm, $\mathbf{k}_9^{(3)} = \mathbf{b}_2/2$, of the $\{\mathbf{k}_9\}$ Lifshitz star.

[§] For a detailed description of all stars $\{\mathbf{k}_s\}$ of the wave vectors of the first Brillouin zone and their arms for a crystal with a fcc lattice, see Refs 2, 3 and 70.

C1 (vacancy)	1 (a)	0	0	0
C2	1 (b)	1/2	1/2	1/2
M1	2 (c)	1/4	1/4	1/4

The non-metal sublattice of completely ordered trigonal structure M_2C (space group $R\bar{3}m$) is characterised by alternation of the $(1\bar{1}1)_{B1}$ atomic planes with completely occupied (by interstitial atoms) and completely vacant sites along the $[1\bar{1}1]_{B1}$ direction. This superstructure must have a highly distorted metal sublattice. In completely ordered, ideal trigonal superstructure M_2C all metal atoms occupy identical sites of the M_3^4 type with three vacancies in the first and four vacancies in the second coordination sphere.

The X-ray diffraction pattern of annealed carbide $\text{TiC}_{0.62}$ exhibited both the $\{1/2 \ 1/2 \ 1/2\}$ ($2\theta \approx 18.0^\circ$) and $\{3/2 \ 3/2 \ 3/2\}$ ($2\theta \approx 55.2^\circ$) superstructure reflections from the trigonal ordered phase Ti_2C (space group $R\bar{3}m$) and some other superstructure reflections that were absent in the X-ray diffraction patterns of the carbides of compositions $\text{TiC}_{0.50}$, $\text{TiC}_{0.52}$, $\text{TiC}_{0.54}$, $\text{TiC}_{0.55}$ and $\text{TiC}_{0.58}$ (see Ref. 21). These are the reflections in the ranges $2\theta \approx 30.6 - 30.7^\circ$, 41.2° , 42.6° and $55.4 - 55.5^\circ$ with reduced wave vectors of lengths $|\mathbf{q}| \approx 1.488$, 1.970 , 2.038 and 2.607 , respectively. The first two reflections are associated with the $\mathbf{k}_4^{(1)} = \{2/3 \ 2/3 \ 0\}$ and $\mathbf{k}_4^{(2)} = -\mathbf{k}_4^{(1)}$ arms of the $\{\mathbf{k}_4\}$ star, while the other two reflections are associated with the $\mathbf{k}_3^{(3)} = \{1/3 \ -2/3 \ -1/2\}$, $\mathbf{k}_3^{(4)} = -\mathbf{k}_3^{(3)}$, $\mathbf{k}_3^{(5)} = \{-1/3 \ 2/3 \ -1/2\}$ and $\mathbf{k}_3^{(6)} = -\mathbf{k}_3^{(5)}$ arms of the $\{\mathbf{k}_3\}$ star. This set of superstructure reflections can correspond only to the orthorhombic ordered phase Ti_3C_2 (space group $C222_1$). The transition channel involving the formation of this phase includes two arms of the $\{\mathbf{k}_4\}$ star and four arms of the $\{\mathbf{k}_3\}$ star (see Ref. 126). Characteristic of this superstructure are the $\{1/3 \ -2/3 \ -1/2\}$ and $\{2/3 \ 2/3 \ 0\}$ reflections which should be observed in the regions $2\theta \approx 18.4^\circ$ and 19.4° , respectively. The experimental X-ray diffraction pattern in this interval of angles exhibited a slightly ‘swollen’ slope of the $\{1/2 \ 1/2 \ 1/2\}$ superstructure reflection of the trigonal phase Ti_2C .²¹

The orthorhombic unit cell of the M_3C_2 superstructure is shown in Fig. 24. Its translation vectors and the atomic and

Figure 24. Orthorhombic unit cell (space group $C222_1$) of the Ti_3C_2 superstructure in the lattice with the $B1$ -type structure.^{2, 3, 17, 27, 126}

vacancy coordinates in this superstructure are listed in Table 8. The existence of orthorhombic ordered phase M_3C_2 (space group $C222_1$) of titanium carbide $TiC_{0.64}$ was suggested¹² based on the results of Monte Carlo simulations. In completely ordered orthorhombic structure M_3C_2 two thirds of all metal atoms occupy the sites of the type M_2^3 while the rest metal atoms occupy the sites of the type M_2^2 .

Metallographic tests of annealed carbides $TiC_{0.50}$ and $TiC_{0.55}$ in reflected polarised white light showed that the former exhibited neither grain interference from the disordered phase nor surface precipitate interference from the ordered phase.²¹ This can occur if both phases belong to the cubic crystal system. Particular grains of annealed carbide $TiC_{0.55}$ were coated with plate-like and prismatic precipitates of the ordered phase. The symmetry of these precipitates was different from that of the disordered phase while their shape was typical of the crystals that belong to the trigonal crystal system and, unlike the crystals of the disordered cubic phase, exhibit an interference pattern (*i.e.*, are anisotropic). Therefore, the results of diffraction studies of the ordered phases of non-

stoichiometric carbide TiC_y were confirmed by the results of metallographic tests.

Thus, low-temperature annealing of carbide TiC_y leads to the formation of some ordered phases. These are the cubic phase Ti_2C (space group $Fd\bar{3}m$) in the composition range $TiC_{0.50}$ – $TiC_{0.54}$, the trigonal phase Ti_2C (space group $R\bar{3}m$) for $TiC_{0.55}$ – $TiC_{0.58}$ and the orthorhombic phase Ti_3C_2 (space group $C222_1$) in the range $TiC_{0.63}$ – $TiC_{0.68}$.

Figure 25 presents the calculated X-ray diffraction patterns of the cubic and trigonal ordered phases Ti_2C formed in carbides of composition $TiC_{0.50}$ ($a_{B1} = 0.4305$ nm) and $TiC_{0.55}$ ($a_{B1} = 0.4310$ nm), respectively. The X-ray diffraction patterns were calculated assuming the maximum degree of long-range order characterised by the parameter η equal to 1.00 and 0.90 for the ordered carbides $TiC_{0.50}$ and $TiC_{0.55}$, respectively. The X-ray diffraction patterns of the cubic and trigonal ordered phases Ti_2C exhibit identical sets of superstructure reflections; however, distortion of the ideal lattice of the trigonal phase [slight extension along the $(1 - 1 1)_{B1}$ axis] leads to splitting of the $(311)_{B1}$, $(222)_{B1}$, $(420)_{B1}$ and $(422)_{B1}$ reflections. Trigonal splitting of the $(222)_{B1}$ reflection into two lines, *viz.*, the $(0 0 12)$ and $(0 2 4)$ lines, is shown in the inset in Fig. 25 *b* as an example; the doublet $\alpha_{1,2}$ is due to the use of $CuK_{\alpha 1,2}$ radiation. The superstructure reflections are of rather high intensity: for instance, the intensity of the first superstructure reflection is 30 times lower than that of the $(111)_{B1}$ reflection and only 3 times lower than the intensity of the $(222)_{B1}$ reflection. This makes the ordered phase Ti_2C readily detectable.

Figure 25. X-Ray diffraction patterns of cubic (space group $Fd\bar{3}m$, $a = 0.861$ nm) (a) and trigonal (space group $R\bar{3}m$, the lattice constants for hexagonal setting are $a = b = 0.3048$ and $c = 1.4982$ nm) (b) ordered Ti_2C phases formed in titanium carbide of the compositions $TiC_{0.50}$ ($a_{B1} = 0.4305$ nm) and $TiC_{0.55}$ ($a_{B1} = 0.4310$ nm), respectively. The long-range order parameter, $\eta = \eta_{max}$, equals 1 (a) and 0.90 (b). The inset demonstrates trigonal splitting of the $(222)_{B1}$ reflection into the $(0 0 12)$ and $(0 2 4)$ lines due to slight extension of the basic cubic lattice along the $(1 - 1 1)_{B1}$ axis (lattice constant, $c = 1.4982$ nm, is increased compared to the value $c = 1.4930$ nm for the ideal trigonal cell). Calculated for $CuK_{\alpha 1,2}$ radiation.

Figure 26. X-Ray diffraction pattern of the completely ordered ($\eta = 1.00$) orthorhombic Ti_3C_2 phase (space group $C222_1$, $a = 0.6109$, $b = 1.2328$ and $c = 0.864$ nm) formed in titanium carbide of composition $\text{TiC}_{0.667}$ ($a_{B1} = 0.432$ nm). Calculated for $\text{CuK}\alpha_{1,2}$ radiation.

The X-ray diffraction pattern of the ordered orthorhombic phase Ti_3C_2 (space group $C222_1$) formed in the carbide of composition $\text{TiC}_{0.667}$ is shown in Fig. 26. A characteristic feature of the orthorhombic superstructure Ti_3C_2 is the presence of three superstructure reflections in the range $19^\circ < 2\theta < 31^\circ$.

A hexagonal ordered phase Ti_6C_5 with the packing defects characteristic of the 4H polytype was found in the Ti–C thin films.¹³⁰ The translation vectors of the unit cell are as follows: $\mathbf{a} = \{2\bar{1}\bar{1}\}_{B1}$, $\mathbf{b} = \{\bar{1}2\bar{1}\}_{B1}$ and $\mathbf{c} = \{111\}_{B1}$. The films were prepared by electron beam sputtering of sintered carbide $\text{TiC}_{0.9}$, by magnetron sputtering of titanium and carbon and by laser beam sputtering of titanium and graphite or carbide $\text{TiC}_{0.9}$. The ordered phase Ti_6C_5 corresponds to disordered carbide $\text{TiC}_{0.83}$ with a lattice constant, a_{B1} , of 0.4326 nm; however, the lattice parameters of the hexagonal ordered phase¹³⁰ correspond to disordered carbide TiC_y with the basis cubic lattice constant $a_{B1} = 0.4319$ nm characteristic of carbide $\text{TiC}_{0.68-0.70}$ (see Fig. 6). The underestimated a_{B1} value can be due to oxygen impurity.

Ordering of nonstoichiometric carbides MC_y can cause the formation of monoclinic and trigonal superstructures M_6C_5 with $C2/m$ (or $C2$) and $P3_1$ symmetry, respectively. The unit cell of monoclinic superstructure M_6C_5 (space group $C2/m$) is shown in Fig. 27 while its translation vectors and the atomic and vacancy coordinates are listed in Table 9. Translation of all superstructure

sites of the reciprocal lattice of the monoclinic ordered phase M_6C_5 (space group $C2/m$) showed that the first Brillouin zone of the disordered fcc lattice contains five inequivalent superstructure vectors belonging to three stars, $\{\mathbf{k}_9\}$, $\{\mathbf{k}_4\}$ and $\{\mathbf{k}_3\}$. These superstructure vectors are included in the MC_y (space group $Fm\bar{3}m$) $\rightleftharpoons$ M_6C_5 (space group $C2/m$) phase transition channel involving the formation of the monoclinic ordered phase M_6C_5 .

The non-metal sublattice of the monoclinic superstructure M_6C_5 (space group $C2/m$) is divided into four inequivalent sublattices differing in site occupation probabilities by carbon atoms. Because of this, the non-metal sublattice is characterised by alternation of two types of non-metal atomic planes along the $[1\bar{1}1]_{B1}$ direction. In the first type of atomic planes one third of all sites belongs to the first sublattice while the other sites belong to the third sublattice, each site of the first sublattice being surrounded by six sites of the third sublattice. In the second type of planes one third of all sites belongs to the second sublattice while the other sites belong to the fourth sublattice; each site of the second sublattice is surrounded by six sites of the fourth sublattice.

The trigonal unit cell (space group $P3_1$) of superstructure M_6C_5 is shown in Fig. 28. Its translation vectors and the atomic and vacancy coordinates in ideal trigonal superstructure M_6C_5 are listed in Table 10. The disorder–order phase transition channel involving the formation of the trigonal superstructure M_6C_5 includes thirteen arms of three stars, $\{\mathbf{k}_9\}$, $\{\mathbf{k}_4\}$ and $\{\mathbf{k}_3\}$.

The unit cell of monoclinic superstructure M_6C_5 (space group $C2$) is presented in Fig. 29. The translation vectors of this unit cell and the atomic and vacancy coordinates in ideal monoclinic

superstructure M_6C_5 are given in Table 11. The transition channel involving the formation of this ordered phase M_6C_5 includes nine superstructure vectors of the reciprocal lattice belonging to four stars, $\{\mathbf{k}_9\}$, $\{\mathbf{k}_4\}$, $\{\mathbf{k}_3\}$ and $\{\mathbf{k}_0\}$. The non-metal sublattice of this superstructure is divided into five inequivalent sublattices and is characterised by alternation of two types of non-metal atomic planes along the $[1\bar{1}1]_{B1}$ direction. The first type of atomic plane contains an equal number of sites of the first, third and fifth sublattices, each site of a given sublattice being surrounded by the sites belonging to the other two sublattices. The second type of atomic plane is formed by the sites belonging to the second and fourth sublattices; here, each site of the fourth sublattice is surrounded by six sites of the second sublattice.

In Fig. 30 we present the X-ray diffraction patterns of the ideal, completely ordered monoclinic phases Ti_6C_5 (space groups $C2/m$ and $C2$) formed in titanium carbide $TiC_{0.83}$ ($a_{B1} = 0.4326$ nm). Positions and intensities of superstructure reflections in the X-ray diffraction pattern of the ideal, completely ordered trigonal phase Ti_6C_5 (space group $P3_1$, $a = b = 0.5299$, $c = 1.4987$ nm) match those of the monoclinic phase Ti_6C_5 (space group $C2/m$), since the transition channels involving the formation of both phases include the same superstructure vectors. For the real monoclinic and trigonal ordered phases Ti_6C_5 , the intensities of superstructure reflections should be different due to

the difference between the directions and magnitudes of static atomic displacements. Analysis of the X-ray diffraction pattern taking into account these displacements allows unambiguous symmetry determination (monoclinic or trigonal) of the ordered phase Ti_6C_5 .

The intensities of superstructure reflections of the Ti_6C_5 phases are very low: for instance, the intensity of the first superstructure reflection is 230–240 and 30–32 times lower than those of the $(111)_{B1}$ and $(222)_{B1}$ reflections, respectively. Comparison of the X-ray diffraction patterns of completely ordered phases Ti_2C

**Figure 30.** X-Ray diffraction patterns of completely ordered ($\eta = 1.00$), ideal monoclinic Ti_6C_5 phases (space group $C2/m$ and $C2$) formed in titanium carbide of composition $TiC_{0.83}$ ($a_{B1} = 0.4326$ nm). Calculated for $CuK_{\alpha 1,2}$ radiation.

Characteristics of the monoclinic Ti_6C_5 phase:

space group $C2/m$, $a = c = 0.5299$ nm, $b = 0.9177$ nm, $\beta = 109.47^\circ$ (a);
space group $C2$, $a = 0.5299$ nm, $b = 0.9177$ nm, $c = 1.0597$ nm,
 $\beta = 109.47^\circ$ (b).

and Ti_6C_5 shows that the intensity of the first superstructure reflection of the Ti_2C phase is nearly an order of magnitude higher than that of the Ti_6C_5 phase.

For all completely ordered phases M_6C_5 the relative stoichiometric concentration of interstitial atoms (y_{st}) equals 5/6. Consideration of the non-metal sublattices of these superstructures reveals that the $[\bar{1}\bar{1}\bar{1}]_{B1}$ direction is characterised by alternation of the $(\bar{1}\bar{1}\bar{1})_{B1}$ atomic planes with completely occupied (by interstitial atoms) sites and the defect $(\bar{1}\bar{1}\bar{1})_{B1}$ planes in which one third of sites is vacant (see Figs 27–29). Each vacancy is surrounded by six interstitial atoms that form a regular hexagon. Peculiarities of completely ordered carbide structures M_6C_5 have been studied in detail.¹³⁴

Completely ordered monoclinic and trigonal carbide structures M_6C_5 with $C2/m$ (or $C2$) and $P3_1$ symmetry, respectively, are characterised by the identical environment of the metal atoms by the sites of the non-metal sublattice that form the first and second coordination spheres. Indeed, there are only two types of site for the metal atoms in these structures, *viz.*, M_1^1 (metal atom with one vacancy in the first and one vacancy in the second coordination sphere) and M_1^2 (metal atom with one vacancy in the first and two vacancies in the second coordination sphere). In ideal, completely ordered structures M_6C_5 (space groups $C2/m$, $P3_1$ and $C2$) two thirds of all metal atoms occupy the sites of the type M_1^1 while the other metal atoms occupy the sites of the type M_1^2 .

V. Phase diagrams of the Ti–C system constructed with allowance for the ordering of TiC_y

The results of experimental,^{14, 17, 70, 126, 127} theoretical^{1–3, 12, 22, 135–137} and numerous structural studies of nonstoichiometric carbides MC_y with the $B1$ -type basis structure including titanium carbide TiC_y , revealed the possibility of formation of superstructures of the types M_2C , M_3C_2 and M_6C_5 . Particular types of superstructures formed during the ordering of a given carbide MC_y and the corresponding concentration ranges are determined by the positions of the upper and lower boundaries of the homogeneity region of the disordered carbide and by the equilibrium conditions at these boundaries.

The most efficient method for calculating the low-temperature phase equilibria associated with the ordering of nonstoichiometric compounds is the above-mentioned OPF approach. Calculations of the phase diagram of an ordering system by this method require only knowledge of the $F_0(T)$, $F_1(T)$ and $F_2(T)$ parameters of the free energy $F(y, 0, T)$ of disordered nonstoichiometric carbide MC_y . These parameters for TiC_y are listed in Section II.2.

According to the results of thermodynamic calculations^{8, 60, 65} and crystal structure analysis,⁴ the M_2X_3 , M_4X_3 , M_6X_5 and M_8X_7 superstructures can be formed by the first-order phase transition mechanism, whereas the M_2X superstructure can be formed by the second-order phase transition mechanism. Transition between two ordered phases occurs as a first-order phase transition.

1. Calculated phase diagrams of the Ti–C system

Let us consider the phase diagram of the Ti–C system obtained from the OPF calculations with allowance for the ordering of nonstoichiometric titanium carbide TiC_y .^{1, 20}

There is only one compound capable of ordering in the Ti–C system, cubic carbide TiC_y . At the lower boundary of the homogeneity region, titanium carbide is in equilibrium with metallic α -Ti (at $T < 1150$ K) or β -Ti (at $T > 1150$ K). According to calculations,¹⁸ at $1000 < T < 1900$ K the carbide that exists near the lower boundary of the homogeneity region of the disordered phase TiC_y has composition $\text{TiC}_{0.32}$ – $\text{TiC}_{0.37}$. The exact position of the lower boundary of the homogeneity region has not experimentally been determined so far; different estimates gave $\text{TiC}_{0.48}$ (see Ref. 8) or $\text{TiC}_{0.47}$ (see Ref. 41) at 1900 K. According to calculations,⁴⁴ at 1900 K near the lower boundary of the homogeneity region the carbide has a $\text{TiC}_{0.52}$ composition. Calculations^{8, 41, 44} revealed that as the temperature is lowered,

the lower boundary of the homogeneity region of disordered TiC_y is shifted towards the region with higher y at a rate that is somewhat higher than that predicted by calculations.¹⁸

The low-temperature portion of the phase diagram of the Ti–C system, corresponding to the ordering of carbide TiC_y , was calculated by the OPF method.^{18, 20}

The broad homogeneity region of TiC_y allows the formation of phases of the types Ti_2C , Ti_3C_2 and Ti_6C_5 (Fig. 31) during the ordering under thermodynamic equilibrium conditions. According to calculations, an ordered phase Ti_2C is formed by the second-order phase transition mechanism with the disorder–order transition temperature $T_{\text{trans}} = 920$ – 950 K. The homogeneity region of the Ti_2C phase is fairly broad ($\text{TiC}_{0.42}$ – $\text{TiC}_{0.56}$ at 700 K and $\text{TiC}_{0.40}$ – $\text{TiC}_{0.54}$ at 800 K) and is confined from the left and from the right by two-phase regions, (α -Ti + Ti_2C) and (Ti_2C + Ti_3C_2), respectively. The ordered Ti_3C_2 and Ti_6C_5 phases have homogeneity regions of comparable width ($\text{TiC}_{0.59}$ – $\text{TiC}_{0.71}$ for Ti_3C_2 and $\text{TiC}_{0.74}$ – $\text{TiC}_{0.87}$ for Ti_6C_5 at 700 K) and are formed by the first-order phase transition mechanism. All order–order phase transformations in titanium carbide also occur as first-order phase transitions. The calculated values of T_{trans} , ΔS_{trans} and the heat of phase transition, ΔH_{trans} , for all possible order–order and disorder–order first-order phase transformations of titanium carbide are listed in Table 12. By and large, the ordering in carbide TiC_y occurs at $T < 1000$ K.

Figure 31. Equilibrium phase diagram of the Ti–C system constructed with allowance for atomic ordering of nonstoichiometric cubic titanium carbide TiC_y (see Ref. 1). A portion of the ordering region corresponding to peritectoid transformation $\text{Ti}_3\text{C}_2 + \text{TiC}_y \rightarrow \text{Ti}_6\text{C}_5$ ($T = 963$ K) is shown in the inset (magnified); the coordinates, $y = \text{C/Ti}$, of points 1, 2 and 3 are 0.5236, 0.524 and 0.5255, respectively.

The calculated phase diagram of the Ti–C system (see Fig. 31) is in agreement with the results of experimental studies (see Section IV). Different authors reported the formation of an ordered phase Ti_2C with cubic or trigonal symmetry (space group $Fd\bar{3}m$ or $R\bar{3}m$, respectively) in carbide TiC_y in the region $0.5 \leq y \leq 0.65$ at $T < 1100$ K. The X-ray diffraction patterns of annealed titanium carbide of composition $\text{TiC}_{0.60}$ – $\text{TiC}_{0.70}$ exhibited superstructure reflections characteristic of the ordered phase Ti_3C_2 . Recently,¹³⁰ an ordered phase Ti_6C_5 with hexagonal symmetry was found in thin Ti–C films.

The existence of a trigonal ordered phase Ti_2C and an orthorhombic ordered phase Ti_3C_2 was also confirmed by the Monte Carlo calculations of the phase diagram of the Ti–C system for the composition range $\text{TiC}_{0.57}$ – $\text{TiC}_{0.70}$ (Fig. 32).^{10, 12} Landesman *et al.*¹³⁸ showed that short-range order and disorder–

SRO denotes a phase with the B1-type structure and short-range order.

order transitions in nonstoichiometric carbides and nitrides can be described by using the Ising Hamiltonian for the non-metal fcc sublattice. In this case the Hamiltonian is defined as the sum of the effective energies, V_n , of the pairwise interactions between the sites

in the non-metal sublattice that are the n th neighbours. The energies V_n of the pairwise interactions in the non-metal sublattice of the carbides $\text{TiC}_{0.76}$ and $\text{TiC}_{0.65}$ were calculated^{10, 12} not only for the nearest (V_1) and next-nearest (V_2) neighbours, but also for more distant sites in the third (V_3) and fourth (V_4) coordination spheres. The energies of the pairwise interactions were calculated from the experimental data on high-temperature diffuse neutron scattering¹³⁹ using three methods, namely, the mean field approximation, the inverse Monte Carlo method and the cluster variation method. The best agreement with the experiment was achieved when the phase diagram was calculated by the Monte Carlo method. The formation of an ordered orthorhombic phase Ti_3C_2 , was reported to occur as a first-order phase transition.^{12, 139} This conclusion is consistent with the results of OPF calculations of the ordering in TiC_y .^{18, 20}

Some distinctions in the mutual positions of the ordered phases Ti_2C and Ti_3C_2 in the phase diagrams of the Ti–C system obtained from the OPF (see Fig. 31) and Monte Carlo calculations (see Fig. 32) are due to the fact that the OPF method treats the free energy of a compound as a function of its composition and long-range order parameters, whereas in the second method the energies of the interatomic interactions are determined by the short-range order parameters.

2. Experimental phase diagram of the Ti–C system constructed with allowance for low-temperature (at $T < 1000$ K) equilibria

The phase diagram of the Ti–C system at $T < 1000$ K was constructed based on the experimental results on the ordering of carbide TiC_y .²¹ Using the data on the structure and electrical

resistance of annealed and quenched samples of TiC_y , it was shown that cubic ordered phase Ti_2C (space group $Fd\bar{3}m$) has a homogeneity region extending from $\text{TiC}_{0.49-0.51}$ to $\text{TiC}_{0.54-0.55}$, while the trigonal superstructure Ti_2C (space group $R\bar{3}m$) is formed in the composition range $\text{TiC}_{0.55-0.59}$. The $\text{TiC}_{0.59-0.63}$ range corresponds to a two-phase region [Ti_2C (space group $R\bar{3}m$) + Ti_3C_2 (space group $C222_1$)]. The existence region of the orthorhombic ordered phase Ti_3C_2 (space group $C222_1$) is fairly narrow and does not exceed $\text{TiC}_{0.63-0.67}$. The lowest annealing temperature was 770 K. Since no ordered phase Ti_6C_5 was detected after annealing the $\text{TiC}_{0.83}$ and $\text{TiC}_{0.85}$ samples at such a low temperature, the transition temperature of this phase was assumed to be lower than 770 K. The portion of the equilibrium phase diagram of the Ti–C system corresponding to the ordering of nonstoichiometric titanium carbide TiC_y is presented in Fig. 33. A consecutive transition was suggested²¹ in the range $0.54 \leq y \leq 0.57$

The ordered orthorhombic phase Ti_3C_2 is formed following a peritectoid reaction

at 990 ± 10 K in the composition range $0.61 \leq y < 0.63$. The ordered phases Ti_2C with cubic and trigonal symmetry can be observed over a broad composition range of nonstoichiometric titanium carbide, from $\text{TiC}_{0.40}$ to $\text{TiC}_{0.63}$. However, only in the $\text{TiC}_{0.49-0.50-0.58-0.59}$ range is the homogeneity region of the ordered phase Ti_2C (see Fig. 33). The composition range in which the formation of an ordered phase Ti_6C_5 is possible is shown tentatively since this phase was not found experimentally. The hysteresis in the temperature dependences of the electrical resistance²¹ suggested that the $\text{TiC}_y \rightleftharpoons \text{Ti}_2\text{C}$ and $\text{TiC}_y \rightleftharpoons \text{Ti}_3\text{C}_2$ transformations are first-order phase transitions with $T_{\text{trans}} = 980-1000$ K. This value is in good agreement with the value $T_{\text{trans}} \approx 1000$ K found for titanium carbide $\text{TiC}_{0.55}$ from electrical resistance measurements.¹⁴⁰

Thus, experiments revealed that ordering of TiC_y in the ranges $0.52 \leq y \leq 0.55$, $0.56 \leq y \leq 0.58$ and $0.62 \leq y < 0.68$ at $T < 1000$ K leads respectively to the formation of the cubic

Figure 33. Low-temperature portion of the equilibrium phase diagram of the Ti–C system.²¹

Formation of the ordered orthorhombic Ti_3C_2 phase occurs at 990 ± 10 K as the peritectoid transformation $\text{Ti}_2\text{C} + \text{TiC}_y \rightarrow \text{Ti}_3\text{C}_2$; the region of phase equilibria involving ordered Ti_6C_5 phase is tentatively shown by the dashed line.

(space group $Fd\bar{3}m$) and trigonal (space group $R\bar{3}m$) ordered phase Ti_2C and orthorhombic ordered phase Ti_3C_2 (space group $C222_1$). This is consistent with the phase diagram of the Ti–C system (see Fig. 31) obtained from OPF calculations¹⁸ (note that for Ti_2C -type superstructures the OPF method leads to a common region of existence, from $\text{TiC}_{0.46}$ to $\text{TiC}_{0.58}$, without separation into the cubic and trigonal phases).

As mentioned above (see Section III), recent studies of the Ti–C system revealed the existence of molecular cluster-like compounds Ti_8C_{12} and $\text{Ti}_{13}\text{C}_{22}$ in addition to nonstoichiometric cubic titanium carbide TiC_y . The phase diagram of the Ti–C system constructed with allowance for the ordering of nonstoichiometric carbide TiC_y and for the existence of molecular cluster-like compounds Ti_8C_{12} and $\text{Ti}_{13}\text{C}_{22}$ (TiC_2) is shown in Fig. 34.

Figure 34. Phase diagram of the Ti–C system constructed with allowance for the existence of molecular cluster-like compounds Ti_8C_{12} and $\text{Ti}_{13}\text{C}_{22}$ (TiC_2) and for the atomic ordering of nonstoichiometric cubic titanium carbide TiC_y .

Ti_2C (space group $Fd\bar{3}m$) (1), Ti_2C (space group $R\bar{3}m$) (2), Ti_3C_2 (space group $C222_1$) (3) and Ti_6C_5 (Ti_2C , Ti_3C_2 and Ti_6C_5 are the ordered phases of titanium carbide TiC_y) (4).

VI. Conclusion

For more than a century it was thought that there is only one compound in the Ti–C system, namely, cubic titanium carbide TiC_y with a broad homogeneity region. However, the studies of this system carried out in 1990s revealed the formation of (i) ordered phases of nonstoichiometric titanium carbide with different composition and symmetry and (ii) molecular cluster-like compounds.

Among the new phases of titanium carbide, the ordered phase Ti_2C , which can have a cubic or trigonal symmetry, has been studied in most detail. This phase is readily formed as a result of annealing the TiC_y samples at 1300–1500 K followed by gradual lowering of the temperature down to 600–700 K over a period of several hours. It can also be found even in the TiC_y samples ($y = 0.5-0.58$) synthesised by solid-phase vacuum sintering of titanium and carbon at 2000–2200 K and cooled down to 300 K during further self-cooling of the furnace. Using a special regime of long-term annealing, one can obtain the Ti_2C phase with the maximum extent of long-range order.

Ordered phases of the Ti_3C_2 and Ti_6C_5 types are much more hard to obtain. Similar to the Ti_2C phase, they can be of different symmetry while their chemical composition remains unchanged.

Bulk samples of these phases can be obtained only after long-term (several hundreds of hours) annealing at $T < 1000$ K. The results of experimental and theoretical studies suggest that these phases are in thermodynamic equilibrium at temperatures below 900–1000 K. A hexagonal Ti_6C_5 phase was found in thin films synthesised by electron beam and laser sputtering of titanium carbide.

Molecular cluster-like compounds Ti_8C_{12} (Ti_2C_3) and $\text{Ti}_{13}\text{C}_{22}$ ($\sim \text{TiC}_2$) were obtained by laser-assisted plasmachemical synthesis. The most convenient procedure for preparation of these compounds in the crystalline form is to stabilise them in thin films deposited on a substrate (molecular clusters with a characteristic atomic ratio, $\text{C}:\text{Ti} = 1.5$ or 2).¹⁴¹ This allows one to obtain thin films of a compound Ti_2C_3 or TiC_2 with the crystal structure similar to that of the substrate. Indeed, the synthesis of titanium oxide, fullerene and amorphous carbon nanocrystals with a different structure on the solid surfaces of different chemical nature (graphite, polymers, oxides) was reported.¹⁴² Chemical modification of the substrate surface or heat treatment of the film cast provide additional possibilities of forming a particular type of the crystal structure of the film.

The main methods of experimental detection of new compounds and phases include X-ray, electron or neutron diffraction. We believe that the model X-ray diffraction patterns of most of the phases of the Ti–C system, first reported in this review will essentially facilitate identification of new phases and interpretation of the results obtained.

Thus, analysis of studies on the Ti–C system carried out in 1985–2000 showed that not only titanium carbide TiC_x , but also other chemical compounds and phases are formed in this system. They were discovered using novel, advanced methods of synthesis, thorough studies of phase equilibria at temperatures below 1300 K and highly sensitive mass spectrometric and diffraction methods of analysis of products of the chemical interaction. One can expect (and some experimental proofs have already been reported) that binary systems comprising carbon and other transition metals can appear to be no less interesting than the Ti–C system.

Redox reactions of actinides in carbonate and alkaline solutions

V P Shilov, A B Yusov

Contents

I. Introduction	465
II. Redox potentials	465
III. Reactions in carbonate solutions	465
IV. Reactions in alkaline media	473
V. Conclusion	486

Abstract. Data on redox reactions involving uranium, neptunium, plutonium and americium ions in carbonate and alkaline solutions are generalised. The results of kinetic studies of these reactions are analysed and their mechanisms are discussed. The bibliography includes 169 references.

I. Introduction

Progress in the chemistry of actinides has long been associated predominantly with the necessity of solving technological problems. Early chemical investigations were concerned primarily with the reactions of actinides in acidic media, whereas the reactions in alkaline media were little studied. However, these scarce data are of most interest. Thus, the use of carbonate and alkaline solutions made it possible to stabilise valence states of actinides, which are either unstable or difficult to prepare in acidic media. For instance, Am(IV) was stabilised and Cf(V) and Cm(VI) were first obtained in carbonate media. The most prominent example is the discovery of heptavalent neptunium, plutonium and americium, which gave impetus to the outburst of studies of alkaline solutions of actinides in the late 1960s and in the early 1970s. In recent years, interest in redox reactions of actinides in alkaline media was rekindled. The reason is that there is an acute need to solve a number of problems associated with storage and processing of alkaline waste of radiochemical industry, which were accumulated in large amounts at plants both in Russia and abroad. Extensive studies in this field gave new interesting results, which are not only of applied but also of scientific importance.

In the last decade, the properties of actinides in carbonate and alkaline media were surveyed in reviews. For example, the compositions and structures of carbonate complexes in solutions and in the solid state were covered in detail in the review;¹ however, no consideration was given to redox reactions. The report² was devoted to the chemistry of actinides in alkaline media, including redox reactions. Unfortunately, this report is not easily accessible to Russian researchers. Besides, the results of more recent investigations were published in the literature.

The aim of the present review is to systematise and analyse the available data on redox reactions of uranium, neptunium, plutonium, americium and curium in bicarbonate, carbonate and alkaline solutions.[†] We do not consider the data on photochemical and radiochemical reactions, which were generalised in the publications^{3,4} in sufficient detail. Studies of electrochemical reactions involving actinide ions are also beyond the scope of our review.

II. Redox potentials

To predict the possibility of a particular redox reaction occurring, the data on redox potentials (hereinafter referred to as potentials) of actinide pairs in carbonate and alkaline media are required. The measured and estimated (calculated) formal potentials (*i.e.*, potentials at equal concentrations of the oxidised and reduced forms) are given in Table 1.

III. Reactions in carbonate solutions

It can be seen from Table 1 that tri- and tetravalent uranium, neptunium and plutonium can be oxidised by molecular oxygen, whereas trivalent neptunium and plutonium can also be oxidised by water (in the pH range of 9–12, the potentials of the O₂/H₂O and H₂O/H₂ pairs vary from 0.70 to 0.52 V and from –0.53 to –0.71 V, respectively).³⁸ Besides, U(V), Pu(V) and Am(IV) are unstable in disproportionation reactions, Np(VI) must oxidise Np(IV), whereas Am(VI) can oxidise Am(III) and Am(IV).

1. Disproportionation and reproporation reactions

a. Disproportionation of actinides(V)

The kinetics of disproportionation of U(V) in carbonate solutions was examined by cyclic chronopotentiometry.³⁹ It was found that U(V), which was generated on the electrode surface through reduction of U(VI), rapidly disappeared in solution. This process is best described by a model on the basis of the second-order reaction

[†] It should be noted that the reaction mechanisms were not considered in most of original studies and it is impossible to make justified conclusions about these mechanisms based on the available data. In this connection, we write the reaction equations in the formal form, *i.e.*, denote actinide ions as Np(VI), Pu(IV), *etc.* In addition, many reactions proceed in rather broad ranges of pH or alkali concentrations due to which the valence state of the actinide ion may vary.

Table 1. Formal potentials of actinide pairs.

^a Determined by polarography. ^b Determined by cyclic voltammetry scan. ^c The diffusion potential between a 2 M Na₂CO₃ solution and a saturated calomel electrode was ignored. ^d Estimated by us based on the data of the study;²⁴ under these conditions, an equilibrium mixture of Pu(VI), Pu(V) and Pu(IV) was formed.

$$-\frac{d[U(V)]}{dt} = 2k_d[U(V)]^2, \quad (1)$$

where k_d is the rate constant of disproportionation.

The rate constants for disproportionation of U(V) in a 1 M NaHCO₃ solution (pH 8.57, $T = 25^\circ\text{C}$) remains unchanged as the concentration of U(VI) is varied in the range from 1 to 10 mmol litre^{−1}. An increase in pH[‡] leads to a decrease in the constant k_d both at a constant CO₃^{2−} content (17 mmol litre^{−1}) and at a constant HCO₃[−] content (0.68 mol litre^{−1}). In the pH range of 8.57–9.23, the constant k_d varies from ~15–20 to 2–3 litre mol^{−1} s^{−1}.

The following mechanism of the process was proposed:³⁹

The experimental $\log k_d - \log[HCO_3^-]$ plot yields a straight line with a slope of 0.84 ± 0.06 . Consequently, the reaction order with respect to the bicarbonate ion is close to unity. The slope of the plot of k_d vs. the concentration of free carbonate ions (on the logarithmic coordinates) is equal to -1.87 ± 0.1 , i.e., is close to -2 .

It should be emphasised that the reaction (2) proceeds on the electrode surface, whereas the reactions (3) and (4) take place in solution. In 0.25–1 M NaHCO₃ solutions, the solvated electron can lose the ‘reducing’ properties. Thus, it was found that Np(V) was oxidised to Np(VI) upon γ irradiation of its aerated or argon-

[‡] In bicarbonate–carbonate solutions, pH is generally controlled by changing the ratio between [CO₃^{2−}] and [HCO₃[−]].

saturated bicarbonate solutions. This oxidation did not take place in a solution of Na_2CO_3 , whereas irradiation of Np(VI) led to its reduction.⁴⁰

Disproportionation of Pu(V) was not examined. It was only noted that Pu(V) , which was generated upon electrochemical reduction of Pu(VI) in a bicarbonate solution, underwent disproportionation with a high rate and exclusively Pu(IV) was accumulated in the solution.²³ An increase in pH slows down disproportionation of Pu(V) [like disproportionation of U(V)]. At pH 11.0, the process is completed in 6–8 h. The hexa-, penta- and tetravalent plutonium ions were found in the equilibrium mixture, *i.e.*, the following reaction took place

b. Disproportionation of Am(IV)

Americium(IV), which was prepared in bicarbonate-carbonate solutions by electrolytic oxidation of Am(III) , was reduced with water (the first-order reaction with respect to americium) and underwent disproportionation (second-order reaction).^{32, 33}

In a 1.3 M $\text{NaHCO}_3 + \text{Na}_2\text{CO}_3$ solution (pH 10), the activation energy of the second-order reaction in the temperature range of 30–65 °C is $100.8 \pm 4.0 \text{ kJ mol}^{-1}$.

In a 1.5 M $\text{NaHCO}_3 + \text{Na}_2\text{CO}_3$ solution, the rate constant for disproportionation of Am(IV) was measured at different pH by spectrophotometry.⁴¹ Americium(IV) was prepared by irradiating a solution of Am(III) containing the BrO^- ions with UV light. After termination of irradiation, Am(IV) was transformed spontaneously into Am(III) and Am(V) according to the reactions (6) and (7) in a time varying from a few minutes to 3–4 days (depending on pH). The conversion of Am(IV) into Am(III) was 50%–65%.

Taking into account the final proportion of Am(III) , it can be concluded that the second-order reaction (7) prevailed. The rate constant of this reaction increased from 6.6×10^{-2} to $262 \text{ litre mol}^{-1} \text{ s}^{-1}$ as pH was increased from 10.39 to 12.13.

In a 1.5 M $\text{KHCO}_3 + \text{K}_2\text{CO}_3$ solution, $2k_d$ increased from 6.6×10^{-2} to $450 \text{ litre mol}^{-1} \text{ s}^{-1}$ as pH was increased from 8.40 to 11.70.

Judging from the slopes of the plots of $2k_d$ vs. pH (on the logarithmic coordinates), the disproportionation reaction of Am(IV) in $\text{KHCO}_3 + \text{K}_2\text{CO}_3$ and $\text{NaHCO}_3 + \text{Na}_2\text{CO}_3$ solutions is second order with respect to the OH^- ions. This is attributable to the fact that the first step involves hydrolysis of americium carbonate complexes:

If the concentration of K_2CO_3 in a $\text{KHCO}_3 + \text{K}_2\text{CO}_3$ solution is higher than 3 mol litre^{-1} , disproportionation of Am(IV) proceeds much more slowly and this reaction is very slow at a concentration of $4.0\text{--}5.88 \text{ mol litre}^{-1}$. Apparently, this is associated with an increase in the number of the carbonate groups in the coordination sphere of Am(IV) resulting in a decrease in the potential of the Am(IV)/Am(III) pair and an increase in the potential of the Am(V)/Am(IV) pair. As a consequence, the equilibrium of the reaction (9) is sharply shifted to the left and Am(IV) becomes stable.

c. Reproportionation of $\text{Np(IV)} + \text{Np(VI)}$

The reaction

was examined in 1.7–4.0 M K_2CO_3 solutions by spectrophotometry ($\lambda = 490 \text{ nm}$).⁴² The concentrations of Np(VI) and Np(IV) are lowered according to the equation

$$-\frac{d[\text{Np(vi)}]}{dt} = -\frac{d[\text{Np(vi)}]}{dt} = k'[\text{Np(vi)}][\text{Np(IV)}]. \quad (11)$$

The apparent rate constant of the reaction k' remains virtually unchanged upon a twofold change in the concentrations of Np(VI) and Np(IV) and decreases by a factor of 4 as the K_2CO_3 content is increased from 1.71 to 4 mol litre^{-1} . The authors of the cited study⁴² attributed this fact to an increase in the number of the carbonate groups in the complex Np(IV) ion [like in the Am(IV) ion, see above], which hinders charge transfer.

In the temperature range of 52–76.5 °C, the activation energy of the reaction (10) in K_2CO_3 solutions is $103 \pm 2 \text{ kJ mol}^{-1}$, which is virtually equal to this value (104 kJ mol^{-1}) for the reproportionation reaction $\text{Np(IV)} + \text{Np(VI)}$ in solutions of HClO_4 and HNO_3 .

In the presence of sulfate ions, the reaction (10) slows down. The addition of SO_4^{2-} ($0.21 \text{ mol litre}^{-1}$) to a 2.08 M K_2CO_3 solution led to a decrease in k' from 1470 to $390 \text{ litre mol}^{-1} \text{ min}^{-1}$. Hence, the sulfate ion has a more substantial effect on the reaction rate than the carbonate ion. This fact remains to be explained.

2. Reactions analogous to disproportionation and reproportionation

a. Reactions of Am(III) with Am(VI)

Judging from the potentials of the Am(VI)/Am(V) and Am(IV)/Am(III) pairs in carbonate-bicarbonate solutions (see Table 1), Am(VI) can oxidise Am(III)

Actually, Am(IV) and Am(V) are accumulated in solution when equimolar carbonate solutions containing tri- and hexavalent americium ($6.2 \times 10^{-4} \text{ M}$) are mixed in different proportions.³⁰ If the difference between the formal potentials is 60 mV ($[\text{CO}_3^{2-}] = 1 \text{ mol litre}^{-1}$), the rate constant

$$K = \frac{[\text{Am(IV)}][\text{Am(V)}]}{[\text{Am(III)}][\text{Am(VI)}]}$$

must be equal to 10 (the experimental value is 11.2 ± 1.5).

Hence, four valence forms, *viz.*, Am(III) , Am(IV) , Am(V) and Am(VI) , can coexist in solutions with pH 9.5–10.5.

b. Reactions of Np(V) with Am(V)

The reaction

was studied by spectrophotometry from the intensity of light absorption of Am(III) ($\lambda = 508 \text{ nm}$) and Np(VI) (470 nm) in 0.45–1.71 M Na_2CO_3 solutions.⁴³ The Am(III) concentration was increased half as rapidly as the Np(VI) concentration. Hence, the following equation was proposed for this reaction:

and a change in the concentrations of the reacting compounds is described by the equation

$$-\frac{d[\text{Am(v)}]}{dt} = -\frac{1}{2} \frac{d[\text{Np(v)}]}{dt} = k'[\text{Am(v)}][\text{Np(v)}]. \quad (14)$$

The validity of the Eqn (14) is confirmed by the fact that the constant k' ($T = 64 \text{ °C}$) is independent of the initial concentrations of Np(V) ($0.65\text{--}1.9 \text{ mmol litre}^{-1}$) and Am(V) ($0.65\text{--}1.3 \text{ mmol litre}^{-1}$). The reaction rate (the order with respect to the CO_3^{2-} ions $n = -1.53$) decreases monotonically as the Na_2CO_3 content is increased. In the temperature range of

50.5–69.7 °C, the activation energy is $60 \pm 4 \text{ kJ mol}^{-1}$ regardless of the Na_2CO_3 concentration.

Most likely, the process starts with dissociation of the Am(V) and Np(V) carbonate complexes [like in the case of disproportionation of U(V)]. Hence, we believe that at a constant ionic strength of solution (μ), the reaction order with respect to CO_3^{2-} would be more close to -2 . In this medium, pentavalent actinides can exist as tricarbonates complexes.¹ In this case, it can be assumed that the following reactions proceed:

Next, the following charge transfer processes take place

where Z is an activated complex.

c. Reactions of Am(III) with Np(VII)

In a 2.82 M $\text{KHCO}_3 + \text{K}_2\text{CO}_3$ solution, the potential of the Am(IV)/Am(III) pair varies from 0.99 to 0.81 V as pH is increased from 8.9 to 11.2.³⁴ In carbonate and bicarbonate media, the potentials of the Np(VII)/Np(VI) pair vary in the ranges which are apparently comparable with the range mentioned above or are even broader. Actually, the potential of this pair in a 1 M NaOH solution is 0.582 or 0.587 V (see Table 1) and increases by 0.118 V as pH is decreased by unity ($\mu = 1$),¹⁶ i.e., this potential at pH 11 and pH 10 must be no lower than 0.9 V and no higher than 1 V, respectively. In carbonate solutions, these values may vary due to the formation of the Np(VI) and Np(VII) complexes with the carbonate ions, but these changes are insignificant. Hence, Np(VII) can serve as an oxidiser of Am(III) in bicarbonate and carbonate media. However, Np(VII) is reduced with water under the same conditions. The yield of Am(IV) depends on the ratio between the reaction rates

After the addition of an aliquot of an alkaline solution of neptunium(VII) to a 1.5 M KHCO_3 solution of americium(III), the latter is oxidised already in the course of stirring (10–30 s).⁴⁴ The intensity of the absorption band of Am(III) carbonate complexes with a maximum at 507 nm decreases (in some cases, the band even disappears). The light absorption resulting from superposition of broad bands belonging to Am(IV) and Np(VI) is observed at wavelengths shorter than 450 nm. When the dry salt $\text{K}_4\text{Fe(CN)}_6 \cdot 3\text{H}_2\text{O}$ was placed in a cell, light absorption at 350–400 nm was decreased and the band with a maximum at $\sim 507 \text{ nm}$ simultaneously regained its initial intensity. This unambiguously indicates that Np(VII) oxidises Am(III) to Am(IV) . The rate constant for the bimolecular reaction (20) is larger than $5 \times 10^3 \text{ litre mol}^{-1} \text{ s}^{-1}$.⁴⁴ This value is many orders of magnitude larger than the rate constant of the reaction (21) for which the conversion of Np(VII) at pH 9.08 reaches 50% in 1.2 min.⁴⁵ In the presence of a two- or threefold excess of Np(VII) , Am(III) is also oxidised only to the tetravalent state.

The same phenomena are observed in $\text{KHCO}_3 + \text{K}_2\text{CO}_3$ or $\text{NaHCO}_3 + \text{Na}_2\text{CO}_3$ mixtures at $\text{pH} \leq 10.9$. At higher pH (including 1.5 M K_2CO_3 or Na_2CO_3 solutions without additives of bicarbonate), the addition of a stoichiometric amount of Np(VII) leads to complete oxidation of Am(III) to Am(IV) , which then disappears due to disproportionation [see the reaction (7)]. This is evidenced by the appearance of Am(III) in an amount half as large as the initial value. The reaction of Am(III) with Np(VII)

taken in a threefold excess afforded Am(VI) , which is characterised by light absorption at 450–600 nm. Hence, Np(VII) oxidises not only Am(III) but also Am(V)

The addition of $\text{K}_4\text{Fe(CN)}_6 \cdot 3\text{H}_2\text{O}$ crystals to this solution led to a decrease in absorption at 450–600 nm but the absorption of Am(III) was not observed, i.e., Am(VI) was reduced to Am(V) .

The addition of a solution of Np(VII) in 0.01 M NaOH to a solution of Am(III) in 6 M K_2CO_3 resulted in oxidation of approximately one-half of the initial amount of Am(III) . However, the absorption bands of Am(IV) and Am(VI) were not observed. The concentration of Am(III) was not increased upon the addition of $\text{K}_4\text{Fe(CN)}_6 \cdot 3\text{H}_2\text{O}$. Hence, Am(III) is partially oxidised to Am(V) in this medium

d. Reactions of Am(IV) with Np(IV) or Pu(IV)

In a 0.5 M $\text{NaHCO}_3 + 1 \text{ M Na}_2\text{CO}_3$ solution, americium(IV) oxidises neptunium(IV), which is taken in an equimolar amount, to neptunium(VI) in 1–2 min.⁴⁶ The process starts with the reaction

followed by the more rapid reaction (19), because only Am(III) , Np(VI) and Np(IV) are present in the solution after the disappearance of Am(IV) , i.e., the process is described by the equation

Compared to the reaction (24), oxidation of Pu(IV) with americium(IV)

proceeds more slowly.⁴⁷ The subsequent reaction

must proceed faster.

3. Oxidation reactions

a. Oxidation with molecular oxygen

Oxidation of uranium(V) in a 1 M Na_2CO_3 solution and oxidation of uranium(IV) in a 1 M NaHCO_3 solution with atmospheric oxygen were examined in the study.⁵ In both cases, U(VI) was accumulated in the reaction products. The kinetic parameters of the reactions were not reported. The kinetics of U(IV) oxidation in carbonate-bicarbonate solutions was investigated.⁴⁸ When air was passed with a rate of 130 ml min^{-1} through a 1 M $\text{NaHCO}_3 + 0.25 \text{ M Na}_2\text{CO}_3$ solution (40 ml) containing uranium ($1.3 \times 10^{-2} \text{ mol litre}^{-1}$), U(VI) was formed with a rate of $1.3 \times 10^{-5} \text{ mol litre}^{-1} \text{ min}^{-1}$. A threefold decrease in the concentration of $\text{HCO}_3^- + \text{CO}_3^{2-}$ led to an increase in the rate of oxidation by $\sim 30\%$; the addition of copper ammoniate caused acceleration of oxidation.

Plutonium(III), which was prepared by electrolysis of Pu(IV) in a 1 M K_2CO_3 solution, underwent oxidation with atmospheric oxygen within a few minutes after termination of electrolysis. The supply of atmospheric oxygen was increased on stirring of the solution and oxidation was accelerated.²⁴

Dissolution of NpO_2 crystals in an aerated 1 M NaHCO_3 solution was examined.⁴⁹ The rate of dissolution of NpO_2 in this solution (210 ppm per day) proved to be much higher than that in water (2.5 ppm per day) or in a saturated NaCl solution (25 ppm per day). Neptunium(V) was detected in bicarbonate solutions, which indicates that NpO_2 is oxidised under the action of O_2 and HCO_3^- .

b. Oxidation with hydrogen peroxide

Hydrogen peroxide was also used for uranium oxidation (a suspension of a UO_2 powder in 0.5 M NaHCO_3 or NH_4HCO_3

solutions, $T = 20\text{ }^{\circ}\text{C}$).⁵⁰ To accelerate dissolution of UO_2 , $\text{Fe}(\text{CN})_6^{4-}$ and $\text{Fe}(\text{CN})_6^{3-}$ were added to the system. The proportion of uranium oxidised during the same period was approximately halved when pH was increased from 7.5 to 9, whereas a subsequent increase in pH has no effect on the oxidation rate.

c. Oxidation with water

Neptunium(III), which was prepared by an electrochemical method in a carbonate solution,¹² was spontaneously oxidised with water, which hindered the measurement of its absorption spectrum.

d. Oxidation with ozone

In the study,⁵¹ solutions of Am(VI) and Am(V) were prepared with the use of ozone. When oxygen containing 5% O_3 was passed through a 0.1 M NaHCO_3 solution containing a suspension of $\text{Am}(\text{OH})_3$ during 1 h, Am(VI) was formed quantitatively at any temperature in the range from 0 to $90\text{ }^{\circ}\text{C}$.

In a 2 M Na_2CO_3 solution, Am(III) is oxidised with ozone to Am(VI) at room and lower temperatures. In heated solutions, accumulation of Am(V) takes place.

Americium(V) involved in double carbonate with sodium was readily oxidised to Am(VI) with ozone in NaHCO_3 solutions at room temperature. However, ozone oxidised $\text{Am}(\text{OH})_3$ in 0.03–0.1 M KHCO_3 solutions to form Am(V), which precipitated as the salt KAmO_2CO_3 .

The kinetics of ozonation was not studied in detail. Nevertheless, some conclusions can be made about the mechanisms of the reactions that take place. Experiments on oxidation of Pu(III) with ozone in aqueous 0.25–1 M HClO_4 solutions enriched with the ^{18}O isotope demonstrated that water and ozone each supply one oxygen atom to form the PuO_2^{2+} ion.⁵² Oxidation of U(IV) with ozone is also accompanied by the transfer of the oxygen atom from ozone (apparently, as an inner-sphere process).⁵³ Oxidation of Am(III) with ozone may be schematically described by the following equations (without considering the complex formation with the carbonate ions):

In carbonate solutions, Am(III) exists as the complex AmCO_3^+ , $\text{Am}(\text{CO}_3)_2^-$ or $\text{Am}(\text{CO}_3)_3^{3-}$ ions depending on the composition of these solutions.⁵⁴ Based on the two last-mentioned complex ions, the crystalline compounds $\text{NaAm}(\text{CO}_3)_2 \cdot 4\text{H}_2\text{O}$ and $\text{Na}_3\text{Am}(\text{CO}_3)_3 \cdot 3\text{H}_2\text{O}$ containing water molecules in the coordination sphere of Am(III) were obtained.⁵⁵ Oxidation with ozone is accompanied by the replacement of the water molecule in the coordination sphere of Am(III) followed by elimination of the oxygen molecule [see the reaction (27)]. This mechanism was confirmed by our experiments on oxidation of Am(III) with ozone in a 5 M K_2CO_3 solution. Apparently, an increase in the concentration of the carbonate ions leads to an increase in the number of the CO_3^{2-} groups in the coordination sphere of Am(III) due to the displacement of the water molecules as a result of which the insertion of the ozone molecule is hindered and oxidation occurs as an outer-sphere process to form Am(IV).

e. Oxidation with $\text{S}_2\text{O}_8^{2-}$ ions

Neptunium(V). The kinetics of Np(V) oxidation with the persulfate ions was studied by spectrophotometry from the change in absorption of Np(VI) at 470 nm.⁵⁶ A decrease in the concentration of Np(V) is described by the following equation

$$-\frac{d[\text{Np(V)}]}{dt} = 2\{k_1 + k_2[\text{Np(V)}]\}[\text{S}_2\text{O}_8^{2-}]. \quad (31)$$

It was found that two competitive reactions take place, viz., the first-order (rate constant k_1) and second-order (rate constant k_2) processes (the zero and first orders with respect to neptunium, respectively).

Variation in the $\text{S}_2\text{O}_8^{2-}$ concentration from 50 to 500 mmol litre⁻¹ ($[\text{Np(V)}] = 16\text{ mmol litre}^{-1}$ at $50\text{ }^{\circ}\text{C}$) has no effect on the rate constants k_1 and k_2 for Np(V) oxidation in a 0.94 M Na_2CO_3 solution. As the Na_2CO_3 concentration is increased from 0.84 to 1.92 mol litre⁻¹ ($T = 50.4\text{ }^{\circ}\text{C}$), k_1 decreases from 4.7×10^{-5} to $2.3 \times 10^{-5}\text{ min}^{-1}$, whereas the constant k_2 ($k_2 = 0.15\text{ litre mol}^{-1}\text{ min}^{-1}$) remains unchanged.

In a 0.93 M K_2CO_3 solution, the constants k_1 and k_2 remain unchanged as $[\text{Np(V)}]_0$ is increased from 1.07 to 2.13 mmol litre⁻¹ and $[\text{S}_2\text{O}_8^{2-}]_0$ is increased from 30 to 150 mmol litre⁻¹, but an increase in the K_2CO_3 concentration from 0.93 to 4.50 mol litre⁻¹ ($T = 51.0\text{ }^{\circ}\text{C}$) is accompanied by a decrease in k_1 and an increase in k_2 .

The activation energies of the first- and second-order reactions (E_1 and E_2 , respectively) are 138 and 71 kJ mol⁻¹, respectively. The energy E_1 is virtually equal to the activation energy of thermal decomposition of $\text{S}_2\text{O}_8^{2-}$ (140 kJ mol⁻¹).⁵⁷ Hence, it can be assumed that the direct reaction of $\text{S}_2\text{O}_8^{2-}$ with Np(V) in carbonate solutions occurs simultaneously with thermal decomposition of $\text{S}_2\text{O}_8^{2-}$ followed by the reaction of the $\text{SO}_4^{\cdot-}$ radical ions with Np(V).

Neptunium(IV). Oxidation of Np(IV) with persulfate ions was studied in 0.86–3.30 M K_2CO_3 solutions by spectrophotometry from a change in absorption of Np(VI) ($\lambda = 490\text{ nm}$) and Np(IV) ($\lambda = 800\text{ nm}$).⁵⁸ Typical kinetic curves for a decrease in the amount of Np(IV) and accumulation of Np(VI) assume an S shape. The concentration of Np(V) (calculated) passes through a maximum, which is reached within 10–15 min after the beginning of the reaction.

At constant temperature and concentration of K_2CO_3 , the initial oxidation rate (V_0) of neptunium(IV) is independent of its initial concentration. The rate V_0 is comparable with the rate of thermal decomposition of the $\text{S}_2\text{O}_8^{2-}$ ions and is directly proportional to their concentration. Consequently, the process starts with the reactions (32) and (33) followed by the reaction

The rate constant for this reaction was estimated at $6.9 \times 10^3\text{ litre mol}^{-1}\text{ s}^{-1}$.⁵⁹ As Np(V) is accumulated, the contribution of the reactions (34) and (35) becomes more and more noticeable. Neptunium(VI) reacts with neptunium(IV) according to the reaction (10).

Neptunium(VI). In bicarbonate solutions containing Np(VI) (1.5 mmol litre⁻¹) and $\text{S}_2\text{O}_8^{2-}$ (50 mmol litre⁻¹), Np(VI) was only partially oxidised at $60\text{ }^{\circ}\text{C}$ in the presence of alkali metal (potassium, sodium or lithium) or ammonium cations.⁶⁰ Accumulation of Np(VII) as MNP_4O_4 took place within first 30 min after mixing of the reagents, whereas subsequent storage of these reagents for 120 min led to only a slight increase in the Np(VII) content. As the concentration of MHCO_3 was increased from 16 to 46 mmol litre⁻¹, the yield of Np(VII) was increased from 17% to 44% in a KHCO_3 medium (pH 7.30–7.70) and from 18% to 29% in a NaHCO_3 medium (pH 7.30). A further increase in the MHCO_3 concentration led to a decrease in the yield of Np(VII). In aqueous solutions containing KHCO_3 (93 mmol litre⁻¹) or NaHCO_3 (46 mmol litre⁻¹), the formation of Np(VII) was not observed. In solutions of LiHCO_3 and NH_4HCO_3 , the maximum yields of Np(VII) were lower.

The following scheme of the process can be proposed. Thermal decomposition of $\text{S}_2\text{O}_8^{2-}$ affords the $\text{SO}_4^{\cdot -}$ radical ions [see the reaction (32)]. Then, the following reactions proceed:

At a bicarbonate concentration of 10–100 mmol litre⁻¹, the $\text{SO}_4^{\cdot -}$ radical anions are predominantly consumed in the reaction (38). However, it is known that the $\text{CO}_3^{\cdot -}$ radical anion cannot oxidise Np(VI) in a carbonate medium.⁶² Hence, either the $\text{SO}_4^{\cdot -}$ radical anion or the $\text{S}_2\text{O}_8^{2-}$ ion must serve as an oxidiser of Np(VI)

Neptunium(VII) is involved in two competitive processes. In one process, neptunium(VII) partially precipitates as the solid compound MNP_2O_4 (see Ref. 63) and is stabilised. In another process, the remaining Np(VII) is involved in a carbonate complex and reduced with water.⁴⁵

Plutonium(IV). The kinetics of Pu(IV) oxidation with the $\text{S}_2\text{O}_8^{2-}$ ions in 1.07–1.57 M Na_2CO_3 solutions was studied by spectrophotometry from a change in light absorption of Pu(IV) and Pu(VI).⁶⁴ The initial oxidation rates of Pu(IV) to Pu(VI) linearly increased as the concentration of Pu(IV) was increased from 2 to 8 mmol litre⁻¹ according to the empirical dependence

$$V_0 = a + b[\text{Pu(IV)}]. \quad (41)$$

It was assumed that two competitive processes of Pu(IV) oxidation occurred. The rate V_0 nonlinearly increased as the concentration of the $\text{S}_2\text{O}_8^{2-}$ ions was increased. Based on analysis of the experimental data, the following sequence of Pu(IV) oxidation with the $\text{S}_2\text{O}_8^{2-}$ ions was proposed. First, the reactions (32) and (33) proceed followed by the reactions

Simultaneously, Pu(IV) reacts with the $\text{S}_2\text{O}_8^{2-}$ ions that remain undecomposed

It was assumed⁶⁴ that Pu(IV) is oxidised directly with the $\text{SO}_4^{\cdot -}$ radicals. However, this reaction plays virtually no part in this medium. A change in the concentration of $\text{CO}_3^{\cdot -}$ has a substantial effect on the mechanism of the radical pathway of Pu(IV) oxidation and is only slightly reflected in intramolecular oxidation.

In the temperature range of 70–81.5 °C, the activation energies of radical and intramolecular oxidation are 134 ± 8 and $96 \pm 8 \text{ kJ mol}^{-1}$, respectively.

Americium(III) and americium(V). Upon heating in a 0.1 M NaHCO_3 solution, americium(III) is oxidised under the action of $\text{Na}_2\text{S}_2\text{O}_8$ to Am(VI).⁵¹ In a 2 M Na_2CO_3 solution in the presence of $\text{Na}_2\text{S}_2\text{O}_8$ (0.01 mol litre⁻¹), americium(VI) is formed only at 90 °C.⁵¹ In a 0.1 M $\text{KHCO}_3 + \text{K}_2\text{CO}_3$ solution, americium(III) is oxidised under the action of the $\text{S}_2\text{O}_8^{2-}$ ions to americium(V), which precipitates as the KAmO_2CO_3 complex.

The kinetics of Am(III) oxidation with the persulfate ions was examined in solutions of K_2CO_3 (see Refs 65 and 66), $(\text{NH}_4)_2\text{CO}_3$ and Na_2CO_3 (see Ref. 66).⁸ The course of the reaction was followed from a change in light absorption of Am(III)

($\lambda = 508 \text{ nm}$) and Am(VI) ($\lambda = 688 \text{ nm}$ ⁶⁵ or 550 nm ⁶⁶). The concentration of Am(III) was decreased with a constant rate and this change slowed down only toward the end of the process. Accumulation of Am(VI) started when only 10%–20% of Am(III) remained in the solution. Until then Am(VI), apparently, disappeared due to the involvement in the reaction (12) although the data on this process at high temperature are lacking. The higher was the CO_3^{2-} concentration and the lower was the $\text{S}_2\text{O}_8^{2-}$ concentration, the longer was the induction period. After completion of the induction period, Am(VI) was accumulated in solution almost linearly.

The rate of Am(III) oxidation is independent of the concentrations of americium (in the range of 0.25–1.58 mmol litre⁻¹) and K_2CO_3 and is directly proportional to the concentration of $\text{S}_2\text{O}_8^{2-}$ (12.5–200 mmol litre⁻¹).^{65, 66} At the same time, the rate of Am(V) oxidation, *i.e.*, the rate of Am(VI) accumulation, increases as the concentration of Am(V) is increased only to 0.6 mmol litre⁻¹ and then remains constant. The formation of Am(VI) is accelerated as the concentration of $\text{S}_2\text{O}_8^{2-}$ is increased, whereas an increase in the K_2CO_3 content slows down the Am(VI) formation.

The activation energy of Am(III) oxidation is equal to that of Am(V) oxidation. These values are $143 \pm 8 \text{ kJ mol}^{-1}$ in a 1.9 M K_2CO_3 solution ($T = 58\text{--}83^\circ\text{C}$),⁶⁵ $143 \pm 8 \text{ kJ mol}^{-1}$ in a 1.5 M Na_2CO_3 solution and $159 \pm 8 \text{ kJ mol}^{-1}$ in a 1.9 M $(\text{NH}_4)_2\text{CO}_3$ solution.⁶⁶

The following sequence of Am(III) and Am(V) oxidation can be proposed. Thermal decomposition of $\text{S}_2\text{O}_8^{2-}$ [see the reactions (32) and (33)] affords the $\text{SO}_4^{\cdot -}$ and $\text{CO}_3^{\cdot -}$ radical anions followed by the reactions

and the reaction (12). The rate constant of the reaction (47) is $2.5 \times 10^7 \text{ litre mol}^{-1} \text{ s}^{-1}$.⁶⁷

To our knowledge, americium(IV) does not react with $\text{CO}_3^{\cdot -}$ and, hence, Am(V) may be formed only upon disproportionation of Am(IV).

The plot of the rate constant for An(V) oxidation ($\text{An} = \text{U}$, Np or Pu) with the $\text{CO}_3^{\cdot -}$ radical anions *vs.* the potential of the An(VI)/An(V) pair yields a straight line on the logarithmic coordinates, which is characteristic of the Marcus outer-sphere electron transfer.⁶ It is reasonable to suggest that oxidation of Am(V) will be described by an analogous plot. Extrapolation of the straight line to the potential of 0.92 V [*i.e.*, to Am(V)] gave $\log k \approx 6$ ($\text{litre mol}^{-1} \text{ s}^{-1}$). This value is smaller than $\log k$ for the reaction (47) although the Am(VI)/Am(V) and Am(VI)/Am(III) pairs have similar potentials (see Table 1) and oxidation of both ions occurs without the structural rearrangements. Apparently, the lower rate of Am(V) oxidation as compared to the rate of Am(III) oxidation is responsible for the occurrence of the induction period observed upon accumulation of Am(VI). Taking into account that

$$k_{\text{Am(III)}}[\text{Am(III)}] \approx k_{\text{Am(V)}}[\text{Am(V)}],$$

for oxidation of Am(III) and Am(V) with persulfate ions we have

$$k_{\text{Am(V)}} \approx 0.1 k_{\text{Am(III)}}.$$

The results obtained with the use of this ratio agree with the results of extrapolation. Our data on radiolysis and photolysis of Am(III) and Am(V) also indicate that these ions differ in their ability to be oxidised in carbonate solutions. Apparently, the $\text{CO}_3^{\cdot -}$ radical anions interact with Am(III) and Am(V) through different mechanisms. Oxidation of Am(V), like oxidation of U(V), Np(V) and Pu(V), proceeds through the outer-sphere charge transfer. By contrast, oxidation of Am(III) can be accompanied by hydrogen abstraction from the water molecule. It should be noted that oxidation of Am(III) with the $\text{OH}^{\cdot}$ radical in HClO_4 solutions proceeds through hydrogen abstraction from the water molecule involved in the hydration shell about the Am(III) ion.⁶⁸

§ Semiquantitative data on the kinetics of this process published in earlier studies were surveyed in the review.⁶⁵

A comparison of the calculated rates of formation of the $\text{SO}_4^{\cdot -}$ radical ions and oxidation of Am(III) shows that $\sim 40\%$ of the radical oxidisers goes into the latter reaction. The fact that Am(III) oxidation is somewhat accelerated in solutions containing more than 2 mol litre^{-1} of K_2CO_3 is indicative of the less significant role of side reactions rather than of the direct interaction of Am(III) with $\text{S}_2\text{O}_8^{2-}$ as has been suggested in the study.⁶⁶

f. Oxidation with silver compounds

Americium(IV), which is unstable in acidic media, was stabilised in carbonate solutions. Americium(III) was subjected to the action of a mixture of AgNO_3 and $\text{K}_2\text{S}_2\text{O}_8$. In this case, several oxidisers appeared in the solution⁶⁹

In addition, the reactions (33) and (47) took place.

Solid AgO also oxidises Am(III) to Am(IV).⁶⁹ Silver oxide was used also for oxidation of Pu(IV) in a 45% K_2CO_3 solution.^{10, 70} In the temperature range of $75\text{--}90^\circ\text{C}$, complete oxidation of plutonium occurred during 45 min. Apparently, the following reactions proceeded:

along with the reaction (5).

g. Oxidation with ClO^- ions

It is known that macroamounts of Pu(IV) in a 45% K_2CO_3 solution are oxidised to Pu(VI) with the hypochlorite ions.⁷⁰ When heated to an above-room temperature, the reaction was completed in 5–10 min. The data on this process are scarce, which does not allow one to make conclusions about the reaction mechanism.

h. Oxidation with xenon compounds

The reactions of the americium ions with xenon compounds in bicarbonate and carbonate media were examined in the studies.^{71–73} Xenon compounds were chosen as oxidisers in view of the fact that the potentials of the Xe(VIII)/Xe(VI) and Xe(II)/Xe(0) pairs are higher than the potentials of the Am(IV)/Am(III) and Am(VI)/Am(V) pairs. The calculated potential of the XeF_2/Xe pair in an acidic medium is 2.3 V .⁷⁴ In an alkaline medium, the potential of this pair was not determined but it was found that xenon difluoride partially oxidises Pu(VI) to Pu(VII) in $0.2\text{--}1.2 \text{ M}$ NaOH solutions.⁷⁵ In a 1 M NaOH solution, the potential of the latter pair is 0.85 V . Hence, XeF_2 must oxidise Am(III).

The addition of a XeF_2 solution, which was cooled to 0°C , to a 1.5 M KHCO_3 solution of Am(III) led to oxidation of the latter to Am(IV) in the course of stirring, which was established by spectrophotometry. The stoichiometric coefficient $n = \Delta[\text{Am(IV)}]/\Delta[\text{XeF}_2]$ is 0.23 .^{71, 72} It should be noted that this is yet another known procedure for the chemical preparation of Am(IV) in carbonate solutions (photo- and electrochemical methods are not considered). Upon the addition of dry $\text{K}_4\text{Fe(CN)}_6 \cdot 3 \text{H}_2\text{O}$ to the resulting solution, americium reverted to Am(III). In the presence of a tenfold excess of XeF_2 , americium(III) was completely oxidised to Am(IV). Other valence states were not found. In a $\text{KHCO}_3 + \text{K}_2\text{CO}_3$ solution, the coefficient n decreased as the K_2CO_3 content was increased. In a 1.5 M K_2CO_3 solution, $n < 0.01$. In this medium, Am(III) was oxidised by at most 5% . In more concentrated K_2CO_3 solutions, americium(III) was not oxidised.

In aqueous solutions, not only does XeF_2 react with reducing agents but it also undergoes hydrolysis. The scheme of hydrolysis was proposed in the studies^{76, 77} and was thereafter substantiated.⁷⁸ Taking into account this scheme and the reactions of

Am(III) and Am(IV), the following sequence of processes occurring in the course of Am(III) oxidation can be suggested. The reactions

are followed by the reaction (47) and then by the reactions

The direct reactions of Am(III) with xenon compounds are also not ruled out.

Oxidation of Am(III) under the action of Na_4XeO_6 in carbonate solutions was examined in the studies.^{71, 73} In an alkaline medium, the potential of the Xe(VIII)/Xe(VI) pair is close to 0.9 V .⁷⁹ This potential increases as pH is decreased and its values in a carbonate medium is higher than 1 V . Hence, the perxenate ion can oxidise americium(III) in bicarbonate and carbonate solutions. When $\text{Na}_4\text{XeO}_6 \cdot n \text{H}_2\text{O}$ was added to a 0.75 M $\text{KHCO}_3 + \text{K}_2\text{CO}_3$ solution (pH 10) containing Am(III) ($2 \times 10^{-4} \text{ mol litre}^{-1}$) until the concentration of the former reached $1 \times 10^{-4} \text{ mol litre}^{-1}$, the mixture turned yellow already in 1 min. Analysis of the solution for different valence states of americium [by spectrophotometry and by reduction with $\text{K}_4\text{Fe(CN)}_6 \cdot 3 \text{H}_2\text{O}$] revealed the presence of Am(IV), Am(V) and Am(VI). [Recall that XeF_2 oxidises Am(III) only to Am(IV)]. The $-\Delta[\text{Am(III)}]/\Delta[\text{Xe(VIII)}]$ ratio varied from 0.3 to 0.7. In the presence of a 30-fold excess of perxenate ions, americium was quantitatively oxidised to the hexavalent state. The same situation was observed in a 1.5 M KHCO_3 or K_2CO_3 solution. In a 5.9 M K_2CO_3 solution, perxenate ions decomposed and did not oxidise Am(III). As regards the mechanism of the reaction of Na_4XeO_6 with Am(III), the following conclusions can be made. If the process

took place, the subsequent reaction (47) would afford only Am(IV), which does not react with the $\text{CO}_3^{\cdot -}$ radical anions. For instance, this situation was observed upon photochemical oxidation of Am(III) in the presence of $\text{S}_2\text{O}_8^{2-}$, N_2O , BrO^- or BrO_3^- at pH $8.5\text{--}10.5$.^{41, 80–82} The appearance of Am(V) and Am(VI) in solutions, where disproportionation of Am(IV) proceeds very slowly, indicates that Xe(VIII) serves as an oxidiser of americium to the pentavalent state

Two-electron reactions can proceed, for example, through the transfer of the oxygen atom. Americium(IV) involved in the reaction (69) is generated in the reaction (12). Like Xe(VIII), xenon(VII) can apparently oxidise Am(III), Am(IV) and Am(V). In addition, it was suggested that Xe(VII) is involved in the following processes:⁸³

The rate constant of the reaction (72) is $2 \times 10^7 \text{ litre mol}^{-1} \text{ s}^{-1}$.

The reactions of Am(III) and Am(IV) with the perxenate ions can also proceed by a one-electron mechanism:

The ability of Na_4XeO_6 to oxidise Am(IV) was proved as follows. Trivalent americium ($0.13 \text{ mmol litre}^{-1}$) in a $1.5 \text{ M KHCO}_3 + \text{K}_2\text{CO}_3$ solution was quantitatively oxidised to Am(IV) under the action of XeO_3 with the use of the photochemical method.⁷¹ The addition of perxenate ions to the solution led to the rapid formation of Am(V) and Am(VI). The stoichiometric coefficient $-\Delta[\text{Am(IV)}]/\Delta[\text{Xe(VIII)}]$ was 0.2.

The potential of the XeO_3/Xe pair was estimated⁸⁴ at 2.10 and 1.24 V in acidic and alkaline solutions, respectively. Hence, XeO_3 could oxidise Am(III) in carbonate solutions. However, we experimentally established⁷¹ that this reaction proceeded only under UV or γ irradiation.

i. β Decay as an oxidative process

Attempts to prepare curium(VI) by chemical methods failed due to the high oxidation potential of the Cm(IV)/Cm(III) pair and, presumably, low stability of curium(V). At the same time, there is reason to believe that Cm(VI) in carbonate solutions must be rather stable. Hence, another procedure for the preparation of Cm(VI) was chosen. This procedure makes use of β decay of the ^{242}Am isotope (half-life is 16.07 h). The compound $\text{K}_3\text{AmO}_2(\text{CO}_3)_2$, which was synthesised in the study,⁸⁵ contains americium with the following isotopic composition: 92% ^{241}Am , 1.4% ^{242}Am and 6.6% ^{243}Am . Before the synthesis, the starting americium specimen was purified from ^{242}Cm that was accumulated. The resulting compound was kept over a period from 18 to 40 h and then dissolved in a 0.1 M NaHCO_3 solution upon ozone bubbling to oxidise Am(V) to Am(VI). Under these conditions, curium(III) was not oxidised. It was expected that the daughter curium-242 isotope, which was generated *via* β decay of the ^{242}Am isotope in the course of storage of $\text{K}_3\text{AmO}_2(\text{CO}_3)_2$, would exist as the 'hot' ion, which has the parent composition but whose charge is larger by unity, *i.e.*,

The estimation, which was carried out taking into consideration all nuclear-physics processes attendant on β decay of the ^{242}Am isotope, demonstrated that up to 60%–70% of the daughter ^{242}Cm isotope must be stabilised as the CmO_2^{2+} ions. The latter can be found after dissolution of $\text{K}_3\text{AmO}_2(\text{CO}_3)_2$. With the aim of establishing the valence state of ^{242}Cm , $\text{K}_4\text{UO}_2(\text{CO}_3)_3$ was precipitated from the resulting solution. The precipitate captured 96%–99% of AmO_2^+ and AmO_2^{2+} ions and only 3%–5% of Cm(III) ions. When the solution was in contact with freshly precipitated LaF_3 , 97%–99% of the Cm(III) ions and no more than 3% of the Am(VI) ions were sorbed. Under the same conditions, 92%–95% of the NpO_2^+ ions (analogues of CmO_2^+) were sorbed. Experiments demonstrated that curium-242 was concentrated either with penta- and hexavalent actinides [in the $\text{K}_4\text{UO}_2(\text{CO}_3)_3$ precipitate] or only with hexavalent actinides (in a solution over the LaF_3 precipitate). Hence it follows that ^{242}Cm differs in chemical properties from curium(III), *i.e.*, ^{242}Cm was obtained in the hexavalent state.

This procedure was used also for the preparation of californium(V).⁸⁶ In carbonate solutions, the ^{249}Cf isotope, which is generated upon β decay of tetravalent berkelium-249, exists as Cf(V) sorbed on the $\text{Na}_4\text{UO}_2(\text{CO}_3)_3$ precipitate.

4. Reduction reactions

a. Reduction with water

Neptunium(VII). The gradual transformation of Np(VII) into Np(VI) in carbonate solutions was studied by spectrophotometry from a change in the intensity of absorption at $\lambda = 460 \text{ nm}$.⁴⁵ For a $0.5 \text{ M KHCO}_3 + \text{K}_2\text{CO}_3$ solution with $\mu = 1$, the change in the Np(VII) concentration is described by the equation

$$-\frac{d[\text{Np(VII)}]}{dt} = k[\text{Np(VII)}]. \quad (75)$$

At 25°C , the constant k decreases from 56.4×10^{-2} to $0.79 \times 10^{-2} \text{ min}^{-1}$ as pH is increased from 9.08 to 11.03. The plot of $\log k$ vs. pH yields a straight line with a slope of -0.98 , *i.e.*, this reaction is first order with respect to the hydrogen ions (or reciprocal first order with respect to the OH^- ions). In the temperature range of 25 – 35°C , the activation energy of reduction of Np(VII) to Np(VI) was estimated⁴⁵ at 33 kJ mol^{-1} (pH 10.0).

Instability of Np(VII) in carbonate solutions results from the high oxidation potential of the Np(VII)/Np(VI) pair ($\geq 1 \text{ V}$; see Section III.2.c). Under these conditions, the potential of oxygen liberation from water is 0.64 V .

It is commonly assumed that the first step of H_2O decomposition under the action of strong oxidisers involves hydrogen abstraction to form the $\text{OH}^\bullet$ radical. However, the oxidation potential of the $\text{OH}^\bullet/\text{OH}^-$ pair at pH 10 is 2.1 V . Due to the large difference in the potentials of the above pairs, reduction of Np(VII) with water cannot proceed through the formation of the $\text{OH}^\bullet$ radical. However, another reaction, *viz.*, oxidation of water to H_2O_2 is also thermodynamically possible. The standard potential of the $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ pair is 1.77 V . In carbonate solutions, this potential is lowered to 1.1 – 1.2 V . For the reaction to follow this pathway, two Np(VII) ions must be simultaneously involved in this reaction. However, this reaction is first order with respect to neptunium. To resolve this contradiction, it was suggested^{87,88} that the thermally excited Np(VII) ion and the nonexcited Np(VII) ion form a dimer through two OH groups. This dimer subsequently decomposes into two Np(VI) ions and the H_2O_2 water molecule. Hydrogen peroxide reduces two more Np(VII) ions.

Americium(VI) and americium(IV). The overall equation for reduction of Am(VI) with water in a $1.3 \text{ M Na}_2\text{CO}_3$ solution (pH 11.25) has the form

(taking into account the high pH of the medium, the hydroxy ions rather than water molecules formally serve as a reducing agent).

At 25°C , the rate constant for the first-order reaction was estimated at $(0.14 \pm 0.01) \times 10^{-4} \text{ s}^{-1}$. In the temperature range of 25 – 75°C , the activation energy is $63.8 \pm 4 \text{ kJ mol}^{-1}$ (see Refs 32 and 33).

In a $1.3 \text{ M NaHCO}_3 + \text{Na}_2\text{CO}_3$ solution (pH 10), the rate constant (at 30°C) for reduction of Am(IV) with water [see the reaction (6)] is $(0.6 \pm 0.3) \times 10^{-4} \text{ s}^{-1}$. In the temperature range of 30 – 65°C , the activation energy is $96.6 \pm 12.0 \text{ kJ mol}^{-1}$ (see Ref. 33).

Probably, the mechanisms of Am(VI) and Am(IV) reduction with water are analogous to the mechanism of Np(VII) reduction.

b. Reduction with hydrogen peroxide

Plutonium(VI). The reaction of Pu(VI) with H_2O_2 was studied in 0.005 – 0.1 M NaHCO_3 solutions by stopped-flow spectrophotometry.⁸⁹ The results of this study indicate that the following reaction takes place

It was established experimentally that Pu(VI) forms a complex with H_2O_2 . Thus, a 0.05 M NaHCO_3 solution containing Pu(VI) ($0.6 \text{ mmol litre}^{-1}$) was injected into a 0.05 M NaHCO_3 solution containing H_2O_2 ($3 \text{ mmol litre}^{-1}$). The rate constant for the formation of the Pu(VI) complex with H_2O_2 (k) was estimated at

$(6.9 \pm 0.8) \times 10^3$ litre mol⁻¹ s⁻¹. Doubling of the initial H₂O₂ concentration led to an increase in the constant k to $(7.2 \pm 0.7) \times 10^3$ litre mol⁻¹ s⁻¹. The rate of disappearance of the complex cannot be described by the first-order equation. Reduction began with the reactions⁸⁹

According to the scheme proposed in the study,⁸⁹ the subsequent step involves the reaction of Pu(VI) with HO₂[•] followed by other reactions. However, rather high pH was not taken into account. Since the reaction (57) is efficient at pH 8.5, it is apparently followed by the processes

and then by the reactions (60) and (43).

When Pu(VI) and H₂O₂ were taken at the initial concentrations of 0.11 and 11.2 mmol litre⁻¹, respectively, the apparent rate constant of the first-order reaction [see Eqn (79)] increased from 1.12 to 24.2 s⁻¹ as the concentration of HCO₃⁻ was decreased from 0.05 to 0.005 mol litre⁻¹. An increase in the concentration of H₂O₂ in a 0.005 M NaHCO₃ solution from 11 to 22 mmol litre⁻¹ led to an increase in the first-order rate constant from 24 to 34 s⁻¹.

c. Reduction with Fe(CN)₆⁴⁻ ions

Neptunium(VI). Reduction of Np(VI) with the Fe(CN)₆⁴⁻ ions was studied in aqueous solutions of Na₂CO₃ ([Na₂CO₃] ≤ 0.05 mmol litre⁻¹) by the stopped-flow method.⁹⁰ For the process in a 0.05 M Na₂CO₃ solution,

$$\frac{\Delta[\text{Np(VI)}]}{\Delta[\text{Fe(CN)}_6^{4-}]} = 1.01 \pm 0.01,$$

which corresponds to the reaction

The kinetics of the reaction is described by the empirical equation

$$-\frac{d[\text{Np(VI)}]}{dt} = k'[\text{Np(VI)}][\text{Fe(CN)}_6^{4-}], \quad (83)$$

where $k' = (a + b[\text{CO}_3^{2-}])^{-1}$.

In a 0.004 M Na₂CO₃ solution (μ was maintained at 0.2 by adding NaCl) $k' = 2.8 \times 10^3$ litre mol⁻¹ s⁻¹ (at 25 °C). At a constant concentration of Na₂CO₃ (0.004 mol litre⁻¹), the change in the ionic strength from 0.1 to 1 had no effect on k' but the same increase in μ in a 0.05 M Na₂CO₃ solution led to doubling of k' .

The mechanism of reduction involves the following reactions:

where A is an intermediate formed upon the replacement of one CO₃²⁻ group in NpO₂(CO₃)₃⁴⁻ by the Fe(CN)₆⁴⁻ ion.

Plutonium(VI). The reaction of Pu(VI) with the Fe(CN)₆⁴⁻ ions proceeds⁹¹ analogously to the reaction of Np(VI) with these ions considered above

In a 0.05 M Na₂CO₃ solution (25 °C), $k_f = 1214 \pm 20$ and $k_r = (3.64 \pm 0.20) \times 10^4$ litre mol⁻¹ s⁻¹ for the forward (f) and reverse (r) reactions, respectively. The empirical dependence of the

rate constant for the forward reaction on the concentration of the carbonate ions takes the form

$$\ln k_f = \ln a + n \ln [\text{CO}_3^{2-}]. \quad (87)$$

At 25 °C, $\ln a = 4.74 \pm 0.11$ and $n = 0.80 \pm 0.03$ for $\mu = 0.2$ (NaCl), $[\text{Pu(VI)}] = 0.2$ mmol litre⁻¹, $[\text{Fe(CN)}_6^{4-}] = 0.4$ mmol litre⁻¹. The rate constant k_f is virtually independent of the CO₃²⁻ concentration.

The reactions (82) and (86) have much in common. However, it is not improbable⁹¹ that these reactions proceed through different mechanisms. In particular, the characteristics of the reaction (82) are inconsistent with the mechanism of the outer-sphere electron transfer, which seemed to be most probable.

Americium(IV) and americium(VI). The reactions of Am(IV) and Am(VI) with the Fe(CN)₆⁴⁻ ions were not studied in detail. Nevertheless, it is known that these reactions in bicarbonate-carbonate media afford Am(III) and Am(V), respectively. Americium(V) is resistant to the hexacyanoferrate(II) ions. As mentioned above, the ratio between Am(IV) and Am(VI) in the initial mixture can be precisely established with the use of reduction with the Fe(CN)₆⁴⁻ ions followed by the determination of the reaction products by spectrophotometry.

d. Reduction with the [Tc(DMPE)₃]SO₃CF₃ and [Re(DMPE)₃]SO₃CF₃ compounds

The [M(DMPE)₃]SO₃CF₃ compounds [M = Tc, Re, DMPE is 1,2-bis(dimethylphosphino)ethane] serve as outer-sphere reducing agents. These compounds were used in studies of the reactions with Np(VI) and Pu(VI) in carbonate solutions.⁹² The equilibrium constants of the reactions

($T = 25$ °C, $\mu = 0.3$, $[\text{CO}_3^{2-}] = 0.05$ mol litre⁻¹) were calculated. The rate constants and the activation energies of these reactions were determined. The rate constants of the self-exchange reactions for the Np(VI)/Np(V) and Pu(VI)/Pu(V) pairs, which were calculated according to the Marcus equation, are 0.69 and 3.0 litre mol⁻¹ s⁻¹, respectively, when Tc(DMPE)₃⁺ was used as a reducing agent and are 0.64 and 8.9 litre mol⁻¹ s⁻¹, respectively, when Re(DMPE)₃⁺ was used as a reducing agent.

IV. Reactions in alkaline media

1. Disproportionation and reproporation reactions

a. Disproportionation of Np(VI) and Am(VI)

The necessary condition for self-oxidation–self-reduction reactions of hexavalent actinides is the similarity of the formal potentials E_f for the VII/VI and VI/V pairs. In the case of neptunium and americium, the potentials of these pairs in 1 M NaOH solutions differ by ~0.4 V. An increase in the alkali concentration leads to a sharp decrease in the potentials $E_f^{\text{VII/VI}}$, whereas $E_f^{\text{VI/V}}$ are changed only slightly. Hence, penta-, hexa- and heptavalent neptunium or americium can coexist in 10 M and more concentrated NaOH solutions.

Upon rapid 10–20-fold dilution with a 17 M NaOH solution, a colourless 5×10^{-3} M neptunium(VI) solution turned green, which is characteristic of Np(VII).⁹³ The visible regions of the absorption spectra of these solutions, which were measured after the removal of a suspension of air bubbles, were similar to the absorption spectrum of Np(VII). The difference was observed only in the short-wavelength region [due to the presence of Np(VI) in the solution]. The equilibrium

was established at room temperature in less than 1 min. The position of the equilibrium depends substantially on the NaOH concentration. The determined equilibrium constants

$$K = \frac{[\text{Np(VII)}][\text{Np(V)}]}{[\text{Np(VI)}]^2}$$

in solutions with different compositions are given in Table 2.

Disproportionation of Np(VI) was studied also in hot NaOH solutions.⁹⁴ Under these conditions, the solubilities of neptunates are much higher as compared to those in the cold. In addition, the viscosity of alkaline solutions decreases as the temperature is increased due to which the formation of a suspension of air bubbles ceases. The determined equilibrium constants are well reproducible.

Table 2. Equilibrium concentrations of Np(VII) and equilibrium constants K for disproportionation reactions of Np(VI) in alkaline solutions ($T = 21-23^\circ\text{C}$).⁹³

[NaOH] /mol litre ⁻¹	10 ⁴ [Np(VI)] ₀ /mol litre ⁻¹	10 ⁴ [Np(V)] /mol litre ⁻¹	10 ⁵ [Np(VII)] _p /mol litre ⁻¹	10 ² K
8.7	9.52	—	1.2	0.017
10.7	9.52	—	3.5	0.16
11.8	2.38	—	1.4	0.44
12.4	5.00	—	3.8	0.8
13.6	2.38	—	2.8	2.4
14.8	4.55	—	7.8	6.8
15.3	2.38	—	4.3	8.0
17.2	2.38	—	5.1	13.2
13.6	2.38	0.33	1.8	2.2
13.6	2.38	0.84	1.5	3.4
13.6	2.38	2.50	0.45	2.5

Interestingly, the equilibrium constants are virtually independent of the temperature under the conditions studied. Consequently, the activation energies of Np(VI) disproportionation and Np(VII) reduction with pentavalent neptunium must be equal within the experimental error.

When studying disproportionation of actinides in aqueous solutions of KOH and CsOH and in aqueous-methanolic solutions of KOH, Tananaev⁹⁵ found that the nature of alkali is of little importance, whereas a decrease in the water content is favourable for disproportionation. For example, disproportionation in a solution containing 60 vol.% of methanol proceeds to a noticeable extent even at $[\text{KOH}] = 4 \text{ mol litre}^{-1}$.

Disproportionation of Am(VI) was examined in the study.⁹⁶ A 18 M NaOH solution (2.5–3.0 ml) cooled to 0°C and a cooled weakly acidic 0.03 M americium(VI) solution (0.2 ml) were mixed in a quartz cell and the absorption spectrum of the mixture was recorded. This spectrum had a band with a maximum at 740–750 nm, which is characteristic of Am(VII). Since there were no other oxidisers in the solution, the formation of Am(VII) was attributed to self-oxidation–self-reduction of Am(VI)

Table 3. Equilibrium constants for disproportionation reaction of Am(VI) in NaOH solutions at $0-3^\circ\text{C}$.

[NaOH] /mol litre ⁻¹	10 ³ [Am(VI)] ₀ /mol litre ⁻¹	Equilibrium concentration /mol litre ⁻¹			K
		Am(VII)	Am(V)	Am(VI)	
8.5	1.74	not found	—	—	—
12.4	1.61	0.20	0.20	1.21	2.7×10^{-2}
14.2	2.04	0.34	0.34	1.36	6.2×10^{-2}
15.4	2.30	0.80	0.80	0.70	1.3
16.6	1.37	0.45	0.45	0.47	0.9
17.2	1.39	0.61	0.61	0.17	13

The estimated equilibrium constants of this reaction are given in Table 3.

Americium(VI) is somewhat more prone to disproportionation than neptunium(VI). In both cases, the NaOH concentration has a similar effect on the equilibrium of the reaction.

b. Disproportionation of Pu(V)

Comparison of the potentials of the Pu(V)/Pu(IV) and Pu(VI)/Pu(V) pairs shows that Pu(V) must undergo disproportionation in a wide range of alkali concentrations. The kinetics of this process was studied by spectrophotometry.⁹⁷ In experiments, Pu(V) was prepared predominantly by reducing Pu(VI) with H_2O_2 in an alkaline medium

Then the accumulation of Pu(VI) in the solution was tracked. When precipitating, plutonium(IV) captured a portion of Pu(V). Taking into account the balance of all valence states of plutonium in the solution and in the precipitate [without considering reduction of Pu(VI) with α -radiolysis products of water], it was concluded that the following reaction proceeds in the solution:

In alkaline media, Pu(V) exists as the $\text{PuO}_2(\text{OH})_3(\text{H}_2\text{O})^{2-}$ and $\text{PuO}_2(\text{OH})_4^{3-}$ ions, freshly precipitated Pu(IV) exists as $\text{Pu}(\text{OH})_4$ (more precisely, as $\text{PuO}_2 \cdot n\text{H}_2\text{O}$) and Pu(VI) occurs as $\text{PuO}_2(\text{OH})_4^{2-}$ (see Ref. 2). Hence, the reaction (5) can be described as follows:

The constant $2k$ was estimated from the initial rate of disproportionation of Pu(V)

$$V_0 = -\frac{d[\text{Pu(V)}]}{dt} = 2k[\text{Pu(V)}]^2. \quad (92)$$

It was found that the rate constant sharply increased as the NaOH concentration was decreased from 7.6 to $0.5 \text{ mol litre}^{-1}$. On the logarithmic coordinates, the plot of $2k$ vs. the activity of the OH^- ions yields a straight line with a slope of -2.8 . However, taking into account that the activity coefficient of Pu(V) decreases on going from a 0.5 M NaOH solution to a 7.6 M solution, it can be assumed that the reaction order with respect to the OH^- ions is close to -2 . Consequently, the fast step preceding the formation of an activated complex, proceeds with the replacement of the OH group in the Pu(V)-containing $\text{PuO}_2(\text{OH})_3(\text{H}_2\text{O})^{2-}$ ion by the H_2O molecule

i.e., as expected, lower-charged species are involved in the reaction.

The constant $2k$ increases as the temperature is increased. Thus, an increase in the temperature of a 3.3 M NaOH solution from 10 to 30°C leads to an increase in $2k$ from 0.51×10^{-2} to $6.15 \times 10^{-2} \text{ litre mol}^{-1} \text{ s}^{-1}$. The activation energy is approximately 88 kJ mol^{-1} .

The results of experiments with Np(V) in $0.5-1 \text{ M LiOH}$, NaOH, KOH and CsOH solutions at $25-80^\circ\text{C}$ demonstrated that Np(V) remained unchanged in the conditions under study.

c. Reproportionation Np(VII) + Np(V) and Pu(VII) + Pu(V)

As mentioned above, the potential of the Np(VII)/Np(VI) pair sharply increases at the alkali concentration of $\leq 10 \text{ mol litre}^{-1}$ and the reaction (88) goes in the reverse direction

An analogous reaction proceeded also with plutonium

because the potential of the Pu(VII)/Pu(VI) pair is substantially higher than the potential of the Pu(VI)/Pu(V) pair in a wide range of alkali concentrations. The kinetics of the reaction (94) in a LiOH solution was studied by pulse radiolysis.⁹⁸ It was established that the rate constant of the reaction is independent of the alkali concentration in the range of 0.033–2.0 mol litre⁻¹ and its average value in a LiOH solution is $(2.3 \pm 0.9) \times 10^7$ litre mol⁻¹ s⁻¹. In NaOH solutions, the rate constants of the reaction are smaller. Apparently, the reaction (95) also proceeds with a high rate.

d. Reproportionation Np(VI) + Np(IV) and Pu(VI) + Pu(IV)

The reaction

in deaerated 0.025–4.0 M LiOH solutions was examined in the study.¹⁸ The reaction was completed in the course of stirring of a suspension of Np(IV) hydroxide in a LiOH solution with a Np(VI) solution in the same alkali. The formal potential of the Np(V)/Np(IV) pair was estimated from the equilibrium constants.

The addition of an equimolar amount of Pu(VI) to a 4 M NaOH solution containing Pu(IV) hydroxide led to the rapid formation of Pu(V),²⁵ i.e., the following reaction proceeded:

2. Reactions analogous to disproportionation and reproportionation

a. Reactions of Np(VI) with Pu(VII) and Pu(VI)

The reaction

proceeds rapidly at room temperature.⁹⁹ This reaction is irreversible at any concentrations of alkali because Pu(VII) is a stronger oxidiser than Np(VII) and the potentials of the Pu(VII)/Pu(VI) and Np(VII)/Np(VI) pairs change in parallel with the OH⁻ concentration.

In alkaline solutions, Np(VI) can be oxidised not only with heptavalent but also with hexavalent plutonium.²⁸ The reaction

is reversible and proceeds with a high rate, which indicates that the ions of penta-, hexa- and heptavalent actinides in concentrated alkaline solutions have similar structures. According to the recent EXAFS study,¹⁰⁰ neptunium(VII) in alkaline solutions is involved in the $\text{NpO}_4(\text{OH})_2^{3-}$ ion. Hence, neptunium(VII), like Np(V) and Np(VI), is in a tetragonal–bipyramidal environment formed by oxygen atoms due to which the electron transfer is not accompanied by a substantial structural rearrangement of the ions involved in the reaction. The position of the equilibrium depends on the alkali concentration. In a 7.8 M NaOH solution (at 24 °C), the equilibrium constant

$$K = \frac{[\text{Np(VII)}][\text{Pu(V)}]}{[\text{Np(VI)}][\text{Pu(VI)}]}$$

is 1.8×10^{-2} ; its value increases to 14×10^{-2} as the NaOH concentration is increased to 10.1 mol litre⁻¹.

b. Reactions of Np(VI) with Am(VI) and Am(VII)

Neptunium(VII) is rapidly formed upon the addition of a bicarbonate or weakly acidic Am(VI) solution to a 1 M NaOH solution containing Np(VI) (see Ref. 36)

The position of the reaction equilibrium depends on the concentration of the OH⁻ ions. Oxidation of Np(VI) starts at $[\text{OH}^-] \approx 0.016$ mol litre⁻¹. The yield of Np(VII) increases as the alkali concentration is increased and it reaches 100% in 3–4 M NaOH solutions. Americium(V) does not react with Np(VI) in alkaline solutions.

The addition of a cooled freshly prepared (by ozonation) Am(VII) solution in 3–4 M NaOH to an alkaline solution of Np(VI) rapidly affords Np(VII)^{101, 102}

c. Reactions of Pu(VI) with Am(VI) and Am(VII)

The equilibrium of the reaction

is established immediately after mixing the reagents,³⁶ but is noticeably shifted to the right only at an alkali concentration higher than 7.5 mol litre⁻¹. Plutonium(VII) is virtually immediately formed upon the addition of freshly prepared (by ozonation) Am(VII) to a 1 M NaOH solution containing Pu(VI)^{101, 102}

3. Oxidation reactions

a. Oxidation with molecular oxygen

Neptunium(V) and plutonium(V). Oxygen bubbling through 0.5–2 M LiOH or NaOH solutions containing neptunium(V) for 24 h did not yield Np(VI). As the alkali concentration and the reaction time were increased, Np(V) was slowly transformed into Np(VI) under the action of both pure O₂ and atmospheric oxygen.¹⁰³ In an aerated 8 M NaOH solution containing Np(V) (1 mmol litre⁻¹), ~10% of Np(V) was oxidised during 3 months. In the same solution containing F⁻ (0.1 mol litre⁻¹), ~50% of Np(V) was oxidised during one month. A change in the temperature of the solution from 0 to 50 °C exerts only a slight effect on the kinetics of Np(V) oxidation.

Plutonium(V) is also oxidised with atmospheric oxygen in 4 M and 8 M NaOH solutions. In the latter case, the rate constant of the reaction (1.4×10^{-3} h⁻¹) is smaller than the rate constant of Np(V) oxidation (4.7×10^{-3} h⁻¹), whereas plutonium(V) in a 4 M NaOH solution is oxidised faster than Np(V). This is, apparently, associated with a change in the reaction mechanism. Most likely, oxygen reacts with Pu(IV) that is generated through disproportionation of Pu(V).

Neptunium(IV) and plutonium(IV). A freshly precipitated suspension of neptunium(IV) hydroxide [we will denote this compound and plutonium(IV) hydroxide as $\text{NpO}_2 \cdot n\text{H}_2\text{O}$ and $\text{PuO}_2 \cdot n\text{H}_2\text{O}$, respectively] is slowly oxidised with oxygen.¹⁰⁴ At 23 °C, a suspension of $\text{NpO}_2 \cdot n\text{H}_2\text{O}$ (7 mmol litre⁻¹) in 2–14 M NaOH solutions is completely oxidised during ~1–2 days. In addition to neptunium(V), Np(VI) is formed in substantial amounts. As the alkali concentration is increased, the reaction slightly slows down and the proportion of Np(VI) is decreased.

It is believed that oxygen is adsorbed on the surface of Np(IV) hydroxide species followed by successive or synchronous electron transfer. The intermediate that formed in the course of O₂ reduction (hydrogen peroxide) is not accumulated in solution.

A suspension of $\text{PuO}_2 \cdot n\text{H}_2\text{O}$ in 0.5–4 M NaOH solutions does not react with oxygen. Prolonged air bubbling through a 5 M NaOH solution containing this suspension affords different ionic forms of plutonium whose concentration is 10% higher than that obtained upon argon bubbling.¹⁰⁴

b. Oxidation with hydrogen peroxide

Neptunium(IV). The addition of H₂O₂ (100 mmol litre⁻¹) to a 0.5 M NaOH solution containing a $\text{NpO}_2 \cdot n\text{H}_2\text{O}$ suspension (10 mmol litre⁻¹) at 20 °C gave rise to a dissolved Np(V) peroxide complex. Oxidation of Np(IV) was completed in less than 10 min. Then Np(V) gradually precipitated.¹⁰⁵

In NaOH 1–16 M solutions, the formation of Np(V) starts once the reagents have been mixed but the reaction rate decreases as the NaOH concentration is increased. The Np(V) peroxide complex is stable over a long period and the solid phase does not appear for at least 3 h.¹⁰⁵

The formation of Np(V) slows down as the H₂O₂ concentration is decreased. At [H₂O₂] = 5 mmol litre⁻¹, 9% of Np(IV) remains in the precipitate after completion of the reaction. Taking into account that hydrogen peroxide in an alkaline medium exists as the HO₂⁻ ion, it may be written

Decomposition of H₂O₂ proceeds as a competitive reaction.

The formation of Np(V) (and precipitation) is accelerated as the temperature is increased from 20 to 60 °C.

Plutonium(IV). When a 1 M NaOH solution containing a freshly precipitated PuO₂ · nH₂O suspension (1 mmol litre⁻¹) and H₂O₂ (10 mmol litre⁻¹) was kept at 20 °C for 7 h, the concentration of plutonium in the ionic form remained the same as that in a check experiment performed in the absence of H₂O₂. In more concentrated alkaline solutions, the higher is the NaOH concentration, the higher is the rate of Pu(IV) oxidation. Thus in a 12 M NaOH solution containing PuO₂ · nH₂O (10 mmol litre⁻¹) and H₂O₂ (50 mmol litre⁻¹), the Pu(V) peroxide complex was detected in an amount of 0.4 mmol litre⁻¹ already after 8 min.¹⁰⁵

Slow oxidation of Pu(IV) with hydrogen peroxide in a 1 M NaOH solution takes place upon the addition of a trivalent iron salt (to the concentration of 0.1 mol litre⁻¹). The addition of Co(II) and Cu(II) salts has a weaker effect on oxidation of Pu(IV) with hydrogen peroxide. No effect of Ni(II) was observed.¹⁰⁵

Americium(III). Oxidation of Am(OH)₃ to Am(IV) under the action of hydrogen peroxide was first presented in the paper.¹⁰⁶ These data are confirmed by the results of a more detailed study.¹⁰⁷ An acidic solution of Am(III) containing H₂O₂ was neutralised with ammonia. The precipitate that formed [presumably, Am(III) hydroperoxide] was treated with a concentrated ammonia or KOH solution to obtain Am(IV) hydroxide. The process was accelerated upon heating to 90 °C. At this temperature, Am(IV) hydroxide was obtained in quantitative yield according to several procedures:

- by treatment of Am(OH)₃ with a H₂O₂ and KOH solution;
- by treatment of Am(III) hydroperoxide with a H₂O₂ and KOH solution;
- by treatment of Am(III) hydroperoxide with a KOH solution.

c. Oxidation with ozone

Neptunium(VI) and neptunium(V). Neptunium(VII) was first prepared by oxidation of a suspension of sodium or potassium neptunates with ozone in 0.5–3.5 M alkaline solutions.^{108,109} The kinetics of the reaction of ozone with Np(VI) depends on the state of the latter. In the case of ozonation of neptunate suspensions in NaOH (or KOH) solutions, the rate of Np(VII) formation depends on the mode of ozone supply and the properties of the solid phase. Thus, the rate of Np(VI) oxidation is decreased upon prolonged storage of the precipitates. In the study,¹⁴ it was suggested that a suspension of Np(V) hydroxide in NaOH solutions be used in these reactions. In the course of ozonation, Np(V) is oxidised to soluble Np(VI), which is transformed into the heptavalent state. The maximum concentration of Np(VII) obtained in NaOH (or KOH) solutions is 6–8 g litre⁻¹. The Np(VII) content of 30 g litre⁻¹ was achieved upon ozonation of neptunates in 2–3 M LiOH solutions¹¹⁰ due to high solubility of lithium neptunates.¹¹¹

The kinetics of Np(VII) formation in alkaline solutions containing Np(VI) ions is determined by the rate of ozone supply and intensity of stirring, *i.e.*, by diffusion factors.^{109,112,113} At low concentrations of the reagents, the reaction of Np(VI) with O₃ is kinetically controlled. The accumulation of Np(VII) obeys the equation¹¹²

$$\frac{d[\text{Np(VII)}]}{dt} = k[\text{Np(VI)}][\text{OH}^-]^{0.5}[\text{O}_3]^{0.5}. \quad (104)$$

In the temperature range of 0–20 °C, the activation energy is close to 20 kJ mol⁻¹.¹¹²

An analogous dependence of the rate of Np(VII) accumulation on the ozone concentration was found in the study.¹¹³ In a solution with a constant LiOH concentration, the rate of oxidation (*V*) of Np(VI) (10 mmol litre⁻¹) at a constant rate of ozone supply remains unchanged, *i.e.*,

$$V = \frac{d[\text{Np(VII)}]}{dt} = \text{const.} \quad (105)$$

The plot of *V* vs. the LiOH concentration yields a curve with a maximum at [OH⁻] ≈ 1.5–2 mol litre⁻¹. It was proposed that the OH[•] radical¹¹² or the O^{-•} radical ion¹¹³ serve as a direct oxidiser of Np(VI). However, in our opinion, the O₃^{-•} radical ion¹¹⁴ serves as an oxidiser. Thus as the LiOH concentration is lowered beyond 1 mol litre⁻¹, the rate of Np(VI) oxidation decreases due to acceleration of O₃^{-•} decomposition giving rise to O₂^{-•}.

Neptunium(VI) is oxidised with ozone even at pH 9–10 although the reaction rate is noticeably lower.¹¹⁵ Moreover, heptavalent neptunium is partially generated upon ozonation of a NpO₂OH suspension in water.¹¹⁶

The completeness of Np(VI) oxidation with ozone in alkaline solutions depends on its concentration. For example, Np(VI) was oxidised by 80% at its concentration of (2–4) × 10⁻⁵ mol litre⁻¹,¹¹² whereas 98%–100% of Np(VI) was oxidised at the concentration of 3 × 10⁻³ mol litre⁻¹.¹¹³

Neptunium(IV). When a mixture of O₂ and O₃ (0.7 vol.%) is passed through 0.5–1 M NaOH solutions containing a suspension of NpO₂ · nH₂O (1 mmol litre⁻¹), neptunium(IV) is oxidised to Np(V) and Np(VI) already within minutes after the onset of the process and the suspension is dissolved. Further ozonation affords Np(VII). Accumulation of Np(VII) is accelerated as the alkali concentration is increased. In a 14 M NaOH solution, neptunium is quantitatively transformed into the heptavalent state already within 8 min after the onset of oxidation.¹⁰⁴

Ozone can directly oxidise tetra-, penta- and hexavalent neptunium. However, in a strongly alkaline medium, ozone initially reacts with the OH⁻ ions to form the ozonide ions. In this case, the reactions may be described by the scheme¹¹⁷

or the scheme¹¹⁸

The ozonide ions oxidise all valence forms of neptunium to the heptavalent state. The process starts with the reaction

Neptunium(V) is oxidised both in the solid phase and after the formation of the soluble NpO₂(OH)_{*n*}¹⁻ⁿ complex (*n* = 2–3). In this case, the following reactions proceed

the rate constants are (2.1 ± 0.3) × 10⁶ and (2.1 ± 0.2) × 10⁵ litre mol⁻¹ s⁻¹, respectively.¹¹⁴

Accumulation of Np(VII) occurs after the disappearance of Np(IV) and Np(V).

Plutonium(VI). Like Np(VII), heptavalent plutonium was first prepared by ozonation.^{108,119} Presently, this procedure is commonly used for the preparation of pure Pu(VII) solutions with different concentrations.

The reaction of Pu(VI) with O₃ in alkaline media proceeds analogously to the reaction of Np(VI).¹¹³ In homogeneous solutions, the reaction rate is determined by the diffusion factors. In the mode of steady ozone supply, the rate of this reaction is described by the zero-order equation

$$V = \frac{d[\text{Pu(VII)}]}{dt} = \text{const.} \quad (115)$$

The completeness of oxidation of Pu(VI) (7.5 mmol litre⁻¹) in alkaline solutions ([NaOH] < 1 mol litre⁻¹) depends on instability of Pu(VII) whose reduction with water is accelerated as the concentration of the OH⁻ ions is decreased.¹²⁰

Plutonium(IV). Oxidation of Pu(IV) with ozone was examined in the study.¹⁰⁴ A suspension of PuO₂·*n*H₂O (0.3–0.5 mmol litre⁻¹) in a 0.5–8 M NaOH solution was oxidised with a mixture of O₂ and O₃ (0.7 vol.%). The resulting Pu(VII) and Pu(VI) rapidly reacted with Pu(IV). Hence, accumulation of Pu(VII) becomes possible after the complete disappearance of Pu(IV). In a 1 M NaOH solution, Pu(VII) is formed most rapidly (84 min), whereas the time of this reaction increases to 300 min (and more) in an 8 M NaOH solution.

The oxidation process involves the reactions (106)–(108) and reactions analogous to (112)–(114).

Americium(VI). When a gas mixture containing O₃ (20–50 mg litre⁻¹) was passed through a cooled (0 °C) solution of americium(VI) in 3–4 M NaOH during 30–60 min, the colour and absorption spectrum of the solution were changed.^{101,102} After the addition of the resulting freshly ozonated alkaline solution of americium to an excess of Pu(VI) in 1 M NaOH, plutonium immediately took on the colour characteristic of Pu(VII). The absorption spectrum of the resulting solution agrees satisfactorily with the absorption spectrum of pure Pu(VII).

It is known³⁷ that Am(VI) does not oxidise Pu(VI) in solutions containing NaOH at a concentration lower than 3 mol litre⁻¹. Hence, the formation of Pu(VII) in the experiments described above indicates that americium(VI) is transformed into Am(VII) upon ozonation of its alkaline solutions. Heptavalent americium reacts with Pu(VI) according to Eqn (102). The yield of Am(VII) upon ozonation can be estimated from the amount of Pu(VII) formed. In different experiments, its value varied from 40% to 60%. The same results were obtained in the study of the stoichiometry of the reaction (100).

Americium(III). Oxidation of Am(III) was examined in a wide pH range.¹²¹ Ozone oxidises Am(OH)₃ to Am(VI) both in neutral and alkaline (1 M NaOH) media. In a 1 M NaOH solution, oxidation proceeds slowly. Therefore, it is necessary to lower the temperature to 0 °C for the enhancement of solubility of O₃. In a 0.1 M NaOH solution (at 25 °C), Am(OH)₃ is oxidised with a moderate rate to form Am(VI), which gives a soluble yellow complex. The absorption spectrum of this complex is identical to the spectrum of the solution, which was prepared by adding alkali to an acidic solution of AmO₂²⁺. In water, Am(III) is oxidised by passing ozone for 1–2 h (*T* = 90 °C). In the course of ozonation, pH of the solution must be no lower than 5.

Apparently, the mechanism of Am(III) oxidation in solutions with pH lower than 12 is analogous to the mechanism of oxidation in carbonate solutions. This mechanism involves the inner-sphere transfer of the oxygen atom from O₃ as the first step. The general scheme of oxidation is as follows:

In alkaline solutions (pH > 12), the reactions (106)–(108), (118) and (119) and also the reaction

are the major processes.

Americium(V) is oxidised in both the solid phase and in the dissolved form existing as the AmO₂(OH)_{*n*}^{1-*n*} complex (*n* = 2–3)

At 0 °C, Am(VII) is formed in 3–4 M NaOH solutions

d. Oxidation with S₂O₈²⁻ ions

Neptunium(VI). The kinetics of Np(VI) oxidation was examined in 0.1–0.7 M NaOH solutions at *T* > 50 °C.¹²² The initial reaction rate did not depend on the Np(VI) concentration (up to 0.3 mmol litre⁻¹) and increased in directly proportion to the S₂O₈²⁻ concentration (the latter was increased from 25 to 300 mmol litre⁻¹)

$$\frac{d[\text{Np(VII)}]}{dt} = -\frac{d[\text{Np(VI)}]}{dt} = k[\text{S}_2\text{O}_8^{2-}]. \quad (123)$$

In a 0.2 M NaOH solution heated to 60 °C, the rate constant of the reaction is 2 × 10⁻⁴ min⁻¹. At [OH⁻] = 0.7 mol litre⁻¹ and μ = 1, the activation energy is 140 kJ mol⁻¹, which is consistent with the activation energy of thermal decomposition of the persulfate ions.⁵⁷

The first step of Np(VI) oxidation with the persulfate ions in 0.2–0.7 M NaOH solutions involves decomposition of the S₂O₈²⁻ ions [reaction (32)] followed by the reaction

The fast reactions (124), (107) and (108) afford the O₃^{·-} radical ions, which oxidise Np(VI) to Np(VII) according to the reaction (114).

Calculations demonstrated that the rate of Np(VII) accumulation in a NaOH solution is three times lower than the rate of formation of the SO₄^{·-} radical ions. Consequently, decomposition of O₃^{·-} is of considerable importance in this process, as in the case of Np(VI) oxidation with ozone at [OH⁻] < 1 mol litre⁻¹. The rate of Np(VII) accumulation decreases as the alkali concentration is increased to 0.9 mol litre⁻¹. The plot of Np(VII) accumulation in a 1 M NaOH solution (μ = 2) goes through a maximum. In 3–4 M NaOH solutions, neptunium(VII) is not formed at all.

Apparently, decomposition of S₂O₈²⁻ in alkaline solutions proceeds not only through thermal decomposition [reaction (32)] but also under the action of the OH⁻ ions, reducers being formed in the latter case. This pathway becomes dominant in 3–4 M NaOH solutions. On a further increase in the alkali concentration to 5–6 mol litre⁻¹, the formation of Np(VII) resumes. Under these conditions, the mechanism of decomposition of persulfate ions is, evidently, changed once again. An increase in the ionic strength of solution has virtually no effect on the rate of Np(VI) oxidation in a 0.2 M NaOH solution but the reaction rate is decreased in a 0.7 M NaOH solution.

Hydroxides of some *d* elements serve as catalysts of the Np(VII) formation. In a 4 M NaOH solution, the S₂O₈²⁻ ions oxidise N(VI) even at 20 °C in the presence of Fe(III), Ag(I), Cu(II), Ni(II) or Co(II) salts in concentrations of 5 × 10⁻⁵, 1 × 10⁻⁵, 5 × 10⁻⁶, 1 × 10⁻⁷ or 2 × 10⁻⁸ mol litre⁻¹, respectively. In alkaline solutions containing Ni(II) or Co(II) com-

pounds, Np(VII) is completely reduced during 15–20 h. After storage for one day, silver(I) salts retain catalytic activity.

In a 0.5 M NaOH solution, the catalytic activity of the *d*-metal ions is less pronounced.

In the temperature range of 30–50 °C, the activation energies of Np(VI) oxidation in the presence of the Ag(I) and Co(II) ions are 67 and 42 kJ mol⁻¹, respectively.

Neptunium(IV). In deaerated 0.5–14 M NaOH solutions containing a suspension of hydrated Np(IV) oxide (7 mmol litre⁻¹), Np(V), Np(VI) and Np(VII) are successively accumulated under the action of S₂O₈²⁻.¹²³ All steps of oxidation are accelerated as the concentrations of NaOH and S₂O₈²⁻ are increased and the temperature is raised. In a 4 M NaOH solution containing S₂O₈²⁻ (20 mmol litre⁻¹), the transformation of neptunium(IV) into the dissolved Np(VI) form proceeds by 95% at 21 °C during 11–12 min. After the next 5–7 min, Np(VII) is generated. In a 4 M NaOH solution, the activation energy of Np(VI) oxidation with persulfate ions is 68 kJ mol⁻¹. In the presence of insufficient persulfate, Np(V) and Np(VI) were found in the solution (*T* = 36 °C) after completion of the reaction.

The oxidation process involves the following reactions [Np(V) and Np(VI) react both in the solid and liquid phases after the formation of soluble complexes]:

Then, the reactions (124), (107), (108) and (112)–(114) proceed.

Plutonium(VI). It was found¹²⁴ that the reaction of Pu(VI) (0.75 mmol litre⁻¹) with the S₂O₈²⁻ ions in KOH solutions afforded Pu(VII), which was accumulated according to the kinetic equation (reaction is zero order with respect to plutonium and first order with respect to S₂O₈²⁻)

$$\frac{d[\text{Pu(VII)}]}{dt} = -\frac{d[\text{Pu(VI)}]}{dt} = k[\text{S}_2\text{O}_8^{2-}]. \quad (126)$$

In a 1 M KOH solution, the activation energy of Pu(VI) oxidation is 146 kJ mol⁻¹, which is similar to the activation energy of thermal decomposition of the persulfate ions. Oxidation proceeds with the participation of the O₃^{·-} radical ions [see the reactions (32), (124), (107) and (108)]

In hot KOH solutions containing the S₂O₈²⁻ ions, oxidation of Pu(VI) is accompanied by reduction of Pu(VII). As the KOH concentration is increased from 0.2 to 1.2 mol litre⁻¹ ([S₂O₈²⁻] = 0.1 mol litre⁻¹, *T* = 80 °C), the rate of Pu(VII) accumulation initially somewhat increases, peaks at the KOH concentration of 0.5 mol litre⁻¹ and then decreases. The yield of Pu(VII) {the [Pu(VII)]/[Pu(VI)]₀ ratio} is linearly increased as the KOH concentration is increased to ~1 mol litre⁻¹ and then is sharply decreased. At a low alkali concentration, the rate of Pu(VII) reduction with water increases and, hence, its yield is decreased under these conditions. An increase in the KOH concentration leads to the enhancement of stability of Pu(VII) and an increase in its yield. In solutions with [KOH] > 1 mol litre⁻¹, oxidation of Pu(VI) ceases. This is attributed to catalytic decomposition of S₂O₈²⁻ to form reducers. One would expect a change in these dependences at other temperatures and concentrations of persulfate ions.

Plutonium(IV). Hexavalent plutonium is accumulated in 0.5–8 M NaOH solutions containing a suspension of freshly precipitated hydrated Pu(IV) oxide and S₂O₈²⁻ (10–50 mmol litre⁻¹). At [NaOH] ≥ 4 mol litre⁻¹, Pu(VII) is also generated.¹²⁵ The rate of dissolution of hydrated Pu(IV) oxide

increases as the concentrations of NaOH and S₂O₈²⁻ are increased and the temperature is raised from 23 to 62 °C. The following solid-phase reactions are of importance in oxidation and dissolution:

Simultaneously with these reactions, Pu(V) goes into the solution where it is also oxidised to Pu(VI) and undergoes disproportionation. Plutonium(VI) reacts with PuO₂·*n*H₂O. In 4–8 M NaOH solutions, Pu(VI) is oxidised

In addition, O₃^{·-} is formed under these conditions and reactions involving this radical proceed.

Americium(III). Oxidation of Am(OH)₃ (a pink suspension) with the S₂O₈²⁻ ions in an alkaline medium affords a black or dark-brown precipitate of hydrated Am(IV) oxide.¹⁰⁶ The reaction of Am(OH)₃ (5 mg) with excess K₂S₂O₈ in a 0.1 M NaOH solution on a boiling water bath (2 h) gave rise to an olive-brown precipitate. The examination of products of its dissolution in acid demonstrated¹²¹ that the average oxidation number of americium is 4.53, *i.e.*, the precipitate contains not only Am(IV) but also americium in higher oxidation states.

Pure Am(IV) was prepared by adding Am(III) to a hot 7 M KOH solution saturated with K₂S₂O₈. Then the reaction mixture was kept at 90 °C for 1 h. The precipitate was washed with water to remove an excess of the oxidiser. The average oxidation state of americium in hydrated oxide is 4.0 ± 0.1.¹²¹

e. Oxidation with ClO⁻ ions

Neptunium(IV). In deaerated 0.5–16 M NaOH solutions containing NpO₂·*n*H₂O, the successive formation of Np(V), Np(VI) and Np(VII) takes place under the action of the ClO⁻ ions.¹²⁶ The time dependence of the Np(VI) concentration in solution passes through a maximum. Initially, a supersaturated solution of Np(VI) is formed from which Np(VI) hydroxide gradually precipitates. Neptunium(VII) is formed in a 2 M NaOH solution (*T* = 25 °C) at [ClO⁻] = 48 mmol litre⁻¹. In more concentrated alkaline solutions, a lower concentration of the hypochlorite ions is sufficient for the formation of Np(VII). The activation energy of the Np(VII) formation is 34 kJ mol⁻¹ (*T* = 25–60 °C). The oxidation reactions of Np(IV), Np(V) and Np(VI) are accelerated as the temperature is raised and the concentrations of alkali and hypochlorite ions are increased.

The oxidation process involves the following steps:

It is not improbable that Np(IV) is oxidised due to the transfer of the oxygen atom taking into account that oxygen is involved in the oxygenated Np(V) and Np(VI) ions

Then the reaction (10) proceeds in the precipitate.

The mechanism of neptunium oxidation can be conclusively established with the use of the ¹⁸O-labelled hypochlorite ions.

In a precipitate, neptunium(V) reacts with ClO⁻

In solution, the latter reaction proceeds differently

Neptunium(VI) is, in turn, oxidised to Np(VII)

Reproportionation of Np(VII) and Np(V) [reaction (94)] occurs in a dilute alkaline solution, and disproportionation of Np(VI) takes place in 9–16 M NaOH solutions.

Neptunium(VI). In 1–4 M LiOH solutions or 1–8.5 M NaOH solutions, neptunium(VI) is oxidised with K_2IrCl_6 .¹²⁷

Neptunium(VII) thus prepared slowly disappears because IrCl_6^{3-} is hydrolysed and the resulting Ir(III) hydroxide reduces Np(VII).

The addition of a NaClO solution to an alkaline solution of neptunium(VI) containing iridium hydroxides leads to the slow formation of Np(VII) because iridium is transformed into higher oxidation states under the action of the ClO^- ions. The ClO^{2-} radical ions that are formed react with Np(VI) [see the reaction (138)].

Plutonium(IV). The hypochlorite ions oxidise a suspension of freshly prepared $\text{PuO}_2 \cdot n\text{H}_2\text{O}$ even at room temperature.¹²⁶ In a precipitate, plutonium is transformed into a hexavalent state. Plutonium(VI) remains partially in solution. Plutonium(VII) appears at the NaOH concentration of about 10 mol litre⁻¹. The rate and completeness of dissolution of Pu(IV) (6.8 mmol litre⁻¹; 60 °C, $[\text{ClO}^-] = 12$ mmol litre⁻¹) are increased as the NaOH concentration is increased. In a 8 M NaOH solution, 92%–94% of plutonium is dissolved. The initial rate of accumulation of plutonium in solution increases as the ClO^- concentration and temperature are increased.

Oxidation of Pu(IV) proceeds analogously to oxidation of Np(IV) and involves the reactions

which take place in the solid phase. In 0.4–1.5 M NaOH solutions, plutonium(V) either undergoes disproportionation or is oxidised

Plutonium(V) and Pu(VI) partially go into solution where they are further oxidised

Oxidation of Pu(IV) can also occur through the transfer of the oxygen atom from ClO^-

Americium(III). Precipitation of a pink suspension of Am(III) in an alkaline solution containing ClO^- afforded a dark precipitate.¹²⁸ This process was studied in detail.¹²¹ In a 0.2 M NaOH solution containing ClO^- (0.2 mol litre⁻¹), $\text{Am}(\text{OH})_3$ was transformed into hydrated Am(IV) oxide at 100 °C during 30 min.

f. Oxidation with BrO^- ions

Neptunium(VI). In alkaline solutions containing Np(VI) (0.2 mmol litre⁻¹), neptunium(VI) is oxidised with the hypobromite ions upon heating to 70 °C.¹²⁹ In 1.74–6.5 M NaOH solutions, the kinetics of the reaction is described by the empirical equation¹³⁰

$$\frac{d[\text{Np(VII)}]}{dt} = -\frac{d[\text{Np(VI)}]}{dt} = k[\text{Np(VI)}][\text{BrO}^-]^{0.6}[\text{OH}^-]^{1.6}, \quad (147)$$

where $k = (6.65 \pm 0.35) \times 10^{-2}$ litre^{2.2} mol^{-2.2} min⁻¹ at 70 °C. In a 6.5 M NaOH solution, the activation energy of the reaction is 87.5 kJ mol⁻¹ ($T = 50.7$ –70 °C).

The rate of Np(VI) oxidation with the BrO^- ions depends on the OH^- concentration in a complicated manner, which reflects both the participation of hydroxyl ions in the formation of an activated complex and the effect of the ionic strength of solution. The fractional order of the reaction with respect to the BrO^- ions results from the fact that the processes

are accompanied by the reactions of Np(VI) with radical products of BrO^- decomposition.

Oxidation of Np(VI) with the hypobromite ions is accelerated upon the addition of *d*-metal salts. In dilute alkali (0.5 mol litre⁻¹), the formation of Np(VII) was observed only in the presence of 2.5×10^{-5} mol litre⁻¹ of Cu(II) or $(1-5) \times 10^{-6}$ mol litre⁻¹ of Ni(II) or Co(II).

Neptunium(IV). In deaerated 0.8–16 M NaOH solutions containing a suspension of $\text{NpO}_2 \cdot n\text{H}_2\text{O}$ (5 mmol litre⁻¹), Np(V), Np(VI) and Np(VII) are formed in the presence of BrO^- .¹³¹ At 25 °C, the rate of Np(VII) accumulation is approximately proportional to the NaOH concentration and the process is accelerated as the BrO^- concentration is increased. In the temperature range of 25–40 °C, the activation energy of this reaction is 32 kJ mol⁻¹. Oxidation is most likely to occur according to the reactions analogous to the reactions (131)–(136) followed by the reactions (10), (148) and (149).

Plutonium(VI). Oxidation of Pu(VI) (0.85 mmol litre⁻¹) with the hypobromite ions was studied in 10.4–12.4 M KOH solutions at 50–90 °C.¹²⁴ The completeness and rate of oxidation are increased as the concentrations of alkali and KBrO are increased (7–100 mmol litre⁻¹). The initial regions of the kinetic plots yield straight lines, which are indicative of oxidation of Pu(VI) with radical products. The activation energy, which we estimated from the results of the study,¹²⁴ is 45–50 kJ mol⁻¹.

The addition of Co(II) and Ni(II) salts to 10^{-5} mol litre⁻¹ leads to substantial acceleration of BrO^- decomposition and Pu(VII) accumulation, which suggests that these processes correlate with each other.

Plutonium(IV). In 0.8–16 M NaOH solutions containing a suspension of $\text{PuO}_2 \cdot n\text{H}_2\text{O}$, Pu(VI) is accumulated both in the precipitate and solution under the action of the hypobromite ions.¹³¹ Plutonium(VII) is formed in 12–16 M NaOH solutions. The rates of all steps increase as the concentrations of alkali and the oxidiser are increased. The activation energy of the Pu(VI) formation in solution is 23 kJ mol⁻¹ and the activation energy of the Pu(VII) formation in a 16 M NaOH solution is ~35 kJ mol⁻¹. Oxidation of plutonium(IV) proceeds analogously to oxidation of neptunium(IV).

g. Oxidation with $\text{Fe}(\text{CN})_6^{3-}$ ions

Neptunium(VI). The reaction

is reversible and its equilibrium depends substantially on the concentration of the hydroxyl ions. In 1–4 M KOH solutions, the equilibrium constant is proportional to $[\text{OH}^-]^4$, whereas this constant in solutions with $\mu = 4$ is proportional to $[\text{OH}^-]^{3.93}$. In a 3.2 M KOH solution, the equilibrium constant (at 23 °C) is 2.0 ± 0.2 . At the concentrations of the reagents of ~ 0.1 mmol litre $^{-1}$, the rate of the reaction (150) is described by the equation¹³²

$$\frac{d[\text{Np(VII)}]}{dt} = -\frac{d[\text{Np(VI)}]}{dt} = k_1[\text{Np(VI)}][\text{Fe(CN)}_6^{3-}].$$

In a 1.5 M KOH solution (at 10 °C), the ionic strength exerts only a slight effect on the rate constant. Thus the constant k_1 changes from 170 to 215 litre mol $^{-1}$ min $^{-1}$ as μ is increased from 1.5 to 3 (KNO₃). The constant k_1 changes almost directly proportional to the concentration of the hydroxyl ions, *viz.*, it increases from 215 to 400 litre mol $^{-1}$ min $^{-1}$ ($\mu = 3$) as the concentration of OH $^-$ is increased from 1.5 to 3 mol litre $^{-1}$. In a 3 M KOH solution, the activation energy of the reaction (150) is 39 kJ mol $^{-1}$ (10–25 °C).

Neptunium(IV). In a 0.5 M NaOH solution containing a $\text{NpO}_2 \cdot n\text{H}_2\text{O}$ suspension (5.1 mmol litre $^{-1}$) and $\text{K}_3\text{Fe(CN)}_6$ (50 mmol litre $^{-1}$), Np(VI) is formed in less than 15 min.¹⁰⁴ In 6–14 M NaOH solutions, neptunium(VI) is further oxidised to Np(VII).

Plutonium(VI). The reaction of Pu(VI) with Fe(CN)_6^{3-} proceeds at a noticeable rate at $[\text{KOH}] > 8$ mol litre $^{-1}$.¹³³ In a 12 M KOH solution containing the ferricyanide ions (2 mmol litre $^{-1}$), Pu(VI) (0.5 mmol litre $^{-1}$) is completely oxidised. The reaction rate is high even in the cold. However, the resulting Pu(VII) solutions appeared to be unstable. Apparently, the cyanide ions that are generated upon hydrolysis of Fe(CN)_6^{3-} and Fe(CN)_6^{4-} serve as a reducing agent.

Plutonium(IV). In a 0.2 M NaOH solution containing a suspension of freshly precipitated $\text{PuO}_2 \cdot n\text{H}_2\text{O}$ (1 mmol litre $^{-1}$), Pu(VI) (0.08 mmol litre $^{-1}$) was accumulated within 10 min after the addition of $\text{K}_3\text{Fe(CN)}_6$ (3.3 mmol litre $^{-1}$). During the same period of time, the concentration of Pu(VI) reached 0.6 and 0.75 mmol litre $^{-1}$ in 1 M and 14 M NaOH solutions, respectively.¹⁰⁴

Americium(III). In alkaline solutions, Am(III) is oxidised with an excess of the ferricyanide ions to Am(V). This reaction affords the soluble $(\text{AmO}_2)_3\text{Fe(CN)}_6$ complex, which gradually decomposes to give a precipitate of $\text{Na}_2\text{AmO}_2(\text{OH})_3 \cdot \text{H}_2\text{O}$. Hydrated Am(IV) oxide is formed at equal concentrations of Am(III) and $\text{K}_3\text{Fe(CN)}_6$.¹³⁴

h. Oxidation with CrO_4^{2-} ions

In a 1 M NaOH solution, the potential of the $\text{CrO}_4^{2-}/\text{CrO}_4^{3-}$ pair is estimated at 0.1 V.¹³⁵ Hence, the chromate ions can partially or completely oxidise Np(IV). At room temperature, a suspension of $\text{NpO}_2 \cdot n\text{H}_2\text{O}$ in 0.5–2 M NaOH solutions is slowly oxidised with potassium chromate (the reaction does not proceed to completion during several hours).¹⁰⁴ The resulting Np(V) almost completely remains in the precipitate. The completeness of oxidation is increased as the alkali concentration is increased. In a 14 M NaOH solution, the quantitative transformation of Np(IV) into Np(V) can be achieved already during 1 h. Plutonium(IV) does not react with chromate ions in the range of NaOH concentrations from 0.5 to 14 mol litre $^{-1}$.¹⁰⁴

i. Oxidation with MnO_4^- ions

The standard potential of the $\text{MnO}_4^-/\text{MnO}_4^{2-}$ pair is 0.56 V.¹³⁵ The formal potential increases as the ionic strength of the solution is increased. Hence, the MnO_4^- ion must oxidise Np(IV), Np(V), Np(VI) and Pu(VI), Pu(V), Pu(VI).

Neptunium(VI) and plutonium(VI). The reactions of Np(VI) and Pu(VI) with MnO_4^- are reversible^{99, 136}

their equilibria are rapidly established at 20–25 °C and depend on the alkali concentration. Neptunium(VI) is oxidised in 3–4 M NaOH solutions but the formation of Np(VII) is generally accompanied by the side reaction, *viz.*, gradual reduction of excess MnO_4^- ions with water to MnO_4^{2-} . The potential of the Np(VII)/Np(VI) pair sharply increases as the alkali concentration is decreased, whereas the potential of the $\text{MnO}_4^-/\text{MnO}_4^{2-}$ pair remains virtually unchanged. Because of this, neptunium(VII) rapidly oxidises MnO_4^{2-} to MnO_4^- in solutions with pH 11.

At high concentrations of alkali, the equilibrium of the reaction involving plutonium is shifted to the right. Plutonium(VI) is oxidised with the MnO_4^- ions only in 10–14 M NaOH solutions.¹³⁶ The process is accompanied by the side reaction, *viz.*, reduction of excess MnO_4^- ions with water to MnO_4^{2-} . Dilution of alkali to 2–4 mol litre $^{-1}$ leads to rapid oxidation of the manganate ions with plutonium(VII) to MnO_4^- .

Neptunium(IV). In 0.5–1 M NaOH solutions containing a $\text{NpO}_2 \cdot n\text{H}_2\text{O}$ suspension (5 mmol litre $^{-1}$), neptunium (IV) is oxidised with a fourfold excess of potassium permanganate to Np(VI) during 10 min. Approximately a half amount of Np(VI) remains in the precipitate, whereas the remainder of Np(VI) goes into solution. In 2–14 M NaOH solutions, neptunium passes entirely into solution during the same period of time. At $[\text{NaOH}] > 6$ mol litre $^{-1}$, Np(VII) was also found in the solution.¹⁰⁴

Plutonium(IV). In a 0.5 M NaOH solution containing a freshly precipitated suspension of hydrated Pu(IV) oxide (1 mmol litre $^{-1}$), 10% of dissolved Pu(VI) appears within minutes after the addition of a threefold excess of permanganate ions. The Pu(VI) concentration is not increased with time. An increase in the NaOH concentration is accompanied by an increase in the proportion of dissolved plutonium. In a 14 M NaOH solution, 60% of plutonium is already dissolved.¹⁰⁴

Americium(III). In alkaline solutions, a suspension of Am(OH)_3 is oxidised with the MnO_4^- ions to give hydrated Am(IV) oxide.¹²³

j. Oxidation with FeO_4^{2-} ions

In a 1 M NaOH solution, the potential of the Fe(VI)/Fe(III) pair is 0.8 V.¹³⁵ This value is higher than the potentials of the Np(V)/Np(IV), Np(VI)/Np(V), Np(VII)/Np(VI) and Pu(V)/Pu(IV), Pu(VI)/Pu(V) pairs in alkaline solutions with the same concentrations. The FeO_4^{2-} ion can oxidise Np(IV) and Pu(IV), but the multi-electron transition from Fe(VI) to Fe(III) is accompanied by the structural rearrangement, which is reflected in the rates of the processes.

Neptunium(IV). A suspension (5.1 mmol litre $^{-1}$) of hydrated Np(IV) oxide in a 0.5 M NaOH solution is slowly oxidised to Np(V) and Np(VI) under the action of a 10-fold excess of K_2FeO_4 . An increase in the NaOH concentration is accompanied by acceleration of the process. In a 16 M NaOH solution, neptunium(IV) disappears during several minutes and Np(VII) is formed along with Np(V) and Np(VI).¹⁰⁴

Plutonium(IV). In the presence of potassium ferrate (20 mmol litre $^{-1}$), a freshly precipitated suspension of hydrated Pu(IV) oxide in a 0.5 M NaOH solution is slowly dissolved. At $[\text{PuO}_2 \cdot n\text{H}_2\text{O}] = 1$ mmol litre $^{-1}$, 5.7% of plutonium goes into solution after its storage in the presence of an oxidiser for two days, whereas only 1.5% of plutonium passes into solution in the absence of an oxidiser. In a 14 M NaOH solution, 21% of plutonium goes into solution during the same period of time.¹⁰⁴

k. Oxidation with XeO_6^{4-} ions

Neptunium(VI). In alkaline solutions, neptunium(VI) is oxidised with the XeO_6^{4-} ions only upon heating. In a 1 M KOH solution (at 70 °C), 50% of Np(VI) is oxidised with the XeO_6^{4-} ions already in 15 min ($[\text{Np(VI)}] = 0.2$ mmol litre $^{-1}$, $[\text{XeO}_6^{4-}] = 1$ mmol litre $^{-1}$).¹²⁹ The reaction rate somewhat increases as the alkali

concentration is decreased. The addition of the perxenate ions to weakly acidic or neutral solutions of Np(VI) does not afford heptavalent neptunium.

Plutonium(VI). In 0–12 M NaOH solutions, plutonium(VI) does not react with the perxenate ions.¹¹⁹ This is to some extent associated with a decrease in solubility of Na₄XeO₆ in concentrated NaOH solutions. In hot concentrated KOH solutions, plutonium(VI) is partially oxidised with xenon(VIII), but Pu(VII) is formed in low yield.

l. Oxidation with xenon trioxide

In alkaline solutions, xenon trioxide reacts with Np(VI) more actively than the perxenate ions.¹²⁹ A 1 M KOH solution containing Np(VI) gradually turns green upon the addition of XeO₃ even in the cold. The reaction proceeds during 3 h. Oxidation of a half amount of neptunium(VI) occurs in a matter of minutes and during ~1 min on heating to 50 and 70 °C, respectively. Oxidation of Np(VI) slows down when the alkali concentration is decreased to 0.25 mol litre⁻¹, whereas an increase in this concentration leads to acceleration of oxidation. In 10–11 M NaOH solutions, Np(VI) (0.2 mmol litre⁻¹) is completely oxidised with a tenfold excess of XeO₃ at 20 °C during 35 min.⁷⁴ When Np(VI) and XeO₃ are present in equal concentrations, approximately a half amount of hexavalent neptunium is oxidised during the same period of time.

The reaction of Np(VI) with XeO₃ in alkaline solutions is accompanied by a side process, *viz.*, decomposition of the oxidiser to form perxenate, which can also be involved in oxidation of Np(VI).

m. Oxidation with xenon difluoride

Xenon difluoride oxidises Np(VI) only in solutions containing alkali in a moderate concentration.^{74, 75} When the reactions are carried out with the use of solid XeF₂, Np(VII) is formed in solutions containing NaOH in a concentration from 0.01 to 1.7 mol litre⁻¹. For achieving quantitative oxidation of Np(VI) in 0.2–1.0 M NaOH or KOH solutions, it is necessary to use a 200-fold excess of solid XeF₂.⁷⁵ Aqueous solutions of XeF₂ are more efficient and can oxidise Np(VI) in 5 M KOH solutions. (The reaction proceeds rapidly.⁷⁴)

Xenon difluoride can reduce Np(VII). Thus, the addition of XeF₂ (5–200 mg) to a 1 M NaOH solution (20 ml) containing Np(VII) (0.2 mmol litre⁻¹), which was prepared by ozonation, afforded Np(VI) in 3%–12% yields.

The addition of microconcentrations of Co(II) and Ni(II) salts has no noticeable effect on oxidation of Np(VI) with xenon difluoride in a 0.5 M NaOH solution. In the presence of Cu(II) salts (10⁻⁵ mol litre⁻¹), neptunium(VI) is not oxidised.

When 0.2–1.2 M NaOH solutions of Pu(VI) were treated with a 5–200-fold excess of XeF₂, a colour characteristic of Pu(VII) solutions appeared for only a short period (10 min). Within 3 min after the addition of XeF₂, the yield of Pu(VII) was no higher than 10%.⁷⁵ Oxidation of Pu(VI) was not observed in alkaline solutions at a concentration higher than 2 mol litre⁻¹. Upon the addition of XeF₂ to 0.5–3 M KOH or NaOH solutions containing Pu(VII), which was prepared by ozonation, the mixture rapidly turned colourless and the absorption spectra of the solutions were identical with the absorption spectrum of Pu(VI).

n. Oxidation with silver oxides

Neptunium(VI). Neptunium(VII) was prepared in alkaline solutions with the use of Ag₂O and AgO.⁹³ Oxidation of Np(VI) with silver(I) oxide proceeds at a noticeable rate only in solutions containing alkali in a concentration higher than 8 mol litre⁻¹. At room temperature, the reaction rate was low. It is recommended that the solutions be heated to at least 50 °C. At 60 °C, the process was completed in 15–20 min.

Heating of 9 M and 12 M NaOH solutions containing Np(VI) (0.5 mmol litre⁻¹) and freshly prepared Ag₂O (10 mg ml⁻¹) to 60 °C afforded Np(VII) in 10%–15% and 70%–80% yields,

respectively. The yield of Np(VII) was approximately halved as the amount of Ag₂O was decreased from 10 to 2 mg ml⁻¹. The completeness of Np(VI) oxidation was somewhat improved as the temperature was raised to 90 °C.

Oxide AgO oxidised Np(VI) even in a 0.1 M KOH solution. The reaction rate was high even at room temperature. In solutions heated to 50 °C, the reaction equilibrium was established in 3–5 min. In 2–3 M solutions of alkali, an excess of silver(II) oxide oxidised 92%–93% of the total amount of Np(VI).⁹³

Plutonium(VI). Silver(II) oxide oxidises Pu(VI) only at an alkali concentration higher than 8 mol litre⁻¹.¹³⁶ In an 11 M NaOH solution, the yield of Pu(VII) is close to 100%. In the cold, the reaction rate is low. At 80–90 °C, oxidation of Pu(VI) is completed in less than 15 min.

o. Oxidation with IO₄⁻ ions, copper(III) periodate and sodium bismuthate

Neptunium(VI) is oxidised with the periodate ions only in hot alkaline solutions.¹²⁹ At 85 °C, a half amount of Np(VI) in a 1 M KOH solution containing KIO₄ (0.1 mol litre⁻¹) and Np(VI) (0.2 mmol litre⁻¹) was oxidised during 25 min, whereas the reaction in a 5 M KOH solution was completed in ~10 min.

Plutonium(VI) is not oxidised with the periodate ions both in dilute and concentrated alkaline solutions.¹¹⁹

An excess of copper(III) involved in the complex with the periodate ions rapidly oxidises Np(VI) and Pu(VI) in solutions containing NaOH at concentrations higher than 1 and 11 mol litre⁻¹, respectively.¹³⁷

Heterogeneous oxidation of Np(VI) with sodium bismuthate in dilute alkaline solutions proceeds rather rapidly only at the boiling temperature of the solution.¹²⁹ The absorption spectra of the green solutions, which are obtained after completion of the reaction and separation of the excess oxidiser by centrifugation, are characteristic of Np(VII).

4. Reduction reactions

a. Reduction with water

Plutonium(VII). The kinetics of reduction of Pu(VII) (0.16–0.25 mmol litre⁻¹) in 0.044–0.1 M KOH solutions is governed by the equation¹²⁰

$$-\frac{d[\text{Pu(VII)}]}{dt} = k[\text{Pu(VII)}]^{1.2}. \quad (153)$$

The rate constant k decreases as the concentration of the hydroxyl ions is increased. The activation energy of reduction is 60.5 kJ mol⁻¹ ($\mu = 1.0$, $[\text{KOH}] = 0.1 \text{ mol litre}^{-1}$, $T = 25 - 45 \text{ }^{\circ}\text{C}$).

It was suggested¹²⁰ that the OH[•] radical is abstracted from the hydrolysed Pu(VII) anion followed by its transformation into the O^{•-} radical ion [see the reaction(107)] and then into HO₂⁻

The peroxide ion reduces two Pu(VII) ions.

The rate of reduction of Pu(VII) (1.7 mmol litre⁻¹) in 0.3–1.96 M NaOH solutions obeys the equation¹³⁸

$$-\frac{d[\text{Pu(VII)}]}{dt} = k[\text{Pu(VII)}]. \quad (155)$$

The apparent rate constant k is proportional to $[\text{OH}^-]^n$. Here, $n = 1$ and 2 if $[\text{OH}^-] > 1 \text{ mol litre}^{-1}$ and $[\text{OH}^-] = 0.3 - 0.62 \text{ mol litre}^{-1}$, respectively.

To detect the OH[•] radicals, which can be generated in this reaction, Pu(VII) was added to 0.5 M and 1.0 M NaOH solutions saturated with benzene. In both cases, the final product of the reaction of OH[•] with benzene, *viz.*, phenol, was not detected. Hence, it was concluded¹³⁸ that Pu(VII) involved in the complex PuO₄(OH)₂³⁻ anion eliminates 1/2 O₂ and is transformed into Pu(V), which rapidly reacts with Pu(VII). However, no explanation was given as to how one-half of the oxygen molecule was eliminated.

Based on comparison of the standard potentials of the $\text{OH}^\bullet/\text{OH}^-$ (1.9 V) and Pu(VII)/Pu(VI) pairs in a 1 M NaOH solution, it was concluded that one-electron oxidation of OH^- or H_2O with the Pu(VII) ions is thermodynamically impossible. At the same time, the potential of the $\text{HO}_2^-/\text{OH}^-$ pair in an alkaline medium is 0.867 V.¹³⁵ As in the case of Np(VII) reduction in carbonate solutions, the reaction of Pu(VII) with water proceeds through the formation of a dimer.^{87,88} It was established that in an alkaline medium Pu(VII) exists as the $\text{PuO}_4(\text{OH})_2^{3-}$ anion.¹³³ A decrease in the alkali concentration leads to the appearance of the $\text{PuO}_4(\text{OH})(\text{H}_2\text{O})^{2-}$ species, which are dimerised and then decompose into two Pu(VI) ions and H_2O_2 (or HO_2^-).

In a 0.15 M KOH solution, reduction of Pu(VII) is accelerated in the presence of Fe(III) , Cu(II) , Ni(II) or Co(II) salts.¹²⁰ The effect of trivalent iron becomes noticeable starting with the concentration of 7.7×10^{-7} mol litre⁻¹. The rate of Pu(VII) reduction increases proportionally to an increase in the Fe(III) concentration to at least 3.1×10^{-6} mol litre⁻¹. Analogous results were obtained also for Cu(II) and Ni(II) . The effect of Co(II) in a 0.15 M KOH solution is manifested at its concentration of $\sim 10^{-9}$ mol litre⁻¹. The kinetic curves for Pu(VII) reduction take the shape characteristic of the kinetic curves of autocatalytic reactions. The sensitivity of Pu(VII) to the presence of Co(II) decreases sharply as the OH^- concentration is increased and the curves of Pu(VII) reduction assume the form typical of the kinetic curves of the first-order reactions [as in the case of solutions containing additives of Fe(III) , Cu(II) or Ni(II)]. The catalytic action of d elements is attributed to their capability for being transformed into higher valence forms, which rapidly react with water.

b. Reduction with hydrogen peroxide

Neptunium(VI) and neptunium (VII). The kinetics of the reactions

in alkaline solutions containing Np(VI) or Np(VII) (0.1 mmol litre⁻¹) at pH 9.2–13.7 was studied by pulse radiolysis.¹³⁹ The rate constants for all reactions decrease from 10^4 – 10^5 to 10^2 – 10^3 litre mol⁻¹ s⁻¹ as pH is increased in the above-mentioned range. This is associated with a decrease in the oxidation potentials of the Np(VI)/Np(V) and Np(VII)/Np(VI) pairs.

The kinetics and the mechanism of the reactions of Np(VI) and Np(VII) with H_2O_2 in 1–8.5 M NaOH solutions were examined in the study.¹⁴⁰ It was found that Np(VI) interacts with H_2O_2 to form complexes with 1 : 1 and 1 : 2 compositions. In the latter complex, intramolecular reduction takes place to give the nonequilibrium $\text{Np(V)(O}_2^{\bullet-})$ complex. In the presence of an excess of H_2O_2 , the concentration of this complex tends to an equilibrium value. In the presence of an excess of Np(VI) , the $\text{Np(V)(O}_2^{\bullet-})$ complex reacts directly with Np(VI) . In addition, the complex is decomposed to liberate H_2O_2 , which reduces Np(VI) .

Hydrogen peroxide reduces Np(VII) to Np(VI) (outer-sphere reduction).

Plutonium(VI) and plutonium(VII). In 1–7 M NaOH solutions (at 23 °C), the stoichiometric coefficient for the reaction of Pu(VI) with H_2O_2 varies from 1.6 to 2.0 and approaches 2 as the $[\text{Pu(VI)}]_0/[\text{H}_2\text{O}_2]$ ratio is increased. The stoichiometry changes only slightly as the temperature is lowered to 10 °C.¹⁴¹ It can be assumed that the reaction of Pu(VI) with H_2O_2 proceeds according to Eqn (90). At room temperature, the rate of the process in 2–4 M NaOH solutions obeys the equation

$$-\frac{d[\text{Pu(VI)}]}{dt} = k[\text{Pu(VI)}][\text{H}_2\text{O}_2], \quad (160)$$

where $k = 5 \times 10^2$ litre mol⁻¹ s⁻¹.

The mechanism of Pu(VI) reduction involves reactions analogous to the reactions (78) and (80), i.e., Pu(VI) forms complexes with hydrogen peroxide. Intramolecular transformations afford Pu(V)

The rate of the reaction of Pu(VI) with H_2O_2 decreases as alkaline solutions of Pu(VI) are aged. For example, the rate constant for the process in a 2 M NaOH solution ($[\text{Pu(VI)}] = 1$ mmol litre⁻¹), which was previously kept for 4 days, decreased to 5 litre mol⁻¹ s⁻¹. Probably, this effect is caused by slow polymerisation of Pu(VI) .

The reactions of Pu(VII) and Am(VII) with H_2O_2 , like those of Np(VII) , proceed through an outer-sphere mechanism. In the study,¹⁴² the rate constants for the reactions

were estimated at $(4-5) \times 10^4$ and $(1-4) \times 10^6$ litre mol⁻¹ s⁻¹, respectively, from the dependence of $\log k$ on the difference between the redox potentials of the An(VII)/An(VI) and $\text{HO}_2^-/\text{OH}^-$ pairs.

Americium(VI). It is impossible to perform complete oxidation of Am(VI) with ozone because of instability of Am(VII) to reduction with water and also due to side reactions involving ozone.¹⁰² It was expected that an increase in the O_3 concentration in the gaseous phase and solution would lead to acceleration of Am(VI) oxidation, whereas reduction of the resulting Am(VII) with water would be of less importance. However, bubbling of a gaseous mixture with a high ozone content through an alkaline solution of Am(VI) resulted in reduction rather than in oxidation of Am(VI) .¹⁴³ This is associated with the fact that a large amount of $\text{O}_3^\bullet$ radicals was formed due to a high concentration of O_3 and these radicals rapidly decomposed. At a concentration lower than 10^{-5} mol litre⁻¹, the rate of their decomposition is described by the first-order rate equation, whereas this decomposition obeys the rate law for a second-order reaction at a concentration higher than 10^{-5} .¹⁴⁴ In the first case, the reaction affords $\text{O}_2^{\bullet-}$, which rapidly reacts with O_3 and, to a small extent, with Am(VI) . In the second case, the reaction yields $\text{HO}_2^\bullet$, which reacts rather slowly with O_3 but efficiently reduces Am(VI) .

c. Reduction with hydrazine N_2H_4

Neptunium(VII). Neptunium(VII) is rapidly reduced with hydrazine. The examination of the reaction stoichiometry demonstrated¹⁴⁵ that 0.25 g-mol of N_2H_4 were consumed per g-mole of Np(VII)

Neptunium(V). In a 2 M NaOH solution, neptunium(V) (0.2 mmol litre⁻¹) does not react with $\text{N}_2\text{H}_4 \cdot 2\text{HCl}$ and other hydrazine derivatives, except for $\text{N}_2\text{H}_4 \cdot \text{HNO}_3$. The latter reduces Np(V) to Np(IV) at a moderate rate.^{146,147} At 20–65 °C, the reaction with $\text{N}_2\text{H}_4 \cdot \text{HNO}_3$ (0.1–0.2 mol litre⁻¹) may take from several hours to several days to give a precipitate consisting of Np(IV) and a portion of captured Np(V) . Precipitation of neptunium slows down as the NaOH concentration is increased. In a 14 M NaOH solution, the precipitate does not form during the time of the experiment.

Apparently, the starting $\text{N}_2\text{H}_4 \cdot \text{HNO}_3$ specimen contains an active compound, which appears after prolonged storage of the reagent at 18–20 °C. For example, HN_3 or $\text{H}_2\text{N}_2\text{O}_2$ can be accumulated in hydrazine. However, these compounds do not reduce Np(V) in an alkaline medium. Hence, the nature of the active compound remains unclear.¹⁴⁷

In solutions of LiOH containing hydrazine hydrate, Np(V) is not reduced in the temperature range of 40–80 °C. Under the

same condition, the reaction performed in the presence of PdCl_2 affords a finely dispersed palladium metal on which hydrated Np(IV) oxide precipitates. The processes are accelerated as the PdCl_2 and N_2H_4 concentrations are increased and the temperature is raised, whereas an increase in the alkali concentration from 1 to 5 mol litre⁻¹ slows down these processes.¹⁴⁸

Plutonium(VII). In a 2 M NaOH solution, plutonium(VII) is reduced with hydrazine¹¹⁹

Plutonium(VI). It was found¹⁴⁹ that in 5–8 M NaOH solutions, $\text{N}_2\text{H}_4 \cdot \text{HCl}$ or $\text{N}_2\text{H}_4 \cdot \text{HNO}_3$ taken in a molar ratio of 1 : 3 with respect to Pu(VI) reduce the latter to Pu(V) in the course of stirring, *i.e.*, the following reactions proceed

etc.

Plutonium(V). In 0.5–4 M NaOH solutions, Pu(VI) (0.42 mmol litre⁻¹) is reduced with hydrazine (5 mmol litre⁻¹) to Pu(IV) at 25–55 °C during several minutes.¹⁴⁹ Under these conditions, the reactions (163) and (164) are followed by disproportionation of Pu(V) . Accumulation of Pu(IV) , while slows down, does not cease as the NaOH concentration is increased (higher than 4 mol litre⁻¹). Under these conditions, disproportionation of Pu(V) may be ignored, *i.e.*, the whole of Pu(IV) is formed as the product of Pu(V) reduction

An increase in the N_2H_4 concentration or temperature leads to acceleration of the Pu(IV) formation. Selective spectrophotometric analysis of dissolved precipitates showed that these precipitates always contain Pu(IV) , whereas other valence forms were not detected.

Americium(V). In a 3 M NaOH solution (at 22–23 °C), $\text{N}_2\text{H}_4 \cdot \text{HNO}_3$ (10 mmol litre⁻¹) reduces 50% of pentavalent americium (0.2 mmol litre⁻¹) to Am(III) during ~30 h.¹⁵⁰ The process is accelerated as the concentration of hydrazine is increased or the temperature is raised to 50 °C. An increase in the alkali concentration to 6 mol litre⁻¹ leads to acceleration of the reaction, whereas a further increase in the alkali concentration slows down this process.

d. Reduction with hydroxylamine

Neptunium(VII). In a 1 M NaOH solution ($T \approx 20$ °C), NH_2OH rapidly reduces Np(VII) .¹⁴⁵ The consumption of the reducing agent is 0.75–0.80 mol per mole of Np(VII) . Apparently, after the reactions

the NHOH^+ and NOH^+ radicals are partially consumed in dimerisation reactions.

Neptunium(V). In 0.5–6 M NaOH solutions, NH_2OH (0.5 mol litre⁻¹) reduces Np(V) (0.4 mmol litre⁻¹) at a temperature higher than 60 °C.¹⁴⁶ Efficient reduction occurs at 80–95 °C. When precipitating, the resulting Np(IV) captures a portion of Np(V) from the solution.

Plutonium(VII). The reaction of NH_2OH (without an excess) with Pu(VII) rapidly affords Pu(VI) . The reaction stoichiometry is expressed as a fraction,¹¹⁹ *i.e.*, the process occurs analogously to the reaction of NH_2OH with Np(VII) .

Plutonium(VI). In 1–14 M NaOH solutions (at 25–60 °C), NH_2OH (5 mmol litre⁻¹) rapidly reduces Pu(VI) (0.5 mmol litre⁻¹) to Pu(V) .¹⁴⁹

Plutonium(V). In NaOH solutions (at an alkali concentration higher than 4 mol litre⁻¹), hydroxylamine reduces Pu(V) (0.5 mmol litre⁻¹) to Pu(IV) at 25 °C (see Ref. 149)

The rate of Pu(IV) precipitation and, consequently, of Pu(V) reduction decreases as the NaOH concentration is increased. However, this dependence is not so sharp as that observed in the case of hydrazine. At room temperature, NH_2OH reduces Pu(V) at a moderate rate even in a 14 M NaOH solution. The rate of this process depends substantially on the NH_2OH concentration and temperature.

Americium(V). In a 3 M NaOH solution (at 22–23 °C), hydroxylamine (0.1 mol litre⁻¹) slowly reduces Am(V) (0.2 mmol litre⁻¹) to Am(III) .¹⁵⁰ The reaction is accelerated as the NH_2OH concentration is increased, whereas an increase in the alkali concentration slows down this process.

e. Reduction with SO_3^{2-} ions

Neptunium(VII). The kinetics of the reaction of neptunium(VII) with the SO_3^{2-} ions was studied in 0.1–0.5 M NaOH solutions with $\mu = 0.7$ at $T = 20$ –35 °C.¹⁴⁵ Under these conditions, Np(VII) is reduced with an excess of sulfite at a moderate rate. The initial regions of the kinetic curves are satisfactorily described by the first-order reaction equation. However, the rate of reduction increases toward the end of the process. This is associated with the fact that Np(VI) , which is generated in the course of the process, is reduced with sulfite to Np(V) , which reacts with Np(VII) much faster than the sulfite ions. Autocatalytic acceleration of the reaction becomes noticeable when a sufficient amount of Np(VI) is accumulated.

The rate constant for the first-order reaction (k') can be determined from the initial regions of the kinetic curves and then the rate constant k for a bimolecular reaction can be calculated from the $k'/[\text{SO}_3^{2-}]$ ratio. The k value is constant in the range of SO_3^{2-} concentrations from 22 to 135 mmol litre⁻¹, *i.e.*, the reaction order with respect to the sulfite ions is equal to unity. The dependence of k on the OH^- concentration

$$k = \frac{k_1}{[\text{OH}^-]} + \frac{k_2}{[\text{OH}^-]^2}$$

shows that the reaction involves low-charged complex neptunium(VII) anions formed in the processes

In a 0.5 M NaOH solution, the activation energy of Np(VII) reduction is 94 kJ mol⁻¹. The reaction with sulfite proceeds as follows:

and is accompanied by reproporationation [see the reaction (94)].

The process of Np(VII) reduction with sulfite ions is affected by impurities of Cu(II) , Co(II) and Mn(VII) compounds. The catalytic action of copper(II) becomes noticeable at its concentration of 2×10^{-7} mol litre⁻¹.¹⁴⁵ The rate constant for the reaction linearly increases as the CuCl_2 concentration is increased from 5×10^{-7} to $\sim 5 \times 10^{-6}$ mol litre⁻¹

$$k = k^0 + k'[\text{Cu(II)}], \quad (175)$$

where k^0 is the rate constant for the reaction in the absence of a catalyst, $k' = 1.4 \times 10^6$ litre² mol⁻² min⁻¹ at $\mu = 0.7$ and

$T = 25\text{ }^{\circ}\text{C}$. Cobalt(II) and manganese(II) are similar in catalytic activity to copper(II).

In addition to the above-mentioned metal ions, iron(III) also serves as a catalyst of this reaction but the concentration of the latter must be no lower than $10^{-5}\text{ mol litre}^{-1}$. Silver(I) compounds have no effect on the rate of Np(VII) reduction with the SO_3^{2-} ions.

Neptunium(V). At a concentration of 5 mmol litre^{-1} , the sulfite ions have no effect on Np(V).¹⁴⁶ High concentrations of sulfite are required for reduction of Np(V) in $3\text{--}5\text{ M NaOH}$ solutions at $20\text{ }^{\circ}\text{C}$. However, Np(V) ($0.2\text{ mmol litre}^{-1}$) is reduced only by 15% during 24 h even at $[\text{SO}_3^{2-}] = 1\text{ mol litre}^{-1}$.¹⁵¹

Plutonium(VII) and plutonium(V). In $1.2\text{--}2.5\text{ M KOH}$ solutions ($T = 25\text{ }^{\circ}\text{C}$), Pu(VII) is rapidly reduced with the SO_3^{2-} ions.¹⁵² In a 4 M NaOH solution, plutonium(V) does not react with sulfite ions at a concentration of $0.1\text{ mol litre}^{-1}$.¹⁴⁹

Americium(V). The SO_3^{2-} ions slowly reduce Am(V). In a 1.5 M NaOH solution containing Am(V) ($0.23\text{ mmol litre}^{-1}$) and Na_2SO_3 ($0.11\text{ mol litre}^{-1}$), a half amount of Am(V) is reduced at $22\text{--}23\text{ }^{\circ}\text{C}$ during 9 h.¹⁵⁰ The reaction is accelerated as the sulfite concentration is increased.

f. Reduction with $\text{S}_2\text{O}_3^{2-}$ ions

Neptunium(VII) and neptunium(V). The thiosulfate ion acts as a weak reducing agent with respect to Np(VII) and Np(V). In a 2 M NaOH solution containing $\text{Na}_2\text{S}_2\text{O}_3$ ($0.05\text{ mol litre}^{-1}$), a half amount of Np(VII) is reduced at $25\text{ }^{\circ}\text{C}$ in a time longer than 100 min,¹⁴⁵ whereas Np(V) is reduced only by 18% even under the action of $\text{Na}_2\text{S}_2\text{O}_3$ (1 mol litre^{-1}) during 24 h.¹⁵¹ Heating or a decrease in the NaOH concentration to $0.1\text{ mol litre}^{-1}$ leads to a slight acceleration of Np(VII) reduction.¹⁴⁵

Plutonium(VII). The reaction of Pu(VII) with the thiosulfate ions proceeds at a moderate rate. The time of reduction of a half amount of Pu(VII) ($0.5\text{ mmol litre}^{-1}$) in a 2.5 M KOH solution containing $\text{Na}_2\text{S}_2\text{O}_3$ ($2.5\text{ mmol litre}^{-1}$) is 2 min. The reaction rate increases as the concentration of the reducing agent is increased.¹⁵²

g. Reduction with $\text{S}_2\text{O}_4^{2-}$ ions and thiourea dioxide

The dithionite ions and thiourea dioxide also reduce Np(V), Pu(V) and Am(V). In a 4 M NaOH solution, dithionite ($0.1\text{ mol litre}^{-1}$) reduces only 30% of neptunium(V) ($0.4\text{ mmol litre}^{-1}$) at $20\text{ }^{\circ}\text{C}$ during one day. In the presence of $(\text{NH}_2)_2\text{CSO}_2$ ($0.1\text{ mol litre}^{-1}$), 20% of Np(V) is reduced at $65\text{ }^{\circ}\text{C}$ for 3 h.¹⁴⁶

In a 4 M NaOH solution containing $\text{S}_2\text{O}_4^{2-}$ (5 mmol litre^{-1}), 90% of plutonium(V) ($0.4\text{ mmol litre}^{-1}$) precipitates at $50\text{ }^{\circ}\text{C}$ for 20 min. In the presence of thiourea dioxide (5 mmol litre^{-1}), the same amount of plutonium precipitates during 2 min.¹⁴⁹ The Pu(IV) and Pu(V) contents in the precipitate are unknown.

In a 1.5 M NaOH solution containing dithionite (5 mmol litre^{-1}), 50% of Am(V) ($0.23\text{ mmol litre}^{-1}$) is reduced at $22\text{--}23\text{ }^{\circ}\text{C}$ for 5 h. In the presence of $(\text{NH}_2)_2\text{CSO}_2$ ($0.1\text{ mol litre}^{-1}$), the same amount of Am(V) is reduced during 0.2 h. Reduction is accelerated as the concentrations of the reagents are increased.¹⁵⁰

h. Reduction with iodide ions

Neptunium(VII). The iodide ions ($90\text{--}160\text{ mmol litre}^{-1}$) reduce Np(VII) at a moderate rate without heating at $[\text{OH}^-] < 0.03\text{ mol litre}^{-1}$.¹⁴⁵ The reaction of Np(VII) directly with I^- proceeds rather slowly. The reaction is accelerated as oxidation products of iodide ions are accumulated in solution. The addition of a mixture of I_2 and KI, i.e., the I_3^- ions, to the reaction mixture exerts an even stronger effect. The presence of Np(VI) has no effect on the reaction. Reduction of Np(VII) is accelerated as the I^- concentration is increased or the alkali concentration is decreased. The process involves the reactions

The possibility of the reaction of Np(VII) with IO^- was not examined.

The addition of microamounts of Co(II), Cu(II) or Mn(II) leads to acceleration of Np(VII) reduction with the I^- ions. The catalytic effect becomes noticeable when these metals are present in concentrations of $(1\text{--}2) \times 10^7\text{ mol litre}^{-1}$.

Plutonium(VII). In KOH solutions, plutonium(VII) is reduced with equimolar amounts of KI at a high rate even at room temperature.¹⁵² The reaction proceeds to completion even if the concentration of the reducing agent is 7–8 times lower than the concentration of Pu(VII). Consequently, all intermediate products of oxidation of I^- to IO_4^- (or $\text{H}_3\text{IO}_6^{2-}$) react with Pu(VII) due to the high potential of the Pu(VII)/Pu(VI) pair. The possibility of Pu(VII) reduction with the IO^- and IO_3^- ions was confirmed experimentally. Hence, the reaction of Pu(VII) with insufficient I^- proceeds according to the equation

In the presence of an excess of the reducing agent, the character of the reaction depends substantially on the alkali concentration. At $[\text{KOH}] < 2\text{ mol litre}^{-1}$, the rate of Pu(VII) reduction is described by the equation

$$-\frac{d[\text{Pu(VII)}]}{dt} = k[\text{Pu(VII)}][\text{I}^-]. \quad (183)$$

In a 1 M KOH solution (at $25\text{ }^{\circ}\text{C}$), the constant k is $6.5 \times 10^3\text{ litre mol}^{-1}\text{ min}^{-1}$. The constant k decreases by a factor of ~ 50 as the alkali concentration is increased to $3.3\text{ mol litre}^{-1}$. For a 2.5 M KOH solution, the temperature dependence of k in the range of $25\text{--}53\text{ }^{\circ}\text{C}$ corresponds to the apparent activation energy of 25 kJ mol^{-1} . Reduction of Pu(VII) begins with the reaction

followed by the reaction (177)

and then the reactions (179) and (180) take place.

The kinetic curves for Pu(VII) reduction with an excess of KI in solutions with $[\text{KOH}] > 2\text{ mol litre}^{-1}$ are distorted, the distortion being stronger at higher alkali concentrations. For 4 M KOH solutions, the curves assume an S shape, which was attributed¹⁵² to the fact that intermediate products of I^- oxidation to I(VII) are involved in Pu(VII) reduction to an increasing extent. In our opinion, under these conditions I_2^- reduces Pu(VI) to Pu(V), which rapidly reacts with Pu(VII).

i. Reduction with iodate ions

Plutonium(VII). In $0.5\text{--}3.5\text{ M KOH}$ solutions (at $15\text{--}35\text{ }^{\circ}\text{C}$), reduction of Pu(VII) with iodate ions proceeds irreversibly according to the stoichiometric equation¹⁵²

The rate of the process is governed by the equation

$$-\frac{d[\text{Pu(VII)}]}{dt} = k[\text{Pu(VII)}][\text{IO}_3^-]. \quad (187)$$

In a 1 M KOH solution (at $25\text{ }^{\circ}\text{C}$), the rate constant for the reaction (186) is $1.1 \times 10^3\text{ litre mol}^{-1}\text{ min}^{-1}$. As the alkali concentration of increased from 0.17 to $1.7\text{ mol litre}^{-1}$, the constant k decreases in an inverse proportion to $[\text{OH}^-]$ and then remains virtually unchanged up to $[\text{KOH}] = 3.5\text{ mol litre}^{-1}$.

An increase in the temperature leads to a rather small increase in the rate of Pu(VII) reduction. In a 2.5 M KOH solution, the apparent activation energy is 24 kJ mol⁻¹.

The mechanism of Pu(VII) reduction with the iodate ions can be described by the following scheme:

j. Reduction with Fe(CN)₆⁴⁻, tin(II) and vanadium(IV) ions

The Fe(CN)₆⁴⁻ ions rapidly reduce Np(VII) in a 1 M NaOH solution¹⁴⁵ [the equilibrium of the reaction (150) is shifted to the left] and Pu(VII) in a 5 M NaOH solution.¹¹⁹ According to our estimation, the equilibrium constant of the reaction (150) in a 1.5 M KOH solution is 0.1 (*T* = 23 °C). We estimated the rate constant for oxidation [the equilibrium of the reaction (150) is shifted to the right] as 350 litre mol⁻¹ min⁻¹ in going from 10 to 23 °C. The rate constant for reduction was estimated at 3500 litre mol⁻¹ min⁻¹.

Tin(II) reduces Np(VII) in a 1 M NaOH solution¹⁴⁵ and Pu(VII) in 1.5–2.5 M NaOH solutions in the course of stirring.¹⁵²

At 20–80 °C, vanadium(IV) (20 mmol litre⁻¹) reduces Np(V) (0.2 mmol litre⁻¹) in 1–5 M NaOH solutions as a result of which Np(IV) precipitates and captures a portion of Np(V) from the solution.¹⁵³ Reduction slows down as the alkali concentration is increased and is accelerated as the temperature is raised.

k. Reduction with organic compounds

Neptunium(VII). The ascorbate ions rapidly reduce Np(VII).¹⁴⁵ The semiquantitative data on reduction of Np(VII) with other organic compounds are given in Table 4.

At 25 °C, Np(VII) does not virtually react with ethanol, acetate ions and oxalate ions both in 2 M and 0.1 M alkaline solutions. The resistance of Np(VII) to ethanol and oxalate ions is decreased (particularly, at a low concentration of the OH⁻ ions) when the temperature is raised to 65 °C. Formaldehyde rapidly reduces Np(VII) under all conditions being studied, whereas the other compounds react with Np(VII) at a moderate rate.

The kinetics of the reactions of Np(VII) with aliphatic alcohols, formaldehyde and formate ions in alkaline solutions was examined in the studies.^{154–159} For all systems, the reaction rate is governed by the equation

$$-\frac{d[\text{Np(VII)}]}{dt} = k[\text{Np(VII)}] = k_0[\text{Red}]^n[\text{OH}^-]^m[\text{Np(VII)}],$$

Table 4. Time of reduction of a half amount of Np(VII) ($\tau_{1/2}$) with organic compounds.¹⁴⁵

Reducing agent (Red)	[Red] ^a $\tau_{1/2}$ /min		[OH ⁻] = 0.1 mol litre ⁻¹		[OH ⁻] = 2 mol litre ⁻¹

^a In mol litre⁻¹.

where k_0 is the rate constant at [Red] = 1 mol litre⁻¹, [OH⁻] = 1 mol litre⁻¹, *T* = 25 °C. The kinetic parameters are given in Table 5.

Analysis of the data from Table 5 shows that the rate constant for oxidation decreases as the number of atoms in normal alcohols is increased. Oxidation products of alcohols are more reactive than alcohols as such.

Neptunium(V). In 1–5 M NaOH solutions containing up to 1 mol litre⁻¹ of HCOONa, Np(V) is not reduced at 60–90 °C during 5 h. Under the same conditions, the reactions performed in the presence of palladium salts afford palladium metal on which hydrated Np(IV) oxide precipitates. Platinum salts also exert a catalytic effect on Np(V) reduction, although this process is less efficient than that occurring in the presence of palladium salts. Reduction of neptunium(V) with the formate ions proceeds on its contact with an anion-exchange resin covered with palladium or platinum metal.¹⁶¹

Plutonium(VII). The ascorbate ions rapidly reduce Pu(VII).¹⁵² The semiquantitative data on the reactions with some other compounds, which react with Pu(VII) more slowly, are presented in Table 5.

It can be seen that the reaction of Pu(VII) with ethanol is less efficient than that with methanol and the rate constants for Pu(VII) reduction with these alcohols are much higher than the analogous constants for Np(VII).

Table 5. Effect of the nature of the reducing agent (Red) and the reaction conditions on stability of Np(VII) and Pu(VII).

^a NaOH was used as the medium.

I. Reduction with metals

Reduction of Np(VII), Pu(VI) and Am(VI) in alkaline solutions with aluminium metal was examined in the study.¹⁶² The reactions were carried out at room temperature. A 2–6 cm² aluminium plate was submerged in an alkaline solution of actinide, which was vigorously stirred. Reduction of neptunium(VII) (0.1–2 mmol · litre^{−1}) in a 0.1–2 M NaOH solution was completed in 8–20 min depending on the alkali concentration and the size of the plate. Neptunium (25%–50%) partially precipitated on the aluminium plate as a thin layer, which was firmly attached to the support. The precipitate contained only Np(V). Reduction of Pu(VI) was completed in 5–20 min to give a colloid of Pu(IV) and a precipitate of hydrated Pu(IV) oxide; 5–7 µg cm^{−2} of plutonium precipitated on the aluminium surface. The amount of the precipitate varied with the concentrations of plutonium and alkali.

A precipitate of Am(III) hydroxide rapidly formed upon reduction of Am(VI). The amount of americium precipitated on the aluminium surface was no higher than 6 µg cm^{−2}.

The reactions of Np(V) and Pu(VI) with zinc, chromium, tin and their alloys in 0.5–4 M NaOH solutions were examined under static and dynamic conditions (filtration of solutions through a column filled with metal granules).¹⁶³ Reduction of actinides and precipitation of hydroxides took place on the surface of metallic granules. In the case of plutonium, the best result was achieved on contact of chromium granules with a solution of Pu(VI) in 0.5 M NaOH at 60 °C for 2–5 h. The best sorption of neptunium from a 1 M NaOH solution was attained upon prolonged contact with chromium and zinc granules.

An increase in the alkali concentration and the addition of chromate ions and complex-forming agents slow down sorption of plutonium.

V. Conclusion

Abundant data were accumulated on redox reactions of actinides in carbonate and alkaline solutions. Procedures for oxidation of low-valence forms of neptunium, plutonium and americium and stability of high-valence forms of these elements were studied in detail. In many cases, the transitions between the oxidation states V, VI and VII proceed easily because they do not require substantial structural rearrangements of the ions. By contrast, the transition IV → V giving rise to an 'yl' group proceeds slowly. The proposed mechanisms of redox processes are consistent with the concepts of general chemistry. However, many of these mechanisms call for experimental or quantum-chemical verification.

Among the reactions to be studied, the following reactions, in our opinion, are of most interest: disproportionation of Pu(V) in a wide range of concentrations of bicarbonate and carbonate ions; the reactions of Np(IV), Pu(IV) and Am(IV) with ozone in carbonate solutions; oxidation of Np(V) and Pu(V) with ferricyanide ions in concentrated carbonate solutions; reactions of Np(VI) and Pu(VI) with hydrogen peroxide in bicarbonate-carbonate solutions; and disproportionation of Pu(VI) in concentrated alkaline solutions (if this process does not occur, it is necessary to establish the causes).

Problems of the preparation of macroamounts of curium(VI) (attempts to solve this problem were unsuccessful¹⁶⁴) and Pu(VIII) are of particular interest. It was suggested¹⁶⁵ that Pu(VIII) can be produced upon β decay of ²³⁹Np(VII) in the solid state

In this connection, the fundamental question arises as to the form of existence of Pu(VIII) and its stability. The estimated potential of the Pu(VIII)/Pu(VII) pair is higher than 3 V,¹⁶⁶ which excludes the existence of Pu(VIII) in solution or the gaseous phase. However, it was reported^{167, 168} that plutonium was oxidised with molecular oxygen to PuO₄ under the conditions of gas thermo-chromatography. This compound is comparable in volatility to octavalent osmium oxide (OsO₄). Undoubtedly, there is a need to

carry out further experiments on the determination of the composition of the volatile plutonium compound, including studies with the use of modern methods of analysis, which allow one to determine the structures and compositions of specimens with a weight of several nanograms (in particular with the use of X-ray synchrotron radiation).¹⁶⁹

VI. Conclusion	506

Abstract. This review deals with cryotropic gelation in polymeric systems, which takes place on moderate freezing, storing in a frozen state and subsequent thawing of solutions or colloidal dispersions containing monomeric or polymeric precursors. The polymer materials formed under these conditions are termed as cryogels. They are macroporous heterophase gels in which poly-crystals of the frozen solvent act as porogens during gel formation. The current knowledge about the structure of moderately frozen solutions of low- and high-molecular-mass compounds is considered, the general regularities of the cryotropic gelation processes and their similarity to and differences from gelation at positive temperatures are discussed, the fields of application of cryotropic gelation techniques are described, and examples of using polymeric cryogel-based materials for solving applied problems are given. The bibliography includes 433 references.

I. Introduction

The applications of processes based on freezing are quite diverse. They include food technology,¹ ground freezing for the construction of underground utilities, the formation of cryobanks for storage of biological objects (blood, semen), ice preparation in sports centres, cryoconcentration of brines in chemical technology and fruit juices during processing of agricultural products, freeze-drying (lyophilisation) of drugs and many other. Branches of science such as low-temperature physics, cryobiology and cryo-medicine, geocryology, glaciology, *etc.*, are developing. Cryo-chemistry is in progress,² including those fields concerned with frost resistance of polymers, low-temperature polymerisation, cryoresistance of latexes, *etc.* This review is devoted to one line of research in polymer cryochemistry, namely, cryotropic gelation processes. Despite the fact that systematic studies along this line were started only in the 1970s, the number of patented processes and materials has already exceeded several hundred. However, no surveying papers have been published so far. All known reviews

are concerned either with particular cases of gelation (for example, radiation-induced polymerisation in frozen solutions giving rise to cross-linked gel materials³) or with only one type of gel [in particular, the macroporous gels resulting from freezing–thawing of concentrated solutions of poly(vinyl alcohol) (PVA)^{4–11}]. The main goal of this review is to summarise and describe systematically the information on the cryotropic gelation in general and on the specific features that distinguish it from the processes traditionally used to prepare chemical (covalently cross-linked) and physical (non-covalent) gels.

The explanation of the main notions and terms such as cryotropic gelation, cryostructuring and cryogel(s), *etc.*, can be found in the literature.^{6,9,10,12–14} In addition, the author proposes that the processes yielding gels of various natures would be termed by words with Greek or Latin roots constructed as follows: ‘... + tropic’ [from τροπος (tropos), which implies directed or induced¹²], *e.g.*, chemotropic — induced by the formation of chemical bonds between polymer chains and resulting in a three-dimensional covalent network of the gel; ionotropic — induced by ion exchange (the formation of ionic bonds); chelatotropic — induced by chelation; thermotropic — induced by heating; psychrotropic — induced by cooling without freezing [from ψυχρία (psychria), which means chill¹²], by analogy with the well-established terms such as psychrometer, a psychrophilic microorganism, *etc.*; cryotropic — induced by freezing; solvotropic (or solvatotropic) — induced by a change in the solvent properties (quality).

The notions of positive and negative temperatures (referred normally to 0 °C) and the notions of moderately frozen systems also require more accurate definition. As applied to the objects discussed in this review, positive temperatures are those above the freezing point of any solvent, while negative temperatures are those below this point. Systems are considered to be moderately frozen if they retain a fraction of non-frozen solvent (usually, this refers to a temperature region lower than the freezing point of the neat solvent by not more than several tens of degrees).

II. What are cryotropic gelation and cryogels?

The structured polymeric physical bodies called gels (or lyogels, in colloid chemistry) can be characterised as immobilised solvent–polymer systems, in which macromolecules are connected in a three-dimensional network by non-fluctuating bonds that are rather stable in time. The nature of these bonds and the network morphology (single-phase and heterophase systems are the 1st-

Uspekhi Khimii 71 (6) 559–585 (2002); translated by Z P Bobkova

and 2nd-kind gels, respectively, according to Papkov's classification¹⁵) are determined by the chemical structure and the method of preparation of the gel. The solvent retained by the cross-linked polymer plays a very important role, as it prevents the system from collapsing into a compact mass and ensures diffusion of soluble substances from the surrounding liquid medium into the gel and back.^{16–18} Gels, except for thixotropic ones, are normally able to undergo substantial reversible deformations in the absence of a flow.¹⁹

Two basic methods for the preparation of gels are known^{15,20} to exist (Fig. 1): first, swelling of either a polymer (as a block, a film, a fibre or a powder) or a xerogel (cross-linked polymer without a solvent) in an appropriate low-molecular-weight liquid; second, gel formation in a liquid medium (solution or colloid dispersion of the corresponding gel-forming agents).

In the former case, a gel is formed due to limited swelling of a non-cross-linked polymer or swelling (exhausting swelling, if the equilibrium is reached) of a xerogel, which, in turn, can be prepared by a solvent-free synthesis or by mere drying of a lyogel.

The latter case represents the most widely used route to gel formation. In this case, the initial system can be a solution of monomers in which branching polymerisation or polycondensation is initiated; or a solution of high-molecular-weight compounds containing appropriate cross-linking agents (ionotropic and chelotropic types of cross-linking are possible); or a solution of a polymer converted into a physical gel due to a change in the thermodynamic quality of the solvent (by which, one means its affinity towards the polymer) or to partial crystallisation of the polymer; or colloidal sol, which undergoes a phase transition to a gel-like state.

Starting from these precursors, one can prepare chemotropic (covalently cross-linked) gels, ionotropic and chelotropic gels (in which the three-dimensional network junction knots are stabilised by slightly dissociating salt or coordination bonds, respectively), and also thermotropic and psychotropic non-covalent (physical) gels. Ageing of colloidal sols usually gives gels of a sophisticated morphology (coagulation and condensation-crystallisation gels, according to Rebinder²¹).

It was shown²² that all types of gelation that take place in a solvent can also be realised in a cryogenic version for the corresponding initial systems using appropriate conditions for freezing, storing in the frozen state, and thawing (see Fig. 1). Thus, cryotropic gelation is a specific type of gelation that takes place upon cryogenic treatment of the initial systems potentially capable of forming a gel. A necessary condition for the processes resulting in the formation of cryogels is crystallisation (freezing) of

the main bulk of the low-molecular-weight liquid present in the initial system.

The polymer gel phase can be formed in one of the stages of cryogenic treatment: either directly during freezing of the initial system [this refers, for example, to colloid dispersions of gelatinised starch²³ or to aqueous solutions of polygalactomannan from the locust bean gum (LBG), which is a block polysaccharide giving rise to thermally reversible physical cryogels],^{24–26} or during storage of samples in the frozen state (this mainly refers to the formation of chemically cross-linked cryogels^{14,27–30}), or during thawing of the frozen specimens (this is typical of non-covalent cryotropic gelation of, for example, aqueous solutions of PVA^{9,31–34}). This will be considered in more detail below in the discussion of the cryotropic gelation kinetics.

First, we shall consider the structure and properties of moderately frozen solutions of low- and high-molecular-weight compounds in order to formulate the current views on the medium in which the cryogel formation proceeds.

III. The structure of frozen solutions of low- and high-molecular-weight compounds. The notion of non-frozen liquid microphase (NFLMP)

The freezing and melting (thawing) of frozen solutions of various substances are fairly complex phenomena dependent on a large number of factors. Although studies in this field have long been carried out, new data providing more precise and more in-depth understanding of the mechanisms of these processes constantly appear in scientific literature. The progress of these studies is promoted to a large extent by the advent of experimental instrumentation and involvement of new methods and theoretical approaches. It is noteworthy that the traditional views according to which frozen solutions are polycrystalline solids at temperatures below the eutectics cannot explain, for example, the occurrence of chemical reactions with diverse mechanisms in these systems. These views do not allow interpretation of the spectroscopic data (ESR, NMR) concerning the maintenance of the high mobility of some of the solute and solvent molecules down to temperatures tens of degrees lower than the freezing point of the initial system.

The cryotropic solidification of neat crystallisable liquids and solutions of low-molecular-weight compounds (LMWC) in such liquids has been studied most extensively, mainly under conditions close to equilibrium.^{35–37} However, freezing of these objects under conditions far from equilibrium brings about specific

Figure 1. Generalised chart of the techniques for the formation of polymer gels.

effects, depending on the cooling rate, the specimen geometry, the vessel material, the duration of storage in the frozen state, and lots of other factors.^{38–41} The processes taking place during the cryogenic treatment of solvent–polymer, solvent–polymer–monomeric additive, and solvent–swollen gel systems are even more complex. The course of freezing or thawing of such systems is strongly influenced by the polydispersity of the polymers (an exception is represented by narrow homogeneous fractions of molecular-weight standards or purified protein specimens). This gives rise to non-equivalence of the liquid–solid phase diagrams for the same solvent–polymer pair characterised by different molecular weights (MW) or molecular-weight distributions (MWD) of the polymeric component. Due to the polymer polydispersity, Smith and Pennings⁴² proposed that the solvent–polymer systems subjected to freezing should be called pseudo-binary, to distinguish them from the solvent–LMWC binary systems. In addition, due to the slow relaxation processes in high-viscosity media, the attained phase states of the frozen specimens depend appreciably on the thermal pre-history during freezing. The capability for association in solutions at low temperatures, inherent in many polymers, results in the situation that the phase diagram of one system at the same negative temperature would depend in each particular case on the dynamics of cooling of the given specimen and the rate of solvent crystallisation.

In addition, high rates of liquid crystallisation in solutions and, especially, in swollen gels bring about the risk of mechanical destruction of polymer chains (so-called cryocracking) under the action of shear or wedging stresses in the zones of movement of the solvent crystallisation fronts (see, for example, Refs 43–46).

Below we mainly consider the phenomena that are significant for the cryotropic gelation processes. The anomalous depression of the freezing temperature of cross-linked gels^{44,47–52} or the effect of the polymer MW and concentration on the trend of its solution to undergo either crystallisation or glass transition on cooling⁵³ are beyond the scope of this review, as well as some other aspects concerning freezing of polymer solutions and gels but not related directly to cryostructuring processes.

1. The liquid microphase in frozen multicomponent solutions

The pioneering studies demonstrating the possibility of chemical reactions in moderately frozen solutions (*i.e.*, in systems retaining a fraction of non-frozen solvent) were published in the 1960s.^{54–60} Grant *et al.*⁵⁴ discovered a higher (compared to that at room temperature) degree of hydrolysis of the β -lactam ring in penicillin G and 6-aminopenicillanic acid in the presence of alkaline catalysts in frozen aqueous solutions of the reactants. The highest degree of conversion was observed at -18°C . Study of the reaction products showed⁵⁵ that after thawing, the solution of 6-aminopenicillanic acid contained 7–8-unit oligomeric peptides. These were not formed in a similar solution kept at 20°C for the same period. Thus, oligomerisation took place only on cryogenic treatment. Similar results have also been obtained in the synthesis of oligopeptides by polycondensation of *N*-carboxyanhydrides of several amino acids in frozen dioxane ($T_m = 11.4^\circ\text{C}$).⁵⁶ This process was most efficient in the crystallised reaction system at 1°C rather than at positive temperatures.

Butler and Bruce^{57,58} were, apparently, the first to suggest that the systems obtained by moderate freezing of multicomponent solutions of LMWC contain, after macrosolidification, apart from the solid phase, liquid regions between the solvent crystals in which the reactants are accumulated. Subsequently, this idea was further developed in Pincock's and Kiovisky's works (see, for example, reviews^{59,60}). Having studied the kinetics of some usual (*i.e.*, not involving oligomer or polymer formation) reactions of LMWC in frozen solvents (both water and organic solvents), the researchers concluded that these reactions proceed in 'liquid holes, present among the crystalline solid, which contain high concentrations of the reactants'.⁶¹

This early stage of investigation resulted in the following conclusions:⁶⁰

(1) moderate freezing of a solution of reactants in a crystallisable solvent does not terminate the reaction because substances are accumulated in the liquid regions; over a certain range of negative temperatures, this may even accelerate the reaction;

(2) if the total volume of the liquid inclusions remains unchanged during the reaction (the temperature does not change and the products and the reactants are in solution), the observed (apparent) rate (v_{obs}) of substance transformation can be described (with good agreement with experimental results) by the usual kinetic equation

$$v_{\text{obs}} = \frac{1}{V} \frac{dm}{dt}, \quad (1)$$

where V is the volume of the reaction phase, *i.e.*, the total volume of liquid inclusions; m is the number of moles of reactants in the reaction phase; and t is time. With v_{obs} determined by analytical methods, it is possible to estimate the V value;

(3) the dependence of the reaction rate on temperature for moderately frozen solutions does not obey the Arrhenius equation and passes through an extremum;

(4) reactions in moderately frozen media differ fundamentally from solid-phase reactions because the reactant molecules in the regions that remain liquid can execute forward motion, which is hardly possible in a solid (at both macroscopic and microscopic levels).

A significant contribution to the development of the concept of structural and phase inhomogeneity of multicomponent frozen solutions (in particular, at temperatures below eutectic ones) was made by Sergeev and Batyuk (see reviews^{2,62–64}). They confirmed that frozen solutions actually contain regions, the mobility of molecules in which is comparable with that in liquids, and developed kinetic models suitable for quantitative description of reactions proceeding in such systems.

Ultimately, it was established quite definitely that moderately frozen solvent–LMWC systems are not entirely solid not only in the phase diagram region between the liquidus and solidus lines but also well below this region. In non-solidified regions which Sergeev and coworkers called the 'non-frozen liquid microphase' (NFLMP), the molecules possess high mobility; this shows itself as narrow signals in high-resolution NMR spectra. If the reactants are readily soluble, they are accumulated (in the limiting case, completely) in the NFLMP. From the thermodynamic standpoint, the formation of the liquid microphase in multicomponent frozen systems stems from the fact that 'inclusion of dissolved substances in the crystal lattice of a solid solvent requires more energy than that spent for the increase in the chemical potentials upon an increase in the concentrations of components in the liquid microphase'.⁶²

The existence of NFLMP in frozen solutions of monomeric substances at temperatures below the eutectic point of the corresponding system can be detected, in particular, by examining the NMR spectra of dissolved substances^{66,67} or ESR spectra of spin probes.^{68–70} For example, the triplet signal for 2,2,6,6-tetramethyl-4-hydroxypiperidin-1-oxyl in liquid benzene ($T_m = 5.5^\circ\text{C}$) remains such in a frozen sample down to $\sim -50^\circ\text{C}$ and degenerates completely into a singlet only at liquid nitrogen temperatures, due to the fact that the solid microenvironment of the nitroxide probe suppresses its rotation.⁶² It was found⁷¹ that hydrolysis of *p*-nitrophenyl acetate in aqueous salt systems (solutions of Na_2HPO_4 or $\text{Na}_2\text{B}_4\text{O}_7$) with an eutectic composition prepared beforehand occurs at temperatures at least 10° lower than the eutectic point; the liquid-phase nature of this process was proved by special experiments.

After a thermodynamic equilibrium has been reached, frozen systems in which no reactions take place are characterised by the same NFLMP composition independent of the way of freezing of the initial solution.⁶⁵ However, during cooling of the initial system to a specified negative temperature, every instant of time is matched by a particular phase state, which depends on the conditions of cooling. The farther the cooling conditions from

equilibrium, the more pronounced the changes which occur in the frozen system during relaxation to the thermodynamic equilibrium. In solutions of polymers frozen under non-equilibrium conditions, relaxation proceeds much more slowly than that in LMWC systems. It is noteworthy that the liquid–solid diagrams constructed for such non-equilibrium conditions of freezing (this is almost always the case for chemical reactions carried out in moderately frozen solutions) are called non-equilibrium state diagrams rather than phase diagrams,³⁹ and the former can differ appreciably from the equilibrium diagrams. All these specific features of the phase state of systems subjected to freezing are especially important for those cryochemical processes whose rates are commensurable with the dynamics of crystallisation of the initial solution in which the amount (volume) and composition of the liquid microphase vary continuously during freezing until a phase equilibrium is reached.

Thorough experimental research of a number of cryochemical reactions in frozen multicomponent solutions and theoretical analysis of the results made it possible to derive kinetic equation (2), which differs from the above Eqn (1), referring to the simplest case, and allows the calculation of the reaction rates in these systems.^{2, 62–64}

$$v_{\text{obs}} = k^0 e^{-E/RT} \left[\frac{T_0 - T}{\Delta \sum_i C_i} \right]^{\left(\sum_j n_j - 1 \right)} \Pi_j C_j^{n_j}, \quad (2)$$

where k^0 is the pre-exponential factor; E is the activation energy of the reaction determined for the liquid medium; R is the absolute gas constant; T_0 is the crystallisation point for the neat solvent; T is the temperature of the frozen sample; Δ is the cryoscopic coefficient of the solvent; C_i is the concentration of substances (i components) in the initial solution; C_j is the concentration of a j th reactant in the non-frozen region of the system; n_j is the reaction order with respect to the j th reactant.

The structure–kinetic model, which underlies this theory of chemical processes in frozen multicomponent solutions, interprets the non-monotonic pattern of the temperature dependence of the rates of reactions (whose overall order is more than one) in these systems as being due to the competition of the opposite trends, namely, the increase in the reaction rate caused by cryoconcentration and the decrease in the rate following the decrease in the temperature.

For the temperature corresponding to the maximum reaction rate T_{max} , the following relation was derived:^{2, 62–64}

$$T_{\text{max}} = \left\{ \frac{E^2}{4R^2 \left(\sum_j n_j - 1 \right)^2} + \frac{ET_0}{R \left(\sum_j n_j - 1 \right)} \right\}^{0.5} - \frac{E}{2 \left(\sum_j n_j - 1 \right)}. \quad (3)$$

It can be seen from Eqn (3) that T_{max} decreases with an increase in the overall reaction order. In the case where all the reaction components are concentrated in the NFLMP, and conditions for fast attainment of T_{max} have been found, selective acceleration of one of the several reactions proceeding in parallel becomes possible (and this has been confirmed by experiments^{63, 64, 72, 73}).

The deviation of the physicochemical characteristics of the NFLMP (viscosity, density, dielectric constant, heat capacity, *etc.*) from those of non-frozen solutions caused by the change in the microenvironment has an influence on the reactivity of the solutes and their capacity for association. This, in turn, has an impact on the kinetics of cryochemical reactions in frozen multicomponent solutions. The data presented above lead to the conclusion that for a large number of moderately frozen solutions of individual substances and mixtures, NFLMP exists over a fairly broad range of negative temperatures. Both the initial compo-

nents and the reaction products (if any reactions proceed) are accumulated in this microphase (provided that they are sufficiently soluble). These reactions are liquid-phase processes, despite the fact that the frozen specimen as a macroscopic body looks like a solid.

The information concerning such cryochemical processes and their mechanisms available from the literature mainly deals with frozen solutions of LMWC. The behaviour of polymer–solvent systems under these conditions is much more complex; the polydispersity of polymers (see above) is not the only reason for this difference. Another reason is the fact that polymer macromolecules not only execute translational and rotational motions as a single whole. In addition, they (first of all, flexible-chain polymers) possess a large set of intramolecular conformational degrees of freedom, in particular, segmental mobility. This accounts for the high sensitivity of these systems to freezing regimes.

2. Non-frozen solvent in polymer solutions and gels at temperatures below the freezing point of the system.

In the subsequent Sections of this review we shall demonstrate, using a number of particular examples, how moderate freezing, storage in the frozen state and subsequent thawing of a gel-forming polymer system result in the formation of a cryogel. Even the mere formation of the gel indicates that the reactants present in a frozen system (including polymers) do not lose mobility after crystallisation of the main bulk of the low-molecular-weight solvent. At least, they retain sufficient mobility for participation in intermolecular interactions giving rise to cross-links (either covalent or not) to form the three-dimensional cryogel network. It is clear that this type of motion can occur only in the solvent region that has not crystallised (or vitrified), *i.e.*, in the NFLMP.

It is noteworthy that most of the publications dealing with the properties of NFLMP in frozen polymeric systems concentrate on the non-frozen solvent rather than on macromolecular components because the physical methods used in the studies [most often, NMR and DSC (differential scanning calorimetry)] provide information mainly about the solvent. However, in some recent publications, the behaviour of polymers under these conditions has also been studied (see below). Since the interest in this field is related, first of all, to the development of cryobiology, cryomedicine and food technology, aqueous systems were studied most often.^{1, 9, 22, 37, 39, 63, 64, 67, 70, 74–83} although Oikawa and Murakami^{52, 84} considered organic solvent–polymer frozen systems. It was found that, on moderate freezing of polymer solutions or gels, after crystallisation of the main bulk of the solvent, its certain fraction (which is, moreover, much greater than that in solvent–LMWC systems) is not incorporated into the solid phase. Further cooling of samples may result in freezing out of an additional amount of the liquid component but, nevertheless, some remains non-frozen.

Physicochemical studies (NMR, ESR, DSC) of these frozen polymeric objects show the presence of non-frozen solvent at temperatures several tens of degrees lower than the freezing point of the system. For example, this is manifested in the NMR spectra as relatively narrow signals of the corresponding nuclei.^{39, 77, 79, 81, 85–88} The ESR spectra of the spin probes introduced into the polymer solution before freezing are typical of the liquid microenvironment of the probe;^{70, 89–92} calorimetry also shows incomplete crystallisation of the initial liquid.^{39, 74, 76, 93–111} The fraction of the solvent which remains non-frozen can be rather high. For example, for aqueous polymeric systems (solutions of swollen slightly cross-linked networks), the amount of non-crystallised water reaches 0.4–1.0 g per g of the polymer, depending on the temperature, and the layer of non-frozen water firmly fixed by the polymer is ~ 1 nm thick, which corresponds to two or three molecular hydration shells.³⁹ This value is an average because it was obtained by dividing the amount of non-frozen liquid into the polymer weight in the initial system. This did not

take into account the preferred solvation by water of hydrophilic sites of the polymer chains and the tendency of hydrophobic regions to expel water, which is the case for heteropolymers such as proteins or so-called protein-like synthetic hydrophilic-hydrophobic copolymers.^{112–114} Therefore, the real sizes (volumes) of the areas which remain liquid after crystallisation of the main bulk of the solvent in water–polymer systems appear to be greater. This, in turn, creates conditions for the retention of mobility of chains or chain segments in the non-frozen region of the solvent. This is confirmed by high-resolution NMR spectra of frozen solutions of PVA in D₂O, which resembled the usual liquid-phase ¹H and ¹³C NMR spectra of PVA, although the signals were markedly broadened. Thus, under these conditions, the polymer retains, at least, segmental mobility.^{81, 87, 88} Analogous results were obtained for frozen aqueous solutions of polyacrylamide.⁶⁷

The data indicating that some enzymes do not lose activity in moderately frozen solutions^{2, 115–125} also attest to the maintenance of segmental mobility of polymer chains under these conditions, because the transformation of a substrate into a product normally requires a conformational change in the enzyme macromolecule (especially, in the vicinity of the active site).^{126, 127}

The volume of polymer-containing NFLMP in a particular range of negative temperatures can be estimated using a special procedure proposed by Mikhalev *et al.*^{70, 89–92} for processing of the ESR spectra of spin probes (stable nitroxides) introduced into the system subjected to freezing. Hysteresis phenomena were observed,⁷⁰ that is, the NFLMP volumes measured during freezing and thawing were unequal.

For frozen aqueous solutions of polyhydroxy polymers (in particular, polysaccharides), data on the properties of water molecules of the first solvation layer occurring in direct contact with the polymer OH groups have been obtained. These H₂O molecules connected to the polymer through hydrogen bonds do not participate in the crystallisation–melting phase transitions; when a definite negative temperature (so-called T_g' point) is attained, they are vitrified together with the polymer. This fraction of liquid is referred to as non-freezable solvent.^{93–99} Normally, each hydroxy group of the polymer chain retains approximately one water molecule.¹⁰⁸ In the case of polyelectrolytes, the ionic groups retain even larger amounts of non-freezable water due to Coulomb forces.⁹⁹ It should be emphasised that the non-freezable solvent is not identical to the non-frozen solvent (which failed to crystallise under particular conditions). The amount of the latter depends on the temperature and thermal pre-history of a particular specimen. For example, for the frozen D₂O–PVA system, the non-frozen solvent is responsible for a relatively narrow signal in the NMR spectrum down to a temperature 55 °C lower than the freezing point of the system. Only on further cooling, is it possible to record a broad signal from the non-freezable solvation water.⁸¹ In the general case, the non-freezable solvent is a constituent part of the non-frozen solvent.¹⁰²

As noted above, the amount of solvating non-freezable solvent depends on the conformation of macromolecules, for example, on the density of packing of the polypeptide chain in the protein globule. Thus it was found by NMR spectroscopy⁸⁵ that in a solution of serum albumin frozen at –35 °C, the amount of non-freezable water is 0.30 g per g of the protein. If the same macromolecules have been treated with urea, the packing of the polypeptide chains becomes loose and the quantity of non-freezable water increases to 0.44 g per g of the protein.

Thus, the higher the degree of solvation of the polymer in the initial solution, the greater the fraction of non-freezable solvent in the crystallised sample at negative temperatures, because in this case, more groups with high solvent affinity in the polymer become accessible for the solvent molecules.

Indeed, determination [by DTA (differential thermomechanical analysis), DSC and dilatometry] of the dependence of the non-frozen portion on the initial concentration of poly(*N*-vinylpyrrolidone) in aqueous solutions frozen at various temperatures

Table 1. Dependence of the weight of water non-frozen at –45 °C on the concentration of poly(*N*-vinylpyrrolidone) in the initial solution.¹²⁸

Concentration (%)	Weight of non-frozen water (%)	Relative fraction of non-frozen water /g of H ₂ O per g of the polymer
5.0	10.9	2.18
15.0	21.0	1.19
30.9	36.6	0.80
39.2	48.9	0.77
46.4	53.6	0.62

showed that the overall weight of the liquid that has not crystallised increases with an increase in the polymer content but the proportion of this liquid decreases to reach some limiting value, which corresponds to the amount of non-freezable solvent (Table 1).

In the case of freezing of swollen cross-linked polymers, the behaviour of the NFLMP has a number of specific features. For example, in cross-linked polyacrylamide hydrogels (PAAG), the amount of non-frozen water obeys an almost linear dependence on the temperature of the crystallised specimen in the –8 to –60 °C range.^{77, 129} In the subzero temperature range (0 to –8 °C), differences in the mobility of molecules in the liquid part of the solvent depending on whether the temperature of measurements was approached during cooling or heating of the specimen were detected by relaxation NMR spectroscopy.¹²⁹ In the case of system cooling, the spin–lattice relaxation time (T_1) measured at –6 °C was 4 times as long as T_1 found for the system obtained by heating of an identical PAAG specimen from a colder state, *i.e.*, the plot for the temperature dependence of T_1 has a hysteresis loop.¹²⁹ Nearly the same picture is observed at subzero temperatures for frozen gelatin or α_s -casein hydrogels.⁷⁹ One reason for these hysteresis phenomena may be the fact that during heating, the diffusion of water molecules from the crystalline to liquid phase is hampered due to the presence of the polymer network.⁷⁷ This demonstrates once again the important role of conditions (cooling or heating) used to prepare frozen specimens for phase equilibration.

These effects are inherent in not only aqueous systems. A certain mobility of polymer chains in moderately frozen lyogels can also be detected in cross-linked polymers swollen in organic solvents. For example, measurement of the spin–spin relaxation times (T_2) of protons in a cross-linked rubber swollen in deuterio-benzene ($T_m = 6.8$ °C) shows that down to ~ -33 °C, chain segments still execute thermal motion in the medium of the crystallised solvent.¹³⁰ It has been shown⁵² using NMR spectra of benzene-d₆ (solid-echo technique) that the mobility of the solvent molecules is still retained at temperatures lower by 15–18 °C.

It should be emphasised that various NMR techniques are most useful for investigations of frozen solvent–polymer systems.

To conclude this Section, we would like to summarise the important features of cryotropic gelation.

1. Crystallisation of a monomeric liquid during freezing of polymer solutions is accompanied by a minor temperature depression, which differs only slightly from the crystallisation point of the pure solvent.

2. In moderately frozen multicomponent solutions, some of the low-molecular-weight liquid remains non-crystallised at temperatures below the eutectic point. The non-frozen solvent molecules retain rather high mobility; these microregions (NFLMP) of the macroscopically frozen solutions accumulate the solutes, which also possess certain molecular (in the case of LMWC) or segmental (in the case of polymers) mobility.

3. The volume of the NFLMP depends on the system temperature, concentration of soluble (or swollen) components and, if

the phase equilibrium has not yet been established, on the instant of the measurement.

4. Due to cryoconcentration effects and some other factors (for example, the increase in the dielectric constant of the medium on cooling), acceleration of chemical reactions can be observed in a definite range of negative (for the used solvent) temperatures.

IV. Effects inherent in cryogel formation processes

As noted in the previous Section, moderate freezing of solvent–LMWC and solvent–polymer systems gives rise to phase inhomogeneous systems which include a non-frozen liquid microphase. If the initial specimen contains gel-forming agents, the polymer framework of the corresponding cryogel is formed exactly in these non-frozen microregions of the frozen material. This is sketched in Fig. 2.⁶

Figure 2. Basic diagram of cryotropic gelation.^{6,22}

(a) initial sample, (b) sample after freezing, (c) cryogel; (1) polymer precursors, (2) solvent, (3) low-molecular-weight compounds or monomer precursors, (4) polycrystals of the frozen solvent, (5) NFLMP, (6) polymer network of the gel phase of the heterophase cryogel, (7) macropores, (8) solvent.

The volume of NFLMP depends on numerous factors, in particular, on the nature of the solvent and the initial concentration and MW of the solutes (for polymers, also on the chain conformation), the system temperature, the regime of specimen freezing, the presence of soluble or insoluble admixtures, etc. In Fig. 2, all components are shown for clarity on an arbitrary (large) scale. It has been found^{67,70,80–83} for several gel-forming systems that the NFLMP volume (Fig. 2b) varies from fractions of a percent to several percent of the solvent volume in the initial specimen (Fig. 2a). Thawing of the specimen gives rise to a macroporous cryogel (Fig. 2c) containing large pores with variable size and geometry. The polycrystals of the frozen solvent (in some cases, crystal solvates or cryoprecipitate particles if these arise during cooling of the initial specimens) act as pore-forming agents (porogens) in this case. On melting or dissolution of these porogens after thawing, cavities filled with the melted solvent remain in the cryogel bulk. Due to the surface tension forces of the gel phase, the surface of the macropore walls is bent; the faceted shape of the walls, typical of the crystalline porogen particles, is replaced by a round shape. In addition, the wall material possesses its own (gel) porosity. Since this gel is formed at high concentrations of precursors, the resulting polymer phase is a dense network with a microporous structure.

A typical feature of various polymeric cryogels is heterophase and heteroporous (often, supermacroporous, spongy or cellular) morphology. The macropores in the cryogel thus formed are usually interconnected because during freezing, each crystal of the solvent grows, as a rule, from the vessel periphery towards the

centre (if no directional freezing is involved) until it comes into contact with the face of another crystal.

An increase in the precursor concentrations in the NFLMP (with respect to that in the initial system), i.e., cryoconcentration is one of the main reasons for some specific effects typical of cryogel formation. A number of examples classified according to the types of gel-forming systems (see Fig. 1) are presented below.

1. Cryogels formed by polymerisation or polycondensation

The preparation of gel structures by polymerisation or polycondensation of monomer precursors is one of the most extensively used pathways to solvated polymer networks.^{15–18,131–134} Apparently, the first description of gels synthesised by polymerisation of unsaturated monomers in frozen media, i.e., polymerisation cryogels, was described in publications^{3,135–138} devoted to the γ -radiation-induced gelation of frozen aqueous solutions of 2-hydroxyethyl methacrylate (2-HOEMA). It was found that at -24°C and at an initial monomer concentration of 10%–40%, turbid cellular (spongy) cryogels containing interconnected micrometer-size macropores are produced. When the monomer concentration is increased to 50%–80%, a foam-plastic-like material with isolated macropores is formed, because the frozen system represents a vitrified matrix of the monomer with small ice crystals dispersed in it. When the initial content of water is low ($<10\%$), the process yields a transparent polymeric monolith because cooling of these specimens results in vitrification instead of ice crystallisation,¹³⁷ while polymerisation, evidently, occurs as a solid-phase process.¹³⁹ For the irradiation doses used (~ 1 Mrad) post-polymerisation does not occur in any of the systems, i.e., the polymer is formed only during irradiation. The fact that a monomer with one double bond is converted into a cross-linked gel points to a branching mechanism of polymerisation, i.e., chain transfer to a side functional group of the monomer takes place.

In addition to materials based on 2-HOEMA,^{3,4,138,140–165} a similar procedure is used to prepare macroporous cryogels based on oligo(ethylene glycol) methyl ether methacrylates **1a–d**¹⁶⁶ and oligo(ethylene glycol) diacrylates **2a** and dimethacrylates **2b**.^{167–169}

When the initial concentrations of the structurally related nine-unit mono-¹⁶⁶ and diacrylates¹⁶⁸ are identical, a lower swelling capacity is observed for cryogels based on the oligomer containing two double bonds, pointing to a higher degree of polymer cross-linking. The partial replacement of moderately hydrophilic 2-HOEMA in the initial composition by highly hydrophilic *N*-vinylpyrrolidone sharply increases the degree of swelling of the resulting cryogels in water and, as noted in a publication,¹⁷⁰ makes the polymer sponge 'softer'.

An interesting way of controlling the microporosity of the polymer phase in heterogeneous cryogels of this type has been reported.¹⁷¹ Oligo(ethylene glycol) with an MW of 1000 Da is introduced as a 'molecular' porogen into the initial solution of a mixture of acrylic acid and methyl methacrylate. After radiation-induced cryopolymerisation of the unsaturated monomers, this additive is washed out of the gel phase by a large excess of water. Apart from the usual micropores present in the polymer network, this gel contains additional (a sort of calibrated) pores.

In order to synthesise cryogels with reactive aldehyde groups, acrolein is added to a solution of 2-HOEMA [or poly(oxyethylene dimethacrylates)]. Irradiation of the frozen solution of the comonomers affords a functionalised macroporous carrier suitable for

covalent coupling of specific antibodies for the preparation of immunosorbents.¹⁷²

Thus, by varying the concentration and the nature of monomer precursors, one can change, over a wide range, the physical and chemical properties of the gels formed in the radiation-induced cryopolymerisation and used as carriers of immobilised enzymes,^{140, 142, 149–153, 158, 160–164, 171} antibodies,¹⁴³ non-proteinaceous biopolymers¹⁶⁵ and microbial cells^{141, 144–148, 156, 157, 159, 166} (see Section V).

Systematic studies of cryotropic gelation induced by polymerisation in frozen solutions induced by chemical initiators have been mainly carried out using polyacrylamide cryogels (cryo-PAAG).^{22, 29, 30, 173–177} The radical copolymerisation of acrylamide (AAM) with *N,N'*-methylenebis(acrylamide) (MBAAM) in water was initiated by the redox system used traditionally for this type of comonomer, namely, ammonium persulfate (APS)–*N,N,N',N'*-tetramethylethylenediamine (TMEDA), capable of generating radical ions, which initiate polymerisation even at low temperatures.¹⁷⁸

The critical concentration for gelation (CCG) at 20 °C for a mixture of the AAM and MBAAM monomers in the synthesis of polyacrylamide gels (PAAG) amounts to ~2% (depending on the monomer ratio).¹⁷⁸ However, if the reaction mixture is frozen immediately after addition of the initiator (for example, kept at –10 °C for several hours) and thawed, it is possible to obtain cryoPAAG at a twice lower initial concentration of the same comonomers (Table 2).^{22, 30} Thus, polymerisation cryogels can also be formed with chemical initiation; in this case, the CCG decreases. In reality, this decrease is only apparent, the main reason being the accumulation of reactants in the polymerisation region, *i.e.*, in the NFLMP. It is significant that this seeming decrease in the CCG is observed for any type of cryotropic gelation.

Table 2. Formation of polyacrylamide gels from low-concentration aqueous solutions of an AAM–MBAAM mixture at 20 and –10 °C in the presence of an initiator.^{22, 173}

Total concentration of AAM and MBAAM /g dl ^{–1}	The ratio [AAM]:[MBAAM] /mol mol ^{–1}	Formation of PAAG or cryoPAAG

2.0	10:1	+	+

Notes. Initiator: APS, 0.025 g dl^{–1} and TMEDA, 0.05 g dl^{–1}. The following designations are used: – means that the system remains liquid; + / – means that a very weak gel is formed; + means the formation of a gel or a cryogel.

Polyacrylamide cryogels have a spongy morphology, which is mainly dictated by the temperature regime of cryotropic gelation. Figure 3 presents the photomicrographs which show the structure of cryogels synthesised at –10 and –20 °C from identical solutions of comonomers frozen by different procedures: by placing the reactant solution into a cryostat with a specified temperature (freezing from above) (Fig. 3 *a, b*); and by initial fast freezing of the system in liquid nitrogen to –196 °C followed by transferring the specimens into a cryostat with a specified moderate negative temperature (Fig. 3 *c, d*). The latter procedure, which minimises the influence of the duration of cooling and

Figure 3. Electronic photomicrographs (scanning electron microscopy) of cryoPAAG specimens formed from aqueous solutions with a total comonomer concentration of 3% and [AAM]:[MBAAM] = 30:1 at different conditions of cryogenic treatment.^{22, 176}

(*a*) Freezing from above, –10 °C; (*b*) freezing from above, –20 °C; (*c*) low-temperature quenching, –10 °C; (*d*) low-temperature quenching, –20 °C. Scale: 20 μm to 1 cm.

freezing stages on the kinetics of cryochemical reactions, is sometimes called low-temperature quenching.

When cryogels are prepared by freezing from above, lowering of the synthesis temperature from –10 to –20 °C leads to a greater number of porogen particles (small crystals of ice) having, however, a smaller size; this has a noticeable influence on macropore diameter in the cryoPAAG (Fig. 3 *a, b*). In addition, the lower the temperature, the greater the amount of solvent that freezes out, *i.e.*, the NFLMP volume decreases, while the concentration of soluble substances in this phase grows. The walls of the macropores thus formed are thinner; however, according to measurements of the swelling capacity of the network material, they are built of a more concentrated gel.^{22, 175} When the low-temperature quenching procedure is employed, the cryoPAAG morphology changes (Fig. 3 *c*).^{22, 176} The cryogel architecture formed at –10 °C combines the porosity typical of the sample obtained by freezing from above at the same temperature and the structure of macropore walls inherent in the material prepared at –20 °C also by freezing from above. This means that, as the reacting system is warmed from –196 to –10 °C, the main structural elements of the gel phase have time to be formed during those several minutes when the system is at about –20 °C. Simultaneously, this indicates that polymerisation is rather fast under these conditions.

The porous structure of various cryogels can be characterised as an intricate three-dimensional maze. This is observed most often for aqueous systems due to the branched shape of ice polycrystals, which give rise to macropores of complex configurations in the specimen bulk. To prepare cryogels with a rather regular arrangement of macropores, it is necessary to use directional cooling and a solvent that forms oblong crystals on freezing. Thus formamide ($T_m = 2.8$ °C) crystallises as long thin needles. When cryoPAAG is prepared in this solvent and one end of the tube with the reaction solution is cooled, directional growth of formamide crystals takes place. The resulting cryogel contains long capillary channels oriented along the temperature gra-

dient.^{22, 174} Thus, the macroporosity of the polymer cryogels can be 'governed' to a certain extent by selecting the solvent and crystallisation regime.

The osmotic characteristics (swelling behaviour in various media) of spongy cryogels similar to cryoPAAG are mainly determined by the initial concentrations of precursors, the nature of the solvent used, and conditions of cryogenic treatment. The total volume of the liquid absorbed by a cryogel during swelling consists of two components, namely, the solvating solvent firmly kept by the polymer network and the capillary solvent which fills the macropore space and can be removed rather easily even by slight compression of the cryogel. It can be seen from the photomicrographs shown in Fig. 3 that the latter component is markedly greater than the former one as the internal volume of macropores accounts for the greater part of the cryogel volume. For example, for the cryoPAAG specimen formed at -10°C from a 3% solution of comonomers (in 40:1 molar ratio), the overall swelling capacity in water is ~ 80 ml per g of dry polymer, while the degree of swelling of the macropore wall material is only ~ 4 ml g^{-1} (see Ref. 173). The last-mentioned value corresponds to the swelling in water of usual PAAG prepared at positive temperatures from 10%–20% solutions of the same precursors. This indicates that the polymer network of the cryogel is formed in the NFLMP, *i.e.*, in the medium highly concentrated as compared to the initial solution.

In this connection, of interest is one more specific effect inherent in the cryotropic gelation dynamics. Figure 4 shows^{22, 176} the variation of the yield of the gel fraction during the PAAG and cryoPAAG formation at temperatures of 25 and 15°C and at -15 and -25°C . Cryopolymerisation was carried out using the freezing from above (Fig. 4*a*) and low-temperature quenching procedures (Fig. 4*b*). A mere decrease in the temperature of the process in the liquid solvent from 25 to 15°C decreases the rate of PAAG formation and the yield of the gel

fraction. Meanwhile, polymerisation in a moderately frozen system, in particular at -15°C , is much faster than, for example, at 25°C , and the final yield of cryogels is much higher. In other words, at definite negative temperatures, gelation is accelerated compared to the gelation of analogous specimens in a non-frozen medium. This phenomenon is typical of the formation of cryogels.

It is also noteworthy that the curves for the corresponding positive temperatures in Figs 4*a, b* follow nearly the same pattern. This implies that the low-temperature quenching itself has no influence on the given reacting system; after fast freezing in liquid nitrogen and the subsequent fast warming of the reaction mixture, the usual gelation kinetics does not change (*cf.*, for example, the curves corresponding to 25°C in Figs 4*a* and 4*b*).

The temperature dependences of the gelation rate in frozen media pass through extrema. The time it takes to reach the gel point (for given systems, this implies an approximately 10% yield of the gel fraction) actually reflects the process rate in the initial stage (Fig. 5). A decrease in the temperature in the positive region entails an increase in the gelation time, whereas in a certain range of negative temperatures in the frozen medium, the time required to reach the gel point sharply diminishes, *i.e.*, the rate of the formation of cryoPAAG increases. In the case of freezing from above, this temperature dependence has a clear-cut extremum, the initial gelation rate being a maximum in a fairly narrow range of negative temperatures. A somewhat different pattern is observed when low-temperature quenching is used, namely, the extremum is less pronounced and a high initial rate of the process is observed over a wider temperature range. This attests to non-equivalence of the conditions of copolymerisation of AAM with MBAAM in specimens brought to the reaction temperature along different routes. In other words, the process of formation of cryoPAAG depends on the method of freezing, although special experiments with a thermocouple embedded in the frozen specimen show^{22, 176} that during the fast warming-up from -196°C , the system temperature reaches a specified value before the gel point is attained. The non-equivalence of NFLMP characteristics in these reacting systems for the use of these freezing procedures is also indicated by NMR spectroscopy data,⁶⁷ which reveal the differences between the amounts of the solvent remaining in the liquid state in the specimens frozen by different procedures. Thus, in the case of relatively fast cryotropic formation of chemically cross-linked polymer networks, the regime of freezing of a reacting system is an important factor which influences, even at the stage of crystallisation, the properties and the formation dynamics of cryogels.

Nuclear magnetic resonance spectroscopy is one of the few physical methods that allow direct detection of chemical reactions

Figure 4. Dynamics of formation of PAAG and cryoPAAG (the temperature of synthesis is indicated near the corresponding curve) during freezing of the reacting system from above (*a*) and using the low-temperature quenching technique (*b*).^{22, 176} The initial total comonomer concentration is 3 mass %, [AAM]:[MBAAM] = 30:1.

Figure 5. Time required for the formation of 10% of gel fraction in the reacting system *vs.* temperature of PAAG and cryoPAAG synthesis for freezing of the system from above (1) and for the low-temperature quenching version (2).^{22, 176} The initial total comonomer concentration is 3 mass %, [AAM]:[MBAAM] = 30:1.

Figure 6. Evolution of the ^1H NMR spectra of a solution of a mixture of AAM, MBAAM, TMEDA, and APS in D_2O frozen using low-temperature quenching at -11.2°C .^{22,67} The initial total comonomer concentration is 3 mass %, $[\text{AAM}]:[\text{MBAAM}] = 30:1$. The digits near the curves represent the period of time (min) from the instant the system reaches a specified negative temperature to the instant of recording the spectrum.

in moderately frozen systems without thawing the sample. For instance, the evolution of the ^1H NMR spectra recorded at definite intervals (Fig. 6) for a solution of reactants (AAM–MBAAM–TMEDA–APS) frozen in D_2O proves unambiguously that in this case, cryopolymerisation in the frozen medium takes place but neither pre- nor post-polymerisation during freezing or thawing, respectively. For an initial period, the spectra of the frozen solution of the reactants remain identical to the spectra of a similar specimen that does not contain the initiator. Subsequently (starting from about the tenth minute of the process), the intensity of the narrow signals due to the monomer protons [6.15 and 6.03 ppm (CH_2), 5.60 ppm (CH)] starts to decrease, and a broad signal [~ 5 ppm (CH_2)] for the protons of the polymer chains appears.⁶⁷ In addition, NMR spectroscopy shows that the reactant ratio in the NFLMP differs from this ratio in the initial solution due to the partial crystallisation of AAM and MBAAM at temperatures below the eutectic point; therefore, the reaction medium is enriched in the initiator (the spectra contain an intense common signal for the protons of the CH_3 and CH_2 groups of TMEDA with a maximum at ~ 2 ppm). As polymerisation advances, the crystallised monomers are again dissolved in the liquid regions of the macrofrozen system and participate in the reaction, resulting ultimately in a high yield of the gel fraction. The measurement of spectroscopic characteristics of the non-frozen fraction of the solvent shows that an initial stage of polymerisation develops under conditions of increasing volume of the liquid microphase, and only when a certain degree of conversion of the monomers into polymeric products has been attained, does the solvent content reach a constant value.⁶⁷ Thus, depending on the cryopolymerisation temperature and freezing conditions, the composition and the volume of the reaction solution in the microreactor (non-frozen liquid microphase) can vary, which influences the gelation dynamics.

Since the variation of the temperature regimes of cryopolymerisation allows the macroporous morphology of gel materials to be controlled over certain limits, this approach has been used to prepare cryogels based on so-called stimuli-responsive⁷⁹ or sensitive¹⁸ polymers. In recent years, gel materials prepared from these polymers have attracted increasing attention both for fundamental research and for applied purposes. In particular, hydrogels that collapse reversibly upon a change in the environment parameters (temperature, pH, ionic strength, thermodynamic quality of the solvent, applied electric field, and so on) are considered to be promising materials for biomedical and biotechnological purposes.^{17, 18, 179–182} For example, in temperature-sensitive hydrogels in which the chains of the corresponding linear polymer undergo a reversible conformational change on passing through

the upper or lower critical solution temperature (UCST or LCST), substantial thermally induced reversible changes in the degree of swelling take place. Hydrogels based on cross-linked poly(*N*-isopropylacrylamide), poly(*N,N*-diethylacrylamide) (PDEAAM), poly(*N*-vinylcaprolactam) and so on are examples of thermally sensitive polymer systems.^{181–187}

Important characteristics of these materials which determine their performance characteristics include the temperature range in which the network collapses and the rate of system response to external treatment. Normally, the larger the specimen under study, the lower this rate, because the kinetics of collapse (or swelling) is controlled by heat transfer within the bulk of the gel and by the solvent diffusion and, hence, depends on the geometric dimensions of the specimen. However, if a macroporous structure is imparted to the material, the intrinsic response time of the macroporous specimen to a change in the temperature would decrease with respect to that observed for a fine-pored material, despite the fact that the weight and heat transfer rates in the gel phase remain the same. In this case, mass and heat transfer processes occur within the thin walls of macropores, *i.e.*, at short distances; as a consequence, the intrinsic time of collapse for this specimen is shorter than that for the microporous gel having the same total volume.

One approach to the synthesis of stimuli-responsive gels with enlarged pores is synthesis at temperatures above the collapse point of the cross-linked polymer (*i.e.*, above the LCST for the corresponding non-cross-linked polymer).^{188–190} In this case, phase segregation results in the formation of a coarser-pored gel (with pores of up to several hundred of Ångström) compared to that prepared from the same solution of monomer precursors but in the homogeneous medium at temperatures below the LCST (with pores of several tens of Å). The use of auxiliary porogens, for example foaming agents,¹⁹¹ at the stage of gel formation provides the possibility of producing an even coarser-pored material. In this case, some pores are closed but the rate of collapse or swelling of this gas-filled macroporous stimuli-responsive gel in reply to a change in the external conditions is much higher than that observed for homophase gel materials of the same chemical nature because the gel layer around each gas bubble is very thin.

As noted above, cryotropic gelation allows one to form gel systems with open interconnected capillary-sized macropores. Thus redox-initiated copolymerisation of *N,N*-diethylacrylamide or *N*-isopropylacrylamide with MBAAM in a frozen aqueous medium affords the corresponding macroporous (with pore size of several tens of micrometers) spongy temperature-sensitive cryogels.^{192,193} Gel materials of this type, in particular PDEAAM cryogels, collapse on heating much faster (Fig. 7a, curve 2) than usual PDEAAM gels formed in the liquid medium (Fig. 7a, curve 1).¹⁹² During the decrease in the swelling capacity, the main bulk of water retained by the cryogel is separated in the first 10–15 s. This includes almost all the capillary solvent and some fraction of the solvating liquid. The concentration of PDEAAM in the polymer phase of the cryogel (Fig. 7b) reaches very high values (50%–70%), whereas for a collapsed usual gel, these values are lower (17%–42%). In other words, during the thermally induced decrease in the swelling capacity, a cryogel displaces more liquid from the polymer phase than the usual gel. At temperatures above the LCST and in the shrunk state, PDEAAM cryogels retain not more than 3.5–5 water molecules per monomer unit, while the polymer network of a usual gel with the same composition retains up to 10–35 water molecules per unit. A unit of PDEAAM has three lone electron pairs (two at the carbonyl oxygen atom and one at the amide nitrogen atom) able to form hydrogen bonds with three water molecules. Hence, it can be concluded that the degree of hydration of PDEAAM cryogels after the collapse is close to the lowest possible value. Thus, the use of cryotropic gelation techniques allows one to create a new type of gel material combining the properties of a network of stimuli-responsive gels and a supermacroporous structure typical of cryogels.

Figure 7. Properties of PDEAAM gels and cryogels.¹⁹² (a) dynamics of the thermally induced collapse of the PDEAAM gel (1) and cryogel (2); (b) content of the dry polymer in the gel phase at temperatures below (20 °C, curves 1, 3) and above (60 °C, curves 2, 4) the point of thermally induced collapse of the PDEAAM gel (1, 2) and cryogel (3, 4) for specimens with different initial ratios of the vinyl and divinyl comonomers and a constant total concentration (5.66%).

Unlike polymerisation cryogels, polycondensation analogues have been little studied, although actually, the only restriction hampering the synthesis of the latter may be the fact that many polycondensation reactions giving the corresponding polymers are endothermic and require heating of the monomer solution. In the case where the synthetic route chosen uses reactions with positive heats and the reactivity of monomers is rather high, the formation of polycondensation cryogels almost does not differ from the formation of polymerisation cryogels.

In particular, freezing is known^{194–199} to exert a structuring effect on hydrated sols of weak inorganic hydroxides (for example, iron hydroxide). The transformation of these sols into gels follows a polycondensation mechanism with water evolution to give a three-dimensional network of the inorganic oxide. The formation of silica gel on ageing of silicic acid sols is known^{200, 201} to proceed in a similar way; therefore, the cryogenic variant of this process can be regarded as polycondensation cryotropic gelation. Freezing of a silicic sol which liberates water during a chemical reaction, *i.e.*, forced dehydration of the system, should apparently shift the equilibrium towards the final product.

Preparation of silica cryogel is not an easy experimental task,²² because it requires a rather accurate acid titration of an alkaline solution of a silicate with cooling until a silicic sol is formed. Then the colloid system must be rapidly frozen to ensure that polycondensation (*i.e.*, ageing of the sol) occurs mainly in the NFLMP of the macrofrozen specimen. An interesting feature of the formation of silica cryogel is the fact that after thawing, the inorganic gel is obtained as scales rather than as a lump. The size of particles (2–5 mm) depends on the temperature of the cryogenic treatment. This is due to the fragility of silica cryogel, which is crushed by the growing ice crystals. In the preparation of elastic

cryogels based on organic polymers, sample destruction of this type is hardly ever observed.

The structure and properties of silica cryogels are mainly determined by the concentration of reactants and the temperature of freezing (Table 3). In particular, when the initial silicate concentration is above 0.5 mol litre⁻¹, the specific surface areas of the usual silica gel and silica cryogels formed at –10, –20, and –30 °C almost do not differ. However, cryogenic treatment of less concentrated systems affords silica cryogels whose specific surface areas are greater than that of the silica gel prepared from the reaction mixture with the same composition at a positive temperature. Silica cryogels formed at –10 °C possess a greater specific surface area than the specimens prepared at –20 and –30 °C. Unfortunately, the experimental data concerning inorganic cryogels of this type available to date are inadequate for a well-posed interpretation of this trend.

Table 3. Dependence of the specific surface area of silica gels and silica cryogels on the SiO₂ concentration in a silicic acid sol and on the gelation temperature.²²

Concentration of SiO ₂ in the silicic acid sol /mol litre ⁻¹	Specific surface area (m ² g ⁻¹) of the dry material formed at different temperatures			
	20 °C	–10 °C	–20 °C	–30 °C

^a Determined from adsorption of argon.

To the best of the author's knowledge, there are no publications dealing with polycondensation cryogels based on organic polymers. These cryogels are still to be prepared and comprehensively studied.

2. The formation of cryogels in solvent – polymer – cross-linking agent systems

Cross-linking in solutions of macromolecular precursors on treatment with appropriate cross-linking reagents has long been known and is widely used both in the laboratory and in industry for the preparation of lyogels. Moderate freezing of initial systems of this type, incubation in the frozen state for a required period of time and subsequent thawing lead to macroporous cryogels.

It is notable that cryostructures formed by cross-linking of polymer precursors in frozen media were known a long time ago. Indeed, the porous foodstuff 'kori-tofu', rather popular in Japan for several centuries, is nothing more than a cryogel based on soya proteins (so-called 11S-globulins) with covalent cross-linking by intermolecular disulfide bonds.²⁰² Moreover, cross-linking of polypeptide chains at cysteine residues takes place just during the cryogenic treatment.^{203, 204} Using model thiol-containing polymers (SH derivatives of carboxymethylcellulose and PAAM), it has been shown²⁰⁵ that atmospheric oxygen dissolved in the aqueous medium acts as the oxidant in these systems.

Thiol-containing water-soluble polymers proved to be very convenient objects for the study of the kinetics of cryotropic gelation of this type^{83, 206} because the course of the reaction can be monitored by highly sensitive spectrophotometric titration of the SH groups. Figure 8 shows the time variation of the concentration [calculated as the ratio of the current to initial SH titres expressed in per cent (Q_{rel})] of sulfhydryl groups in liquid and frozen aqueous solutions of the thiol derivative of PAAM at various temperatures. It can be seen that in frozen specimens (at –15 and –20 °C), the concentration of the SH groups decreases much faster than in liquid solutions; this markedly accelerates cryo-

Figure 8. Kinetics of gelation of the SH derivative of PAAM at various temperatures in a liquid and frozen aqueous solution of the polymer (concentration 2 g dl^{-1} , pH 7.8).^{22, 83}

tropic gelation. For example, at -15°C , a cross-linked gel is formed over a period of approximately 1 h (shown by the black arrow), whereas at 25°C , this occurs only after 24 h (light arrow). In other words, for the cryostructuring of solvent–polymer–cross-linking agent systems, as for the formation of polymerisation cryogels, gelation in a definite range of negative temperatures is accelerated compared to that for non-frozen specimens.

At -5°C , an aqueous solution of SH-PAAM with a polymer concentration of 2 g dl^{-1} does not become frozen due to undercooling effects; therefore, the reaction is very slow under these conditions. When low-temperature quenching is used, the system is frozen at -5°C and the reaction rate is high owing to cryoconcentration (Fig. 9). The temperature dependence of the rate of variation of Q_{rel} in systems frozen by two different procedures passes through an extremum, which is typical of cryotropic gelation. Comparison of the pattern of variation of the SH-group concentration with the NMR data on the amount of mobile non-frozen solvent in the specimens shows⁸³ that after a specified negative temperature has been attained, the volumes and properties of liquid microphases in the specimens frozen in different ways are non-equivalent for a certain period of time. In the case of freezing from above, after crystallisation of the main bulk of the solvent, the reactions proceed initially under conditions of gradually decreasing volume of the liquid component, *i.e.*, with increasing concentrations of reactants. Conversely, in the speci-

Figure 9. Initial rate (v_{init}) of gelation of the SH derivative of PAAM vs. temperature (concentration 2 g dl^{-1} , pH 7.8).^{22, 83} (1) Low-temperature quenching, (2) freezing from above, (3) variation of v_{init} for the region of positive temperatures.

mens frozen in liquid nitrogen and then heated to a specified negative temperature, the smallest volume of the microreactor and, hence, the greatest degree of substance concentration is attained almost simultaneously when the temperature of the environment (the cryostat refrigerating fluid) becomes equal to the temperature of the frozen reaction mixture. These dynamic differences between the phase states of the specimens brought to the temperature of a cryochemical reaction *via* different routes account for the non-equivalence of temperature dependences 1 and 2 in Fig. 9.

Cryotropic gelation in the solvent–polymer–cross-linking agent systems, like the synthesis of polymerisation cryogels, is accompanied by an apparent decrease in the CCG. For example, Fig. 10 shows the dependences of the yield of the gel fraction on the polymer concentration in the initial solution (Fig. 10a) and on the amount of the cross-linking agent (Fig. 10b) during the formation of normal gels and cryogels of chitosan [poly- β -(1 $\rightarrow$ 4)-D-glucosamine] cross-linked by glutaraldehyde at 25°C and in a moderately (-8°C) frozen medium. Cryogels are formed at substantially lower initial concentrations of both the polymer (Fig. 10a) and the cross-linking agent (Fig. 10b).^{13, 22} Undoubtedly, this decrease in the CCG is due to the cryoconcentration of the reactants in the NFLMP.

The normal gels of cross-linked chitosan are typical homophase hydrogels; in the swollen state, they are transparent and rather brittle, especially when the cross-linking degrees are relatively high. The whole bulk of the solvent present in the specimens swollen to equilibrium occurs in the bound (solvation) state. As in the case of other chemically cross-linked gels, it cannot be removed by squeezing out without disruption of the gel integrity. Conversely, cryogels formed from the same initial reaction solutions are heterophase spongy non-transparent materials in which the capillary-bound solvent can be separated rather easily by compression even at low mechanical loads.

Figure 10. Yield of the gel fraction vs. the initial concentration of chitosan (a) and vs. the ratio of the number of glutaraldehyde CHO groups to the number of polymer amino groups for a fixed (2.5 g dl^{-1}) initial concentration of chitosan (b) ^{13, 22} at (1) 25°C , (2) -8°C .

The above examples refer to the synthesis of cryogels in frozen aqueous media. However, there are no obstacles preventing, in principle, the preparation of cryogels from precursors soluble in organic solvents. A necessary condition is that the organic solvent should undergo crystallisation rather than vitrification to ensure the separation of the solid and liquid phases and the formation of an NFLMP with an enhanced concentration of reactants.

Figure 11 shows the dependence^{22,30} of the yield of the gel fraction on the polymer concentration in the initial solution (Fig. 11 *a*) and on the temperature (Fig. 11 *b*) during the SnCl_4 -catalysed cross-linking of polystyrene with 1,4-xylylene dichloride according to the Friedel–Crafts reaction in liquid (13.5°C) and crystallised (-13.5°C) nitrobenzene ($T_m = 5.5^\circ\text{C}$). These data indicate that processes in organic solvents actually obey the same regularities as gelation in aqueous media, namely, the apparent decrease in the CCG for cryogenic processes (Fig. 11 *a*) and an extremal pattern of dependence of their efficiency on the temperature of the frozen system (Fig. 11 *b*). The polystyrene cryogels formed in crystallised nitrobenzene have a spongy morphology (similarly to cryogels based on hydrophilic polymers considered above) and during swelling absorb substantial amounts of organic solvents compatible with polystyrene, for example, benzene or toluene. The main bulk of the liquid absorbed by the cryogel is the capillary solvent which can be easily squeezed out. Thus, it can be concluded that the type of morphology of cryogels cross-linked by covalent bonds and the effects involved in their formation are rather general and do not depend on the nature of the crystallisable solvent used.

Figure 11. Yield of the gel fraction vs. the initial concentration of polystyrene expressed as the molar concentration of monomer units (*a*) and vs. the temperature (the initial concentration of monomer units of polystyrene is $0.3 \text{ mol litre}^{-1}$) (*b*);^{22,30} (1) formation of gels (13.5°C); (2) formation of cryogels (-13.5°C).

3. Ionic cryogels

Ionic, coordination, and coordination–ionic polymer gels represent special types of gel-like systems. On the one hand, they are thermally irreversible, like covalently cross-linked gels, and on the other hand, the change in the pH or the salt composition of the

liquid which surrounds the specimen can induce fast dissolution of swollen ionotropic and chelatotropic networks, which are converted again into the gel upon an appropriate change in the medium composition; this reversibility makes these systems similar to physical gels. A specific feature of many ionotropic gels is heterogeneity caused by impediments to the diffusion of new portions of counter-ions into deep regions of the gelling specimen through the gel membrane, which is formed rapidly at the sample surface (periphery).

Traditional ionotropic gels, *i.e.*, those formed at positive temperatures, can be divided conventionally into three groups.

The first group includes solvated networks based on polyelectrolytes whose macromolecules are cross-linked to give a three-dimensional structure through low-molecular-weight ions forming low-dissociated salt bridges with the ionogenic groups of the polyelectrolyte chains at the network junction knots. When complexing agents are used for cross-linking, a chelate (coordination) network is formed. These ionotropic and chelatotropic gels are capable of substantial repeated swelling after drying.

The second group includes polymer gels formed with the change in the charge of polyelectrolyte ionogenic groups, resulting in a decrease in the polymer solubility and phase separation. The gel-like systems formed in this case usually possess low mechanical strengths and, after drying, they are unable to swell to a substantial extent in the same medium as was used for gelation.

The third group comprises ionotropic gels formed during preparation of polyelectrolyte complexes (PEC). In essence, these systems represent swollen three-dimensional networks cross-linked by poorly dissociating salt bonds (similarly to the first-group ionic gels). However, in this case, it is often impossible to establish which of the PEC components (either polycation or polyanion) is the gel-forming and cross-linking component, especially if the MW and the initial concentrations of these compounds are similar.

Examples of preparation of ionotropic and chelatotropic cryogels that can be attributed (although with some reservations) to the first two groups have now been reported. Cryogels based on PEC have not yet been described.

The major obstacle faced during the formation of ionotropic cryogels is a too high rate of gelation, which proceeds even at the stage of component mixing. Indeed, if low-molecular-weight counter-ions inducing gelation are added to a polyelectrolyte solution in a concentration higher than the CCG, a lyogel is formed very rapidly. On subsequent freezing, the solvent crystallises in the gel phase, *i.e.*, it is virtually impossible to freeze the system when it still exists in the liquid state. This situation is encountered, for example, in the attempt to prepare a calcium alginate cryogel: the addition of a solution of a calcium salt to an aqueous solution of sodium alginate (the sodium salt of the linear block copolymer of D-mannuronic acid and L-guluronic acid) entails fast formation of a gel network, and the system loses fluidity. This specimen can be frozen, but this would not be accompanied by accumulation of precursors and by chain cross-linking in the NFLMP, peculiar to cryotropic gelation (Fig. 12, pathway *a*). Preparation of the cryogel by recharging the alginate carboxy groups is impossible either, because acidifying the solution results in fast formation of a thixotropic gel of alginic acid, whose freezing–thawing does not afford a macroporous material typical of cryogels (Fig. 12, pathway *b*).

Two approaches have been proposed to surmount these obstacles (Fig. 12, pathways *c* and *d*).

If a finely powdered salt having a negative temperature factor of solubility is added (as a source of cross-linking counter-ions) to a polyelectrolyte solution (Fig. 12, pathway *c*) and the resulting suspension is subjected to moderate freezing, gradual dissolution of this salt in the NFLMP and cross-linking of the polyelectrolyte chains take place at low temperature. After thawing, a macroporous ionotropic cryogel is produced. A crucial point is the choice of an appropriate salt because the solubility of most salts increases with increasing rather than decreasing the temperature.

Figure 12. Basic diagram of the formation of ionic cryostructures.²²

The degree of salt grinding is also significant. This strategy has been employed to prepare an alginate cryogel^{22, 207, 208} using calcium salts with the solubility increasing upon decreasing temperature [in particular, calcium butyrate, pentanoate, succinate, glycerophosphate, and some other calcium salts have negative temperature factors of solubility in water (see Ref. 209, p. 1353)]. In this case, as in the formation of covalent cryogels, the properties of the final material depend not only on the precursor concentrations and the temperature of cryogenic treatment but also on the time of keeping the specimens in the frozen state. In particular, when the initial concentrations of sodium alginate and calcium glycerophosphate are 0.5 mass %, keeping frozen specimens at -10°C for 1.5 h gives ultimately (*i.e.*, after thawing, washing and drying) a cryogel with a rupture strength of 250 kg cm^{-2} . An increase in the duration of the cryogenic treatment to 3 h leads to a material with a rupture strength of 420 kg cm^{-2} , and incubation of the sample in the frozen state for 24 h makes this parameter about twice as high (800 kg cm^{-2}).^{22, 208} These data indicate that cross-linking and structuring of alginate require a certain time for dissolution of the solid cross-linking agent and for slow diffusion of calcium ions into the high-viscosity medium of the liquid microphase.

However, this strategy for the preparation of ionotropic cryogels is subject to numerous restrictions, related, most of all, to the admissible concentrations of precursors. Above a definite concentration of either the polyelectrolyte or the salt, too fast gelation taking place at positive temperatures prevents the formation of a 'true' cryogel.

Almost no limitations of this type are involved in the procedure shown as pathway *d* in Fig. 12. This strategy allows the preparation of macroporous ionotropic cryogels by both the recharge of ionogenic groups and cross-linking with appropriate counter-ions, although cryotropic gelation does not actually occur in this case.^{22, 210, 211} To prepare the target material, a polyelectrolyte solution with any desired concentration limited only by the polymer solubility is merely frozen at a required temperature. This is followed by removal of the crystallised solvent without thawing,

for example, by vacuum sublimation (freeze-drying) or cryoextraction (treatment at a negative temperature with a liquid which acts as a solvent for the crystalline phase but a non-solvent for the polyelectrolyte). Finally, cryogenically structured macroporous polymeric framework is obtained, which is then transformed into an insoluble state either by treatment with cross-linking counter-ions or by recharging ionogenic groups. The last-mentioned operation is also carried out in the polymer non-solvent and this no longer requires low temperatures.

For instance, freezing of a solution of sodium alginate and freeze-drying of the specimen thus formed followed by immersion of the porous material into an ethanol solution of calcium acetate results in an ion exchange reaction in which the material structure is fixed by poorly dissociating salt bridges. This yields a calcium alginate cryostructure²¹⁰ which is not dissolved in a physiological salt solution for several days, whereas a usual alginate gel prepared from the same precursors at a positive temperature loses its integrity in several minutes and is promptly dissolved. When substances capable of forming poorly dissociating coordination (more precisely, coordination – ionic) bonds with alginate groups, for example, chromium salts, are used as cross-linking agents, this procedure leads to chelotropic cryostructures.²²

Treatment of plates or grains of a frozen solution of sodium alginate with acidified acetone in the cold (*e.g.*, at -20°C) induces cryoextraction of ice with simultaneous transformation of the polymer network into alginic acid due to recharge of ionogenic groups. The final macroporous polymer is insoluble in water but is wetted by water and readily swells.²¹⁰

A similar strategy can be utilised to prepare a macroporous material from a polymeric base. A specimen prepared by freezing a solution of a macromolecular salt followed by removal of the solvent is treated, for recharge of ionogenic groups, with an alkaline reagent in a medium that is a non-solvent for the polymer.²¹¹ For example, dropwise addition of a solution of chitosan in dilute acetic acid to cooled (*e.g.*, to -15°C) octane results in frozen spherical particles, treatment of which with a saturated solution of NaOH in acetone or methanol at a negative temperature affords granulated macroporous chitosan base. This material is stable in alkaline or neutral media and is capable of coordinating heavy metal ions (for example, its capacity with respect to Cu^{2+} or Co^{3+} ions equals $5.2\text{--}5.5\text{ mmol g}^{-1}$).^{22, 211}

Thus, it is possible to carry out cryogenic structuring of polyelectrolytes, although it requires more sophisticated approaches, and to prepare ionic or coordination polymer materials possessing macroporous morphology, typical of cryogels.

4. Cryogels with a physical network of the polymer phase

As has been noted in the Introduction, non-covalent (physical) cryogels are the best known and investigated gel materials formed by the freezing–thawing strategy. This refers most of all to PVA cryogels. A detailed analysis of publications (by the end of 1997) devoted to the formation of PVA cryogels, the influence of cryogenic treatment parameters on these gels, and their properties has been given in a review.⁹ In this Section, we consider only the general fundamental items of non-covalent cryotropic gelation and the data on physical cryogels based on other polymers. However, at the end of the Section, some other results concerning PVA cryogels (published in 1998–2001) are also considered.

Generally, non-covalent physical gels form a very extensive class of gel systems produced in both aqueous and organic media (see, for example, the publications^{15, 20, 212}). In principle, non-covalent gels can be prepared by either cooling (if the solvent–polymer system has an UCST) or heating (if the system has an LCST). In the former case, one deals with psychrotropic gels, and in the latter case, thermotropic gels are involved. It is clear that the latter cannot be cryogels. But in the case of psychrotropic gel-forming systems, it is not always possible to prepare a physical cryogel by mere freezing. When the polymer concentration is above the critical point and the rate of material solidification on cooling is high, then, as in the case of polyelectrolytes with cross-

linking counter-ions (Section IV.3), fast gelling takes place. In this case, the system that undergoes freezing is no longer a solution but a gel; therefore, the structure of the polymeric material after thawing differs from that obtained in the case of 'standard' cryotropic gelation. An example of such a system is an aqueous solution of agarose (neutral polysaccharide, the major component of agar-agar), which is converted into a gel over a period of several minutes even at 40–30 °C when the polymer concentration is above 1%. An agarose macroporous cryogel can be prepared only from relatively dilute (<0.2%) solutions of the polymer. However, strength characteristics of such a cryogel are poor.

Solutions of PVA (in water or DMSO),^{9, 31–34, 213} amylopectin,²¹⁴ maltodextrin (a mixture of partially depolymerised starch polysaccharides with MW < 20 kDa),²¹⁵ starch,^{23, 216–219} or LBG^{23–26} are more convenient for the formation of non-covalent cryogels because they belong to systems gelling rather slowly on decreasing the temperature. They can be frozen without complications, stored for a required period at a specified negative temperature and then thawed to give the corresponding cryogels. The cryogels based on these polymers are thermally reversible: they fuse at elevated temperatures and repeated freezing–thawing of the solution results again in a cryogel.^{22, 31, 220}

Depending on the type and initial concentration of the polymer and the regimes of cryogenic treatment, this gives either spongy cryostructures with moderate strength similar to cryo-PAAG, described in Section IV.1, or elastic non-spongy cryogels (which are exemplified by PVA cryogels). Most likely, these distinctions in the morphology of materials are related to the amount of free (unbound) solvent able to crystallise at a chosen negative temperature and to the size of porogen polycrystals thus formed. In some cases, the same solvent–polymer system with different contents of the macromolecular component can be converted in both spongy and non-spongy cryogels.

For example, dilute (0.05–0.75 g dl⁻¹), semidilute (0.75–2.0 g dl⁻¹) and concentrated (>2.5 g dl⁻¹) aqueous solutions of LBG remain liquid at room temperature for several months.²²¹ Freezing–thawing (–10 to –30 °C) of these solutions gives very weak spongy cryostructures in the first case, good polymeric sponges in the second case, and elastic non-spongy cryogels in the third case.^{23–26}

Aqueous solutions of maltodextrin containing less than 15–20 g of the polymer per dl (the concentration depends on the MW) cannot be transformed into a gel without cryogenic treatment. Concentrated aqueous solutions of PVA containing no residual acetyl groups form gels very slowly, whereas the freezing–thawing procedure always gives cryogels.^{9, 22, 31–34, 213, 215} Thus, thermally reversible physical cryogels are obtained at lower initial concentrations of the macromolecular precursors and often much faster than without freezing. This indicates that non-covalent cryotropic gelation, like the formation of covalently cross-linked cryogels, is subject to the effects of the apparent decrease in the CCG and accelerated gelation.

The chemical nature of the intermolecular bonds stabilising the junction knots of the three-dimensional polymer network in physical cryogels depends on the structure of the gel-forming polymer material. Usually, these are either hydrogen bonds (the predominant type of contacts between the chains in thermally reversible cryogels, similar to cryogels based on PVA, starch, and other polyhydroxy polymers)^{222–224} or hydrophobic interactions, which play an important role in the formation of new protein cryogels,^{82, 225} or various weak (but cooperative) dispersion interactions. For PVA cryogels, the formation of microcrystallinity zones acting as junction knots in the supramolecular network has been shown experimentally.^{226–228} The sizes of microcrystallites are determined by the temperature conditions of cryostructuring and the number of freezing–thawing cycles. At these knots, syndiotactic sites of PVA chains form numerous hydrogen bonds.^{9, 22} Apparently, microcrystallinity zones function as the physical network junction knots also in the structure of cryogels formed from starch, maltodextrin, and LBG polysaccharides.

The macro- and micromorphology and physicochemical and thermal properties of non-covalent cryogels depend appreciably on some characteristics of the polymer precursors, which are not so important in the case where cryogels are formed through covalent cross-linking of macromolecules. For example, in the cryotropic gelation of PVA solutions, apart from essential properties of the polymer such as the MW and chain tacticity, the number of residual *O*-acyl groups [*O*-acetyl groups for the PVA prepared from poly(vinyl acetate)] is also a significant factor, as the presence of even ~5 mol. % of these substituents is sufficient for inhibiting the complementary ('side-by-side') interaction of neighbouring chains.^{213, 229–232} In other words, *O*-acyl groups act as sort of distance bars preventing the formation of numerous intermolecular hydrogen bonds and thus interfering with the formation of PVA cryogels. In the case of starch cryogels, an important parameter is the ratio of the linear to branched polysaccharides (amylose and amylopectin) in the system subjected to freezing, which depends on the type of starch used and, in some cases, on the procedure of its pretreatment.^{23, 214–219, 233–236} When non-covalent cryogels such as albumin cryogels are formed through hydrophobic interactions, the accessibility of hydrophobic regions for intermolecular contacts becomes the crucial factor. This is determined by the conformation of chains, in particular, by denaturation-related changes in the macromolecules of these globular proteins, which are specially induced by pretreatment (prior to freezing) such as the addition of chaotropic agents (which destroy the cluster structure of water), heating, or high-pressure treatment.^{82, 237–243} Thus, as in the case of 'usual' psychrotropic gelation, for the formation of physical cryogels, too, the chemical structure and the degree of exposure of the chain groups involved in intermolecular interactions are important factors.

The conditions of all stages of cryogenic treatment are highly significant for the objects considered. Whereas in the synthesis of cryogels cross-linked by covalent or ionic bonds, the conditions of thawing of specimens usually have little influence on the properties of final gels, the parameters of non-covalent cryogels are often fairly sensitive to the thawing conditions.^{9, 10, 14, 26, 31–34, 214, 215, 235, 244}

For example, Fig. 13 shows the variation of the apparent instantaneous modulus of elasticity (E_0) and the fusion temperature (T_f) of the LBG cryogels vs. the thawing rate of the specimens (the v_{th} values are laid-off along the abscissa axis on a logarithmic scale).^{22, 26} The specimens were prepared by freezing aqueous solutions of a polysaccharide (2.0 g dl⁻¹) at –20 °C for 18 h. It can be seen that the lower the thawing rate, the greater the rigidity and the thermal stability of these physical cryogels. This trend is typical of those thermally reversible cryogels in which hydrogen bonding is the predominant type of intermolecular contacts stabilising the polymer network junction knots (cryogels

Figure 13. Properties of LBG cryogels vs. v_{th} .^{22, 26}
(1) Apparent instantaneous modulus of elasticity, (2) cryogel fusion temperature.

based on PVA, LBG, starch polysaccharides, gelatin, agar-agar, *etc.*, are examples of such systems).

The nature of this effect has been studied in most detail for PVA cryogels.^{9, 22, 31, 33, 34, 80, 244, 245} The data of Table 4 indicate that the shear modulus (G_0) of PVA cryogel specimens prepared from aqueous solutions with different polymer concentrations increases severalfold as the thawing rate decreases from 0.3 to 0.03 °C min⁻¹.^{34, 245} Conversely, in the case of high thawing rates (> 5–10 °C min⁻¹), PVA cryogels cannot be prepared at all, as, instead of an elastic gel, thawing gives a muddy thick liquid.^{31, 33, 34} These data indicate that the formation of PVA cryogels takes place exactly at the thawing stage. One can follow the kinetics of gelation and choose the temperature range corresponding to the highest intensity of this process (Fig. 14) using the following procedure: aqueous solutions of PVA are first frozen, for example, at –20 °C, then the specimens are transferred into a cryostat with a specified subzero temperature and, after incubation over particular periods of time, selected specimens are rapidly thawed (at a rate of ~3 °C min⁻¹) in order to eliminate the effect of the thawing rate.^{22, 34}

Table 4. Effect of the thawing rate on the rheological properties of PVA cryogels.^{22, 34, 245}

Concentration of PVA in the initial solution /g dl ⁻¹	Rate of thawing of frozen specimens /°C·min ⁻¹	Shear modulus of PVA cryogel specimen /kPa
3.0	0.30	< 0.3
3.0	0.03	< 0.3
5.0	0.30	< 0.3
5.0	0.03	1.73
7.0	0.30	1.80
7.0	0.03	3.93
10.0	0.30	4.94
10.0	0.03	10.6
10.0 ^a	3.0	1.40
10.0 ^a	0.30	3.20
10.0 ^a	0.03	9.40

Note. The materials were prepared by freezing at –20 °C for 18 h a completely deacetylated PVA with MW of 115 kDa. ^a PVC deacetylated to 99% with MW of 69 kDa.

The 0-h points in the plots correspond to the onset of incubation of frozen specimens at a specified subzero temperature (which is written near the corresponding curves in Fig. 14a). Figure 14b shows the duration of this incubation. The shear modulus of the PVA cryogels prepared using this technique increases rather weakly whilst keeping the frozen specimens at –10 °C. At higher negative temperatures, gelation becomes much more intense. The observed temperature dependence is non-monotonic, the process being faster in the –2 to –3 °C range than at –1.5 °C. Thus, in this case, the regularities are qualitatively analogous to the features of covalent cryotropic gelation during the synthesis of cryogels by polymerisation of monomer precursors (see Fig. 5) or by chemical cross-linking of polymer precursors (see Fig. 8b and Fig. 11b), *i.e.*, the temperature dependence of the efficiency of formation of non-covalent PVA cryogels at negative temperatures passes through an extremum.

Study of frozen solutions of PVA by ESR and NMR spectroscopy shows^{70, 81} a sharp increase in the amount of the mobile solvent above a certain threshold temperature range, which is 4–6 °C below the crystallisation point of the system. At these temperatures, together with firmly bound non-freezable water, an additional amount of liquid water appears in the solid, frozen specimen. This partial melting of ice increases the NFLMP volume; therefore, the mobility of macromolecules (or their segments) and the efficiency of polymer–polymer interactions

Figure 14. Dynamics of formation of PVA cryogels (completely deacetylated PVA with MW of 115 kDa, initial concentration 7 g dl⁻¹, freezing at –20 °C over a period of 24 h) at subzero temperatures.^{22, 34} (a) Time variation of rigidity of PVA cryogels; (b) temperature dependences of the rigidity of specimens kept in the subzero region.

increase. Finally, this results in the formation of microcrystallites which act as junction knots of the cryogel network. In particular, this mobility can be detected in ¹³C NMR spectra: ~8 °C below the melting point of the main bulk of the solvent, the resonance peaks for the carbon atoms of PVA virtually cannot be detected but when the temperature rises by ~3 °C, quite resolved, although weak signals arise. On further increasing the temperature (2–3 °C prior to thawing of the specimen), a real ¹³C NMR spectrum for the polymer solution is recorded. From this it follows that a temperature 5–6 °C below the system's thawing point corresponds to a boundary of retardation of the fast (on the NMR time scale) motions of the PVA carbochain backbone. Estimation of the spin–lattice relaxation correlation times for the carbon nuclei in the polymer, which serve as the criterion for the mobility of kinetic chain segments, shows that reorientation of the ¹³C nuclei in the PVA methylene groups in a system frozen at subzero temperatures occurs ~100 times more slowly than that in the initial liquid solution. This points to a very high viscosity of the NFLMP.⁸¹

On the basis of these data, it is possible to interpret the influence of the thawing rate or the duration of incubation of frozen specimens at moderate negative temperatures on the properties of PVA cryogels (see Fig. 14). The slower the thawing and the closer its conditions to equilibrium, the longer the period the specimen is at the temperatures optimal for gel network formation. Therefore, slow warming-up during thawing of the preparations is equivalent, in a sense, to storing the specimen for a long period at temperatures where the strongest cryogels are formed. Although a high polymer concentration in the NFLMP is favourable for gelation, this requires a fairly long period of time due to substantial viscosity of the NFLMP and low mobility of chains. The extremal dependence of the physicochemical properties of PVA cryogels on the cryostructuring temperature (see

Fig. 14 b) is due to the competition of factors favourable and unfavourable for gel formation. On the one hand, at temperatures above the extremum point, the amount of mobile solvent is greater, *i.e.*, the specific concentration of the gel-forming reagent in the NFLMP is lower, so is the probability of formation of effective intermolecular contacts (intensification of thermal motions in the system also counteracts stabilisation of the contacts). On the other hand, at temperatures below the extremum, the amount of mobile solvent decreases, the polymer becomes poorly solvated and retains only the firmly bound water, *i.e.*, the liquid medium in which the motion bringing together the interacting sections of the neighbouring chains takes place is no longer present.

Since concentrated aqueous solutions of PVA usually do not freeze in the subzero temperature range, *i.e.*, at temperatures of most intense gelation, due to undercooling effects, the initial specimens always need to be frozen at lower temperatures. The properties of PVA cryogels can be varied by varying the rate of thawing or the time of storage of the frozen materials at subzero temperatures.

Figure 15 shows the pattern of porosity of specimens of PVA cryogels thawed at rates of 0.3 and 0.03 °C min⁻¹. The photomicrographs of thin sections of cryogels dyed by Congo Red were taken using optical microscopy; the dark areas represent the gel phase and the light areas are macropores.^{22, 245} Whereas in the first specimen (Fig. 15 a), the macropore size and arrangement are rather irregular, the specimen of the PVA cryogel formed under slow thawing conditions (Fig. 15 b) possesses quite a perfect morphology with a clear-cut alternation of oblong macropores and strands of the gel phase. Undoubtedly, higher rigidity of slowly thawed cryogels of PVA of this type compared to the specimens thawed more rapidly (see Table 4) is due, among other factors, to the more regular macrostructure of the former.

Figure 15. Photomicrographs (optical microscope) of thin sections of specimens of PVA cryogels formed from an aqueous solution (12 g dl⁻¹) of a polymer (MW 69 kDa, degree of deacetylation 99 mol. %) on freezing at -20 °C for 18 h followed by thawing at a rate of 0.3 (a) or 0.03 °C min⁻¹ (b) (see Refs 22, 34). Scale: 40 µm to 1 cm.

It is worth noting that the morphology of PVA cryogels has been studied most often by electron microscopy techniques, which imply dehydration of specimens,^{4, 22, 226, 246–253} resulting inevitably in some changes in the dimensions and shapes of the structural units of these objects.^{246, 249, 250, 253} The use of optical microscopy for these studies is more legitimate because it permits one to observe the real structure of a swollen cryogel.^{226, 245, 253–255}

Yet another interesting feature of non-covalent cryogels is an increase in the rigidity upon freezing and thawing repeated many times.^{4, 5, 9, 11, 25, 32, 226–228, 230–232, 256–258} For example, the dynamic modulus of elasticity of a PVA cryogel prepared from a 15% aqueous solution of the polymer (MW 75 kDa) is an order of magnitude higher after four cycles of cryogenic treatment (each cycle includes 24 h freezing at -20 °C and 7 h thawing at 15 °C) than after one such cycle.²⁵⁹ According to the data of X-ray diffraction analysis and DSC,^{226–228, 260} every subsequent freezing–thawing procedure increases the content and the size of

crystallites in the PVA cryogel. Apparently, repeated occurrence of the system in the temperature of the most intense gelation gives rise to new additional intermolecular contacts and extends those present previously. This is manifested, in particular, as numerous thickened regions observed through an optical microscope.²²⁶ In addition, the possible compaction of the supramolecular strands of the cryogel network, which approach one another under the action of growing ice crystals, cannot but be taken into account.

Thus, various procedures of cryogenic treatment of the water–PVA system make it possible to vary the properties and morphology of non-covalent cryogels of a given polymer over wide limits,^{9, 88, 245, 261–268} the duration of the occurrence of the frozen specimen at moderate negative temperatures being the crucial factor determining the efficiency of non-covalent cryotropic gelation.

This conclusion is also true for the formation of other physical cryogels. An important role of thawing or incubation at subzero temperatures was demonstrated for the cryotropic gelation of LBG,²⁶ maltodextrin,²¹⁵ amylopectin,²¹⁴ and mixtures of amylopectin with amylose.²³⁵ However, individual features of each of these polymers also make a contribution to the observed regularities.

For instance, in the case of highly crystalline starch polysaccharides, the primary cryogel is formed immediately during freezing, while thawing conditions influence the further formation (adjustment) of intermolecular contacts.^{214, 235} This can be clearly seen in a study of dilute systems in which the freezing–thawing cycle affords a cryoprecipitate rather than a cryogel over the whole specimen bulk. The precipitate can be readily separated from the solution and the yield of the gel fraction can be measured. This parameter shows that a decrease in the rate of thawing results in a substantial increase in the structuration efficiency compared to that in rapidly thawed preparations.²³⁵

To conclude this Section, it should be noted that non-covalent intermolecular interactions play an important role also in the formation of cryogels based on colloidal dispersion systems: suspensions, pastes and colloid sols. Such cryostructures are often produced on freezing–thawing of dispersions of food biopolymers; they are formed as coagulates upon cryogenic treatment of latexes, and so on. However, subtle physicochemical mechanisms of these processes have not yet been adequately studied, although the need for these studies is obvious.

Generally, the formation of non-covalent (physical) polymeric cryogels is characterised by the same effects as covalent cryostructuring, *i.e.*, the formation of macroporous gel-like bodies, apparent decrease in the CCG, acceleration of gelation over a definite range of negative temperatures and extremal temperature dependences of process rates. The main difference between non-covalent cryotropic gelation and the processes of formation of covalently cross-linked cryogels is the important role of the thawing stage (incubation at subzero temperatures) in the former case.

V. Applications of cryotropic gelation processes and materials based on polymeric cryogels

In recent years, the interest in polymeric cryogels as not only objects of scientific research but also promising materials for the solution of applied problems has constantly increased. The range of applications of the cryotropic gelation techniques and the gel materials is fairly broad. The unique porous structure of cryogels proves to be useful in many cases. An especially large number of publications including reviews^{3, 4, 6, 10, 11, 269} have been devoted to the use of various cryogels as materials for biomedical and biotechnological purposes. The development of cryogenic processes for the production of new food forms, new sorbents, filters, mechanochemical gel actuators (manipulator mechanisms), leather-like materials, catalyst systems, and many other things is in progress. The data demonstrating the fields and branches in which diverse cryogels have already been successively used are summarised in Table 5. It should be emphasised that the range of

Table 5. Fields of application of cryotropic gelation processes and materials based on polymeric cryogels.

Gel-forming reagents	Cryogel type	Application of a material or cryotropic gelation procedure	Ref.
2-HOEMA	IV.1(<i>r</i>)	carriers for enzyme immobilisation	3, 140, 142, 149–153, 158, 160–164
2-HOEMA + acrolein	IV.1(<i>r</i>)	carriers for antibody immobilisation and preparation of immunosorbents	143, 172
2-HOEMA + hyaluronic acid	IV.1(<i>r</i>)	gel matrices for controlled drug release	165
Hydroxy- and methoxyoligoglycol methacrylates	IV.1(<i>r</i>)	carriers for immobilisation of microbial cells	141, 144–148, 156, 157, 159, 166
Oligoethylene glycol monomethacrylates and dimethacrylates	IV.1(<i>r</i>)	gel matrices for cultivation of animal cells	168
AAM + MBAAM	IV.1(<i>c</i>)	carriers for immobilisation of microbial cells	22, 270, 271
	IV.1(<i>c</i>)	gel bases for supermacroporous bioaffinity sorbents	269, 272
AAM + MBAAM + allyl glycidyl ether	IV.1(<i>c</i>)	gel bases for supermacroporous bioaffinity sorbents	269, 272
Cryo(silica gel)	IV.1(<i>pc</i>)	carriers for immobilisation of microbial cells	22, 273
Gelatin + formaldehyde	IV.2	immobilisation of yeast cells	274
Serum albumin + glutaraldehyde	IV.2	immobilisation of photosynthetically active cell organelles of lettuce	275–278
	IV.2	immobilisation of the submembrane fraction of photosystem II of spinach cells	279, 280
	IV.2	immobilisation of photosynthetically active cyanobacteria	281
	IV.2	immobilisation of thermophilic bacterial cells	282
Polystyrene–polybutadiene block copolymer + Pd or Rh salts	IV.2	preparation of heterogeneous catalysts containing zerovalent metal nanoparticles	283
Collagen + dialdehyde (diepoxide, epichlorohydrin, diisocyanate, etc.)	IV.2	collagen materials for medical purposes	22, 284–287
A dispersion tanned by heavy metal salts of leather-processing wastes in the presence of cross-linking agents	IV.2	leather-like materials for domestic and technical purposes	22, 288–290
Sodium alginate + calcium gluconate	IV.3	polymeric scaffold of implants containing adsorbed hepatocytes	291, 292
Sodium alginate + calcium salt with a negative temperature factor of solubility	IV.3(<i>c</i>)	alginate sponges for medical purposes	22, 208, 209
Chitosan + β -tricalcium phosphate	IV.3(<i>c</i>)	polymer matrix of bone tissue implants	293
Polymeric acids	IV.3(<i>d</i>)	highly porous adsorbents for preconcentration of volatile bases	210, 294
Polymeric bases	IV.3(<i>d</i>)	highly porous adsorbents for preconcentration of volatile acids	211
PVA	IV.4	gel materials for calibration of NMR tomographs	266, 295, 296
	IV.4	immobilisation of AOT micelles containing enzymes	262
	IV.4	preparation of composites containing supported catalyst particles as fillers	297–299
	IV.4	gel matrices for controlled drug release	11, 300–306
	IV.4	carriers for enzyme immobilisation	307–325
	IV.4	carriers for immobilisation of microbial cells	6, 10, 22, 224, 252, 326–381
	IV.4	carriers for immobilisation of animal cells	382
	IV.4	gel bases for solid nutritional media for microbe cultivation	6, 22, 383
	IV.4	gel bases for solid nutritional media for plant cell cultivation	6, 22, 384
	IV.4	Support for the preparation of immunosorbents meant for isolation, purification, and modification of viruses	385, 386
	IV.4	chromatographic materials	387
	IV.4	protective coatings for frozen fish and meat	388–392
	IV.4	composite ice as a structural material	22, 393
	IV.4	thawed soil densification	22, 394
	IV.4	artificial baits for sports and amateur fishing	395
	IV.4	biocompatible materials for medical purposes	396–405
	IV.4	macroporous membranes	406, 407
PVA + chitosan or dextran	IV.4	biocompatible gel materials	408, 409
PVA + polyacrylic acid	IV.4	gel matrix for controlled drug release	168, 261, 410
PVA + alginate	IV.4	support for immobilised microbial cells	411–413
PVA + polyelectrolyte	IV.4	gel materials for mechanochemical actuators	7, 414–422
PVA + gellan	IV.4	gel matrix for controlled drug release	423
PVA + collagen fibres	IV.4	biocompatible gel materials	248, 424, 425
PVA + Fe salts	IV.4	gel dosimetric system	426
Solutions and dispersions of food biopolymers	IV.4	production of structured food forms	236–243, 427–433

problems solved using cryogels is permanently extending. In Table 5, types of cryogels are designated according to the numbers of the Sections of the review in which these cryogels are considered:

IV.1 are cryogels formed upon polymerisation (r implies radiation initiation, c means chemical initiation) or polycondensation (pc);

IV.2 are cryogels prepared by covalent cross-linking of polymeric precursors;

IV.3 are ionic cryogels (the letters correspond to the pathways of cryogel formation presented in Fig. 12);

IV.4 are non-covalent cryogels with a physical network of the polymeric phase.

VI. Conclusion

To summarise the discussion on the most important features of cryotropic gelation of polymeric systems, the properties of the gel specimens thus formed and some applications of these materials, several conclusions can be drawn.

1. Cryotropic gelation and concomitant chemical reactions (including the non-covalent interactions between the precursor molecules) are liquid-phase processes occurring in the non-frozen liquid microphase of moderately frozen (macroscopically solid) specimens.

2. Cryotropic gelation can take place in both aqueous and organic frozen media provided that the solvent used and the conditions of cooling ensure crystallisation rather than vitrification of the system.

3. The final products of cryotropic gelation (cryostructuring) are macroporous, often spongy gel-like materials called cryogels (cryostructures). The role of the porogen in the formation of these polymeric materials is played by crystals of the frozen solvent; therefore, the pattern of porosity of the cryogels is determined by conditions of freezing, incubation in the frozen state, and, in some cases, thawing of the gelling system. The polymeric network of the gel phase (walls of macropores) possess intrinsic microporosity.

4. Due to the accumulation of soluble components in the non-frozen liquid microphase, cryotropic gelation is characterised by an apparent decrease in the CCG with respect to that observed for the gelation in the same initial systems at positive temperatures.

5. As a rule, moderate freezing of the initial system accelerates gelation.

6. The temperature dependences of the rate and efficiency of cryotropic gelation usually pass through an extremum due to the competition between factors that favour (cryoconcentration effects) and hamper (low temperature, high viscosity, and so on) the process.

7. The properties of the polymeric cryogels are determined by the temperature of the cryogenic process, the nature of the solvent used, the type (monomer or polymer precursors) and the concentration of gel-forming reagents, the presence of other soluble materials and insoluble fillers, the rate of freezing, the duration of storage in the frozen state, thawing dynamics, and some other factors.

8. A unique combination of a number of properties, first of all, high porosity and interconnection of macropores and the facility of the process technology for the preparation of gel materials with this type of morphology allow cryogels to be regarded as a new type of polymer systems interesting in both scientific and applied aspects. The cryotropic gelation technique opens up prospects for the perfection of existing materials and development of new materials for various practical applications.

The author is grateful to A N Chumakovskaya (Institute of Organoelement Compounds, Russian Academy of Sciences) for performing the patent search and to R V Ivanov and A A Korenev (Institute of Organoelement Compounds, Russian Academy of Sciences) for assistance in the preparation of pictorial data for this review.

The review was written with partial financial support of the INTAS (Grant, No. 00-0057).

Synthesis of 2'-O-alkylnucleosides

T S Zatsepin, E A Romanova, T S Oretskaya

Contents

I. Introduction	513
II. Alkylation of nucleosides with diazomethane and trimethylsulfonium hydroxide	514
III. Alkylation of nucleosides with methyl iodide in the presence of silver(I) oxide	515
IV. Alkylation of nucleosides in the presence of bases	515
V. Preparation of 2'-O-alkylnucleosides by glycosylation of heterocyclic bases	522
VI. Alkylation of the activated <i>cis</i> -diol group of nucleosides in the presence of transition metal compounds	527
VII. Synthesis of pyrimidine 2'-O-alkylnucleosides from O ² ,2'-anhydronucleosides	530
VIII. Other methods for the synthesis of 2'-O-alkylnucleosides	531
IX. Conclusion	532

Abstract. The published data on the synthesis of 2'-O-alkylnucleosides are reviewed. The known methods are systematised and their advantages and disadvantages are discussed. The bibliography includes 174 references.

I. Introduction

Synthesis of modified oligonucleotides is a popular trend in the modern organic chemistry of nucleic acids. The introduction of modified fragments into the oligonucleotide chain allows one to solve diverse problems, such as the enhanced transport of DNA fragments through cell membranes, the increase in their resistance against nucleases and the increase in thermodynamic stabilities of various NA duplexes. The introduction of chemically reactive groups into oligonucleotides allows the preparation of various conjugates with peptides, dyes, *etc.* Post-synthetic random modifications or modifications at the 3'- and/or 5'-ends of oligonucleotides are possible in principle, but direct incorporation of a modified unit into a predetermined position of an oligomeric chain in the course of oligonucleotide synthesis is the most versatile approach.

This review surveys the synthesis of modified nucleosides containing alkoxy groups at positions 2' of the carbohydrate moieties. These compounds are used as precursors of monomeric components in oligonucleotide synthesis. Preparation of now commercially available building blocks for the oligoribonucleotide synthesis, of conformationally locked nucleic acids (LNA)

(their synthesis is not confined to the alkylation of the 2'-hydroxy group) and 2'-O-(β -D-ribofuranosyl)nucleosides (for reviews see Refs 1 and 2) are not considered here.

Modified oligonucleotides containing an alkoxy group at the 2'-position of the carbohydrate moiety cannot be prepared by modification of natural oligonucleotides. The only possible approach is the synthesis of a modified monomer and its incorporation into the oligonucleotide chain in the course of automated oligonucleotide synthesis.

2'-O-Methyladenosine was isolated for the first time from a natural source in 1959;³ approaches to the synthesis of this class of compounds were developed soon thereafter (in 1965–1966).^{4–6}

In the past decade, modified oligonucleotides containing an alkoxy group in position 2' of the carbohydrate fragment are actively employed as antisense probes. The results of these studies are summarised in several books^{7–9} and reviews.^{10–13} It was demonstrated that 2'-O-methyloligonucleotides form duplexes with RNA which are kinetically and thermodynamically more stable and simultaneously more sensitive to mismatches than non-modified oligoribonucleotides,¹⁴ which makes them indispensable tools in antisense biotechnology. Besides, 2'-alkyloligonucleotides are used in the design of ribozymes¹⁵ which are more resistant to nuclease digestion than their natural counterparts, and in studies of the processing of genetic material.^{16–19} 2'-O-(3-Aminopropyl)-oligonucleotides are especially resistant against 3'-exonucleases due to the interaction of the amino group with the metal-binding domain. This was demonstrated by X-ray diffraction analysis using the Klenow fragment from *E. coli* as an example.²⁰ 2'-O-(2-Aminoethyl)oligonucleotides are the most potent inhibitors of the *in vivo* gene expression according to the antigenic mechanism, *viz.*, the formation of a triplex with genomic DNA, in comparison with other known modified analogues of nucleic acids.^{21,22} Oligonucleotides containing chemically reactive groups in position 2' of the carbohydrate fragment are used for conjugation with various compounds, *e.g.*, fluorophores²³ (these conjugates are used for structural analyses of various RNAs), electrochemically active compounds²⁴ (design of DNA analysers), metal ion complexes²⁵ (chemical nucleases), DNA and RNA duplexes with covalently linked chains.^{26,27}

The alkylation of the 2'-hydroxy group of nucleosides usually follows a nucleophilic substitution mechanism.

X, Y are H or protective groups; B is a heterocyclic base; AlkZ is an alkylating reagent.

Blocking of reaction centres of heterocyclic bases, 3'- and 5'-hydroxy groups to avoid side reactions is the central problem in the synthesis of 2'-*O*-alkylnucleosides. The choice of suitable protective groups still remains a topical problem. The majority

of currently known alkylation procedures imply the use of strong organic or inorganic bases, therefore classical protective groups are not always compatible with the reaction conditions.

The review considers recent advances in the synthesis of 2'-*O*-alkylnucleosides and historically significant methodologies. Such a choice of literature sources is determined by the fact that the main approaches to the synthesis of 2'-*O*-alkylnucleosides have been known since the 1970's–1980's. However, modified 2'-*O*-alkyloligonucleotides came into use only in the early 1990's. Studies in this field have led to the development of novel methods for the synthesis of 2'-*O*-alkylnucleoside and optimisation of the existing methods.

II. Alkylation of nucleosides with diazomethane and trimethylsulfonium hydroxide

The alkylation procedures of nucleosides with diazomethane and trimethylsulfonium hydroxide have been proposed at different times, but here we consider them together because these reactions follow similar mechanisms. In addition, both these methods have only a historical significance at present.

Broom and Robins⁴ have synthesised 2'-*O*-methyladenosine by treatment of adenosine with diazomethane in aqueous dimethoxyethane (Table 1) and these results were reproduced by different authors.^{28–35} Later, diazomethane was used for the alkylation of other nucleosides (Cyd, **1a–c**, see Table 1). The reaction with diazoethane proceeds in a similar way,³³ but a mixture of methyl and ethyl derivatives is formed in a ~ 1 : 1 ratio. The formation of methyl ethers is rationalised by solvent participation. Alkylation of 3',5'-di-*O*-tritylarabinouridine (**2**) under similar conditions led to the dialkylation product, viz., 2'-*O*,3-dimethyl-3',5'-di-*O*-tritylarabinouridine.³⁵ With 3-deazaauridine (**1c**), the reaction proceeded selectively with the heterocyclic base (see Table 1).³⁴

The use of trimethylsulfonium hydroxide as an alkylating reagent in the synthesis of 2'-*O*-methylnucleosides was proposed and developed by Kinoshita *et al.* in 1978–1980^{36–38} (Table 2).

Table 2. Alkylation of the 2'-hydroxy group of nucleosides with oxonium derivatives and trimethyl phosphate in DMF at 110 °C.

Cyd	Me ₃ S ⁺ OH [–] (see ^a)	5–10	41

^a The reaction was carried out in DMSO with B(OH)₃ addition at 110 °C.

This alkylating reagent is less reactive than diazomethane; therefore, the reaction is carried out in DMF at 110 °C. The alkylation with trimethylanilinium hydroxide³⁹ and trimethyl phosphate⁴⁰ gave similar results. An attempt to use trimethylsulfonium iodide³⁸ resulted in compounds in which only the heterocyclic base was alkylated. The addition of boric acid to trimethylsulfonium hydroxide also led to the alkylation of heterocyclic bases.⁴¹

The main disadvantage of both methods is their low selectivity, since the alkylation products of both the sugar residue and the heterocyclic base are formed. These possess similar chromatographic mobilities, which impedes separation of the reaction products. The yields of the target products are usually low.

III. Alkylation of nucleosides with methyl iodide in the presence of silver(I) oxide

Historically, the alkylation of nucleosides with methyl iodide in the presence of Ag₂O was the first method for the preparation of 2'-O-methylnucleosides. Furukawa *et al.*⁶ performed the alkylation of 3',5'-di-*O*-trityluridine (**3a**) devoid of protective groups in the heterocyclic base; therefore, the reaction partly involved the uracil residue (Table 3). This method was not further used until the early 1980's when this was rekindled for the alkylation of nucleosides with 3'- and 5'-hydroxy groups blocked by the 1,1,3,3-tetraisopropylidisiloxane-1,3-diyl protective group (TIPDS, the Markiewicz protection) and the protected heterocyclic base (Table 3, compounds **3b–f**, **4a,b**, **5**).

Beigelman *et al.*⁵¹ made an attempt to synthesise 2'-*O*-methylcytidine from 5'-*O*-dimethoxytrityl-3'-*O*-*tert*-butyldimethylsilyl-*N*⁴-isobutyrylcytidine (**4c**), which is an intermediate product in the preparation of building blocks for the oligoribonucleotide synthesis. This attempt was unsuccessful, since the alkylation was accompanied by the 3'→2' migration and partial removal of the silyl protective group; 2',3'-di-*O*-methylcytidine

and 3'-*O*-methylcytidine were formed as side products. Hodge and Sinha⁵² have synthesised 2'-*O*-methyl-, -ethyl-, -allyl-, -propyl and -pentyl nucleoside derivatives **4d,f** (the reaction was carried out in the presence of 0.1–0.2 equiv. of pyridine). The yields of 2'-*O*-alkynucleosides decreased with an increase in the size of the alkyl group but remained at a sufficiently high level. Special mention should be made of the fact that this approach is suitable for large-scale (tens of grams) syntheses (see Table 3, compound **4d**).⁵²

Today, the alkylation with methyl iodide in the presence of silver(I) oxide has proved to be a fairly efficient approach to the synthesis of pyrimidine 2'-*O*-alkynucleosides. At the same time, it is seldom used for the synthesis of purine derivatives. It is of note that the methylation of partially protected 2-thiouridine (**6**)⁵³ gave a complex mixture, which may be due to the interaction of Ag₂O with the thioketone group and subsequent alkylation of the heterocyclic base.

IV. Alkylation of nucleosides in the presence of bases

1. The use of alkali metal hydroxides

There are two approaches to the alkylation of nucleosides in the presence of alkali metal hydroxides: the reaction may be carried out in non-aqueous or in aqueous media.

In the mid-1960's, Reese *et al.*⁵ performed the alkylation of 3',5'-di-*O*-trityluridine (**3a**) with benzyl chloride in the presence of potassium hydroxide in dry dioxane, which resulted in protected 2'-*O*-benzyluridine (**7**) (Table 4).

Note: Hereinafter, Ura is the uracil residue, Cyt is the cytosine residue, Ade is the adenine residue. ^a The yield over two steps (alkylation and detritylation) is indicated; ^b the yield over two steps (protection of 5'- and 3'-hydroxy groups and alkylation) is indicated.

The advantage of this method is that the heterocyclic base is not alkylated; however, the yields of the steps of the synthesis of the starting compound (3',5'-di-*O*-trityluridine) do not exceed 30%–45%. Later, in the 1990's, the alkylation was performed with more complex alkyl halides.^{54, 55}

In the early 1970's, it was proposed⁵⁶ to use dialkyl sulfates as alkylating reagents in the presence of alkali metal hydroxides in aqueous media (see Table 4, compounds **8**, **9**). It was shown⁵⁶ that at pH > 13, no alkylation of the heterocyclic base occurs. The alkylation of adenosine and cytidine 3',5'-cyclophosphates (**10a**, **b**) with alkyl halides in water–organic media has been described.⁶³ No side alkylation products at the 5'- and 3'-hydroxy groups were formed, which resulted in higher yields and facilitated the chromatographic isolation of the reaction products.

As can be seen from Table 4, the alkylation of the nucleoside **3a** in non-aqueous media gives fairly good yields even in the case of rather complex alkyl halides, but drastic reaction conditions significantly restrict the use of this method. Alkylation by dialkyl sulfates and alkyl iodides in aqueous and water–organic media proceeds as a rule with low yields and is of low practical value.

2. The use of organic bases

Alkylation of nucleosides in the presence of organic bases was first proposed by Sproat *et al.*^{64–70} (Table 5). The alkylation of

partially protected nucleosides with alkyl halides was carried out in the presence of 2-*tert*-butylimino-2-diethylamino-1,3-dimethylperhydro-1,3,2-diazaphosphorine (BDDDP) (see Ref. 71). This reaction and subsequent extraction are not accompanied by the formation of hydroxides; therefore, the protective groups of heterocyclic bases are preserved. It is of note that in addition to the known groups, *e.g.*, compounds **11a**, **b**, **d**, **12**, novel protective groups were introduced, *viz.*, the pivaloyloxymethyl group (compound **13**) for the protection of the N³-position of uracil and the *tert*-butyldiphenylsilyl group (compound **11c**) for the blocking of the O⁶-position of guanine (see Table 5). The pivaloyloxymethyl protective group is more stable than the conventional benzoyl group. In addition, the N³-pivaloyloxymethyl derivative **13** is obtained in a higher yield than the N³-benzoyl derivative. The use of the *tert*-butyldiphenylsilyl protective group made it possible to increase the total yield and to reduce the number of steps in the synthesis of 2'-*O*-propargylguanosine, since the 3'- and 5'-hydroxy groups and the O⁶ atom of the heterocycle are deprotected simultaneously under the action of tetrabutylammonium fluoride.⁶⁴

The alkylation of compound **14a** was accompanied by a side reaction at the exocyclic amino group; compound **14b** did not undergo alkylation under these conditions.⁶⁴

Note. The yield of compound **11c** is indicated over two steps (alkylation and desilylation). Hereinafter, TBDPS is Bu^tPh₂Si; ^a the yields over two steps (alkylation and reduction of the crotyl residue to the butyl residue) are indicated.

R¹ = NH₂, R² = Ph₂NCO₂ (**a**); R¹ = PrⁱCONH, R² = Ph₂NCO₂ (**b**).

It was also shown⁶⁴ that the introduction of the carbamoyl protective group at the exocyclic N² atom of guanosine decelerates the alkylation reaction and strongly decreases the yields.

Nearly all the works from Sproat's laboratory are methodologically flawless: as a rule, all reactions proceed with high yields and result in the formation of single products. The syntheses are multistep, but the total yields are rather high. The main disadvantage of this method is the high cost of BDDDP; therefore, the preparation of compounds in gram quantities using this method is hardly possible. These works are also interesting with respect to

the application of novel protective groups for the heterocyclic bases.

3. The use of alkali metal hydrides

With alkali metal hydrides as the bases, the alkylation may be carried out with both the unprotected and the partially protected nucleoside. In the former case, the selectivity of the reaction involving the 2'-hydroxy group is due to its higher acidity in comparison with the 3'- and particularly the 5'-hydroxy group.⁷² Nevertheless, this is accompanied by the formation of side products including the 3'-isomer with similar chromatographic mobilities; therefore, protected adenosine derivatives are sometimes used (Table 6). In the case of other (especially, pyrimidine) nucleosides, the alkylation partly involves the heterocyclic base. The use of alkali metal hydrides as the bases demands careful selection of protective groups, since some of them are unstable under the reaction conditions. In addition, post-synthetic workup results in the formation of alkali metal hydroxides, which precludes the application of certain standard protective groups. Nevertheless, at present this approach is one of the most popular ones.

The method proposed by Robins *et al.*³² back in 1966 and recently employed by Yano *et al.*⁷³ in which 2-amino-6-chloro-

Note. ^a Abbreviations: Im, imidazolyl, Phth, phthaloyl; ^b The yield for a three-step synthesis (protection of the heterocyclic base, dimethoxytritylation, alkylation) is indicated; ^c the yield of a mixture of 2'- and 3'-isomers is indicated; ^d the yield over two steps (Markiewicz protection and alkylation) is indicated; ^e the total yield over two steps is indicated; ^f the yield over two steps (alkylation and desilylation) is indicated; ^g the yield of 2'-*O*-benzyl-3',5'-di-*O*-trityl-3-benzyluridine is indicated.

purine riboside was used as the starting compound seems to be a very promising approach to the large-scale synthesis of 2'-*O*-alkylguanosine derivatives. The total yield of alkylation and hydrolysis to 2'-*O*-alkylguanosine is ~ 45%; the use of expensive reagents is avoided.

V. Preparation of 2'-*O*-alklynucleosides by glycosylation of heterocyclic bases

The data on the synthesis of 2'-*O*-alklynucleosides by glycosylation of heterocyclic bases are summarised in Tables 7 and 8. This involves two steps, *viz.*, the alkylation of a partially protected carbohydrate and the glycosylation itself. In some cases, the alkylation of the 2-hydroxy group of the carbohydrate **A** is followed by a series of transformations in order to obtain the glycosyl donor **B**.

B^{TMS} is a silylated heterocyclic base;

$X^1, X^2, Y^1, Y^2, Z^1, Z^2$ are protective groups.

The synthesis of 2'-*O*-alklynucleosides by glycosylation of heterocyclic bases was proposed in the early 1970's by Haines.¹⁰⁹ 2'-*O*-Methyluridine was synthesised starting from the partially protected β -D-ribofuranoside **15**, the total yield being as low as 5%.

In the early 1980's, Imbach *et al.*^{110, 111} performed the synthesis of pyrimidine 2'-*O*-methylnucleosides (total yield 50% – 55%) starting from the accessible 1,3,5-tri-*O*-benzoyl- β -D-ribofuranose (**16**). Later, this approach was used by Cook *et al.*¹¹² for the synthesis of 2'-*O*-methyluridines containing various substituents at C⁵. The use of $CF_3SO_3SiMe_3$ instead of $SnCl_4$ as a glycosylation catalyst made it possible to increase the yields of target nucleosides in some cases (see Table 8).

Keller and Haner¹¹³ carried out the alkylation of the partially protected β -D-ribofuranoside (**17**) with *tert*-butyl bromoacetate in the presence of sodium hydroxide under conditions of phase-transfer catalysis. The desilylation with methanol and sulfuric acid was accompanied by transesterification of the *tert*-butyl ester and partial anomerisation. The glycosylation of thymine and adenine derivatives was stereoselective, the total yield was 15%.

Parmentier *et al.*¹¹⁴ have succeeded in obtaining methyl 2-*O*-methyl-D-ribofuranoside in four steps without the isolation of intermediate products (yield ~ 75%). If the intermediate products had to be isolated in each step, the total yield decreased to 8%.

Cook *et al.*^{78, 79} have performed the alkylation of the partially protected methyl β -D-ribose (**19**) (see Table 7) with ethyl bromoacetate. Subsequent glycosylation according to Vorbrüggen¹²¹ gave the target nucleoside (see Table 8).

Table 7. Synthesis of protected 2-*O*-alkylcarbohydrates as precursors of 2'-*O*-alklynucleosides.

Both anomers of 1-*N*-(2-*O*-methyl-D-arabinofuranosyl)thymine were prepared from the blocked carbohydrate **20** by Gotfredsen *et al.*^{117, 118} (see Table 7). It should be noted that no alkylation of the α -anomer of the monosaccharide derivative occurred in the presence of sodium hydride, whereas the yield of the alkylation product in the presence of BDDDP was only 42%. In the case of the β -anomer, the reaction with sodium hydride as a base was virtually quantitative.

In 1994, Chanteloup *et al.*¹¹⁹ published a paper, which described conversion of compound **21** into the *O*-trichloroacetimidate **22**. The latter served as a stereoselective and a high-

yielding donor (see Table 8). The total yield was 35%–45%. Later, the glycosylation of compound **22** was studied in more detail.¹²⁰ It is known¹²² that glycosylation with β -D-ribofuranose *O*-trichloroacetimidates follows the S_N2 mechanism with inversion of configuration of the C¹ atom. This suggests that the synthesis of the target β -nucleoside requires the α -anomer of the *O*-trichloroacetimidate. However, the thermodynamically and kinetically more stable β -anomer [yields 39% (α : β = 7:93) and 77% (α : β = 1:99), respectively] is predominantly formed in the presence of NaH and DBU (diazabicycloundecene). The α -anomer was predominantly formed only with K₂CO₃ as the base (total yield 71%, α : β = 93:7). Hence, this approach can be used for the synthesis of both α - and β -nucleosides.

An elegant synthesis of 2'-*O*-alkynucleosides **23** and **24** (total yields 35%–40%) from the commercially available allofuranose derivative **18** has been described (Scheme 1).^{51, 116}

Although glycosylation is rather tedious and is seldom used, it is appropriate for the synthesis of 2'-*O*-alkylated ribothymidine^{78, 79, 112, 113, 118–120} and large-scale syntheses of modified 2'-*O*-alkynucleosides.

Glycosylation is the limiting step. It often proceeds non-stereoselectively and yields a mixture of α - and β -anomers. In addition, it strongly depends on the nature of the substituent at the C(2') atom and does not always give satisfactory yields of target products in the case of purine bases.

VI. Alkylation of the activated *cis*-diol group of nucleosides in the presence of transition metal compounds

In the alkylation of the *cis*-diol group of nucleosides with alkyl halides or diazoalkanes in the presence of transition metal compounds (Tables 9–11), the transition metal is activated due to complex formation. In this case, the reaction may be carried out with nucleosides with non-protected 2'- and 3'-hydroxy groups. The main advantage of this approach is that the reaction proceeds in the absence of a base, which eliminates the necessity to protect the imino groups of the heterocyclic bases and functional groups of alkyl halides. However, the alkylation by this method yields considerable amounts of 3'-isomers which are hardly separable from the target 2'-*O*-alkynucleosides owing to their similar chromatographic mobilities. In some cases, the isomeric mixture can be separated by crystallisation; more often, the modified nucleoside is first subjected to 5'-*O*-dimethoxytritylation and then to chromatography. The best ratio of the 2'- and 3'-isomers was achieved by alkylation of nucleosides in the presence of tin chloride^{123–134} (see Table 9). In this reaction, it is the tin derivative **A** initially formed that undergoes alkylation.

B = Ura.

B = Ura, Cyt^{Ac}, Ade^{Bz}, Gua^{PheAc}.

(a) SnCl₂; (b) RCHN₂ or MeI.

Yet another alkylation procedure in the presence of tin derivatives was proposed by Wagner *et al.*¹³⁵ The starting compound is treated consecutively with dibutyltin dichloride and dibutyltin oxide and alkyl halide with 2',3'-*O*-dibutylstannylene nucleosides **B** as intermediates. Later, this method was used for

tested,^{131, 146} but the degree of conversion in the alkylation and the ratio of the 2'- and 3'-isomers could not be increased.

It should be noted that sometimes the alkylation of the *cis*-diol group in the presence of cesium fluoride¹⁴⁷ affords larger amounts of the 2'-isomer. However, the addition of CsF in the alkylation of 2',3'-*O*-dibutylstannylene-*N*³-benzoyluridine slightly increased the selectivity, but the total yield of the reaction products decreased^{144, 145} (see Table 10).

The methylation of nucleosides with trimethylsulfonium hydroxide in the presence of transition metal acetylacetonates (Cu, Co, Zn, *etc.*) (see Table 11) is less popular.^{148, 149}

acac is the acetylacetonate residue, M is the transition metal.

This approach eliminates the alkylation of heterocyclic bases (except for uracil) and provides high yields in certain cases. Later, it was shown⁹¹ that the maximum selectivity of nucleoside alkylation is achieved in the presence of silver acetylacetonates (for protected guanosine), strontium acetylacetonate (for adenosine) and magnesium acetylacetonate (for cytidine and protected uridine).¹⁴⁹ Nevertheless, this procedure is hardly suitable for the introduction of other alkyl groups into nucleosides.

VII. Synthesis of pyrimidine 2'-*O*-alkynucleosides from O²,2'-anhydronucleosides

In addition to direct alkylation of ribonucleosides, pyrimidine 2'-*O*-alkynucleosides are synthesised starting from O²,2'-anhydronucleosides. This approach is attractive because the synthesis of the anhydronucleoside results in both the activation of the C(2') atom and elimination of the possibility of the reaction of the N³ atom of the heterocyclic base.

The synthesis of the now commercially available O²,2'-anhydrouridine and its derivatives is performed using different methods.^{150, 151} Most often, this involves heating of uridine and its derivatives with diphenyl carbonate in the presence of sodium hydrogen carbonate as base. The O²,2'-anhydrouridine deriva-

tives **25** are easily purified by recrystallisation; the yields are ~ 90% (Table 12).

X is H or protective groups; R = H, Me.

It has been shown¹⁵² that no alkoxylation of nucleosides with magnesium alkoxides occurs in the presence of blocked 3'-hydroxy groups, presumably due to the necessity of its involvement in the coordination of magnesium. Similar conclusions were made by Ross *et al.*¹⁵⁴ for the alkoxylation with trialkyl borates. It is suggested that if magnesium alkoxides are used, the 5'-hydroxy group was protected with the dimethoxytrityl group. Later,¹⁵³ the alkoxylation of anhydrouridine containing a non-protected 5'-hydroxy group with magnesium methoxide was carried out under similar conditions. If aluminium alkoxides and trialkyl borates are used, the alkoxylation at the C(2') atom occurs with a free 5'-hydroxy group.^{154, 157} Blommers *et al.*¹⁵⁸ did not synthesise alkoxides beforehand, but carried out a reaction with an alcohol in the presence of tetra(isopropoxy)titanium.

The alkoxylation of O²,2'-anhydrouridine with trimethyl borate was successfully employed by other authors.^{91, 159} Besides, the 2'-*O*-methylated product was obtained by the reaction of the fluorescent uridine analogue 1-(β-D-ribofuranosyl)-2,2'-anhydrobenzo[*g*]quinazoline-2,4(3*H*)-dione **26** with a twofold excess of (MeO)₃B [(MeO)₃CH, NaHCO₃, MeOH].¹⁶⁰

VIII. Other methods for the synthesis of 2'-O-alkynucleosides

A modified procedure for a two-step methylation of nucleosides involving alkylation with 1,3-benzodithiolium tetrafluoroborate and subsequent reduction of the intermediate product **27** over Raney nickel was proposed by Sekine *et al.*¹⁶¹ This excludes the necessity of protecting the heterocyclic base and the amino groups additionally introduced into the heterocycle, but the overall yield is only 35%–45%.

R = H, CH₂N(Bn)CH₂CO₂Et.

Sproat *et al.*¹⁶² have succeeded in developing an efficient procedure for the synthesis of 2'-O-alkynucleosides by alkylating nucleosides with 3'- and 5'-hydroxy groups protected (the Markiewicz protective group) with allyl ethyl carbonate in the presence of a Pd(0) complex. A 2,5-dichlorobenzyl protective group was used to protect the OH group of the heterocycles.⁶⁶ The degree of conversion in the allylation of compounds **11a,b** and **12**¹⁶³ was 90% in 30 min and no side products were formed. However, this reaction can only be used for the synthesis of allyl ethers, since it proceeds *via* the intermediate allylpalladium(0) complexes. Later, this approach was used by Froehler *et al.*¹⁶⁴ for the preparation of 2'-O-allyl derivatives of 5-(propyn-1-yl)uridine and 5-(propyn-1-yl)cytidine.

Sproat *et al.*¹⁶⁵ have designed novel protective groups for heterocyclic bases which made it possible to reduce the number of steps in the synthesis of the 2'-O-allyl derivatives **28a–c** and to increase the overall yields of the target products, especially, in the case of the guanosine derivative **28a**.

Direct allylation of the TIPDS-protected cytidine and adenosine derivatives (**29b,c**) is also possible, whereas earlier alkylation of uridine and inosine derivatives followed by transamination had to be performed.

A similar allylation procedure in which tetrakis(triphenylphosphine)palladium was used as a catalyst was proposed by Kumar *et al.*¹⁶⁶ This procedure allowed the alkylation of nucleosides bearing only the 5'-hydroxy protected group. With a 2.5-fold excess of allyl ethyl carbonate, the yields of the target allylation products of 5'-O-dimethoxytrityluridine and 5'-O-dimethoxytrityl-N⁴-benzoylcytidine were ~60%, whereas in the case of the stoichiometric ratio of the reactants the reaction involved predominantly the heterocyclic base (90%).

Subsequent modification of the allyl derivatives leading to the introduction of the aldehyde groups was repeatedly employed in different laboratories.^{167–170}

The alkylation of compounds **30** with dimethyl sulfide in the presence of dibenzoyl peroxide (yield 55%–70%) has been carried out.^{171,172} Later,¹⁷³ compounds **31** were prepared by the reaction with DMSO and acetic anhydride in the presence of acetic acid.

B = Ura, Cyt^{Bz}, Ade^{PhOAc}, Gua^{Buⁱ}.

(a) Me₂S, Bz₂O₂, 2,6-lutidine; (b) DMSO, Ac₂O, AcOH.

This approach was used⁵¹ in a two-step synthesis of the 2'-O-methyluridine derivative **32** by alkylation of compound **33** with methyl phenyl sulfide and subsequent desulfurisation.

(a) MeSPh, Bz₂O₂, dimethylaminopyridine; (b) Bu₃SnH, Bz₂O₂.

Matsuda *et al.*¹⁷⁴ have synthesised 2'-O-trifluoromethyladenosine **34** *via* the intermediate 2'-methyl xanthate **35**.

(a) BuLi, CS₂, -78 °C; (b) MeI, -78 °C; (c) BzCl, Py;

(d) HF, Py, 1,3-dibromo-5,5-dimethylhydantoin.

The yield calculated over two steps was as low as 24% due to the formation of side products and partial removal of the Markiewicz protective group under the reaction conditions.

IX. Conclusion

The data considered above suggest that currently the methods for the synthesis of 2'-O-alkylnucleosides are well-developed, especially for the simplest representatives of this type of modified nucleoside, viz., 2'-O-methylnucleosides. Presumably, the main application of 2'-O-alkylnucleosides consists in their incorporation into oligonucleotides. The majority of modified oligonucleotides prepared from 2'-O-alkylnucleosides meet the major requirement, viz., the ability to form stable duplexes with the complementary regions of nucleic acids.

At present, the synthesis of 2'-O-alkylnucleosides is performed using two ideologically different approaches. One of them entails the maximum protection of all reactive centres of the molecule and, as a consequence, involves many steps. The other, in contrast, is aimed at the reduction of steps, which inevitably results in side reactions and, correspondingly, complicates the chromatographic separation of the reaction mixture. It should be noted that the total yield of the target product in the former approach is higher, as a rule. The advantage of the latter approach consists in the reduction of the time and cost of the synthesis.

Currently, the methods of nucleoside alkylation with diazomethane and trimethylsulfonium hydroxide, as well as with dialkyl sulfates in aqueous media, have only a historical significance. The most efficient procedure for the preparation of pyrimidine 2'-O-alkylnucleosides is the synthesis via O²,2'-anhydronucleosides and treatment with alkyl iodides in the presence of silver(I) oxide.⁴³ The alkylation of pyrimidine nucleosides with alkyl halides in the presence of transition metal derivatives can be recommended only for those cases where the reactants contain groups sensitive to strong bases, since this procedure yields a large amount of the 3'-isomer.

Alkylation in the presence of alkali metal hydrides is the method of choice for adenosine and its derivatives. It is of note that this method excludes the protection of 3'- and 5'-hydroxy groups as well as the functional groups of the heterocyclic base.

The use of cyclic sulfates as alkylating reagents is especially attractive, since the alkylation product can be subjected to further nucleophilic substitution.^{91, 92}

The alkylation of uridine and thymidine in the presence of alkali metal hydrides affords considerable amounts of the 3'-isomers. Therefore, the 3'- and 5'-hydroxy groups as well as the heterocyclic base should be protected. If this approach is chosen, 2'-O-alkylcytidine is prepared preferably by transamination of 2'-O-alkyluridine.

The optimum procedure for the synthesis of 2'-O-alkylguanosine and its derivatives proposed by Sproat *et al.*⁶⁴ is rather costly and cost reduction is hardly possible. The alkylation of 9-(β-D-ribofuranosyl)-6-chloro-2-aminopurine and subsequent conversion of the reaction product into guanosine derivatives is a promising alternative to this method.⁹¹ However, the conditions of this reaction were not optimised and the possibility of its

application in large-scale syntheses was not investigated. The use of transglycosylation is another promising approach;⁹¹ however, this reaction is extremely sensitive to both the structure of the aglycon and the substituent at the C(2') atom of the carbohydrate fragment and will hardly ever be used as a versatile procedure.

VII. Conclusion	558

Abstract. The thermodynamic studies of fullerenes and their stable derivatives, namely, endohedral metallofullerenes and exohedral fullerene fluorides, are generalised. The methods of synthesis and purification of fullerene fluorides are considered and the structures of these compounds are characterised. The thermodynamic properties of fullerenes and fullerene fluorides are discussed. The bibliography includes 150 references.

I. Introduction

In 1985, it was established experimentally that carbon, one of the most abundant elements in the Earth, can form stable cage structures consisting of 60 or more atoms.¹ This new allotropic form of carbon was termed 'fullerene.' The discovery of fullerenes was recognised as a remarkable and one of the most important events in science of the XX Century. In 1990, methods for the preparation of macroscopic quantities of fullerenes were developed² and methods for their isolation and purification were found.³ In addition, important structural and physicochemical characteristics of C₆₀ fullerene, which is the most frequently encountered representative of this class of compound, were determined. Currently, the total number of publications dealing with fullerenes exceeds 10 000, and the 'fullerene rush' has embraced fields of knowledge that seem to be far from one another such as astronomy and organic chemistry, solid-state physics and medical biology, inorganic chemistry and geology. Fullerenes can be classified as both inorganic materials (a new allotropic modification of carbon) and organic compounds because they exhibit many properties of unsaturated hydrocarbons in chemical transformations. More recently, unique possibilities of chemical modification of fullerenes have been found, including the addition of various functional groups at the double bonds to give exo derivatives, in particular, complexes with transition metals; insertion of atoms and whole clusters inside the carbon sphere (endo

derivatives) and replacement of some carbon atoms by heteroatoms (heterofullerenes).

It is impossible to cover all the results obtained during the last 10 years within the framework of one review. The purpose of this review is to shed light on some lines of research that have developed successfully in the chemistry of fullerenes and their endo metal and fluoro derivatives. The structure of this review corresponds to the chronological sequence of investigations. For example, in the early stages, especially in the experiments leading to the discovery of fullerenes, the crucial role was played by mass spectrometry. Therefore, the review begins with a description of mass-spectrometric studies dealing with determination of the fundamental characteristics of higher fullerenes and endohedral metal fullerenes such as ionisation energy and electron affinity.

The next important stage — fullerene functionalisation — is reflected by a series of works dealing with the synthesis of fluorinated derivatives. Primary attention is devoted to selective synthesis of individual compounds, which has required modification of traditional or development of new methods. The use of HPLC for separation and purification of fullerenes is described. Chromatographic studies in which the authors succeeded in isolating geometric isomers of individual fluorofullerenes are specially noted.

Systematic research into the physicochemical properties of fullerenes and their derivatives became possible only after thorough development of methods for the synthesis and purification of macroscopic quantities of these compounds. Study of fluorofullerenes by NMR spectroscopy and X-ray diffraction analysis revealed that the addition of fluorine atoms to the fullerene carbon atoms with formation of strong valence bonds results in a pronounced deformation of the carbon cage. This is illustrated taking the structures of flattened, squashed and indented fluorofullerenes as examples. The thermodynamic properties of fullerenes and their fluoro derivatives are discussed and the possible applications of fluorofullerenes are considered.

II. Ions and molecules of fullerenes and their derivatives in the gas phase

Electron affinity (*EA*) and ionisation energy (*IE*) are fundamental characteristics of molecules. For C₆₀ ([60]fullerene), the *EA* and *IE* values are equal to 2.667 ± 0.001 eV (see Ref. 4) and 7.57 ± 0.01 eV (see Ref. 5), respectively. This *EA* value is substantially higher than these values for most aromatic compounds, indicating a fairly high electron-withdrawing capacity of fullerene molecules.

Received 10 October 2001

Uspekhi Khimii 71 (7) 611–640 (2002); translated by Z P Bobkova

The combination of rather high electron affinity with low ionisation energy (for comparison, for the benzene molecule, IE is 9.24 eV and EA is negative), which is seldom encountered in chemistry, indicates that fullerene molecules can act as both electron donors and electron acceptors in chemical processes. The data concerning other representatives of this class of compound, so-called higher fullerenes, C_{2n} ($n > 30$), some of which can also be prepared in macroquantities, showed that they differ substantially in their properties from [60]fullerene. These differences are manifested, first of all, in fundamental characteristics such as ionisation energy and electron affinity.

Experimental research of negative ions in the gas phase has been actively carried out since the 1970s. One experimental method used successfully to determine ions of non-volatile inorganic compounds was called 'the method of ion-molecular equilibria' (IME).⁶ This method is based on either the classical effusion technique with mass-spectroscopic detection of vaporisation products or high-temperature mass-spectrometry (Knudsen Cell Mass Spectrometry, KCMS), which is used to assess the contents of neutral species. The improved KCMS–IME procedure allows one to detect charged species present in the saturated vapour of inorganic compounds. To obtain measurable concentrations of ions in the vapours of inorganic compounds, salts such as $KAlF_4$ characterised by a low energy of heterolytic dissociation into ions, are added. Even at 1000 K, the vapours of these salts contain such high amounts of cations and anions that the Debye shielding radius becomes smaller than the effusion cell dimensions and, consequently, electron-free plasma is formed. The pressure of neutral species remains 5 to 7 orders of magnitude higher than the ion pressure.⁶ The addition of these salts to other inorganic compounds whose vapours do not contain measurable concentrations of ions results in systems with large amounts of ion-molecular associates. In particular, the addition of KF to the $Pt-MnF_3$ system gave rise to a set of negative ions including PtF_4^- and PtF_6^- and enabled the first direct experimental measurements of the EA values of platinum tetra- and hexafluorides.⁷ Subsequently, a series of studies dealing with the determination of the electron affinities of transition metal oxides and fluorides have been carried out.⁸ For several years, the authors of the review⁸ attempted to extend this method to organic compounds (in particular, compounds containing electronegative substituents and having high thermal stability, for example, perfluorinated derivatives) but were unable even to detect thermal anions (*i.e.*, those resulting from thermal ionisation). Therefore, when publications appeared pointing to unique properties of fullerenes⁹ and data on their thermal stability were obtained,^{10,11} it became clear that the use of the IME method to study compounds of this class may prove successful. The first publication opening a series of IME experiments aimed at determining the electron affinity and ionisation energy of fullerenes appeared in 1993.¹² The description of the IME method as applied to fullerenes has been reported in detail.¹² Here, we shall only consider several key procedural points and the most important results.

1. Procedure for the measurement of equilibrium constants of ion–molecule reactions and the proof of thermodynamic equilibration

The first task to be accomplished by experimentalists was to generate thermal negative ions in the fullerene vapour under equilibrium conditions and within temperature limits where fullerenes are still thermally stable. Of numerous experimental parameters, the electron work function of the metal surface is the most significant, because the efficiency of thermal ionisation resulting in the generation of ions largely depends on the properties of the surface where thermal ionisation takes place. In the IME method, this is the internal surface of the Knudsen effusion cell the work function for which can vary over a broad range. For example, the addition of alkali metals and their compounds to the cell decreases, while fluorination of the walls increases the electron work function for the internal surface of the effusion cell. Practi-

cally, it was possible to control the work function in the 4–6.5 eV range.^{13,14} The EA and IE values of fullerenes were found to be at the boundaries of this range. This opened up broad and unique opportunities for the generation of both positive and negative thermal ions of fullerenes and initiated an extensive series of studies involving fullerene gas-phase ions.

In the KCMS–IME analysis of charged species, the technique of relative measurements is widely used; this implies measurement of the equilibrium constants of isomolecular reactions with participation of a reference species (B), whose thermochemical characteristics have been reliably established

where ΔH_0° is the standard enthalpy of the reaction at 0 K, and EA and FA are the electron and fluoride-ion affinities, respectively.

The reference should have a volatility close to that of the specimen under study, and the absolute magnitude of the enthalpy of reactions (1) and (2) should not exceed 100 kJ mol⁻¹. Thus, the thermochemical characteristics of the reference should be similar to those of compound A under study determined in the reaction. When investigating the negative ions of fullerenes, the addition of alkali metal compounds was used to lower the work function. When working with cations, iron trifluoride was added to increase the electron work function of the internal surface of the nickel effusion cell.¹⁴

Yet another difficulty arising in the production of measurable concentrations of ions in fullerene vapours lies in the fact that the temperature of thermal ionisation of fullerenes does not coincide with their sublimation point. To attain the required degree of ionisation, the vapour should, most often, be superheated. It was proposed to use double effusion cells of 'Russian matreshka' type (Fig. 1). The more volatile substance (fullerene) was placed in the smaller cell and an inorganic fluoride was put in the larger one. By controlling the relative sizes of the effusion orifices in the internal and external cells, it was possible to desaturate the vapour of the volatile component by a factor of 7–10, so it became possible to raise the temperature without violating the conditions of molecular effusion from the orifice of the external cell.¹³ The experimental setup permitted the ratios of the partial pressures of both neutral and charged components of the vapour to be measured consecutively within one experiment. The neutral species were measured by recording the ion currents resulting from the electron impact on the molecular beam coming from the effusion cell. Then the ratio of partial pressures (p) was calculated using the equation relating the ion currents to the partial pressures of neutral species

$$\frac{p_A}{p_B} = \frac{I_A}{I_B} \frac{\sigma_B}{\sigma_A},$$

where I is the ion current intensity; σ the full ionisation section of the molecule.

Figure 1. Effusion cell of the 'Russian matreshka' type: (1) internal cell with the fullerene; (2) external cell with the metal fluoride.¹³

The partial pressures of charged species were measured by recording the ion currents generated upon direct drawing of thermal ions out of the effusion cell by an electric field. The ratios of the pressures of thermal anions were calculated from the equation

$$\frac{p_{A^-}}{p_{B^-}} = \frac{I_{A^-}}{I_{B^-}} \frac{\sqrt{M_{A^-}}}{\sqrt{M_{B^-}}},$$

where M is the molecular mass. This gave the equilibrium constants of the ion–molecule reactions.

Particular attention was devoted to verification of the thermodynamic equilibration. For this purpose, the composition of the gas phase was varied over a broad range and the equilibrium constants were measured. At equilibrium, the constants determined for the same temperature should remain invariable, no matter how the partial pressures of the reactants (or products) may change.

The experimental data^{12,15} obtained for the reaction

indicate that even upon a change in the $C_{60}:C_{70}$ ratio by two orders of magnitude, the equilibrium constant remains invariant to within the experimental error (Table 1). Similar verifications of

the thermodynamic equilibration by varying the composition of the reaction mixtures have also been carried out for other reactions, in particular, for electron exchange in the vapours of higher fullerenes and for fluorine exchange. Conversely, it was found that in ionic and molecular reactions involving rearrangement of the fullerene carbon skeleton

no equilibrium is established, and the number of components in a mixture of higher fullerenes is determined as the number of substances.

2. Electron affinity, ionisation energy and electronegativity of higher fullerenes

Owing to the use of the KCMS–IME procedure, in addition to the frequently encountered C_{70} , C_{76} , C_{78} and C_{84} fullerenes, it was also possible to study other fullerenes¹⁵ present in the specimens in minor amounts (the dynamic range of measurable concentrations reaches eight orders of magnitude), up to C_{106} fullerene, which have not been isolated in a pure state. Due to the high sensitivity together with the capacity of mass-spectrometric analysis of the components, the KCMS–IME procedure is superior over traditional spectroscopic methods used to determine the EA and IE values, although the latter are, in principle, more accurate. An EA value for C_{60} fullerene found by the photodetachment method has been reported.⁹ The first experimental EA value for C_{70} fullerene was reported by Boltalina *et al.*;¹² later, this value was estimated from the photodetachment threshold of an electron from the C_{70}^- anions, which were preliminarily cooled upon collisions with helium atoms in an ASTRID storage ring.⁴ The resulting vertical electron affinity of C_{70} fullerene (2.68 eV) proved to be somewhat lower than the value (2.73 eV) determined from the KCMS–IME measurement of the electron exchange enthalpy, which is the adiabatic EA value.¹⁵ Note that the last-mentioned result is in good agreement with the results of measurements of the relative ion mobility of C_{60} and C_{70} in non-polar solvents¹⁶ and also with the EA estimates from the reduction electrochemical potentials of C_{60} and C_{70} , which also refer to the adiabatic electron affinity.¹⁷ Experimental data on the EA of higher fullerenes have been obtained only using the KCMS–IME procedure.¹⁵ Theoretical calculations^{18,19} have been carried out only for C_{74} – C_{84} molecules.

Particular attention should be paid to studies devoted to determination of isomer compositions of mixtures of higher fullerenes and to assignment of the experimental ionisation characteristics to the molecules of particular geometric isomers. According to published data, only for several fullerenes (C_{78} – C_{92}), was the isomer composition determined sufficiently reliably by analysing the structures of individual compounds obtained by chromatographic separation and by using NMR spectroscopy. Thus it was found that C_{76} fullerene forms only one isomer, C_{78} has two major isomers, and for C_{84} , seven geometric isomers have been found, the isomers with D_{2d} and D_2 symmetry being the most widespread;²⁰ the calculated EA values for these two isomers virtually coincide.

Curious observations have been made for C_{72} and C_{74} fullerenes, which fall out of the general series of C_{2n} fullerene homologues, first of all, due to the fact that they have not yet been isolated as individual compounds from typical fullerene extracts. It can be seen from the dependence of the EA on the fullerene size (Fig. 2, curve 2) that the values for the C_{72} and C_{74} molecules are abnormally high, which violates the monotonic pattern of EA variation. The diagram of the energy levels of molecular orbitals (MO) of C_{74} fullerene (Fig. 3)²¹ indicates that the energy difference between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO), which allows one to judge the relative kinetic stability of a molecule, is very small and equals only 0.05 eV, whereas for C_{60} , this difference is 1.6 eV. This finding is in line with the fact that C_{74} fullerene, which is present in perceptible amounts in soot, is lost almost entirely during subsequent extraction with organic solvents (apparently, due to degradation or polymerisation and transition into an insoluble form). Only recently, two research groups in the USA²¹ and China²² proposed procedures for the synthesis and isolation of C_{74} fullerene; however, this compound has not yet been isolated in a pure state or characterised by spectroscopic methods.

Comparison of the experimental EA values for C_{72} fullerene with the theoretical values for the single isomer that obeys the rule of isolated pentagons and for isomers in which this rule is violated

Figure 2. Ionisation energy (1), electron affinity (2) and their half-sum (Mulliken electronegativity) (3) vs. the number of carbon atoms (n) in the fullerene molecule.¹⁴

Figure 3. Diagram of the MO energy levels for the C_{74} molecule (the D_{3h} group of symmetry) calculated by the BLYP/6-31G*/3-21G* procedure. The numerals at the energy levels are energies (in eV).²¹

showed that the best agreement between the experimental and theoretical results is attained for the molecule with C_{2v} symmetry, which contains both isolated and conjugated five-membered rings.²³

Later, thermal cations in the vapours of higher fullerenes have been studied,¹⁴ and for a series of C_{2n} molecules, the equilibrium constants for the reaction

where $n = 35-53$, were measured. The resulting EA and IE values for the higher fullerenes and the corresponding electronegativity values are shown in Fig. 2.

The simple physical model in which fullerene is considered as a rigid conducting sphere¹⁴ makes it possible to derive an equation that relates the electron affinity and the ionisation energy to the radius of a sphere (R_N)

$$EA = \varphi_\infty - 0.5R_N^{-1},$$

$$IE = \varphi_\infty + 0.5R_N^{-1},$$

where φ_∞ is the electron work function of a graphite monolayer, which is the limiting value for both the EA and the IE as the size of the fullerene molecule tends to infinity; a theoretical estimate of this value gives 5.37 eV. The effective sphere radius R_N is proportional to the square root of its mass, because the surface area of the molecule is proportional to the number of carbon atoms located on it. The appropriate proportionality coefficients can be found using the known geometric parameters and the known EA and IE values for [60]fullerene. However, in reality, the shapes of many fullerene molecules deviate from a sphere, which may result in deviations of experimental data from theoretical predictions

concerning the pattern of the dependence of the EA on the fullerene size. Nevertheless, this simple model generally provides a satisfactory description of experimental data — both the monotonic increase in the electron affinity and the decrease in the ionisation energy following an increase in the size of the molecule. The rate of variation of both parameters markedly decreases on passing to heavy fullerenes with about 100 carbon atoms in the molecule. Noteworthy are clearly mirror patterns of variation of the EA and IE curves, which shows itself as a rather narrow energy range fitting the electronegativity values $(EA + IE)/2$ for the whole series of fullerenes studied, 5.2 ± 0.2 eV (see Fig. 2); the above-mentioned theoretical estimate of the electron work function for a graphite monolayer also falls in this range.

3. Ion-molecular equilibria in the vapours of fullerene derivatives

Fullerene derivatives can be classified into two main groups, namely, exo- and endohedral fullerenes. Exohedral fullerenes are those compounds in which functional groups add on the outside of the fullerene cage; as a rule, the species add in pairs with rupture of the double bonds. The term ‘endohedral’ means ‘enclosed inside’. These derivatives have been obtained by admixing oxides of some metals (mainly, lanthanides) to the graphite rods used in fullerene synthesis in the discharge arc. The space inside the fullerene cage suffices to accommodate one, two and, according to the latest data, even three or four metal atoms, some of these compounds being characterised by high thermal stability. Endohedral compounds of noble gases are also known.

In studies of ion–molecule equilibria involving fullerene derivatives, the researchers meant to find out how these two types of functionalisation influence the electron-withdrawing properties of fullerenes. Whereas in the case of fluorofullerenes, one could expect an increase in the EA compared to that for the initial C_{60} due to the high electronegativity of fluorine, it was difficult to predict the effect of the intra-sphere metal on the electron-withdrawing properties of fullerene. This problem could not be solved until experimental results were obtained.

a. Endohedral metallofullerenes

The equilibrium constants for the ion–molecule reactions of the type

where $n = 37-41$, were measured using specimens manufactured by the ‘TDA Research’ company by evaporation of graphite rods in the discharge arc, followed by sublimation of fullerenes and metallofullerenes from the soot accumulated on the cold walls of the reactor. These specimens were free from soot; hence, there was no need to carry out extraction in a Soxhlet apparatus, which may be accompanied by solvent-induced destruction of metallofullerenes. Although the content of endohedral compounds in the mixtures did not exceed several percent, $Gd@C_{2n}$ ions were detected in the mass spectra recorded at 900–960 K. The ratio of the partial pressures of endohedral and empty fullerenes proved to be higher for negative ions than for neutral molecules, which points to more pronounced electron-withdrawing properties of endohedral fullerenes compared to the analogues containing no metal atoms. The calculations of the EA values for $Gd@C_{2n}$ showed that all values are fitted into a narrow range (3.2–3.3 eV, Table 2) and, on average, they are higher than the EA of the corresponding hollow fullerenes. Thus, it was found that accommodation of a rare earth metal (gadolinium) inside the fullerene cage results in an increase, although slight, in the EA with respect to that of the hollow fullerene molecule; the only exception is $Gd@C_{74}$, which shows an opposite effect. In addition, it was found that for fullerenes containing the same metal atom inside the cage, an increase in the size of the C_{2n} molecule in the series $C_{74}-C_{84}$ has no substantial influence on the electron affinity. This result differs from the pattern of EA variation established for

hollow fullerenes, where C₇₄ fullerene exhibits an abnormally high EA value. These data suggest that in the case of endohedral compounds, the electron-withdrawing properties of the molecule are dictated by the charge on the intra-sphere metal atom. This hypothesis is supported by theoretical calculations. We were also able to determine the EA for some endohedral metallofullerenes with two scandium atoms inside the sphere and for a new type of endo compound with a trimetallic nitride cluster, Sc₃N@C₈₀ (Fig. 4, see Table 2).

**Figure 4.** Structures of the compounds La@C₈₂ (a), Sc₂@C₈₂ (b) and Sc₃N@C₈₀ (c). [The structure of Sc₃N@C₈₀ is published by authority of the journal Nature (www.nature.com)].

Endohedral metallofullerenes had attracted the attention of theoretical chemists even before they were prepared in macro-quantities. The first quantum-chemical study of the model La@C₆₀ molecule with the lanthanum atom located at the centre of gravity was reported by Rosen and Wastberg.²⁶ The calculations showed strong interaction between the 5*d* orbitals of the lanthanum atom and the π -system of the carbon cage, which results, in particular, in an increase in the electron affinity of the endohedral molecule relative to that of the hollow C₆₀ molecule by several tenths of electron-volt. Subsequently, the theoretical studies devoted to the structure of endohedral metallofullerenes have also been ahead of experiments and usually gave correct predictions.

In a series of quantum-chemical works performed by Japanese researchers^{27–29} and devoted to endohedral metallofullerenes

containing Group III metal atoms (Sc, Y) and lanthanide atoms, it was shown, first, that the metal atom is markedly shifted out of the centre of the molecule, and, second, that substantial charge transfer from the metal atom to the carbon cage takes place; as a consequence, the former acquires a charge of 2+ to 3+ (this is true for both mono- and di- or trimetallofullerenes). The ionisation potential of the endohedral metallofullerene is markedly lower, while the electron affinity is somewhat higher, despite the negative charge on the carbon cage, compared to that of the corresponding metal-free fullerene.^{27–29}

Evidence supporting these theoretical conclusions was first obtained in electrochemical investigations of endohedral metallofullerenes.³⁰ The oxidation and reduction potentials of these compounds demonstrated that they give off or accept an electron more easily than fullerenes themselves. This was also confirmed by the results of mass-spectrometric studies (see above). The presence of a charge on metal atoms was confirmed indirectly by EPR data,³¹ according to which the putative terms of electron states corresponded to metal ions rather than to atoms. Later, it was found by photoelectron spectroscopy^{32,33} that the HOMO in the molecules of endohedral metallofullerenes have higher energies than similar orbitals of hollow fullerenes.

With progress in developing methods of isolation and purification of endohedral molecules, direct evidence confirming the theoretical predictions also appeared. An important role was played by powder X-ray diffraction studies of the polycrystalline specimens of endohedral metallofullerenes, Y@C₈₂, Sc₂@C₈₄, Sc@C₈₂ and Sc₃@C₈₂ with utilisation of the Rietveld method and the maximum entropy method.^{34–37} The maps of electron density distribution in these molecules constructed on the basis of these results clearly demonstrated the displacement of metal atoms from the centre of the molecule and the presence of a charge of ~2+ on these atoms. The cross-sections of the electron density maps for scandium endohedral fullerenes are shown in Fig. 5. Similar data on the distances between the metal atom and the nearest carbon atoms in an endohedral fullerene have been obtained for some molecules by EXAFS.³⁸

**Figure 5.** Cross-sections of the electron density maps for the molecules of Sc@C₈₂ (a), Sc₂@C₈₄ (b) and Sc₃@C₈₂ (c).^{34–37} Level lines for bulk charge density from 0.3 (1.0 for Sc₂@C₈₄) to 6.0 e Å^{–3} with a step of 0.3 e Å^{–3} are shown. (Published by authority of the American Physical Society and Elsevier publishing house).

Since the distribution of the products of synthesis of endohedral fullerenes over the number of carbon atoms in the molecule differed appreciably from that for hollow fullerenes, the question arose as to whether the carbon cage topology is the same for the major isomers of hollow and endohedral fullerenes for a given number of carbon atoms. An answer to this question was provided, first of all, by X-ray diffraction results. It was found that the symmetry of the carbon cage in Sc@C₈₂ differs from that in C₈₂ fullerene, while the Sc₂@C₈₄ molecule has the same carbon cage as one of the major isomers of C₈₄. It is noteworthy that these results were also first predicted by a group of Japanese theoretical chemists,^{27–29} who thus demonstrated high efficiency of quantum-chemical techniques for the study of fullerenes and their derivatives.

b. Fluorofullerenes

The electron affinity of fullerene difluorides was determined using the reactions

The *EA* values of C_{60}F_2 and C_{70}F_2 fluorofullerenes found in this way are equal to 2.73 and 2.82 eV, respectively.³⁹ These data indicate that upon the addition of two fluorine atoms to C_{60} and C_{70} fullerenes, the *EA* increases, although insignificantly. Naturally, a higher electron affinity is expected of a molecule with a higher content of fluorine atoms. Evidence supporting this assumption was gained from measurements of the reduction electrochemical potentials of $\text{C}_{60}\text{F}_{36}$ fluorofullerene and by comparison of the results with the data for C_{60} . On the basis of a known correlation between the electrochemical potential and the electron affinity, the *EA* for $\text{C}_{60}\text{F}_{36}$ was estimated to be 3.48 eV.⁴⁰ In a study by the 'brackets' method in terms of the ion cyclotron resonance mass spectrometry of the electron exchange between $\text{C}_{60}\text{F}_{44}$ – $\text{C}_{60}\text{F}_{48}$ fluorofullerenes and various standards, a substantial increase in the *EA* (4.05 ± 0.5 eV)⁴¹ with an increase in the number of fluorine atoms added was found.

Experiments on the determination of the dissociation energy of the C–F bond in fluorofullerene molecules and anions were carried out using the same equipment as was used for *EA* measurements; however, this time fluorine exchange between fullerenes and fullerene anions was the object of investigation. The compounds FeF_3 , UF_4 , UO_2F_2 and $\text{C}_{60}\text{F}_{48}$ were used as mild fluorinating agents. In these systems, fullerene mono- and difluoride anions were detected at 800–1000 K (Fig. 6).^{42,43} This allowed the researchers to calculate the absolute magnitudes of the C–F bond energy for C_{60}F_n fluorofullerenes from the reaction

or

It was found that the C–F bond energy in the fullerene difluorides under study and their anions is 370–400 kJ mol^{−1}, *i.e.*, this bond is much stronger than was predicted by theoretical calculations (Tables 3, 4). A similar value was found, for example, for the C–F bond energy in the difluoroethane molecule. It is of interest to compare these results with the data on the thermodynamic stability of highly fluorinated fullerenes. The measurements of the combustion energies for C_{60} ,⁴⁶ $\text{C}_{60}\text{F}_{36}$ ⁴⁷ and $\text{C}_{60}\text{F}_{48}$ ⁴⁸ and

the enthalpies of sublimation of these compounds gave average values for the C–F bond energy in $\text{C}_{60}\text{F}_{36}$ and $\text{C}_{60}\text{F}_{48}$ fluorofullerenes equal to 295.0 ± 5.6 and 287.5 ± 3.5 kJ mol^{−1}, respectively. These data also made it possible to estimate the enthalpy of the reaction

per fluorine atom; the result was 265 kJ mol^{−1}.⁴⁷ This value can be regarded as being approximately equal to the average C–F bond energy for the formation of $\text{C}_{60}\text{F}_{48}$ from $\text{C}_{60}\text{F}_{36}$. It follows from these results that the bond energy decreases, although slightly, with an increase in the number of fluorine atoms attached. This is apparently due to the enhancement of the steric strain in the molecules of highly fluorinated fullerenes. Presumably, the decrease in the bond energy would not be monotonic: the most pronounced changes in the *D*(C–F) value would be expected for the formation of energetically and kinetically favourable compounds, namely, $\text{C}_{60}\text{F}_{18}$, $\text{C}_{60}\text{F}_{36}$ and $\text{C}_{60}\text{F}_{48}$. Although no quantitative data confirming this hypothesis have been obtained yet, the assumption is supported by the highly selective formation of compounds of exactly this composition observed experimentally.

III. Synthesis of fluorofullerenes

1. Mass-spectrometric studies of reactions of fullerenes with transition metal fluorides

The idea of using a mass-spectrometric setup as a chemical reactor is not new; it is widely employed in investigations of the reactivity of gaseous species (neutral molecules and ions). An attractive feature of these investigations is that they provide information about the reaction 'just as it is', *i.e.*, not complicated by processes

Figure 6. Electron impact (EI) mass spectrum of thermal anions in the vapour of the C_{60} – $\text{C}_{60}\text{F}_{46}$ system.^{42,43}

I is relative intensity.

of solvation (if the reaction takes place in solution) or by the state of reactants in heterogeneous processes. A typical scheme of these experiments is as follows. Gaseous species of a reactant are generated by vaporisation of appropriate chemical compounds and are let into a cell in which they are mixed with the other reactant. By recording the mass spectrum of the gas phase formed in the cell, one can gain information about the reactivity of the species and about the reaction products. More complex cases include the study of reactions as functions of temperature, reactant pressure or the charge of the reacting species.

The use of a mass-spectrometric setup as the main tool in the investigation of fullerene fluorination was started, as a matter of fact, due to a fortuitous discovery. As noted in the previous Section, the preparation of $C_{60}F_n$ in the gas phase and the determination of the energies of addition of fluorine atoms and fluoride ions to fullerene molecules was associated with the use of transition metal fluorides. The ion–molecule equilibria in the vapours of these compounds have been studied in detail previously and, what is especially important, the energies of addition of F atoms and F^- ions to transition metal difluorides and trifluorides have been determined.⁴⁹ Therefore, these compounds served not only as good fluorinating agents in the synthesis of fluorofullerenes but also as standards in the calculation of thermochemical characteristics from the equilibrium constants of fluorine exchange.

In one experiment, manganese trifluoride was used to generate fluorinated species in the gas phase.⁵⁰ When this compound was heated as a mixture with fullerene, it was noted that in a narrow temperature range, the vapour consisted mainly of $C_{60}F_{36}$ molecules. The condensate formed on the cold parts of the ion source was subjected to mass-spectrometric analysis, which confirmed that the fullerene reaction with manganese trifluoride occurs selectively, *i.e.*, $C_{60}F_{36}$ is formed as the predominant product.⁵⁰ This finding, fortuitous in a certain sense, gave impetus to the development of a new method of solid-phase selective synthesis of fluorofullerenes accompanied by evaporation of volatile products. The last-mentioned circumstance, *i.e.*, the removal of the target products from the reaction area, is a crucial factor, because the attempts to perform a similar synthesis in a closed reactor failed. They resulted in fullerene destruction to give thermodynamically the most stable compound — tetrafluoromethane.

The subsequent studies included the search for new fluorinating agents having different fluorinating capacities, which would enable the preparation of products with fluorine contents varying over a broad range. In the study,⁵¹ researchers' attention was focused on the fluorides of transition and rare earth metals in higher oxidation states.

All fluorination experiments were carried out in two stages. The first stage included *in situ* experiments in a mass spectrometer with continuous monitoring of gaseous reaction products. The reaction mixture consisting of thoroughly blended fullerene and fluorinating agent taken in definite mass ratios was charged to the effusion cell of the high-temperature evaporating chamber of the ion source of a mass spectrometer and heated under a high vacuum over a broad temperature range. The gaseous products of fluorination were detected as positive (electron impact) or negative (thermal ionisation) ions by the output recording unit of the mass spectrometer.

The use of this approach, which included a preliminary stage of synthesis inside the mass spectrometer, provided obvious advantages over the traditional one-step synthesis⁵⁰ carried out in a chemical reactor. First, it was possible to gain information on the product distribution as a function of time and temperature directly during the reaction. Second, the number of experiments needed to select the optimal conditions for the preparation of compounds of particular stoichiometric composition markedly diminished.

Thus it was found that fluorination of [60]fullerene by MnF_3 at 615 K gives virtually a single compound, $C_{60}F_{36}$, whereas the reaction of C_{60} with K_2PtF_6 at 730 K gives mainly $C_{60}F_{18}$.⁵² In

addition, experiments in the Knudsen cell require much less reactants and minimise the loss of products, which is especially important for expensive fullerenes C_n ($n > 70$) or derivatives such as bisazafullerene $(C_{59}N)_2$ (see Ref. 53).

The second stage included preparation of macroquantities of compounds in a setup representing a vacuum reactor with a cooling area for collection of volatile products. A detailed description of these experiments has been published.⁵⁴ This procedure was used to prepare gramme amounts of $C_{60}F_{36}$ and $C_{60}F_{18}$ fluorofullerenes, which were used for physicochemical investigations, in particular, for determination of the enthalpies of their formation by combustion (bomb) calorimetry.

2. Solid-phase topochemical reactions with evaporation of the volatile products $C_{60}F_{18}$ and $C_{60}F_{36}$

Heterogeneous solid-phase fluorination reactions proceed in mechanical mixtures of fullerenes with higher metal fluorides, which can give off fluorine on heating, thus being converted into fluorides with a lower oxidation state of the metal. The temperatures at which fluorofullerenes are formed (350–400 °C) are sufficiently high for these products to be removed from the reaction mixture *via* the gas phase and to condense on cooler surfaces of the reactor. Meanwhile, the temperatures are insufficient for evaporation of the reactants and decomposition products formed from metal fluorides; this allows one to avoid contamination of the resulting fluorofullerenes by the initial compounds or side products. By selecting an appropriate solid fluorinating agent (SFA) and reaction conditions, the researchers accomplished a selective process and prepared for the first time virtually pure $C_{60}F_{18}$ (see Ref. 51) and $C_{60}F_{36}$ (see Ref. 50).

It should be noted that selective solid-phase synthesis of fluorofullerenes normally gives, along with the major $C_{60}F_{2m}$ product, side products with similar chemical compositions. Thus in the case of a $C_{60}-MF_n$ reaction mixture ($M = Mn, Co$) in a dynamic vacuum at temperatures of 330–380 °C, apart from $C_{60}F_{36}$ fluorofullerene formed predominantly, its close analogues $C_{60}F_{34}$ and $C_{60}F_{38}$ also pass to the gas phase.^{50, 51} The contents of the side products, as shown by experiments, depend somewhat on both the degree of dispersion of the initial materials and the procedure used for mixing them, in particular, on how thorough the mixture components have been blended or on the degree of pressing. The latter circumstance is illustrated in Table 5 in relation to the reaction of C_{60} with CeF_4 . The compaction of the

mixture under pressure decreases the content of $C_{60}F_{34}$ in the reaction products and, at a definite temperature, this allows one to attain an almost 100% yield of the major product, $C_{60}F_{36}$. The influence of the reactant ratio on the product yield is shown in Table 6, which presents the data for reactions of C_{60} with MnF_3 carried out over a broad range of initial concentrations. It can be seen from Table 5 that the dependence of the product composition on the procedure of sample preparation is rather weak and has no substantial influence on the qualitative pattern of fluorination. It is also noteworthy that the reaction rate (monitored based on the intensity of product vaporisation) remains nearly constant throughout almost the whole process (except for the initial section where the temperature approaches the specified one and for the final stage), although the composition of the reaction mixture constantly changes during fluorination because of gradual accumulation of the decomposition products of the SFA, which are lower metal fluorides (see Table 6).

Thus, the qualitative outcome of reactions, including the selectivity with respect to a particular compound or the absence of selectivity, is determined by the nature of the SFA used. It was found that the reactions of C_{60} with MnF_3 , CoF_3 or CeF_4 give $C_{60}F_{36}$ as the major product.^{50, 51, 54, 56} Potassium hexafluoroplatinate ensures the selective synthesis of $C_{60}F_{18}$.⁵² Iron trifluoride does not react with C_{60} to give highly fluorinated derivatives, whereas TbF_4 (the strongest SFA) yields a rather broad spectrum of $C_{60}F_{2m}$ fluorofullerenes including those with the number of fluorine atoms $m > 24$ and even slight amounts of hyperfluorinated molecules ($m > 30$).⁵⁶

In view of the constant accumulation of the SFA decomposition products, *i.e.*, lower metal fluorides, it would be reasonable to expect that the reaction rate would decrease with time; however, this is at variance with experimental results. Evidently, heterogeneous solid-phase reactions take place only in limited areas where the solid reactants are in direct contact with each other. In particular, it can be assumed that the MnF_2 formed in the area where C_{60} reacts with MnF_3 would hamper the contact between grains of the reactants. Thus, there must exist an effective mechanism to compensate for the deficiency of fluorine and to maintain a steady-state reaction course. It is rather unlikely that the gas phase plays any significant role in the transfer of fluorine from SFA to C_{60} , as the equilibrium partial pressures of both molecular and atomic fluorine above the metal fluorides used are too low at given temperatures to ensure the observed concentrations of the fluorination products, which correspond to pressures of about 0.1 Pa. Perhaps, atomic fluorine, which is rather mobile, enters the reaction area through surface diffusion. Note that the high mobility of F atoms in systems based on inorganic metal fluorides has been confirmed experimentally.⁵⁷ Finally, it was found⁵⁵ that evaporation of fluorofullerenes is not only a

convenient way to accumulate the products of synthesis as a condensate but it is also a necessary condition for fluorination to take place. The attempts to obtain a fluorofullerene in the reaction between C_{60} and MnF_3 in a sealed tube kept in a furnace at 330 °C for several hours have not met with success. Mass-spectrometric analysis did not reveal any traces of fluorinated fullerene. Evidently, the presence of even microscopic amounts of these compounds between the surfaces of the reactant grains results in the cessation of fluorination.

3. Selectivity of fluorination

The question naturally arises of why the solid-phase reactions of C_{60} with SFA, unlike those with molecular fluorine, can proceed as selective fluorination to give $C_{60}F_{18}$ and $C_{60}F_{36}$ fluorofullerenes. To answer this question, a number of experiments have been conducted on fluorination of [60]fullerene by molecular fluorine with evaporation of volatile reaction products and continuous monitoring by mass spectrometry (see Fig. 7).⁵⁸ To this end, a mass-spectroscopic setup equipped by a Knudsen effusion cell and a system for the inlet of molecular fluorine was used. A [60]full-

Figure 7. Composition of the gas phase vs. temperature for similar fluorination times and a constant fluorine flow rate in the $C_{60}(\text{solid})$ – F_2 system.⁵⁸

$T = 510$ (a), 615 (b), 670 (c), 720 (d) and 760 K (e).

Here and in Figs 9 and 10, the following designations are used: c_{rel} is the relative concentration of $C_{60}F_n$, n is the number of fluorine atoms.

erene powder was placed in the cell. Fluorination was studied in the temperature range of 500–800 K with fluorine delivered to the reaction area at two flow rates which differed by an order of magnitude and created fluorine pressures of 10^{-4} and 10^{-5} atm, respectively, in an empty reactor. The volatile products of the reaction, fluorofullerenes, came out of the reactor through the effusion orifice and entered the ionisation area where they were subjected to the impact of the electron beam with an energy of 60–100 eV. The positive ions thus formed were analysed on a mass spectrometer and the results of analysis were used to determine the molecular composition of the reaction products (Fig. 7). It can be seen from Fig. 7 that the gaseous products are characterised by a broad distribution over the number of fluorine atoms: they contain almost all $C_{60}F_n$ molecules with even n values up to 44. This distribution depends on the temperature, fluorination time and the flow rate of fluorine entering the reaction area. For constant flow rates and fluorination times, raising the reaction temperature results in displacement of the distribution maximum towards smaller n values, which is illustrated in Fig. 7.

No signs of selectivity are observed in the fluorination in this case. In particular, at 615 K (which is the optimal temperature for selective solid-phase fluorination of [60]fullerene by manganese trifluoride), the electron impact mass spectrum of the $C_{60}-F_2$ system exhibits a series of peaks for $C_{60}F_{28}^+$ – $C_{60}F_{44}^+$ with a feebly defined maximum at about $n = 30$. Conversely, in the mass spectrum of the $C_{60}-MnF_3$ system, the signal for $C_{60}F_{36}^+$ clearly stands out against the background of the closest homologues; the reaction products do not contain measurable amounts of the $C_{60}F_{32}^+$ ion or ions with lower contents of fluorine (Fig. 8).

The partial pressures of the products of fullerene fluorination in the experiments described were 0.1–1.0 Pa. The distribution of the products of direct fluorination of [60]fullerene over the number of F atoms starts to change when manganese difluoride is added to the mixture. These changes become visible in the mass spectrum when the mole fraction of manganese difluoride is $\sim 50\%$. If the fluorination system contains C_{60} and 97 mol.% of MnF_2 , selective formation of $C_{60}F_{18}$ can be observed at 720 K, and $C_{60}F_{36}$ is formed selectively at 615 K. This is illustrated in Figs 9 and 10.⁵⁹

Thus, it can be concluded that direct fluorination with molecular fluorine of a mechanical mixture $C_{60}-MnF_2$ (97 mol.%) provides the possibility of selective preparation of both $C_{60}F_{18}$ and $C_{60}F_{36}$ in the gas phase. If fluorination is carried out at 615 K, the major volatile reaction product is $C_{60}F_{36}$.⁵⁹ This result coincides with the results of experiments on solid-phase fluorination of C_{60} with manganese trifluoride, which also gives predominantly $C_{60}F_{36}$. If fluorination is carried out at 720 K, the major volatile product formed is $C_{60}F_{18}$,⁵⁹ which is in line with the results of experiments on solid-phase fluorination of [60]fullerene with potassium hexafluoroplatinate (K_2PtF_6).

Figure 8. Electron impact mass spectrum of the volatile products of the solid-phase reaction between C_{60} fullerene and MnF_3 .

Figure 9. Composition of the gas phase after fluorination with molecular fluorine of a mixture of solid C_{60} with MnF_2 at approximately equal time intervals (2.5 h, initial stage) at $T = 720$ K.⁵⁹ (a) pure C_{60} ; (b) $C_{60} + MnF_2$ (50%); (c) $C_{60} + MnF_2$ (90%); (d) $C_{60} + MnF_2$ (97%).

At present, we have data at our disposal on the saturated vapour pressures of $C_{60}F_{18}$ and $C_{60}F_{36}$ fluorofullerenes (see Section VI), which can be used to explain the results obtained. At 720 K (see Fig. 9), the $C_{60}F_{18}$ fluoride is sublimed and fluorination stops at this stage. When the process is carried out

Figure 10. Composition of the volatile products of fluorination with molecular fluorine of a mixture of solid C_{60} and MnF_2 (97%) for 4.68 h at $T = 615$ K.⁵⁹

at 615 K (see Fig. 10), the $C_{60}F_{18}$ fluoride remains in the reaction mixture and fluorination goes on up to the formation of $C_{60}F_{36}$, which is sublimed at this temperature. The formation of the same product, $C_{60}F_{36}$, in the direct fluorination of a C_{60} – MnF_2 mixture by molecular fluorine and in the solid-phase reaction of C_{60} with MnF_3 indicates that these two processes include a common step responsible for selectivity. Apparently, this is the transition of F atoms from the chemisorbed state to the chemically bound state in the fluorofullerene molecule. The fluorination process can be represented as a sequence of three steps: (1) surface diffusion of fluorine to the reaction area; (2) transition of the F atoms adsorbed on the surface of the lower metal fluoride to the chemically bound (C–F) state in the fluorofullerene molecule; (3) transfer of the resulting fluorinated molecules to the gas phase. In the case of heterogeneous fluorination, the first step is preceded by adsorption of molecular fluorine from the gas phase on the surface of metal fluoride.

The surface diffusion is involved both in the direct fluorination by molecular fluorine and in the solid-state synthesis. Indeed, in the former case, selectivity is attained only after fluorine has passed through the layer of manganese difluoride and occurs in the chemisorbed state. The same is true for the solid-state synthesis because MnF_3 and C_{60} are separated by a layer of manganese difluoride formed during the reaction. Note that in both cases, the deficiency of fluorine in the reaction area at the boundary between the reactants is made up by the ‘flow’ of fluorine over the manganese difluoride surface, and the reactions proceed at a constant rate.

In the final step, evaporation of the reaction products takes place, which prevents them from accumulating in the reaction mixture. Apparently, due to this fact and to the relatively high rate of fluorine diffusion over the difluoride surface, the observed pattern of time variation of the reaction rate is atypical of topochemical reactions, *i.e.*, the rate remains constant and shows no significant attenuation caused by accumulation of the reaction products.

The key step can be represented as the following equation:

or

where ads is adsorbate and s is solid, and the fullerene-containing components are either taken as solid solutions (sol) [reaction (4)] or (with allowance for the final step) occur as gases (g) [reaction (5)].

The question arises as to why this manner of fluorine transfer easily ensures predominant formation of a particular single product, whereas the use of F_2 or some other gaseous fluorinating agents affords, as a rule, mixtures of fluorofullerenes of different compositions.

A correlation is known to exist between the reaction rate and enthalpy. Highly exothermal reactions usually proceed faster. This implies that the activation energy of the reaction (E_a) decreases as the enthalpy (ΔH) becomes more negative. If a quantitative relationship between these values is established, thermodynamic characteristics of reactions, in particular, the enthalpy, can be used to estimate the relative reaction rates. Usually, a set of reactions is chosen for this purpose in which the reactants differ from one another only by the functional group involved in the reaction. (This is called a one-parameter sequence. An example is the empirical correlation established by Brønsted between the reaction rates and the strength of acids or bases that catalyse these reactions.)

The reactions (4) and (5) considered here are members of such a one-parameter sequence in which the parameter is represented by the number of fluorine atoms ($2m$) in the reacting fluorofuller-

ene molecule. This gives grounds for using the correlation approach similar to the so-called Bell–Evans–Polanyi (BEP) model, well-known in organic chemistry.⁶⁰

The BEP model is based on consideration of rather large numbers of reactions as processes of independent rupture and formation of chemical bonds in ensembles of isomeric molecular species which yield the same products. According to this model, the energy characteristics of reactions are described using two potential curves dependent on the same reaction coordinate. The first (descending) curve corresponds to the formation of a chemical bond between two species of the ensemble, while the second (ascending) curve describes the energy variation in the rupture of the same bond in one of the isomeric species. The point of intersection of these curves corresponds to the transition state; its y -coordinate determines the activation energy of the reaction (E_a).

The groups of reactions that obey the BEP principles are characterised by a nearly linear relationship between the activation energy and the reaction enthalpy; the latter should vary insignificantly within this group

$$E_{ai} = a + b\Delta H_i. \quad (6)$$

The proportionality factor b tends to decrease as $|\Delta H|$ increases, therefore, in comparison of two groups of reactions with markedly different enthalpies, the most pronounced dependence of E_{ai} on ΔH_i is expected for the group where the enthalpies are close to zero, because even a slight shift of ΔH_i would ensure a considerable change in the E_{ai} value. The described concept forms the basis of the Brown selectivity rule for aromatic substitution.

Figure 11 shows the possible pattern of the Evans–Polanyi curves for a pair of neighbouring homologues of fluorofullerenes ($\Delta m = 1$), each reacting with two SFA ($M^I F_n$ and $M^{II} F_n$) which differ appreciably in fluorinating capacity.⁵⁵ Due to this difference, if the ΔH_i^I values for the reactions of fluorofullerenes with the first SFA (group I) are small, their reactions with the second SFA (group II) are highly exothermal. Correspondingly, in the case of the ‘weaker’ $M^I F_n$ reagent, the $a_1(I)$ and $a_2(I)$ curves for the formation of bonds in fluorofullerene molecules intersect the $b(I)$ curve for the abstraction of fluorine from SFA in the region where the slope of this curve is much greater than that in the case of the ‘stronger’ $M^{II} F_n$ reagent. As a consequence, the change in the activation energy for the first reaction (δE_a^I) is much greater than that for the second reaction (δE_a^{II}), although the enthalpy jumps ($\delta \Delta H_i^I$) are equal in both cases.

The relationship between the reaction rate constant and the activation energy is described by the equation

$$K = A \exp\left(\frac{E_a}{RT}\right).$$

By substituting into this expression [see Eqn (6)] the E_a values determined for two successive steps with the rate constants k and K and by taking their ratio, we obtain the key condition of selectivity

$$\frac{k}{K} = \exp \frac{b\delta\Delta H}{RT} \ll 1, \quad (7)$$

where k and K are the rate constants for the slow and fast steps, respectively, in the sequence of successive reactions. We neglected the difference between the pre-exponential factors, *i.e.*, we assumed that $A(k) = A(K)$.

Thus, if the BEP principles are applicable to solid-phase reactions of the given type, we can conclude that in the optimal case, the selective formation of a particular product requires transition from a slightly exothermal to slightly endothermal reaction to take place for the sequence member that corresponds to the fluorination of the given compound. However, this is not an obligatory condition. It is only necessary that the jump in enthalpy should ensure a sufficient change in the activation energy. Recall

Figure 11. Evans–Polanyi curves for an elementary step of the solid-state reaction $C_{60}F_x + M^IF_k$ (TS is the transition state).⁵⁵ For explanations, see the text.

also that we are dealing with the enthalpies of reactions (4) determined by the difference between the C–F bond energies in fluorofullerene molecules and in the SFA.

A specific feature of fluorofullerenes hampering the selective synthesis of these compounds is, apparently, the fact that the reactivity with respect to fluorine changes only slightly over the $C_{60}F_{2m}$ series ($m = 1–24$). The difference between the energies of successive cleavage of the C–F bonds for this series is also relatively small. The success in the synthesis of individual $C_{60}F_{18}$ and $C_{60}F_{36}$ is attributable to the appearance of slow steps at $m = 9$ and 18 in the sequence of reactions of successive addition of fluorine atoms to [60]fullerene. These steps are due to the decrease in the exothermal effect of fluorination and the corresponding increase in the activation energies of each individual reaction.

It follows from the foregoing that, according to the approach proposed by Borcshevsky *et al.*,⁵⁵ the energy characteristics of one elementary step of solid-phase fluorination, namely, the step of fluorine transfer from the SFA to fullerene, is the criterion for the selection of reagents for preparation of individual fluorofullerenes. As noted above, by selecting the SFA in such a way that ΔH of the step responsible for the selectivity of the whole process is close to zero, we ensure the jump in the activation energy for two consecutive reactions, needed for the selectivity, and thus trigger the whole set of transformations along the chosen pathway.

Analysis of the experimental results from the standpoint of this approach provides an explanation for the non-selective pattern of direct fluorination. The enthalpy of dissociation of the F_2 molecule is $\sim 150 \text{ kJ mol}^{-1}$. The average C–F bond energies in the $C_{60}F_{48}(g)$ and $C_{60}F_{36}(g)$ molecules are 287.5 and 295 kJ mol^{-1} , respectively.^{47,48} This allows one to calculate the average C–F bond energy for the addition of 12 fluorine atoms to the $C_{60}F_{36}$ molecule, which equals 265 kJ mol^{-1} (see Section VI.3.b). On the basis of these data, the jump in the C–F bond energy on passing from $n < 36$ to $n > 36$ in the series of $C_{60}F_n$ is estimated as 30 kJ mol^{-1} . These values imply that the direct fluorination by molecular fluorine is a highly exothermal reaction. As compared with the enthalpy of this reaction, the difference between the enthalpies of two successive steps involving $C_{60}F_{34}$ and $C_{60}F_{36}$ (30 kJ mol^{-1}) is too small, and, hence, the change in the sign of ΔH is by no means expected. However, when MnF_2 is added, the crystals of [60]fullerene become mainly isolated from

direct contact with gaseous fluorine. As a consequence, the vast majority of fluorine atoms get into the reaction area (near the contact between C_{60} and MnF_2 grains) through surface diffusion over the crystals of manganese difluoride on which they are adsorbed. This reproduces the conditions inherent in the solid-phase fluorination by manganese trifluoride, and, hence, the selectivity is ensured. If the enthalpy of fluorine desorption is taken to be equal to the enthalpy of the reaction $MnF_3(s) = MnF_2(s) + F(g)$ (244 kJ mol^{-1}),⁶¹ the exothermal effect of the reaction of [60]fullerene with the fluorine attached to the surface of manganese difluoride sharply decreases, giving rise to conditions under which the difference between the properties of individual representatives of the $C_{60}F_{2m}$ series becomes observable. In particular, slow steps appear and the key condition of selectivity holds [see Eqn (7)].

Yet another important feature of solid-phase fluorination with evaporation of volatile products is that the reaction takes place in the fullerene–SFA contact area without accumulation of products in the solid phase. In this case, in the sequence of fluorination processes, sublimation proceeds as a side reaction having a lower order and independent of the fluorine concentration. As a result, fulfillment of the key condition of selectivity [see Eqn (7)] does not suffice for the preparation of the target product, and additional conditions taking into account the ratios between the rates of fluorination and the rates of sublimation of fluorination products need to be satisfied. This has been reported in more detail.⁵⁵

4. Preparation of the $C_{60}F_{48}$ fluorofullerene

The reaction of [60]fullerene with molecular fluorine proceeds even at room temperature; the products are normally mixtures of highly fluorinated $C_{60}F_n$ compounds ($n = 36–48$). Gakh *et al.*⁶² passed a stream of molecular fluorine above a mixture of C_{60} fullerene with NaF at 250 °C and, after 20 h, they obtained a product, which was extracted with $CFCl_3$, dried, and treated again with an F_2 stream for 30 h at 275 °C with the addition of a fresh portion of NaF. After extraction and drying, the sample composition was estimated by mass-spectrometric analysis. The content of $C_{60}F_{48}$ was $\sim 70\%$. The NMR spectrum of this compound was recorded, which exhibited eight equal-intensity lines.

Somewhat later, one-step synthesis of C₆₀F₄₈ was performed.⁶³ In order to find the optimal conditions for fluorination, a number of experiments have been carried out with variation of the conditions, duration and temperature of the reaction of C₆₀ fullerene with molecular fluorine. Series of specimens were synthesised in three regimes, namely, static, quasi-static and dynamic ones (Table 7). In the static regime, C₆₀ fullerene powder was kept at a temperature of 315 °C and at a fluorine pressure of 50–300 Torr in a closed cell for 2.3 and 10 h. Under these conditions, the highest degree of fluorination, estimated conventionally as the ratio of the intensity of the signal of the C₆₀F₄₈⁺ ion to the total intensity of ion signals in the mass spectrum, was 63%. The quasi-static reaction conditions, embodied as the periodical renewal of fluorine portions in the reactor at 315 °C, resulted in a higher degree of fluorination of fullerene (68%). In the dynamic regime of fluorination where a fluorine flow (1 atm) was passed at 315 °C over powdered C₆₀ fullerene at a constant rate, the proportion of C₆₀F₄₈ in the resulting mixture of fluorofullerenes increased with an increase in the reaction time. As a result, fluorination for 10.5 h at 315 °C yielded a sample, whose elemental analysis corresponded to the ratio C : F ≈ 60 : 48 (see Table 7). The mass spectrum of this product contains only C₆₀F₄₈⁺ and C₆₀F₄₆⁺ molecular ions, the other peaks correspond to fragment ions (Fig. 12).

Meanwhile, at these high temperatures, the loss of fluorofullerenes due to destruction induced by fluorine becomes noticeable. This is indicated by analysis of a sample of the gas phase taken directly from the reaction area. According to mass-spectrometry

data, CF₄ and C_{*n*}F_{2*n*+2} perfluorocarbons (*n* = 2–4) were the major combustion products.

5. 'Hyperfluorination' of C₆₀ fullerene

The interest in C₆₀F₆₀ perfluorofullerene, in which the double bonds have been fully utilised for the addition of fluorine was triggered by the publication in 1991 of a study by Kroto and coworkers,⁶⁴ who suggested that the perfluorinated fullerene can prove to be an analogue of Teflon and possess unique properties (for example, it could be suitable as a lubricant). Theoretical calculations⁴⁵ showed that this molecule can, in principle, exist; however, its structure should be distorted due to steric crowding. Moreover, the formation of structures with cleavage of several C–C bonds and arrangement of fluorine atoms inside the fullerene carbon cage has been suggested.

The phenomenon of fullerene 'hyperfluorination' was discovered in a study of the fluorination products obtained under more rigorous conditions such as UV irradiation of a mixture of C₆₀ with molecular fluorine,⁶⁵ or the use of powerful fluorinating oxidants (KrF₂).⁶⁶ These experiments were aimed at the attainment of the highest degree of fluorination and, finally, preparation of the perfluorinated fullerene (C₆₀F₆₀).

Later, the formation of [60]fullerene hyperfluorides was observed in the reaction of C₆₀ with terbium tetrafluoride.⁵⁶ In the reaction of [60]fullerene with terbium tetrafluoride, when a temperature of 350 °C has been attained, an explosion-like blow-out of the reaction mixture from the hot zone of the reactor takes place, and the fluorination products are found to contain C₆₀F_{*n*} (*n* > 60) fluorides. This reaction carried out below 350 °C also gives fluorofullerenes but no hyperfluorinated species are detected in the mass spectrum of the products. Apparently, in the explosion mode, the C–C bonds of the fullerene carbon skeleton are partially cleaved and excess fluorine atoms are added. Although this has not been confirmed by structural experiments due to the too small content of these species in the synthesised samples. Nevertheless, as noted above, species corresponding to C₆₀F_{*n*} hyperfluorides (*n* > 60) were still detected in the mass-spectrometric investigation of the products obtained in the reaction of C₆₀ with KrF₂⁶⁶ or TbF₄⁵⁶ (Fig. 13).

It is notable that these structures are not destroyed under the action of high temperatures (300 °C) or electron impact ionisation (70 eV), although the content of these species is relatively low and equals 0.01%–0.10% relative to the content of major components, C₆₀F₄₂–C₆₀F₄₆. Analysis of the mass spectra shows that hyperfluoride molecules undergo more extensive fragmentation than C₆₀F_{*n*} molecules with lower contents of fluorine (*n* < 48); the intensity of signals corresponding to fragment ions formed upon abstraction of the CF₃ group reaches 50%–60%, whereas for species containing less than 48 fluorine atoms fragmentation is insignificant under the same ionisation conditions and equals 5%–10%. This suggests that further progress in the study of fullerene hyperfluorides would depend on the choice of investigation techniques. In particular, 'mild' methods of ionisation such as electrospray and field desorption may prove rather promising. Note that the use of laser ionisation (which is a harsher method than electron impact), even in the matrix isolation variant, did not show the presence of any hyperfluorides in the mass spectra of the same specimens.

The phenomenon of hyperfluorination is still to be studied, in particular, in the context of possible applications of these compounds. Thus it is necessary to develop methods of analysis and techniques for the synthesis of macroquantities of fullerene hyperfluorides in the condensed phase. Nevertheless, even at the current stage, one can understand the fundamental significance of this type of transformation in which 'windows' with sizes exceeding those of five- or six-membered rings are formed with retention of the basic cage as a whole. Hypothetically, these 'windows' could be used to insert atoms and molecules into the fullerene cavity, which would result finally in the preparation of endohedral compounds of a new type.

**Figure 12.** Electron impact mass spectrum (70 eV) of C₆₀F₄₈ vapour (*I* is the ion current intensity).⁶³

Figure 13. Electron impact mass spectrum of the products of fluorination of C_{60} fullerene with terbium tetrafluoride ($T = 350\text{ }^{\circ}\text{C}$).⁵⁶ The left-hand and right-hand parts of the spectra are given with different magnifications.

6. Fluorination of C_{70} and higher fullerenes

Functionalisation of higher fullerenes has scarcely been studied. Only several works have been reported dealing with the preparation of hydrides of a number of higher fullerenes.⁶⁷ In experiments on hydrogenation of C_{76} and C_{84} fullerenes, it was found that 40–50 hydrogen atoms can add to the former molecule and 54 hydrogen atoms can be attached to the latter one.⁶⁸ Heating of these compounds in an effusion cell entails thermal degradation of hydrides of higher fullerenes. This is accompanied by not only partial loss of the hydrogen atoms but also destruction of the carbon cage itself to give C_{60} and C_{70} hydrides containing 36 and 38–40 hydrogen atoms, respectively.⁶⁹

The theoretical studies dealing with functionalisation of higher fullerenes have not progressed significantly either. Higher fullerenes are characterised by a lower symmetry than C_{60} , and large numbers of isomers are possible for them, which greatly complicates the calculations.

Experiments on fluorination of higher fullerenes have been reported.⁷⁰ It was found that, as in the case of [60]fullerene, reactions with transition metal fluorides proceed selectively, the ‘magic numbers’ of the fluorine atoms added being different for different fullerenes. Fluorination of C_{84} on treatment with K_2PtF_6 , which is a milder fluorinating agent, gives mainly $C_{84}F_{40}$, while C_{76} adds only 26 fluorine atoms. Surprisingly, the reaction of C_{70} fullerene with K_2PtF_6 does not yield fluorinated products at all, no matter how the experimental conditions (temperature, composition of the reaction mixture) are varied. The $C_{70}F_{36}$ – $C_{70}F_{40}$ fluorofullerenes can be readily obtained by the reaction of C_{70} with MnF_3 , while the fluorinating capacity of K_2PtF_6 does not suffice for the formation of these products. Apparently, due to specific features of the structure of the C_{70} molecule, the first step of fluorination gives $C_{70}F_{36}$ – $C_{70}F_{40}$, while a stable intermediate structure similar to $C_{60}F_{18}$ simply does not exist.

In the case of higher fullerenes C_{76} and C_{84} , both reactions proceed to give similar degrees of fluorination, although the products prepared on treatment with MnF_3 contained slight amounts of more extensively fluorinated compounds, which, in principle, corresponds to the difference between the fluorinating capacities of these reagents.

Thus, the stability regions for functionalisation of higher fullerenes have been established:⁷⁰ for $C_{84}F_m$ and $C_{76}F_m$, the m values are 40 and 26, respectively. The results are presented in Table 8 and in Fig. 14. Detailed reviews of the studies on direct fluorination of fullerenes by molecular fluorine⁷¹ and transition metal fluorides⁵⁴ have been published.

Table 8. Fluorination products of higher fullerenes.⁷⁰

Fullerene	Fluorinating agent	T/K	$m_{\max}$ in $C_{2n}F_m$	Major products
C_{70}	K_2PtF_6	670	—	—
	MnF_3	660	40	$C_{70}F_{38}$
	F_2	590	56	$C_{70}F_{54}$
C_{76}	K_2PtF_6	711	30	$C_{76}F_{26}$
	MnF_3	660	30	$C_{76}F_{26}$
C_{78}	MnF_3	660	36	$C_{78}F_{32}$ – $C_{78}F_{36}$
	F_2	590	54	$C_{78}F_{54}$
C_{84}	K_2PtF_6	711	40	$C_{84}F_{40}$
	MnF_3	660	44	$C_{84}F_{40}$
	F_2	590	62	$C_{84}F_{56}$, $C_{84}F_{58}$, $C_{84}F_{60}$

IV. The use of HPLC for the separation of fluorofullerenes

Chromatography is used successfully to separate the product mixtures resulting from the synthesis of fullerenes in a discharge arc followed by extraction with organic solvents from soot in the Soxhlet apparatus.³ The use of chromatography for the separation of endohedral metallofullerenes⁷² and numerous exohedral derivatives⁷³ is documented. Nevertheless, this method was considered to be inapplicable to mixtures of fluorinated fullerenes

because their properties are virtually identical. The attempts to separate mixtures of highly fluorinated fullerenes by fractional sublimation were unsuccessful.⁷⁴ Experiments on sublimation of fluorofullerene mixtures have shown that the sublimate becomes depleted in more extensively fluorinated components compared to the initial specimen, apparently, due to their predominant thermal degradation, but separation of the mixture into individual components does not take place.

The first publication on the use of HPLC for the separation of fluorofullerenes, devoted to the preparation of $C_{60}F_{18}$ in a pure state, appeared in 1996.⁵² Since $C_{60}F_{18}$ is much more polar than the unreacted C_{60} or the side product impurities present in the specimen after the synthesis, the retention times of these compounds were found to be markedly different. This stipulated the successful use of chromatography for the isolation of the pure product. For key fluorofullerenes, a correlation has been established between the number of fluorine atoms in the molecule and the retention time: the higher the degree of fluorination, the shorter the retention time ($C_{60}F_{18} > C_{60}F_{36} > C_{60}F_{48}$). However, the compound $C_{60}F_2$ is eluted far ahead of the $C_{60}F_{18}$ fluoride, which is due to the high polarity of the latter.

Subsequently, it was shown⁷⁵ that HPLC is suitable for the separation of not only compounds with substantially different compositions and molecular structures but also fluorofullerenes with rather similar structures, for example, two $C_{60}F_{36}$ isomers. An even more vivid example should be mentioned, namely, the isolation and spectroscopic characterisation (IR spectroscopy, mass spectrometry and, in some cases, NMR spectroscopy) of 49 isomers of C_{70} fluorides.⁷⁶ In the two last-mentioned cases, the composition of the eluent had to be changed stepwise during the separation, ranging from pure toluene through toluene–hexane mixtures of various compositions to pure hexane. Thus, in the early stages, the most polar fractions with long retention times were separated and, after that, fractions with short retention times were subjected to separation in mixed eluents.

In addition to the $C_{60}F_{36}$ and $C_{70}F_{2m}$ isomers mentioned above, a series of low-fluorinated oxides of C_{60} fullerene were isolated from a sample synthesised by the reaction of C_{60} with potassium hexafluoroplatinate.⁷⁷ Note that according to mass-spectra, the fluorination products did not contain any noticeable amounts of fluorofullerene oxides, while the corresponding $C_{60}F_2$, $C_{60}F_4$, $C_{60}F_6$ and $C_{60}F_8$ fluorides were present in concentrations of the order of several percent of the concentration of the major component, $C_{60}F_{18}$. Nevertheless, the cycles of chromatographic purification and separation into fractions gave the $C_{60}F_4O$, $C_{60}F_6O$ and $C_{60}F_8O$ oxyfluorides in amounts sufficient for spectroscopic characterisation. Presumably, these oxyfluorides were not formed during the synthesis but appeared as a result of interaction of the corresponding fluorides with traces of water, present inevitably in the solvents used in chromatographic experiments. Thus, the above examples of using HPLC for the separation and purification of some fullerenes convincingly demonstrate that virtually any mixtures of fluorinated fullerenes can be separated by chromatography into individual compounds. However, when performing these works, special precautions are required because even traces of water present in the solvent can destroy fluorofullerenes.

V. Characterisation of the structure of fluorofullerenes by NMR spectroscopy and X-ray diffraction analysis

The most interesting feature of fullerenes is that they combine the properties of dienes and aromatic compounds. This can be clearly seen upon comparison of the C–C bond lengths in benzene (1.40 Å), butadiene (1.35 and 1.47 Å for the double and single bonds, respectively)⁷⁸ and [60]fullerene in which the distances between the carbon atoms at double and single bonds are 1.40 and 1.46 Å, respectively.⁷⁹ It is clear that the addition of functional

groups to the fullerene double bonds giving rise to isolated aromatic rings, diene chains, or isolated double bonds on the carbon sphere changes the π -electron system of the molecule. These aspects were discussed back in 1991–1993,^{80,81} when the first fullerene derivatives were prepared and characterised. Naturally, the mutual arrangement of functional groups on the carbon cage depends on their size. It is known that the addition of several bulky functional groups results in adducts with a uniform distribution of these groups over the carbon sphere. For example, in the hexaadduct of [60]fullerene with diethyl malonate, the functional groups are symmetrically distributed over the surface of the sphere.⁸² This gives rise to eight aromatic rings, which contribute to the stabilisation of the molecular system formed. A large number of other cycloaddition products have been described. The most frequently encountered situation is the formation of a bridging bond with addends at the 6–6 bond between two neighbouring hexagonal rings. A large variety of products is observed in the synthesis of fullerene derivatives with small functional groups or halogen or hydrogen atoms. Oxygen derivatives of fullerene can contain not more than three O atoms; therefore, they are not of special interest.

Two fundamental problems are to be solved in considering polyaddition reactions to fullerene double bonds. The first one is to elucidate the pathway along which the carbon sphere is covered successively by X atoms added in pairs and to understand the factors that dictate this pathway. The other task concerns the determination of the most preferable geometric isomers of the many thousands of isomers theoretically possible. Below, we present the numbers of theoretically possible positional isomers for the addition of X atoms to [60]fullerene.⁸³

n in $C_{60}X_n$	The number of isomers	n in $C_{60}X_n$	The number of isomers
2	23	10	628 330 629
4	4 190	12	11 661 527 055
6	418 470	20	34 932 048 763 560
8	21 330 558	30	985 538 239 868 528

It can be seen that even for $n = 8$, the number of possible $C_{60}X_8$ isomers is an astronomical value which is beyond the potential of theoretical calculations. Therefore, various approaches are used to restrict the number of probable structures. It is clear that much fewer isomers can really be synthesised. The researchers need to find out what factors favour stabilisation of particular structures and also to elucidate the cases where either kinetic or thermodynamic factors play crucial role.

It may seem that the C_{60} –hydrogen system is the most natural model system for these studies. Indeed, several hydrides of [60]fullerene have been described: $C_{60}H_2$, $C_{60}H_4$ and $C_{60}H_6$; the molecular structure of $C_{60}H_{18}$ has been determined; the compound $C_{60}H_{36}$ has been obtained in macroscopic quantities.⁶⁸ However, the structural characterisation of hydrides is far from being complete due to the low stability of these species in solutions. In particular, the isomeric composition of $C_{60}H_{36}$, which is prepared most easily, is still unknown. No successful X-ray diffraction studies have been carried out for this class of compound.

The number of fullerene halides characterised to date increases in the series: $C_{60}I_x$, $C_{60}Cl_x$, $C_{60}Br_x$, $C_{60}F_x$. Whereas for iodinated derivatives, only the formation of an unstable molecular complex $C_{60} \cdot I_2$ has been described,⁸⁴ the chloride $C_{60}Cl_6$ has been fully characterised,⁸⁵ and unconfirmed data on the existence of $C_{60}Cl_{24}$ and $C_{60}Cl_{40}$ have been reported.^{86,87} Three bromofullerenes are known, $C_{60}Br_6$, $C_{60}Br_8$ and $C_{60}Br_{24}$; for each of them, X-ray diffraction data have been reported.^{88,89} The C_{60} –fluorine system clearly stands out in this series of halogenated derivatives. First, the existence of the whole series of $C_{60}F_{2x}$ fluorofullerenes, from $C_{60}F_2$ to $C_{60}F_{60}$ has been proven experimentally.⁵³ Second, the three most stable compounds,

$C_{60}F_{18}$, $C_{60}F_{36}$ and $C_{60}F_{48}$, have been obtained in macroscopic amounts and their structures have been determined. Third, the chemical structures of a series of fluorofullerenes with low fluorine contents, including $C_{60}F_2$, have been determined. Thus fluorinated fullerenes can serve as a 'training ground' for working-out the main approaches to the preparation of fullerene derivatives with small functional groups. First of all, this is associated with the fact that, due to the exceptional strength of the C–F bond, fluorofullerenes are stable in air, rather thermally stable and can be subjected to virtually any type of physicochemical investigations. The good solubility of these compounds in many organic solvents has played an important role in the development of methods for chromatographic separation of fluorofullerenes according to the number of added groups or into individual geometric isomers. After the first successful experiments on chromatographic isolation of individual $C_{60}F_{18}$ fluoride and separation of the two major isomers of $C_{60}F_{36}$, it became clear that it is possible to prepare pure products of C_{60} fluorination over a broad range of fluorine contents. Although not all fluorinated fullerenes have been isolated and characterised, the spectroscopic and X-ray diffraction data concerning their structures make it possible to establish some important features of successive addition of fluorine atoms to the fullerene double bonds.

1. [60]Fullerene difluoride

The difluoride of [60]fullerene and difluorides of higher fullerenes have been detected^{13,39} during mass-spectrometric analysis of fluorofullerene vapours (the results of experiments on determination of the electron affinity and the C–F bond energies of these molecules are described in Section II). However, it was not until the year 2000 that [60]fullerene difluoride was prepared in macroscopic amounts.⁹⁰ The ^{19}F NMR spectrum of the $C_{60}F_2$ fluorofullerene exhibits a singlet at 148.3 ppm. The 1,2- and 1,4-isomers have been considered as possible alternatives, because, according to theoretical calculations, they are much more stable than the other formally conceivable isomers and also because of the fact that the first fluorine atom added polarises most of all the nearest region of the π -system of the molecule.⁹⁰ The 1,2-isomer of $C_{60}F_2$ is more stable than the 1,4-isomer, as the latter contains a double bond in a five-membered ring, which destabilises the compound. This compound is formed only with relatively large substituents. For example, methylation of [60]fullerene gives a mixture of 1,2- and 1,4-methyl derivatives, whereas benzylation results in the formation of the 1,4-benzyl derivative.⁹¹ Since the fluorine atom is smaller than the carbon atom, there are no pre-requisites for the formation of the 1,4-derivative.

The position of the peak in the ^{19}F NMR spectrum of $C_{60}F_2$ fluorofullerene is more consistent with the 1,2-isomer rather than with the 1,4-isomer. In the latter compound, each sp^3 -hybridised carbon atom bearing a fluorine atom is surrounded by three sp^2 -hybridised carbon atoms, whereas in the 1,2-isomer, only by two

sp^2 carbon atoms. Therefore, in the case of the 1,4-isomer, it would be reasonable to expect a peak in the region of 120–130 ppm.

Additional information on the structure of $C_{60}F_2$ was gained from its ^{13}C NMR spectrum. The 1,4-isomer of $C_{60}F_2$ (C_s symmetry) should account for $27 \times 2C + 4 \times 1C = 31$ lines in the spectral region corresponding to sp^2 atoms, while the 1,2-isomer (C_{2v} symmetry) should give rise to $3 \times 2C + 13 \times 4C = 16$ lines. The spectrum of the $C_{60}F_2$ fluorofullerene displays less than 28 peaks. This confirms once again that the 1,2-isomer of $C_{60}F_2$ was isolated.

2. Oxyfluoride $C_{60}F_4O$

The ^{19}F NMR spectrum of the $C_{60}F_4O$ oxyfluoride consists of two lines of equal intensity. The structure proposed for this compound⁷⁷ is presented in Fig. 15a. As can be seen from the Figure, the fluorine atoms added occur in positions 1, 2, 3 and 4, and the oxygen atom is, apparently, attached to the carbon atoms of the 6–5 bond, *i.e.*, this compound is an intramolecular ether.

3. Oxyfluoride $C_{60}F_6O$

The ^{19}F NMR spectrum of $C_{60}F_6O$ reported by Boltalina *et al.*⁷⁷ consists of six lines of equal intensity. The positions of lines lead to the conclusion that the fluorine atoms in $C_{60}F_6O$ fall into two groups, one comprising two F atoms and one comprising four F atoms. The chemical shifts of the first-group fluorine atoms are much smaller. This suggests that they are attached to the same carbon atoms as oxygen. In addition, two fluorine atoms of the second group are characterised by similar chemical shifts, which may attest to their similar positions with respect to the oxygen bridge. On the basis of these data, a structure was proposed for this compound (Fig. 15b).

4. Oxyfluoride $C_{60}F_8O$

The ^{19}F NMR spectrum of $C_{60}F_8O$ consists of four lines of equal intensity.⁷⁷ It was concluded that the $C_{60}F_8O$ molecule has, most probably, C_s symmetry. A structure consistent with these conditions was proposed (Fig. 15c).

5. Fluorofullerene $C_{60}F_{16}$

The ^{19}F NMR spectrum of $C_{60}F_{16}$ fluorofullerene consists of eight lines of equal intensity.⁹² The fluorine atoms attached to the carbon atoms that are surrounded by three sp^3 -hybridised C atoms are responsible, in most cases, for a signal at about –150 to –160 ppm. The $C_{60}F_{16}$ molecule contains two fluorine atoms of this type (B). The signals of fluorine atoms attached to the carbon atoms whose environment comprises one sp^3 and two sp^2 carbon atoms are usually displayed in the region of –120 to –130 ppm. Two pairs of these fluorine atoms (A and H) are present in the $C_{60}F_{16}$ molecule. The positions of other fluorine atoms were established using 2D COSY ^{19}F NMR spectra. On the basis of the results obtained, a structure for $C_{60}F_{16}$ was proposed

Figure 15. Schlegel diagrams of $C_{60}F_4O$ (a), $C_{60}F_6O$ (b) and $C_{60}F_8O$ (c).⁷⁷ The dark circles show the positions of fluorine atoms.

Figure 16. Schlegel diagrams of C₆₀F₁₆ (a)⁹² and C₆₀F₂₀ (b)⁹³. The dark circles show the positions of fluorine atoms.

(Fig. 16 a). Researchers were able to prove convincingly that this structure differs from the structure established for the C₆₀F₁₈ fluorofullerene (see below) only by the absence of the two fluorine atoms attached to the 6–6 bond.

6. Fluorofullerene C₆₀F₂₀

The ¹⁹F NMR spectrum of C₆₀F₂₀ fluorofullerene contains only one line at –138.8 ppm (see Ref. 93). The structure proposed in the study cited is shown in Fig. 16 b. A specific feature of the structure is that all 20 fluorine atoms are arranged along the equator, while the poles are occupied by five-membered rings surrounded by five six-membered aromatic rings. This molecule, the carbon cage of which is ‘squashed’ along a fivefold axis and is surrounded by an annulus made of fluorine atoms along the equator, has been called ‘saturnene.’

7. Compounds C₆₀F₁₈ and C₆₀F₁₈O

These two compounds are remarkable due to the fact that single crystals suitable for X-ray diffraction analysis were grown for them and the full set of interatomic distances was obtained. Therefore, we shall discuss these compounds in more detail.

The ¹⁹F NMR spectrum of C₆₀F₁₈ fluorofullerene (376.14 MHz, CDCl₃) was first recorded in 1996.⁵² The spectrum consists of four lines with $\delta = -131.6$ (d); –136.0 (dd); –143.4 (d) and –158.1 ppm (dt) with an intensity ratio of 1:2:2:1 (Fig. 17).

Of all kinds of structures, the isomer with C_{3v} symmetry complies best with this spectrum; the Schlegel diagram for this molecule is presented in Fig. 18. This structure was confirmed by ¹³C NMR spectroscopy. As can be seen from Fig. 18, all the fluorine atoms are located in one hemisphere. The six-membered ring consisting of *sp*²-hybridised carbon atoms is entirely sur-

Figure 17. ¹⁹F NMR spectrum of C₆₀F₁₈ fluorofullerene.⁵²

Figure 18. Schlegel diagram (a) and the structure (b) of the C₆₀F₁₈ molecule.⁹⁵ The dark circles show the positions of fluorine atoms.

rounded by the *sp*³-hybridised carbon atoms that bear fluorine atoms.

The C₆₀F₁₈O oxyfluoride was first isolated by HPLC in 1998 as a side product of the reaction between C₆₀ fullerene and K₂PtF₆; the ¹⁹F NMR spectrum of this compound was recorded.⁹⁴ The fluorine atoms are arranged in the same way as in the C₆₀F₁₈ molecule. Elucidation of the position of oxygen appears to be a key point because the character of the C–O bond in this compound is of prime importance for the understanding of the structure of other fullerene oxyfluorides. If oxygen is incorporated either along or across the plane of symmetry (three options), the ¹⁹F NMR spectrum should consist of ten lines, 8 × 2F and 2 × 1F. For other variants of oxygen addition, the number of lines

in the spectrum should increase to eighteen due to the loss of symmetry. Analysis of the ^{19}F NMR spectrum (10 lines) and 2D COSY ^{19}F NMR spectrum showed that this isomer has C_s symmetry. The positions of three peaks are characteristic, namely, at -94.60 (K), -161.27 (B) and -168.81 ppm (G). The peak of atoms K occurs in the spectral region typical of fluorine atoms located in the close vicinity of the oxygen atom. The positions of peaks of atoms B and G are similar to the peaks in the spectra of fullerene fluorides for the fluorine atoms attached to carbon atoms surrounded by three sp^3 -hybridised C atoms.

The structure of $\text{C}_{60}\text{F}_{18}\text{O}$ will have C_s symmetry in the case where oxygen adds either at the cleaved 6–5 bond forming an ether bridge (to the fullerene cage) or at the 6–6 bond to give an epoxide. In one publication,⁹⁴ preference was given to the epoxide structure on the basis of NMR data. In 2000, we succeeded in growing single crystals and performing full X-ray diffraction analysis of the molecular complexes of $\text{C}_{60}\text{F}_{18}$ and $\text{C}_{60}\text{F}_{18}\text{O}$ with toluene and the complexes of $\text{C}_{60}\text{F}_{18}$ with *m*- and *p*-xylenes. These were the first crystallographic data for fluorinated fullerenes.^{95–97} The resulting structures of the $\text{C}_{60}\text{F}_{18}$ and $\text{C}_{60}\text{F}_{18}\text{O}$ molecules are presented in Fig. 19. First of all, note that $\text{C}_{60}\text{F}_{18}\text{O}$ is an ether in which the ether bridge is located in place of the 6–5 bond (see Fig. 19a). The oxygen atom is inserted into the weakest (longest) C–C bond to give the so-called intra-ether derivative. This is the first structure of this type among fullerene compounds. Relying on the results obtained for $\text{C}_{60}\text{F}_{18}\text{O}$,⁹⁵ structures with ether bridges were ascribed to all oxyfluorides considered. The X-ray diffraction analysis of molecular complexes formed by $\text{C}_{60}\text{F}_{18}$ confirmed the NMR data pointing to the location of the 18 fluorine atoms on one half of the carbon sphere. Moreover, it was shown that this accumulation of fluorine around one six-membered ring results in a substantial change in the C–C bond lengths, in particular, the bond lengths in this six-membered fragment become equal, and it becomes a fully aromatic (benzene-like) ring. Global changes in the fluorinated hemisphere itself have also been noted: in particular, the curvature radius of the benzene-like fragment substantially increases, the fragment is flattened, whereas the second half not occupied by fluorine largely retains its size and shape, as in the initial fullerene molecule.^{95–97} The carbon cage of this molecule has been termed ‘flattened’.

8. Fluorofullerene $\text{C}_{60}\text{F}_{36}$

The first fullerene derivative, obtained in 1991,⁶⁸ was the $\text{C}_{60}\text{H}_{36}$ hydride. Since then, attempts at determining the structure of this compound were repeatedly undertaken; however, no apparent progress was made. A large number of theoretical studies have been devoted to calculations of the molecular structure of $\text{C}_{60}\text{X}_{36}$ ($\text{X} = \text{H}, \text{F}$). The isomer with T symmetry containing four isolated benzene-like rings was found to be the most stable.⁹⁸

It was natural to suggest that the products of hydrogenation and fluorination of [60]fullerene (C_{60}H_x and C_{60}F_x) would be isostructural at identical x . An important factor is the similarity of steric effects; the fluorine and hydrogen atoms are smaller than the carbon atom, and similar radical mechanisms have been suggested for both reactions.

Initially, it was found that the first stages of both fluorination and hydrogenation give compounds with 18 addends, which are characterised by a highly symmetric structure (C_{3v} symmetry), and the X atoms are arranged on the carbon cage like a crown framing a six-membered ring.⁵²

The second stage of both hydrogenation and fluorination is the formation of the $\text{C}_{60}\text{X}_{36}$ structure. In the fluorination of C_{60} on treatment with MnF_3 , $\text{C}_{60}\text{F}_{36}$ is the major product.

Nevertheless, the ^{19}F NMR spectrum of the resulting material displayed up to 30 lines; this can indicate either low symmetry of the $\text{C}_{60}\text{X}_{36}$ molecule or the presence of a mixture of positional isomers.

After purification of the sample by sublimation, the number of lines decreased to 12, and analysis of the 2D COSY spectrum pointed to the presence of several positional isomers. It was

Figure 19. Schlegel diagram (a) and the structure (b, two projections are given) of the $\text{C}_{60}\text{F}_{18}\text{O}$ molecule.⁹⁵ The dark circles show the positions of fluorine atoms.

assumed that one isomer responsible for only three lines with equal intensity had T symmetry. Chromatography gave two major fractions exhibiting virtually identical mass spectra. The ^{19}F NMR spectrum of the first fraction that had a shorter retention time contained 12 equally intense lines. Theoretical

analysis indicated that this spectrum could correspond to a structure with C_3 symmetry.

The ^{19}F NMR spectrum of the second fraction exhibited only three lines with an intensity ratio of 1 : 1 : 1, as was to be expected for a structure with T symmetry. However, three isomers with D_{3d} symmetry also comply theoretically with the observed spectrum. The final decision in favour of the T structure was based on the ^{13}C NMR spectrum of the second fraction, which contained two equally intense lines at 136.6 and 137.5 ppm (the region corresponding to sp^2 -hybridised carbon atoms). Meanwhile, the D_{3d} isomers would require the presence of three lines with a 1 : 1 : 2 intensity ratio. The Schlegel diagram for the $\text{C}_{60}\text{F}_{36}$ fluorofullerene with T symmetry⁷⁵ is shown in Fig. 20a.

Figure 20. Schlegel diagrams of T (a)⁷⁵ and C_3 isomers (b)¹⁰⁰ of $\text{C}_{60}\text{F}_{36}$ fluorofullerene. The dark circles show the positions of fluorine atoms.

The isomer with C_3 symmetry was suggested initially to contain three benzene-like rings of the four rings present in the T isomer and three isolated double bonds of the 6–6 type.⁹⁹ This conclusion was based on kinetic reasoning according to which pairs of fluorine atoms are added successively to 6–6 double bonds; therefore, the double bonds of the same type remaining in the molecule should not change positions. Boltalina *et al.*⁹⁹ have found evidence for this assumptions in a study of $\text{C}_{60}\text{F}_{36}$ by 2D COSY ^{19}F NMR spectroscopy. However, according to the data of quantum-chemical calculations, the proposed isomer was markedly less stable than the isomer with T symmetry. Conversely, a recent NMR study of the C_3 isomer of $\text{C}_{60}\text{F}_{36}$ attests in favour of a structure that also contains three benzene-like rings and three isolated double bonds but the latter occupy 6–5 positions.¹⁰⁰ The Schlegel diagram of this isomer is shown in Fig. 20b. According to theoretical calculations, it is comparable in stability with the isomer having T symmetry, which suggests thermodynamic control in the formation of $\text{C}_{60}\text{F}_{36}$. This might imply the possibility of rearrangements of fluorine atoms on the carbon cage during fluorination.

9. Fluorofullerene $\text{C}_{60}\text{F}_{48}$

The first experimental data on the structure of $\text{C}_{60}\text{F}_{48}$ were obtained by Gakh *et al.*⁶² Later, these data were confirmed using more pure specimens.¹⁰¹ The ^{19}F NMR spectrum of the $\text{C}_{60}\text{F}_{48}$ fluorofullerene was found to display eight equally intense lines corresponding to eight nonequivalent fluorine atoms. According to theoretical data, this spectrum is consistent with nine possible structures, namely, five enantiomer pairs with D_3 symmetry and four S_6 isomers. The Schlegel diagrams for the $\text{C}_{60}\text{F}_{48}$ molecule with D_3 symmetry⁶² and for the molecule with S_6 symmetry, which are the most stable according to calculations,¹⁰² are shown in Fig. 21.

It should be noted that analysis of 2D COSY spectra recorded in the study cited⁶² showed the presence of 1,2-interactions (A–E, A–G, B–F, B–G, C–H, D–F, D–H, E–F), which corresponded to the theoretical structure with D_3 symmetry; however, of the set of predicted 1,3-interactions (A–B, A–D, A–F, B–C, B–D, B–E, C–D, D–E, E–G, F–G, F–H), only the first, the second, the fourth and the seventh ones were detected. Later,¹⁰¹ a 2D COSY spectrum was recorded pointing to the existence of the A–F, D–E, E–G and F–G interactions. This confirms the D_3 structure proposed by Gakh *et al.*,⁶² but does not rule out the molecule with S_6 symmetry. The final decision concerning the structure of this fluorofullerene was based on the results of X-ray diffraction analysis of a $\text{C}_{60}\text{F}_{48}$ single crystal grown from a mesitylene solution,¹⁰³ which showed that the reaction of C_{60}

Figure 21. Schlegel diagrams of D_3 (a) and S_6 isomers (b) of $\text{C}_{60}\text{F}_{48}$ fluorofullerene.⁶²

with gaseous fluorine gives comparable amounts of both isomers. Note that the carbon cage regions near the double bonds in these molecules are characterised by a slight negative curvature; therefore, they are called 'indented'. It is remarkable that of the many millions of $C_{60}F_{48}$ isomers possible theoretically, the reaction with gaseous fluorine gives only two isomers. According to the results of MNDO¹⁰⁴ and AM1¹⁰⁵ semiempirical calculations, these molecules are thermodynamically much more stable than the other possible isomers with exohedral addition of fluorine atoms. Our calculations by the density functional method predict that the isomer with D_3 symmetry is 15 kJ mol^{-1} more stable than that with S_6 symmetry. Note that according to AM1 calculations,¹⁰⁵ an isomer in which six fluorine atoms are attached to the inside of the carbon cage is expected to be even more stable. However, the formation of such a compound should be kinetically hampered, and no experimental data confirming its existence have been obtained.

Thus, the amount of experimental data accumulated to date is sufficient for evaluating its correspondence to the theoretical descriptions of such systems. The good coincidence of the theoretical estimates for the thermodynamically stable $C_{60}F_{48}$ isomers with the experimental data on the enthalpies of formation and the molecular structures of the isomers having S_6 and D_3 symmetry can be taken as the starting point.

The NMR spectra of solid samples usually do not provide enough information to draw conclusions about the molecular structure of the compound, due to the strong interactions between the nuclei in the solid. The fine spectral structure is observed rather rarely in these cases. Nevertheless, having prepared reasonable ($> 1 \text{ g}$) amounts of the $C_{60}F_{48}$ fluorofullerene, Boltalina *et al.*¹⁰¹ attempted to study the crystalline specimen by ^{19}F NMR spectroscopy.

The high-resolution MAS ^{19}F NMR spectrum of crystalline $C_{60}F_{48}$ recorded at 340 K consists of eight principal lines with equal intensity (Fig. 22) corresponding to eight non-equivalent fluorine atoms attached to positions A–H in the $C_{60}F_{48}$ molecule (see Fig. 21). Note that the chemical shifts in the ^{19}F NMR spectrum recorded in solution virtually coincide with those for the solid specimen, indicating the absence of an appreciable influence of the solvent. Apart from the eight principal lines, the spectrum contains four groups of low-intensity lines (10% of the total intensity), which refer apparently to $C_{60}F_{2n}$ ($2n < 48$) impurities or to $C_{60}F_{48}$ with a different symmetry.

The data on the molecular structures of compounds $C_{60}F_4O$, $C_{60}F_6O$, $C_{60}F_8O$, $C_{60}F_{16}$, $C_{60}F_{18}$ and $C_{60}F_{20}$ derived from NMR

spectra and presented as Schlegel diagrams (see Figs 15, 16, 18), allow one to consider the possible mechanism of successive addition of small functional groups to C_{60} fullerene. After addition of the first two fluorine atoms, the localised double bonds in the two conjugated six-membered rings that have lost the common double bond and contain two sp^3 carbon atoms become the reaction centres of choice. Further addition of atoms is directed at these particular bonds and partial or complete aromatisation of the six-membered rings which have retained three double bonds takes place at certain degrees of saturation. Yet another specific feature of the mechanism of fullerene fluorination is that fluorine atoms are able to migrate over the surface of the carbon cage. This results in the formation of thermodynamically the most stable isomers. As a consequence, each subsequent fluorofullerene in the series $C_{60}F_{18}$, $C_{60}F_{36}$, $C_{60}F_{48}$ does not contain the substructure of the preceding one, *i.e.*, it cannot be prepared from the preceding isomer by mere addition of more fluorine atoms. These aspects have been considered in detail.¹⁰⁶

To date, only three compounds of the $C_{60}F_{2n}$ series have been synthesised in macroscopic quantities and comprehensively characterised. These are $C_{60}F_{48}$, $C_{60}F_{36}$ (two isomers with T and C_3 symmetry) and $C_{60}F_{18}$. The stability of two isomers of $C_{60}F_{36}$ and $C_{60}F_{18}$ is due to delocalisation of π -electrons in six-membered rings, *i.e.*, to the formation of aromatic substructures. In addition, one hemisphere of the carbon cage of the $C_{60}F_{18}$ fluorofullerene inherits the π -system of [60]fullerene. However, the existence of the C_3 isomer of the $C_{60}F_{36}$ fluorofullerene indicates that in the presence of 36 attached fluorine atoms, steric factors, namely, deformation of the carbon cage upon transition of some carbon atoms to the sp^3 state and repulsion of substituents, already play an important role. The bond angles typical of both sp^3 - and sp^2 -hybridised carbon atoms cannot be attained simultaneously for all of the atoms due to geometric restrictions, which results in a rather strained structure. In addition, the proximity of the fluorine atoms (in fluorofullerene molecules, especially in $C_{60}F_{48}$, the distances between neighbouring fluorine atoms are often several tenths of an angstrom smaller than twice the van der Waals radius of fluorine¹⁰³) leads to their repulsion and, as a consequence, weaken the σ -bonds in the carbon cage; in some cases, these bonds become $1.63\text{--}1.67 \text{ \AA}$ long. Stabilisation of the carbon cage could, apparently, be expected for a more uniform distribution of the carbon–carbon double bonds, although this results in separation of the bonds from one another and, hence, a decrease in the π – π conjugation. This might account for the formation of an isomer with C_3 symmetry with three isolated carbon–carbon double bonds, apart from the T isomer in which all double bonds are combined in benzene-like aromatic rings. In the case of $C_{60}F_{48}$ fluorofullerene, the steric factor predominates. Note that the remaining six double bonds are practically difficult to access and attempts at further fluorination under more drastic conditions lead to the partial destruction of the carbon cage. It is of interest that according to some theoretical calculations,¹⁰⁵ stabilisation of fullerene fluorides containing ~ 48 fluorine atoms could be attained by repudiating the convexity of the carbon cage, assuming that some fluorine atoms are attached on the inside. In this type of structure containing both *exo*- and *endo*-fluorine atoms, the bond angle could be more consistent with hybridisation states of the carbon atoms, *i.e.*, strain relaxation in the carbon cage could take place. At present, it is difficult to verify this hypothesis because the pathway to these isomers should face, in any case, substantial kinetic impediments.

Full sets of structural parameters have been obtained only for the $C_{60}F_{18}$, $C_{60}F_{48}$, $C_{60}F_{18}O$ and $C_{60}F_{17}CF_3$ fluorinated fullerenes, which crystallise as molecular complexes with various aromatic compounds. The study of $C_{60}F_{36}$ fluorofullerene is appreciably hampered by two factors. These are, first, rotation of molecules and, second, the presence of structural isomers. For other fluorofullerenes, the task is reduced to the preparation of compounds in macroscopic quantities sufficient for growing single crystals. Studies along this line are in progress.

VI. Thermodynamic properties

1. Heat capacity and orientational phase transitions

Low-temperature heat capacities of $C_{60}F_{48}$ and $C_{60}F_{36}$ were determined in 1999¹⁰⁷ (no other data have appeared thereafter). The heat capacity was measured in a fully automated vacuum adiabatic calorimeter described in the literature.^{108, 109}

The temperature dependence of the heat capacity of $C_{60}F_{48}$ (Fig. 23) exhibits a thermal anomaly represented by a reversible order–disorder phase transition in the temperature range of 315–345 K. To establish the nature of the anomaly, the substance was studied by NMR spectroscopy and powder X-ray diffraction analysis.¹⁰⁷ According to calorimetric measurements,¹⁰⁷ NMR spectroscopy and X-ray diffraction data, the $C_{60}F_{48}$ fluorofullerene undergoes a reversible non-isothermal phase transition ‘ordered crystal II $\rightarrow$ plastic crystal I’ accompanied by rearrangement of the body-centered tetragonal (BCT) crystal structure into a face-centred cubic (FCC) structure.¹¹⁰ The phase transition temperature in $C_{60}F_{48}$ was taken to be 329.6 ± 0.4 K. At this temperature, the apparent heat capacity is a maximum. The thermodynamic parameters of the ‘order–disorder’ transitions for $C_{60}F_{48}$ fluorofullerene and C_{60} fullerene¹¹¹ are listed in Table 9. The enthalpies of the transitions ($\Delta_{\text{trs}}H^\circ$) were determined by calorimetry¹⁰⁸ on the basis of the total amount of energy required for the phase transition. The $\Delta_{\text{trs}}H^\circ$ value is lower for

Figure 23. Temperature dependence of the heat capacity of $C_{60}F_{48}$ fluorofullerene.

Here and in the inset in Fig. 24, the initial pattern of the dependence is shown.

Table 9. Thermodynamic parameters of ‘order–disorder’ phase transitions for $C_{60}F_{36}$, $C_{60}F_{48}$ and C_{60} and absolute entropies and entropies of formation of these fluorofullerenes at 298.15 K.

Parameter	Compound		
	C_{60}	$C_{60}F_{48}$	$C_{60}F_{36}$
$\Delta_{\text{trs}}T$ / K	185–275	315–345	
T_{trs} / K	260.7	329.6 ± 0.4	370
$\Delta_{\text{trs}}H^\circ$ / kJ mol ^{−1}	7.46 ± 0.15	7.0 ± 0.7	
$\Delta_{\text{trs}}H^\circ$ / J g ^{−1}	10.4 ± 0.2	4.8 ± 0.4	
$\Delta_{\text{trs}}S^\circ$ / J mol ^{−1} K ^{−1}	28.6 ± 0.6	21.2 ± 2.4	
S_m° / J mol ^{−1} K ^{−1}	426.5	1137.2 ± 6	1014.5 ± 5
$\Delta_f S_m^\circ$ / J mol ^{−1} K ^{−1}	84.5	-4071.6 ± 6	-2978.2 ± 5

Note. ΔT_{trs} , T_{trs} , $\Delta_{\text{trs}}H^\circ$ and $\Delta_{\text{trs}}S^\circ$ are the temperature range, the temperature, and the enthalpy and entropy of the phase transition, respectively; S_m° and $\Delta_f S_m^\circ$ are the absolute entropy and the entropy of formation of fluorofullerene, respectively.

$C_{60}F_{48}$ fluorofullerene than for C_{60} fullerene. The resulting temperature dependences of the heat capacities, enthalpy, and entropy of phase transitions were used to calculate the thermodynamic functions at 298.15 K¹¹² (see Table 9).

It can be seen from Fig. 24 that the temperature dependence of the heat capacity of $C_{60}F_{36}$ plotted using the data of adiabatic calorimetry displays no anomalies in the range of 8–356 K. A phase transition was discovered by differential scanning calorimetry (DSC) at a higher temperature, namely, at 370 K.¹¹³ The high-temperature phase of $C_{60}F_{36}$ existing at $T > 370$ K has a FCC lattice, which passes to a simple cubic (SC) lattice as the temperature decreases.¹¹⁴ According to NMR and powder X-ray diffraction data, this is also an orientational transition. The orientational transitions discovered in fluorofullerenes are similar to the well-known phase transition in [60]fullerene. The molecules of C_{60} are known to form a FCC lattice at temperatures $T > 260$ K and an SC lattice at $T < 260$ K.¹¹⁵ It was found that at 260 K, a first-order phase transition takes place caused by transformation of a high-temperature orientationally ordered phase into a low-temperature orientationally ordered one. As this takes place, the centres of gravity of the molecules virtually do not shift, and the C_{60} molecules assume a quite definite orientation, thus changing the translational symmetry of the crystal. A specific feature of the orientational phase transition is that the C_{60} molecules execute re-orientations, fast on the ¹³C NMR time scale ($\nu \approx 10^{-13}$ s^{−1}). At high temperatures ($T > 260$ K), these are chaotic isotropic re-orientations, while at $T < 260$ K, correlated group re-orientations take place.¹¹⁵

Figure 24. Temperature dependence of the heat capacity of $C_{60}F_{36}$ fluorofullerene.

During calorimetric measurements of the characteristics of the orientational phase transition (enthalpy and temperature) in a C_{60} fullerene crystal, an interesting feature was discovered: after mechanical grinding in a mortar, the temperature and the enthalpy of phase transition of the C_{60} specimen decreased down to the complete disappearance of the maximum in the temperature dependence of heat capacity, the fullerene crystallinity being retained.^{116–119} Meanwhile, the NMR study of the temperature dependence of the spin–lattice relaxation time of ¹³C nuclei showed that at 260 K, this value changes jumpwise for both the initial and ground C_{60} specimens, although the jump is less pronounced in the latter case.^{119, 120} These results were interpreted¹²¹ in the following way. The spatial defects that originated upon the mechanical treatment of a [60]fullerene specimen break the crystalline phase of C_{60} into a great number of regions in which the orientational ordering of the C_{60} molecules occurs independently. In other words, local transitions take place instead of a collective effect throughout the whole phase (specimen). Finally, the orientational phase transition in a calorimetric experiment becomes smeared, but the low-temperature phase is still formed (as indicated by the step in the temperature dependence of the spin–lattice relaxation time of ¹³C nuclei). It should also be noted that the presence of impurities (solvent molecules) barely influences the parameters of the orientational phase transition,¹¹⁸ but it

does influence the ^{13}C spin – lattice relaxation time, although only in the high-temperature phase,¹²⁰ in which the C_{60} molecules execute orientationally disordered motion.

The influence of an increase in the rate of crystallisation (from solutions) or vacuum sublimation is similar to mechanical grinding: both processes increase the degree of defectiveness of crystals, which results in smearing of the orientational phase transition. Unfortunately, no theoretical description of these phenomena is available to date. The works that can be regarded as the latest achievements along this line include the development of theoretical approaches to the description of the orientational phase transition in the C_{60} crystal, namely, the model of thermal behaviour of a thermoelastic medium with internal orientation based on the Landau theory and the model of anisotropic reorientations of the C_{60} molecules for the description of the spin – lattice relaxation time.^{122, 123}

The characteristic features of phase transformations in $\text{C}_{60}\text{F}_{36}$ or $\text{C}_{60}\text{F}_{48}$ fluorofullerenes, which are molecular crystals, are probably similar to those in crystalline C_{60} fullerene. In any case, mechanical grinding of both C_{60} and $\text{C}_{60}\text{F}_{36}$ and $\text{C}_{60}\text{F}_{48}$ specimens brings about the same effect, namely, disappearance of the phase transitions from the temperature dependences of heat capacity.¹¹³ No data on the heat capacity of $\text{C}_{60}\text{F}_{18}$ fluorofullerene have been obtained yet, although works along this line are in progress. Apparently, the presence of a dipole moment in $\text{C}_{60}\text{F}_{18}$ would also influence the heat capacity curves and would stipulate substantial differences between the behaviours of $\text{C}_{60}\text{F}_{18}$, on the one hand, and $\text{C}_{60}\text{F}_{36}$ or $\text{C}_{60}\text{F}_{48}$, on the other hand, during heating. The heat capacities of higher and endohedral fullerenes have not yet been determined.

2. Enthalpy of sublimation

a. Fullerenes C_{60} , C_{70} , C_{78} and C_{84}

After crystalline [60]fullerene had been obtained in macroscopic quantities at the end of 1990,² vigorous studies into the physico-chemical properties of this compound were started. Later, studies of higher fullerenes also began (as these compounds have been isolated in a pure state). As soon as 1991, it was found¹²⁴ that C_{60} fullerene is sublimed *in vacuo* (1 Pa) without decomposition even at temperatures of about ~ 1000 K. This result is a sort of sensation if one recalls that graphite is sublimed at this pressure at temperatures of about 3000 K. Thus, there appeared the possibility of producing pure carbon in the gas phase at temperatures of ~ 1000 K. Later, this property of fullerene has been used in diamond synthesis from the gas phase.¹²⁵

The high thermal stability of fullerenes and the possibility of transferring them to the gas phase allowed determination of the characteristics of their free molecules. The electron affinity and ionisation energy of C_{60} , the electron capture and light absorption energies, and cross-sections of various chemical reactions of fullerenes have been determined. For these measurements and for film deposition experiments or growth of single crystals from the vapour phase, data on the saturated vapour pressure of fullerene are needed. The saturated vapour pressure and the enthalpy of sublimation have been measured repeatedly (see, for example, the review¹²⁶). Virtually all measurements were carried out by the Knudsen effusion method implemented either in the classical version or with mass-spectrometric analysis of the vaporisation products. Since the experiments were carried out by research groups from different countries (Germany, India, Italy, Russia, Slovenia, and the USA), naturally, some scatter of the results can be noted.

Analysis of the data on the saturated vapour pressure of fullerene shows that the scatter in the obtained values goes far beyond the inaccuracy inherent in the effusion method. At present, the reasons for the substantial discrepancies are more or less clear. First, this is the quality of specimens. Preparation of sufficiently pure and thoroughly characterised specimens is a fairly difficult task. The second, more specific reason for the discrepancies is related to the fact that fullerene represents a

metastable phase and transition to more stable phases (amorphous carbon) might take place, and this transition can often be catalysed by an impurity or the surface of the container. Finally, the most significant point responsible for the differences between the data on the saturated vapour pressure is the fact that experiments were carried out in different temperature regimes. Elevated temperatures required for the generation of measurable saturated vapour pressures accelerate the thermal degradation of fullerenes, giving rise to noticeable amounts of the amorphous carbon phase. The accumulation of this non-volatile form results in underestimated saturated vapour pressures. This destruction of fullerene is markedly facilitated by an organic solvent contained in fullerene specimens. However, it has been reported¹²⁷ that fullerene specimens containing no solvent also undergo this transformation but to a substantially lesser extent. It was shown that the time of storage has a more pronounced influence on the degree of conversion than temperature.¹²⁷ This, apparently, accounts for the fact that the non-fullerene carbon forms are sometimes present even in the initial specimens not subjected to high temperatures.¹²⁸

The effusion experiments on fullerene sublimation were normally carried out after prolonged many-hour storage of specimens at 400–500 K in a dynamic vacuum. Under these conditions, the solvent should have been completely removed. However, it is still retained in the samples in concentrations of 0.01%–1.0% and occurs in the adsorbed state in closed space dislocations.¹²¹ These minor amounts of the solvent barely influence the weight loss of the specimen but they accelerate the transformation of fullerene into non-fullerene carbon. As a consequence, the saturated vapour pressure decreases in the course of measurements, giving rise to substantial scatter of the thermodynamic data obtained. As noted above, the destruction rate depends on many factors but the presence of solvents is normally the most significant among them. The saturated vapour pressures for the number of fullerenes recommended in a study by Markov *et al.*¹²⁶ are shown in the logarithmic form in Fig. 25, and the parameters of the corresponding equations are given in Table 10. It can be seen that the enthalpy of sublimation increases rather smoothly with an increase in the size of the fullerene molecule, *i.e.*, heavier fullerenes are less volatile. Apparently, this trend should be retained throughout the whole series of higher fullerenes. At present, more precise determination of the saturated vapour pressures of C_{76} (see Refs 129, 130) and C_{84} (see Ref. 128, 131) using repeatedly sublimed samples and the study of the sublimation of other higher fullerenes as they are prepared in macroscopic quantities remain topical tasks. Indirect experimental data attest that endohedral metallofullerenes exhibit lower volatilities than the corresponding hollow fullerenes. However, no quantitative data have been obtained so far.

In conclusion, we would like to mention the problem of interpretation of thermodynamic data obtained for higher full-

Figure 25. Logarithmic dependence of the saturated vapour pressure of fullerenes C_{60} (1), C_{70} (2), C_{76} (3) and C_{84} (4) on temperature.¹²⁶

Table 10. Equations for the temperature dependence of the saturated vapour pressure and recommended values for the sublimation enthalpy.¹²⁶

Fullerene	Temperature range	$\log p = -BT^{-1} + A^a$		T/K (see ^b)	$\Delta_{\text{sub}}H_T^\circ$ /kJ mol ⁻¹
		B/K	A		
C ₆₀	560–990	8738 ± 472	10.85 ± 0.76	750	167 ± 9
C ₇₀	650–904	9768 ± 774	11.23 ± 1.49	773	187 ± 15
C ₇₆	637–1069	10027 ± 253	10.94 ± 0.33	831	192 ± 6
C ₈₄	658–1190	10760 ± 267	10.92 ± 0.29	899	206 ± 5

^a The pressure in this equation (p) is expressed in Pascals. ^b The temperature to which the $\Delta_{\text{sub}}H_T^\circ$ value should be referred.

erenes, which is related to the existence of various geometric isomers. For fullerenes containing 78 or more carbon atoms, two or more isomers which obey the rules of isolated pentagons have been obtained;¹³² however, thermodynamic measurements were carried out only for isomer mixtures. Quantum-mechanical estimates show that the difference between the energies of stable isomers, for example of C₈₄ fullerene, can reach 100–120 kJ mol⁻¹ (see Ref. 133). Hence, the enthalpies of sublimation of these isomers may also be appreciably different. It is clear that the data advised in a study by Markov *et al.*¹²⁶ for C₈₄ refer to a mixture of isomers (according to an original publication,¹³⁴ a C₈₄ specimen isolated by chromatography consists of at least seven isomers). The success of further work on the determination of the saturated vapour pressures of higher fullerenes will be directly related to the progress in the elaboration of effective and economical techniques both for isolation and collection of individual fullerenes and for separation of them into pure isomers.

b. Fluorofullerenes C₆₀F₁₈, C₆₀F₃₆, C₆₀F₄₈

Two experimental methods were used for the measurements, namely, the classical Knudsen effusion method (KEM) combined with the mass analyser (KCMS)^{135, 136} or with effusion-torsional (ET) technique.¹³⁷

Fluorofullerene C₆₀F₃₆. The recommended¹³⁷ value for the enthalpy of sublimation $\Delta_{\text{sub}}H_T^\circ(\text{C}_{60}\text{F}_{36})$ was calculated by least-squares processing of experimental data obtained by both the KEM and KCMS methods. The values obtained by different methods were averaged with weight factors inversely proportional to their variances; and the resulting recommended value is $\Delta_{\text{sub}}H_{466}^\circ(\text{C}_{60}\text{F}_{36}) = 135 \pm 8$ kJ mol⁻¹.

Combination of the above value of the sublimation enthalpy and the absolute pressure measured by the Knudsen effusion method gave the following equation for the temperature dependence of the saturated vapour pressure of C₆₀F₃₆ in the temperature range of 408–539 K:¹³⁷

$$\ln p(\text{C}_{60}\text{F}_{36}) = (-16292 \pm 939)T^{-1} + (30.90 \pm 1.97).$$

Here and in the subsequent equations, pressure is expressed in Pascals and the temperature is in Kelvins

Fluorofullerene C₆₀F₄₈. The saturated vapour pressure above C₆₀F₄₈ in the temperature range of 473–527 K was determined by the Knudsen effusion method (KEM) and, in parallel, by the effusion-torsional measurements.¹³⁷ On the basis of these measurements, the average molecular masses at temperatures of 499, 508 and 530 K were calculated; the resulting values were 1616, 1660 and 1620 amu, respectively. The average value, 1633 amu, is in good agreement with the molecular mass of C₆₀F₄₈ (1632 amu). This proves convincingly that C₆₀F₄₈ is sublimed without decomposition. This result is confirmed by mass spectra, in which C₆₀F₄₈⁺ was identified as the predominant fullerene-containing ion. The overall pressures measured by the effusion-torsional method at the temperatures mentioned above were 0.10, 0.13 and 0.56 Pa, respectively, which is in good agreement with the KEM results.¹³⁷

The enthalpy of sublimation of C₆₀F₄₈ is 108 ± 7 (KEM) or 111 ± 7 kJ mol⁻¹ (KCMS). In order to compare the partial pressures of C₆₀F₃₆ and C₆₀F₄₈, an additional KCMS experiment was carried out.¹³⁷ Fluorofullerene specimens were placed in two separate compartments of a double Knudsen cell. On the basis of direct measurements of the C₆₀F₄₈⁺:C₆₀F₃₆⁺ ratio of ion currents, the ratio of partial pressures was calculated. The ratio of ionisation cross-sections $\sigma(\text{C}_{60}\text{F}_{36}):\sigma(\text{C}_{60}\text{F}_{48}) = 0.93$ found using the additivity rule, was utilised in the calculations.¹³⁸ The ratios of the partial pressures of C₆₀F₃₆ and C₆₀F₄₈ at 481 and 528 K were 0.37 and 0.54, respectively.

The recommended¹³⁷ enthalpy of sublimation is $\Delta_{\text{sub}}H_{476}^\circ(\text{C}_{60}\text{F}_{48}) = 109 \pm 7$ kJ mol⁻¹. The temperature dependence of the saturated vapour pressure in the temperature range of 395–528 K is described by the following equation:¹³⁷

$$\ln p(\text{C}_{60}\text{F}_{48}) = (-13146 \pm 827)T^{-1} + (24.34 \pm 1.71).$$

Fluorofullerene C₆₀F₁₈. The saturated vapour pressure was measured by the effusion method.¹³⁹ The recommended¹³⁹ equation for the temperature dependence of the saturated vapour pressure in the temperature range of 591–671 K has the form

$$\ln p(\text{C}_{60}\text{F}_{18}) = (-23739 \pm 1234)T^{-1} + (33.23 \pm 1.97).$$

The enthalpy of sublimation $\Delta_{\text{sub}}H_{627}^\circ(\text{C}_{60}\text{F}_{18})$ determined by the classical effusion method equals 197 ± 10 kJ mol⁻¹. According to KCMS data, $\Delta_{\text{sub}}H_{585}^\circ(\text{C}_{60}\text{F}_{18}) = 186 \pm 9$ kJ mol⁻¹.

Comparison of the data on the vapour pressure of C₆₀F₁₈, C₆₀F₃₆ and C₆₀F₄₈. In the temperature range studied by Boltalina *et al.*,¹³⁷ the saturated vapour pressures of C₆₀F₃₆ and C₆₀F₄₈ are rather similar to each other. This can be easily explained in terms of the structures of these molecules. Both molecules can be represented as spheres whose radius is equal to the sum of the radius of the fullerene cage (3.5 Å) and the C–F bond length (1.29 Å). The enthalpy of sublimation of C₆₀F₃₆ (135 ± 8 kJ mol⁻¹) is markedly higher than that for C₆₀F₄₈ (109 ± 7 kJ mol⁻¹). This difference indicates that the enthalpy of sublimation of fluorinated fullerenes tends to decrease with an increase in the total number of fluorine atoms on the carbon cage. {For comparison, the enthalpy of sublimation of [60]fullerene¹²⁶ is $\Delta_{\text{sub}}H_{298}^\circ(\text{C}_{60}) = 172 \pm 11$ kJ mol⁻¹.} The entropies of sublimation of C₆₀F₃₆ and C₆₀F₄₈ (see Ref. 137) are also substantially different

$$\Delta_{\text{sub}}S_{466}^\circ(\text{C}_{60}\text{F}_{36}) = 161 \pm 16 \text{ J mol}^{-1} \text{ K}^{-1},$$

$$\Delta_{\text{sub}}S_{476}^\circ(\text{C}_{60}\text{F}_{48}) = 107 \pm 14 \text{ J mol}^{-1} \text{ K}^{-1}.$$

The value for the enthalpy of sublimation obtained for C₆₀F₁₈ was much higher than those for C₆₀F₃₆ and C₆₀F₄₈. Even pure C₆₀ fullerene has a lower enthalpy of sublimation. Thus, C₆₀F₁₈ clearly does not comply with the general trend of the enthalpy to decrease in the series C₆₀, C₆₀F₃₆, C₆₀F₄₈. This anomaly in the thermal properties of C₆₀F₁₈ can be easily explained by specific features of its molecular structure. All the 18 fluorine atoms are located in one hemisphere of the carbon cage, and the C₆₀F₁₈ molecule (C_{3v} symmetry) has a dipole moment of 6.3 or 6.9 D according to MNDO or density functional theory (DFT) calculations. The C₆₀ and C₆₀F₄₈ molecules have no dipole moment and in the case of C₆₀F₃₆, the dipole moment is also absent for the *T* isomer. The dipole moment of the C₃ isomer of C₆₀F₃₆ (2.3 D, according to our estimates done by MNDO) is much lower than that of C₆₀F₁₈ (7–9 D).¹³⁹ The presence of a dipole moment results in a stronger interaction between the C₆₀F₁₈ molecules in the crystal compared to the dispersion interactions in the crystals of C₆₀, C₆₀F₃₆ or C₆₀F₄₈. As a consequence, more energy is required to transfer C₆₀F₁₈ molecules from the solid state to the vapour. The relatively long retention time of the C₆₀F₁₈ fluorofullerene in the HPLC separation (~40 min vs. 2.9 min for C₆₀F₃₆)¹³⁹ also points to the polar structure of this molecule.

3. The enthalpies of formation

a. Fullerenes C₆₀ and C₇₀

The thermal properties of [60]- and [70]fullerenes are surveyed in detail in a review by Dikii and Kabo.¹⁴⁰ Here we shall consider only the most recent studies devoted to this topic.^{46, 141}

Fullerene C₆₀. An *et al.*¹⁴¹ measured the energy of combustion of [60]fullerene using a liquid calorimeter with an isothermal shell. The average energy of combustion of C₆₀ fullerene found from five experiments was $-36036.06 \pm 6.04 \text{ J g}^{-1}$, and the enthalpy of formation of solid C₆₀ was $2359.47 \pm 9.72 \text{ kJ mol}^{-1}$. A significant difference between the study cited¹⁴¹ and the preceding works is that the authors¹⁴¹ had a substantial amount of [60]fullerene at their disposal. In combustion experiments, 0.5 g weighed portions of fullerene were used, and the energy of combustion of C₆₀ accounted for up to 70% of the total energy evolved in the experiment. This increases the reliability of the values presented above compared to other data on the energy of combustion. In 1997, An *et al.*¹⁴² determined once again the enthalpies of combustion and formation of C₆₀ fullerene using a microcalorimeter. The researchers did not analyse the gaseous products of combustion for carbon dioxide. The energy of combustion of [60]fullerene they found ($-36004.6 \pm 11.8 \text{ J g}^{-1}$) was close to the value determined previously.¹⁴¹

Kolesov *et al.*⁴⁶ were the first to pay attention to the dependence of the enthalpies of combustion and formation of [60]fullerene on the crystal size. They studied two specimens of C₆₀. One specimen prepared by a standard procedure (fast crystallisation of fullerene from a solution and removal of the solvent *in vacuo*) was a brown-coloured finely crystalline powder. The other specimen was prepared using a special procedure: small crystals (0.1–0.2 mm) were grown by slow crystallisation of C₆₀ from a solution in toluene. This material was coloured black and had a characteristic metallic lustre. HPLC analysis showed that the former specimen contained 0.4 mol.% of C₇₀, and the second one was found to contain neither C₇₀, nor C₆₀O.

To determine the energy of combustion of C₆₀ fullerene, Kolesov *et al.*⁴⁶ used a liquid calorimeter with an isothermal shell and a stationary bomb. The energy of combustion of the first specimen found in a series of three experiments was -35896 J g^{-1} , and that for the second specimen found in eight experiments was $-36030 \pm 16 \text{ J g}^{-1}$.

In the study in question,⁴⁶ the gaseous products of combustion were analysed for carbon dioxide. For the first material, the amount of CO₂ found experimentally was markedly lower than the value calculated theoretically, the average content of CO₂ being 99.80%. In the second specimen, the content of CO₂ in the combustion products virtually coincided with the calculated value ($99.99 \pm 0.02\%$). These results of the analysis for the second C₆₀ specimen point to complete burning of the substance and confirm additionally the material purity.

Proceeding from this fact, the researchers⁴⁶ chose as reliable the standard energy of combustion determined for the second C₆₀ specimen with a well-developed crystal structure. The standard enthalpy of formation of crystalline C₆₀ fullerene is equal to $2355 \pm 15 \text{ kJ mol}^{-1}$ (see Ref. 46); this is the most reliable value. The results of An's and Kolesov's studies described above are in good agreement with each other.

Fullerene C₇₀. In 1997, An *et al.*¹⁴² also determined the energy of combustion of [70]fullerene. The energy of combustion of C₇₀ calculated based on the sample weight was $-35629.4 \pm 10.6 \text{ J g}^{-1}$ and the enthalpy of formation was $2410.4 \pm 8.9 \text{ kJ mol}^{-1}$, which did not coincide with earlier data (see the review¹⁴⁰).

The same year Kolesov *et al.*¹⁴³ determined the energy of combustion of C₇₀ fullerene using a liquid calorimeter with an isothermal shell. According to HPLC, the C₇₀ specimen contained an impurity of C₆₀ fullerene (2.0 mass %). Five experiments were carried out, each being accompanied by analysis of the gaseous products of C₇₀ combustion for carbon dioxide; the average result was $99.81\% \pm 0.02\%$. The energy of combustion of C₇₀ fullerene (specimen 1) calculated from the sample weight with correction

for the energy of combustion of the C₆₀ impurity amounts to $-35664 \pm 44 \text{ J g}^{-1}$. The same procedure was also used to burn the coarsely crystalline C₇₀ fullerene (specimen 2), which contained 0.23 mass % of C₆₀ and 0.40 mass % of C₈₄. Nine experiments were carried out for specimen 2; in all experiments, the gaseous products did not contain carbon monoxide. In seven experiments, the gaseous products were analysed for carbon dioxide. The amount of CO₂ determined experimentally (on average, $99.95\% \pm 0.05\%$) coincided, to within the accuracy of analysis, with the theoretical value. The average energy of combustion of C₇₀ for specimen 2 amounted to $-35679 \pm 38 \text{ J g}^{-1}$ (see Ref. 144), which is very close to the value obtained previously for specimen 1. The enthalpies of formation of crystalline C₇₀ reported in two publications^{143, 144} are 2439 ± 38 and $2452 \pm 33 \text{ kJ mol}^{-1}$, respectively. As in the case of [60]fullerene, the data of the two last-mentioned works coincide within experimental error with the results obtained by An *et al.*¹⁴²

b. Fluorofullerenes C₆₀F₄₈ and C₆₀F₃₆

The enthalpies of formation of C₆₀F₄₈ (see Ref. 48) and C₆₀F₃₆ (see Ref. 47) fluorofullerenes were first determined experimentally at the laboratory of thermochemistry of the Moscow State University.

The energies of combustion of fluorofullerenes were found using a calorimeter with an isothermal shell and with a rotating bomb platinum-lined from the inside. The rise of temperature was recorded by a copper resistance thermometer included in a bridge circuit. The sensitivity of the temperature measurement was $5 \times 10^{-5} \text{ K}$.

Each of the two fluorofullerenes was pressed to form a pellet, which was then crushed into pieces. Several pieces with a total weight of 60–70 mg were placed into a terylene-film bag (produced and weighed beforehand), the bag was hermetically sealed, weighed, and heated in a platinum crucible together with a weighed pellet of benzoic acid. Benzoic acid served as the auxiliary material that ensured virtually complete combustion of fluorofullerenes to give only a small amount of soot in the crucible. The correction for this non-burnt residue was only 0.6–2.3 J, while the total amount of heat evolved in the experiment was $\sim 13\,000 \text{ J}$. The heat of combustion of the auxiliary substances, benzoic acid and the terylene film, accounted for 92%–93% of the whole measured heat in the case of C₆₀F₄₈ and 90%–92% for C₆₀F₃₆. After the calorimetric experiments, the combustion products were analysed for the contents of CO₂, HF and HNO₃. The results of the analysis were used to calculate the amount of tetrafluoromethane formed upon combustion, and appropriate corrections were applied (2–10 and 0–4 J for C₆₀F₄₈ and C₆₀F₃₆, respectively).

After all the corrections were applied (including those for impurities contained in the specimens and those for adjustment to the standard conditions), the standard energies of combustion were found in relation to the reactions

Five experiments were carried out for each substance. The average standard energies of combustion thus obtained and the standard enthalpies of combustion and formation calculated from these values are presented in Table 11. The errors were determined for a 95% significance level. The same Table presents the enthalpies of sublimation of fluorofullerenes¹³⁷ and the standard entropies measured by Druzhinina *et al.*¹⁰⁷ Proceeding from these values, the standard enthalpies of formation of fluorofullerenes in the gaseous state and the Gibbs energies of formation of these compounds in the crystalline state were calculated.

Table 11. Thermodynamic characteristics of C₆₀F₄₈ and C₆₀F₃₆ fluorofullerenes at 298.15 K.^{47, 48, 107, 137}

Parameter	C ₆₀ F ₄₈	C ₆₀ F ₃₆
–Δ _c U _m ^o (cr)/kJ mol ^{–1}	24668 ± 163	24714 ± 199
–Δ _c H _m ^o (cr)/kJ mol ^{–1}	24638 ± 163	24692 ± 199
–Δ _f H _m ^o (cr)/kJ mol ^{–1}	7563 ± 166	5362 ± 201
Δ _{sub} H _m ^o /kJ mol ^{–1}	109 ± 7	139 ± 8
–Δ _f H _m ^o (g)/kJ mol ^{–1}	7454 ± 166	5223 ± 201
S ^o /J mol ^{–1} K ^{–1}	1137.2 ± 5.7	1014.5 ± 5.1
–Δ _f G _m ^o (cr)/kJ mol ^{–1}	6349 ± 166	4474 ± 201

Note. Δ_cU_m^o is the standard combustion energy, Δ_cH_m^o, Δ_fH_m^o and Δ_{sub}H_m^o are the standard enthalpies of combustion, formation and sublimation, respectively, S^o is the standard entropy, and Δ_fG_m^o is the Gibbs energy of formation of fluorofullerenes.

The resulting Δ_fH_m^o(g) values for C₆₀F₄₈ and C₆₀F₃₆, the enthalpy of formation of crystalline C₆₀ recommended above (2355 ± 15 kJ mol^{–1}), the enthalpy of sublimation of C₆₀ (181 ± 2 kJ mol^{–1})¹⁴⁵ and the enthalpy of formation of gaseous molecular fluorine (79.38 ± 0.30 kJ mol^{–1})¹¹² were used to calculate the enthalpies of gas-phase decomposition of the fluorofullerenes into fullerene and gaseous fluorine

This gave Δ_rH(8) = 13800 ± 167 kJ mol^{–1} (or 287.5 ± 3.5 kJ per C–F bond) and Δ_rH(9) = 10617 ± 202 kJ mol^{–1} (or 294.9 ± 5.6 kJ per C–F bond).

For the reaction

the calculations gave Δ_rH(10) = 3184 ± 261 kJ mol^{–1} (or 265 ± 22 kJ for each of the twelve C–F bonds that are cleaved on passing from C₆₀F₄₈ to C₆₀F₃₆). Thus, the first experimental data on the energy characteristics of the C–F bonds in fluorofullerenes with high fluorine contents were obtained.

VII. Conclusion

We shall consider some promising lines of research related to fullerenes and their derivatives. A necessary condition for further advancement of thermochemical studies, *i.e.*, accumulation of fundamental thermochemical characteristics of individual fullerene compounds, is the preparation of these compounds in macroscopic amounts (about hundreds of milligrammes) and with satisfactory purity. One may expect that the progress along this line would depend, among other factors, on the practical interest in useful properties of fullerene derivatives. From a fundamental standpoint, it would be of interest to obtain data on the enthalpies of formation and heat capacities of a number of simple fullerene halides (for example, C₆₀Br₂₄, C₆₀Cl₆), the synthesis of which is documented. In combination with the currently available data on C₆₀, C₇₀ and [60]fullerene fluorides and hydrides (C₆₀X₃₆), this would provide a more comprehensive picture of the energy characteristics of the fullerene–hydrogen and fullerene–halogen systems. In turn, creation of even a small thermodynamic database based on experimental results would facilitate development of new theoretical approaches to the description of these systems. For example, this would increase the accuracy of calculations of the relative stability of various fullerene derivatives. It appears rather unlikely that the thermochemical characteristics of endohedral or organic derivatives of fullerenes will be determined in the near future, because in the vast majority of cases, preparation of pure compounds of this class (free from side products and having a homogeneous isomer

composition) is associated with a tedious and expensive HPLC procedure.

Studies of fullerene derivatives in the gas phase will undoubtedly be continued in the near future, because insufficient amounts and purity of substances will not hold up mass-spectrometric measurements. For example, previously, ion–molecule equilibria have been studied successfully even with 3–5 mg samples of mixtures of endohedral metallofullerenes.

The number of objects with interesting ionisation characteristics is constantly extending. For example, mention should be made of a new class of endofullerenes with inner-sphere nitrogen clusters of lanthanides and recently discovered small fullerenes C₂₀¹⁴⁶ and C₃₆.¹⁴⁷

The synthetic works of fluorination of fullerenes would be carried out in the following directions. First, the search for pathways to the fully saturated compound C₆₀F₆₀ and fullerene hyperfluorides, the possibility of whose existence has been shown experimentally,^{65,66} still is of interest. The use of superoxidants, fluorides of metals in higher oxidation states, can lead to new compounds with unique properties. Naturally, it is necessary to continue the attempts to perform the targeted synthesis of compounds with low content of fluorine. These compounds could serve as convenient objects for investigating addition reactions and replacement of fluorine atoms by functional groups. A reaction of this type was first reported in 1997, when the compound C₆₀F₁₅Ph₃ (the product of the replacement of the three sterically most accessible fluorine atoms by three phenyl groups) was synthesised and its structure was characterised.¹⁴⁸

The development of reliable and effective procedures for the preparation of individual fluorofullerene derivatives accomplished in the last two or three years, the presence of data on their structure and purity, and determination of the key physical properties (thermal stability, solubility, air stability, volatility) make it possible to thoroughly and systematically research the chemical and physical properties of these compounds. The few publications on electrochemical properties of fluorofullerenes¹⁴⁹ indicate that fluorofullerenes can prove to be valuable materials for cathodic coatings in electrochemical cells. By varying the fluorine content in fluorofullerene molecules, it should be possible to design materials with desired electrochemical redox potentials; the reductive potential was found to increase by 0.5 V on passing from C₆₀F₃₆ to C₆₀F₄₈.⁴⁰

We have mentioned above that C₆₀F_x fluorofullerenes can be used as fluorinating agents or oxidants; however, this point has not been studied in detail. An interesting applied aspect is the use of C₆₀F₁₈ as a component in the construction of nanostructural charge transfer complexes. Quite recent works on the synthesis of such complexes with C₆₀ resulted in the design of solar batteries based on these compounds.¹⁵⁰ The replacement of [60]fullerene by C₆₀F₁₈ fluorofullerene, which is a more polar molecule with higher electron affinity, can markedly improve characteristics of light-sensitive devices. The exceptionally high polarity of the C₆₀F₁₈ molecule makes this fluorofullerene rather attractive for new fields of electronics; in particular, it could be of interest in the development of molecular transistors.

The authors are grateful to Doctor of Chemical Science A Ya Borshevsky and to PhDs (Chemistry) N B Tamm and I N Ioffe for discussion and valuable remarks.

This work was carried out with the financial support of the Russian Science and Engineering Program 'Fullerenes and Atomic Clusters,' the Russian Foundation for Basic Research (Project Nos. 00-03-32702a, 00-03-32964a), and the INTAS-RFBR (Grant IR-97-1015).

IV. Addition of pyrroles to acetylenes	580
V. Substitution reactions at the double bond	582
VI. Other procedures for the introduction of the vinyl group into the pyrrole ring	584
VII. Conclusion	588

Abstract. The latest advances in the synthesis of C-vinylpyrroles are generalised and systematised. Methods for the synthesis based on reactions of acylpyrroles and dicarbonyl compounds or their synthetic equivalents are still of most importance. New promising methods for the synthesis of C-vinylpyrroles are considered, among them the reactions of alkenyl ketone oximes with acetylene in the KOH – DMSO system and base-catalysed condensation of pyrrolecarbodithioates, which have recently become available, with CH-acids. The bibliography includes 195 references.

I. Introduction

The chemistry of pyrroles attracts continuing interest because of the enormous biological potential of these compounds and the possibility of their use in the design of new pharmaceuticals as well as of electro- and photoconducting materials. Functionalised vinylpyrroles occupy a special place as promising intermediates in the synthesis of new heterocyclic compounds,^{1–4} valuable monomers^{5–8} and also as ligands for new photocatalysts and biologically active complexes.⁹

Fragments of 2-vinylpyrroles are involved in life-supporting systems, such as porphyrins, vitamin B₁₂, bile pigments, chlorins, florins, oxoflorins, biliverdins and stercobilins. 3-Vinylpyrrole structures are present in haemoglobin and myoglobin, which are responsible for oxygen transport from the lungs to tissue cells of organisms and for oxygen storage, respectively, and also in chlorophyll which is responsible for photosynthesis. C-Vinylpyrroles bearing functional groups at the double bond (or deprived of these groups) serve as reactive intermediates for the directed synthesis of conjugated and fused heterocyclic compounds simulating natural pyrrole ensembles. This generates

continuing interest in the development of new procedures for their synthesis and gives impetus to the examination of the reactivities and biological activities of C-vinylpyrroles.

1-Vinylpyrroles have been studied extensively and comprehensively in the last three decades. These compounds have become readily accessible owing to the discovery and development of a simple procedure for their synthesis from ketoximes and acetylene in the MOH – DMSO system, where M = Li, Na or K (Trofimov's reaction^{10–16}). The data on the synthesis, structures, reactivities and biological activities of 1-vinylpyrroles were exhaustively surveyed in monographs^{11, 13} and reviews.^{16–27}

Since the publication of the latest monographs^{16, 28, 29} covering different aspects of the structures, reactivities and synthesis of C-vinylpyrroles, a substantial body of literature has evolved, which called for systematisation, analysis and generalisation of the new data.

The present review is devoted to procedures for the synthesis of C-vinylpyrroles, including those containing different functional substituents both in the vinyl group and pyrrole ring, and surveys the data, which were published in the last decade and were not covered in monographs and reviews.

Procedures for the synthesis of C-vinylpyrroles can be classified into several main categories: (1) syntheses based on acylpyrroles; (2) syntheses starting from functionalised aliphatic compounds; (3) addition of pyrroles to compounds with an activated triple bond (C-vinylation); (4) substitution at a double bond.

II. Synthesis of C-vinylpyrroles from acylpyrroles

Presently, 2- and 3-acylpyrroles (primarily, formylpyrroles) are the most commonly used starting compounds in the synthesis of C-vinylpyrroles.

1. Condensation of formylpyrroles with CH-acids

The ability of 2- and 3-formylpyrroles to be readily involved in condensation with different CH-acids is widely used in the synthesis of C-vinylpyrroles.

a. Condensation with malononitrile

2-(2,2-Dicyanovinyl)pyrrole (**2**) was prepared from 2-formylpyrrole (**1**) and malononitrile in the presence of glycine.³⁰

Received 22 April 2002

Uspekhi Khimii 71 (7) 641–671 (2002); translated by T N Safonova

Tetrahydropyrrollopyridine **3** was synthesised by refluxing 2-formyl derivative **4** with malononitrile.³¹

The reactions of 2- and 3-formylpyrroles **5** with malononitrile in the piperidine–methanol system afforded the corresponding 2- and 3-dicyanovinyl derivatives **6** in 87% and 75% yields, respectively.³²

Pip is piperidine.

Under analogous conditions, 3-, 4- and 5-(piperazinylmethyl)-2-formylpyrroles **7** reacted with malononitrile to form the corresponding 2-(dicyanovinyl)pyrroles **8** in 49%–90% yields.³³

R = H, Cl.

Condensation of 4-acetoxy-3-ethoxycarbonyl-5-formyl-2-methylpyrrole (**9a**) with malononitrile in the presence of triethylamine gave rise to derivative **10** in high yield,³⁴ and subsequent heating of the latter with piperidine led to elimination of the acetyl group to form the stable piperidinium salt of 4-hydroxypyrrrole **11**. Subsequent acidification of the salt **11** produced 5-(2,2-dicyanovinyl)-3-ethoxycarbonyl-4-hydroxy-2-methylpyrrole (**12**). Tosyl derivative **13** was generated both in the reaction of the pyrrole **12**

with *p*-toluenesulfonyl chloride and upon condensation of tosyl-oxy aldehyde **9b** with malononitrile.³⁴

The reactions of formylpyrroles with malononitrile or cyanoacetic ester yielding the corresponding vinylpyrroles are often used for protection of the aldehyde function in the synthesis of porphyrins. The aldehyde group is readily regenerated upon treatment of these pyrroles with alkali. Thus Woodward *et al.*³⁵ performed the synthesis of chlorophyll starting from 2,4-di(ethoxycarbonyl)-3,5-dimethylpyrrole (Knorr pyrrole) through condensation of 4-formyl-substituted pyrrole **14** with malononitrile, oxidation of the methyl group in compound **15** to the corresponding methyl ester **16** and hydrolysis, which resulted in regeneration of the aldehyde group to give pyrrole **17**. The latter was transformed into 4-(2-nitrovinyl)pyrrole **18** upon refluxing with nitromethane in the presence of triethylamine. The pyrrole **18** was used as the starting compound in the synthesis of chlorophyll.

Analogously, the reaction of substituted 2-formylpyrrole **19** with malononitrile yielded 2-(2,2-dicyanovinyl)-4-ethyl-3,5-dimethylpyrrole (**20**) whose treatment with suluryl chloride afforded 5-chloromethyl-2-(2,2-dicyanovinyl)-4-ethyl-3-methylpyrrole (**21**).³⁵

b. Condensation with alkoxycarbonyl- and amidomalnonitriles

Condensation of the tosyl-oxy aldehyde **9b** with ethyl cyanoacetate and cyanoacetamide proceeded upon refluxing in isopropyl alcohol in the presence of piperidine. Water that was liberated hydrolysed the sulfonate group either partially or completely. The reaction with cyanoacetamide afforded 5-(2-carbamoyl-2-cyano-vinyl)-4-hydroxypyrrrole **22**, whereas the reaction of ethyl cyanoacetate gave rise to 5-(2-cyano-2-ethoxycarbonylvinyl)-3-

ethoxycarbonyl-4-hydroxy-2-methylpyrrole (**23**) along with compound **24** containing the *p*-toluenesulfonate group.³⁶

The reaction of 5-formyl-substituted pyrrole **25** with cyanoacetamide or ethyl cyanoacetate produced the corresponding 5-vinylpyrroles **26**.³⁷

R = CONH₂, CO₂Et.

Condensation of aldehyde **27** with ethyl cyanoacetate was used for protection of the aldehyde group of pyrrole in the synthesis of the acetylene- and cumulene-containing porphyrinoid **28**.³⁸ Scheme 1 was employed for the preparation of functionalised vinylpyrroles **29–31**. Thus the 5-vinylpyrrole **29** generated in the first step was successively transformed into pyrrolecarboxylic acid **30** and then to iodopyrrole **31**, which gave 3,4-diethyl-2-formyl-5-iodopyrrole upon refluxing in methanol with NaOH. Subsequent cross-coupling and cyclisation afforded the porphyrinoid **28**.³⁸

Functionalised vinylpyrroles **32–34** were prepared by treatment of 2-*tert*-butoxycarbonyl-5-formyl-3,4-dimethylpyrrole (**35**)

with methyl cyanoacetate. Hydrolysis of the ester group in the resulting vinylpyrrole **32** under the action of trifluoroacetic acid yielded vinylpyrrolecarboxylic acid **33**, which was transformed into 5-bromo-2-vinylpyrrole **34**.³⁹

4-Bromo-2-(2-cyano-2-methoxycarbonylvinyl)pyrrole (**36**) was prepared by condensation of 4-bromo-2-formylpyrrole (**37**) with methyl cyanoacetate.⁴⁰

c. Condensation with malonic acid and its esters

Functionalised 5-hydroxy-4-vinylpyrrole **38** was synthesised from 4-formyl-5-hydroxypyrrole **39** and malonic acid.⁴¹

Scheme 1

4-Vinylpyrrole **40** was prepared from the 4-formyl-substituted pyrrole **14** and malonic acid ³⁵ by decarboxylating condensation in the presence of aniline.

The reaction of 4-formyl-substituted pyrrole **41** with diethyl malonate afforded 4-vinylpyrrole **42**. Reductive elimination of the methylthiocarbonyl group from the pyrrole **41** under the action of Raney nickel (acetone, refluxing, 30 min) and successive treatment with potassium hydride and methoxybenzenesulfonyl chloride (THF, -78°C) gave rise to pyrrole **43**.⁴²

Functionalised 3,4-divinylpyrrole **44** was synthesised by condensation of 3,4-diformylpyrrole **45** with diethyl malonate. Treatment of the potassium derivative, which was prepared by the reaction of compound **44** with potassium hydride, with benzenesulfonyl chloride afforded *N*-substituted divinylpyrrole **46**.⁴²

Classical Knoevenagel condensation of 2-formylpyrroles **47** with isopropylidene malonate (Meldrum's acid, **48**) in the presence of piperidinium acetate as a catalyst was used in the synthesis of 2-vinylpyrroles **49**.⁴³

R = Me, MeO, CO₂Me.

The 5-formyl-substituted pyrrole **25** reacted with Meldrum's acid on refluxing in isopropyl alcohol in the presence of triethylamine to give 5-vinylpyrrole **50**.³⁷

Condensation of 2-acetylpyrrole (**51**) with Meldrum's acid (**48**) in the presence of titanium tetrachloride produced 2-vinylpyrrole **52**.⁴³

d. Condensation with acid derivatives containing the active methylene group

2-Vinylpyrroles **54** were synthesised by the Claisen reaction from 2-formylpyrroles **53** and ethyl acetate.⁴⁴

R = H, 4-MeO, 2-NO₂, 4-Cl.

Stobbe condensation of 2-formylpyrrole (**1**) with dimethyl succinate **55** afforded functionalised 2-vinylpyrrole **56** from which diester **57** was obtained in quantitative yield. Reduction of the latter gave rise to 1,4-diol **58**.⁴⁵

2,5-Diformyl-1-methylpyrrole (**59**) reacted with ethyl azidoacetate to form bis(azidovinyl)pyrrole **60**. Treatment of the latter with triphenylphosphine afforded divinylpyrrole **61** containing the iminophosphorane functional groups.⁴⁶

Substituted 2-vinylpyrrole **62** was prepared by refluxing 2-formylpyrrole (**1**) with 5-acetylamino-4-cyano-2-ethoxycarbonyl-3-ethoxycarbonylmethylthiophene (**63**).⁴⁷

Heating of the formylpyrroles **9a,b** with hippuric acid (which was transformed into azlactone **64** under the reaction conditions) in acetic anhydride afforded 4-acetoxy- or 4-tosyloxy-5-pyrrolylmethyleneoxazolines **65a,b** containing the vinylpyrrole fragment.⁴⁸

$\text{R} = \text{Ac}$ (**a**), Ts (**b**).

e. Condensation with cyanomethylhetarenes and alkenes (hetaryl- and alkenylacetonitriles)

2-Formylpyrrole (**1**) undergoes condensation with nitriles of pyrazolylacetic acids to form the corresponding 1,2-dihetarylcyanoalkanes **66**. The ratio between the *Z* and *E* isomers of the compounds **66** depends on the temperature and reaction time.^{49, 50}

$\text{R} = \text{Ph}$, 4- MeC_6H_4 , 4- MeOC_6H_4 , 4- FC_6H_4 , 4- ClC_6H_4 , 4- BrC_6H_4 , 3- MeOC_6H_4 , 3- BrC_6H_4 .

At 20°C , the *Z* isomers of the alkenes **66** were selectively generated during 4–5 h (the yields were 88%–95%). At

90 – 100°C (20–24 h), the thermodynamically more stable *E* isomers were obtained as the major reaction products (the yields were 52%–60%). In the latter case, the yields of the *Z* isomers were no higher than 25%–30%. The ratio between the isomers remained unchanged as the duration of heating was increased, which indicates that an equilibrium was established. Attempts to transform the *Z* isomers of the compounds **66** into the *E* isomers by refluxing in methanol were unsuccessful. However, the degree of isomerisation reached 100% upon the addition of Bu^tONa to the reaction mixture.⁴⁹

2-Formylpyrrole (**1**) reacted with 2-cyanomethylbenzothiazole to give 2-vinylpyrrole **67** in 85% yield.³⁰

Condensation of 2-formylpyrrole (**1**) with glutakonitrile in the presence of β -alanine afforded butadiene derivative **68**.⁵¹

f. Condensation with ketones

2-Vinylpyrroles **69** were synthesised by base-catalysed condensation of 2-formylpyrrole (**1**) with aromatic ketones **70**.⁵²

$\text{R} = \text{CH}_2\text{CO}_2\text{Et}$, $(\text{CH}_2)_2\text{OH}$.

2-Formyl-*N*-propargylpyrrole (**71**), which was prepared from 2-formylpyrrole (**1**) and propargyl bromide under the conditions of phase transfer catalysis, reacted with acetophenone in the presence of NaOH to give benzoylvinylpyrrole **72**.⁵³

2-[2-Benzoyl-2-(benzimidazol-2-yl)]vinylpyrrole (**73**) was prepared by condensation of 2-formyl-1-methylpyrrole with ketone **74** in the presence of β -alanine.⁵⁴

5-Vinylpyrrole **76** was synthesised from 5-formylpyrrole **25** and dimedone (**75**).³⁷

g. Condensation with nitroalkanes

The reaction of 2-formyl-3-(4-iodophenyl)pyrrole (**77**) with nitromethane in the presence of a small excess of methylamine hydrochloride afforded 2-(2-nitrovinyl)pyrrole **78**.⁵⁵

The reactions of *N*-aryl-2(3)-formylpyrroles **79** with nitroalkanes produced the *E* isomers of the corresponding 2- and 3-(2-nitrovinyl)pyrroles **80** in 64%–78% yields.^{44, 56}

$R^1 = \text{H, 4-MeO, 2-NO}_2, 4\text{-Cl}$; $R^2 = \text{H, Me, Et}$.

2-(2-Chloro-2-nitrovinyl)-1-methylpyrrole (**81**) was synthesised by condensation of 2-formyl-1-methylpyrrole with nitrochloromethane in the presence of catalytic amounts of ethylenediamine.⁵⁷

h. Condensation with sulfones

Condensation of 2-formyl-*N*-methoxymethylpyrrole (**82**) with sulfones **83** or **84** in the presence of 50 equiv. of sodium methoxide afforded 1,2-diaryl-1-sulfonyl-ethenes **85** and **86** in 76% and 78% yields, respectively.⁵⁸ Under these conditions, aldehyde **87** underwent condensation with sulfone **88** to give a mixture of diester **89** and a product of its hydrolysis with water generated in the course of the reaction. The compound **89** was isolated in 89% yield after treatment of the resulting mixture with thionyl chloride.

Under analogous conditions, the reaction of the sulfone **84** with thiophene-2-carbaldehyde (**90**) gave rise to thienyl-substituted vinylpyrrole **91** in low yield.

Apparently, the low yield is attributed to the Cannizzaro side reaction to which thiophenecarbaldehyde is more susceptible than aldehydes of the pyrrole series.

Condensation of thiophene-2-carbaldehyde (**90**) with the lithium derivative of sulfone **84** followed by hydrolysis with 10% HCl afforded a mixture of diastereomers of alcohol **92**. The latter was transformed into the alkene **91** by treatment with mesityl chloride.⁵⁸

2. Wittig reaction

The reactions of formyl- and acetylpyrroles with alkylidenephosphoranes, which are generated upon dehydrohalogenation of quaternary phosphonium salts under the action of bases (Wittig reaction) is one of the most commonly used approaches to the synthesis of *C*-vinylpyrroles.^{59–78}

Carbonyl derivatives of 1-vinylpyrroles **93**, which were prepared by dehydrohalogenation of 1-(2-chloroethyl)pyrroles **94** under the action of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in DMSO at 80 °C, underwent methylenation upon treatment with methyltriphenylphosphonium bromide in the presence of sodium amide (the **93**:CH₂=PPh₃ ratio is 1:2) to give vinylpyrroles **95**. Dehydrohalogenation and methylenation of the chloroethyl derivatives **94** can be carried out in one step by using larger amounts of the phosphonium salt and sodium amide as well as by increasing the reaction time.⁵⁹

R = H, Me.

The analogous reactions of 3-acyl-1-tosylpyrroles **96** with methyltriphenylphosphonium bromide afforded 1-tosyl-3-vinylpyrroles **97**.⁶⁰

R = Me, Prⁱ, Ph.

The same procedure was used for the synthesis of substituted 2-vinylpyrroles **99** from 2-formylpyrroles **98** and methyltriphenylphosphonium bromide.^{61, 62}

R¹ = Me, Ts, CO₂Bu^t (Boc); R² = H, Me, NO₂;

R³ = H, Me, (CH₂)₂CN.

The reactions of 2-formyl-1-methylpyrrole with substituted benzyltriphenylphosphonium bromides produced (*E*)- and (*Z*)-*N*-methyl(styryl)pyrroles **100**.⁶³ In some cases, isomers were separated by column chromatography. Photochemical isomerisation of the initially formed *Z* isomers into *E* isomers was observed.⁶³

R¹ = 4-Br, 3-CN, 4-CN, 3-NO₂, 4-Cl; R² = H, Cl.

The Wittig reaction of diphosphonium salt **101** proceeded with two 2-formylpyrrole molecules to give 2,2'-(1,2-phenylenedivinyl)dipyrroles **102** (a mixture of stereoisomers) in 32% (R = H) and 40% (R = Me) yields.⁶⁴

2-Styrylpyrroles **103** were generated as by-products due, apparently, to steric hindrances caused by the *o*-substituents in the diphosphonium salt **101**, which prevent the reaction of this salt with the second aldehyde molecule.⁶⁴

The reaction of the dialdehyde **59** with phosphonium salt **104** proceeded at both aldehyde groups to yield 2,5-distyrylpyrrole **105**.⁶⁵

Under the analogous conditions, the reaction of *p*-xylylenebis(triphenylphosphonium) chloride **106** with 2-formyl-1-methylpyrrole proceeded selectively to produce 1,1-dimethyl-2,2'-(1,4-phenylenedivinyl)dipyrrole (**107**) in 50% yield.⁶⁵ The initially formed mixture of the *E,E*, *E,Z* and *Z,Z* isomers of the compound **107** was isomerised into the pure *E,E* isomer upon refluxing in toluene in the presence of catalytic amounts of iodine.

A series of studies performed by Arai and co-workers^{66–70} was devoted to the examination of isomerisation of 2-(2-hetarylvinyl)pyrroles **108–111** containing the pyridine,^{66, 67} quinoxaline,⁶⁶ quinoxaline⁶⁸ or phenanthroline substituents.⁶⁹

The compounds **108–111** were prepared by the reactions of 2-formylpyrrole (**1**) with ylides generated from the corresponding halogen-containing heterocycles and methylenetriphenylphosphorane. For example, the pyridine-substituted 2-vinylpyrrole **108** was synthesised from 2-formylpyrrole (**1**), 2-bromopyridine and methyltriphenylphosphonium bromide.⁶⁶

When irradiated with UV light ($\lambda = 366 \text{ nm}$) in methanol, benzene or acetonitrile at 20°C under an atmosphere of nitrogen, the initially formed *E* isomers of the compounds **108–111** were transformed into the *Z* isomers due, apparently, to intramolecular hydrogen bonding between the proton of the NH group of the pyrrole fragment and the nitrogen atom of the heterocycle. For example, the structure **A** was obtained in the case of 2-[2-(2-pyridyl)]vinylpyrrole **108**. The reverse transformation of the *Z* isomers into the *E* isomers proceeded in the presence of NiCl_2 .⁶⁹

The pyrrole analogue of prostaglandins **112** was synthesised from 2-formylpyrrole (**1**) and phosphorane **113** followed by alkylation of the pyrrole fragment of compound **114** with methyl 7-iodoheptanoate (**115**) and reduction of the carbonyl group in the reaction product **116** with sodium borohydride.⁷¹

The reactions of 2-formyl-5-methylpyrrole (**117a**) and 3-acetyl-5-formyl-2-methylpyrrole (**117b**) with ethoxycarbonylmethylenephosphorane afforded 2-vinylpyrroles **118a,b** in 93% and 73% yields, respectively.⁷²

R = H (**a**), Ac (**b**).

2-Vinylpyrroles **121** and **122** (a mixture of the *E,E*, *E,Z* and *Z,Z* isomers) were synthesised by the reactions of 2-formylpyrroles **1** and **47** with phosphoranes **119** and **120**, respectively.⁷³

$\text{R}^1 = \text{H}$ (**1**), Me (**47**); $\text{R}^2 = \text{H}$, Me, MeO, CO_2Me , CN; $\text{R}^3 = \text{Me}$, Et.

Optically active 3-vinylpyrrole **123** was prepared by refluxing unstable 3-formylpyrrole **124** with chiral Wittig reagent **125** in acetonitrile.⁷⁴

The sodium salt of functionally substituted 3-vinylpyrrole **127**, which is a potential inhibitor of HMG-CoA reductase, was prepared by a series of transformations of the vinylpyrrole **123** involving removal of the silyl protective group, stereoselective reduction of the carbonyl group and hydrolysis of methyl ester **126**.⁷⁵

A broad spectrum of (*E*)-3-[2-(*N*-phenylcarbamoyl)vinyl]pyrrole-2-carboxylic acids **128** containing various substituents at positions 4 or 5 of the pyrrole ring were synthesised by olefination of the corresponding 3-formylpyrroles **129** with phosphoranes, which were prepared from triphenyl- or tri-*tert*-butyl(*N*-phenylcarbamoyl)methylphosphonium bromides **130** followed by hydrolysis of the ester group in the resulting compounds **131**.^{76,77}

$\text{R}^1 = \text{Me, Et; R}^2 = \text{H, Me, Et, Pr}^i, \text{OEt, OBn, Br, Cl;}$
 $\text{R}^3 = \text{H, Me, Et, Pr}^i, \text{Ph, 2,4-Cl}_2\text{C}_6\text{H}_3, \text{Br; R}^4 = \text{Bu}^t, \text{Ph.}$

4-Iodo-5-methyl-3-[2-(*N*-phenylcarbamoyl)vinyl]pyrroles (**132a**) and 4,5-diiodo-3-[2-(*N*-phenylcarbamoyl)vinyl]pyrroles (**132b**) were synthesised by iodination of the pyrroles **131** ($\text{R}^2 = \text{H}$, $\text{R}^3 = \text{H}$ or Me) with one or two equivalents of *N*-iodosuccinimide (NIS). Vinylpyrroles **133** were prepared by Friedel–Crafts acylation of the pyrroles **131** ($\text{R}^2 = \text{H}$).⁷⁶

The active antibiotic, *viz.*, 3-[2-(2-pyrrolyl)vinyl]cefalosporin **134**, was prepared as a mixture of *E* and *Z* isomers in a ratio of 1 : 3 in a total yield of 30% from 7-aminocefalosporanic acid **135**. The scheme for the synthesis involves the transformation of the acetoxymethyl group into the iodomethyl group, the formation of the phosphonium salt through the reaction of the 3-iodomethyl derivative with triphenylphosphine and its reaction with 2-formylpyrrole (**1**).⁷⁸

3. Horner reaction

Procedures for the synthesis of C-vinylpyrroles from acylpyrroles and dialkyl phosphonates in the presence of bases (Horner or Wittig–Horner reactions) are being extensively developed.^{73, 79–87}

Olefination of 2-formylpyrrole (**1**) with phosphonate **136** was carried out with the use of $\text{Cs}_2\text{CO}_3 \cdot 3\text{H}_2\text{O}$ (1.5-fold excess) as a base. The reaction was conducted in dioxane in a two-phase system to yield 2-[2-(ethoxycarbonyl)vinyl]pyrrole **137**.⁷⁹

Functionalised 2-vinylpyrroles **138** (*E* and *Z* isomers) were prepared from the 2-formylpyrroles **1** and **47** and the phosphonates **136** and **139**.⁷³

$\text{R}^1 = \text{H (1), Me, MeO, CO}_2\text{Me, CN (47);}$

$\text{R}^2 = \text{CO}_2\text{Et (136), CO}_2\text{Me (139).}$

Bis(ethoxycarbonylvinyl)pyrrole **140** was synthesised by the Horner reaction from 3,4-diformyl-2,5-dimethylpyrrole **45** and the phosphonate **136**. Oxidation of the methyl groups in the latter compound afforded 3,4-bis(2-ethoxycarbonylvinyl)-2,5-diformylpyrrole (**141**).⁸⁰

Ethyl (*E*)-3-[4-(4-*R*-benzoyl)-1-methylpyrrol-2-yl]acrylates **142** were prepared by the reactions of 4-(4-*R*-benzoyl)-2-formyl-1-methylpyrroles **143** with the phosphonate **136**. Alkaline hydrolysis of the esters **142** in ethanol afforded the corresponding acids **144**, which were transformed into [2-(*N*-hydroxyamido)vinyl]pyrroles **145**.⁸¹

$\text{R} = \text{H, NO}_2, \text{Cl, F, MeO, NMe}_2, \text{imidazol-1-yl.}$

Substituted 2-vinylpyrrole **147**, which was prepared from 2-formylpyrrole **148** and the phosphonate **136**, served as the key intermediate in the synthesis of the precursor of the DNA-dialkylating agent, *viz.*, activated amide **146**. Subsequent hydrolysis of the compound **147** followed by acidification with HCl gave rise to acid **149** in 67% yield. When treated with 1,1'-carbonyldiimidazole (**150**) in DMF, the latter was transformed into the target 2-vinylpyrrole **146**.⁸²

N-Substituted 3-formylpyrrole **151** reacted with phosphonate **152** in the presence of Bu^tOK to produce 3-ethoxycarbonylvinylpyrrole **153**.⁸³

The scheme for the synthesis of the benzannulated analogue of the antibiotic CC-1065 involves the Horner reaction as the first step. *N*-Benzyl-2-(2-methoxy-2-phenylvinyl)pyrrole (*E*-**154**) was synthesised from 1-benzyl-2-formylpyrrole **155** and phosphonate **156** in dry DMF by the portionwise addition of Bu^tOK during 8 h.⁸⁴

2-Butadienylpyrroles **157**, which are used in the synthesis of retinoids, were prepared as a mixture of the *E,E* and *E,Z* isomers

in a ratio of 7 : 3 by the reactions of 2-formyl-1,5-dimethylpyrroles **158** with phosphonate **159**.⁸⁵

R = Ac (77%), CO₂Et (82%).

Functionalised 3-vinylpyrrole **160** was synthesised by the Horner–Emmons reaction from 3-formylpyrrole **161** and trimethyl *N*-(benzyloxycarbonyl)phosphonoglycine (**162**) in the presence of tetramethylguanidine **163**.⁸⁶

The two-step synthesis produced a mixture of the *E* and *Z* isomers of 2-(4-tolylsulfinyl)vinylpyrrole **164** (in a ratio of 67 : 33) in a total yield of 82%.⁸⁷ The process involved *N*-allylation of 2-formylpyrrole (**1**) with 3-bromo-2-iodopropene followed by olefination of aldehyde **165** with phosphonate **166**.

TEBA-Cl is benzyltriethylammonium chloride; LDA is Pr₂NLi; Tol is 4-MeC₆H₄.

4. Dimerisation of acylpyrroles

The intermediates in the synthesis of *meso*-substituted porphyrinoids, *viz.*, 1,1- and 1,2-dipyrrolylethenes, are often prepared by reductive dimerisation of 2-formylpyrroles. In these reactions, titanium compounds are generally used as catalysts.^{88–95}

Thus dipyrrolylethenes **167a–d** were prepared by refluxing *N*-substituted 2-formylpyrroles with TiCl₃ in dry dimethoxyethane in the presence of metal lithium in argon.⁸⁸ The yields of the reaction products depend on the nature of the substituent. The reactions of 2-formyl- and 2-formyl-1-methylpyrroles proceeded non-selectively to give complex mixtures of products, whereas dimerisation of 1-ethoxycarbonyl- and 1-acetyl-2-formylpyrroles afforded dipyrrolylethenes **167c,d** in 30% and 50% yields, respectively.⁸⁸

R = H (**a**), Me (**b**), COMe (**c**), CO₂Et (**d**).

1,2-Di(pyrrol-2-yl)ethenes **168** (*E* and *Z* isomers) were synthesised from pyrroles **169** in the presence of TiCl₄ and Zn.^{89, 90}

R = Et, COMe, CO₂Et, CH₂CH₂CO₂Et.

Refluxing of 2-formylpyrroles **170a–c** with the TiCl₃·(DME)_{1.5} complex in dimethoxyethane in the presence of the Zn–Cu system (15 equiv.) afforded the *E* isomers of 1,2-di(pyrrol-2-yl)ethenes **171a–c**.^{91, 92} The lower yields of the pyrroles **171b, c** are apparently attributed to lability of the methoxycarbonyl and *tert*-butoxycarbonyl ester groups in the presence of the titanium reagent.

Compound	R ¹	R ²	Yield (%)
172a	Bn	Me	81
172b	Bu ^t	Et	22
173	Bn	(CH ₂) ₂ CO ₂ Me	46

An attempt to perform cross-coupling of the pyrroles **170a** and **170c** to obtain mixed 1,2-di(pyrrol-2-yl)ethene failed; instead, the reaction afforded the pyrrole **171a** as the major product (20%).⁹¹

Treatment of ethyl 4-formyl-3,5-dimethylpyrrole-2-carboxylate (**14**) with the TiCl₄–Zn system in THF gave rise to a complex mixture of the reaction products. From this mixture, acid **174** was isolated in 10% yield through dimerisation of the 3-formylpyrrole **14** followed by hydrolysis of the ester groups in dimer **175**.⁹³

However, the reaction of the 5-formylpyrrole **171** performed under the same conditions afforded reductive dimerisation product **173** (*E*:*Z* = 1:4) in 86% yield. In this case, hydrolysis of the ester groups did not take place.⁹³

Friedel–Crafts acylation of 3,4-dimethylpyrrole-5-carboxylates **176** containing no substituents at position 2 with acetic anhydride in the presence of tin chloride afforded symmetrical 1,1-di(pyrrol-5-yl)ethenes **177** as by-products due to condensation of ketones **178** with the starting pyrroles **176**, which proceeded under the reaction conditions.^{91, 94}

R = H, Et, Bn.

The proposed⁹¹ reaction mechanism involves the electrophilic attack of the acylium ion on the pyrrole **176** giving rise to the cationoid intermediate **179**. The latter lost the proton at the α position to form the 2-acetylpyrrole **178**. The cation **179** can attack the second molecule of the pyrrole **176** to generate intermediate hydroxydipyrrolyethane **180** whose dehydration afforded the 1,1-di(pyrrol-2-yl)ethene **177**.⁹¹

Ketone **181** reacted with the TiCl₄–Zn system to give 2,3-dipyrrolylbut-2-ene **182** in low yield. The reaction produced benzyl chloride rather than benzyl alcohol as a by-product. Cheng *et al.*⁹³ believed that this fact indicates that it is not the treatment that led to hydrolysis of the ester groups.

Reductive dimerisation of di(pyrrol-2-yl) ketone **183** in the presence of Ti(0) yielding 1,1,2,2-tetra(pyrrol-2-yl)ethene **184** may also be assigned to this type of reactions.⁹⁵

5. Other reactions involving acylpyrroles

Dehydration of 3-(1-hydroxyalkyl)-1-tosylpyrroles **185**, which were synthesised by reduction of 3-acylpyrroles **96** with sodium borohydride, afforded 3-vinylpyrroles **186**.⁹⁶ Detosylation of the latter with NaOH gave rise to 3-vinylpyrroles **187** in 66%–87% yields.^{60, 96}

$R^1 = \text{Me}, R^2 = R^3 = \text{H}; R^1 = \text{Et}, R^2 = \text{H}, R^3 = \text{Me};$
 $R^1 = \text{Bn}, R^2 = \text{H}, R^3 = \text{Ph}; R^1 = \text{Pr}^i, R^2 = R^3 = \text{Me}.$

The reactions of 3-acetyl-1-tosylpyrrole (**96**) with Grignard reagents in THF produced 3-(1-hydroxyethyl)-1-tosylpyrroles **188**, which lost water upon heating in DMSO to give 3-(1-*R*-vinyl)pyrroles **97**.⁶⁰

$R = \text{Me}, \text{Pr}^i, \text{Ph}.$

The reaction of alcohol **189**, which was synthesised from 1-methyl-2-trifluoroacetylpyrrole **190** and methylmagnesium iodide, with trifluoroacetic acid (0.1 M solution in CCl_4) afforded a mixture of products from which pyrroles **191**–**194** were isolated by chromatography in a ratio of 4 : 7 : 8 : 74.⁹⁷

The reaction of 4-acetyl-2-ethoxycarbonyl-1,3,5-trimethylpyrrole (**195**) with POCl_3 gave rise to 3-(1-chlorovinyl)pyrrole **196**.⁹⁸

The reaction of 2-formyl-*N*-tosylpyrrole (**98**) with tetrabromomethane in the presence of triphenylphosphine yielded 2-(2,2-dibromovinyl)pyrrole **197**.⁶¹

Successive treatment of 2-acetylpyrroles **198a–c** with lithium diisopropylamide and trimethylchlorosilane produced 2-[1-(trimethylsilyloxy)vinyl]pyrroles **199a–c**.⁹⁹ Silylation of 2-acetyl-1-ethoxycarbonylpyrrole **198d** in acetonitrile at 20 °C in the presence of triethylamine and catalytic amounts of ZnCl_2 afforded compound **199d**.⁹⁹

$R = \text{Me}$ (**a**, 85%), Me_3Si (**b**), SO_2Ph (**c**, 85%), CO_2Et (**d**, 93%).

1-(1-Methylpyrrol-2-yl)-2-(*p*-tolylazo)alkene **200** (predominantly, the *E* isomer) was prepared from 2-acetyl-1-methylpyrrole **198a** in three steps.

In the first step, diketone hydrazone **201** was prepared by the reaction of the enol form of 2-acetyl-1-methylpyrrole (**198a**) with *tert*-butyl *p*-tolylazo sulfide **202**. The second step involves selective reduction of the carbonyl group of the compound **201** with sodium borohydride. Hydrazone **203** was dehydrated to the diazadiene **200** either in a two-phase system (dilute sulfuric acid–diethyl ether) at 25 °C or in an acetic anhydride–pyridine mixture at 50 °C.¹⁰⁰

Condensation of γ -(trimethylsilyl)crotylborane **204**, which was prepared from trimethylsilyllallene **205** and 9-borabicyclo[3.3.1]nonane (**206**), with 2-formyl-1-methylpyrrole afforded intermediate **207**. Treatment of the latter with a base (to initiate Peterson olefination) led to the virtually selective formation of the *Z* isomer of 1-(pyrrol-2-yl)isoprene **208**.¹⁰¹

2-Formylpyrrole (**1**) smoothly reacted with *N,N,N',N'*-tetramethylacetimidium methyl sulfate **209** to produce *N,N,N',N'*-tetramethyl-3-(2-pyrrolyl)acrylamidinium methyl sulfate **210**.¹⁰²

Aminomethylation of 2- and 3-acetylpyrroles **211** with dimethylformamide dimethyl acetal afforded 2- and 3-aminovinyl ketones **212** in 92% and 93% yields, respectively. The reactions of these ketones with POCl₃ in the presence of sodium hexafluorophosphate gave rise to (1-chlorovinyl)pyrroles **213** in 75% and 78% yields, respectively. The latter were transformed into (amino-vinyl)pyrroles **214** (the yields were 64% and 69%, respectively) by treatment with dimethylamine.¹⁰³

Condensation of the chromium carbene complex **215** with 2-formyl-1-methylpyrrole yielded product **216**.¹⁰⁴

Protected 2-acetylpyrrole **198e** reacted with furylpyrrole **217** in the presence of methyl orthoformate and catalytic amounts of chlorosulfonic acid. The initially formed unstable compound **218** was transformed into 2-vinylpyrrole **219**, which was subsequently transformed into 2-vinylpyrrole **220** after removal of the *tert*-butoxycarbonyl protection.¹⁰⁵

2-Vinylpyrrole **221**, which is an analogue of the natural antibiotic prodigiosin, was synthesised by condensation of formylpyrrole **222** with 3-ethyl-2,4-dimethylpyrrole (**223**) in the presence of POCl₃.¹⁰⁶

2-(2-Diethoxyphosphoryl-2-fluorovinyl)-1-methylpyrrole (**224**, a mixture of the *E* and *Z* isomers in a ratio of 76:24) was prepared by condensation of 2-formyl-1-methylpyrrole with diethyl α -fluoro- α -lithio- α -(trimethylsilyl)methylphosphonate (**225**), which was synthesised from diethyl dibromofluoromethylphosphonate (**226**).¹⁰⁷

The reaction proceeded instantaneously in spite of the presence of the (EtO)₂PO group stabilising the carbanion. Attempts to isolate the intermediate pyrrole after hydrolysis of alkoxide **227** failed. β -Elimination of the trimethylsilyloxy group from the initially formed intermediate **227** took place, *i.e.*, exclusively Peterson olefination (rather than the Wittig–Horner reaction) proceeded under these conditions.¹⁰⁷

III. Synthesis of C-vinylpyrroles from functionalised aliphatic compounds

1. Synthesis from tosylmethyl isocyanide and activated alkenes

In the last decade, a procedure for the preparation of 4-vinylpyrrole derivatives containing no substituents at positions 1 and 5 has been extensively developed. This procedure relies on the base-catalysed addition of tosylmethyl isocyanide to activated alkenes.^{22, 61, 108–115} The successive reactions of isocyanide **228** with BuⁿLi and then with an excess of Me₃SnCl afforded derivative **229**, which reacted with dienones **230a,b** to give 3-acetyl- (**231a**) or 3-benzoyl-4-(*E*)-styryl-2-(trimethylstannyl)-pyrroles (**231b**).¹⁰⁸ The reactions unexpectedly gave rise to 2-stannylpyrroles rather than to 5-stannylpyrroles, which are adducts of TsCLi(SnMe₃)N≡C with dienones. In this process, the stannylated isocyanide derivative **229** serves, apparently, as the reactive species. In the study,¹⁰⁸ the possibility of the migration of the Me₃Sn group from position 5 to position 2 of the pyrrole ring was also not excluded.

R = Me (**a**), Ph (**b**).

N-Substituted 2-(trimethylstannyl)pyrroles **232a,b** containing the styryl group at position 4 were prepared either by methylation of the pyrrole **231b** under the conditions of phase transfer catalysis or by acylation of di-*tert*-butyl carbonate.¹⁰⁸

R = Me (**232a**), Boc (**232b**).

The compounds **232a,b** were also prepared by the introduction of the trimethylstannyl group into pyrroles **233**, which were synthesised by the reaction of the tosylmethyl isocyanide **228** with the dienone **230b** in the presence of Bu^tOK followed by alkylation or acylation of intermediate **234**.¹⁰⁸

R = Me, Boc; LiTMP is lithium 2,2,6,6-tetramethylpiperidide.

The reaction of the isocyanide **228** with an equimolar amount of 1,4-dicyclohexyl-2,3-dinitrobuta-1,3-diene (**235**) in THF in the presence of diazabicycloundecene afforded a mixture of ethynylpyrrole **236** (58%), 4,4'-bipyrrole **237** (9%) and nitrovinylpyrrole **238** (12%).¹⁰⁹

Intermediate **239**, which is a precursor of the pyrrole **238**, was generated through the addition of the tosylmethyl isocyanide anion to one nitrovinyl group of the dinitrobutadiene system and intramolecular cyclisation of the resulting anion **240**.¹⁰⁹

Conjugated nitrodiene **241a** and nitrotriene **241b** reacted with the isocyanide **228** in the presence of an excess of Bu^tOK in THF to form 4-styryl- (**242a**) and 4-(4-phenylbuta-1,3-dienyl)-3-nitropyrroles (**242b**), respectively.¹¹⁰

n = 1 (**a**, 73%), 2 (**b**, 75%).

2,3-Dialkenyl-4-nitropyrroles **243** were prepared by the analogous reactions of the nitrodiene **241a** or the nitrotriene **241b** with 1-isocyano-1-tosyl-2,2-disubstituted alkenes **244**, which are products of condensation of tosylmethyl isocyanide **228** with ketones.^{110–112}

$n = 1$ (**a**), 2 (**b**); $\text{R}^1 = \text{H}, \text{Me}$; $\text{R}^2 = \text{Me}, \text{Ph}$; $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_4$.

The synthesis with the use of ethyl hexa-2,4-dienoate **245** as the Michael acceptor afforded isomeric pyrroles **246** and **247**. The direction of the reaction depends on its conditions. Thus the use of a more polar solvent in combination with a more dissociated ionic pair facilitates the addition of the anion derived from the isocyanide **228** to the δ position of the ester **245** bearing the highest positive charge. For example, the reaction of the sodium derivative of the isocyanide **228** with the ester **245** in a DMSO– Et_2O mixture afforded pyrrole **246**, whereas the reaction of the lithium derivative of the isocyanide **228** in tetrahydrofuran gave rise to 1,2-adduct **247**.¹¹³

Condensation of ester **248** with the sodium derivative of the isocyanide **228** in the DMSO– Et_2O system produced a mixture of regioisomers **249** and **250** in a ratio of 7 : 1 in 55% yield. The use of the lithium derivative in THF at -78°C afforded only pyrrole **250** with an impurity of the starting isocyanide **228**. The compound **250** was isolated as the *N*-benzyl derivative after treatment with benzyl bromide (NaH , DMF).¹¹³

$\text{R} = \text{Bu}^t\text{Me}_2\text{Si}$.

The reaction of nitrile **251** with the isocyanide **228** in the presence of sodium hydride in the DMSO– Et_2O system produced a mixture of (*E*)- and (*Z*)-3-(2-cyanovinyl)pyrroles **252**.⁶¹

2. Synthesis from unsaturated ketone oximes and acetylene

Heterocyclisation of unsaturated ketone oximes with acetylene in the superbasic KOH–DMSO system (Trofimov's reaction) is a promising procedure for the synthesis of C-vinylpyrroles.^{114,115} This procedure enables one to carry out a two-step transformation of readily available ketones to pyrroles and their 1-vinyl derivatives (in the presence of an excess of acetylene).

For example, 2-methyl-3-(prop-2-enyl)pyrrole (**254**) was prepared from hex-5-en-2-one oxime **253** and acetylene.¹¹⁴ Heating of compound **254** with calcined KOH under an atmosphere of nitrogen led to prototropic isomerisation to form an equilibrium mixture of the *E* and *Z* isomers (in a ratio of 7 : 3) of 2-methyl-3-(prop-1-enyl)pyrrole (**255**) in a total yield of 93%.

The reaction with an excess of acetylene afforded only 2-methyl-3-(prop-1-enyl)-1-vinylpyrrole (**256**) (the yield was 80%, a mixture of the *E* and *Z* isomers in a ratio of 7 : 3).¹¹⁵ Hence, the prop-1-enyl substituents are thermodynamically more favourable for these compounds due, apparently, to conjugation of the double bond with the pyrrole ring.

Isomerisation of 3-allylpyrroles **257a,b** in the KOH–DMSO (120°C , 1 h, the molar ratio KOH : pyrrole **257** = 1 : 1) or Bu^tOK –DMSO system ($60-65^\circ\text{C}$, 1 h) afforded an equilibrium mixture of the pyrroles **257a,b** and (*E*)- and (*Z*)-3-(prop-1-enyl)pyrroles **258a,b**.¹¹⁵

$\text{R}^1 = \text{H}, \text{CH}=\text{CH}_2$; $\text{R}^2 = \text{R}^3 = \text{Me}$ (**a**), $\text{R}^2 - \text{R}^3 = (\text{CH}_2)_5$ (**b**).

The allyl substituents in the 1-vinylpyrroles **257a,b** are isomerised into the corresponding prop-1-enyl substituents by 75%–100%. For the corresponding 1*H*-pyrroles, the conversion was at most 30%. The higher conversion in the case of 1-vinylpyrroles results from conjugation between the 3-(alk-1-enyl) and 1-vinyl fragments through the double bonds and the nitrogen atom of the pyrrole ring.¹¹⁵

3. Synthesis from 1,4-dicarbonyl compounds

One of the most commonly used procedures for the preparation of pyrroles involves the transformation of 1,4-dicarbonyl compounds into pyrroles under the action of ammonia or amines (Paal–Knorr synthesis). In some cases, this procedure is applicable also to the synthesis of C-vinylpyrroles. These reactions performed with the use of unsaturated γ -ketoaldehydes, such as an analogue of levuglandin **259**, as the dicarbonyl component and

neopentylamine as the amino component, afforded pyrrole **260**.¹¹⁶ Condensation was performed in dry degassed ethanol at 20 °C. However, the pyrrole **260** is unstable and completely decomposes in one day even under an atmosphere of argon. Stable functionalised β -C-vinylpyrrole **261** was prepared from the pyrrole **260** under the action of trifluoroacetic anhydride under an atmosphere of argon.¹¹⁶

Refluxing of aminolactone **262** with 2,9-dimethyldeca-2,8-diene-4,7-dione (**263**) in benzene or toluene in the presence of titanium isopropoxide for 24 h afforded 2,5-diisobutenylpyrrole **264** in 53% yield.^{117, 118}

It should be noted that TiCl_4 , which is widely used as a catalyst in the Paal–Knorr synthesis, is inefficient in this reaction. Thus, the pyrrole **264** was obtained only in trace amounts.

Under analogous conditions, the reaction of the diketone **263** with benzylamine gave rise to 1-benzyl-2,5-diisobutenylpyrrole (**265**) in 63% yield.¹¹⁸

4. Synthesis from imines and butadiene

Condensation of alkylidenebenzylamines **266** with butadiene in the presence of catalytic amounts of sodium metal proceeded as the [3 + 2]-cycloaddition accompanied by imine–imine isomerisation to give a complex mixture of products containing alkyl(vinyl)phenylpyrrolidines **267** as the major component and pyrroles **268** (in small amounts).^{119–121}

$\text{R} = \text{Pr}^i, \text{Bu}^i$.

The pyrroles **268** can also be prepared by catalytic dehydrogenation of the pyrrolidines **267** in the presence of Pd/C (250 °C, 5 h, the yield was 52%).¹¹⁹

Ylide **269**, which was generated upon desilylation of a mixture of the *E,Z* and *E,E* isomers of salt **270**, reacted with different dipolarophiles, such as dimethyl acetylenedicarboxylate, dimethyl maleate or dimethyl fumarate, to form dihydropyrroles **271** or stereoisomeric pyrrolidine derivatives (**272a,b**).¹²² Oxidation of the dihydropyrroles **271** and pyrrolidines **272a,b** gave rise to 2-styrylpyrroles **273**.¹²²

$\text{R} = \text{H}, \text{Me}, \text{MeO}, \text{Cl}$.

5. Synthesis from vinylacetylenic amides

Nitrogen-protected β -bromo- α -styrylpyrroles **274** and **275** were synthesised by cyclisation of diene amidoketones **276** (generated from vinylacetylenic amidoketones **277**) or aminoacetals **278** (prepared from vinylacetylenic aminoacetals **279**) in the presence of HBr.¹²³

6. Synthesis involving carbenes

Imine **280** reacted with difluorocarbene in the presence of dimethyl acetylenedicarboxylate to give 5-fluoro-2-(*E*)-styrylpyrrole **281**.¹²⁴

Apparently, difluorocarbene attacks the lone electron pair of the nitrogen atom to form azomethine ylide **282**, which adds as the 1,3-dipole to acetylenedicarboxylic ester to form dihydropyrrole **283**. Its subsequent dehydrofluorination affords the pyrrole **281**.¹²⁴

Vinylcarbenes **284** were prepared from 1-(2,2,3,3-tetrachloro-1-methylcyclopropyl)isoxazolines **285** by treatment with methyl-lithium followed by isomerisation of the resulting 1,2-dichlorocyclopropenes **286**. The attack of the carbene centre on the isoxazoline substituent was accompanied by rearrangement to give methylene-2*H*-pyrroles **287**, which underwent aromatisation under the reaction conditions to give 2-(2-acylvinyl)pyrroles **288**.¹²⁵

R = Et (82%), Buⁿ (85%).

7. Other procedures for the synthesis

A mixture of isomeric pyrrole-2-carbonitriles **289** and **290** (in a ratio of 1 : 4) containing a hex-1-enyl substituent at the β position was prepared in a total yield of 53% from 1-phenyloct-3-en-1-yne (**291**) and trimethylsilyl cyanide in the presence of the cobalt cyclopentadienyl complex.¹²⁶

Thermolysis of β -cyclohexenyl α -azidoacrylates **292** in a solution of xylene, cyclohexane or DMF proceeded quantitatively to give substituted tetrahydrobenzo-2*H*-pyrroles **293** stable up to 130 °C.¹²⁷ Upon refluxing in xylene, the latter compounds were slowly rearranged through, apparently, the double 1,5-shift of the vinyl group to give 4,5,6,7-tetrahydro-2-methoxycarbonyl-3-vinylindoles **294**.¹²⁷

R = H, Ph, CH=CHPh.

Treatment of *trans*-1,2-di(*N*-benzylammonio)cyclopropane dibromides **295a,b** with cinnamaldehyde (**296**) in an acetate buffer afforded 1-benzyl-2-(*E*)-styrylpyrroles **297a,b**.^{128, 129}

R = H (**a**, 54%), Ph (**b**, 71%).

The reactions of K_2HPO_4 with salts of 3-phenylcyclopropane-1,2-diamines **295b** (R = Me, Bn) proceeded with the opening of the three-carbon ring to produce imminium ions **298**. The latter reacted with the salts **295** to give cyclopropane intermediates **299**. The ring opening in these intermediates afforded bipolar ions **300**. 2-Styrylpyrroles **301** were generated by cyclisation of intermediates **302** followed by aromatisation of 3,4-dihydro-2*H*-pyrroles **303**. The styrylpyrroles **301** were also derived from two molecules of the salt **295b** upon treatment with an aqueous solution of K_2HPO_4 (the yield was 59%) or AcONa (the yield was 60%).¹²⁹

R = Me, Bn.

Tetraacetylene (**304**) reacted with methyl 3-aminobut-2-enoate (**305**) under mild conditions to give a mixture of dihydropyrrole **306** and tetrasubstituted furan **307**.¹³⁰ Upon refluxing in methanol, the latter underwent recyclisation to produce a mixture of *N*-acyl- (**308**) and NH-pyrroles (**309**).¹³⁰

Condensation of 1,3-bis(dimethylamino)-2-[dimethylamino(methoxy)methyl]-1-methoxyprop-2-ene (**310**) with ketones **311a–c** did not furnish the expected polyenic bis(dimethylamino) ketones **312** containing the *N,O*-acetal groups at the γ, γ' positions; instead, products of their intramolecular cyclisations, *viz.*, di[β -(*N*-methylpyrrol-3-yl)vinyl] ketones **313**, were isolated.^{131–133}

R¹ = R² = H (**a**), R¹–R² = (CH₂)₂ (**b**), (CH₂)₃ (**c**).

The reactions of conjugated dimethylamino ketones **314** with the compound **310** taken in an equimolar ratio proceeded analog-

ously to give unsaturated amino ketones **315** containing the pyrrole ring in one of the β positions.^{131–133}

R¹ = R² = H; R¹ = , R² = H; R¹–R² = (CH₂)₂, (CH₂)₃; n = 0–2.

The reactions of complexes **316** with dimethyl acetylenedicarboxylate proceeded as the 1,3-dipolar cycloaddition to the Fe–N=C fragment to form the 1,4,3*a*,6*a*-dihydropyrrolo[3,2-*b*]pyrrole complexes **317** in good yields. Treatment of the latter with Ce(IV) led to liberation of dihydropyrrolo[3,2-*b*]pyrrole **318**.¹³⁴ Heating of the compound **318** in benzene caused the ring opening to give vinylpyrrole **319**.

E = CO₂Me; R = CO, CNBu^t, CNBn, CNC₆H₁₁-cyclo, CNC₆H₄Me-2, CNC₆H₃Me₂-2,6.

IV. Addition of pyrroles to acetylenes

The direction of the reaction of pyrroles with activated acetylenes depends on the reaction conditions and the structures of the starting reagents. For example, diene condensation as well as C- or N-nucleophilic attack on the triple bond can occur.^{16,28,29} In recent years, the addition of pyrroles as C-nucleophiles to the electron-deficient triple bond has been extensively studied because this reaction provides the most direct approach to functionally substituted *C*-vinylpyrroles.

Thus, the non-catalytic reactions of pyrroles **320** with terminal acylacetylenes **321** proceeded under mild conditions both without a solvent and in protic (methanol or ethanol) or aprotic (diethyl ether, benzene, hexane or acetonitrile) solvents to give 2-(2-acylvinyl)pyrroles **322** (predominantly, the *Z* isomers).^{135–139} In the course of isolation and purification and even upon storage, the *Z* isomers are readily transformed into the *E* isomers.^{135–139}

R¹ = H, Prⁿ, Ph; R² = H, Me, n-C₇H₁₅; R¹–R² = (CH₂)₄; R³ = Ph, 2-thienyl.

Unlike the alkynes **321**, 1-acyl-2-phenylacetylenes **323** are less reactive and do not react with pyrroles at 20 °C. The latter reaction was performed upon heating of equimolar amounts of the reagents in the presence of a 5–10-fold excess of silica gel. The *Z* isomers of 2-(2-acyl-1-phenylvinyl)pyrroles **324** were obtained in 71%–89% yields.^{139, 140}

$\text{R}^1 = \text{H, Ph}; \text{R}^2 = \text{H}; \text{R}^1-\text{R}^2 = (\text{CH}_2)_4;$
 $\text{R}^3 = \text{Ph, 2-thienyl, 2-furyl, CCl}_3.$

The reactions of the pyrroles **320** with ethynyl ketones **323** ($\text{R}^3 = \text{Ph, 2-furyl}$) in the superbasic KOH–DMSO system afforded a mixture of N- (**325**, *E* and *Z* isomers) and C-adducts (**324**, *Z* isomers) (in a total yield of 60%–80%), the ratio of the products being dependent on the structure of the starting pyrrole.¹⁴¹

$\text{R}^1 = \text{H, Ph}; \text{R}^2 = \text{H}; \text{R}^1-\text{R}^2 = (\text{CH}_2)_4; \text{R}^3 = \text{Ph, 2-furyl}.$

Regio- and stereospecific C-vinylation of 1-vinylpyrroles **326** with benzoylacetylene proceeded at 20 °C on the surface of silica gel under the conditions of mechanochemical activation to form *E* isomers of 1,2-divinylpyrroles **327**.¹⁴²

$\text{R}^1 = \text{H, Me, Bu}^n, 2,5\text{-Me}_2\text{C}_6\text{H}_3, \text{Ph}; \text{R}^2 = \text{H, Me, Et, Pr}^n.$

The reactions of the pyrroles **326** ($\text{R}^1 = \text{Me}$ and $\text{R}^2 = \text{Pr}^n$ or $\text{R}^1 = \text{Ph}$ and $\text{R}^2 = \text{Et}$) afforded compounds **327** along with the adducts **322**, which do not contain the vinyl substituent at the nitrogen atom. The formation of the latter compounds is associated with hydrolysis of the *N*-vinyl group both in the starting pyrroles **326** and in the reaction products **327** that occurs on SiO_2 .¹⁴²

Trisubstituted pyrroles **328** reacted with phenylbenzoylacetylene (**323**, $\text{R}^3 = \text{Ph}$) in ethanol in the presence of HClO_4 to give vinylpyrroles **329** (mixtures of the *E* and *Z* isomers).¹⁴³

$\text{R}^1 = \text{COMe, CO}_2\text{Me, CO}_2\text{Et}; \text{R}^2 = \text{Me, (CH}_2)_2\text{CO}_2\text{H}.$

The yields of the vinylpyrroles **329** and the ratio of the *E* and *Z* isomers depend substantially on the structures of the starting

compounds **328**. At $\text{R}^1 = \text{CO}_2\text{Me}$ and $\text{R}^2 = \text{Me}$, the yield of the corresponding adduct **329** was 75% (the ratio *E*:*Z* = 7:1), whereas the adducts were obtained in yields of only 56% (*E*:*Z* = 2:1) and 12% (*E*:*Z* = 9:1) at $\text{R}^1 = \text{CO}_2\text{Me}$, $\text{R}^2 = (\text{CH}_2)_2\text{CO}_2\text{H}$ and $\text{R}^1 = \text{COMe}$, $\text{R}^2 = (\text{CH}_2)_2\text{CO}_2\text{H}$, respectively.¹⁴³

The reactions of substituted 2-amino-4,5-dimethylpyrroles **330a–f** with ethyl propiolate proceeded predominantly as the cycloaddition resulting in functionalised dihydroindoles **331a–f**. Under the analogous conditions, the reaction of pyrrole **332**, which contains no substituents at positions 1 and 2, gave rise to (*E*)-2-vinylpyrrole **333** in 68% yield.¹⁴⁴

$\text{R}^1 = \text{Pr}^n$ (**a**), $(\text{CH}_2)_2\text{OMe}$ (**b**), $(\text{CH}_2)_2\text{Ph}$ (**c**), **Bn** (**d**),
 2-pyridylmethyl (**e**), 3-pyridylmethyl (**f**).

N-Substituted pyrroles add to dimethyl acetylenedicarboxylate to form mixtures of the *E* and *Z* isomers of 2-vinylpyrroles **334**. The reactions proceed upon stirring of the reagents at 20 °C or upon ultrasonic irradiation. In the latter case, the pyrroles are produced in substantially higher yields.¹⁴⁵

$\text{R} = \text{Me, (CH}_2)_2\text{CN, Ph}.$

A mixture of 2-vinyl- (**335**) and *E,Z*-2,5-divinylpyrrolo[3,2-*b*]pyrroles **336** was obtained in the reaction of pyrrolopyrrole **337** with an excess of dimethyl acetylenedicarboxylate at 20 °C.¹⁴⁶ A mixture of the *E* and *Z* isomers of the divinylpyrrole **336** (in 24% and 47% yields, respectively) can also be prepared by the addition of the monoadduct **335** to dimethyl acetylenedicarboxylate under the same conditions.¹⁴⁶

Recyclisation of indolizine-3-carbonitriles **338** under the action of dimethyl acetylenedicarboxylate selectively afforded the *Z* isomers of functionally substituted 3-styrylpyrroles **339**.¹⁴⁷

$R^1 = \text{H, Me; } R^2 = \text{H, Me, CN, Bn; } R^3 = \text{H, Me.}$

The reaction of 2,3,4-trimethylpyrrole (**340**) with dicyanoacetylene produced (*E*)-2-(1,2-dicyanovinyl)pyrrole **341** as the major product (in 63% yield), whereas the yield of the *Z* isomer was only 9%.¹⁴⁸

1-Methylpyrrole reacted with di(*tert*-butylsulfonyl)acetylene (**342**) to give (*E*)-2-[1,2-di(*tert*-butylsulfonyl)vinyl]-1-methylpyrrole (**343**).¹⁴⁹

Heating of pyrrolisosulfolene **344** with the acetylene **342** produced a mixture of *E* isomers of 2-vinyl- (**345**) and 2,5-divinylpyrroles (**346**).¹⁵⁰

The photochemical reactions of pyrrole with phenyl- and diphenylacetylenes afforded 2-(1-phenylvinyl)- (**347a**) and 2-(1,2-diphenylvinyl)pyrroles **347b** (a mixture of the *E* and *Z* isomers in approximately equal amounts) in yields of only 7% and 9%, respectively.¹⁵¹

$R = \text{H (a), Ph (b).}$

The low yields of the adducts were accounted¹⁵¹ for by photoinduced dimerisation of arylacetylenes and the instability of the adduct **347a** in air.

V. Substitution reactions at the double bond

1. Substitution of functional groups in electron-deficient alkenes

In recent years, the substitution of functional groups at the electrophilic double bond or the catalytic replacement of the hydrogen atom of the alkene fragment by halogenopyrroles (Heck and Stille reactions) have found wide use in the synthesis of *C*-vinylpyrroles.

The reactions of 1*H*- and 1-methylpyrroles with 4-ethoxy-1,1,1-trifluorobut-3-en-2-one (**348a**) and 3-(ethoxymethylidene)-1,1,1,5,5,5-hexafluoropentane-2,4-dione (**348b**), which are products of mono- and bistrifluoroacetylation of ethyl vinyl ether, respectively, led to the substitution of the ethoxy group and the formation of 2-(2-trifluoroacetyl)vinylpyrroles **349a,b**. The reactions proceeded under mild conditions in the presence of 25 mol.% ZnCl_2 . In the presence of other Lewis acids, the reactions are accompanied by substantial resinification. The reaction of the ketone **348a** proceeded stereospecifically to produce the *E* isomer.^{152–154}

$R = \text{H, Me; } X = \text{H (a, 53%), COCF}_3 \text{ (b, 88%).}$

The pyrrole **349a** ($R = \text{H}$) was also synthesised from 1*H*-pyrrole and 1,1,1-trifluoro-4-(phenylsulfonyl)but-3-ene-2,2-diol (**350**), which was prepared by oxidation of the trifluoroacetylation product of vinyl sulfide. The reaction proceeded under mild conditions as addition–elimination.^{154, 155}

The reactions of iminium complex **351**, which was generated in the reaction of 4-dimethylamino-1,1,1-trifluorobut-3-en-2-one with POCl_3 or trifluoromethanesulfonic anhydride, with pyrroles proceeded stereospecifically to give finally (after hydrolysis of intermediates **352**) the *E* isomers of 2-vinylpyrroles **353**.^{154, 156}

$R = \text{H, Me, Ph; } X = \text{OP(O)Cl}_2, \text{CF}_3\text{SO}_2\text{O; } Y = \text{Cl, POCl}_2, \text{CF}_3\text{SO}_2\text{O.}$

Condensation of 3-bromo-1-(triisopropylsilyl)pyrrole with nitrodieneamine **354** led to the replacement of the dimethylamino group to form 3-(4-nitrobuta-1,3-dienyl)-1-(triisopropylsilyl)pyrrole (**355**). Desilylation of the latter afforded pyrrole **356**.¹⁵⁷

Refluxing of bispyrrole **357** with bromomethylidene-2,5-dihydropyrrol-2-one **358** in methanol produced homorubin **359**.⁹⁰ Initially, the compound **357** underwent α -decarboxylation and then the α -unsubstituted pyrrole reacted with the compound **358**.⁹⁰

Vilsmeier double formylation of 3,4-dimethylpyrrole **360a**^{158, 159} and dipyrinone **360b**¹⁵⁹ with 3-(dimethylamino)-acrolein (**361**) afforded 2-vinylpyrroles **362a,b**.

Bispyrrole **363** was formylated with the acrolein **361** at both α positions to give bis[(formylvinyl)pyrrol-2-yl]methane **364**.¹⁶⁰

The reactions of 2-methyl- and 2-phenylpyrroles with the methoxymethylidene derivatives of Meldrum's acid **365** proceeded regioselectively under mild conditions to give 2-vinylpyrroles **366** in 60% and 70% yields, respectively.⁴³ Under analogous conditions, the reaction of 3-phenylpyrrole with the

compound **365** produced a mixture ($\sim 1:1$) of 3- and 4-phenyl-2-vinylpyrroles **367**.⁴³

In the reactions of the pyrroles **320** with tetracyanoethylene (**368**), one of the nitrile groups in the latter compound was replaced to form 2-(tricyanovinyl)pyrroles **369** in quantitative yields.¹⁶¹

The pyrroles **370** containing substituents at both α positions reacted with tetracyanoethylene (**368**) under the same conditions to give 3-tricyanovinylpyrroles **371**.^{162, 163}

5-Methyl-2-(2-thienyl)pyrrole (**372a**) reacted with tetracyanoethylene (**368**) to yield 3-tricyanovinyl isomer **374a** along with 4-tricyanovinyl derivative **373a**.^{162, 163} Under these conditions, 2-(2-furyl)-5-methylpyrrole (**372b**) behaved differently, *viz.*, the major direction of the reaction with tetracyanoethylene involves the attack on the α position of the furan ring giving rise to product **375b**.

X	Yield (%)		
	373	374	375
S (a)	75	15	—
O (b)	18	9	67

The reactions of 1-vinyl- and 1-prop-2-enyl-substituted pyrroles **376a,b** with tetracyanoethylene (**368**) taken in equimolar amounts in DMSO afforded 3-tricyanovinyl-1-vinyl- (**377a**) and 1-(prop-2-enyl)-3-tricyanovinyl-substituted (**377b**) derivatives, respectively, as the only products.^{162, 163}

R = H (**a**, 92%), Me (**b**, 91%).

Hence, the *N*-alkenyl substituent in the pyrroles **376a,b** does not react with tetracyanoethylene according to the [2 + 2]-cycloaddition mechanism typical of other 1-vinyl-substituted heterocyclic compounds.¹⁶⁴

2. Catalytic vinylation of halogenopyrroles

The Heck reaction of 4-iodopyrrole **378** with acrylonitrile in the presence of bis(triphenylphosphine)palladium chloride afforded a mixture of (*E*)- and (*Z*)-4-vinylpyrroles **379a** in 45% and 17% yields, respectively. The corresponding reactions involving methyl acrylate or methyl vinyl ketone proceeded stereoselectively to give pyrroles **Z-379b** or **E-379c**, respectively.¹⁶⁵

R = CN (**a**), CO₂Me (**b**), COMe (**c**).

Under analogous conditions, the reaction of 3-bromopyrrole **380** with methyl acrylate also proceeded selectively to form the *E* isomer of pyrrole **381**.¹⁶⁵

The reactions of 4-halogenopyrroles **382** with vinyltributyltin (Stille reaction) were examined. 4-Iodopyrroles produced 4-vinylpyrroles **383** in 80%–92% yields. The reactions proceeded upon refluxing of the reagents in toluene in the presence of bis(triphenylphosphine)palladium chloride. Under analogous conditions, 4-bromopyrrole gave the corresponding 4-vinylpyrroles in low yields (10%–15%), whereas the reaction of 4-chloropyrrole with vinyltributyltin did not proceed at all.¹⁶⁶

R¹ = H, Me, C(=O)Ph, Ts; R² = H, Me; R³ = H, Me;

R⁴ = CHO, CO₂Et; X = Cl, Br, I.

Alkenyl derivatives of heteroaromatic compounds can also be prepared by Tl(III)–Pd(II) transmetalation. This reaction does not require thorough drying of the reagents and solvents and the use of an inert atmosphere and proceeds under mild conditions

(often regio- and stereospecifically), Pd(II) complexes being used in catalytic amounts.

Thus hydrogen was readily replaced in methyl acrylate and styrene under the action of ethyl 4-[(acetoxypyrrolyl)thallio]-3,5-dimethylpyrrole-2-carboxylate (**384**), which was synthesised from ethyl 3,5-dimethylpyrrole-2-carboxylate (**385**) and Tl(OAc)₃.¹⁶⁷ Olefination was carried out in the presence of PdCl₂, MgO or LiCl with the molar ratio pyrrole:alkene: (PdCl₂–LiCl) = 1 : (5–10) : 0.1. It is necessary to add a base (generally, magnesium oxide or potassium carbonate) with the aim of preventing side reactions of pyrroles, which proceed in the presence of strong acids generated in the course of alkenylation. The reactions proceeded selectively to give pyrroles **386a,b** in 43% and 65% yields, respectively.¹⁶⁷

R = CO₂Me (**a**), Ph (**b**).

VI. Other procedures for the introduction of the vinyl group into the pyrrole ring

1. Synthesis from pyrrolecarbodithioates

Once a convenient and versatile procedure has been developed for the synthesis of pyrrole-2- and -3-carbodithioates by the direct reactions of pyrroles with carbon disulfide in the KOH–DMSO system,^{168–178} these compounds found wide use in the synthesis of functionalised *C*-vinylpyrroles.^{178–181}

The reactions of pyrrole-2-carbodithioates **387** with CH-acids (malononitrile, cyanoacetamide and ethyl cyanoacetate) in the KOH–DMSO system followed by alkylation of intermediate thiolates **388** with alkyl halides produced 2-vinylpyrroles **389**.^{179–181} All three steps of the reactions were carried out in one pot.

The reactions of the pyrrole-2-carbodithioates **387** with malononitrile and cyanoacetamide afforded 2-vinylpyrroles **389** along with small amounts of products of their intramolecular cyclisation, viz., 3-imino-3*H*-pyrrolizines **390**. The reactions of the pyrrole-2-carbodithioates **387** with ethyl cyanoacetate gave rise to pyrrolizin-3-ones **391** as the major condensation products.

X = CN, CONH₂.

$\text{R}^1 = \text{Me, Pr}^n, \text{Bu}^n, \text{Ph}$; $\text{R}^2 = \text{H, Me, Et, Pr}^n$; $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_4$;

$\text{R}^3 = \text{Me, Et, Bu}^n, \text{Al}$; $\text{X} = \text{CN, CONH}_2, \text{CO}_2\text{Et}$.

Under analogous conditions, pyrrole-3-carbodithioates **392** selectively reacted with nitriles containing the activated methylene group to form 3-vinylpyrroles **393**.¹⁷⁸

$\text{R}^1 = \text{Me, Ph}$; $\text{R}^2 = \text{H, Me}$; $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_4$;

$\text{R}^3 = \text{Me, Et}$; $\text{X} = \text{CN, CONH}_2, \text{CO}_2\text{Et}$.

3-Vinylpyrroles **393** were obtained in low yields due to instability of the pyrrole-3-carbodithioates **392**, which partially (by 10%–20%) decomposed to 3-unsubstituted pyrroles under the reaction conditions.

(2,2-Dicyano-1-methylthiovinyl)pyrrole (**394**) was synthesised from methyl pyrrole-2-carbodithioate **395** and epoxide **396**.¹⁸²

2. Vinylation of osmium complexes of pyrroles

In the pentaammineosmium complex of 1-methylpyrrole **397**, which was prepared from 1-methylpyrrole and $\text{Os}(\text{NH}_3)_5(\text{OTf})_3$ in quantitative yield, the electrophilic activity of the C(3) atom is much higher than that of the C(3) atom in free pyrrole. This complex can be readily transformed into the 3-vinylpyrrole complexes according to several procedures.^{183–186}

One procedure involves the reaction of complex **397** with a twofold excess of ketone in the presence of 1 equiv. of *tert*-butyldimethylsilyl triflate to form silylated aldol adducts **398**. Diazabicycloundecene-catalysed elimination of silanol $\text{HOSiMe}_2\text{Bu}^t$ followed by deprotonation of azafulvenium intermediates **399** afforded 3-vinylpyrrole complexes **400**.^{183, 185}

Hereinafter, $[\text{Os}^{2+}] = [\text{Os}^{\text{II}}(\text{NH}_3)_5]^{2+}$; $\text{R}^1 = \text{Me, Et, Pr}^i, \text{Ph}$;

$\text{R}^2 = \text{H, Me}$; $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_4$.

Another procedure involves the reaction of the complex **397** with acetaldehyde diethyl acetal in the presence of *tert*-butyldimethylsilyl triflate. In this case, 3*H*-pyrrole adduct **401** is generated. After deprotonation and elimination of ethanol catalysed by trifluoromethanesulfonic acid, compound **401** gives azafulvenium complex **402** in 93% yield (a mixture of stereoisomers in a ratio of 3:2).

Deprotonation of the complex **402** afforded unstable complex **403**, which was isolated as a product of the reaction with *N*-phenylmaleimide.¹⁸⁵

Yet another approach to 3-vinylpyrrole complexes of osmium is based on acylation of the pyrrole **397** with acid anhydrides in the presence of 4-dimethylaminopyridine (DMAP). Due to the nucleophilic properties, the oxygen atom of the carbonyl group in complex **404** can be methylated with methyl trifluoromethanesulfonate to give 2-azafulvenium complex **405**. The addition of diazabicycloundecene to the complex **405** led to deprotonation and the formation of methoxy-substituted 3-vinylpyrrole complex **406**.¹⁸⁵

$\text{R} = \text{H, Me}$.

The addition of the complex **397** to activated acetylenes also afforded 3-vinylpyrrole complexes **407**.^{184, 185}

$\text{R}^1 = \text{H, CO}_2\text{Me, Ph}$; $\text{R}^2 = \text{COMe, CO}_2\text{Me}$.

3. Synthesis from allyl derivatives

2-Allylpyrrole was transformed into *N,C*-dilithium derivative **408** in high yield under the action of 2 equiv. of Bu^nLi in the hexane–diethyl ether system. The compound **408** selectively reacts with various electrophilic agents (H_2O , MeI, Me_3SiCl) to form 2-(alk-1-enyl)pyrroles **409–411**.¹⁸⁷

The reactions in Et_2O at 0°C gave rise to the *E* isomers, whereas the reactions in THF afforded the *Z* isomers of compounds **409–411**.

The reactions of the *N,C,C*-trilithium derivative of 2,5-diallylpyrrole **412** with electrophiles (H_2O , D_2O , MeI, Me_3SiCl and Me_3SnCl) in THF proceed selectively to produce the *Z* isomers, whereas these reactions in the hexane–diethyl ether system give rise to mixtures of the *E* and *Z* isomers of 2,5-di(alk-1-enyl)pyrroles **413**.¹⁸⁸

$\text{R} = \text{H}, \text{Me}, \text{SiMe}_3, \text{SnMe}_3$.

4. Condensation with carbonyl compounds and their synthetic equivalents

2-Lithio-1-methylpyrrole (**414**) reacted with cyclopropyl phenyl ketone (**415**) to form alcohol **416** whose three-carbon ring was opened under the action of either HBr in AcOH or Me_3SiBr in EtOH to give (*E*)-4-bromo-1-(1-methylpyrrol-2-yl)-1-phenylbut-1-ene (**417**).¹⁸⁹

Alkylation of ethyl 1,2,3,6-tetrahydropyridine-3-carboxylate with the bromine-containing derivative **417** followed by hydrolysis of ester **418** produced acid **419**.¹⁸⁹

Successive treatment of pyrrole **420** with Bu^nLi , benzaldehyde and methyl iodide in hexamethylphosphoramide (HMPA) afforded pyrrole **421**. The nucleophilic replacement of the benzotriazole group in the latter compound by the nitrile group followed by elimination of methanol gave 2-vinylpyrrole **422**.¹⁹⁰

$\text{Bt} =$; (a) Bu^nLi , THF, -78°C ; (b) PhCHO, THF, -78°C ;

(c) MeI, HMPA, -78 to 20°C ; (d) NaCN, DMF, Δ , 12 h.

Base-catalysed condensation of 1,2-dimethyl-3-nitropyrrole (**423**) with benzaldehyde in the KOH–DMSO system afforded a mixture of 2-vinylpyrrole **424** and alcohol **425**.¹⁹¹

Condensation of pyrrole **426** with chloroacetaldehyde dimethyl acetal **427** proceeded upon heating in the presence of *p*-toluenesulfonic acid to form (chloromethyl)di(pyrrol-5-yl)methanes **428** in 75%–91% yields. The use of montmorillonite K-10 as an acid catalyst makes it possible to perform this process at 20°C with retention of high yields of dipyrrolylmethanes **428**.⁹¹

Elimination of HCl from (chloromethyl)dipyrrolylmethanes **428** afforded 1,2-di(pyrrol-5-yl)ethenes **171** (a mixture of the *E* and *Z* isomers) along with 1,1-di(pyrrol-5-yl)ethenes **177**. This pathway allows one to prepare the 1,1-di(pyrrol-5-yl)ethenes **177** in higher yields compared to those obtained by acylation of the 3,4-dimethylpyrrolecarboxylic esters **176** (see Section II.4).^{91, 94}

Treatment of substituted 2-vinylpyrrole **429**, which was synthesised from 2-(methoxycarbonylmethyl)-1-methylpyrrole **430** and dimethyl oxalate, with trifluoromethanesulfonic anhydride afforded a mixture of *E*- and *Z*-triflates **431** in a ratio of 5:1.¹⁹²

5. Synthesis from enaminoketones of the pyrrole series

Enaminoketone **432a** reacted with malononitrile to form salt **433a** whose acidification gave rise to 5-(2,2-dicyanovinyl)-3-ethoxycarbonyl-4-hydroxy-2-methylpyrrole **434a**.^{34, 37}

Vinylpyrroles **434b,c** were synthesised from enaminoketone **432b** and derivatives of cyanoacetic acid upon refluxing in isopropyl alcohol.³⁴

Under the same conditions, the enaminoketone **432b** reacted with Meldrum's acid and dimedone to give vinylpyrrole derivatives **434d,e**.³⁴

Condensation of the enaminoketone **432c** with ethyl cyanoacetate was accompanied by further cyclisation of pyrrole **434f** to 6-cyano-3-ethoxycarbonyl-2,7-dimethyl-5-oxopyrano[3,2-*b*]pyrrole (**435**).³⁴

Vinylpyrrole **434c** can be prepared from immonium salt **436**, which was generated upon treatment of the enaminoketone **432b** with acetyl chloride.³⁶

The pyrrole **65c** containing the azlactone substituent at the vinyl group was synthesised according to two procedures, viz., by aminomethylation of ketone **437** with dimethylformamide diethyl acetal followed by the reaction of hippuric acid and by the reaction of the enaminoketone **432b** with hippuric acid in acetic anhydride.⁴⁸

6. Other reactions

Elimination of trimethylsilyl trifluoroacetate $[(\text{CF}_3\text{CO})_2\text{O}$, DMAP, dichloroethane] from compound **438** afforded intermediate **439**, which produced functionalised 2-vinylpyrrole **440** in the

presence of pyridine and DMAP.¹⁹³ The compound **440** is unstable due to its high sensitivity to hydrolysis and is transformed into vinylpyrrole **441** after treatment with dilute acetic acid.¹⁹³

Refluxing of substituted pyrrole **442** in DMF in the presence of potassium carbonate led to elimination of benzotriazole to give 2-(pent-1-enyl)pyrrole **443** in 57% yield (*E*:*Z* = 3:1).¹⁹⁰

4-Vinylpyrrole **444** was prepared in 65% yield by selective hydrogenation of 4-ethynylpyrrole **445** in the presence of the Lindlar catalyst partially deactivated with 3,6-dithiaoctane-1,8-diol.⁹⁸

Substituted *N*-ureidopyrroles **446** were transformed into 5-vinylpyrroles **447** with the *E* configuration upon refluxing in DMF in the presence of Bu^tOK .¹⁹⁴ Their formation was attributed to the intramolecular nucleophilic attack of the deprotonated ureido group on the isoxazole nitrogen atom followed by isomerisation of intermediate **448** to azocarbonyl compound **449**, which gave the pyrroles **447** under the reaction conditions.

R = Me, OEt.

Vacuum pyrolysis of dihydrothienopyrrole *S,S*-dioxide **450** led to elimination of SO_2 to give 2-vinylpyrrole **451** whose formation proceeded, apparently, through the [1,8-*H*]-shift in the 1,7-bipolar system **452**.¹⁹⁵

VII. Conclusion

The data surveyed in the present review demonstrate considerable advances in the synthesis of functionalised *C*-vinylpyrroles achieved in the last decade. Known procedures for the synthesis, which are based on reactions of acylpyrroles with CH-acids and the Wittig and Wittig–Horner reagents, are being improved and new preparative reactions, which could enable one to prepare *C*-vinylpyrroles from more readily accessible starting compounds, are being searched for. In particular, the reactions of alkenyl ketone oximes with acetylene in the KOH–DMSO system and base-catalysed condensation of pyrrolocarbodithioates, which have recently become available, with CH-acids are being extensively developed. These reactions provide simple approaches to groups of *C*-vinylpyrroles, which have previously been not easily accessible or unknown, starting from available compounds.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 02-03-07015).

III. Structure and properties of liquid-containing materials	599
IV. NMR porosimetry	605
V. Supplement	610

Abstract. This review concerns the state-of-the-art in the field of NMR tomography. The scope and limitations of the method, its capabilities, and some of the most widely used applications in physical chemistry are discussed. It is demonstrated that the technique is able to provide a vast variety of information about the state of objects under study and on the physicochemical processes occurring in them, which can be gained owing to the specific features of the technique. The review predominantly covers the studies of the structure and properties of various liquid-containing objects. The bibliography includes 232 references.

I. Introduction

Nuclear magnetic resonance tomography, or magnetic resonance imaging (MRI), has long been used in medical and biological research. Currently, this technique is being utilised for not only diagnosis of diseases but also operative control in clinical therapy and in studies of functional activity of the human brain. Recently, magnetic resonance imaging has also been used in studies of various objects of inanimate matter. Modern methods of multi-nuclear magnetic resonance allow one to image the internal structure of a vast variety of samples and to investigate the properties of and processes occurring in materials with a spatial resolution of the order of hundreds and even tens of micrometres.

Today, an extensive literature on the physicochemical applications of MRI has evolved, concerning a vast variety of applications. Therefore, the authors of this review tried to give the readers an idea of the most widespread avenues of applications of this technique and to present some appropriate illustrative examples. The choice of both applications and examples is to a great extent subjective. In most cases, it was dictated by authors' opinion about the importance of a particular application and by the field of research they are involved in.

There is also a number of objective factors that preclude unambiguous classification of particular experiments. For

instance, any NMR experiment can in principle be carried out with spatial resolution, which leads to an almost infinite number of possible imaging experiments. This review leaves the communications concerned with obtaining spectral rather than spatial information as well as the NMR studies performed without spatial resolution out of consideration. The authors also leave aside specific biological and medical applications of this technique in spite of enormous literature in this field. It should be noted that there are no fundamental differences between particular experimental techniques employed in medical experiments and those used in physicochemical studies and that many physicochemical research strategies were initially developed for medical applications of MRI. A vast variety of processes occurring in living organisms, *e.g.*, pulsatory flow of liquids, gas diffusion in porous media, *etc.*, are also of considerable interest for chemists. At the same time, many experimental techniques employed in medical research have initially been tested and evaluated using model objects of inanimate matter. Therefore, it is impossible to leave biomedical applications of MRI out of consideration altogether.

Some features basically differentiate MRI from other modern methods of imaging the internal structure of various objects. Therefore, this review pays considerable attention to specific features of the technique, which is of great importance for assessing possible fields of its applications. The review mainly covers the publications concerned with the imaging and studies of the properties of liquid-containing objects.

II. The nuclear magnetic resonance imaging technique

1. General remarks

Magnetic resonance imaging^{1–4} undoubtedly owes its origin to the emergence and development (in the mid-1940s) of radio-spectroscopy as a field of experimental science and first of all to successful pioneering ESR experiments by Zavoiskii⁵ and studies on the observation of NMR signals in condensed matter carried out by the research groups headed by Bloch⁶ and Purcell.⁷ Studies of the spin echo carried out by Hahn⁸ in the 1950s are also of great importance for the development of MRI, since recording the spin echo signals serves as the basis for many particular MRI techniques. In 1966, Ernst and Anderson⁹ proposed a promising method of extracting spectral information using the Fourier transform. This was a breakthrough in the development of modern pulsed NMR^{10–12} which is the basis of magnetic resonance imaging. Since the early 1970s, commercial NMR spectrometers have been equipped with computers for acquisition, processing and presentation of experimental data. Modern experi-

ments are so sophisticated and the amount of information is so large that computers are an integral part of NMR equipment. In 1971, Jeener[†] proposed the use of two-dimensional Fourier transform in NMR and thus laid the groundwork for multidimensional NMR spectroscopy.^{13–16} In essence, magnetic resonance images represent a kind of multidimensional NMR spectra.¹⁷ Moreover, both NMR spectroscopy and MRI can be considered as particular cases of multidimensional NMR experiments in a generalised space of coordinates, frequencies and time. In 1973, Lauterbur¹⁸ reported the first tomographic image obtained using the ¹H NMR signals. Commercial NMR tomographs for medical research have been produced since the early 1980s. The mid-1980s were marked by the development of hardware, design of novel experimental techniques, which allowed considerable enhancement of spatial resolution and the emergence of NMR microtomography or magnetic resonance microimaging (MRM).

It should be noted that it is hard to discriminate between MRI and MRM.[‡] Similarly to the commonly accepted term ‘microscopy’, a formal line between them can be drawn through a volume element of the order of (0.1 mm)³, which represents the resolution limit for the naked eye.¹⁹ Nevertheless, even such a conventional distinction is sometimes ambiguous, since the spatial resolution is often anisotropic. For instance, many experiments are performed with an in-plane resolution of tens of micrometres and a slice thickness of several millimetres.

2. Obtaining an image

The basis for nuclear magnetic resonance is the interaction between the nuclear spins and the static and alternating magnetic fields. In practice, a spin system usually represents an ensemble of nuclear spins which is described by the total magnetisation vector **M**. At thermal equilibrium in a static magnetic field **B**₀, the nuclear spins tend to line up with the field so that the vector **M** is directed along **B**₀. Conventionally, the magnetic field is aligned along the *z* axis of the laboratory frame of reference, **B**₀ = **B**_{0z}. A 90° flip of the longitudinal magnetisation vector **M** = **M**_z about the *x* axis creates the transverse magnetisation **M**_y ⊥ **B**₀. In pulsed NMR, the magnetisation vector is flipped by applying the radiofrequency (RF) pulses for which the magnetic field **B**_{1x} is perpendicular to the field **B**₀ while the flip angle, α, depends on the amplitude of the field **B**_{1x} and the duration of the RF pulse. In particular, the pulse that flips the magnetisation vector 90° is called the 90°-pulse. After the flip, the transverse magnetisation vector experiences free precession about the **B**_{0z} direction and creates the observed signal at the resonance frequency ω equal to the spin precession frequency in the external field **B**₀.

Precession of the transverse magnetisation vector is accompanied by its irreversible decay with the characteristic time *T*₂ as a result of transverse, or spin-spin, relaxation. Often, the actual decay time, *T*₂^{*}, of the observed signal is shorter than *T*₂ (*T*₂^{*} < *T*₂) owing to different spin precession frequencies that can be due to the differences in the local magnetic fields. For a system of immobile spins such a dephasing is reversible and the spin system can be rephased by reversal of the applied field gradient or by inversion of the phase of the spin precession by applying a 180°-pulse. Rephasing of the magnetisation leads to creation of the spin echo signal. In the case of NMR, the width of a spectral line is determined by the time *T*₂ (*T*₂^{*}). Return of the spin system to thermal equilibrium and recovery of the longitudinal magnetisation vector **M**_z ∥ **B**₀ is associated with the effect of the longitudinal, or spin-lattice, relaxation occurring with the

characteristic time *T*₁. Knowledge of the relaxation times *T*₁, *T*₂, *T*₂^{*} and the relaxation time in the rotating frame of reference, *T*_{1ρ}, allows one to extract valuable information on the structure of and processes in the objects under study. Generally, the relaxation times depend on the magnitude of the applied magnetic field and the relaxation time measurements have been a routine procedure in the NMR experiments.^{10–12}

The basics of MRI are very simple. The position of a single line in the NMR spectrum is determined by the resonance frequency, ω, which is to a first approximation proportional to the applied external magnetic field **B**₀:

$$\omega = \gamma \mathbf{B}_0, \quad (1)$$

where γ is the gyromagnetic ratio of the nucleus under study with a nonzero spin. The NMR spectrum of water in two tubes placed in a uniform magnetic field (see Fig. 1) will exhibit a single, relatively narrow line (see Fig. 1*a*) regardless of the amount of water in the tubes and their arrangement. However, if the magnetic field is nonuniform (*i.e.*, it is a function of the spatial coordinates), the resonance frequency also becomes a function of the spatial coordinates of the nuclear spin. Most of experiments are carried out using constant magnetic field gradient; in this case the magnitude of the magnetic field is a linear function of coordinate:

$$\mathbf{B}_z = \mathbf{B}_{0z} + \left(\frac{d\mathbf{B}_z}{dx} \right) x = \mathbf{B}_{0z} + G_x x, \quad (2)$$

(here, the magnetic field gradient, *G*_x, is applied along the *x* axis). It should be emphasised that applying the *G*_x gradient does not change the orientation of the total magnetic field at any point of the sample along the *z* axis, while the magnetic field amplitude becomes a linear function of the coordinate *x*. Usually, the second term in expression (2) is smaller than the first one. The gradients *G*_y and *G*_z are defined analogously.

Thus, if two tubes shown in Fig. 1 are placed in a magnetic field given by expression (2), different locations of the tubes on the *x* axis denote that they experience different magnetic fields and, hence, give the NMR signals at different frequencies (Fig. 1*b*). Moreover, inhomogeneity of the magnetic field within each tube leads to different resonance frequencies of microscopic volumes of

Figure 1. A schematic representation of the NMR spectrum of water in two tubes placed in the magnetic field **B**_z. Homogeneous magnetic field (*a*), magnetic field strength is a linear function of coordinate *x* (*b*).

[†] See J Jeener, in *Ampere International Summer School, Basko Polje, Yugoslavia, 1971*

[‡] The term ‘MRI’ is mostly used in medical literature; however, many non-medical applications of the method cannot also be called ‘microimaging’. Since in fact we deal with the same experimental method, in this review we prefer to use a more general term, ‘MRI’, while the term ‘MRM’ is used in those cases where high spatial resolution should be emphasised.

water at different coordinates x . It is easily seen that applying the G_x gradient allows one to obtain an integrated projection of the sample under study on the direction of the gradient vector.

The approach illustrated in Fig. 1 can be used in NMR spectroscopy for simultaneous analysis of several samples to increase the throughput of experimental technique, which is of particular importance in, *e.g.*, combinatorial chemistry.²⁰

Even such a simple one-dimensional (1D) experiment allows the obtaining of useful information in studies of samples of appropriately chosen symmetry. For instance, by applying the field gradient along the axis of a cylindrical sample one can obtain the 1D profiles of the liquid content. Experiments with sequential recording of the 1D profiles in studies of the adsorption of water on a cylindrical bead pack of the adsorbent particles are illustrated in Fig. 2. The advantages of this technique are its simplicity and the possibility of fast recording the 1D profiles (data acquisition times are of the order of hundreds of microseconds), since in this case the signal is recorded after a single application of the pulse sequence. In the MRI studies the pulse sequence includes the RF pulses and pulsed magnetic field gradients G_i , which are applied between the RF pulses or simultaneously with them.

Figure 2. One-dimensional water distribution profiles in the axial direction of the cylindrical bead pack (internal cylinder diameter was 21 mm) comprised of small adsorbent granules (2–3 mm) recorded during the pumping of moist air through initially dry adsorbent. Recording each profile took 260 s. A total of 64 profiles were collected within 4 h 40 min. Air flow direction from right to left.

Practical implementation of such a 1D experiment is based on recording the temporal evolution of the transverse magnetisation of the sample (in the form of the free induction decay or the spin, stimulated or gradient echo) in the presence of a field gradient. In this case, the spin precession frequencies are different during the acquisition time; therefore, this technique is called the frequency encoding of spatial information. The angle of rotation, or the phase, of the magnetisation vector precessing in the xy plane continuously changes during the signal acquisition time $0 \leq t \leq T_{\text{reg}}$

$$\varphi = \omega t = \gamma \mathbf{B}_z t = \gamma \mathbf{B}_{0z} t + \gamma \mathbf{G}_x x t. \quad (3)$$

The MRI experiments can be conveniently described using the concept of the k -space. Let us define the components of the wave vector $\mathbf{k}$ as follows:

$$k_x = \frac{\gamma G_x t}{2\pi}; \quad (4)$$

The components k_y and k_z are defined analogously. During the recording of a signal in the presence of the gradient G_x , the k_x

value is continuously changed, so the detection process is equivalent to a discrete sampling of the NMR signal intensity at a discrete set of equidistant time or k_x values. Thus, in contrast to some other imaging techniques,²¹ the MRI experiments involve scanning the space of the wave vector $\mathbf{k}$ rather than real space. Therefore, n -dimensional imaging of an object requires scanning the k -space of the same dimension n with the centre at $\mathbf{k} = 0$. Image reconstruction in the real coordinate space is possible using, *e.g.*, the n -dimensional Fourier transform

$$S(\mathbf{k}) = \int \rho(\mathbf{r}) \exp(i 2\pi \mathbf{k} \mathbf{r}) d\mathbf{r}, \quad (5)$$

$$\rho(\mathbf{r}) = \int S(\mathbf{k}) \exp(-i 2\pi \mathbf{k} \mathbf{r}) d\mathbf{k}, \quad (6)$$

where $S(\mathbf{k})$ is the experimental NMR signal recorded by scanning the k -space and $\rho(\mathbf{r})$ is the spin density. The $\rho(\mathbf{r})$ value is proportional to the concentration of the substance under study.

The frequency encoding of the NMR signal (see above) allows the recording of a line in the k -space, *e.g.*, a line along the k_x direction if $k_y = k_z = 0$. Obtaining a two-dimensional (2D) image in, *e.g.*, the xy plane requires additional recording of the NMR signal at those points of the k -space for which $k_y \neq 0$. To this end, a pulsed gradient G_y is applied to the transverse magnetisation before the beginning of signal acquisition. As a result, the spin system is displaced in the k -space along the k_y direction by an increment

$$k_y = \frac{\gamma G_y \delta}{2\pi}, \quad (7)$$

where δ is the duration of the pulse gradient. Then, after recording the NMR signal in the presence of G_x , one gets a new line of points in the k -space, which is parallel to the preceding line. Multiple repetition of this procedure with step-by-step variation of the amplitude of the pulsed gradient G_y allows collecting the necessary 'two-dimensional' array of the signal amplitudes in the k -space. Since the pulsed gradient G_y is applied before recording the NMR signal, it changes the phases rather than the precession frequency of the magnetisation vectors contributing to the observed signal during the acquisition time. Therefore, this procedure is called the phase encoding of spatial information or signal.

A drawback of the phase encoding procedure is multiple repetition of experiments to obtain a complete set of k_y values. Prior to each repetition of the pulse sequence the spin system should return to thermal equilibrium. This takes time T_r of the order of $3T_1 - 5T_1$. For an analogue-to-digital converter with a maximum sampling rate of $1/(2.5 \mu\text{s})$, recording a line of 128 points in the k -space takes $128 \times 2.5 \mu\text{s} = 320 \mu\text{s}$. Obtaining a two-dimensional image of size 128×128 pixels requires 128 lines in the k -space to be recorded. For instance, in the case of bulk water ($T_1 = 2.7$ s) it would take $128 \times 3 \times T_1 \approx 17$ min. This way of scanning the k -space is inefficient since only 0.004% of the total duration of experiments is spent for recording the NMR signal. In addition, an increase in the image dimension leads to reduction of the size of the volume elements contributing to each image pixel, which in turn reduces the signal-to-noise ratio. Therefore, signal averaging is required which even greater extends the duration of experiments.

A three-dimensional (3D) image can be obtained by recording the signals from a set of planes in the k -space, corresponding to different k_z values ($k_z = \gamma G_z \delta / 2\pi$). This can be done using the phase encoding along the z axis, namely, the pulse sequence is augmented with the pulsed gradient G_z of duration δ . Clearly, such experiments take a very long time. Obtaining an image of size $128 \times 128 \times 128$ pixels requires 128×128 lines in the k -space to be recorded, which takes more than 36 h ($128 \times 128 \times 3 \times T_1$). However, an experiment with a sample with $T_1 = 10$ ms takes only

Figure 3. A reconstructed three-dimensional image of a cluster comprised of porous fine-grained (200 μm) alumina impregnated with Vaseline oil and filling out the interstices of a bead of large (5 mm) alumina granules. The latter contain no liquid and do not contribute to the NMR signal.

8 min. An example of a reconstructed three-dimensional image of an object is shown in Fig. 3.

Another approach to studies of three-dimensional objects involves recording two-dimensional images from one or several slices rather than the entire object (Fig. 4). Slice selection is most often achieved by using selective RF pulses. Any RF pulse has a limited excitation bandwidth, the bandshape being dependent on the parameters of the pulse. Many types of pulses nearly equally affect all spins in the frequency range $\omega_0 \pm \Delta\omega/2$ (ω_0 is the frequency of the RF pulse and $\Delta\omega$ is the bandwidth) while the spins with characteristic frequencies lying beyond this frequency range remain nearly unaffected. The $\Delta\omega$ value is inversely proportional to the duration of the RF pulse; therefore, a relatively long RF pulse range has a narrow excitation bandwidth. In the case of

Figure 4. Two-dimensional image of a slice of a glass capillary-bundle column saturated with water.

The nominal in-plane spatial resolution was $5 \times 5 \mu\text{m}^2$ at a slice thickness of 15 mm. The diameter of individual capillaries was 40 μm . White spots in the image correspond to the blocked capillaries containing no water.

homogeneous magnetic field this can be used for, *e.g.*, selection of a particular signal in the entire NMR spectrum and obtaining a spatially resolved image for one of the components of a mixture. If the selective pulse is applied simultaneously with the field gradient G_z , this pulse becomes spatially selective and affects only those spins within a slice perpendicular to the axis along which the gradient is applied. As mentioned above, the time of the two-dimensional experiments is mainly spent for the recovery of the equilibrium magnetisation. Since selective pulses have no effect on the magnetisation outside the selected slice, one can scan lines in the k -space, corresponding to other slices of the sample while the magnetisation within a given layer relaxes to the equilibrium value. This allows imaging of a number of slices that do not intersect within the sample instead of one slice nearly without extension of the duration of the experiments. Since the directions of the gradients G_x , G_y and G_z are mutually orthogonal, the use of their linear combinations makes it possible to select a slice with arbitrary spatial orientation and to carry out a two-dimensional scan of a slice in the k -space without physical rotation of the sample. To obtain an excitation pattern with steeper transition regions at the edges of a slice, the so-called shaped RF pulses are employed.^{22–25}

Practical implementation of the frequency encoding of an NMR signal involves application of the gradient echo or a combination of the gradient echo and the spin echo. In the former case, rephasing of the spin precession is achieved by reversal of the gradients in the pulse sequence, while in the latter case this is achieved by rephasing using a 180° pulse. In contrast to the gradient echo, the spin echo also eliminates the effects caused by internal field gradients, differences in chemical shifts and heteronuclear spin-spin interaction.

In recording the echo signal an important parameter is the echo time T_e , *i.e.*, the effective time of the evolution of the transverse magnetisation, which is equal to the time interval between the instants of creation and rephasing of the transverse magnetisation and corresponds to the maximum spin echo signal. Often, the relaxation time of the transverse magnetisation, T_2 , is shorter than the shortest achievable T_e value. This leads to considerable loss of sensitivity of the experimental technique. The effective time of the transverse relaxation, T_2^* , of samples with large internal magnetic field gradients can be shorter than T_2 . In the latter case, it is more appropriate to use the spin echo technique, since the spin echo amplitude decays with the characteristic time T_2 , while the gradient echo signal decays with the time constant T_2^* . If T_2 is much shorter than the shortest achievable T_e , in some cases the free induction decay in the presence of the external field gradient is recorded instead of the echo signal, which corresponds to radial trajectories in the k -space. Subsequent image reconstruction can be performed by either interpolation of the signal at the nodes of a rectangular grid followed by multi-dimensional Fourier transformation²⁶ or from projections.^{27,28} A number of experimental techniques,²⁹ *e.g.*, single point imaging (SPI)^{30,31} and single point ramped imaging with T_1 enhancement (SPRITE)^{32–35} are based exclusively on the phase encoding (no frequency encoding is used).

Generally, the imaging time depends on the image dimension, imaging procedure, sensitivity, relaxation times of the nuclear spins used for recording the NMR signal and is to a great extent determined by the desired spatial resolution. Shortening the duration of the experiments is particularly important when dealing with fast dynamic processes. There is a number of approaches that were used as the basis for creation of fast imaging techniques for obtaining two- and three-dimensional NMR images.^{36–39} These techniques employ shortening the recovery time between the repetitions of the pulse sequences, recording more than one line in the k -space during each application of the pulse sequence, optimisation of the trajectories in the k -space, *etc.* For instance, each repetition of the pulse sequence in fast procedures based on acquisition of the gradient echo signal⁴⁰ uses only a small part of the longitudinal magnetisation of the sample due to the applica-

tion of the RF pulse with a small flip angle, $\alpha \ll 90^\circ$. As a result, the spin system is not fully saturated and there is no complete NMR signal loss even if the recovery time T_r is much shorter than T_1 . Yet another approach involves acquisition of a large set of the echo signals, each of them being corresponded to a different line in the k -space, during a single application of the pulse sequence.^{41–43} Recently, considerable attention has been given to spiral rather than linear scan of the k -space.^{44–46}

Magnetic resonance imaging can be used for mapping the RF field⁴⁷ and the static magnetic field^{48–50} within the sample giving the NMR signal. Therefore, shimming the magnetic field in the NMR experiments is now transformed from a kind of art⁵¹ into a field of exact science. This feature is used in MRI experiments for visualisation of the electromagnetic fields of the gradient coils and the fields created by eddy currents upon switching the external field gradients.^{52–54} Visualisation of the electric fields in a sample is used for the determination of the densities of the electric currents flowing within the sample.^{55–57}

Summing up, it should be mentioned that MRI experiments can be carried out using the gradients of the RF field B_1 (the so-called B_1 -imaging)^{58–61} instead of the gradients of the static field B_0 . The advantage of this technique is its insensitivity to internal inhomogeneities of the static magnetic field. One can use the RF field gradients to obtain images as well as to determine the relaxation times, diffusion coefficients and flow rates of fluids.^{62,63}

3. Spatial resolution of MRI method

Magnetic resonance imaging is characterised by a relatively low spatial resolution. Experiments with a resolution of the order of $(5\text{ }\mu\text{m})^3$ should be considered exceptions. In most cases, a spatial resolution is of the order of tens and even hundreds of micrometres. Often, the slice thickness ($\sim 1\text{--}10\text{ mm}$) in two-dimensional NMR imaging studies exceeds the in-plane spatial resolution. It should be noted that the experimentally achievable spatial resolution is not the major advantage of the MRI technique.

The spatial resolution that can be achieved in the experiment depends on several factors. In many instances, the major contribution comes from the relatively low sensitivity of NMR. Often, almost no information can be extracted from an image obtained with high (nominal) spatial resolution because of the noisiness of the image. This is due to the fact that enhancement of spatial resolution is associated with a decrease in the size of the volume element of the image (voxel), which in turn causes a proportional reduction of the signal-to-noise ratio for each image pixel.¹ This ratio can be improved by accumulating the NMR signal by means of multiple repetition of the experiments; however, the duration of the experiments becomes unacceptably long.

Another factor responsible for the spatial resolution is the spectral width of the NMR signal used in the imaging experiments. As mentioned above, the NMR images can be treated as multidimensional NMR spectra, namely, as the dependences of the signal amplitude on one or a number of frequency coordinates. The nominal resolution equals the actual one if two neighbouring pixels of an NMR image correspond to two non-overlapped spectral peaks, *i.e.*, if the NMR signal is narrower than the frequency difference between the centres of the neighbouring image pixels. In principle, this limitation can be surmounted by increasing the amplitude of the field gradient whereby the image is stretched in the frequency coordinates. In practice, the field gradient amplitudes are limited by the operating range of experimental equipment ($100\text{--}1000\text{ G cm}^{-1}$). Increasing the field gradient amplitudes is a challenge to MRI studies of solids,^{27,64–69} since the width of the NMR signals of solids (up to hundreds of kilohertz) much exceeds the values typical of liquids. Therefore, MRI studies of solids are often carried out using the field gradients of the order of 10^4 G cm^{-1} .

It should be emphasised that limitations associated with the linewidth of the NMR spectra are characteristic of the frequency

rather than phase encoding of the NMR signal. In addition, phase encoding excludes the appearance of artifacts in the NMR image originated from inhomogeneity of the magnetic field and differences in the chemical shifts.²⁹

Yet another factor that limits the spatial resolution is displacement of the nuclear spins in space (including molecular diffusion) during the acquisition time. The self-diffusion coefficient, D , of bulk water at 20°C is $2.0\text{ cm}^2\text{ s}^{-1}$. If the acquisition time of one echo signal, T_{reg} , is 1 ms, the characteristic displacement of water molecules along the direction of the magnetic field gradient is $(2DT_{\text{reg}})^{1/2} \approx 2\text{ }\mu\text{m}$. If the diffusion motion of the molecules is restrained, the diffusion-controlled resolution limit can be in principle reduced. In the case of motion of macroscopic parts of the object under study one should use another time scale and consider the motion (displacement) during a much longer time interval, that is, the acquisition time of the entire NMR image rather than the acquisition time of one echo signal. In particular, displacement of the entire object (*e.g.*, a patient undergoing an MRI evaluation) during the time interval needed to perform all measurements should not be larger than the desired spatial resolution. In the case of periodic motions of the object under study (cardiac muscle contractions, pulsatory blood flow, *etc.*), imaging is often controlled by the period of the motion (*e.g.*, synchronisation with the electrocardiogram signal).

Currently, there has been intensive research aimed at enhancing the spatial resolution of the MRI technique.⁷⁰ An avenue of biomedical research is based on the possibility of using MRM with a spatial resolution of the order of $1\text{ }\mu\text{m}$ in studies of plant cells and in animal experiments. Miniaturisation of the receiver RF coils allows improvement of the signal-to-noise ratio. However, further enhancement of spatial resolution using this approach faces severe difficulties. Much more promising seem to be other strategies (in particular, the use of magnetic resonance force microscopy which combines NMR imaging and atomic force microscopy).^{71–74}

4. Specific features, advantages and drawbacks of MRI techniques

An unquestionable advantage of MRI is the possibility of non-destructive (non-invasive) investigation of the internal structure and properties of various (including opaque) objects, which is of particular importance in medical research. Another advantage of the method is the lack of preferential direction, which allows obtaining spatial information along any direction or simultaneously along the three spatial coordinates.

Magnetic resonance imaging requires no probes or molecular tracers to be introduced into the object under study. Here, the nuclear spins of the molecules constituting the object under study are employed as inherent tracers. In principle, any nucleus with nonzero spin can give an NMR signal. The prospects for the MRI applications of a particular nucleus are first of all determined by the sensitivity of this nucleus and by the characteristic relaxation times. In practice, the number of different nuclei used in MRI experiments is limited and most of studies utilise the ^1H NMR signals.

In addition, in the case of multicomponent systems combining the NMR spectroscopy and MRI allow one to obtain separate images for each type of molecules or even each group of atomic nuclei in the molecules. Both approaches can also be used to obtain spatially resolved NMR spectra including those of a preselected volume element of arbitrary shape inside the sample (localised spectroscopy).^{75–79} The capabilities of spatially localised MRI are illustrated in Fig. 5.

As mentioned above, the major drawback of MRI consists in relatively low spatial resolution. Besides, NMR in general and MRI in particular can be used to study a large number but not all kinds of materials. Operation with electromagnetic radiation in RF range ($100\text{--}1000\text{ MHz}$) imposes severe restrictions on the possibilities of studying metals and other conducting materials, since in this frequency range the skin layer is thin and the RF

Figure 5. An image of the logo of the International Tomography Centre of the Siberian Branch, Russian Academy of Sciences. The image was obtained by spatial selection of the NMR signal using a simple 10-mm cylindrical tube filled with water as the sample.

radiation does not penetrate into the interior of the entire sample. Placing a conducting object into a RF coil causes a considerable loss of the energy stored in the resonant circuit, which reduces its Q -factor and affects the sensitivity of the method employed. In addition, MRI utilises pulsed magnetic field gradients which induce eddy currents responsible for the loss of signal and image distortion in studies of conducting materials. Dielectric losses in samples with high dielectric constant also reduce the Q -factor of the RF circuit. Investigations of magnetic materials in static magnetic fields of strength less than 20 T are also impossible.

Often, some limitations are also imposed on the size of sample under study. Magnetic resonance microimaging allows one to achieve the highest spatial resolution and the signal-to-noise ratio; however, the size of the sample usually does not exceed several centimetres. Using biomedical MRI instruments, one can investigate objects of size from ~ 10 cm up to a human body size. Currently, devices with open configuration are finding increasing application. They allow studies of objects of any size; this is achieved by moving the object under study or the device itself. In medicine, this type of systems is used for, *e.g.*, visualisation of internal organs during surgical operations^{80,81} and diagnosis.⁸² The NMR logging systems, a 'hydroscope' device designed for the exploration and characterisation of the underground pools of water and other fluids (see below), a GARfield device⁸³ for laboratory investigations of samples tens or hundreds of micrometres thick and the 'NMR Mouse', or a mobile explorer of the near-surface regions of large objects⁸⁴ can serve as examples of open design applications in other fields.

5. Image contrast mechanisms and informativity of the method

All things being equal, an n -fold increase in the spin density (concentration of the nuclear spins) causes an n -fold increase in the amplitude of the NMR signal. However, it is not necessarily true that if two signal amplitudes differ by a factor of n , the corresponding spin densities also exhibit the n -fold difference. This is due to the fact that the signal amplitude is a complex function of many parameters and first of all the spin relaxation times T_1 and T_2 . As a result, in practice the value $\rho(\mathbf{r})F(P)$ is measured instead of the spin density $\rho(\mathbf{r})$ [see expression (6)]. The function F determines the degree of image contrast due to parameters P that are different from $\rho(\mathbf{r})$. Therefore, sometimes quantitative MRM measurements of the spatial distribution of, *e.g.*, water in an object under study are difficult or even impossible since the influence of other factors on the NMR signal cannot be avoided completely. It is this apparent disadvantage that makes magnetic resonance imaging a powerful tool which is much more versatile compared to other modern spatial imaging methods.²¹

Spin density measurements (by, *e.g.*, integrating signals in an NMR spectrum) provide no way for discriminating the liquid and frozen water. However, the relaxation times of water in the liquid and solid state are appreciably different, which creates a contrast

Figure 6. Image of a pine bar of a square cross section of $(1.7 \text{ cm})^2$ and 5 cm in height. The bar was initially frozen and was melting during the MRI experiments.

The two-dimensional image was obtained in the horizontal plane without slice selection. Brighter gradations of gray correspond to more intense NMR signal. The early and late zones of the growth rings are clearly visualised as bright and dark stripes, respectively. The dark spot at the centre of the image corresponds to the frozen liquid.

in the NMR image of an object containing water in different states of aggregation (Fig. 6). The molecular spin relaxation times are rather sensitive to the environment, which allows this feature to be used in medical diagnosis. Often, pathological changes in tissues have virtually no effect on the spin density; however, they affect the T_1 and T_2 values, which leads to changes in contrast of corresponding regions in the NMR image. Sometimes contrast between the healthy and malignant tissues can be improved by introducing a contrast agent, *i.e.*, a paramagnetic compound that is capable of changing the relaxation times of the spin systems of water or lipids in tissues. The relaxation times are also sensitive to the concentration of oxygen, which allows studies of, *e.g.*, the dynamics of changes in the oxygen concentration in blood and tissues. In particular, this is used for visualisation of the brain regions responding to a particular external stimulus (functional MRI).⁸⁵

A broad spectrum of applications of NMR imaging is to a great extent due to the fact that the nature of contrast of the NMR image depends on the experimental conditions and can be chosen by researchers in a targeted manner depending on particular problems. For instance, by shortening the time delay between repetitions of the pulse sequence one can obtain NMR images with T_1 -contrast — $\rho(\mathbf{r})F(T_1)$, — *i.e.*, the images in which the colour of a particular pixel characterises not only the local concentration of the resonance spins, but also their local spin-lattice relaxation time. This is due to the fact that the amplitude of the NMR signal of the nuclear spins with $T_1 \ll T_r$, which have time to return to thermal equilibrium during the time interval between successive repetitions of the pulse sequence, is maximum and independent of T_r , whereas the NMR signal of the spins with $T_1 \geq T_r$ is partially suppressed and its amplitude is a function of the T_1/T_r ratio. This is the case of the so-called T_1 -weighted image.

Clearly, by varying the image contrast in a targeted manner one can obtain information not only on the time T_1 but also many other parameters characterising the spin system. However, the relaxation times (T_1 , T_2 , T_2^* , $T_{1\rho}$) occupy a special position among all these parameters. Nuclear spin relaxation is due to the fluctuating local magnetic interactions of the nuclear spins with their environment. The efficiency of the nuclear spin relaxation depends on the frequency spectrum corresponding to a particular type of interactions. The spectrum is to a great extent determined by both the motion of the probe molecule (and its fragments) and the motions of the molecular environment. The relaxation time T_1

is sensitive to components of the motion occurring at frequencies of the order of hundreds of megahertz, whereas the times T_2 and $T_{1\rho}$ are sensitive to the motions occurring in the kilohertz range. Therefore, by measuring the relaxation times one can study the frequency spectra of the molecular and atomic group motions and determine the correlation times and activation energies of such motions as well as particular distances in the system under study at the molecular level.

In addition to the spin density and relaxation times, the chemical shift, local magnetic fields, spin polarisation and spin-spin interactions can be used as the basis for image contrast in MRI studies. These parameters are sensitive to many physico-chemical properties of objects under study (*e.g.*, temperature, viscosity, mechanical stress, diamagnetic susceptibility, *etc.*) and processes occurring in them (*e.g.*, interaction with the surface, chemical transformations, flow and other types of motion, ordering, filler distribution, cross-linking, vulcanisation, ageing of materials, *etc.*). Experiments are designed in such a way that the changes in a property (process) of interest be responsible for changes in a certain spin-system parameter related to changes in a particular parameter of the measured NMR signal (resonance frequencies, amplitude, linewidth or phase).

Thus, virtually any property (process) influencing a certain parameter of the NMR signal can provide image contrast in the NMR imaging experiments. This allows both qualitative and quantitative studies of the spatial distribution of a particular property of the object at hand. Since the NMR signal is sensitive to some properties (processes), often the major problem is to separate the contributions of the process under study or the property of the object to this signal. Often, creation of the pulse sequences for MRI experiments and interpretation of the results obtained are substantially simplified when using a modular approach. In this case, the pulse sequence is augmented with a module responsible for creation of a particular type of contrast, which is executed before the module designed for collecting spatial information.

III. Structure and properties of liquid-containing materials

1. General remarks

Magnetic resonance imaging studies of liquid-containing solid porous materials allow one to elucidate their structure and properties as well as the distribution of the fluid within the pore space without performing solid-state NMR experiments.

The amplitude of the NMR signal of an image pixel characterises the pore volume filled with the liquid within the corresponding volume element. If the size of the liquid-filled pores exceeds the spatial resolution of the experimental method ($> 10\ \mu\text{m}$), NMR imaging permits investigations of the morphology of porous materials. For instance, the pore size in most of rocks can be as large as $200\ \mu\text{m}$ and even greater (in limestone rocks).⁸⁶ For smaller pores, each pixel of an NMR image corresponds to the NMR signal averaged over the particular volume element of the sample. If the pore size is much smaller than the spatial resolution, each image pixel characterises the local porosity of the sample and the presence of large non-porous inclusions and voids. If the pore size is comparable with the spatial resolution, the partial volume effects become of great importance for correct interpretation of experimental data.

As mentioned above, the amplitude of the NMR signal depends not only on the spin density (amount of liquid in the volume element) but also on some other parameters. By appropriately choosing the mechanism of image contrast formation one can obtain the distribution maps of various characteristics of the objects under study after processing the experimental data. Very often, investigations into porous materials involve mapping the nuclear spin relaxation times (T_1 , $T_{1\rho}$, T_2 , T_2^*). Relaxation-weighted NMR images are useful in revealing inhomogeneities of the properties of a porous medium,⁸⁷ while quantitative

relaxation time measurements allow one to determine the permeability,⁸⁸ wettability, pore saturation levels,⁸⁹ pore size and many other characteristics. Quantitative distribution maps of these parameters can be derived from the relaxation time distribution maps using appropriate models. Spatial inhomogeneity of a sample can be quantified by constructing histograms and evaluating the nonzero distribution moments for the maps obtained as well as by calculating the spatial correlation functions of the measured parameters.⁸⁶

Usually, the spin relaxation times of the liquids filling the pore system are shorter than those of bulk liquids. Because of the shortening of the time T_2 the amplitude of the NMR signal in the magnetic resonance images is often out of proportion to the content of the liquid (spin density) in a porous sample. Therefore, quantitative information is often extracted from a set of NMR images characterised by different degree of relaxation weighting. Computer simulation of the relaxation curves for each image pixel can then be used for deriving separate spin density and relaxation time maps.^{86,90}

In practice, studies of systems containing a number of immiscible and miscible liquids are not infrequent. For instance, the distribution of water and hydrocarbons in rocks is of considerable interest for the gas and petroleum extraction industry, while the reagent-to-product ratio is an important parameter in studies of chemical reactions. In the case of multicomponent systems selective NMR imaging is possible. This can be achieved using a number of methods. If the NMR signals of the liquids differ in chemical shifts, selective pulsed excitation of a particular line in the NMR spectrum allows one to carry out imaging studies using the signal of this spectral line (chemical shift selective imaging, CSSI).^{91,92} Selective pulses can also be used to suppress (saturate) all spectral lines except for that involved in the imaging procedure.⁹¹ However, it should be noted that shortening of the spin relaxation times can lead to appreciable line broadening in the NMR spectra of the liquids in the pores (up to hundreds of Hz and more), which precludes separation of the contributions of particular spectral lines to the NMR signal based on differences in chemical shifts.⁸⁶

Another approach is based on recording the free induction decay or the spin echo signal in the absence of external field gradients, which preserves the spectral information (chemical shift imaging, CSI).^{93–95} Having aimed at extracting spatial information, in this case one should reject the frequency encoding of the NMR signal. Low-resolution spectral information can also be obtained using the phase encoding of the signal. In such a case it is convenient to reconstruct spectral information by, *e.g.*, simulating the temporal evolution of the signal by the sum of several exponentially decaying sine curves rather than using the Fourier transformation.⁹⁶

If resonances are overlapped, chemical shift selective NMR imaging is impossible. In this case one should use distinctions between other parameters of the NMR signal. The contributions of different components of the system under study can be separated using differences in the spin relaxation times.^{97–99} For instance, by choosing an appropriate echo time, T_e , one can observe the contribution of the liquid characterised by the longest time T_2 . If the times T_1 differ appreciably, the pulse sequence can be augmented with an inversion pulse and a time delay that are applied prior to image readout. The time delay is chosen in such a way that the signal be recorded at a time instant corresponding to zero magnetisation of a particular liquid in a binary mixture during the spin-lattice relaxation process.^{92,100} Collecting a set of images with different degree of relaxation weighting followed by computer simulation of the relaxation curves for each image pixel allows one to obtain separate relaxation time and spin density maps. If the relaxation times of the liquids in the mixture are substantially different, this feature can be used to obtain the separate spin density maps for the individual components of the mixture.¹⁰¹ Scalar interactions occurring between inequivalent nuclei can also be used for separation of the contributions of

different liquids to the NMR signal by, *e.g.*, creating and detecting two-quantum coherence.^{97, 102}

Doping water with paramagnetic ions makes it possible to 'hide' its NMR signal owing to the short T_2 time. This can be used for selective observation of the NMR signal of a hydrocarbon in pores containing both liquids.¹⁰³

Yet another experimental technique involves the use of different magnetic nuclei¹⁰⁴ and their isotopes. For instance, saturation of porous rocks with D₂O/hydrocarbon or H₂O/fluorocarbon mixtures allows selective acquisition of the signal of a particular liquid.^{94, 103} The possibility of recording NMR signals from other nuclei extends the range of useful chemical substances.

Porous materials are characterised by the presence of numerous interfaces between phases with substantially different magnetic susceptibilities. Placing samples of porous materials in a strong magnetic field of the NMR spectrometer produces large field gradients near the interfaces. In this case, the decay time of the transverse magnetisation, T_2^* , becomes much shorter than the spin-spin relaxation time, T_2 . The reasons are the dephasing of the spin precession since all spins experience different magnetic fields and incoherence of the spin motion (owing to, *e.g.*, diffusion) in non-uniform magnetic field. As a result, gradient echo imaging allows better visualisation of structural defects. The NMR images obtained by the spin echo technique often exhibit artifacts in the form of bright spots near structural defects (due to difference in magnetic susceptibilities).¹⁰⁵ On the other hand, for many systems with T_2^* values in the submillisecond range, the gradient-echo technique produces no NMR signals at all. To prevent substantial shortening of the time T_2^* , experiments are usually carried out in relatively low fields and/or using multiple rephasing of the magnetisation by applying the sequence of 180° pulses¹⁰ (the so-called Carr–Purcell–Meiboom–Gill, or CPMG, pulse sequence). It should be noted that the magnitudes of local field gradients allow assessment of the pore shape and evaluation of the pore sizes.¹⁰⁶ Using the relaxation time of the transverse magnetisation of a system of immobile spins, one can extract information on the distribution of the square of the strength of local field gradients, which serves as a measure of the difference between the actual pore shape and an ellipsoid.¹⁰⁷ The values obtained from comparison of the calculated and experimental parameters can serve as semiempirical characteristics of the pore space (in particular, the shape and size of pores and inter-pore channels).

In addition to the aforesaid, diffusion in external field gradients applied to encode spatial information also causes shortening of the time T_2^* . Obtaining high spatial resolution requires application of large external gradients; however, this can be accompanied by substantial shortening of the times T_2^* . When studying samples with the T_2 (T_2^*) values lying in the sub-millisecond range it is appropriate to use experimental methods based on the phase encoding of spatial information (SPI, SPRITE)^{30–35} or on recording and collecting the free induction decay signals followed by image reconstruction from projections.²⁷ The relaxation times can also depend on the mechanical prehistory of the sample.¹⁰⁸

Magnetic resonance imaging studies should be carried out taking into account specific features of systems of different nature. For instance, in most of biological objects the spin systems do not exhibit a single-exponential relaxation due to structural inhomogeneity at the cell and tissue level.¹⁰⁹ Plant tissues are saturated with air bubbles; therefore, the magnetic field can be strongly inhomogeneous. Some liquid-containing porous materials (*e.g.*, rocks) possess electrical conductivity. This reduces the signal-to-noise ratio as a result of reduction of the Q -factor of the resonant RF circuit, changes its resonance frequency and can lead to a limited penetration depth of the RF field into the sample due to the skin effect.⁸⁶ In this case, experiments are carried out in relatively weak magnetic fields (*i.e.*, at lower frequencies). Rocks and synthetic porous materials can contain paramagnetic impurities that are responsible for appreciable shortening of the T_2 times

of liquids in pores, which can result in partial or complete loss of the NMR signal.

2. Model and synthetic porous materials

The internal structure of catalyst granules determines their efficiency in heterogeneous catalysis, service life and other properties. Rigby¹¹⁰ has reported a more accurate structural representation of a porous medium (catalyst granules) which was based on complementary information obtained from the results of NMR imaging experiments (visualisation of the pores of size greater than 10 μm) and low-temperature nitrogen adsorption (pores of size less than 10 μm) and mercury porosimetry measurements. Then, he modelled the void space of a porous solid by separate representations of both the macroscopic and mesoscopic length scale properties of the material.¹¹⁰ Nuclear magnetic resonance images (more correctly, spin density maps) of fluid-saturated solid granules can be used for determination of the local concentration of the fluid, *i.e.*, inhomogeneity of the sample porosity. The NMR images of alumina spheres saturated with an ethanol–water mixture revealed¹¹¹ a uniform structure with spherically layered solid material and voids, which is consistent with the manufacturing process of these particles. The spin density and T_1 time distributions of water in alumina were mapped.¹¹²

The T_1 maps allow one to reveal spatial inhomogeneities of the pore size distribution, while the effective diffusivity maps show inhomogeneities of the transport properties.¹¹³ Experiments with water-saturated alumina and silica granules showed that these types of inhomogeneities are not necessarily correlated.^{114, 115} Mention may be made that the case in point is structural inhomogeneities with a characteristic size exceeding the spatial resolution of the experimental technique. Microscopic structural inhomogeneities are averaged in the imaging experiments. It should be noted that if for porosity there is a simple statistical averaging, the dynamic averaging of the T_1 and diffusivity values is nontrivial. Gladden *et al.*¹¹⁶ proposed quantitative characterisation of the sample inhomogeneity in terms of a fractal dimension of two-dimensional NMR images of the sample. Water-saturated cylindrical alumina granules placed in a tube filled with D₂O exhibited different effective diffusivity and, hence, tortuosity of the pore space in the radial and axial directions. This is in agreement with different fractal dimensions of the two-dimensional NMR images of the same granules, whereas the fractal dimensions of two-dimensional T_1 maps obtained in the axial and radial directions were identical.

Different diffusivity measurement techniques are 'sensitive' to the structure of the pore space at different length scales. An assumption was made¹¹⁷ that the ratio of the pore space tortuosity determined in the experiments with H₂O/D₂O exchange to the tortuosity determined from the pulsed field gradient studies^{8, 25, 118, 119} provides an estimate of the tortuosity associated with the sample inhomogeneity at a length scale of the order of the sample size. This assumption was confirmed by calculations of the tortuosity coefficient carried out with construction of the pore space grid using the NMR images of water-saturated porous granules. This allowed one to represent the tortuosity coefficient of the pore space as product of several tortuosity coefficients obtained for different length scales. Based on these concepts, an attempt has been undertaken at constructing a correct model of a porous medium taking into account the structural hierarchy, that is, the micro(meso)scopic and macroscopic length scales.¹²⁰ A mathematical model for prediction of the properties of porous media at the micro(meso)scopic length scale was constructed using information on porosity and the average pore size obtained from conventional porosimetry measurements. Reliability of the model constructed at the length scale less than 10 μm was evaluated by comparing the calculated and experimental T_1 values of water filling the pores. The model for description of the macroscopic structure at the length scale spanning the range from 40 μm (typical spatial resolution of NMR images) to the size of the object (several millimetres) was constructed in such a

way that the fractal dimensions of the calculated two-dimensional NMR images (and/or T_1 maps) be in agreement with the experimental fractal dimensions. A complete hierarchical model was validated by comparing the calculated and experimental values of the effective diffusivities and pore space tortuosity coefficients.

A study of a porous Pyrex glass filter containing cyclohexane (average pore diameter was 160 μm) has been reported.¹²¹ The 1D NMR profiles obtained with a spatial resolution of 26 μm exhibited rather large signal amplitude fluctuations indicating some structural disorder at this length scale. From the distances between the neighbouring amplitude peaks one can extract statistically averaged information on the pore size and inter-pore distances. Both statistical analysis of the distribution histogram of the distances between the neighbouring peaks and calculations gave close values of the estimates of the average inter-pore distance. At distances from zero to 2–4 mm, the spatial correlation function of the signal amplitude fluctuations has a constant value while it rapidly decreases at longer distances. The results obtained are in good agreement with the data of the scanning electron microscopy (SEM) studies which, in contrast to MRI experiments, require a labour-consuming pre-treatment of the sample.

Signal amplitude fluctuations can also be due to a low signal-to-noise ratio. Lengthening the signal accumulation time allows the defects in a water-saturated, disk-shaped porous glass sample to be identified with ease.¹⁰⁵ If the in-plane spatial resolution is comparable with the average pore size, it is convenient to use thick-slice NMR imaging of the samples of relatively low porosity. At higher in-plane resolution, the best image contrast is achieved in the experiments carried out with the same resolution along the three spatial dimensions. The NMR images of different disk-shaped samples (average pore size varied from 5 to 200 μm) obtained with an isotropic spatial resolution of 100 μm exhibited only minor distinctions. Experiments revealed shortening of the relaxation times of water filling the pores of sizes 5 to 200 μm with a decrease in the pore size.¹⁰⁵ Magnetic resonance images of water in a glass bead pack have also been obtained.¹²² Studies of porous systems in packed bed reactors by MRI technique have been reported.¹²³

To determine the fractal properties of porous systems, two-dimensional and three-dimensional model porous structures obtained by computer simulation were fabricated on polystyrene layers using a plotter to construct two-dimensional or three-dimensional percolation clusters. Three-dimensional objects were composed as stacks of two-dimensional layers. Then water was allowed to fill the clusters to visualise the pore space. The measured fractal dimension was found to be in good agreement with that of the model. Based on the possibility of distinguishing the liquid in motion and at rest^{25, 124–127} when analysing the flow pattern along the percolation cluster, the dead ends were excluded from consideration and the fractal dimension of the percolation backbone was determined. For model objects, this parameter was found to be lower than that of the entire cluster dimension. Experiments with natural porous systems (natural sponge, pumice stone, quartz sand and glass bead agglomeration) showed that the pore space is much more highly interconnected and the backbone can hardly be distinguished from the total pore space in terms of the fractal dimension.¹²⁸

Relaxation times of the fluids contacting solid surfaces are strongly dependent on the surface properties. In particular, the relaxation times of fluid filling the pore system are shortened in the presence of paramagnetic atoms or molecules adsorbed on the surface. Catalyst poisoning with weakly paramagnetic coke formed in the pore space can change the relaxation times of fluids and cause partial blocking of pores. This feature was used for obtaining the NMR profiles of macroscopic distributions of coke formed in the reaction of ethanol dehydrogenation in alumina pellets.¹²⁹ After reduction of conversion degree to a particular value in the range from 100% to 50% the alumina pellets were removed from the reactor and saturated with water. MRI-studies

revealed high inhomogeneity of coke formation in the pellets and strong dependence of coke profiles on the pellet position in the reactor. Analogous studies of zeolite HY were carried out using 2,3-dimethylpentane or xenon as the probe molecules.¹³⁰ Contacting coke causes a change in the chemical shift of xenon. Relaxation time measurements of 2,3-dimethylpentane showed an inhomogeneous composition of coke within the sample.

Diamagnetic adsorbates can also change the relaxation times of the fluids filling the pore system due to, *e.g.*, steric shielding of paramagnetic ions adsorbed on the pore walls from the fluid molecules.¹³¹ For instance, adsorption of platinum hexachloride (PtCl_6^{2-}) on the developed surface of a porous support causes an increase in the nuclear spin relaxation times of protons of the liquids that fill the pore space of the support.^{131, 132} This fact was used¹³² for determining the type of macroscopic spatial distribution of the active component over the surface of the support, which is an important characteristic of supported catalysts. Experiments were carried out using $\gamma\text{-Al}_2\text{O}_3$ pellets with different types of spatial distribution of platinum hexachloride. The NMR images confirmed good agreement between the T_1 maps of the fluids filling the pore space and the platinum distribution profiles obtained using conventional visualisation techniques. Magnetic resonance microimaging studies allowed the real-time redistribution dynamics of adsorbed platinum hexachloride to be traced for the first time during competing adsorption of PtCl_6^{2-} and oxalic acid from solution on a single $\gamma\text{-Al}_2\text{O}_3$ pellet.¹³² Analogous experiments were carried out with palladium (PdCl_4^{2-}) and it was found that adsorption of PdCl_4^{2-} on $\gamma\text{-Al}_2\text{O}_3$ also causes an increase in the relaxation times of the fluids filling the pore system.¹³³

The opposite influence of diamagnetic and paramagnetic adsorbates on the relaxation times of fluids in pores was used for studying the redistribution dynamics of PtCl_6^{2-} and Cu^{2+} upon their simultaneous adsorption on the same alumina pellet. The results obtained showed that copper is gradually displaced inward from the surface of the pellet.^{133, 134}

3. Rocks

Magnetic resonance imaging of brine-saturated sandstone rock cores and mapping the spin density and relaxation times of the spin systems in them has been reported.^{86, 112, 135} The experiments revealed the presence of shale interlayers with small pore sizes and high content of clay, which appreciably suppress the amplitude of the water signal. Bedding planes ~ 1 mm thick were also clearly seen in the images.¹³⁵ Analogous magnetic resonance images of limestone rock samples exhibited large voids and porosity variations. The signal amplitude and relaxation times distribution histograms of partially dried samples showed a much more inhomogeneous structure of limestone rock compared to the alumina structure.⁸⁶ Three-dimensional images of water or brine in rock cores revealed inhomogeneity of the porous structure or inhomogeneous saturation of the samples with water.¹³⁶ The results of the MRI studies of brine-saturated sandstone rock cores were compared with the data obtained by X-ray computerised tomography.¹⁰³

The difference in the chemical shifts of water and dodecane was used for separation of their images in a sample comprised of two sandstone rock plugs placed one on top of the other, one of them being saturated with water and the other with n-dodecane,⁹⁵ and in a core saturated with a mixture of these fluids.⁹⁶ Two-dimensional chemical shift selective imaging of water and hydrocarbon in limestone rocks has also been reported.⁹⁴ In this case, a specified amount of hydrocarbon (water) was injected into the sample saturated with water (hydrocarbon). No complete displacement of one fluid by the other occurred. Experiments on displacement of H_2O by heavy water revealed the presence of a clearly seen interface between the two fluids. Two-dimensional images of kerosene distribution in a kerosene-saturated core are shown in Fig. 7.

Figure 7. Sequential two-dimensional MRI images of adjacent slices of a kerosene-containing core. Darker regions in the image correspond to more intense NMR signal.

Each slice was 1.2 mm thick and the in-plane spatial resolution was $0.16 \times 0.16 \text{ mm}^2$.

Separate three-dimensional images of water and motor oil in sandstone rock samples have been obtained on the basis of the differences in relaxation times.¹⁰⁰ Biexponential analysis of the relaxation decay curves obtained for each image pixel was used in studies of a chalk core saturated with water and petroleum crude.¹⁰¹ The T_1 histograms exhibited two well-resolved peaks of finite width corresponding to the spin-lattice relaxation of water and petroleum. This allowed one to perform separate two-dimensional image reconstruction of water and petroleum, to establish that the regions with high concentration of water correspond to low content of petroleum (and *vice versa*) and to find cracks filled with water inside the core. Chemical shift selective imaging experiments were also carried out. The relaxation time histogram of the sample saturated only with water had one peak shifted towards longer times T_1 compared to the water peak of the preceding sample. This was explained by higher pore filling with water (assuming the same surface area of water contacting the pore surface) as a result of the removal of petroleum.

Magnetic resonance imaging studies of the dolomite cores dried under mild conditions and then saturated with oil⁹² revealed the presence of cracks, voids and microporous domains. Experiments carried out taking into account the differences in the chemical shifts and relaxation times of water and oil revealed large amounts of residual water in the sample. The results were compared with those obtained by X-ray computerised tomography.

Multinuclear NMR has been investigated as a method for discriminating the contributions of the organic and aqueous phases to the NMR signal in studies of flooded petroleum crude cores.¹⁰⁴ To this end, a sandstone rock plug with four openings 0.5 to 2.9 mm in diameter was sequentially saturated with aqueous LiCl solution and pure trifluorotoluene and the three-dimensional images were recorded using the ^7Li and ^{19}F NMR signals.

The Earth is the largest sample that can be studied by NMR imaging technique. Simultaneously, this is the least effective magnet that is used in the NMR studies. To carry out the NMR imaging experiments in the geomagnetic field,^{61, 137, 138} a 'hydro-scope' device was created, which has been used in search for and the determination of the depths of occurrence and evaluation of the field volumes of proton-containing fluids at depths up to 200 m. A wire loop ~ 100 m in diameter placed on the terrestrial surface is used for generation of the RF pulses and reception of the NMR signal. Very low signal-to-noise ratio is compensated by multiple accumulation of the NMR signal.

4. Polymers and gels

From the NMR standpoint, the properties of polymeric materials are intermediate between those of liquids and solids. This feature determines the choice of experimental techniques that can be used for studying this specific class of substances. Swelling of polymers in solvents allows imaging using the NMR signal of the solvent. Swelling also enhances the mobility of the polymer macromolecules, which sometimes permits a number of conventional liquid-state NMR techniques to be implemented to obtain the images of the polymer itself.^{139, 140} In addition, an increase in size due to swelling allows better visualisation of the sample morphology.

The NMR images of a sample of a water-saturated polymeric composite reinforced with carbon fibre exhibited well-resolved structural defects filled with water.¹⁴¹ These results were confirmed by sectioning the sample. If the size of structural defects and microcracks is smaller than the spatial resolution of the image, the amplitude of the NMR signal of the image pixel can be used for evaluating the defect size. Clearly, imaging of voids using the NMR signal of water is impossible; this can be done based on the NMR signal of the polymer itself.

Spin relaxation time measurements of polymers and gels allow one to obtain particularly valuable information. The time T_1 is sensitive to fast motions of atomic groups in the megahertz frequency range, while the times T_2 and $T_{1\rho}$ characterise slow, cooperative low-frequency motions and depend on the cross-link density and chain entanglement.^{139, 140, 142} Useful information can also be extracted from the relaxation times of solvents since the behavior of the solvent molecules is to a great extent determined by their interactions with the polymer molecules.

Magnetic resonance imaging studies of swollen butadiene rubber¹⁴⁰ and *cis*-1,4-polyisoprene¹⁴² of different initial compositions and cross-link density were carried out by detecting the NMR signal of the solvent (cyclohexane) or polymer (when cyclohexane- d_{12} was used).^{139, 140} The images obtained exhibited clearly seen spatial inhomogeneities of the samples as well as structural defects and voids and allowed one to establish structural changes as function of the rubber vulcanisation time. Lower solvent concentration corresponded to the regions with higher cross-link density. The regions near the surface contacting the mould were characterised by higher cross-link density and by a decrease in the cross-link density as a result of reversion effects (at long vulcanisation times).¹⁴⁰ The signal intensity histograms constructed using the images obtained by solvent imaging technique can be used for characterisation of the cross-link density and sample homogeneity. The results of the T_2 measurements allowed one to assess changes in the molecular mobility. Analysis of the T_2 maps of the solvent showed¹³⁹ that the T_2 value is determined by the polymer-solvent interactions and the cross-link density. As the cross-link density increases during vulcanisation, the molecular motions slow down and the relaxation time T_2 of the polymer is shortened, thus weakening the NMR signal of the polymer. This revealed spatial inhomogeneity of the cross-link density distribution over the sample. The T_2 maps were converted into corresponding histograms. Analysis of the histograms showed that the T_2 distributions become narrower and their maxima shift towards shorter T_2 values as the vulcanisation time increases. There are in fact two T_2 values corresponding to the monomer units of the polymer chain located at long and short distances to the cross-link points.^{139, 142} If triallyl cyanurate is used as vulcanising agent (at the vulcanisation temperature, this is a liquid whose mobility is sufficiently high for the domain formation), the polymers obtained are less homogeneous compared to those containing zinc diacrylate.

External perturbations can cause specific changes in the state of polymers and gels, *e.g.*, a temperature-induced volume-phase-transition. For instance, poly(*N*-isopropylacrylamide) gel swollen in water is in the equilibrium state at temperatures below the lower critical solution temperature (31–32 °C) and in the collapsed state above this temperature, the phase transition being reversible. The NMR images of this gel in different states, obtained using the

relaxation and diffusion contrast techniques provided an insight into the changes in the state of water and the mobility of the polymer molecules.¹⁴³

Two-dimensional spin density and T_2 maps of water in a cross-linked poly(methacrylic acid) hydrogel were obtained.¹⁴⁴ Analysis of these maps revealed a uniform distribution and high mobility of the water molecules in the gel.¹⁴⁴ Applying mechanical stress causes a decrease in the content of water within the compressed region of the gel due to migration of water molecules to the surrounding uncompressed regions. The molecular motion of water in the compressed region of the gel becomes lower, which leads to shortening of the time T_2 . Therefore, NMR imaging allows one to obtain information on the propagation of the strain induced by mechanical stress within the sample. Hydropolyelectrolyte gels can shrink in response to electric field. Imposing a voltage of 3 V across two platinum electrodes placed in contact with a gel led to its shrinkage which was larger near the positive electrode.¹⁴⁵ Using the two-dimensional gel images and T_2 maps, one can trace the changes in the shape of an initially cylindrical sample and determine the content and mobility of water in different regions of the gel sample. Analogous experiments were performed with the sample prepared using aqueous MnSO_4 solution and consisting of two parts with a different degree of cross-linking of the polymer.¹⁴⁶ The T_2 maps of water were converted into the Mn^{2+} ion concentration maps which showed that manganese ions migrate towards the negative electrode and this is responsible for the appearance of Mn^{2+} ion concentration gradients.

Nuclear magnetic resonance imaging has been used for quantitative studies of the properties of polysaccharide solutions and gels.¹⁴⁷ Gels were prepared by dialysing sodium alginate solutions against a solution containing calcium ions. The NMR images of the samples showed that the gels were inhomogeneous, that is, the gel concentration increased towards the centre of the sample. More homogeneous samples were obtained when NaCl was present in both solutions. The effect of the gel concentration (1%–4%) and degree of O-acetylation on the relaxation times, diffusion coefficient and magnetisation transfer parameters was studied taking into account the exchange of water molecules between bulk water and the chemisorbed water.

Freshly prepared agarose gels are characterised by a single-exponential transverse relaxation and direct proportionality of the relaxation rate to the agarose concentration. This is associated with small sizes of structural inhomogeneities of the gel ($< 0.3 \mu\text{m}$). However, relaxation measurements performed after the 'slow freeze–thaw' cycle revealed a multiexponential behaviour. Crystal growth under conditions of slow freezing causes essential changes in the gel morphology, namely, the formation of structural inhomogeneities with a characteristic size of several micrometres, which are retained after thaw. Multiexponential behaviour of the transverse relaxation is due to the fact that diffusion of water cannot induce averaging at this length scale. On the other hand, the longitudinal relaxation is single-exponential for all samples. The results of experiments are in agreement with the data of calculations carried out based on a model which includes the relaxation due to proton exchange with hydroxyl groups and the physical interaction between water molecules and agarose spiral aggregates.¹⁴⁸ The T_1 , T_2 and T_2^* maps of an Mn(II) -doped agarose gel and polyethylene have also been obtained.¹⁴⁹

5. Suspensions, emulsions and compacts

Magnetic resonance imaging can be useful in nondestructive studies of fabrication of ceramics, *e.g.*, slip casting. For instance, cross-sectional two-dimensional images of a plaster of Paris mould filled with an aqueous Al_2O_3 suspension (initial content of water was 30 mass %) were obtained.¹⁵⁰ The images exhibited clearly showed suspension, and solid deposits on the mould walls and the mould walls themselves, through which water was removed. The suspension and the solid deposits were character-

ised by the same content of water; however, the relaxation times of water in these regions were appreciably different. Growth of the deposit layer with time was observed.

Ceramics can also be fabricated by pressure moulding. In this case, it is possible to study the distribution of organic components (binder, plastifier, anti-adhesives) within the sample, which has a strong effect on quality of the ceramic materials. Visualisation of the distribution of the polymeric binder in green ceramics allows sorting out substandard articles before reaching the dewaxing and sintering stages. Different strategies of magnetic resonance imaging and recording spatially resolved NMR spectra of a polymeric binder were compared taking the compacts prepared by compacting alumina powder mixed with polymeric binder (2.5 mass % or 15 mass %) as examples.^{108, 151} No effect of the average particle size on the binder distribution was found; however, a decrease in the length-to-diameter ratio of the compact down to 0.17 led to increased concentration of the polymer around the periphery of the sample, which was associated with features of the pressing mechanics. The signal intensity histograms constructed based on the two-dimensional images of the compacts can be used for controlling the binder distribution homogeneity.¹⁰⁸ An NMR imaging study of a Si_3N_4 sample pressed in the form of a disk with openings of different diameters containing organic binder (15 mass %) has been reported.¹⁵¹ The relaxation times of low-molecular-mass poly(ethylene oxide), polyvinyl alcohol and poly(ethylene terephthalate) used as binders in fabrication of ceramics are $\sim 1 \text{ ms}$ (T_2) and $\sim 300 \mu\text{s}$ (T_2^*).¹⁰⁸

When growing large zeolite crystals, it is important to know the mixing degree of the starting components. Nuclear magnetic resonance was used for the determination of the mixing quality of two starting solutions in a batch mixer.¹⁵² The process was investigated under laboratory conditions. Zeolite A was synthesised from a sodium aluminate solution with triethanolamine (TEA) additives (TEA is an inhibitor of nucleation) and a silica suspension or sodium silicate solution. The NMR signal of the TEA protons was recorded; all other reagents were used in deuterated form. Analysis of the magnetic resonance images revealed the appearance of a large gradient of the TEA concentration after the first mixing cycle in the reaction with silica suspension. The concentration of TEA increased in a downward direction because of the higher density of the TEA–sodium aluminate mixture compared to the silica suspension density. Further mixing led to homogenisation of the TEA distribution in the mixture and after eleven cycles the mixture was almost homogeneous. The NMR images of the samples of the mixture exhibited clearly seen air bubbles trapped by the viscous medium. When the reaction was carried out with sodium silicate as the second component, homogenisation of the reaction mixture was even more complicated due to an increase in the viscosity of the mixture caused by gelation that started several seconds after placing the components in contact. Further mixing[§] led to the formation of aluminosilicate hydrogel clots. Clots of different compositions are clearly seen in the magnetic resonance images. Analogous studies were also carried out during the synthesis of zeolite X. Attempts at using this approach to study the synthesis of mordenite failed. In this case, tetraethylammonium bromide (cross-linking agent) was used instead of TEA. Unlike TEA, this compound is not involved in complexation with aluminium or silicon and, hence, one cannot use its distribution for evaluating the mixing degree of the reagents.

The size and distribution of voids and gas bubbles in secondary explosives have strong effect on the initiation and propaga-

[§] The efficiency of mixing strongly depends on the batch mixer design. The best batch mixer design was chosen based on analysis of the images of the samples obtained using four different types of batch mixers that were specially developed for the on-board synthesis of zeolites during space shuttle missions.

tion of detonation wave. The shock wave causes an adiabatic 'collapse' of voids, thus initiating a burst-like combustion. Void-containing samples can be obtained by mixing the explosives with hollow particles or by conducting a chemical reaction involving ammonium nitrate and sodium nitrite followed by liberation of dinitrogen. Concentrated oil-in-water emulsions can serve as examples of the secondary explosives. Two samples of the oil-in-water emulsions have been investigated.¹⁵³ One sample contained almost no voids while the other one was prepared using aqueous sodium nitrite solution to favour the formation of dinitrogen bubbles. Two-dimensional magnetic resonance images of the second sample exhibited voids of size up to 0.5 mm, whereas no voids were observed in the images of the first sample. These results are in agreement with the data of scanning electron microscopy studies.

Phase separation in the emulsion of sunflower oil in D₂O has been studied¹⁵⁴ taking a number of bulk samples and a sample prepared in the form of a film less than 600 μm thick as examples. Experiments revealed gravimetric separation of the dispersed phase from the continuous emulsion phase with time (creaming). An oil concentration gradient in the near-surface layer and an increase in the oil concentration with time were observed for all samples. Both facts seem to be associated with polydispersity of the sizes of the oil drops that become more 'close-packed' as a result of the action of the underlying layers.

6. Food products and plants

The potentialities of the MRI method in revealing the internal structure of and water distribution in the food systems containing small amounts of liquids was demonstrated¹⁵⁵ taking studies of the morphology of cookies, soft caramel with chocolate cream filler and a mixture of corn starch and water as examples.

Two-dimensional images and maps of the water spin density and T_2 distribution in plant tissues (Fig. 8) have been reported.¹⁰⁹ The relaxation time distribution maps give an accurate account of the peculiarities of the sample morphologies. For apples, the width of the NMR signal in a 4.7 T field is twice as large as that determined in the 2.35 T field. This is indicative of the local magnetic field gradients due to the difference in magnetic susceptibilities between the tissues and microscopic air bubbles.¹⁵⁶ Two-dimensional mapping of the distribution of the diffusion coefficient ($1.08\text{--}1.66 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$) and the RMS local magnetic field gradient ($8.6\text{--}17.9 \text{ G cm}^{-1}$ in the 2.35 T field) was also performed. Mealiness in apples and peaches stored under various conditions was assessed using MRI techniques.¹⁵⁷ Spatially

Figure 8. Two-dimensional MRI image of a fragment of a cucumber.

resolved T_2 distribution maps were converted into corresponding T_2 histograms. Development of mealiness in apples leads to more pronounced asymmetry of the T_2 histograms. Analogous process in peaches causes transition from a Gaussian to a broad distribution with a flat top. This points to different physiological processes. The results of the MRI experiments were compared with the data obtained by conventional (mechanical) methods of fruit quality determination.

A MRI study of voidage in watermelons¹⁵⁸ involved recording the profiles of corresponding 1D projections on two orthogonal directions in the plane of a slice 20 mm thick. Then, these profiles were compared with analogous profiles expected for an ideal sphere. Out of 30 samples, 28 watermelons were correctly identified, which was confirmed by two-dimensional imaging.

Heat stress can retard the ripening of many fruits. Studies of tomato fruits kept at 42 °C revealed no changes in the size and overall content of water.¹⁵⁹ After 36 h the relaxation times T_1 and T_2 of water remained unchanged in the pericarp and became shorter for all other plant tissues. Then, the fruits were kept at 25 °C for 24 h; however, no lengthening of the relaxation time T_2 up to the initial value was observed. Probably, heat stress causes the formation of associates of some unbound water molecules with denatured proteins. No complete regeneration of the structure occurred during 24 h after heat stress, which seems to be responsible for a 120 h delay of change in colour, though the rate of ethylene and carbon dioxide production recovered virtually immediately after return to ambient temperature.

Bulk analysis of tobacco and cigarettes by magnetic resonance imaging was performed to map the spin density and relaxation time distributions.¹⁶⁰ The more mobile components (water and tobacco wax) were spin echo imaged while the solid components (cell wall polymers) were observed using the SPI technique. More dense packing of tobacco and lower content of water at the cigarette tip was pointed out. The region near the lateral surface of the cigarette is characterised by higher content of water in tobacco. Partial redistribution of water from tobacco to the filter region was also observed.

Knowledge of the internal morphology of wood is of great importance for wood-working industry. For instance, the possibility of revealing internal (hidden) defects of a log allows one to determine an optimum strategy of sawing beforehand. Cross-sectional two-dimensional images of white oak and black cherry samples 15 to 25 cm in diameter exhibited clearly seen heart-wood and sap-wood regions, the pith, the medullary rays and the growth rings.¹⁶¹ Besides, the eccentricity of the growth rings in the image pointed to the presence of the tension wood which is indistinguishable by the naked eye. The wet-wood region, which is hard to dry, looks as a bright strip in the image. Some water is evaporated through the cracks in the bark during long-term bulk storage of wood. As a result, the sap-wood contains regions characterised by the NMR signals of low intensity. For black cherry, the pith and the medullary rays are indistinguishable in the image owing to their small size; however, one can see gum spots, which are hard to polish when working, as well as hidden knots and scars, worm-holes and wood decay regions. The bark cannot be seen in the images because of the low content of water. Magnetic resonance imaging studies of plant roots have also been reported.^{162, 163}

7. Other materials

Three-dimensional images of the distribution of mobile components in coal were obtained in the temperature range from 25 to 475 °C.¹⁶⁴ It was found that this distribution is inhomogeneous and different for different sorts of coal. The fraction and homogeneity of distribution of the mobile proton-containing component increase as the temperature increases up to 450 °C and then dramatically decrease at higher temperatures as a result of sintering and coking.

Ice coated with gas hydrate melts at room temperature. The process involves the formation of liquid water encapsulated into a solid shell and the sample looks as a white powder-like solid. The

gas hydrate coating is formed in the reaction of ice crystals with CD_4 or xenon at high pressure.^{165, 166} Hyperpolarised xenon^{167–170} was used in studies of the formation of clathrate hydrates and in measurements of the rate constant for this process. Confirmation of the fact that the activation energy is negative¹⁷¹ was also obtained in the experiments with hyperpolarised Xe.

The distribution of water in foam churned from egg white and water has been studied.¹⁷² As time passes, the content of water increases in the lower part and decreases in the upper part of the sample (the liquid flows down under the action of the gravity force). This is accompanied by an increase in the relaxation time T_2 , which can be associated with growth of the foam bubbles. For the foam prepared by shaking water with additives (surfactants, polymer and alcohols), the upper part of the sample was characterised by a reduced spin density; this visually corresponded to much larger bubbles compared to those in the other regions of the sample.¹⁷³ Transformation of essentially non-rectangular water distribution profiles with time was compared with the results of model calculations carried out with inclusion of the downward flow of the liquid under the action of the gravity force. It was found that the model incorrectly describes the early stages of the process; however, it provides an adequate description at long times.

The 1D MRI profiles were also obtained, which illustrated the phase separation in the critical binary mixture aniline–cyclohexane after cooling below the upper critical equilibrium temperature.¹²¹

IV. NMR porosimetry

1. General remarks

In this Section we will consider some methods of the pore size determination based on the effect of the pore sizes on the nuclear spin relaxation times or on the freezing points of liquids in porous media. Besides, many other NMR measurements are to some extent sensitive to the pore size and other characteristics of the pore space. If pores are larger than 10 μm , their exact sizes can be determined by direct visualisation of the liquid that fills the pore space. Information on the pore sizes and tortuosity of the pore space can be extracted from, *e.g.*, the results of measurements of the diffusion coefficients of fluids that fill the pores.^{25, 174–179} The chemical shifts of the substances adsorbed from solution on the surface¹⁸⁰ and of the adsorbed gases (first of all, xenon^{181–185}) are sensitive to the pore size. The pore size distribution determines the shape of the water distribution profiles recorded during drying of liquid-saturated porous materials.^{186–188} The local magnetic field gradients can also reflect the shape and sizes of pores.^{189, 190}

The properties of the molecules of a liquid contacting a solid can be substantially different from the properties of bulk liquid. For instance, the properties of water adsorbed on the surface of silica glass are strongly different from those of bulk water due to the formation of hydrogen bonds with the surface hydroxyl groups.¹⁹¹ This leads to, *e.g.*, reduction of the density of the surface water layer, considerable reduction of rotational mobility of the molecules, anisotropy of the molecular mobility and to the freezing point depression. The NMR properties of the molecules that interact with the surface also change.

Most of the experiments on the NMR porosimetry were carried out without spatial resolution; however, this method can also be used in combination with the MRI technique. In the latter case, it is possible to determine the average pore size (or even the pore size distribution) and the pore volume (this parameter correlates with the local porosity of the sample) for each image pixel.¹¹⁰ It should be mentioned that the changes in the T_1 and T_2 values caused by the interaction with the surface can lead to relative enhancement or suppression of the NMR signal near the macroscopic interfaces when using relaxation-weighted imaging

and that the liquid in the smallest pores can have very short relaxation times T_2 and make no contribution to the NMR signal.

2. Relaxation porosimetry

Often, the spin relaxation (T_1 , T_2 , T_2^* , $T_{1\rho}$) in a liquid or gas contacting the surface of a solid occurs much faster than in the bulk. Detailed NMR investigations of the surface relaxation have been carried out for long. The results of the early studies of the relaxation of the liquids contacting solid silica (silica gel), alumina, coal and zeolite surfaces were generalised by Packer.¹⁹²

One of the reasons for higher relaxation rate of the nuclear spins of the fluid molecules contacting the surface is a substantial change in the correlation time of molecular motions caused by changes in the mobility of the molecules located on the wall or in the near-wall region. Besides, either the interaction between protons of the liquid and the spins of hydrogen atoms of the surface hydroxyl groups or proton exchange can produce additional fluctuating magnetic fields.^{148, 193} Paramagnetic ions or other paramagnetic centres that can exist on the surface or in the near-surface layer of the solid have the strongest effect on the relaxation of fluids.

The relaxation of liquids in silica-based rocks (sandstone rocks) is mostly associated with the presence of paramagnetic ions (*e.g.*, iron or manganese ions).^{194, 195} Their concentration can be as high as several per cent, the iron ions being more abundant.¹⁹⁶ In this case, relaxation is due to the dipole and scalar interactions between the electron and nuclear spins. These interactions are frequency modulated by the relaxation flips of the electron spin and by finite residence time of the molecule on the surface of the solid. The latter reason seems to be insignificant since no pronounced temperature effect was observed.¹⁹⁴ In addition, sandstone rocks sometimes contain particles of magnetic minerals, such as magnetite (Fe_3O_4), which favour an increase in the relaxation rate.¹⁹⁷ Often, sandstone rocks contain clays that possess a rather large specific surface area but have weaker effect on the relaxation parameters.¹⁹⁶ Carbonates are characterised by longer relaxation times compared to sandstone rocks.¹⁹⁷

The relaxation times of systems containing several liquids can strongly depend on the wettability of the pore surface and on the procedure for sample preparation (*e.g.*, on the order in which the pores are filled with different liquids). For instance, experiments with hydrocarbons and water contained in the pores of rock samples showed that the former have longer relaxation times than the latter. This is presumably due to the presence of a monolayer of water on the pore surfaces even in the initially dried samples.¹⁹⁴

Exchange between the surface layer and the bulk of the liquid or gas in the pore is responsible for a finite residence time of the molecules on the surface. The exchange rate strongly affects the results of measurements. The evolution of the magnetisation of a liquid in an isolated pore was studied in detail earlier.^{198, 199} In the case of slow exchange the amplitude of the relaxing magnetisation is different at different distances from the pore surface and the relaxation behaviour is a multiexponential superposition of the amplitudes of the magnetisation of different pore regions. At moderate exchange rates, interpretation of the relaxation behaviour is complicated. For a binary system with two times T_1 , the magnetisation relaxation is described by a sum of two exponents; however, the T_1 values and the contributions of the two components can be substantially different from true values. Moreover, at $T_1 > T_2$ the T_2 -relaxation can exhibit a biexponential behaviour while the T_1 -relaxation can remain single-exponential.¹⁹² The times T_1 and T_2 of the molecules in the surface layer can mainly be determined by different motions (*e.g.*, molecular rotation and reorientation of the axis of rotation).

The simplest case is fast molecular exchange between the near-wall layer and the volume of the pore (fast diffusion or slow surface relaxation). In this case the liquid in the pore exhibits a single-exponential relaxation behaviour even provided a non-

exponential temporal dependence of the relaxation of the molecule located on the pore wall. This holds if²⁰⁰

$$T_1 > \frac{r^2}{6D}, \quad (8)$$

where r is the pore radius and D is the diffusion coefficient of the molecules of the liquid. This condition is met if $r < 10\text{--}100\text{ }\mu\text{m}$ (e.g., for many sandstone rocks). In this case, the simplest model of relaxation of the liquid in the pore is a two-site model with fast exchange, according to which²⁰¹

$$\frac{1}{T_1} = \frac{a}{T_{1v}} + \frac{b}{T_{1p}}, \quad (9)$$

where a and b are the fractions of the liquid in the bulk and on the surface, respectively; and T_{1v} and T_{1p} are the corresponding relaxation times T_1 . The volume of the surface layer is often assumed to be equal to the product of the pore surface area, S , and the layer thickness, λ , though this can be not universally true for the smallest pores owing to high curvature of their surfaces.²⁰² Then one gets¹⁹⁴

$$\frac{1}{T_1} = \left(1 - \frac{\lambda S}{V}\right) \frac{1}{T_{1v}} + \frac{\lambda S}{V} \frac{1}{T_{1p}} \approx \frac{1}{T_{1v}} + \rho_1 \frac{S}{V}, \quad (10)$$

where V is the pore volume and ρ_1 is the surface relaxivity of the nuclear spins.

The reasons responsible for shortening of the times T_1 also cause shortening of the times T_2 of the liquid in pores. In addition, the rate of the transverse relaxation also increases due to molecular diffusion in the presence of local field gradients that can be produced owing to inhomogeneity of the external magnetic field near the boundary between the phases with different magnetic susceptibilities.^{86,203} Therefore, the T_2 time distribution allows characterisation of the pore sizes only if the experiments are carried out in relatively weak fields ($< 500\text{ G}$) and/or with multiple refocussing of the NMR signal using the CPMG pulse sequence. In this case, one can write for T_2 an expression analogous to Eqn (10):

$$\frac{1}{T_2} = \frac{1}{T_{2v}} + \rho_2 \frac{S}{V}. \quad (11)$$

Often, the first term in the right side of expressions (10) and (11) is small and can be neglected.¹⁹⁴

Interpreting the T_2 values is a challenge;²⁰⁴ nevertheless, relaxation porosimetry based on the T_2 measurements has found a number of practical applications. To take into account the effect of the local magnetic field gradients on the T_2 values, the parameter ρ_2 is sometimes assumed to be a function of the applied magnetic field. This implies a non-spherical shape of the pore; otherwise, application of external magnetic field cannot produce local field gradients. However, the pore surface is not ideally smooth; therefore, even for a spherical pore one should expect rather large local field gradients in the immediate vicinity of the surface.²⁰⁵

If all pores have an identical shape, the V/S ratio is a measure of the pore size. In the case of non-spherical pores (long cylindrical pores or slit-like pores) the relaxation porosimetry measurements are sensitive to the smaller size.²⁰⁴ Determination of the pore size requires knowledge of the surface relaxivity which can be found from calibrations which utilise sample-independent techniques of pore size measurements. In practice, the surface of the pore space has fractal character (that is, the measured value of the surface area is a function of the length scale that is used for measurements). Therefore, the surface relaxivity values strongly depend on the type of the sample-independent calibration technique. In particular, the V/S ratio and the surface relaxation parameters can be extracted from an analysis of the results of the effective diffusion coefficient measurements of the gas or liquid molecules

in the pores, as it was done in, e.g., studies of some natural rocks.¹⁷⁴ Another procedure for determining the ρ_1 and ρ_2 values involves measurements of the relaxation times using the samples characterised by a monolayer coverage of the surface of the pore space.²⁰⁶ For the model media (e.g., bead packs), the V/S ratio can be calculated.²⁰⁷

The surface relaxivity values vary over a wide range from 10^{-7} to 10^{-3} m s^{-1} . For water in synthetic materials the ρ_1 values usually span the range from 1×10^{-4} to $20 \times 10^{-4}\text{ m s}^{-1}$ (see Ref. 196). Typical of water in sandstone rocks are the values $\rho_1 \sim 2.5 \times 10^{-6}\text{ m s}^{-1}$ and $\rho_2 \sim 5 \times 10^{-6}\text{ m s}^{-1}$, while water in carbonate rocks is characterised by the parameters $\rho_1 \sim 0.8 \times 10^{-6}\text{ m s}^{-1}$ and $\rho_2 \sim 1.7 \times 10^{-6}\text{ m s}^{-1}$. Experiments with different samples of natural rocks showed that the ρ_1 value varies only slightly despite the fact that the concentration and type of paramagnetic impurities can vary over a wide range from one sample to another (see below). The ρ_1 parameter of water in limestone rock, chalk and sandstone rock cores was reported to vary from $\sim 7 \times 10^{-6}$ to $23 \times 10^{-6}\text{ m s}^{-1}$.²⁰⁷

The effect of paramagnetic ions on the relaxation times of liquids has been studied in detail. For instance, calcite powder packs with known concentration of manganese were prepared by centrifuging the suspension of calcite particles (10 or $30\text{ }\mu\text{m}$) in water with addition of aqueous MnCl_2 solution.¹⁹⁵ Then, the surface layer of the liquid was removed. For all samples, the spin-lattice relaxation was found to be single-exponential. The specific surface areas of the powder packs were measured using low-temperature adsorption of nitrogen. It was found that high concentrations of adsorbed manganese increased the parameter ρ_1 by a factor of ~ 50 (up to a value of $2.4 \times 10^{-5}\text{ m s}^{-1}$) and that an increase in the initial concentration of manganese led to saturation of this parameter. This can be the reason why various natural rock samples are characterised by similar ρ_1 values. Moreover, long contact times of calcite with manganese caused a decrease in the ρ_1 value despite an increase in the amount of the adsorbed manganese. Presumably, some adsorbed manganese becomes buried by freshly precipitated calcite. NMR experiments revealed that only the ions in the outermost atomic layer affect the relaxation. Analogous experiments with Co^{2+} ions showed that these ions have virtually no effect on the relaxation times of water, whereas adsorbed iron ions shorten the T_1 value of water (however, to much lesser extent compared to Mn^{2+} ions). Thus, relaxation owing to the presence of manganese predominates for limestone rocks and possibly plays an important role for sandstone rocks. Flowing a $4\text{ }\mu\text{M}$ aqueous solution of a Mn^{2+} salt through a sample of natural limestone rock led to a decrease in the T_1 value of water by a factor of ~ 6 due to adsorption of Mn^{2+} ions on the surface. Partial desorption of manganese and dissolution of the sample under the action of an aqueous solution of ethylenediaminetetraacetic acid caused partial recovery of the initial T_1 value of water.

Kleinberg *et al.*¹⁹⁶ prepared powder packs of the α -modification of calcium silicate with known concentrations of iron or manganese paramagnetic ions by centrifuging suspensions in water and measured the relaxation times T_1 and T_2 of the samples with different content of Mn and Fe. It was found that the T_1 and T_2 values are virtually temperature independent in the range between 25 and $175\text{ }^\circ\text{C}$. Hence, diffusion, molecular motions and the residence time play an insignificant role and the surface relaxation cannot be due to thermally activated processes such as adsorption and translational and rotational motions. The parameters ρ_1 and ρ_2 were found to be linearly proportional to the manganese and iron concentration, the slopes of the corresponding plots constructed for Fe and Mn being comparable in magnitude. In the limit of zero concentration of these elements, the ρ_1 and ρ_2 values can be determined by the concentration of point defects on the crystal surfaces. Clay-bound water does not mix with water filling the pores and gives a separate peak in the T_2 distribution.

Clearly, in real porous media the pores are interconnected and voids are not filled with fluid. Therefore, the model of the evolution of the magnetisation in isolated pores^{198, 199} is a particular case of a more general model that treats a system of pores filled with a fluid and interconnected by narrow channels.²⁰⁸ If no fluid transport occurs in the system of pores, the relaxation time distribution corresponds to a superposition of the relaxation times of the fluid in individual pores. If the connectivity of the system of pores is low, the relaxation time distribution is broadened and shifted towards shorter times. If the connectivity of the system of pores is high, the relaxation time distribution again becomes narrower and exhibits a maximum at a value determined by the ratio of the total surface area to the total volume of the pores in the sample. If the pores are connected by very narrow channels, the latter can act as efficient relaxation sinks. From the standpoint of the fluid relaxation measurements, this allows one to treat the pores as isolated.^{201, 209} It should be emphasised that if the surface relaxation dominates, the rate of the change in the magnetisation at short times is proportional to the ratio of the total surface area to the total volume of the pore space irrespective of the pore system connectivity.

Samples of synthetic porous materials are characterised by relatively small structural inhomogeneities. Therefore, the molecules have time to 'explore' the pores of all sizes during the NMR experiment; this often leads to single-exponential relaxation. On the other hand, relaxation of fluids in rocks is non-exponential since the observation time is too short for the molecules to travel the distances comparable with the length scales of structural inhomogeneities.

Thus, if pores can be considered isolated in the time scale of the NMR experiments, the magnetisation relaxation is a superposition of the contributions of pores of different sizes and the relaxation time distribution correlates with the pore size distribution. The results of relaxation measurements are analysed using the average T_1 value or a number of models that represent the experimental data by the sum of several (from 1 to 3) exponents or as stretched exponential functions

$$M_{xy}(t) = M_0 \exp \left[- \left(\frac{t}{T_2} \right)^\alpha \right], \quad (12a)$$

$$M_z(t) = M_0 \left\{ 1 - 2 \exp \left[- \left(\frac{t}{T_1} \right)^\alpha \right] \right\}. \quad (12b)$$

Computer simulation of the magnetisation relaxation by the random walk method showed that expressions of the type (12) are physically substantiated. However, this model has a significant drawback consisting in the impossibility of back extrapolating the experimental data to time zero at $\alpha < 1$, which precludes a correct estimation of the spin density (amount of fluid). To overcome this problem, a modified model²¹⁰ has been suggested

$$M_{xy}(t) = M_0 \exp \left[- \frac{t}{\tau_0} \left(1 + \frac{t}{\tau_c} \right)^{\beta-1} \right], \quad (13)$$

where τ_0 , τ_c and β are empirical parameters.

At short times, this function describes a single-exponential decay corresponding to the weighted sum of the initial rates for each relaxation time in the entire distribution of relaxation times. At long times, the function is transformed into expression (12a). Using this model, relaxation measurements of a total of 50 rock samples saturated with different fluids were carried out in different magnetic fields. The model (13) exhibited some advantages in determining the amount of fluid by back extrapolation of the experimental data to time zero, especially for partially saturated samples after centrifuging. Correlation between the parameters of the model and the petrophysical properties of the samples has been discussed. Applicability of the model for representing the T_1 -relaxation data has been pointed out.²¹⁰ The virtue of the models (12) and (13) is their compactness.

Theoretical approaches involving either discrete or continuous distributions, $f(T_1)$, have been widely used in fluid relaxation studies. In this case, the magnetisation relaxation is described by the following expression

$$M(t) = M_0 \left[1 - 2 \int_0^\infty f(T_1) \exp \left(- \frac{t}{T_1} \right) dT_1 \right]. \quad (14)$$

Using appropriate models, the $f(T_1)$ distributions can be converted into the pore size distributions. For rocks, the T_1 values usually span the range from 1.5 to 3 orders of magnitude. Reconstruction of the relaxation time distribution function from experimental data is an ill-posed problem. Solving this problem requires specific theoretical approaches (*e.g.*, regularisation).^{203, 207}

Typical of many samples is fast diffusion within pores. This is confirmed by, *e.g.*, the lack of strong temperature dependence of the relaxation times in the range between 25 and 75 °C, which indicates that diffusive motion is not a rate-limiting process.¹⁹⁴ In this case, each pore of a particular size is characterised by exponential relaxation with its own time constant T_1 . More sophisticated models involve a multisite exchange and a number of T_1 values for arbitrary rate of exchange between the components within each pore. This is significant for mesoscopic and macroscopic pores in which the fast diffusion limit cannot be reached. For instance, relaxation of the longitudinal magnetisation was simulated with a pore size distribution in the form of a sum of three log-normal distributions. The procedure was evaluated using a model data set with known pore size distribution and the factors affecting the reliability of the reconstructed pore size distribution were analysed.²⁰¹ The results of computer simulation of the experimental T_1 measurements allowed one to obtain the pore size distributions for brine-saturated sandstone rock and limestone rock samples.²⁰⁹ The ρ_1 value was assumed to be 10^{-4} m s^{-1} . Inapplicability of this technique to large pores (hundreds of micrometres) due to the loss of sensitivity to the exact shape of the pore size distribution was pointed out.

In the case of (quasi-)continuous distributions the values of the function $f(T_1)$ are often reconstructed²¹¹ using a discrete set of argument values (~ 100 points). This is an ill-posed problem complicated by noisiness of the experimental data. Considerable attention has been given to solving this problem.²¹² The major drawbacks of most of algorithms consist in broadening sharp $f(T_1)$ peaks and replacing broad $f(T_1)$ distributions by a set of narrower peaks. An algorithm has been proposed, which is free from these drawbacks.^{212, 213} The procedure was evaluated taking a model data set as an example and then used for reconstruction of the function $f(T_1)$ for a number of samples of water-containing ceramics and brine-saturated sandstone rock cores.

The nuclear spin relaxation times of water in crushed porous glass of different pore sizes and amounts of the adsorbed fluid were studied.^{191, 214} Nearly single-exponential relaxation (T_1 , $T_{1\rho}$, T_2) was observed in all the experiments. The measured relaxation times were analysed in the framework of the model of fast proton exchange between the surface layer and bulk water. The relaxation times of water in the first monolayer were found to be $T_1 = 150$ and $T_2 = 0.5 \text{ ms}$.²¹⁴ Relaxation (at least, the T_1 relaxation) is due to modulation of the dipole–dipole interaction of the nuclear spins, which allowed one to estimate the correlation times, τ , of rotational molecular motion. It was found that $\tau \sim 20\tau_0$ for water in the first monolayer, $\tau \sim (6-10)\tau_0$ for water in the second monolayer and $\tau \sim \tau_0$ for the rest of adsorbed water, where τ_0 is the correlation time of bulk water (of the order of 10^{-11} s), the lifetime of the water molecules in each state being no longer than 0.5 ms .²¹⁴ According to the results of $T_{1\rho}$ dispersion measurements (dependence on the amplitude of the RF field in the spin-locking experiments), fast rotational motions with a characteristic correlation time of 10^{-8} s are accompanied by much slower motions, namely, reorientations of the rotation axis of the molecule after every 10^{-5} s .¹⁹¹

Correctness of the relaxation model was confirmed by the results of relaxation studies with controlled variation of pore saturation level which was achieved either by adsorption of a known amount of liquid by a dry sample or by centrifuging a saturated sample.^{194, 204} In the latter case, an increase in the centrifugation rate led to removal of the liquid from progressively smaller pores. Experiments with water in porous glass showed that smaller pores have a stronger effect on the relaxation times¹⁹¹ that are shortened as the pore saturation level decreases,^{191, 214} which is consistent with the relaxation model.

Gradual increase in the content of water in silica samples with different pore sizes revealed the biexponential T_2 relaxation.²⁰² A model of the pore filling with water, which takes into account the dependence of the contributions and the individual relaxation times of the two water components, is as follows. Initially, an increase in the pore saturation level leads to an increase in the surface area covered by the water monolayer and to an increase in the number of the smallest water droplets at the pore corners. Then the surface is covered by the second monolayer of water molecules while water droplets begin to grow and merge until complete filling of the pores. Another picture was observed for cyclohexane in conventional silica and for water in hydrophobic silica with methyl groups attached to its surface. In these cases the pore filling occurred uniformly starting from the smallest pores. Analysis of the experimental data allowed determination of the surface-area-to-volume ratio for water and of the number of water droplets at the pore corners at different saturation levels.²⁰²

Various rock cores saturated with water or brine have been studied using controlled variation of the saturation level. Computer simulation of the relaxation data was carried out with the sum of three exponents,²⁰⁰ expressions of the types (12a) and (12b)²⁰⁶ or with continuous relaxation time and pore size distributions.^{92, 207} In all cases, the measured relaxation times agreed with the assumption that during the saturation process the smallest unoccupied pores are filled out first, while during the drainage the largest occupied pores are first to be emptied. The pore size distribution peaks also shifted towards smaller pore sizes, which can be associated with the presence of partially filled pores.²⁰⁷ It was found that the relaxation times of water in sandstone rock²⁰⁶ are temperature independent in the range between 13 and 60 °C and that the T_1/T_2 ratio lies between 1.4 and 3.2. The longest-to-shortest T_1 ratio is 1800, which is in satisfactory agreement with the largest-to-smallest pore radius ratio in the sample.²⁰⁰ Analysis of results of measurements at different saturations allowed extraction of the pore size range without determining the S/V ratio for the entire sample with completely filled pores. It was found that the relationship between the average relaxation time and the saturation level (C) has the form

$$\langle T_1 \rangle = 1.29 C^{1.26}. \quad (15)$$

This correlation can be useful when determining the absolute values of saturation levels of the sample from relaxation measurements.

Agreement between the calculated and experimental data can be substantially improved by using a model with inclusion of narrow inter-pore channels that are filled first, thus determining the relaxation properties at low saturations.²⁰⁶ This allowed one to estimate the volume ($\sim 4.5\%$) and diameter (0.75 μm) of these channels. The channel size is in agreement with the observed water–vapour percolation threshold occurring when the thickness of the adsorbed layer becomes equal to the radius of the channel. The pore sizes obtained from mercury porosimetry studies are by an order of magnitude smaller since this technique is mostly sensitive to the sizes of the inter-pore throats.²⁰⁷ Mass transport can alter the NMR signal from the liquid in small pores. The residual saturation is due to the presence of capillary-bound water and, probably, water in isolated cavities.⁹²

Spatially resolved relaxation porosimetry experiments are also possible. This allows mapping the pore saturation level and pore sizes for each pixel of the image. For instance, catalyst granules¹¹⁰

and water-saturated sandstone rock cores were studied using this technique. Some samples were modified by attaching a silane chain to the surface of the pore space.⁹⁰ The experimental porosity values of these samples were found to be in agreement with the results of mercury porosimetry measurements. It was found that modification of the surface causes a twofold increase in the T_1 and T_2 values of water in pores, which permits wettability studies of the surface of the pore space. The modified sample was characterised by equal T_1 values of the surface water and bulk water, which means that the surface has no effect on the spin-lattice relaxation.

Relaxation porosimetry can also be applied to studies of other materials. In particular, the sizes of the pores left in the food systems and gels after freeze-drying at a reduced pressure characterise the sizes of initial ice crystals. Knowledge of the size distribution allows optimisation of sublimation conditions to improve, *e.g.*, quality of food after thaw. For instance, starch gel was freeze-dried at a reduced pressure and then filled with acetone.²⁰⁵ Samples of different compositions were studied at different freezing rates and the T_2 distributions were determined (T_2 values varied from 55 ms to 2.5 s). Measurements in different magnetic fields revealed rather large local field gradients. Freezing of a cylindrical sample caused the formation of ice crystals (pores), whose sizes increased in the radial direction from the centre to the surface of the sample. The pore sizes in the samples of 10% and 15% gels were different. Calculations performed assuming spherical pores led to the ρ_2 values spanning the range from 1.2×10^{-5} to $4.2 \times 10^{-5} \text{ m s}^{-1}$, which is of the same order of magnitude with the surface relaxation coefficient at the water/glass interface ($3.5 \times 10^{-5} \text{ m s}^{-1}$). The results of these experiments were compared with those of the scanning electron microscopy studies.

Nuclear magnetic resonance logging is one of the most prominent examples of practical implementation of the NMR porosimetry. Borehole logging is used in studies of the deep-earth properties of rocks. One of the most important applications of this method is investigation of the properties of the petroleum and gas fields (in particular, determination of the content of petroleum, gas and water and studies of the interactions of these fluids with rocks). The NMR logging experiments involve lowering a device containing the source of the magnetic field (a magnet or a coil) and a RF coil for creation of the RF field and reception of the NMR signal down a borehole. In this case, the NMR signal comes from the region that is outside the device (within the thickness of the rock mass)^{197, 215–218} at a depth up to several centimetres from the borehole wall. (For comparison, in an NMR spectrometer the sample is located inside the probe). There is a number of different designs of the NMR logging devices.¹⁹⁷ All of them use relatively low magnetic fields; therefore, only the ^1H NMR measurements provide sufficiently high sensitivity. Weak non-uniform magnetic field precludes separation of the contributions of the hydrocarbons and water to the NMR signal based on the chemical shifts.¹⁹⁷ On the other hand, the amplitude of the NMR signal characterises the content of the fluid while the relaxation times correlate with the pore sizes and the types of the fluids filling the pores. This allows determination of such borehole characteristics as the free fluid index, porosity and rock permeability.²¹⁹ Because of the low sensitivity of the method, the T_2 measurements are most often used since they can be performed much faster compared to the T_1 measurements. The relaxation times T_2 of unbound fluid are usually much longer than those of the bound fluid; therefore, analysis of the results of measurements of the T_2 distributions permits separation of the contributions of the unbound and capillary-bound fluid.^{197, 219} Most of rocks possess hydrophilic properties; therefore, the hydrocarbon is at the centre of the pore and does not contact the surface. In this case, the relaxation times of the hydrocarbons of low viscosity are much longer than those of water, which makes it possible to separate their contributions to the NMR signal.¹⁹⁷ Using empirical correlations between the viscosity and the T_2 values of hydrocarbons, one can determine the properties of the hydrocarbon pools and the hydrocarbon

type.²¹⁹ Based on the knowledge of the pore size distribution, the permeability of and the capillary pressure in porous media can be estimated. It was empirically found that the permeability of water-saturated sandstone rocks is proportional to the square of the relaxation time.¹⁹⁷ This is in agreement with expressions (10) and (11) assuming the rock permeability to be proportional to the $(S/V)^{-2}$ ratio.

The contributions of water and hydrocarbons to the NMR signal can be separated even at equal relaxation times.²¹⁹ To avoid explosive outbursts, drilling is carried out under excessive pressure which causes permeation of the fluid from the borehole into the rock. Therefore, the near-wall region used for the NMR measurements contains a mixture of the formation and borehole fluids. By doping the fluid injected in the borehole with water-soluble paramagnetic additives one can substantially shorten the relaxation times of water in the rock without changing the relaxation rates of hydrocarbons. In practice, a number of different types of the logging devices is simultaneously lowered down the borehole. Comparison of the results obtained by different methods allows better characterisation of the borehole.

3. Cryoporosimetry

Using the NMR technique, one can easily distinguish between the fluid and the solid based on considerably different relaxation times. For instance, freezing of water leads to shortening of the time T_2 from 1.8 s to 6 μ s (see Ref. 220). A short time T_2 means that the transverse magnetisation (the NMR signal) experiences a rapid decay. Therefore, the use of a time delay of the order of 20 μ s before recording the free induction decay or the recording of the spin echo signal allows one to exclude the contribution of the frozen fluid to the NMR signal. In addition, the T_1 value of ice (~ 900 s at 263 K in a 7.05 T field)²²¹ much exceeds the T_1 value of liquid water (2.7 s). Hence, the NMR signal of ice is additionally suppressed due to saturation. This permits selective detection of the signal of the liquid phase (see Fig. 6).

The pore liquid has a lower temperature of the liquid–solid phase transition. This effect is analogous to the capillary effect and is a result of a change in the free energy caused by the curved surface of the liquid. Reduction of the temperature of the liquid–solid phase transition can be described by the Gibbs–Thomson (Kelvin) equation written in the form^{222, 223}

$$\Delta T = T_0 - T_c = \frac{2\sigma T_0}{R\Delta H\rho} = \frac{K}{R}, \quad (16a)$$

or as follows²²¹

$$\Delta T = T_0 - T_c = \frac{K}{R - d}, \quad (16b)$$

where T_0 is the phase transition temperature for the bulk liquid; T_c is the phase transition temperature for the pore liquid; σ is the surface energy at the liquid–solid interface; R is the radius of ice crystal; ΔH is the molar heat of fusion; ρ is the density of the solid; and d is the thickness of the surface layer which freezes at a lower temperature compared to the rest of the liquid in the pore of radius R . The parameters K and d depend on the nature of the system under study. The surface layer behaves as part of the pore surface;²²⁴ therefore, the pore radius is $R - d$. Sometimes, calculations give negative values of the parameter d and this interpretation loses its meaning. After rewriting²²⁵ expression (16b) in another form

$$\Delta T = T_0 - T_c = K^* \frac{R}{R - d} \frac{1}{R}. \quad (16c)$$

one gets a new physical interpretation, namely, the molar heat of fusion that appears in the expression for K becomes pore size dependent.

The parameter K can be found by comparing the results of the NMR experiments with the data obtained by conventional methods, e.g., low-temperature adsorption of nitrogen. The

parameters for water were found to be $K_w = 495$ K $\text{\AA}$, $d_w = 3.5$ $\text{\AA}$,²²⁴ and $K_w \approx 515$ K $\text{\AA}$ and $d_w \approx 3$ $\text{\AA}$.²²⁵ Benzene ($T_0 = 278.5$ K) or cyclohexane ($T_0 = 279.5$ K), which are more sensitive to small variations of temperature, are used instead of water in the case of large pore sizes. The parameters for cyclohexane are $K_c \approx 1800$ K $\text{\AA}$ (see Refs 222 and 226) and $K_c \approx 870$ K $\text{\AA}$, $d_c \approx -1.4$ $\text{\AA}$ ²²⁵ while those for benzene are $K_b \approx 1100$ K $\text{\AA}$ and $d_b \approx 7$ $\text{\AA}$.²²⁵ For all liquids, the parameter K was found to be only slightly dependent on the nature of the porous material.²²⁴ Formulae (16b) and (16c) lose their meaning at $R \leq d$; in addition, the filling of micropores is strongly affected by the properties of the fluid and the microporous material. Therefore, the application of this method to microporous objects is still to be clarified. Nevertheless, the technique allows experimental determination of the volume fraction of micropores.²²⁴

Nuclear magnetic resonance porosimetry experiments with slow cooling of the pore fluid or heating of a preliminarily frozen sample are used to obtain the plots of the dependences of the integrated amplitude of the NMR signal on temperature (IT -curves) or on the inverse temperature $I(1000/T) = I(X)$. For some samples the cooling–heating cycles exhibit hysteresis effects of the order of several degrees. Often, measurements are carried out only during heating the sample to avoid supercooling of the fluid. The experimental data should be processed taking into account the temperature dependences of other parameters affecting the NMR signal, such as the Boltzmann factor (Curie law), the Q -factor of the RF coil and the relaxation times. Usually, the integrated intensity of the NMR signal is determined to an accuracy of several per cent.

Often, experiments are carried out with excess amount of fluid to ensure a complete pore filling. The fluid on the outer surface of the material freezes at the normal freezing temperature and is readily distinguishable in the IT -curves, which allows determination of the S/V ratio for the sample under study.

The $I(X)$ curve is given by the following expression²²⁴

$$I(X) = \sum_{i=1}^N \frac{I_{0i}}{\sqrt{\pi}} \int_0^{(X-X_{ci})/\sqrt{2\Delta_i}} \exp(-u^2) du. \quad (17)$$

The derivative,

$$\frac{dI}{dX} = \sum_{i=1}^N \frac{I_{0i}}{\sqrt{\pi}} \exp\left(-\frac{X-X_{ci}}{\sqrt{2\Delta_i}}\right)^2 \quad (18)$$

is the sum of Gaussian functions with the transition temperatures $T_{ci} = 1/X_{ci}$, widths Δ_i and weights I_{0i} . The correlation time distribution of molecular motions is assumed to be log-normal.

Taking into account Eqn (16a), the differential pore size distribution can be represented as follows:²²⁵

$$\frac{dI}{dR} = -\frac{K}{R^2} \frac{dI}{dR}. \quad (19)$$

The pore sizes that can be measured using the NMR cryoporosimetry technique span the range from ~ 10 to 2000 $\text{\AA}$.^{221–223, 225}

The IT -curves of water in silica were measured.^{224, 225} The broad component corresponding to the largest X value ($T = 210$ K) was attributed to the phase transition at the interface between the pore surface and the rest of the solid ice within the pore.²²⁴ Simultaneous fitting of the data obtained for samples with different pore sizes allowed one to avoid the necessity of independent determination of the parameters K and d . The silanol groups were found to contribute to the NMR signal.²²⁵ The NMR spectrum of benzene in silica and zeolite Y (pore size 7.4 $\text{\AA}$) at 227 K comprises several broad overlapped lines. Assuming fast proton exchange between the fluid at the pore wall and the rest of the fluid in the pore, the average chemical shift value was found to be dependent on the thickness, d , of the surface layer. Estimations from positions of the NMR signals give the same value as that obtained from analysis of the IT -curves. The chemical shift

appreciably changes as the pore radius R changes in the mesopore range (at $R > 10$ Å) while it remains virtually unchanged for micropores ($R < 10$ Å). This can be used for the determination of the volume fraction of micropores in the sample. The results obtained were found to be in good agreement with those found by low-temperature adsorption of nitrogen.

It is convenient to perform model experiments using the mesoporous material MCM-41 which possesses a hexagonal array of identical one-dimensional mesopores of size in the range from 18 to 100 Å. Some of the IT -curves of water exhibited characteristic hysteresis effects between cooling and heating processes, while the results of several cooling–heating cycles were identical, which means that the phase transition causes no mechanical damages to the pore space.²²⁴ The IT -curves of MCM-41 with a pore size of 26 Å exhibited¹⁹³ a narrow phase transition at 226 K. In addition, a broad (without hysteresis) transition was observed^{193,227} in the temperature range 200–207 K, which corresponds²²⁷ to a total of more than 60% of the overall amount of water and cannot be attributed to the fluid in micropores due to their lack. It was assumed²²⁷ that the pore contains a layer of the fluid ~ 5 Å thick, which gradually freezes at a lower temperature compared to the rest of the fluid in the pore. This is in agreement with substantial broadening of the NMR signal on cooling due to a decrease in the molecular mobility and to enhancement of the effects associated with differences in the magnetic susceptibilities.²²⁷

At the same time, it is possible that the low-temperature phase transition is only an apparent transition. Mention has been made¹⁹² that if the correlation time distribution of the molecular motions is broad, cooling can lead to observation of an apparent phase transition when performing the T_2 NMR measurements. This transition is associated with reduction of the molecular mobility and with passage from exponential relaxation to the rigid lattice regime with a Gaussian relaxation decay. Such a transition is not accompanied by changes in the phase state and is manifested only in the NMR experiments. For instance, studies of water adsorbed on silica gel and on porous glass with the pore sizes 60 to 240 Å revealed not only the phase transitions at 273 K for the excess water and at 265 K (with hysteresis) for the pore water but also an apparent transition in the temperature range 120–255 K, which occurs smoothly without hysteresis.²²⁰ Only a water layer two or three monolayers thick is involved in the apparent transition. The corresponding distribution of correlation times is shifted towards longer times as the temperature decreases. This is accompanied by retardation of proton exchange between the molecules with different T_2 values. Studies of the samples with controlled pore filling showed that initially the amount of non-freezing water increases as the amount of adsorbed water increases and then is saturated at a level corresponding to coverage of the surface of the pore space by two or three monolayers of water. The ‘non-freezing water’ does not assume the structure of ice on cooling below the freezing point and differs from liquid water at high temperatures.

Combining the results of analysis of the temperature dependences of the parameters ΔT and $1/T_1$ allowed determination of the enthalpy of freezing of bound water and of the width of the correlation time distribution of water molecules.^{193,220} The ΔT and $1/T_1$ values are inversely proportional to the pore sizes; because of this, a linear correlation between ΔT and $1/T_1$ was observed²²⁸ for water in MCM-41 with the pore sizes ranging from 19 to 38 Å at 263 K.

The results obtained for water in MCM-41 are in good agreement with the data obtained by low-temperature adsorption of nitrogen and by high resolution electron microscopy.²²⁴ However, expression (18) cannot describe the experimental data for the microporous material (aluminophosphate molecular sieves VPI-5).

By varying the pore saturation level one can study the process of filling of porous materials with fluids. Controlled saturation (10%–100%) studies of porous silica (silica gel with 60 Å pores)

with water or cyclohexane have been reported.²²⁶ The samples were initially cooled down to 173 K (cyclohexane) or 223 K (water) and the measurements were carried out during heating. It was found that cyclohexane fills out the entire pores starting from the smallest ones, whereas water initially forms droplets whose size is much smaller than that of the smallest pores in the sample. The size of the water droplets increases as the saturation level of the sample increases. The freeze–thaw cycles have no effect on the characteristics of the pore space. The character of the relaxation time distribution of cyclohexane is such that the pore size distributions exhibit false peaks.²²⁶ In addition, solid cyclohexane undergoes a phase transition from a monoclinic crystal structure to a plastic f.c.c. crystal at 186 K.²²⁹ Measurements of the relaxation times T_2 and $T_{1\rho}$ in the temperature range 77–295 K for cyclohexane in silica gel with pores of size 60, 200 and 500 Å revealed a phase transition in solid cyclohexane in the two last-named samples.

Spatially resolved (1D, 2D and 3D) IT -curves of water and cyclohexane in porous silica of different pore sizes have been reported.^{222,223} The NMR signal was calibrated against that of isopentane which has a low freezing point. The results obtained allowed determination of the pore size distribution at any point of the sample²²³ and imaging of those regions of the object that contained pores of preset sizes.²²² The relaxation time T_2 of solid cyclohexane was ≤ 2 ms.

Spatially resolved NMR cryoporosimetry was used for determination of the size of filled pores in partially dried concrete prepared from white Portland cement and quartz filler.^{230,231} On cooling, freezing began at the centre of the sample (this region is characterised by larger amount of water and by filling of larger pores).²³⁰ Further cooling led to uniform freezing of water along length of the sample. No freezing of water occurred in the gel pores even at -53 °C. The apparent phase transition in the form of a slow (without hysteresis) change in the amplitude of the NMR signal was also observed. The 1D moisture profiles of cylindrical concrete and mortar samples were obtained simultaneously and their changes were traced during cooling down to 223 K. This experiment allowed one to determine the size of the filled pores along the length of a cylindrical sample.²³² The sample completely saturated with water exhibited a phase transition at ~ 273 K corresponding to a wide range of mesopores. The samples of partially water-saturated concrete and mortar exhibited identical distributions of the filled pore sizes. It was found that most of the water resides in the pores of size less than 6 nm. Characteristic of all samples was a dramatic decrease in the NMR signal amplitude at ~ 223 K. This is associated with desorption of water followed by the formation of ice in another regions of the sample. At 218 K, nearly 50%–55% of water exists in the form of ice. The relaxation times (T_1 , T_2 and T_2^*) were mapped and it was shown that the times T_2 and T_2^* are shortened while the time T_1 is lengthened as temperature decreases.

* * *

The features of NMR image contrast formation allows the use of the NMR imaging technique for obtaining a vast variety of information on the objects under study. The authors of this review tried to emphasise some salient features and to illustrate potential applications of this method. Additional information on the studies of the structure and properties of liquid-containing materials is presented in the Supplement.

This work has been written with the financial support of the Russian Foundation for Basic Research (Project Nos 02-03-32770 and 00-15-97450) and the Siberian Branch of the Russian Academy of Sciences (the ‘Integration’ Programme Project No. 46).

V. Supplement

Additional information on the studies of the structure and properties of liquid-containing materials is given in Table S.1.

Table S.1. Applications of the MRI technique based on the ^1H NMR signals.

Magnetic field /T	Object, process	Technique	Dimension	Spatial resolution characteristics ^a	Recording time	Ref.
1.4	Water + 0.1% CuSO_4 in a pipe with abrupt contraction (expansion)	spin echo + PRI	2D	64×64 , a slice 0.33 mm thick	—	19
0.73	Plastic or rubber articles	gradient echo with oscillating gradients	3D	$64 \times 64 \times 64$, (0.5 mm) ³	3 h 38 min	26
4.7	Vulcanised rubber impregnated with aluminium and sodium sulfate crystals; filled phenol-formaldehyde resin; a 72-h <i>Manduca sexta</i> caterpillar	spin echo or PRI	2D	180° FIDs, (35 μm) ² for PRI 128×128 , a slice 1 mm thick or without slice selection	from 2 to 17 h	27
0.7	Sandwich-type layered model sample; alkyd resin film coated with cobalt catalyst	spin echo	1D	256, 512; 13, 6.5 μm	17 min	83
0.4	Various solid materials	the same	—	WSR	—	84
2.0	Water in Al_2O_3 , water + NaCl in sandstone rock or limestone rock cores	"	2D, 3D	128×128 , (200 μm) ² , a slice 5 mm thick (2D); $128 \times 128 \times 256$, (300 μm) ³ (3D)		86
0.1	Water in sandstone rock plugs	"	1D, 3D	1 mm (1D); $2.4 \times 2.4 \times 7$ mm (3D)	3 min (1D); 1 h (3D)	90
2.0	Oil + water or brine in dolomite plugs	—	2D	—	—	92
4.7	$\text{H}_2\text{O}/\text{D}_2\text{O}$ or H_2O /hydrocarbon mixture in limestone rock sample	spin echo	2D	128×128 , (0.94 mm) ² , a slice 5 mm thick	35 min	94
1.9	Water or n-dodecane in sandstone rock cores	the same	2D	256×256	—	95
2.0	Aqueous KCl solution and dodecane in sandstone rock core	"	2D	128×128 , (0.44 mm) ² , a slice 5 mm thick	43 min	96
2.0	Water, sunflower oil or sunflower oil-in-water emulsion flowing in a pipe	gradient echo	2D, 3D	64×64 , (850 μm) ² , (780 μm) ² , a slice 2 mm or 2.5 mm thick (2D); $64 \times 64 \times 64$, (710 μm) ³ (3D)	20–60 s (2D); 23 min (3D)	97
0.5	Decane in peroxide vulcanised natural rubber	gradient echo with oscillating field gradients	2D	250 (400) μm for decane, 600 μm for rubber, a slice 5 mm thick	20 min	98, 99
1.89	Water or motor oil/ $\text{H}_2\text{O}/\text{D}_2\text{O}$ mixture in sandstone rock sample	spin echo with inversion–recovery	3D	$256 \times 256 \times 256$, $20 \times 19 \times 930$ μm	—	100
2.0	Water + salt and petroleum in chalk core	—	2D	(800 μm) ² , a slice 3 or 5 mm thick	—	101
2.0	Acetone + benzene in vulcanised rubber cylinder	chemical shift selective spin echo	2D	a slice 4 mm thick	2 min	102
2.0	Isooctane in vulcanised rubber cylinder saturated with cyclohexane	gradient echo for two-quantum coherence	2D	a slice 8 mm thick	8 min	102
	Salt solution in sandstone rock sample	—	2M	—	—	103
4.7	LiCl brine or trifluorotoluene in sandstone rock samples ^b	—	3D	$64 \times 64 \times 16$, $1 \times 1 \times 5$ mm (^7Li); $128 \times 128 \times 16$, $0.4 \times 0.4 \times 3$ mm (^1H , ^{19}F)	546 min (^7Li); 273 min (^{19}F); 17 min (water); 273 min (^1H of trifluorotoluene)	104
1.5, 4.7	Water in porous glass disk-shaped pellets	spin echo or gradient echo	2D, 3D	256×128 , 128×128 , (0.1–1 mm) ² , a slice 80 μm to 3 mm thick (2D)	from 4 min to 9 h	105
9.4	Methane in zirconia bead pack	FID or spin echo	—	WSR	—	107

Table S.1 (continued).

0.5	White oak or black cherry logs	spin echo	2D	(1.2 mm) ² , (1.95 mm) ²	7.5 min	161
9.45	Coal or coal + pyridine-d ₅	SPI, spin echo	2D, 3D	128 × 128, (50 μm) ² (2D); 128 × 128 × 128, (50 μm) ³ (3D)	8 min (2D); 16 h (3D)	164
9.4	Water inside the CD ₄ + ice gas hydrate	spin echo	2D	128 × 128 (80 μm) ² , a slice 0.5 mm thick	—	165
4.3	Xe (80% ¹²⁹ Xe) (1–3 atm) in nested tubes or capillary bundle ^d	gradient echo (FLASH)	2D	128 × 64, 0.1 mm	—	168
4.3	Xe (80% ¹²⁹ Xe) (1–3 atm) in aerogel ^d	the same	1D	0.1 mm	—	168
9.4	Xe (70% ¹²⁹ Xe) in mice lungs <i>in vitro</i> (in ampoule) ^d	"	2D	128 × 128, (0.37 mm) ²	600 ms	169
2.0	Foam churned from egg white and water	spin echo	1D	—	—	172
1.89	Foam churned from water with surfactant, polymer and alcohol additives	the same	1D	—	—	173
2.0	Salt solution in sandstone rock or limestone rock samples	stimulated echo	—	WSR	7 h	174

Table S.1 (continued).

Magnetic field /T	Object, process	Technique	Dimension	Spatial resolution characteristics ^a	Recording time	Ref.
1.9	C ₂ F ₆ or C ₄ F ₈ in ceramics (Y-stabilised zirconia) ^c	spin echo	3D	—	2 h	175
2.0	Water in a gap between glass plates	the same	—	WSR	—	176
178	Various liquids in rock or alumina samples	stimulated echo	—	"	—	178
7.05	Acetonitrile, benzene, dichloromethane and CCl ₄ in carbonaceous adsorbent	FID	—	"	—	180
0.7	Water in porous glass	"	—	"	—	191
7.05	Water in MCM-41	"	—	"	—	193
0.23	Water in calcium carbonate packs in the presence of Mn, Fe or Co ions	—	—	"	—	195
0.05	Water in calcium silicate packs in the presence of Mn or Fe ions	spin echo	—	"	7 min, 2 h	196
2.0	Water in sandstone rock samples	—	1D	"	—	200
0.47	Water or cyclohexane in silica	spin echo	—	WSR	—	202
2.0	Bentonite + water + NaOH + lignosulfonate dispersant (+ barite) in sandstone rock or limestone rock cores	the same	1D	128	—	203
7.05, 0.55	Acetone in corn starch gel	"	—	WSR	—	205
0.7	Water in sandstone rock plugs	FID, gradient echo or spin echo	1D	WSR, 0.2 mm	—	206
2.0	Water in glass bead pack or in limestone rock, chalk or sandstone rock samples	inversion—recovery, stimulated echo	—	WSR	—	207
1.0	3% Aqueous NaCl solution in sandstone rock or limestone rock cores	FID	—	"	45–60 min	209
0.66, 2.35	Aqueous salt solution, dodecane or cyclooctane in sandstone rock and carbonate rock plugs	FID, spin echo	—	"	—	210
0.78	Water in crushed porous glass	the same	—	"	—	214
2.1	Water in silica gel, porous glass, activated charcoal	FID	—	"	—	220
7.05	Water in silica (amorphous silicate)	the same	—	"	—	221
0.5, 2.5	Water or cyclohexane in porous silica	spin echo	1D, 2D, 3D	64 × 64 (2D), 64 × 64 × 32 (3D)	4.3 min (2D), 1 h (3D)	222
0.5, 2.5	The same	the same	1D, 2D, 3D	64 × 64, a slice 20 mm thick (2D); 64 × 64 × 32 (3D)	4.3 min (2D); 60 min (3D)	223
7.05	Water in MCM-41, aluminophosphate molecular sieves (VPI-5) and amorphous silicate	FID	—	WSR	—	224
7.05	Water, benzene, cyclohexane in porous silica	spin echo or FID	—	"	—	225
	Water, cyclohexane in porous silica	spin echo	—	"	—	226
7.05	Water in MCM-41, silica, zeolite Y and industrial catalyst	FID	—	"	—	227
7.05	Water in MCM-41	"	—	"	—	228
0.5	Cyclohexane in porous silica	FID or spin echo	—	"	—	229

Table S.1 (continued).

Magnetic field /T	Object, process	Technique	Dimension	Spatial resolution characteristics ^a	Recording time	Ref.
2.35	Water in concrete (white Portland cement + quartz filler)	SPRITE	1D	64; 1.6 mm	—	230
2.4	Water in mortar or concrete	"	1D	64; 2.2 mm		231, 232

Notations: PRI is Projection Reconstructed Imaging, WSR is Without Spatial Resolution, FID is Free Induction Decay, EPI is Echo-Planar Imaging, PEPI is Echo-Planar Imaging with Pi-pulses; STRAFI is Stray Field Imaging and FLASH is Fast Low-Angle Shot.

^a Listed are the image dimension (in pixels), spatial resolution and slice thickness. ^b Imaging using the ¹H, ⁷Li and ¹⁹F NMR signals. ^c Imaging using the ¹H and ¹²⁹Xe NMR signals. ^d Imaging using the ¹²⁹Xe NMR signals. ^e Imaging using the ¹⁹F NMR signals.

VI. Other complex phosphates containing mono- and trivalent cations	646
VII. Conclusion	648

Abstract. The review surveys the data on the synthesis, structures, thermal stability and physical properties of complex phosphates containing M^I and M^{III} cations generated from double phosphates by the partial replacement $M^I \rightarrow H^+$ or $PO_4^{3-} \rightarrow X^{n-}$ [$X^{n-} = F^-, OH^-, EO_4^{n-}$ (VO_4^{3-} , MoO_4^{2-}) or $S_2O_3^{2-}$]. The sizes of the M^I and M^{III} cations and their ratio have a dominant role in the structure formation of complex phosphates. The prospects of the use of complex phosphates as polyfunctional materials are discussed. The bibliography includes 161 references.

I. Introduction

In the last two decades, an extensive search has been carried out for new ferroelectric, piezoelectric, laser, luminescent and other materials, which can be applied in quantum electronics and fibre optics and used as sorbents and catalysts. In this connection, complex phosphates containing mono- and trivalent cations, in particular, compounds of the $M_3^I M^{III}(PO_4)_2$ and $M_3^I M_2^{III}(PO_4)_3$ types (M^I are alkali metals), attract considerable interest.¹ These compounds exhibit ionic conductivity as well as nonlinear optical and other interesting properties. Numerous luminophores possessing excellent technical characteristics have been already prepared on the basis of inorganic phosphates.^{2,3}

The classical approach to the design of new materials involves the construction of more compositionally complex compounds and composites. Presently, new methods for the preparation of phosphates containing different combinations of mono- and polyvalent cations as well as procedures for the synthesis of complex phosphates in which the PO_4^{3-} anions are combined

with the F^- , OH^- , VO_4^{3-} , MoO_4^{2-} or $S_2O_3^{2-}$ anions attract considerable attention.

Purposeful changes in the compositions of the cationic and anionic components of complex phosphates allow one to vary the dimensional characteristics of framework structures and inter-layer spaces in layered phases thus influencing various properties of complex phosphates containing M^I and M^{III} cations, in particular, the ionic mobility, ion-exchange processes, catalytic properties and sensor characteristics (gas detection). Complex hydrogen phosphates containing the H^+ ions and polyvalent cations are of obvious interest. The data on these types of complex phosphates have not been generalised. Such complex orthophosphates involving the H^+ ions and anions of different nature along with M^I and M^{III} cations are the subject of the present review. Both the data published in the literature and the results of our studies are surveyed. The review also surveys the data on double orthophosphates containing mono- and trivalent cations. The latter compounds along with hydrogen orthophosphates with trivalent cations are parent compounds of complex phosphates under consideration.

Each group of complex phosphates containing M^I and M^{III} cations is characterised by different compositions. The targeted synthesis of new complex phosphates containing variable combinations of cations and anions and predictions of their physico-chemical characteristics require revealing the composition–structure–property relationships for different types of compounds, in particular, for complex double and hydrogen phosphates containing M^I and M^{III} cations, fluoride phosphates, hydroxide phosphates and phosphates containing other tetrahedral groups.

II. Double phosphates containing mono- and trivalent cations

Studies of the phase formation in the $M_3^I PO_4 - M^{III} PO_4$ systems ($M^I = Na, K$; $M^{III} = REE, Y, In, Sc$)^{4–8} were started in 1970s in connection with a search for new laser, luminescent and other materials. Two types of compounds, viz., $M_3^I M^{III}(PO_4)_2$ (**1**) and $M_3^I M_2^{III}(PO_4)_3$ (**2**), were found.[†] Compounds **1** are known for all rare-earth ($Y, La-Lu$) and some other (Sc, In, Fe) elements,

[†]Data on double phosphates with more complex compositions, viz., $Na_6 M_3^{III}(PO_4)_5$ (**3**), where $M^{III} = Dy, Ho$ or Tm , are limited to the conditions of their formation in the $Na_3 PO_4 - M^{III} PO_4$ binary systems.⁴

whereas compounds **2** are typical only of trivalent cations with the ionic radii $r_{M^{III}} \leq 0.85 \text{ \AA}$. In studies of these compounds, primary attention has been given to their structures, polymorphic transformations, ionic conductivity and luminescent properties.

1. Synthesis

Phosphates with compositions $M_3^I M^{III}(PO_4)_2$ and $M_3^I M^{III}(PO_4)_3$ are generally prepared by the solid-phase synthesis from stoichiometric amounts of oxide $M_2^{III}O_3$, carbonate $M_2^I CO_3$ and alkali-metal and ammonium hydrogen orthophosphates characterised by different degrees of replacement at temperatures from 400 to 1100 °C.^{9–11} Different types of dielectric ceramics with such compositions are produced by hot pressing.¹² The synthesis from aqueous solutions of the corresponding salts at normal¹³ or high¹⁴ pressure (hydrothermal method) is used more rarely. There are also procedures, which, strictly speaking, cannot be considered as preparative. As an example we refer to the reactions of cerium(IV) oxide with sodium and potassium hydrogen phosphates or diphosphates¹⁵ accompanied by oxygen liberation. Another procedure for the preparation of double phosphates involves calcination of mixtures of REE hydrogen phosphates with composition $H_3 M^{III}(PO_4)_2 \cdot 2 H_2O$ with alkali-metal hydroxides or carbonates.¹⁶ Single crystals of $M_3^I M^{III}(PO_4)_2$ were grown under the hydrothermal conditions at high temperatures ($T = 600\text{--}900 \text{ }^\circ\text{C}$)¹⁴ or prepared by crystallisation from flux using an excess of alkali-metal halides (for example, KF).¹⁷

2. Structures and properties

Compounds with composition $M_3^I M^{III}(PO_4)_2$ containing different metal cations are similar in structure and physicochemical characteristics. The main structural feature common to all com-

pounds of this group is the fact that they belong to the glaserite [$K_3Na(SO_4)_2$], arcanite ($\beta\text{-K}_2SO_4$), sodium chromate (Na_2CrO_4) or NASICON $\ddagger$ [$NaZr_2(PO_4)_3$] structural types (Fig. 1).

The $K_3Na(SO_4)_2$ (space group $P3m1$, $a_1 = b_1 = 5.680$, $c_1 = 7.309 \text{ \AA}$),¹⁸ $\beta\text{-K}_2SO_4$ (space group $Pnam$, $a_2 = 7.456$, $b_2 = 10.080$, $c_2 = 5.776 \text{ \AA}$)¹⁹ and Na_2CrO_4 (space group $Cmcm$, $a_3 = 5.862$, $b_3 = 9.251$, $c_3 = 7.145 \text{ \AA}$)²⁰ structural types are widespread among inorganic salts with the PO_4^{3-} tetrahedral anions.^{1,21,22} All these salts belong to layered structures. In the crystals of these salts, the PO_4 tetrahedra have different orientations with respect to the cation positions (denoted as M , X and Y , see Fig. 1)²¹ and can combine with each other to form numerous subtypes. The relationship between the parent structural types can be represented as the relation between the unit cell parameters of glaserite (a_1, b_1, c_1) and those of arcanite (a_2, b_2, c_2) and sodium chromate (a_3, b_3, c_3): $a_2 \approx c_1$, $b_2 \approx a_1\sqrt{3}$, $c_2 \approx a_1$ and $a_3 \approx a_1$, $b_3 \approx a_1\sqrt{3}$, $c_3 \approx c_1$.

It is assumed that the ratio between the radii of the cations is the governing factor responsible for the formation of glaserite- or arcanite-like structures.²¹ The glaserite-like structures are stable for compounds in which the difference between the radii of the M^+ and M^{3+} cations [$\Delta r_{(M^+ - M^{3+})}$]²³ occupying the M , X and Y positions is in the range $0.59 \leq \Delta r_{(M^+ - M^{3+})} \leq 0.89 \text{ \AA}$.^{21,24–27} However, compounds that are characterised by $\Delta r_{(M^+ - M^{3+})} < 0.59 \text{ \AA}$ and have glaserite-like structures are also known. Thus, $\Delta r_{(M^+ - M^{3+})}$ for $Na_3Fe(PO_4)_2$ (glaserite structural type) is $0.38 \text{ \AA}$.²⁴ At $\Delta r_{(M^+ - M^{3+})} < 0.59 \text{ \AA}$, compounds generally crystallise in the arcanite structural type.^{19–22}

$\ddagger$ NASICON stands for Na Super Ionic Conductors.

Figure 1. Projections of the $K_3Na(SO_4)_2$ (a), $\beta\text{-K}_2SO_4$ (b), Na_2CrO_4 (c), and $NaZr_2(PO_4)_3$ (NASICON) (d) structures. Hereinafter, the structures are drawn using the atomic coordinates published in the original studies.

The majority of representatives of the $M_3M^{III}(PO_4)_2$ group have structures of arcanite (β - K_2SO_4) or structures of an intermediate type (combinations of the β - K_2SO_4 and Na_2CrO_4 structures). In particular, the former structural type is typical of $K_3M^{III}(PO_4)_2$ ($M^{III} = La-Yb$)^{1,17,28} and the latter type is characteristic of $K_3In(PO_4)_2$ (see Ref. 29) and β - $Na_3M^{III}(PO_4)_2$ ($M^{III} = La-Lu, In$).^{13,14,30-33} These compounds belong to 'arcanite-like phosphates'.

In the structures of glaserite- and arcanite-like phosphates $M_3M^{III}(PO_4)_2$, the M^I and M^{III} cations occupy the X positions in an ordered fashion. The Y positions are occupied only by monovalent cations. However, the coordination polyhedra of the cations in the structures of $M_3M^{III}(PO_4)_2$ differ from those in the parent structural types due to distortions of the ideal β - K_2SO_4 - and Na_2CrO_4 -type crystal structures caused by displacements of the cations from the ideal positions and rotation of the PO_4 tetrahedra. For example, the coordination sphere about potassium in the structures of $K_3M^{III}(PO_4)_2$ ($M^{III} = Y, La-Yb$) involves nine or ten oxygen atoms, whereas the coordination spheres about the REE atoms are formed by seven oxygen atoms. In $Na_3M^{III}(PO_4)_2$, the coordination numbers of both Na^+ and M^{III} vary from 6 to 8–12.

The NASICON structural type can be described as the $\{[M_{2-x}^{III} \square_x(PO_4)_3]^{3-}\}_{3\infty}$ framework whose channels are occupied by alkali-metal cations.²¹ The $NaZr_2(PO_4)_3$ (NASICON) structural type is widespread among superionic conductors, whereas double phosphates with composition $Na_3M^{III}(PO_4)_2$ containing only REE of the end of the series ($M^{III} = Tm, Yb, Lu$) belong to this structural type. According to the stoichiometry of the framework, the structures of the latter compounds should be described by the $Na_{4.5}M_{1.5}^{III}(PO_4)_3$ formula.³⁴

Most of the sodium-containing phosphates $Na_3M^{III}(PO_4)_2$ ($M^{III} = Y, La-Lu, In$) have two or three crystal modifications each (Fig. 2, Table 1), viz., monoclinic low-temperature β and γ modifications based on the arcanite structure (A type) or a combination of the β - K_2SO_4 and Na_2CrO_4 structures (arcanite-

Figure 2. Occurrence of the structural types of the $Na_3M^{III}(PO_4)_2$ compounds depending on the temperature and nature of the M^{III} cation. **A₁–A₅**, arcanite-like subtypes (a combination of the β - K_2SO_4 and Na_2CrO_4 structures; **G**, **N** and **C**, the structural types of glaserite, NASICON and sodium chromate; **N'**, the NASICON-like phase with variable composition $Na_{3(1+x)}M_{(2-x)}^{III}(PO_4)_3$ ($0 \leq x \leq 0.2$). Solid and empty circles denote polymorphic transformations and decomposition, respectively; the cross indicates incongruent melting.

like structures, **A₁–A₅** subtypes) and high-temperature α modifications derived from the structures of glaserite (**G** type) or NASICON (**N** structural type).^{20,34}

The polymorphism of sodium-containing phosphates is, apparently, associated with a small difference in the ionic radii of sodium and trivalent REE. In arcanite-like structures of β - $Na_3M^{III}(PO_4)_2$, the proportion of the sodium-chromate structural motif in a combination of the β - K_2SO_4 and Na_2CrO_4 structures increases on going from lanthanum [$r_{VIII}(La^{3+}) = 1.18 \text{ \AA}$] to lutetium [$r_{VII}(Lu^{3+}) = 0.85 \text{ \AA}$] and indium

Table 1. Crystallographic characteristics of the $M_3M^{III}(PO_4)_2$ compounds.

^a Z is the number of formula units per unit cell.

[$r_{VI}(\text{In}^{3+}) = 0.76 \text{ \AA}$] to form new subtypes in the temperature range $T < 700\text{--}900^\circ\text{C}$. This is in agreement with the general principle consisting in the fact that trivalent cations in arcanite-like structures [for example, in $\beta\text{-Na}_3\text{La}(\text{PO}_4)_2$] occupy the XO_8 polyhedra corresponding to the XO_9 polyhedra in the structure of $\beta\text{-K}_2\text{SO}_4$, whereas these cations with smaller ionic radii tend to reduce their environment to octahedral, which corresponds to the XO_6 polyhedron in the structure of sodium chromate.^{30,33} The $\text{Na}_3\text{Sc}(\text{PO}_4)_2$ and $\text{Na}_3\text{Fe}(\text{PO}_4)_2$ compounds with the Sc^{3+} or Fe^{3+} cations possessing smaller ionic radii [$r_{VI}(\text{Sc}^{3+}) = 0.745 \text{ \AA}$, $r_{VI}(\text{Fe}^{3+}) = 0.645 \text{ \AA}$] than In^{3+} do not show polymorphism and crystallise in the glaserite structural type.²⁴

As the temperature is increased ($T > 900^\circ\text{C}$), sodium-containing phosphates $\text{Na}_3\text{M}^{\text{III}}(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{La} - \text{Er}$) are transformed from the β and γ modifications into the α modification corresponding to the higher-symmetry glaserite structural type. The high-temperature α modifications of $\text{Na}_3\text{M}^{\text{III}}(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{Tm} - \text{Lu}$) belong to the NASICON structural type.³⁴ At high temperatures, $\alpha\text{-Na}_3\text{In}(\text{PO}_4)_2$ would also be expected to transform into the NASICON-like modification. Instead, this compound decomposes at $T = 910^\circ\text{C}$ to give a NASICON-like phase with variable composition $\text{Na}_{3(1+x)}\text{In}_{(2-x)}(\text{PO}_4)_3$ ($0 \leq x \leq 0.2$) and a solid solution based on $\alpha\text{-Na}_3\text{PO}_4$. Analogous processes were observed upon heating of the $\text{Na}_3\text{Sc}(\text{PO}_4)_2$ and $\text{Na}_3\text{Fe}(\text{PO}_4)_2$ compounds above 790 and 975°C , respectively.^{24,31}

The nature and size of the REE ion have only a slight effect on the formation of a particular structural type of double potassium-containing phosphates $\text{K}_3\text{M}^{\text{III}}(\text{PO}_4)_2$.²⁸ However, a decrease in the ionic radius of the trivalent cation on going from ytterbium to lutetium also leads to the transformation from an arcanite-like to glaserite-like structure, which is accompanied by an increase in the symmetry of the crystal lattice from monoclinic [$\text{K}_3\text{M}^{\text{III}}(\text{PO}_4)_2$ compounds with large M^{III} cations (Y , $\text{La} - \text{Yb}$)^{27,28}] to trigonal [typical of $\text{K}_3\text{M}^{\text{III}}(\text{PO}_4)_2$, where $\text{M}^{\text{III}} = \text{Lu}$ or Sc].^{1,26}

In the structures of $\text{K}_3\text{M}^{\text{III}}(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{La} - \text{Yb}$), two of three potassium atoms are surrounded by ten oxygen atoms each, whereas the third potassium atom is surrounded by nine oxygen atoms. Due to distortion of the initial arcanite structure, the $\text{X}^{[6+3]}\text{O}_9$ polyhedra are transformed into $\text{M}^{\text{III}}\text{O}_7$ seven-vertex polyhedra, viz., trigonal monocapped prisms with the $\text{M}^{\text{III}} - \text{O}$ distances in the range of $2.20\text{--}2.60 \text{ \AA}$. In the virtually non-distorted glaserite-like structures of $\text{K}_3\text{M}^{\text{III}}(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{Lu}$, Sc), the M^{III} cations have an octahedral environment formed by oxygen atoms. Apparently, the transformation from an arcanite-like to glaserite-like structure is associated not only with an increase in the difference between the M^{III} and K^+ radii but also with the effect of the electronic structure of the M^{III} atom. Thus the $\text{K}_3\text{Lu}(\text{PO}_4)_2$ compounds [$\Delta r_{(\text{K}^+ - \text{Lu}^{3+})} = 0.58 \text{ \AA}$] would be expected to have arcanite-like structures stable at $\Delta r_{(\text{M}^+ - \text{M}^{3+})} < 0.59 \text{ \AA}$. However, $\Delta r_{(\text{K}^+ - \text{Lu}^{3+})}$ is actually equal to $0.69 \text{ \AA}$ and the glaserite-like structural type is realised. Because of the larger ionic radius of ytterbium [$\Delta r_{(\text{K}^+ - \text{Yb}^{3+})} = 0.57 \text{ \AA}$] as compared to that of lutetium and the more labile f shell, the ytterbium cation tends to expand the nearest environment. As a consequence, $\text{K}_3\text{Yb}(\text{PO}_4)_2$ crystallises in the $\beta\text{-K}_2\text{SO}_4$ structural type. However, the arcanite-like structure of $\text{K}_3\text{Yb}(\text{PO}_4)_2$ is unstable and is readily destabilised under the action of different factors, in particular, upon the partial replacement of the PO_4^{3-} ions by the bulkier VO_4^{3-} anions.²⁸

The $\text{K}_3\text{In}(\text{PO}_4)_2$ compound may be assigned to a new subtype of arcanite-like phosphates (A_6) characterised by a combination of the $\beta\text{-K}_2\text{SO}_4$ and Na_2CrO_4 structural motifs (Fig. 3).²⁹ Analysis of the crystal structure of $\text{K}_3\text{In}(\text{PO}_4)_2$ demonstrated that the potassium cations displace the indium cations from the X positions to the Y positions corresponding to the Y positions in the structure of sodium chromate (see Fig. 1c), as distinct from double phosphate $\text{Na}_3\text{In}(\text{PO}_4)_2$ in which the Y positions are occupied exclusively by the Na^+ cations. Hence, the larger potassium cation (compared to sodium) causes the indium ions to change an octahedral environment formed by the oxygen atoms

Figure 3. Structure of $\text{K}_3\text{In}(\text{PO}_4)_2$ projected onto the ab plane.

from six PO_4 tetrahedra for an octahedral environment formed by the oxygen atoms belonging to five PO_4 tetrahedra. In the structures of arcanite-like double phosphates $\text{Na}_3\text{M}^{\text{III}}(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{La} - \text{Lu}$), the co-existence of the $\beta\text{-K}_2\text{SO}_4$ and Na_2CrO_4 motifs is achieved due to the presence of REE with different coordination numbers (6–8), whereas the co-existence of these motifs in the $\text{K}_3\text{In}(\text{PO}_4)_2$ structure is, apparently, associated with a substantial distortion of the polyhedra about the potassium atoms. Like the $\text{K}_3\text{M}^{\text{III}}(\text{PO}_4)_2$ compounds ($\text{M}^{\text{III}} = \text{REE}$), $\text{K}_3\text{In}(\text{PO}_4)_2$ does not possess polymorphism below 1000°C . The only difference is that the REE compounds decompose prior to melting ($T = 800\text{--}1000^\circ\text{C}$), whereas $\text{K}_3\text{In}(\text{PO}_4)_2$ melts congruently at a temperature above 1200°C .³⁵ Taking into account the difference in the $\text{K}_3\text{In}(\text{PO}_4)_2$ and $\text{K}_3\text{M}^{\text{III}}(\text{PO}_4)_2$ structures ($\text{M}^{\text{III}} = \text{Lu}$, Sc) and considering that the radii of the M^{III} cations decrease in the series $\text{Lu} - \text{In} - \text{Sc}$, it can be assumed that the size of the M^{III} cation is of secondary importance in the formation of a particular structural type in the group of the $\text{M}_3^{\text{I}}\text{M}^{\text{III}}(\text{PO}_4)_2$ compounds.

Double phosphates with composition $\text{M}_3^{\text{I}}\text{M}_2^{\text{III}}(\text{PO}_4)_3$ (type 2, $\text{M}^{\text{I}} = \text{Li}$, Na , K ; $\text{M}^{\text{III}} = \text{Fe}$, Sc , In , Cr) (Table 2) are typical of small M^{III} cations ($r_{\text{M}^{3+}} < 0.8 \text{ \AA}$).^{36–48} The crystallographic characteristics of such compounds in which M^{III} is an REE atom ($\text{Ce} - \text{Gd}$) are available in the literature.^{10,11} For these compounds, the unit cell parameters were calculated assuming of trigonal system. However, these data are in doubt. Composites of the general formula $\text{M}_{3(1+x)}^{\text{I}}\text{M}_{2-x}^{\text{III}}(\text{PO}_4)_3$ ($0.07 \leq x \leq 0.5$) are known. These composites belong to the region of solid solutions on the basis of high-temperature α modifications of $\text{Na}_{4.5}\text{M}_{1.5}^{\text{III}}(\text{PO}_4)_3$ ($\text{M}^{\text{III}} = \text{Tm}$, Yb , Lu).³⁴

The crystal structures of most of the $\text{M}_3^{\text{I}}\text{M}_2^{\text{III}}(\text{PO}_4)_3$ compounds were established, which made it possible to assign these compounds to the NASICON type. Complex phosphates of the general formula $\text{M}_x\text{M}_2'(\text{PO}_4)_3$, where $\text{M} = \text{M}^+ (\text{Li}$, $\text{Na})$ or $\text{M}^{2+} (\text{Sr}$, $\text{Ba})$ and $\text{M}' = \text{M}^{2+} (\text{Mg})$, $\text{M}^{3+} (\text{Sc}$, In , $\text{Fe})$, $\text{M}^{4+} (\text{Zr}$, $\text{Ti})$ or $\text{M}^{5+} (\text{Ta}$, $\text{Nb})$, belong to this structural type. The occupancies of the M positions can vary over a wide range ($0 \leq x \leq 4$). The exception is the low-temperature β modification of $\text{Na}_3\text{In}_2(\text{PO}_4)_3$, which has an unusual structure.⁴⁵

Depending on the combination of the cations, the symmetry of the unit cell in the $\text{M}_3^{\text{I}}\text{M}_2^{\text{III}}(\text{PO}_4)_3$ compounds changes from trigonal to monoclinic. All structures have framework structures built from the $\text{M}^{\text{III}}\text{O}_6$ and PO_4 polyhedra in a ratio of 2 : 3. The cavities in the framework are occupied by alkali-metal cations (Li^+ , Na^+). The frameworks of the structures are penetrated by channels of two types, *I* and *II*, extended along the b axis of the unit cell (Fig. 4a). The channel of type *III* is perpendicular to the channels *I* and *II* and intersect these channels. The smallest cross-sections of the channels *I*, *II* and *III* are 1.0 , 1.1 and $0.9 \text{ \AA}$, respectively. The large cavities in these channels (at the intersections of the channels *I* and *III* and of the channels *II* and *III*) are

^a The NASICON structural type. ^b The space groups were not unambiguously established.

occupied by alkali-metal cations located in two positions, *viz.*, $M(1)$ and $M(2)$ (Fig. 4*b*). The analysis of the number of the polyhedra and their coordination environments demonstrated that the general crystal-chemical formula of the NASICON structural type can be written as $[M(1), M(2)]_3M(3)_2(PO_4)_3$.

Taking the space group $R\bar{3}c$ (the highest symmetry for the compounds under consideration) as the basis, the $M(1)O_6$ polyhedron can be described as an elongated antiprism with the

$M(1)–O$ distances to the nearest six oxygen atoms equal to $\sim 2.6 \text{ \AA}$ (the other six O atoms are at considerable distances from the metal atom, *viz.*, at $\sim 3.7 \text{ \AA}$). The metal atom in the $M(2)$ position is surrounded by ten oxygen atoms eight of which are involved in the nearest environment, whereas the remaining two O atoms are somewhat remote. The analysis of the cross-sections of the channels showed that the cations with the radii of $\sim 1 \text{ \AA}$ (for example, Na^+) could migrate within these channels. The cations can also pass through narrower regions, *viz.*, through the ABC and ABD faces (see Fig. 4*b*),⁴⁷ due to thermal displacements of the oxygen atoms. This fact is responsible for superionic conductivity of the $M_3M_2^{III}(PO_4)_3$ compounds.⁴⁹ The cations can occupy the $M(1)$ and $M(2)$ positions in different fashions: (1) these positions are completely occupied [$Na_{4.5}M_{1.5}^{III}(PO_4)_3$ or $M_3M^{III}(PO_4)_3$, where $M^{III} = Tm, Yb, Lu$];³⁴ (2) only the $M(2)$ position is completely occupied (together with vacancies), for example, in $\beta\text{-Na}_3Sc_2(PO_4)_3$;⁴⁴ (3) the $M(1)$ and $M(2)$ positions are statistically occupied (together with vacancies), for example, in $\alpha\text{-Na}_3M_2^{III}(PO_4)_3$, where $M^{III} = Sc, In$.^{47, 48}

The low-temperature β modification of $Na_3In_2(PO_4)_3$ is described by the crystal-chemical formula $X(2)X(1)M(1).M(2)_2(PO_4)_3$. Alluaudite-like phosphates have analogous structures [the mineral alluaudite has the formula $Na_{0.6}Mn_{1.2}^{2+}Ca_{0.1}.Fe_2^{3+}Mg_{0.1}(PO_4)_3$]. The structures of indium compounds are characterised by the presence of the In_2O_{10} dimers (bioctahedra) (Fig. 5*a*), which form a framework structure together with the tetrahedral PO_4 groups (Fig. 5*b*). The analysis of the polyhedra in the crystal structure of $\beta\text{-Na}_3In_2(PO_4)_3$ led one to the conclusion that the complete occupancy of the $M(2)$ position by a double- or triple-charged cation according to the crystal-chemical formula $X(2)X(1)M(1)M(2)_2(PO_4)_3$ is a necessary condition for crystallisation of double phosphates in the alluaudite structural type. It should be noted that the ionic radius of the cation in the dimer [$M(2)$ position] must be in the strictly specified range $0.74 \leq r \leq 0.76 \text{ \AA}$. The radii r of the Fe^{2+} and In^{3+} cations fall within this range. Actually, the data on alluaudite-like phosphates $Na_2Fe^{3+}Fe_2^{2+}(PO_4)_3$, $NaCaMn^{2+}Fe_2^{2+}(PO_4)_3$ and $NaCd.In_2^{3+}(PO_4)_3$ are available in the literature.⁵⁰ The fact is that the occurrence of alluaudite-like structures is determined by the size of the PO_4 tetrahedron. Two of ten PO_4 groups in the dimer are bridging and fix the distances between the vertices of the octahedra [$d(O \cdots O) \approx 2.5 \text{ \AA}$], which are equal to the length of the edge of the tetrahedron. As a result, this distance $d[M(2) \cdots M(2)]$ in the

Figure 4. Structure of $M_3M_2^{III}(PO_4)_3$ projected onto the ac plane (*a*) and the oxygen environment about the $M(1)$ and $M(2)$ positions occupied by alkali-metal cations (*b*). The $M(3)$ position is omitted.

Figure 5. The In_2O_{10} biocahedron (a) and the structure of $\beta\text{-Na}_3\text{In}_2(\text{PO}_4)_3$ projected onto the ab plane (b).

dimer must be approximately equal to 3.0 Å. Due to repulsion between the cations, this distance increases to 3.19 Å in $\text{Na}_3\text{Fe}^{3+}\text{Fe}_2^{2+}(\text{PO}_4)_3$, 3.35 Å in $\beta\text{-Na}_3\text{In}_2(\text{PO}_4)_3$ and 3.38 Å in $\text{NaCdIn}_2(\text{PO}_4)_3$. The larger or smaller size of the cation as compared to In^{3+} and (*i.e.*, $r < 0.74$ and $r > 0.76$ Å) will lead to destruction of the dimer as the structural block, which is confirmed by the lack of information on alluaudite-like phases with composition $\text{M}_3^{\text{I}}\text{M}_2^{\text{III}}(\text{PO}_4)_3$, where $\text{M}^{\text{III}} = \text{REE}, \text{Sc}, \text{Fe}, \text{Cr}$.

From the crystal-chemical viewpoint, the transformation of the alluaudite-like β phase into the NASICON-like α phase [which was established from the analysis of the structures of both modifications of $\text{Na}_3\text{In}_2(\text{PO}_4)_3$] involves the radical rearrangement of the atoms. It was demonstrated that the transformation from the β phase to the α phase is accompanied by an increase in the distance between the indium atoms, destruction of the In_2O_{10}

dimers and formation of the isolated InO_6 octahedra. This rearrangement leads to an increase in 'porosity' [$\Delta(V/Z)_{\beta \rightarrow \alpha} = 8.1\%$] of the crystal structure due to the formation of rather large channels, which are statistically occupied by alkali-metal cations. The irreversibility of the polymorphic transformation $\beta\text{-Na}_3\text{In}_2(\text{PO}_4)_3 \rightarrow \alpha\text{-Na}_3\text{In}_2(\text{PO}_4)_3$ at $T = 820^\circ\text{C}$ was confirmed by the DTA data.

Hence, compounds with two compositions, *viz.*, $\text{M}_3^{\text{I}}\text{M}^{\text{III}}(\text{PO}_4)_2$ and $\text{M}_3^{\text{I}}\text{M}_2^{\text{III}}(\text{PO}_4)_3$, are most widespread among double phosphates containing mono- and trivalent cations. The structural types of these compounds are determined by the nature and size of the M^{III} cation as well as by the difference in the radii of the M^{I} and M^{III} cations, which is most pronounced for indium compounds (Table 3).

Investigations of the luminescence properties of REE phosphates showed that the $\text{M}_3^{\text{I}}\text{M}^{\text{III}}(\text{PO}_4)_2$ compounds ($\text{M}^{\text{I}} = \text{Na}, \text{K}$; $\text{M}^{\text{III}} = \text{Y}, \text{La}, \text{Nd}, \text{Gd}$) are promising laser materials.^{27, 51–54} Due to the unique luminescence properties (large absorption and luminescence cross-sections, rather large radiative lifetimes, weak concentration quenching of luminescence, low thresholds of generation, *etc.*), these crystals are quite competitive even with the recognised leader of this class of materials, *viz.*, yttrium–aluminium garnet $\text{YAG}:\text{Nd}^{3+}$, which is traditionally used in compact lasers. Luminophores based on $\text{M}_3^{\text{I}}\text{M}^{\text{III}}(\text{PO}_4)_2$ have the linear current characteristic of luminance at the cathode excitation in the current-density range of 0.1–50 $\mu\text{A cm}^{-2}$ (for the known $\text{Zn}_2\text{SiO}_4\text{–Mn}$ luminophore, the saturation of luminance takes place at the current load of 5–10 $\mu\text{A cm}^{-2}$). The introduction of the second M^{III} cation (diluent) into these materials leads to a noticeable increase in the line width resulting in deterioration of the optical characteristics. This was observed for the $\text{Na}_3\text{Nd}_{1-x}\text{M}_x^{\text{III}}(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{Gd}, \text{Lu}, \text{Y}$) solid solutions.⁵² The introduction of the Ce^{3+} and Tb^{3+} cations into a matrix of the $\beta\text{-K}_2\text{SO}_4$ type leads to an increase in the quantum yield due to the energy transfer from Ce^{3+} to Tb^{3+} .⁵³

The sizes of the polyhedra in the structures of NASICON-like phosphates allow one to predict the positions of the cations in the lattice and their mobility. Thus, a decrease in the size of the structure-forming M^{III} cation hinders the migration of mobile alkali-metal cations within the channels of the framework. It was experimentally found that the ionic conductivity of $\text{Na}_3\text{M}_2^{\text{III}}(\text{PO}_4)_3$ is weakened as the radius of the trivalent cation decreases. At 570 °C, σ is equal to 5.0×10^{-2} , 9.8×10^{-3} and $7.8 \times 10^{-3} \text{ S cm}^{-1}$ for $\text{Na}_3\text{Sc}_2(\text{PO}_4)_3$, $\text{Na}_3\text{Fe}_2(\text{PO}_4)_3$ and $\text{Na}_3\text{Cr}_2(\text{PO}_4)_3$, respectively.^{21, 51} The dependence of the ionic conductivity of NASICON-like REE-containing phases on the temperature and degree of replacement of Zr by M^{III} was studied only for mixed phosphates $\text{Na}_{1+x}\text{Zr}_{2-x}\text{M}_x^{\text{III}}(\text{PO}_4)_3$ ($\text{M}^{\text{III}} = \text{Gd}, \text{Tb}, \text{Dy}, \text{Y}, \text{Er}, \text{Yb}, \text{In}$; $0 \leq x \leq 2$).⁵⁵ For the $\text{Na}_{2.4}\text{In}_{1.4}\text{Zr}_{0.6}(\text{PO}_4)_3$ compound, the maximum σ value ($10^{-1} \text{ S cm}^{-1}$) was found at

Table 3. Characterisation of the structures of different types of double phosphates containing mono- and trivalent cations.

400 °C and the minimum value ($2 \times 10^{-5} \text{ S cm}^{-1}$) was observed at room temperature. Of REE-containing composites, the Yb-doped analogue $\text{Na}_{2.4}\text{Yb}_{1.4}\text{Zr}_{0.6}(\text{PO}_4)_3$ is the most competitive material (σ is $8.5 \times 10^{-2} \text{ S cm}^{-1}$ at 400 °C).

III. Hydrogen phosphates containing mono- and trivalent cations

Complex hydrogen phosphates containing mono- and trivalent cations are characterised by the presence of hydrogen bonds between the oxygen and hydrogen atoms of the HPO_4 groups. Although formally belonging to double phosphates containing mono- and trivalent cations, these compounds possess a series of specific features. Hence, it is reasonable to consider these compounds separately. Hydrogen phosphates containing mono- and trivalent cations are classified into four main types, viz., $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2 \cdot n\text{H}_2\text{O}$, $\text{M}_x^{\text{I}}\text{M}_y^{\text{III}}(\text{HPO}_4)_z(\text{PO}_4)_u \cdot n\text{H}_2\text{O}$, $\text{M}_x^{\text{I}}\text{M}_y^{\text{III}}(\text{H}_2\text{PO}_4)_z(\text{HPO}_4)_u \cdot n\text{H}_2\text{O}$ and $\text{M}_x^{\text{I}}\text{M}_y^{\text{III}}(\text{H}_2\text{PO}_4)(\text{HPO}_4)_2 \cdot (\text{H}_3\text{PO}_4) \cdot n\text{H}_2\text{O}$, where $\text{M}^{\text{I}} = \text{Na, K, Rb, Cs, H}_3\text{O, NH}_4$ and $\text{M}^{\text{III}} = \text{Al, V, Fe, Ga, In}$.

Phosphates $\text{M}_3^{\text{I}}\text{M}^{\text{III}}(\text{OH})(\text{HPO}_4)(\text{PO}_4)$ containing the HPO_4 groups along with the OH groups, which serve as bridges linking the $\text{M}^{\text{III}}\text{O}_6$ polyhedra in infinite chains, are known only for Al and Ga in combination with Na. These compounds will be considered in Section V.

1. Synthesis

The hydrothermal synthesis is one of conventional procedures for the preparation of hydrogen phosphates containing the M^{I} and M^{III} cations.^{56–75} The problems associated with the preparation of compounds with specified compositions consist in choosing the optimum conditions of the synthesis. The compositions of the resulting compounds depend substantially on the parameters of the synthesis (the temperature, the degree of filling of an autoclave or a tube, the concentrations of the starting reagents, the aggregate state, pH of the medium, duration of the synthesis). General procedures for the preparation of this group of compounds are lacking. One of the criteria for the existence of complex hydrogen phosphates containing different cations and anions is the presence of a strongly acidic medium (pH is no higher than 2–2.5). All the aforesaid refer equally to the conditions of the hydrothermal synthesis of hydrogen phosphates with compositions $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2 \cdot n\text{H}_2\text{O}$ ($\text{M}^{\text{I}} = \text{Na, K, Rb, Cs, H}_3\text{O, NH}_4$; $\text{M}^{\text{III}} = \text{Al, Fe, V, In}$; $n = 0–18$) and $\text{M}_x^{\text{I}}\text{M}_y^{\text{III}}(\text{HPO}_4)_z(\text{PO}_4)_u \cdot n\text{H}_2\text{O}$ ($\text{M}^{\text{I}} = \text{Rb, Cs}$; $\text{M}^{\text{III}} = \text{V, Ga, In}$; $n = 0.5–2$). The $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2 \cdot n\text{H}_2\text{O}$ compounds are prepared under rather mild conditions (145–240 °C, see Table 4).

In studies of the phase formation in the $\text{In}_2\text{O}_3\text{--M}^{\text{I}}\text{H}_2\text{PO}_4\text{--H}_3\text{PO}_4\text{--HF}$ and $\text{In}_2\text{O}_3\text{--M}^{\text{I}}\text{Hal--H}_3\text{PO}_4$ systems under hydrothermal conditions ($T = 200$ °C), a series of indium hydrogen phosphates with composition $\text{M}^{\text{I}}\text{In}(\text{HPO}_4)_2$ ($\text{M}^{\text{I}} = \text{K, Rb, Cs, NH}_4$) were prepared. These compounds are stable at pH 0.5–1.5.⁵⁶ The $\text{RbIn}(\text{HPO}_4)_2$ compound was isolated as crystals of two forms (colourless prismatic and elongated bipyramidal) characterised by the same empirical formula. Crystals of hydrogen phosphate $\text{Na}_2\text{In}_2(\text{HPO}_4)_4 \cdot \text{H}_2\text{O}$ were prepared in the synthesis of microporous borophosphates.⁵⁷ Interestingly, the phosphate with the same composition was synthesised under analogous conditions in the absence of $\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$. Attempts to prepare a gallium-containing analogue according to the same procedure failed and led to the formation of new borophosphate with composition $\text{NaGaBP}_2\text{O}_7(\text{OH})_3$.⁵⁷ Attempts to synthesise mixed rubidium gallium hydrogen phosphate were also unsuccessful in spite of the fact that the initial reagent ratio was varied over a wide range. Hydrogen phosphate $\text{Rb}_2\text{Ga}_4(\text{HPO}_4)(\text{PO}_4)_4 \cdot 0.5\text{H}_2\text{O}$ crystallised simultaneously with GaPO_4 (see Ref. 58) due, apparently, to high stability and low solubility of GaPO_4 (the solubility product is 1×10^{-21}).

The field of chemistry dealing with the synthesis of porous compounds has been extensively developed in recent years. These

compounds have inorganic frameworks built from the phosphate tetrahedra. The cavities in these frameworks can capture different positively charged groups, including organic groupings. The preparation of these compounds under hydrothermal conditions is often accompanied by the formation of complex hydrogen phosphates as by-products. For example, prismatic crystals of $\text{NH}_4(\text{Al}_{1-x}\text{Ga}_x)(\text{HPO}_4)_2$ ($x = 0.36$) comprising ~5%–10% of the total weight of the product were obtained under mild conditions ($T = 130$ °C) from a mixture consisting of aluminium and gallium chlorides, tetramethylammonium hydroxide and a cobalt complex with composition $[\Lambda\text{-Co(en)}_3(\text{H}_2\text{PO}_4)_3]$ (en is ethylenediamine).⁵⁹ Two types of crystals were isolated from a mixture of $\text{RbOH--FePO}_4 \cdot 2\text{H}_2\text{O--Me}_2\text{NH--MePO}(\text{OH})_2\text{--H}_3\text{PO}_4$ at 230 °C, viz., colourless elongated parallelepiped-shaped crystals of hydrogen phosphate $\text{RbFe}(\text{HPO}_4)_2$ (see Ref. 60) and prismatic crystals of unknown structure. It should be noted that a powdered product obtained in the course of the synthesis had the same nominal composition as that of the crystals of $\text{RbFe}(\text{HPO}_4)_2$ but was the low-symmetry modification.

Vanadium hydrogen phosphates $\text{M}^{\text{I}}\text{V}(\text{HPO}_4)_2$ ($\text{M}^{\text{I}} = \text{Rb, NH}_4$) were synthesised under slightly modified conditions ($T = 240$ °C).⁶¹ Only triclinic crystals of $\alpha\text{-RbV}(\text{HPO}_4)_2$ were isolated in pure form. Attempts to obtain their monoclinic analogues $\beta\text{-RbV}(\text{HPO}_4)_2$ and $\beta\text{-(NH}_4\text{)}\text{V}(\text{HPO}_4)_2$ in pure form failed even upon variation of the initial reagent ratio over a wide range. According to the results of chemical analysis, the composition of the impurity phase is identical to that of $\beta\text{-(NH}_4\text{)}\text{V}(\text{HPO}_4)_2$. This indicates that the phase formation of vanadium hydrogen phosphates, like that of indium hydrogen phosphates $\beta_1\text{-}$ and $\beta_2\text{-RbIn}(\text{HPO}_4)_2$, is a complex process resulting in co-crystallisation of different modifications of a compound under the same conditions. Attempts to prepare hydrogen phosphates $\text{M}^{\text{I}}\text{V}(\text{HPO}_4)_2$ ($\text{M}^{\text{I}} = \text{K or Cs}$) led to the formation of two phases, viz., $\text{K(V}^{\text{IV}}\text{O)V}^{\text{III}}(\text{HPO}_4)_3(\text{H}_2\text{O})_2$ and $\text{CsV}_2(\text{PO}_4) \cdot (\text{HPO}_4)_2(\text{H}_2\text{O})_2$.⁶² The caesium indium derivative $\text{CsIn}_2(\text{PO}_4) \cdot (\text{HPO}_4)_2(\text{H}_2\text{O})_2$ (see Ref. 63) was isolated from aqueous solutions containing InCl_3 , H_3PO_4 , CsVO_3 and Me_4NOH in a ratio of 2 : 6 : 1 : 1. It should be noted that mixed caesium indium hydrogen phosphate was not produced in the synthesis with the use of CsCl , CsOH and Cs_2CO_3 instead of CsVO_3 . Hydrogen phosphates containing the H_2PO_4^- and HPO_4^{2-} anions were prepared from solutions containing high concentrations of H_3PO_4 ($\geq 3 \text{ M}$). The synthesis with the use of $\text{CsGa}(\text{H}_2\text{PO}_4)_4$ as the starting compound in the presence of Cs_2CO_3 and an excess of H_3PO_4 afforded $\text{Cs}_2\text{Ga}(\text{H}_2\text{PO}_4)(\text{HPO}_4)_2 \cdot \text{H}_3\text{PO}_4 \cdot 0.5\text{H}_2\text{O}$.⁶⁴

2. Structures and properties

The $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2$ compounds possess a series of interesting structural features. These compounds were prepared for the Al, V, Fe, Ga and In cations in combination with K, Rb and Cs^{56, 60, 61, 65} as well as with the single-charged NH_4^+ and H_3O^+ cations.^{56, 59, 61, 66–68} The composition of the unit cell of mixed indium sodium hydrogen phosphate does not correspond to the $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2$ formula, which is associated with the incorporation of water molecules in the crystal lattice of this compound. Two compounds whose compositions correspond to the $\text{Na}_2\text{In}_2(\text{HPO}_4)_4 \cdot \text{H}_2\text{O}$ ⁵⁷ and $\text{Na}_4\text{In}_8(\text{HPO}_4)_{14}(\text{H}_2\text{O})_6 \cdot 12\text{H}_2\text{O}$ formulas were isolated.⁶⁹ The crystallographic characteristic of mixed-cation hydrogen orthophosphates $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2$ and more complex sodium indium phosphates are given in Table 5.

All $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2$ compounds have frameworks built from the vertex-sharing $\text{M}^{\text{III}}\text{O}_6$ octahedra and PO_4 tetrahedra. The cavities and channels of the frameworks are occupied by mono-valent cations. Variations in the sizes of the M^{I} and M^{III} cations give rise to different structural types. Thus, different types of frameworks can be formed, the polyhedra are distorted and the sizes of the channels and cavities are changed. As a consequence, the crystal lattice can incorporate water molecules, which participate in structure formation. It seems essential that in all structures, the protonated vertices of the PO_4 tetrahedra are directed

inside the channels. This arrangement of the protons has an effect on the shape of the channels and their presence compensates the negative charge of the frameworks of these compounds.

Two types of the AlO_6 octahedra and four crystallographically independent PO_4 tetrahedra are the main polyhedra in the structure of $\text{KAl}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$.⁶⁵ The alternating AlO_6 and HPO_4 polyhedra are linked in chains along the a and c axis thus forming a framework (Fig. 6). The size and shape of the cavities in the framework are affected by the potassium cations and protons involved in the HPO_4 groups. The $\text{Al}(1)\text{O}_6$ octahedron, which is formed by four oxygen atoms belonging to four HPO_4 groups and two oxygen atoms of two *cis*-oriented water molecules, is strongly distorted. The $\text{Al}(2)\text{O}_6$ octahedron is less distorted and is formed only by the oxygen atoms of the HPO_4 groups. The $\text{Al}(1)\text{O}_6$ octahedra are arranged along the a axis, whereas the $\text{Al}(2)\text{O}_6$ octahedra are aligned along the c axis. The structure contains two types of the K cations. The coordination sphere about the $\text{K}(1)$ cation is formed by the oxygen atoms of only the HPO_4 groups, whereas the coordination sphere about the $\text{K}(2)$ cation involves the oxygen atom of the H_2O molecule along with the oxygen atoms of the HPO_4 groups. The coordination numbers of the potassium atoms in both polyhedra are equal to 9. In the structure of the deuterated analogue $\text{KAl}(\text{DPO}_4)_2 \cdot \text{D}_2\text{O}$,⁶⁵ seven types of hydrogen bonds were revealed.

Figure 6. Structure of $\text{KAl}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ projected onto the ac plane.

The difference in the size of the M^{I} and M^{III} cations has a substantial effect on the structural features of hydrogen phosphates $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2$ ($\text{M}^{\text{I}} = \text{K, Rb, Cs, H}_3\text{O, NH}_4$; $\text{M}^{\text{III}} = \text{Fe, V, In}$), which crystallise in the monoclinic system. This is particularly clearly seen in the case of indium compounds. For example, the unit cell volume in the family of indium hydrogen phosphates $\text{M}^{\text{I}}\text{In}(\text{HPO}_4)_2$ ($\text{M}^{\text{I}} = \text{K, Rb, NH}_4$, space group $P2_1/c$) increases gradually in the series $\text{K} - \text{NH}_4 - \text{Rb}$. However, the unit cell parameters are sharply changed on going to caesium, which has the largest ionic radius of all the alkali metals under consideration, while the space group ($P2_1/c$) is retained. The $\text{CsIn}(\text{HPO}_4)_2$ compound is more similar in crystallographic characteristics to hydrogen phosphates $(\text{H}_3\text{O})\text{Fe}(\text{HPO}_4)_2$, $\beta\text{-(NH}_4\text{)}\text{V}(\text{HPO}_4)_2$ and $\beta\text{-RbV}(\text{HPO}_4)_2$ than to $\text{M}^{\text{I}}\text{In}(\text{HPO}_4)_2$ ($\text{M}^{\text{I}} = \text{K, Rb, NH}_4$).

In the structure of $(\text{H}_3\text{O})\text{Fe}(\text{HPO}_4)_2$,⁶⁷ the FeO_6 octahedra are linked to each other through four PO_4 tetrahedra. The block of the octahedra and tetrahedra forms a framework consisting of columns along the a axis. The cavities in the framework are

occupied by the oxonium cations.[§] The oxygen atom of the H_3O^+ cation is at distances of 2.90–3.14 Å from the seven nearest oxygen atoms of the HPO_4 groups. The structures of hydrogen phosphates $\beta\text{-M}^{\text{I}}\text{V}(\text{HPO}_4)_2$ ($\text{M}^{\text{I}} = \text{NH}_4, \text{Rb}$)⁶¹ and $\text{CsIn}(\text{HPO}_4)_2$ (see Ref. 56) differ from that of $(\text{H}_3\text{O})\text{Fe}(\text{HPO}_4)_2$ (see Ref. 67) in that the VO_6 (as well as the InO_6) octahedra within the channels in these structures are linked to each other only by two PO_4 tetrahedra. On going from $\beta\text{-RbV}(\text{HPO}_4)_2$ to $\text{CsIn}(\text{HPO}_4)_2$, the oxygen polyhedron about the M^{III} atom is enlarged. Thus, the coordination numbers of rubidium and caesium are 7 and 12, respectively.

The triclinic modification of $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2$ ($\text{M}^{\text{I}} = \text{Rb, NH}_4$; $\text{M}^{\text{III}} = \text{Fe, V}$)^{61,66} and $(\text{NH}_4)(\text{Al}_{1-x}\text{Ga}_x)(\text{HPO}_4)_2$ ($x = 0.36$)⁵⁹ have mixed $\{\text{M}^{\text{III}}[\text{HPO}_4]_2\}_{3\infty}$ frameworks of the $\text{M}^{\text{III}}\text{O}_6$ octahedra and PO_4 tetrahedra. These skeleton frameworks contain large cavities occupied by monovalent cations. The sizes and shapes of the cavities allow mobile ions to migrate in different directions, which indicates that these compounds can exhibit ion-exchange properties.⁶⁸ The $\text{M}^{\text{III}}\text{O}_6$ octahedra share all vertices with six nearest PO_4 tetrahedra. Each tetrahedron shares three vertices with three adjacent octahedra, whereas the fourth proton-bearing vertex of each tetrahedron is not involved in the first coordination sphere of the M^{3+} cations. The functional role of the fourth vertex consists in linking the tetrahedra through hydrogen bonding to form groups of three polyhedra each. The fact that the V^{3+} , Fe^{3+} , Co^{3+} and Ni^{3+} cations have similar radii [$r_{\text{VI}}(\text{M}^{\text{III}}) = 0.64, 0.645, 0.61$ and 0.60 Å, respectively] suggests the existence of the triclinic modification of the $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2$ compounds with $\text{M}^{\text{I}} = \text{Rb, NH}_4$ and $\text{M}^{\text{III}} = \text{Co, Ni}$.

The $(\text{NH}_4)\text{Fe}(\text{HPO}_4)_2$ compound⁶⁸ exhibits antiferromagnetic properties and has two different magnetic subunits analogous to those found in $\text{Li}_3\text{Fe}_2(\text{PO}_4)_3$.⁷⁰ It should be noted that an increase in the ionic radius of the M^{III} cation in the series $\text{Al} - \text{Ga} - \text{V} - \text{Fe}$ in hydrogen phosphates with composition $(\text{NH}_4)\text{M}^{\text{III}}(\text{HPO}_4)_2$ is accompanied by a substantial deformation of the FeO_6 octahedra resulting in rotation of the PO_4 tetrahedra about FeO_6 . This leads to doubling of the unit cell volume of the Fe-containing analogue (triclinic modification). The triclinic modification of the In-containing analogue was not found, which may be indicative of instability of this modification of hydrogen phosphates containing large M^{III} cations.

The monoclinic modification of $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2$ differs from their triclinic modification primarily in the mode of linking of the octahedra and tetrahedra in infinite columns along the a axis. For example, the columns in the structure of monoclinic $\beta\text{-(NH}_4\text{)}\text{V}(\text{HPO}_4)_2$ (Fig. 7a) are linked in a framework through the PO_4 tetrahedra, whereas these columns in the more complex structure of triclinic $\alpha\text{-(NH}_4\text{)}\text{V}(\text{HPO}_4)_2$ (Fig. 7b) are linked along the $[100]$ direction due to the presence of an additional VO_6 octahedron. As a result, the structure $\beta\text{-(NH}_4\text{)}\text{V}(\text{HPO}_4)_2$ contains channels of one type occupied by the ordered NH_4^+ cations, whereas two types of channels occupied by the NH_4^+ ions are present in the structure of $\alpha\text{-(NH}_4\text{)}\text{V}(\text{HPO}_4)_2$ (see Fig. 7a, b).

The structure of $\text{RbFe}(\text{HPO}_4)_2$ belonging to the trigonal system⁶⁰ (Fig. 7c) has a fragment typical of the triclinic modification of the $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2$ compounds. However, in the low-symmetry structure, the tetrahedra through which the octahedra are linked in columns, are 'sunk' into the cavities between the octahedra, whereas the arrangement of the tetrahedra around the FeO_6 octahedra in the trigonal structure corresponds to the symmetry $\bar{3}$.

The structure of $\text{RbFe}(\text{HPO}_4)_2$ contains the $\text{Fe}(1)_2\text{Fe}(2)(\text{HPO}_4)_{12}$ trimers involving two types of the octahedra, viz., $\text{Fe}(1)\text{O}_6$ and $\text{Fe}(2)\text{O}_6$. The trimers form helical columns along the c axis. Each HPO_4 group is linked to one

§ The presence of the H_3O^+ cation was confirmed by IR spectroscopy (a narrow absorption band at 3392 cm^{-1}).

Figure 7. Structures of monoclinic β -(NH_4) $\text{V}(\text{HPO}_4)_2$ (a) and triclinic α -(NH_4) $\text{V}(\text{HPO}_4)_2$ (b) projected onto the bc plane and the structure of trigonal $\text{RbFe}(\text{HPO}_4)_2$ (c) projected onto the ac plane.

$\text{Fe}(1)\text{O}_6$ octahedron and one $\text{Fe}(2)\text{O}_6$ octahedron within the trimer and to one $\text{Fe}(1)\text{O}_6$ octahedron from the adjacent trimer so that the three-dimensional $[\text{Fe}(1)_2\text{Fe}(2)(\text{HPO}_4)_6]_{3\infty}$ framework is formed. The tunnels extended along the $[100]$ and $[110]$ directions are occupied by two types of rubidium cations with the coordination numbers of 12 and 9. As can be seen from the projection of the structure of $\text{RbFe}(\text{HPO}_4)_2$ onto the ab plane, the layers of the $\text{Fe}(1)$ and $\text{Rb}(1)$ atoms alternate with the layers of the $\text{Fe}(2)$ and $\text{Rb}(2)$ atoms and interleaved with the HPO_4 groups. All iron and rubidium atoms are located on threefold axes to form columns along the c axis with the $-\text{Fe}(1)\text{Fe}(2)\text{Fe}(1)\text{Rb}(2)\text{Rb}(1)\text{Rb}(2)\text{Fe}(1)-$ alternation. In $\text{RbFe}(\text{HPO}_4)_2$, the difference between the radii of the rubidium $[r_{\text{XII}}(\text{Rb}^+) = 1.73 \text{ \AA}]$ and iron $[r_{\text{VI}}(\text{Fe}^{3+}) = 0.645 \text{ \AA}]$ cations is $\sim 1.09 \text{ \AA}$. The pair of the caesium $[r_{\text{XII}}(\text{Cs}^+) = 1.88 \text{ \AA}]$ and indium $[r_{\text{VI}}(\text{In}^{3+}) = 0.76 \text{ \AA}]$ cations as well as the pair of rubidium and vanadium $[r_{\text{VI}}(\text{V}^{3+}) = 0.64 \text{ \AA}]$ are characterised by similar values of Δr and, hence, the trigonal modifications of $\text{CsIn}(\text{HPO}_4)_2$ and $\text{RbV}(\text{HPO}_4)_2$ would be expected to occur.

A decrease in $\Delta r_{(\text{M}^+ - \text{M}^{3+})}$ in the series $\text{Cs} - \text{Rb} - \text{K} - \text{Na}$ (for one type of the M^{3+} atoms) leads to a decrease in the coordination number of the alkali-metal cation. As a consequence, a new structural type can be formed. This assumption was confirmed by the structures of indium hydrogen phosphates $\text{M}^{\text{I}}\text{In}(\text{HPO}_4)_2$,

where $\text{M}^{\text{I}} = \text{K}, \text{Rb}$ or NH_4 , which we have established recently. In the framework structures of these compounds, the octahedra and tetrahedra are linked in infinite columns along the $[100]$ and $[001]$ directions. These structures differ from that of $\text{CsIn}(\text{HPO}_4)_2$ in the mode of linking of the columns to form a framework. In addition, the alkali-metal atoms in these structures adopt a smaller coordination number. Thus the coordination number of caesium in $\text{CsIn}(\text{HPO}_4)_2$ is 12, whereas the coordination number of potassium and rubidium in $\text{M}^{\text{I}}\text{In}(\text{HPO}_4)_2$ ($\text{M} = \text{K}$ or Rb) is 9. In $\text{CsIn}(\text{HPO}_4)_2$, each column is linked to four analogous adjacent columns through four PO_4 tetrahedra, whereas there are eight such interactions in the structures of $\text{M}^{\text{I}}\text{In}(\text{HPO}_4)_2$ ($\text{M} = \text{K}, \text{Rb}$) and all tetrahedra are shared by columns (Fig. 8).

The PO_4 tetrahedra in $\text{M}^{\text{I}}\text{In}(\text{HPO}_4)_2$ ($\text{M} = \text{K}$ or Rb) share two vertices with the InO_6 octahedra from one column and one vertex with the octahedron from the adjacent column. The fourth (protonated) oxygen vertex of each tetrahedron is directed inside the channel formed with the participation of three columns linked through the tetrahedra. These channels are occupied by the M^{I} cations. The InO_6 octahedra in the structure of $\text{KIn}(\text{HPO}_4)_2$, unlike those in $\text{RbIn}(\text{HPO}_4)_2$, are strongly distorted. These structural features of $\text{KIn}(\text{HPO}_4)_2$ suggest that the formation of this structural type is highly improbable for the sodium analogue.

Figure 8. Structure of $\text{RbIn}(\text{HPO}_4)_2$ projected onto the ab plane.

Sodium for which $\Delta r_{(\text{M}^+ - \text{M}^{3+})}$ reaches the maximum value ($\sim 0.23 \text{ \AA}$) forms the $\text{Na}_2\text{In}_2(\text{HPO}_4)_4 \cdot \text{H}_2\text{O}$ ⁵⁷ and $\text{Na}_4\text{In}_8(\text{HPO}_4)_{14}(\text{H}_2\text{O})_6 \cdot 12 \text{H}_2\text{O}$ ⁶⁹ compounds with radically different structures.

The $\text{Na}_2\text{In}_2(\text{HPO}_4)_4 \cdot \text{H}_2\text{O}$ compound has the $[\text{In}_2(\text{HPO}_4)_4]_{3\infty}$ framework built from two types of the InO_6 octahedra and PO_4 tetrahedra. This framework can be described as consisting of the characteristic $[\text{In}(1)\text{In}(2)(\text{HPO}_4)_4]$ structural blocks. The InO_6 octahedra of both types each share vertices with six PO_4 tetrahedra, which, in turn, each have three oxygen atoms in common with three adjacent octahedra. The remaining vertices of the HPO_4 polyhedra occupied by the protonated oxygen atoms are involved in formation of five hydrogen bonds. The octahedra and tetrahedra are packed in layers parallel to the a axis. The framework of $\text{Na}_2\text{In}_2(\text{HPO}_4)_4 \cdot \text{H}_2\text{O}$ contains two types of channels. The channels of one type are extended along the $[100]$ direction and occupied by sodium cations and H_2O molecules (Fig. 9a). The channels of another type are extended along the $[010]$ direction and are empty. It should be noted that the mode of binding of the In, P and O atoms in $\text{Na}_2\text{In}_2(\text{HPO}_4)_4 \cdot \text{H}_2\text{O}$ ⁵⁷ is analogous to that observed in the structures of Al_2O_3 (corundum) and $\text{Ti}^{\text{IV}}\text{Ti}^{\text{IV}}(\text{HPO}_4)_4$.⁷¹

The structure of $\text{Na}_4\text{In}_8(\text{HPO}_4)_{14}(\text{H}_2\text{O})_6 \cdot 12 \text{H}_2\text{O}$ consists of the $[\text{In}_8(\text{HPO}_4)_{14}(\text{H}_2\text{O})_6]$ layers formed by the PO_4 tetrahedra and the $\text{In}(1)\text{O}_6$ and $\text{In}(2)\text{O}_5\text{O}_w$ octahedra. The $[\text{In}_8(\text{HPO}_4)_{14}(\text{H}_2\text{O})_6]$ layers are packed in the $ABAB$ order according to the trigonal symmetry $P3c1$, the channels along the $[001]$ direction being lacking. The layers are linked to each other through the $\text{In}(1)\text{O}_6$ octahedra to form a framework with channels along the crystallographic a and b axis (Fig. 9b). These channels have a 12-membered-ring shape in cross-section and include the Na^+ cations and water molecules. The water molecules fulfil two functions. Some water molecules are involved in the first coordination sphere about the $\text{In}(2)$ cation and the remaining water molecules occupy the channels of the structure (zeolite-type water). The partial occupancies of the sodium positions and the nearest oxygen positions are directly associated with the presence of abnormally short bonds ($2.06\text{--}2.19 \text{ \AA}$) between these atoms. The $\text{Na}\text{--}\text{O}$ interatomic distances in the NaO_x polyhedron are close to the interatomic distances outside these polyhedra. This characteristic feature of the $\text{Na}_4\text{In}_8(\text{HPO}_4)_{14}(\text{H}_2\text{O})_6 \cdot 12 \text{H}_2\text{O}$ compound is also common to some hydrated sodium zeolites.⁷²

The second group of complex hydrogen phosphates of the general formula $\text{M}_x^{\text{I}}\text{M}_y^{\text{III}}(\text{HPO}_4)_z(\text{PO}_4)_u \cdot n \text{H}_2\text{O}$ ($\text{M}^{\text{I}} = \text{Rb}, \text{Cs}$; $\text{M}^{\text{III}} = \text{V}, \text{Ga}, \text{In}$; $n = 0.5\text{--}2$) includes three compounds, viz., $\text{Rb}_2\text{Ga}_4(\text{HPO}_4)(\text{PO}_4)_4 \cdot 0.5 \text{H}_2\text{O}$, $\text{CsIn}_2(\text{HPO}_4)_2(\text{PO}_4)(\text{H}_2\text{O})_2$ and

Figure 9. Structure of $\text{Na}_2\text{In}_2(\text{HPO}_4)_4 \cdot \text{H}_2\text{O}$ projected onto the bc plane (a) and structure of $\text{Na}_4\text{In}_8(\text{HPO}_4)_{14}(\text{H}_2\text{O})_6 \cdot 12 \text{H}_2\text{O}$ projected onto the ac plane (b).

$\text{CsV}_2(\text{HPO}_4)_2(\text{PO}_4)(\text{H}_2\text{O})_2$. These compounds crystallise in two structural types (Table 6).

In monoclinic $\text{Rb}_2\text{Ga}_4(\text{HPO}_4)(\text{PO}_4)_4 \cdot 0.5 \text{H}_2\text{O}$,⁵⁸ the GaO_x , HPO_4 and PO_4 polyhedra form an open-type structure with channels containing the rubidium cations and water molecules (Fig. 10a). The presence of the HPO_4 groups and water of crystallisation in the structure was confirmed by IR spectroscopy. The $\text{Rb}(1)$ and $\text{Rb}(2)$ cations are located in the $\text{M}^{\text{I}}\text{O}_9$ and $\text{M}^{\text{I}}\text{O}_{10}$ polyhedra, respectively. Four crystallographically non-equivalent gallium atoms have different coordination environments (an octahedron, two tetrahedra and a trigonal bipyramid). All GaO_x polyhedra share vertices with the phosphate tetrahedra, which, in turn, are coordinated (except for the OH vertices) by the gallium atoms. Two types of channels are formed along the $[100]$ direction. The protonated oxygen vertices of the PO_4 tetrahedra are directed inside the channels of the first type occupied by the $\text{Rb}(1)$ cations. The channels of the second type contain the $\text{Rb}(2)$ cations and H_2O molecules. The minimum $\text{O}\cdots\text{O}$ distances determining the sizes of the channels of the first and second types are 5.34 and $5.43 \text{ \AA}$, respectively. The formation of an analogous structure is also highly probable for the RbAl analogue because the coordination numbers of 6, 5 and 4 are typical of aluminium.

The $\text{CsIn}_2(\text{HPO}_4)_2(\text{PO}_4)(\text{H}_2\text{O})_2$ compound (centrosymmetrical structure)⁶³ has a rather complex structure. The octahedral environment about the In atoms is formed by five oxygen atoms of

Table 6. Crystallographic characteristics of the $M^I_x M^{III}_y (HPO_4)_z (PO_4)_u \cdot nH_2O$ and $M^I_x M^{III}_y (H_2PO_4)_z (HPO_4)_u \cdot nH_2O$ compounds.

the PO_4 tetrahedra and one oxygen atom of the water molecule. The HPO_4 polyhedra share three vertices with the adjacent octahedra and their fourth protonated vertex is not involved in the first coordination sphere of the In^{3+} cation. The PO_4 tetrahedron shares all vertices with the nearest InO_6 octahedra. The InO_6 , PO_4 and HPO_4 polyhedra are linked to each other to form one-dimensional ribbons along the c axis (Fig. 10 *b*). These ribbons are linked in a framework through the HPO_4 groups. The large cavities in the framework are occupied by caesium cations (the coordination number of caesium is 11).

Hydrogen phosphate $CsV_2(HPO_4)_2(PO_4)(H_2O)_2$ has an analogous structure.⁶² However, the coordination polyhedron of caesium is enlarged (the coordination number of caesium is 13) due to the smaller ionic radius of vanadium. In this structure, the interactions between the ribbons somewhat resemble the interactions in the well-known structural type $M^V OPO_4$ with the difference that the $M^V O$ component is replaced by $M^{III}OH_2$ and additional phosphate groups are present between the ribbons. Taking into account the difference in the size of the vanadium and indium cations, it is reasonable to suggest that the structures characterised by an analogous topology of the framework must exist for the $CsFe$ - and $CsSc$ -containing compounds because the ionic radii of Fe and Sc are in the range between $r_{VI}(V^{3+})$ and $r_{VI}(In^{3+})$.

The third type of complex hydrogen phosphates includes compounds of the general formula $M^I_x M^{III}_y (H_2PO_4)_z (HPO_4)_u \cdot nH_2O$ ($M^I = K, H_3O, NH_4$; $M^{III} = Al, Fe$; $n = 2-6$) containing two types of hydrogen phosphate anions, *viz.*, HPO_4^{2-} and $H_2PO_4^-$. The crystallographic characteristics of the monoclinic and trigonal structural types of these compounds are given in Table 6. These compounds are characterised by the ratio $M^I : M^{III} = 1 : 3$. Apparently, their stability is associated with the substantial difference in the radii of the M^I and M^{III} cations.

Hydrogen phosphates with composition $M^I M^{III}_3 (H_2PO_4)_6 \cdot (HPO_4)_2 \cdot 4H_2O$ ($M^I = K, H_3O, NH_4$)⁷³⁻⁷⁷ and the ratio $H_2PO_4 : HPO_4 = 3 : 1$ were obtained for aluminium and iron. In the structures of these compounds, water of crystallisation is not involved in the coordination sphere about the M^{III} cations. The structure of monoclinic phosphate with composition $KFe_3(H_2PO_4)_6(HPO_4)_2 \cdot 4H_2O$ (Fig. 11 *a*)⁷⁵ is characterised by a pronounced layered motif. The layers are composed of characteristic structural blocks, which are built from two different FeO_6 octahedra linked through the phosphate groups of two types, *viz.*, $[HPO_4]^{2-}$ and $[H_2PO_4]^-$ (Fig. 11 *b*). The interlayer space is occupied by water molecules. The layers are related by the symmetry elements of the crystal lattice (space group $C2/c$) so that the channels are not formed along the $[001]$ direction. The layers contain cavities occupied by potassium atoms to form the

**Figure 10.** Structures of $Rb_2Ga_4(HPO_4)(PO_4)_4 \cdot 0.5 H_2O$ (*a*) and $CsIn_2(HPO_4)_2(PO_4)(H_2O)_2$ (*b*) projected onto the bc plane.

Figure 11. Structure of $\text{KFe}_3(\text{H}_2\text{PO}_4)_6(\text{HPO}_4)_2 \cdot 4\text{H}_2\text{O}$ projected along the $[010]$ direction (a) and projected onto the ab plane (b).

KO_{12} polyhedra. The layers are linked through hydrogen bonds between the oxygen atoms of the phosphate groups and water molecules, which impart additional stability to the structure. Taking into account the data on the structures of the $\text{M}^{\text{I}}\text{Fe}_3(\text{H}_2\text{PO}_4)_6(\text{HPO}_4)_2 \cdot 4\text{H}_2\text{O}$ compounds, where $\text{M}^{\text{I}} = \text{K}, \text{H}_3\text{O}$ or NH_4 , and of their $(\text{H}_3\text{O})\text{Al}$ analogue, compounds with such a composition would be expected to exist also for $\text{M}^{\text{III}} = \text{Ga}$ or V .

The $(\text{NH}_4)_{0.33}\text{Al}_{0.89}(\text{H}_2\text{PO}_4)(\text{HPO}_4) \cdot 2\text{H}_2\text{O}$ (see Ref. 77) and $(\text{NH}_4)\text{Fe}_3(\text{H}_2\text{PO}_4)_3[\text{PO}_3(\text{OH})_{0.67}\text{O}_{0.33}]_3 \cdot 6\text{H}_2\text{O}$ (see Ref. 78) compounds are characterised by the presence of water molecules fulfilling different functions. The structures of these trigonal hydrogen phosphates differ in the number of formula units per unit cell (6 and 2, respectively).^{77, 78} Three crystallographically independent M^{III} cations occupy the virtually non-distorted MO_6 octahedra in which the $\text{M}^{\text{III}}-\text{O}$ distance increases in parallel with the ionic radius of M^{III} . The structural formula $(\text{NH}_4)_{0.33}\text{Al}_{0.89} \cdot (\text{H}_2\text{PO}_4)(\text{HPO}_4)(\text{H}_2\text{O}) \cdot \text{H}_2\text{O}$ reflects the different role of the water molecules in the crystal motif of this compound. Three independent OH groups belonging to the HPO_4 [P(1) O_4 tetrahedron] and H_2PO_4 [P(2) O_4 tetrahedron] groups and two water molecules (coordinated to the Al atom and the NH_4 group) participate in hydrogen bonding. The NH_4^+ ions are surrounded by nine oxygen atoms most of which belong to the OH groups or H_2O molecules.

Trigonal NH_4Al and NH_4Fe phosphates have framework structures. In the crystal structures, the $\text{M}^{\text{III}}(2)\text{O}_6$ and $\text{M}^{\text{III}}(3)\text{O}_6$ octahedra are located on threefold axes and share all their vertices with the phosphate tetrahedra. The $\text{M}^{\text{III}}(1)\text{O}_6$ octahedron has three vertices in common with the PO_4 tetrahedra and the remaining three vertices are occupied by the oxygen atoms of water molecules. In the structure of NH_4Fe phosphate (Fig. 12 a, b),⁷⁸ the position of the protonated oxygen atom in the P(1) tetrahedron is statistically occupied by the hydrogen atom $(\text{OH})_{2/3}\text{O}_{1/3}$.

Figure 12. Structure of $(\text{NH}_4)\text{Fe}_3(\text{H}_2\text{PO}_4)[\text{PO}_3(\text{OH})_{0.67}\text{O}_{0.33}]_3 \cdot 6\text{H}_2\text{O}$ projected onto the ac plane (a) and the structural block of two octahedra (b).

The structural block consisting of two octahedra, which are linked to nine tetrahedra through vertices (Fig. 12 b), is present in the crystal structures of many polytypic minerals, for example, of coquimbite, paracoquimbite and ferrinatrite $\text{Na}_3\text{Fe}(\text{SO}_4)_3(\text{H}_2\text{O})_3$. In the latter compound, such fragments formed by the Fe octahedra and SO_4 tetrahedra are linked in chains parallel to the c axis. These chains are 'threaded' on threefold axes of the trigonal unit cell (space group $P\bar{3}$). Hence, the same repeated fragment is present in the crystal motifs of different classes of compounds. The degree of polymerisation of this fragment determines the structural diversity of compounds. It should be noted that if the octahedra with the coordinates $(1/3; 2/3; z)$ located on a threefold axis are linked through tetrahedra to analogous octahedra with the coordinates $(2/3; 1/3; z)$ located on another threefold axis, a large number of structures analogous to NH_4Al and NH_4Fe phosphates are generated. These structures can be assigned to zeolite-type compounds. Compounds in which the M^{I} -cation positions are vacant can also have analogous structures. In this case, the crystal-chemical formula can be written as $\square\text{M}^{\text{III}}(\text{H}_2\text{PO}_4)(\text{HPO}_4)(\text{H}_2\text{O}) \cdot \text{H}_2\text{O}$.⁷⁷

The fourth type of hydrogen phosphates, viz., $\text{M}_2^{\text{I}}\text{M}^{\text{III}}(\text{H}_2\text{PO}_4)(\text{HPO}_4)_2 \cdot \text{H}_3\text{PO}_4 \cdot 0.5\text{H}_2\text{O}$, is known only for gallium.⁶⁴ This compound has a unique composition because it contains protonated phosphate groups of all three types, viz., HPO_4^{2-} , H_2PO_4^- and H_3PO_4 . The $\text{Cs}_2\text{Ga}(\text{H}_2\text{PO}_4)(\text{HPO}_4)_2 \cdot \text{H}_3\text{PO}_4 \cdot 0.5\text{H}_2\text{O}$ compound crystallises in the tetragonal system with a rare non-centrosymmetrical unit cell (space group $I4_1cd$, $a = 20.168$, $c = 18.287$ Å, $Z = 16$). In this compound, the gallium atom is in a slightly distorted octahedral environment formed by four oxygen atoms of the HPO_4 groups and two oxygen atoms of the H_2PO_4 groups (Fig. 13 a). One H_2PO_4 group, two HPO_4 groups and the GaO_6 octahedron are involved in the typical $[\text{Ga}(\text{H}_2\text{PO}_4)(\text{HPO}_4)_2]_{\infty}^{2-}$ structural block. These blocks are linked in infinite columns along the $[001]$ direction with the identity period involving four GaO_6 octahedra (due to the presence of a screw axis 4_1 , Fig. 13 b). Each column is linked to four adjacent columns through hydrogen bonds involving the H_3PO_4 molecules.

The crystal lattice contains large cavities occupied by water molecules and caesium cations. The structure contains two types of Cs atoms. The strongly distorted $\text{Cs}(2)\text{O}_{11}$ polyhedron is formed by the oxygen atoms of the phosphate groups of all three types and by the H_2O molecule, which is involved in formation of

Figure 13. Structure of $\text{Cs}_2\text{Ga}(\text{H}_2\text{PO}_4)(\text{HPO}_4)_2 \cdot \text{H}_3\text{PO}_4 \cdot 0.5 \text{H}_2\text{O}$ projected onto the ab plane (a) and the fragment of the $[\text{Ga}(\text{H}_2\text{PO}_4)(\text{HPO}_4)_2]_\infty$ column in combination with the H_3PO_4 and H_2O molecules and Cs^+ cations (b).

the $\text{Cs}(2)-\text{O}_w-\text{Cs}(2)$ chains. The $\text{Cs}(1)\text{O}_9$ polyhedra are less distorted and are not linked to the water molecules.

Analysis of the interatomic distances in the polyhedra of the $\text{Cs}_2\text{Ga}(\text{H}_2\text{PO}_4)(\text{HPO}_4)_2 \cdot \text{H}_3\text{PO}_4 \cdot 0.5 \text{H}_2\text{O}$ structure showed that the gallium position can, in principle, be occupied by the Al, Fe and V atoms whose ionic radii are not much different from that of gallium. These replacements can lead to distortion of the unit-cell symmetry but the main $[\text{M}^{\text{III}}(\text{H}_2\text{PO}_4)(\text{HPO}_4)_2]_\infty$ structural block must persist. By contrast, the replacement of caesium with rubidium or potassium must lead to degradation of the structure due to the tendency of smaller cations to have smaller coordination polyhedra.

The above-considered structural features of hydrogen phosphates containing mono- and trivalent cations, *viz.*, the presence of the HPO_4 and H_2PO_4 groups and water molecules and the mode of their binding, are responsible both for the temperature range of stability of hydrogen phosphates and the possibility of their use in the synthesis of other classes of compounds.

Thermal decomposition of hydrogen phosphates $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{HPO}_4)_2 \cdot n\text{H}_2\text{O}$ ($\text{M}^{\text{I}} = \text{Na}, \text{K}, \text{Rb}, \text{Cs}$) is accompanied by the formation of pyrophosphates $\text{M}^{\text{I}}\text{M}^{\text{III}}\text{P}_2\text{O}_7$. Decomposition of

$\text{RbFe}(\text{HPO}_4)_2$ is accompanied by the removal of the water molecule in the temperature range of 350–550 °C to give crystalline RbFeP_2O_7 . Thermal decomposition of $\text{M}^{\text{I}}\text{In}(\text{HPO}_4)_2$ ($\text{M}^{\text{I}} = \text{K}, \text{Rb}, \text{Cs}$) starts at about 280 °C and completes at 550–650 °C to form $\text{M}^{\text{I}}\text{InP}_2\text{O}_7$. Decomposition of $(\text{NH}_4)\text{In}(\text{HPO}_4)_2$ at 800 °C affords a mixture of $\text{In}_4(\text{P}_2\text{O}_7)_3$ and $\text{In}(\text{PO}_3)_3$. Thermal decomposition of $(\text{H}_3\text{O})\text{Fe}(\text{HPO}_4)_2$ proceeds in two steps. In the first step (at 670 °C), H_2O is removed and hydrogen pyrophosphate is formed. The latter decomposes at 870 °C to give $\text{Fe}_2\text{P}_2\text{O}_7$ and $\text{Fe}(\text{PO}_3)_2$. Heating of $\text{Na}_2\text{In}_2(\text{HPO}_4)_4 \cdot \text{H}_2\text{O}$ results in the loss of a water molecule (~ 365 °C) followed by crystallisation of a non-identified phase, which melts at 1208 °C.

Thermal decomposition of hydrogen phosphates of the second and third types is a complex process and does not afford single-phase products. In the case of $\text{Rb}_2\text{Ga}_4(\text{HPO}_4)(\text{PO}_4)_4 \cdot 0.5 \text{H}_2\text{O}$, the removal of water of crystallisation followed by dehydration was observed at 250–600 °C. Dehydration of $(\text{NH}_4)_{0.33}\text{Al}_{0.89}(\text{H}_2\text{PO}_4)(\text{HPO}_4) \cdot 2 \text{H}_2\text{O}$ proceeded successively. First, the water molecules and ammonium ions were eliminated at 320 °C and then the hydro- and dihydrogen phosphate anions

Table 7. Characterisation of different structural types of hydrogen phosphates containing M^{I} and M^{III} cations.

decomposed. In the final step, AlPO_4 crystallised (tridymite modification).

A comparison of different procedures for the synthesis and a knowledge of the structural features of hydrogen phosphates containing mono- and trivalent cations lead to the conclusion that the steric factors play the major role in the formation of different types of complex hydrogen phosphates (Table 7). The presence of various organic additives and the use (in some cases) of fluoride ions as a mineraliser have less substantial effects on the compositions of the resulting compounds as compared to the influence of the $\text{M}^{\text{I}}:\text{M}^{\text{III}}$ ratio and the difference in the sizes of these cations. The effect of the M^{I} and M^{III} cations on stability of complex hydrogen phosphates in combination with the use of particular conditions for the formation of various protonated forms of phosphate groups in aqueous solutions provide the basis for the directed synthesis of new compounds.

IV. Fluoride phosphates containing mono- and trivalent cations

Depending on the ratios of the cations (M^{I} and M^{III}) and anions (F^- and PO_4^{3-}), fluoride phosphates containing mono- and trivalent cations form several groups of compounds with compositions $\text{M}^{\text{I}}\text{M}^{\text{III}}\text{FPO}_4$, $\text{M}_2^{\text{I}}\text{M}_2^{\text{III}}\text{F}_3(\text{PO}_4)_2$, $\text{M}_2^{\text{I}}\text{M}^{\text{III}}\text{F}_2(\text{PO}_4)_2$ and $(\text{M}^{\text{I}},\text{M}^{\text{II}},\text{M}^{\text{III}})_5\text{F}(\text{PO}_4)_3$ ($\text{M}^{\text{I}} = \text{Li, Na, K, NH}_4$; M^{II} are alkali-earth elements; M^{III} are *p*-, *d*- or *f*-elements). Four types of REE sodium fluoride phosphates with different compositions were found in studies of the phase formation in the ternary systems $\text{Na}^+,\text{M}^{\text{III}}/\text{F}^-,\text{PO}_4^{3-}$ ($\text{M}^{\text{III}} = \text{La, Nd, Gd, Er}$) by powder X-ray diffraction analysis.^{79,80} Minerals belonging to fluoride phosphates are known, in particular, amblygonite LiAlFPO_4 ,^{81,82} tavorite $\text{LiFe}(\text{OH},\text{F})\text{PO}_4$ (see Ref. 83) and lacroixite NaAlFPO_4 (see Ref. 84) as well as apatite-like deloneite $\text{NaCa}_3\text{CeF}(\text{PO}_4)_3$ and belovite $\text{NaSr}_3\text{CeF}(\text{PO}_4)_3$. In some fluoride phosphates, the fluoride ions are partially replaced with the hydroxide ions of a similar size. The $\text{OH}:\text{F}$ ratio may vary; *cf.*, $\text{Na}_3\text{Fe}_2[(\text{OH})_2\text{F}](\text{PO}_4)_2$ (see Ref. 85) and $\text{M}^{\text{I}}\text{M}^{\text{III}}\text{F}_{1-\delta}(\text{OH})_\delta\text{PO}_4$ ($\text{M}^{\text{I}} = \text{K, Rb, NH}_4$; $\text{M}^{\text{III}} = \text{Al, Ga, In}$; $\delta \approx 0.3, 0.5$).⁸⁶

1. Synthesis

Fluoride phosphates of different types, *viz.*, $\text{M}^{\text{I}}\text{M}^{\text{III}}\text{FPO}_4$ ($\text{M}^{\text{I}} = \text{Na, K, NH}_4$; $\text{M}^{\text{III}} = \text{Al, Cr, Fe, Ga, In, Y, Gd-Ho}$), $\text{Na}_3\text{Fe}_2[(\text{OH})_2\text{F}](\text{PO}_4)_2$, $\text{Na}_3\text{M}_2^{\text{III}}\text{F}_3(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{Al, V, Cr, Fe, Ga}$), $\text{Na}_5\text{M}^{\text{III}}\text{F}_2(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{Al, Cr, Ga}$), and $(\text{Na},\text{M}^{\text{II}},\text{M}^{\text{III}})_5.\text{F}(\text{PO}_4)_3$ (M^{II} are alkali-earth metals; M^{III} are REE), were synthesised in the solid state by crystallisation from flux or by the hydrothermal method.

The $\text{NaM}^{\text{III}}\text{FPO}_4$ compounds ($\text{M}^{\text{III}} = \text{Gd, Tb, Dy}$) were prepared by heating stoichiometric amounts of $\text{M}^{\text{III}}\text{PO}_4$ ($\text{M}^{\text{III}} = \text{Gd, Tb, Dy}$) and NaF in air at 550 °C ($\text{M}^{\text{III}} = \text{Gd, Tb}$) or 500 °C ($\text{M}^{\text{III}} = \text{Dy}$). Potassium fluoride phosphates $\text{KM}^{\text{III}}\text{FPO}_4$ ($\text{M}^{\text{III}} = \text{Cr, Fe}$) were prepared by the reactions of chromium (or iron) oxide with $\text{K}_2\text{O}-\text{P}_2\text{O}_5$ melts in the presence of KF at 600–800 °C. In pure form, these compounds are formed in the $\text{K}_2\text{O}:\text{P}_2\text{O}_5$ range from 1:1 to 1:1.7 ($\text{M}^{\text{III}} = \text{Cr}$) or from 1:1.5 to 1:2 ($\text{M}^{\text{III}} = \text{Fe}$); otherwise the reactions afford the corresponding pyrophosphate $\text{KM}^{\text{III}}\text{P}_2\text{O}_7$.

The solid-phase synthesis of fluoride phosphates $\text{Na}_3\text{M}_2^{\text{III}}\text{F}_3(\text{PO}_4)_2$ containing aluminium, chromium or iron was carried out with the use of two-, three- or four-component mixtures ($\text{NaF}-\text{M}^{\text{III}}\text{PO}_4$, $\text{M}^{\text{III}}\text{F}_3-\text{M}^{\text{III}}\text{PO}_4-\text{Na}_3\text{PO}_4$, $\text{NaF}-\text{M}^{\text{III}}\text{PO}_4-\text{NaCl}-\text{ZnCl}_2$, $\text{Na}_2\text{O}-\text{M}_2^{\text{III}}\text{O}_3-\text{P}_2\text{O}_5-\text{NaF}$).^{85,87–90} The reactions were carried out under an atmosphere of argon at $T = 600-880$ °C. Aluminium (iron) sodium fluoride phosphates were prepared by recrystallisation of fluoride phosphate glasses formed upon heating of the $\text{NaPO}_3-\text{M}^{\text{III}}\text{F}_3$ or $\text{NaF}-\text{M}^{\text{III}}\text{PO}_4-\text{M}^{\text{III}}\text{F}_3$ mixtures ($\text{M}^{\text{III}} = \text{Al, Fe}$) above the melting point followed by cooling in air to the crystallisation temperature. Aluminium-containing glass characterised by a large difference between the

crystallisation and glass-transition temperatures is more stable than iron-containing glass.

Of fluoride phosphates of the $\text{M}_5^{\text{I}}\text{M}^{\text{III}}\text{F}_2(\text{PO}_4)_2$ family ($\text{M}^{\text{III}} = \text{Al, Cr, Fe, Ga}$), only sodium-containing derivatives were prepared. The solid-phase synthesis of most of compounds with this composition was performed in the $\text{M}_2^{\text{III}}\text{O}_3-\text{Na}_2\text{O}-\text{P}_2\text{O}_5-\text{NaF}$ (or NaCl) system ($\text{M}^{\text{III}} = \text{Cr, Fe, Ga}$) at $T \approx 750-1300$ °C by crystallisation from flux.^{91–95} The aluminium derivative was prepared according to two procedures, *viz.*, by the solid-phase reaction in the $\text{AlF}_3-\text{Al}(\text{OH})_3-\text{NaH}_2\text{PO}_4-\text{Na}_3\text{PO}_4$ system at $T = 1000$ °C and precipitation from a solution.⁹⁶ In the latter case, $\text{AlF}_3 \cdot 3\text{H}_2\text{O}$ was added to an aqueous solution of NaH_2PO_4 at 80 °C. The suspension was kept at $T = 60$ °C for several days after which crystallisation started.

Mixed sodium- and REE-containing fluoride phosphates were prepared with the use of two-, three- or four-component $\text{Na}^+,\text{M}^{\text{III}}/\text{F}^-,\text{PO}_4^{3-}$ mixtures ($\text{M}^{\text{III}} = \text{La, Nd, Gd, Er}$). The mixtures were annealed under an inert or reductive atmosphere and also *in vacuo* at a temperature from 750 to 1150 °C.^{79,80} When synthesising REE fluoride phosphates in air, the duration of annealing of the samples must be rigidly controlled because the time of annealing has a substantial effect on the composition of the final product. Thus, annealing of samples for 12–18 h (750 °C) gave rise to fluoride phosphate with specified composition. More prolonged heating (72 h) afforded REE oxofluorides and double phosphates $\text{Na}_3\text{M}^{\text{III}}(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{REE}$).

Apatite-like REE fluoride phosphates were synthesised by the solid-phase method from $\text{M}^{\text{II}}\text{CO}_3$ ($\text{M}^{\text{II}} = \text{Ca, Sr, Ba}$), ammonium hydrogen phosphate, REE oxide and an excess of NaF at ~ 1200 °C.^{97–99} Phases with variable composition $\text{Li}_x\text{M}_x^{\text{III}}\text{Y}_{1-x}\text{F}_{4x}(\text{PO}_4)_{1-x}$ ($\text{M}^{\text{III}} = \text{Gd-Lu}$; Y ; $0 \leq x \leq 0.45$) were prepared by heating stoichiometric amounts of double fluoride $\text{LiM}^{\text{III}}\text{F}_4$ and yttrium orthophosphate at 800 °C.¹⁰⁰

Fluoride phosphates with different compositions can be obtained in the multicomponent $\text{M}^{\text{I}}\text{F}-\text{M}_2^{\text{III}}\text{O}_3-\text{H}_3\text{PO}_4-\text{H}_2\text{O}$ systems ($\text{M}^{\text{I}} = \text{Li, Na, K, NH}_4$; $\text{M}^{\text{III}} = \text{Al, Fe, Ga, In, Y, Ho, Er}$) under the hydrothermal conditions.^{83,85,86,101,102} For example, $\text{LiFe}(\text{OH},\text{F})\text{PO}_4$ (synthetic mineral tavorite)⁸³ and analogues of natural iron phosphates, such as triphylite LiFePO_4 , sarcopside $\text{Fe}_3(\text{PO}_4)_2$ and zieselite Fe_2FPO_4 ,¹⁰² were obtained from the $\text{LiF}-\text{Fe}_2\text{O}_3-\text{H}_3\text{PO}_4-\text{H}_2\text{O}$ system at $\approx 300-500$ °C and $p \approx 1.5$ kbar. Attempts to prepare gallium potassium fluoride phosphate KGaFPO_4 , unlike analogous aluminium and iron compounds, failed although different modes of the solid-phase synthesis ($\text{Ga}_2\text{O}_3-\text{NH}_4\text{H}_2\text{PO}_4-\text{KF}$ mixture) and crystallisation from flux (anhydrous $\text{Ga}_2\text{O}_3-\text{KPO}_3-\text{KF}$ system) were used. Compounds in which the fluoride ions are partially replaced by the hydroxide groups, *viz.*, $\text{M}^{\text{I}}\text{M}^{\text{III}}\text{F}_{1-\delta}(\text{OH})_\delta\text{PO}_4$ ($\text{M}^{\text{I}} = \text{K, Rb, NH}_4$; $\text{M}^{\text{III}} = \text{Al, Ga, In}$; $\delta \approx 0.3; 0.5$)^{86,103,104} and $\text{Na}_3\text{Fe}_2[(\text{OH})_2\text{F}](\text{PO}_4)_2$,⁸⁵ were prepared only under the hydrothermal conditions.

After the successful synthesis of a series of porous crystalline aluminosilicates (zeolites) and aluminophosphates, attempts were made to prepare porous fluoride phosphates of the general formula $\text{A}_n\text{M}_x^{\text{III}}\text{F}_y(\text{PO}_4)_z$ ($\text{M}^{\text{III}} = \text{Ga, Fe, In}$; A is organic amine). It was expected that these compounds would find use as catalysts, molecular sieves or ion exchangers. In studies of the phase formation in the $\text{NH}_4\text{F}-\text{M}_2^{\text{III}}\text{O}_3-\text{H}_3\text{PO}_4$ -amine- H_2O ($\text{M}^{\text{III}} = \text{Ga, Fe}$) and $\text{NH}_4\text{F}-\text{Ce}^{\text{IV}}(\text{SO}_4)_2-\text{H}_3\text{PO}_4$ -amine- H_2O systems at $T = 180$ °C and $p = 18$ bar, ammonium-containing fluoride phosphates $\text{NH}_4\text{M}^{\text{III}}\text{FPO}_4$ ($\text{M}^{\text{III}} = \text{Ga, Fe}$)^{105,106} and $\text{NH}_4\text{Ce}^{\text{IV}}\text{F}_2\text{PO}_4$ (see Ref. 107) were obtained. When Ga_2O_3 was used, ammonium-containing fluoride phosphate with unusual composition $(\text{NH}_4)_2\text{Ga}_2\text{F}_3(\text{PO}_4)(\text{HPO}_4)$ was obtained along with $\text{NH}_4\text{GaFPO}_4$.¹⁰⁶

Polycrystalline samples of the $\text{Na}_3\text{M}_2^{\text{III}}\text{F}_3(\text{PO}_4)_2$ compounds ($\text{M}^{\text{III}} = \text{V, Ga}$) were prepared under low-temperature hydrothermal conditions ($T = 180$ °C, $p = 18$ bar). However, the final products were contaminated by intermediates produced in the synthesis. The procedure used for the synthesis of sodium vana-

dium fluoride phosphate $\text{Na}_3\text{V}_2\text{F}_3(\text{PO}_4)_2$ (see Ref. 87) differs from a conventional method. Vanadium oxide V_2O_5 was dissolved in phosphoric acid and reduced with an aqueous solution of N_2H_4 until the solution turned green (V^{3+} ions) and then NaF was added (the molar ratio $\text{Na}:\text{V} = 4.3:2$). The resulting solution was heated first at 180°C and 18 bar and then at 700°C and 2 kbar after which it was slowly cooled to room temperature with a rate of 10°C per hour to obtain finally fluoride phosphate $\text{Na}_3\text{V}_2\text{F}_3(\text{PO}_4)_2$. The $\text{Na}_3\text{Ga}_2\text{F}_3(\text{PO}_4)_2$ compound⁸⁷ was not isolated in pure form (it contained impurities of GaPO_4 and GaF_3).

Aluminium fluoride phosphates $\text{K}_3\text{Al}_4\text{F}_9(\text{PO}_4)_2$ (see Ref. 108) and $(\text{NH}_4)\text{Al}_2\text{F}(\text{PO}_4)_2$ (see Ref. 109) were obtained by the hydrothermal method as by-products in the studies of the $\text{M}^{\text{III}}\text{F}-\text{M}_2^{\text{III}}\text{O}_3-\text{H}_3\text{PO}_4-\text{H}_2\text{O}$ systems.

2. Structure and properties

Sodium-containing fluoride phosphates with composition $\text{NaM}^{\text{III}}\text{FPO}_4$ are known only for $\text{M}^{\text{III}} = \text{Al}$, REE. In the structures of the $\text{NaM}^{\text{III}}\text{FPO}_4$ compounds ($\text{M}^{\text{III}} = \text{Y}$, Gd–Er),^{110, 111} the M^{III} atoms are located in the $[\text{M}^{\text{III}}\text{O}_6\text{F}_2]$ eight-vertex polyhedra (dodecahedra), the F atoms being in *cis* positions. The $\text{M}^{\text{III}}\text{O}_6\text{F}_2$ polyhedra are linked in infinite chains through common edges composed of two oxygen atoms. Every second polyhedron of one chain shares the edge composed of two fluorine atoms with the polyhedron from the adjacent chain giving rise to layers. These parallel layers are linked to each other through the PO_4 tetrahedra to form a framework (Fig. 14). The channels between the layers are occupied by sodium cations. The NaO_8F_2 coordination polyhedron is most preferable for sodium. The structural motif in the $\text{NaM}^{\text{III}}\text{FPO}_4$ compounds remains unchanged on going from Gd to Er and only the PO_4 tetrahedra are slightly rotated.

Figure 14. Fragment of the structure of $\text{NaM}^{\text{III}}\text{FPO}_4$ ($\text{M}^{\text{III}} = \text{Y}$, Gd–Er).

Considering the crystal structures of this type of compounds and taking into account that REE of the second half of the series (Gd–Er) tend to adopt high coordination numbers (>7), the formation of analogous sodium-containing fluoride phosphates would be highly improbable in the case of small trivalent REE cations (Yb, Lu) as well as in the case of In and Sc cations for which the coordination number of 6 is most typical. The exception is the mineral lacroixite NaAlFPO_4 .⁸⁴ There is evidence for the formation of REE sodium fluoride phosphates with composition $\text{Na}_3\text{M}_2^{\text{III}}\text{F}_3(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{Tm}$, Yb, Lu)[¶] but the structures of these compounds remain to be established.

The $\text{NaM}^{\text{III}}\text{FPO}_4$ compounds ($\text{M}^{\text{III}} = \text{Gd}-\text{Er}$) melt incongruently. According to the DTA data, their melting points decrease in the series Gd–Er from 903 to 837°C . In the case of stepwise annealing in air in the temperature range of $500-850^\circ\text{C}$, decomposition started already at 600°C , proceeded through the intermediate formation of $\text{M}^{\text{III}}\text{OF}$, Na_3PO_4 and $\text{M}^{\text{III}}\text{PO}_4$ and

afforded finally a mixture of double phosphate $\text{Na}_3\text{M}^{\text{III}}(\text{PO}_4)_2$ and oxide $\text{M}_2^{\text{III}}\text{O}_3$.

Potassium-containing fluoride phosphates $\text{KM}^{\text{III}}\text{FPO}_4$ are known for $\text{M}^{\text{III}} = \text{Al}$, Cr, Fe, In. In the crystal structure of KAlFPO_4 ,^{101, 112} the aluminium atoms are located in the $[\text{AlO}_4\text{F}_2]$ octahedra of two types, which differ in the positions of the F atoms (*trans* and *cis*). The structure of KInFPO_4 , unlike KAlFPO_4 , contains octahedra of only one type with a *cis* arrangement of the F atoms. In both $\text{KM}^{\text{III}}\text{FPO}_4$ compounds ($\text{M}^{\text{III}} = \text{Al}$, In), the $\text{M}^{\text{III}}\text{O}_4\text{F}_2$ octahedra are linked in parallel helical chains through fluoride bridges and these chains are linked to each other to form a framework.

Fluoride phosphates $\text{M}^{\text{I}}\text{M}^{\text{III}}\text{FPO}_4$ ($\text{M}^{\text{III}} = \text{Fe}$, Cr, Ga)^{113–116} containing the large monovalent K^+ or NH_4^+ cations are isostructural to potassium titanyl phosphate KTiOPO_4 (KTP).¹¹⁶ In the structures of $\text{M}^{\text{I}}\text{M}^{\text{III}}\text{FPO}_4$ with $\text{M}^{\text{I}} = \text{K}^+$ or NH_4^+ , the PO_4 tetrahedra and $\text{M}^{\text{III}}\text{O}_4\text{F}_2$ octahedra are less distorted than the TiO_6 octahedra in KTiOPO_4 . The $\text{M}^{\text{III}}\text{O}_4\text{F}_2$ octahedra are linked in chains extended in two mutually perpendicular directions (Fig. 15). These chains are linked to each other through the PO_4 tetrahedra to form a framework. The chains differ in that the PO_4 tetrahedra in these chains are oriented in opposite directions. The cavities in the framework are occupied by the potassium or ammonium cations.

Figure 15. Chains of the $\text{M}^{\text{III}}\text{O}_4\text{F}_2$ octahedra in the structure of $\text{M}^{\text{I}}\text{M}^{\text{III}}\text{FPO}_4$ ($\text{M}^{\text{I}} = \text{K}$, NH_4 , $\text{M}^{\text{III}} = \text{Cr}$, Fe, Ga).

Two types of potassium atoms in the structures of $\text{KM}^{\text{III}}\text{FPO}_4$ are in a complicated coordination environment formed by fluorine and oxygen atoms. The coordination numbers of the K(1) and K(2) atoms are 8 and 9, respectively. The structure of KTiOPO_4 contains K atoms of one type with the coordination number of 9. The coordination polyhedra about the potassium atoms have one edge (F–O) in common. The cavities occupied by the potassium atoms are linked in pairs and form two types of helical channels perpendicular to each other. The crystallographic characteristics of the $\text{M}^{\text{I}}\text{M}^{\text{III}}\text{FPO}_4$ compounds are given in Table 8.

In recent years, the structural features and physical properties of KTP-type compounds have attracted considerable attention, which is associated with a search for new promising nonlinear optical materials. Taking into account the results of dielectric measurements and studies of conductivity, it was suggested that the structures of KTP-type compounds are changed at 0°C due to disordering in the potassium sublattice. An analogous phenomenon was found for fluoride phosphates $\text{KM}^{\text{III}}\text{FPO}_4$ ($\text{M}^{\text{III}} = \text{Al}$, Fe). Like in the structure of KTiOPO_4 , disordering in the potassium sublattice was observed in the structure of KFeFPO_4 . As a result, two additional positions are present along with two statistically occupied potassium positions. The occupancies of these four positions are 0.9, 0.92, 0.1 and 0.08. At a temperature of about -100°C , the K atoms are partially ordered, two main and one additional positions with the occupancies of 1.0, 0.94 and 0.06, respectively, being retained. Disorder in the potassium sublattice disappeared as the temperature was lowered to

¶ Our data.

Table 8. Crystallographic characteristics of the $M^I M^{III} FPO_4$ and $M^I M^{III} F_{1-\delta}(OH)_\delta PO_4$ compounds.

Compound (mineral name)	Crystal system	Space group	Z	Unit cell parameters				Ref.

^a Our data.

–173 °C.^{113, 114} Apparently, a more detailed study of this phenomenon will allow one to reveal correlations between the ionic conductivity and nonlinear optical properties of these compounds.

The $KM^{III}FPO_4$ compounds ($M^{III} = Cr, Fe$) exhibit high thermal stability. The chromium compound is more stable and it melts congruently at a temperature above 1600 °C. For fluoride phosphate KFeFPO₄, a phase transition was found at $T = 850$ °C. At $T > 1150$ °C, this compound decomposes with the loss of oxygen to form complex iron(II) phosphates, viz., KFePO₄ and K₂Fe₂P₂O₇F₂ (as black melts).

The formation of complex fluoride hydroxide phosphates with composition $M^I M^{III}(OH)_\delta F_{1-\delta} PO_4$ is typical of such trivalent elements as Al, Fe, Ga and In in combination with lithium and large monovalent cations (K^+ , Rb^+ and NH_4^+) (see Table 8). As examples we refer to synthetic tavorite LiFe[(OH),F]PO₄ (see Ref. 83) and the natural mineral amblygonite LiAl[(OH),F]PO₄.^{81, 82} These compounds have framework structures. The PO₄ tetrahedra and $M^{III}O_6$ octahedra are the main structural elements of tavorite and amblygonite. These polyhedra are linked in chains along the [101] direction through the common (OH, F) vertices. These chains are linked in a three-dimensional framework through the PO₄ tetrahedra (Fig. 16a). The framework is penetrated by a series of rather broad channels occupied by lithium atoms.

The environment about the lithium atom in the structures of tavorite and amblygonite deserves attention (Fig. 16b). Thus, the structure of natural amblygonite contains two lithium positions with occupancies of 1/2, which are separated by a distance of 0.5 Å. These half-occupied positions are located in face-sharing five-vertex polyhedra which together form a distorted octahedron.

In the structure of montebrasite (OH-containing analogue of amblygonite), the nearest environment about the lithium atoms[†] is formed by five oxygen atoms. This is attributed to the fact that

[†] The lithium atoms statistically occupy two positions separated by a distance of 0.24 Å.

the oxygen atom belonging to the AlO₆ octahedron of one chain is involved in hydrogen bonding with the hydroxy group of the adjacent chain. In the structure of synthetic tavorite LiFe[(OH),F]PO₄, the coordination polyhedron about the lithium atom is the axially elongated strongly distorted square pyramid

**Figure 16.** Structure of LiFe[(OH),F]PO₄ projected onto the ac plane (a) and the $[LiO_4(O,F)]$ polyhedra (b).

LiO_4F whose base is formed by the O and F atoms located at virtually equal distances from the Li atom (1.92–2.13 Å). The oxygen atom occupying the fifth vertex is at a distance of 2.44 Å from lithium.

The compositions of the known indium fluoride hydroxide phosphates correspond to the formula $\text{M}^{\text{I}}\text{InF}_{0.7}(\text{OH})_{0.3}\text{PO}_4$ ($\text{M}^{\text{I}} = \text{K}, \text{Rb}, \text{NH}_4$) (see Table 8). Apparently, the most stable structures are formed at the $\text{F}^-:\text{OH}^-$ ratio of 0.7:0.3. This conclusion is confirmed by the occurrence of analogous aluminium fluoride hydroxide phosphate $(\text{NH}_4)_{0.88}(\text{H}_3\text{O})_{0.12}\text{AlF}_{0.67}(\text{OH})_{0.33}\text{PO}_4$,¹⁰³ and gallium fluoride hydroxide phosphate $\text{KGaF}_{0.7}(\text{OH})_{0.3}\text{PO}_4$.⁸⁶ The $\text{M}^{\text{I}}\text{InF}_{0.7}(\text{OH})_{0.3}\text{PO}_4$ compounds ($\text{M}^{\text{I}} = \text{K}, \text{Rb}, \text{NH}_4$) are isostructural to KInFPO_4 and $\text{RbIn}(\text{OH})\text{PO}_4$.¹¹⁷ The $\text{KGaF}_{0.7}(\text{OH})_{0.3}\text{PO}_4$ compound belongs to the KTiOPO_4 structural type.

In the structure of $\text{M}^{\text{I}}\text{InF}_{0.7}(\text{OH})_{0.3}\text{PO}_4$, the fluoride and hydroxide ions statistically occupy one position. This replacement is quite reasonable and results from the similar sizes of these anions [$r(\text{F}^-) = 1.15 \text{ Å}$, $r(\text{OH}^-) = 1.18 \text{ Å}$]. The transformation of structurally similar fluorine-containing indium potassium phases $\text{KInF}_{1-\delta}(\text{OH})_{\delta}\text{PO}_4$ ($\delta = 0$ and 0.3) into hydroxide phosphate $\text{KIn}(\text{OH})\text{PO}_4$ is accompanied by lowering of the symmetry of the crystal lattice from tetragonal to orthorhombic. Hence, even the partial replacement of the OH groups by the fluoride ions in the structure of $\text{KIn}(\text{OH})\text{PO}_4$ leads to stabilisation of a more symmetrical structure, which is confirmed by X-ray diffraction analysis, electron diffraction study and the results of IR and Raman spectroscopy. Decomposition of $\text{KInF}_{0.7}(\text{OH})_{0.3}\text{PO}_4$ in air is a complex process giving rise to fluoride InF_3 and indium oxofluoride InOF as intermediates, which are transformed into $\text{K}_3\text{In}(\text{PO}_4)_2$, InPO_4 and cubic In_2O_3 .

The structure of the $(\text{NH}_4)_{0.93}(\text{H}_3\text{O})_{0.07}\text{GaF}_{0.5}(\text{OH})_{0.5}\text{PO}_4$ compound contains the $\text{GaO}_4(\text{OH})$ trigonal bipyramid and the $\text{GaO}_4[\text{F},(\text{OH})]_2$ octahedron as the main building blocks linked to each other by two PO_4 tetrahedra.¹⁰⁶ These blocks are linked in layers. The channels extended along the [001] direction are occupied by the NH_4^+ cations. The replacement of one-half of fluoride ions in the $(\text{NH}_4)\text{GaFPO}_4$ compound by the hydroxide ions leads to a radical rearrangement of the fluoride phosphate structure. In the structure of the $(\text{NH}_4)_{0.93}(\text{H}_3\text{O})_{0.07}\text{GaF}_{0.5}(\text{OH})_{0.5}\text{PO}_4$ compound,¹⁰⁴ the bridging position linking the gallium cations is completely occupied by the hydroxy groups. The ammonium-containing compounds readily decompose to the corresponding orthophosphates $\text{M}^{\text{III}}\text{PO}_4$.

Polymorphism was found in most of representatives of fluoride phosphates with composition $\text{Na}_3\text{M}_2^{\text{III}}\text{F}_3(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{Al}, \text{V}, \text{Cr}, \text{Fe}$) and several (up to three) polymorphic modification (α, β, γ) were revealed.⁸⁷ The relationships between the unit cell parameters of the α, β and γ modifications are shown in Fig. 17. The high-temperature α modifications of Al, V, Cr and Fe fluoride phosphates are isostructural, whereas the β modifications stable at low temperatures are structurally different (β' and β'') (Table 9). The unit cell volumes of the β' modifications are four times

Figure 17. Relationship between the unit cell parameters of the α, β and γ modifications $\text{M}_3^{\text{I}}\text{M}_2^{\text{III}}\text{F}_3(\text{PO}_4)_2$.⁸⁷ The a and b parameters correspond to the α modification, a' and b' correspond to the β' modification, a'' and b'' correspond to the β'' modification and a''' and b''' correspond to the γ modification.

larger than those of the α modifications of the same compounds. The β' polymorphic modification is typical of Al, Cr(III) and Ga fluoride phosphates. The unit cell volumes for the β'' modification of vanadium(III) and iron(III) fluoride phosphates are twice as large as those for the α modifications. The γ modification was found only for an iron compound.

The β and α modifications differ primarily in the arrangement of the sodium atoms. In the high-temperature tetragonal unit cell of the β' modification (space group $I4/mmm$), the alkali-metal atoms are shifted only slightly as compared to the sodium positions in the unit cell of the α modification, whereas substantial shifts (by 0.3–0.5 Å) are observed in the tetragonal structures of the β' and β'' modifications (space group $I4_2/mbc$ and $I4_2/mnm$, respectively). The volume of the orthorhombic unit cell of the γ modification ($T = -190^\circ\text{C}$) of $\text{Na}_3\text{Fe}_2\text{F}_3(\text{PO}_4)_2$ (space group $Pbam$) is twice as large as the unit cell volume of the β'' modification. The γ and β'' modifications of $\text{Na}_3\text{Fe}_2\text{F}_3(\text{PO}_4)_2$ differ primarily in the positions occupied by sodium cations and distortion of the polyhedra in the structures. The transformation $\gamma \rightarrow \beta''$ is accompanied by deformation of the $[\text{Fe}_2\text{F}_3\text{O}_8]^{3-}$ polyhedron and displacement of the Na^+ cation by 0.7 Å.

The tetragonal α modification of the $\text{Na}_3\text{M}_2^{\text{III}}\text{F}_3(\text{PO}_4)_2$ compounds ($\text{M}^{\text{III}} = \text{Al}, \text{Fe}, \text{Cr}$) consists of the $\text{M}^{\text{III}}\text{O}_4\text{F}_2$ octahedra and the isolated PO_4 tetrahedra as the structural blocks (Fig. 18a). The octahedra are linked in pairs through the fluoride bridges. These doubled octahedra $\text{M}_2^{\text{III}}\text{O}_8\text{F}_3$ are linked in a mixed framework through the phosphate tetrahedra. The sodium atoms occupy the channels. The characteristic structural feature of these compounds is the statistical distribution of the alkali-metal atoms in the unit cell. Due to triple disorder, there are three modes of coordination of the sodium ions, all these atoms being located approximately on a circle with a diameter of 1.9–2.2 Å (Fig. 18b).

At room temperature, the β' - $\text{Na}_3\text{Al}_2\text{F}_3(\text{PO}_4)_2$ compound crystallises in the tetragonal system (space group $P4_2/mbc$) but exhibits a superstructure.

The partial replacement of the fluoride ions in the $\text{Na}_3\text{Fe}_2\text{F}_3(\text{PO}_4)_2$ compound by the hydroxy groups leads to the formation of $\text{Na}_3\text{Fe}_2[(\text{OH})_2\text{F}](\text{PO}_4)_2$ (see Ref. 85) isostructural to β' - $\text{Na}_3\text{V}_2\text{F}_3(\text{PO}_4)_2$ (see Table 9). In the structure of $\text{Na}_3\text{Fe}_2[(\text{OH})_2\text{F}](\text{PO}_4)_2$, the $[\text{Fe}_2\text{O}_8\text{F}_3]$ bioctahedra are deformed resulting in a doubling of the unit cell volume as compared to that of $\text{Na}_3\text{Fe}_2\text{F}_3(\text{PO}_4)_2$.

Ammonium-containing gallium fluoride phosphate $(\text{NH}_4)_2\text{Ga}_2\text{F}_3(\text{PO}_4)(\text{HPO}_4)$ ¹⁰⁶ (see Table 9) was assigned to the 'pseudo-KTP' type related to the KTP type (KTiOPO_4) (Fig. 19a). In compounds of the 'pseudo-KTP' type, only three of four oxygen atoms of each PO_4 tetrahedron are involved in the octahedral environment about gallium to form the GaO_4F_2 and

Figure 18. Structure $\text{Na}_3\text{Al}_2\text{F}_3(\text{PO}_4)_2$. Overall view (a); a one-layer fragment projected onto the ab plane (b).

Figure 19. Relationship between the 'pseudo-KTP'-type structure of $(\text{NH}_4)_2\text{Ga}_2\text{F}_3(\text{PO}_4)(\text{HPO}_4)$ (a) and the KTP-type structure of $(\text{NH}_4)\text{GaF}(\text{PO}_4)$ (b). Layered fragments are shown. The ammonium groups are omitted.

GaO_3F_3 octahedra, as distinct from compounds of the KTP type in which all oxygen atoms of the PO_4 tetrahedra are involved in the $\text{M}^{\text{III}}\text{O}_6$ octahedra. The structure of the 'pseudo-KTP' type can be transformed into the structure of the KTP type by rotation of the corresponding PO_4 tetrahedra and GaO_3F_3 octahedra (see Fig. 19). In the KTP-type structures, the channels extended along the [100] direction have regular hexagonal cross-sections, whereas the channels along the [010] direction have distorted hexagonal cross-sections (Fig. 19 b). The framework structure of the $(\text{NH}_4)_2\text{Ga}_2\text{F}_3(\text{PO}_4)(\text{HPO}_4)$ compound is more distorted as compared to the structure of $(\text{NH}_4)\text{GaFPO}_4$.

Fluoride phosphates $\text{Na}_5\text{M}^{\text{III}}\text{F}_2(\text{PO}_4)_2$ with $\text{M}^{\text{III}} = \text{Al}, \text{Cr}, \text{Ga}$ ^{91, 92} crystallise in the trigonal system (Table 10), whereas an analogous iron compound is characterised by lower symmetry (orthorhombic). The $\text{Na}_5\text{M}^{\text{III}}\text{F}_2(\text{PO}_4)_2$ compounds can be assigned to layered structures. These structures contain corrugated layers parallel to the *ab* plane. The layers are built from the $\text{M}^{\text{III}}\text{O}_4\text{F}_2$ octahedra and the PO_4 tetrahedra (Fig. 20 a,b). One-third of all sodium atoms are located in these layers. The sodium atoms occupy from 6 (in the aluminium-containing compound) to 9 (in the chromium- and gallium-containing compounds) and 10 (in the iron-containing compounds) crystallographically independent positions most of which are statistically occupied. In the structures of these compounds, the alkali-metal atoms are located only in the centres of octahedra, which are formed either by oxygen atoms or together by fluorine and oxygen atoms (NaO_6 , NaO_5F , NaO_4F_2 , NaO_3F_3). For iron, not only fluoride phosphate with composition $\text{Na}_5\text{FeF}_2(\text{PO}_4)_2$ but also oxofluoride phosphates with variable composition $\text{Na}_{5-x}\text{Fe}(\text{O},\text{F})(\text{PO}_4)_2$ ($x = 0.4$ and 0.5) are known. Modulations of the atomic positions were revealed in the structures of the latter compounds.^{93–95} The reversible phase transition from one modulated phase to another (I→II) observed at $T = 257^\circ\text{C}$ is associated with slight displacements of the atoms and a change in the direction of the modulation vector. The investigation of polymorphism in $\text{Na}_{4.5}\text{Fe}(\text{O},\text{F})(\text{PO}_4)_2$ (see Ref. 95) depending on the temperature ($T < 1000^\circ\text{C}$) and pressure ($p = 1 \times 10^5 - 1.2 \times 10^{10}$ Pa) revealed the presence of one (at $T \approx 260^\circ\text{C}$, $p = 101.3$ kPa) and two [at $p_1 = 1.39(8)$ GPa and $p_2 = 4.52(32)$ GPa] polymorphic transformations, respectively. The modulation effect in the structure of $\text{Na}_{4.6}\text{Fe}(\text{O}_{0.6}\text{F}_{0.4})(\text{PO}_4)_2$ has no influence on the ionic transport ($\sigma_0 \approx 1.17 \times 10^4 - 1.88 \times 10^4$ S cm⁻¹, $E_a = 0.33$ eV) and dielectric properties.

The difference in occupancies of the same positions by sodium atoms in the isotopic structures of fluoride phosphates $\text{Na}_3\text{M}^{\text{III}}\text{F}_3(\text{PO}_4)_2$ and $\text{Na}_5\text{M}^{\text{III}}\text{F}_2(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{Al}, \text{Fe}, \text{Ga}$) is indicative of the possible ionic conductivity. At $T = 0^\circ\text{C}$, the

measured specific conductivity (σ) of the $\text{Na}_5\text{M}^{\text{III}}\text{F}_2(\text{PO}_4)_2$ compounds ($\text{M}^{\text{III}} = \text{Al}, \text{Ga}$) is approximately equal to 10^{-7} S cm⁻¹ and it increases by only three orders of magnitude (to $\sigma \approx 10^{-4}$ S cm⁻¹) as the temperature is raised to 327°C .⁹¹ As mentioned above, the Na^+ ions can migrate only in some of the

Figure 20. Structure of $\text{Na}_5\text{M}^{\text{III}}\text{F}_2(\text{PO}_4)_2$ ($\text{M}^{\text{III}} = \text{Al}, \text{Cr}, \text{Ga}$) projected along the [001] direction (a) and the one-layer fragment projected onto the *ab* plane (b).

Figure 21. Structure of $\text{Na}_3\text{Al}_2\text{F}_3(\text{PO}_4)_2$ projected onto the ab plane. Different trajectories of motion of the Na^+ ions are shown.

channels in the structures of $\text{Na}_3\text{M}_2^{\text{III}}\text{F}_3(\text{PO}_4)_2$. The $\text{Na}_3\text{Al}_2\text{F}_3(\text{PO}_4)_2$ compound is characterised by a rather high activation energy (0.80 eV at 500 °C), which prevents the wide use of this fluoride phosphate as a ionic conductor. This compound is inferior to the recognised sodium conductors, such as compounds of the NASICON type ($E_a \approx 0.35$ eV) or $\text{Na}-\beta\text{-Al}_2\text{O}_3$ ($E_a \approx 0.14$ eV).

Based on the analysis of the sizes and geometry of the cavities occupied by the sodium atoms, several possible trajectories of motion of alkali cations in the structure were proposed, *viz.*, the migration from one cavity to another through a distance of 2.72 Å and/or the local motion around a circle within each cavity. These trajectories are schematically shown in Fig. 21.[‡]

Fluoride phosphate $\text{K}_3\text{Al}_4\text{F}_9(\text{PO}_4)_2$ (see Ref. 108) crystallises in another structural type characterised by the presence of the $[\text{Al}_4\text{F}_9\text{O}_8]_n$ chains (Fig. 22 *a*). The structural block of the chain is formed by four vertex-sharing AlO_2F_4 octahedra with the *cis* arrangement of the oxygen atoms (Fig. 22 *b*). In the perpendicular direction, the chains are linked to each other through the PO_4 tetrahedra to form a three-dimensional framework whose channels are occupied by the potassium ions (Table 11). A change in

Figure 22. Structure of $\text{K}_3\text{Al}_4\text{F}_9(\text{PO}_4)_2$ projected onto the ab plane (*a*) and the mode of linkage of the AlO_2F_4 octahedra in the chain (*b*).

the Al:F:P ratio from 1:1:1 corresponding to the KAIFPO_4 compound to 2:4.5:1 corresponding to the $\text{K}_3\text{Al}_4\text{F}_9(\text{PO}_4)_2$ compound is associated with a more complex mode of linkage of the octahedra in the chains in the latter compound.

The data on apatite-type compounds containing M^{I} , M^{II} and M^{III} cations instead of (or along with) calcium are concerned primarily with sodium derivatives of particular REE (see Table 11). The parent compound of this family, *viz.*, potassium fluoride phosphate $\text{Ca}_{10}\text{F}_2(\text{PO}_4)_6$ (fluoroapatite), crystallises in the hexagonal system (space group $P6_3/m$) (Fig. 23 *a*).¹¹⁸ In the unit cell of $\text{Ca}_{10}\text{F}_2(\text{PO}_4)_6$, six PO_4 tetrahedra are located on mirror planes ($z = 1/4$ and $3/4$). The calcium cations occupy two crys-

^a The pressure was 18 bar.

tallographically independent positions. The Ca(1) cations lie on threefold axes in the positions $(1/3, 2/3, z)$ and form the CaO_9 polyhedra in which six Ca–O distances have close values and are substantially shortened (2.43–2.47 Å) as compared to the remaining three distances (2.83 Å). The Ca(2) cations are located on the planes m in the positions $(x, y, 1/4)$ and form the $\text{Ca(2)O}_8\text{F}$ polyhedra in which six O atoms are at distances of 2.36–2.53 Å, the F atom is located at a distance of 2.26 Å and two substantially remote O atoms are at distances of 3.27 Å. Two F^- ions lie on the 6_3 axis.

In apatite-type structures, impurity cations (in particular, REE) are differently distributed over two crystallographically non-equivalent calcium positions (Fig. 23b).[§] In the structure of Nd-doped fluoroapatite, the positions occupied by neodymium atoms depend on the mechanism of replacement.⁹⁷ When neodymium was introduced as trifluoride NdF_3 , the Ca(1) and Ca(2) positions were equally replaced by Nd. By contrast, the use of Nd_2O_3 as a source of REE led to the structure in which neodymium atoms occupy predominantly the Ca(2) position. In the hexagonal structure of $\text{Na}_2\text{Ba}_6\text{La}_2\text{F}_2(\text{PO}_4)_6$, the La^{3+} and Na^+ ions statistically occupy both positions, viz., Ca(1) and Ca(2). In the trigonal structure of $\text{Na}_3\text{Ba}_4\text{Nd}_3\text{F}_2(\text{PO}_4)_6$, two-third of all Nd^{3+} and Na^+ ions occupy the Ca(1) positions, whereas the remaining atoms are disordered in the Ca(2) positions.

Fluoride phosphates with composition $\text{Na}_2\text{Ca}_6\text{M}_2^{\text{III}}\text{F}_2(\text{PO}_4)_6$ ($\text{M}^{\text{III}} = \text{Sm}, \text{Eu}$),^{98, 99} like non-doped fluoroapatite, crystallise in the hexagonal system. The Eu^{3+} ions occupy the Ca(1) positions by approximately 75% and the alkali-metal ions are located only in the Ca(2) positions, whereas the opposite situation is observed in the structure of the samarium compound. In the latter structure, the sodium atoms are located only in the Ca(1) positions, whereas the REE ions replace the Ca(2) atoms by 78.5%. In fluoroapatite-type structures, the REE atoms have different coordination numbers (7 and 9).

The REE compounds, which crystallise in the apatite structural type, can be used as catalysts, ion-exchange phases and luminescent materials. The $\text{Na}_2\text{Ca}_6\text{Tb}_{1.75}\text{Y}_{0.25-x}\text{Eu}_x\text{F}_2(\text{PO}_4)_6$ compound was found to exhibit luminescence properties.¹¹⁹ The introduction of europium leads to weakening of radiation by the Tb^{3+} cations, which is indicative of the charge transfer from Tb^{3+} to Eu^{3+} .

§ Figure 23b was published by P K Rastsvetaeva, A P Khomyakov *Kristallografiya* **41** 831 (1996); [*Crystallogr. Rep. (Engl. Transl.)* **41** 789 (1996)].

Hence, there are several types of fluoride phosphates containing mono- and trivalent cations, which differ in composition and structure (Table 12). Compounds belonging to the same type are either isostructural or structurally related. Variations in the type and ratio of the ions in the cation sublattice as well as a change of the anion composition in complex phosphates containing mono- and trivalent cations by partially replacing the PO_4 tetrahedral groups with anions of different nature (F^-) lead not only to the formation of compositionally different compounds with different $\text{M}^{\text{I}}:\text{M}^{\text{III}}:\text{PO}_4^{3-}$ ratios but also to a radical rearrangement of the

V. Hydroxide phosphates containing mono- and trivalent cations

Like fluoride-containing analogues, hydroxide phosphates are characterised by complex compositions combining tri- and mono-valent cations. The similarity between the effective ionic radii of the F^- and OH^- anions and the formation of bonds between these anions and the M^{III} cations of comparable strength are responsible for the occurrence of the $M^IM^{III}(OH)PO_4$ compounds compositionally similar to $M^IM^{III}FPO_4$. However, hydroxide phosphates with compositions untypical of fluoride phosphates are also known:

Some compounds of the $M^IM^{III}(OH)PO_4$ group as well as a series of phases with composition $M^IM_2^{III}(OH)(PO_4)_2 \cdot 2H_2O$ were found as minerals. Complex hydroxide phosphates of all these types are known for M^{III} cations with small ionic radii (Al, Ga, In, V, Fe, Mn).

1. Synthesis

The mineral tavorite $LiFe(OH,F)PO_4$ is the Fe-containing analogue of montebrazite $LiAl(OH)PO_4$ (see Ref. 81) belonging to the group of amblygonite $LiAl(OH,F)PO_4$. The ideal compositions of tavorite and amblygonite are described by the formulas

$LiFe(OH)PO_4$ (see Ref. 120) and $LiAlFPO_4$ (see Ref. 81), respectively. Being a rare mineral from lithium pegmatites, tavorite is unstable under natural conditions. Various paragenetic associations are typical of minerals of the leucophosphate group of the general formula $M^IM_2^{III}(OH)(PO_4)_2 \cdot 2H_2O$, where $M^I = K, NH_4$ and $M^{III} = Al, Fe$. Leucophosphate $KFe_2(OH)(PO_4)_2 \cdot 2H_2O$ ^{121, 122} by itself is a product formed by the action of organic solutions derived from bat guano with iron oxides in serpentine rocks or is generated in late stages of the hydrothermal transformation of triphylite in pegmatites. Tinsleyite¹²³ (Al analogue of leucophosphate) was found together with $KFe_2(OH)(PO_4)_2 \cdot 2H_2O$ in pegmatites. Spheniscidite $(NH_4)Fe_2(OH)(PO_4)_2 \cdot 2H_2O$ ^{124, 125} is formed by the actions of ammonium phosphate solutions of penguin guano with mica and chlorite minerals. Cyrilovite $NaFe_3(OH)_4(PO_4)_2 \cdot 2H_2O$ ¹²⁶ which is the Fe-containing final member of the series of minerals belonging to the group of wardite $Na(Al,Fe)_3(OH)_4(PO_4)_2 \cdot 2H_2O$, is fragmentary present in pegmatites and can occupy cavities of oxidation zones of ferrous precipitates.

Most of the compounds under consideration were synthesised under hydrothermal conditions (Table 13).^{117, 122, 125, 127–135} The simultaneous action of pressure and temperature leads to a substantial increase in solubility of the compounds under study in active aqueous media and is favourable for the preparation of complex M^{III} hydroxide phosphates as highly crystalline powders and well-faceted crystals, which cannot, in principle, be grown by alternative methods. Unlike Al- and Fe-containing phases of the $M^IM^{III}(OH)PO_4$ type, their indium analogues do not form minerals of their own. Single crystals of hydroxide phosphates $KIn(OH)PO_4$ (see Ref. 127) and $RbIn(OH)PO_4$ (see Ref. 117) were obtained under drastic conditions (900 and 550 °C, respectively) followed by stepwise cooling. It should be noted that these phases are stable at pH 7–8. Attempts to prepare polycrystalline

samples of $\text{MIn}(\text{OH})\text{PO}_4$ ($\text{M} = \text{K}, \text{Rb}$) in pure form failed. These samples contained unconsumed In_2O_3 even when the synthesis was carried out for 2–3 weeks. Under these conditions, the sodium analogue $\text{NaIn}(\text{OH})\text{PO}_4$ is not formed.

The hydrothermal synthesis of hydroxide phosphates of the leucophosphate group is characterised by a wide variety of the starting reagents. In a number of studies aimed at preparing porous organometallic phosphate compounds, hydroxide phosphates with composition $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{OH})(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ were synthesised.^{125, 128} Ammonium leucophosphate was prepared not only by the hydrothermal method with the use of aqueous solutions but also by the low-temperature synthesis from hydrogel ($T = 150^\circ\text{C}$, $\tau = 45$ h, pH of the final solution was 6.52).¹²⁴ The $\text{M}_{1.5}^{\text{I}}[\text{M}_2^{\text{III}}\text{O}_{0.5}(\text{OH})_{0.5}(\text{PO}_4)_2(\text{H}_2\text{O})] \cdot x\text{H}_2\text{O}$ compounds¹²⁹ ($\text{M}^{\text{I}} = \text{K}, \text{Rb}$), which are structurally similar to compounds of the leucophosphate group, are generated from mixtures of $\text{Al}(\text{OH})_3$ and $\text{M}^{\text{I}}\text{H}_2\text{PO}_4$ in the temperature range of $175\text{--}225^\circ\text{C}$. The $\text{NaAl}(\text{OH})\text{PO}_4$ and $(\text{NH}_4)\text{Al}_2(\text{OH})(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ compounds were prepared with the use of NaH_2PO_4 and $(\text{NH}_4)\text{H}_2\text{PO}_4$, respectively.^{130, 131} Hydroxide phosphates of this type are stable in weakly acidic and neutral media at pH 2.5–7.5.

The $\text{M}_4^{\text{I}}\text{M}^{\text{III}}(\text{OH})(\text{PO}_4)_2$ compounds ($\text{M}^{\text{I}} = \text{Na}$; $\text{M}^{\text{III}} = \text{Al}, \text{Ga}$)¹³² are formed as transparent elongated prismatic crystals in an alkaline medium (pH 10–12) under mild hydrothermal conditions in the presence of an excess of alkali cations ($\text{Na} : \text{Al} \geq 3$). The structurally related $\text{M}_2^{\text{I}}\text{M}^{\text{III}}(\text{OH})(\text{HPO}_4)(\text{PO}_4)$ compounds ($\text{M}^{\text{I}} = \text{Na}$; $\text{M}^{\text{III}} = \text{Al}, \text{Ga}$)¹³³ were prepared from weakly alkaline media at high temperatures (600°C) using stepwise cooling. The $\text{Na}_3\text{Al}(\text{OH})(\text{HPO}_4)(\text{PO}_4)$ and $\text{Na}_3\text{Ga}(\text{OH})(\text{HPO}_4)(\text{PO}_4)$ compounds crystallise as colourless prisms and thin platelet-like crystals, respectively.

2. Structures and properties

There is an obvious structural analogy between all hydroxide phosphates, except for compounds belonging to the $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{OH})\text{PO}_4$ group. The crystal chemistry of the latter compounds radically changes depending on the nature of the M^{I} and M^{III} cations.

Recent studies dealing with the determination of the crystal structures of complex hydroxide phosphates were aimed primarily at refining the assignment of a particular compound to the structural type (with a typical alternation of the cations and anions) and revealing the crystal-chemical features of the structures of the compounds synthesised.

Minerals with composition $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{OH})\text{PO}_4$, where $\text{M}^{\text{I}} = \text{Li}, \text{Na}$ and $\text{M}^{\text{III}} = \text{Al}, \text{Fe}$, are isomorphous. These compounds are characterised by high mobility of alkali atoms in the channels of the structures. The structural feature of this group of complex phosphates is the presence of chains built from the vertex-sharing FeO_6 or AlO_6 octahedra linked by OH groups (Table 14). Mixed frameworks containing such chains are also typical of kizerite ($\text{MgSO}_4 \cdot 2\text{H}_2\text{O}$), titanite (CaTiOSiO_4) and isostructural minerals (space group $C2/c$).⁸¹

In a manganese analogue of tavorite, *viz.*, $\text{LiMn}(\text{OH})\text{PO}_4$,¹³⁴ strong distortion of the $\text{MnO}_4(\text{OH})_2$ octahedra gives rise to a substantial ferromagnetic component although this compound

belongs to antiferromagnetics. The elongated $\text{Mn}-\text{O}$ bonds (O are the oxygen atoms of the PO_4 groups) make the main contribution to the direction of the vector of the magnetic moment. As a result, the vectors of the magnetic moments of the $\text{MnO}_4(\text{OH})_2$ octahedra belonging to the same chain are parallel, co-directed and virtually perpendicular to the $\text{M}-\text{OH}-\text{M}$ bond. This direction of the vectors of the magnetic moments is responsible for the ferromagnetic properties of the $\text{LiMn}(\text{OH})\text{PO}_4$ compound.¹³⁴

On going from iron- and manganese-containing compounds [$r_{\text{VI}}(\text{Fe}^{3+}) = 0.645 \text{ \AA}$, $r_{\text{VI}}(\text{Mn}^{3+}) = 0.65 \text{ \AA}$] to indium compounds [$r_{\text{VI}}(\text{In}^{3+}) = 0.79 \text{ \AA}$], the structural type changes attended with an increase in the symmetry from triclinic to orthorhombic and tetragonal (see Table 14). An increase in the ionic radius of alkali metal on going from potassium to rubidium also leads to an increase in the symmetry from orthorhombic to tetragonal. Complex indium hydroxide phosphates containing different monovalent cations have compositions in which the ratio $\text{M}^{\text{I}} : \text{M}^{\text{III}} : \text{PO}_4^{3-} = 1 : 1 : 1$ is retained. The structure of orthorhombic indium hydroxide phosphate $\text{KIn}(\text{OH})\text{PO}_4$ is based on helical chains of the $\text{InO}_4(\text{OH})_2$ octahedra sharing *cis* vertices.¹²⁷ These chains are extended along the *c* axis (Fig. 24*a*). The polyhedra about the potassium cations (KO_7) can be described as distorted trigonal antiprisms. In the structures of NH_4In and RbIn hydroxide phosphates, the presence of screw axes 4_3 leads to an ordered arrangement of the polyhedra in helical chains so that the channels of virtually square cross-section are formed along the $[001]$ direction (Fig. 24*b*). The NH_4^+ and Rb^+ ions are surrounded by nine oxygen atoms each.

In the structures of the $\text{M}^{\text{I}}\text{In}(\text{OH})\text{PO}_4$ compounds ($\text{M}^{\text{I}} = \text{Rb}$ and NH_4), the indium octahedra are almost non-distorted. Thus, the difference in the $\text{In}-\text{O}$ bond lengths is $0.003 \text{ \AA}$ and $0.059 \text{ \AA}$ in $(\text{NH}_4)\text{In}(\text{OH})\text{PO}_4$ (see Ref. 135) and $\text{RbIn}(\text{OH})\text{PO}_4$ (see Ref. 117), respectively. The crystallographically independent indium atoms alternate along the helical chains and are linked to each other through the bridging oxygen atoms of the hydroxy groups, which are not involved in hydrogen bonding with the nearest environment. The presence of independent OH groups in the structures was confirmed by IR spectroscopy ($\nu \approx 3520 \text{ cm}^{-1}$). Each PO_4 tetrahedron shares two vertices with the InO_6 octahedra belonging to the same chain and shares two other vertices with the octahedra from the adjacent chain. The chains are linked through the tetrahedra to form a framework whose large cavities are occupied by single-charged cations. The framework of the $\text{KIn}(\text{OH})\text{PO}_4$ compound is similar to that of $\gamma\text{-NaTiOPO}_4$.¹³⁶ The difference is observed in the positions of the alkali cations located in the tunnels of these structures.

The fact that indium and scandium have similar ionic radii [$r_{\text{VI}}(\text{Sc}^{3+}) = 0.745 \text{ \AA}$] as well as the fact that $\text{KIn}(\text{OH})\text{PO}_4$ and $\text{RbIn}(\text{OH})\text{PO}_4$ belong to different structural types indicate that related hydroxide phosphate $\text{KSc}(\text{OH})\text{PO}_4$ may occur. Apparently, the sodium-containing analogue with composition $\text{NaIn}(\text{OH})\text{PO}_4$ that is structurally similar to $\text{KIn}(\text{OH})\text{PO}_4$ does not occur. In this case, the steric factor is of considerable importance because the difference in the sizes of the potassium and sodium cations is much larger than that in the sizes of the potassium and rubidium cations.

Table 14. Crystallographic characteristics of the $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{OH})\text{PO}_4$ compounds.

Compound (mineral name)	Crystal system	Space group	<i>Z</i>	Unit cell parameters				Ref.
				<i>a</i> / $\text{\AA}$	<i>b</i> / $\text{\AA}$	<i>c</i> / $\text{\AA}$	α, β, γ / deg	
$\text{LiAl}(\text{OH})\text{PO}_4$ (montebrasite)	triclinic	$C\bar{1}$	4	6.713	7.708	7.019	91.31, 117.93, 91.77	81
$\text{LiFe}(\text{OH})\text{PO}_4$ (tavorite)	"	$P\bar{1}$	2	5.340	7.283	5.110	109.29, 97.86, 106.32	120
$\text{LiMn}(\text{OH})_{0.442}(\text{OH})_{0.558}\text{PO}_4$	"	$C\bar{1}$	4	6.719	8.187	7.123	89.5, 117.7, 86.4	134

Figure 24. Chains of the $(\text{OH})_2$ octahedra in the structure of $(\text{NH}_4)\text{In}(\text{OH})\text{PO}_4$ along the $[110]$ direction (a) and the structure of $(\text{NH}_4)\text{In}(\text{OH})\text{PO}_4$ projected onto the ab plane (b).

Hence, analysis of the structural types in the morphotropic series $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{OH})\text{PO}_4$ demonstrates that the structures of these compounds are characterised by the presence of chains or ribbons, which are built from octahedra of the trivalent cations linked to each other through the OH vertices.

Taking into account the structural and compositional similarity, the $\text{M}^{\text{I}}\text{In}(\text{OH})\text{PO}_4$ compounds ($\text{M}^{\text{I}} = \text{K}, \text{Rb}$ and NH_4) can be compared with phases related to KTiOPO_4 . It is known that the TiO_6 octahedra in the structure of KTiOPO_4 are substantially distorted with alternation of short and long bonds along the $-\text{O}-\text{Ti}(1)-\text{O}-\text{Ti}(2)-\text{O}-$ chain. The differences between the long and short $\text{Ti}(1)-\text{O}$ and $\text{Ti}(2)-\text{O}$ bonds are 0.275 and 0.363 Å, respectively.¹¹⁶ These differences in the bond lengths are of importance in determining the nonlinear optical properties of the KTP-type $\text{A}^{\text{I}}\text{B}^{\text{IV}}\text{O}_x\text{V}_y\text{O}_4$ compounds. However, weak distortion of the $\text{M}^{\text{III}}\text{O}_6$ and $\text{M}^{\text{III}}\text{O}_x\text{F}_y$ octahedra in the structures of complex indium phosphates, such as $\text{M}^{\text{I}}\text{In}(\text{OH})\text{PO}_4$ ($\text{M}^{\text{I}} = \text{K}, \text{Rb}, \text{NH}_4$), KInFPO_4 and $\text{M}^{\text{I}}\text{InF}_{1-\delta}(\text{OH})_\delta\text{PO}_4$ ($\text{M}^{\text{I}} = \text{K}, \text{Rb}, \text{NH}_4$), and in the structures of $\text{M}^{\text{I}}\text{M}^{\text{III}}\text{F}_{1-\delta}(\text{OH})_\delta\text{PO}_4$ ($\text{M}^{\text{I}} = \text{K}, \text{NH}_4$; $\text{M}^{\text{III}} = \text{Ga}, \text{Fe}$) is responsible for the fact that these compounds do not exhibit nonlinear optical properties.

Two minerals, viz., wardite $\text{NaAl}_3(\text{OH})_4(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ ¹³⁷ and cyrilovite $\text{NaFe}_3(\text{OH})_4(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$,¹²⁶ belong to hydroxide

phosphates with composition $\text{M}^{\text{I}}\text{M}^{\text{III}}(\text{OH})_4(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$. These compounds crystallise in the tetragonal system (space group $P4_12_12$, $Z = 4$). The unit cell parameters of wardite ($a = 7.030$, $c = 19.040$ Å) are close to those of cyrilovite ($a = 7.313$, $c = 19.315$ Å). The structures of these minerals are composed of the layers located perpendicular to the $[001]$ direction. The layers consist of infinite chains of the alternating *cis*-linked $\text{M}(1)\text{O}_6$ and $\text{M}(2)\text{O}_6$ octahedra extended along the a and b axes (Fig. 25). In the $\text{M}(1)\text{O}_6$ octahedron, the M^{3+} cation is surrounded by three oxygen atoms of the PO_4 tetrahedra, two oxygen atoms of the OH groups and the oxygen atom of the water molecule. In the $\text{M}(2)\text{O}_6$ octahedron, the M^{3+} cation is surrounded by two oxygen atoms of the PO_4 groups and four oxygen atoms of the OH group. The $\text{M}(1)\text{O}_6$ octahedron is linked to two nearest $\text{M}(2)\text{O}_6$ octahedra through bridging hydroxy groups. The $\text{M}(2)\text{O}_6$ octahedron, in turn, is linked to four nearest strongly distorted $\text{M}(1)\text{O}_6$ octahedra through four hydroxy bridges. The cavities in the layers are occupied by sodium ions (coordination number is 8). The PO_4 tetrahedra share three vertices with three octahedra in the layer and one vertex with an octahedron from the adjacent layer, three vertices being involved in the $\text{M}(1)\text{O}_6$ octahedron and one vertex being involved in the $\text{M}(2)\text{O}_6$ octahedron.

In the mixed framework of the octahedra and tetrahedra, two types of channels are extended along the $[100]$ and $[010]$ directions. These channels are occupied by zeolite-type water molecules. The presence of water of crystallisation and bridging OH group in the structures was confirmed by IR spectroscopy. Analysis of the interatomic distances in the $\text{M}^{\text{III}}\text{O}_6$ polyhedra in the $\text{NaM}^{\text{III}}(\text{OH})_4(\text{PO}_4)_2 \cdot n\text{H}_2\text{O}$ compounds and the radii of the M^{III} cations demonstrated that the octahedral positions can be occupied not only by the Al and Fe cations but also by the gallium and vanadium cations with no changes in the crystal structure. The occurrence of potassium analogues is highly improbable because of the small sizes of the cavities in the layers.

Minerals of the leucophosphate of the general formula $\text{M}^{\text{I}}\text{M}_2^{\text{III}}(\text{OH})(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ ($\text{M}^{\text{I}} = \text{K}, \text{NH}_4$; $\text{M}^{\text{III}} = \text{Al}, \text{Fe}$) form a continuous series of low-temperature solid solutions. Three minerals of this series are known, viz., leucophosphate $\text{KFe}_2(\text{OH})(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$, tinsleyite $\text{KAl}_2(\text{OH})(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ and speniscidite $(\text{NH}_4, \text{K})(\text{Al}, \text{Fe})_2(\text{OH})(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$. Besides, the related synthetic KAl , NH_4Al , NH_4Ga and NH_4V analogues^{138–141} belong to this group (Table 15).

Figure 25. Structure of $\text{NaFe}_3(\text{OH})_4(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ projected onto the ab plane.

Table 15. Crystallographic characteristics of minerals of the leucophosphate group of the general formula $M^I M_2^{III}(\text{OH})(\text{PO}_4)_2 \cdot 2 \text{H}_2\text{O}$ and the $M_4 M^{III}(\text{OH})(\text{PO}_4)_2$ and $M_3 M^{III}(\text{OH})(\text{HPO}_4)(\text{PO}_4)$ compounds.

The compounds of this groups are characterised by the presence of the $M_4^{III}(\text{OH})_2(\text{H}_2\text{O})_2(\text{PO}_4)_4$ island fragment formed from four octahedra of two types, viz., $M(1)\text{O}_4(\text{OH})_2$ and $M(2)\text{O}_4(\text{OH})(\text{H}_2\text{O})$. The central core of this fragment consists of two edge-sharing $M(1)\text{O}_6$ octahedra[¶] with two anchored hydroxo groups. The $M(1)\text{O}_6$ octahedra share edges containing two OH vertices with two $M(2)\text{O}_6$ octahedra (Fig. 26 *a, b*). The fragments consisting of four $M^{III}\text{O}_6$ octahedra are linked in a framework through the isolated PO_4 tetrahedra. The channels of the structure are occupied by monovalent cations and water molecules.

In each independent $M^{III}\text{O}_6$ octahedron, four oxygen atoms are at short distances from the M^{3+} ion (these distances differ by only 0.03–0.04 Å), whereas two oxygen atoms are far remote from M^{III} . This distortion of the octahedra results from the fact that the oxygen atoms of the OH groups and water molecules must satisfy the valence balance rule. The octahedral coordination of the M^{III} cations is retained but the $M^{III}-\text{O}$ distances change as the ionic radius increases in the series $\text{Al}-\text{Ga}-\text{V}-\text{Fe}$. Analysis of the interatomic $M^{III}-\text{O}$ distances in the $M^{III}\text{O}_6$ octahedra and the $M^I:M^{III}$ ratio showed that the compounds of all the above-mentioned trivalent cations ($M^{III} = \text{Al}, \text{Fe}, \text{V}, \text{Ga}$) in combination with rubidium can also crystallise in the structural type $M^I M_2^{III}(\text{OH})(\text{PO}_4)_2 \cdot 2 \text{H}_2\text{O}$. It is quite possible that In-containing analogues can also crystallise in this structural type. In all compounds with $M^I = \text{NH}_4$, the NH_4^+ cations are surrounded by four oxygen atoms giving rise to a tetrahedron within which two $\text{N}-\text{H}\cdots\text{O}$ hydrogen bonds occur (Fig. 26 *b*).

The water molecules in the structure of $M^I M_2^{III}(\text{OH})(\text{PO}_4)_2 \cdot 2 \text{H}_2\text{O}$ fulfil different functions. One H_2O molecule is involved in the first coordination sphere of the $M^{III}(2)\text{O}_6$ octahedron, whereas another water molecule is of a zeolite type and is not coordinated to any cation. As a result, the structural formula of these hydroxide phosphates can be written as follows $M^I\{M_2^{III}(\text{OH})(\text{PO}_4)_2(\text{H}_2\text{O})\} \cdot \text{H}_2\text{O}$.

It should be noted that the structures of all the above-considered minerals and their synthetic analogues are derived from the structure of $\text{GaPO}_4 \cdot 2 \text{H}_2\text{O}$.¹³⁹ In this structure, the positions of the hydroxonium ions correspond to the positions of the monovalent K^+ and NH_4^+ cations according to the structural formula $\text{H}_3\text{O}\{\text{Ga}_2(\text{OH})[\text{PO}_4]_2(\text{H}_2\text{O})\} \cdot \text{H}_2\text{O}$. The replacement of

¶ The presence of the edge-sharing $M^{III}\text{O}_6$ octahedra in these structures is responsible for the magnetic properties of iron-containing representatives of this group.

Figure 26. Structure of $(\text{NH}_4)\text{Fe}_2(\text{OH})(\text{PO}_4)_2 \cdot 2 \text{H}_2\text{O}$ projected onto the bc (*a*) and ac planes (*b*). The centrosymmetrical island fragments of the Fe octahedra are displayed (*a*); the positions of the NH_4^+ cations in the channels of the structure are shown (*b*).

one-half of the hydroxide ions in the $M^I\{M_2^{III}(OH)(PO_4)_2(H_2O)\} \cdot H_2O$ compounds by the oxide ions gives rise to compounds with compositions $M_{1.5}^I\{M_2^{III}O_{0.5}(OH)_{0.5}(PO_4)_2(H_2O)\} \cdot xH_2O$ ($M^I = K, Rb$; $M^{III} = Al$).¹²⁹

The presence of the $M_2^{III}O_4$ groups is common to hydroxide phosphates $M^IM_2^{III}(OH)(PO_4)_2 \cdot 2H_2O$ and their topological analogues deprived of OH groups, such as $(NH_4)Mo_2 \cdot P_2O_{10} \cdot H_2O$ ¹⁴² and $RbMo_2P_2O_{10} \cdot (1-x)H_2O$.¹⁴³ In the $Al_3(PO_4)_3 \cdot H_2O \cdot en$ and $Ga_3(PO_4)_3 \cdot H_2O \cdot en$ compounds (*en* is ethylenediamine), the $M_2^{III}O_4$ groups are involved in trigonal bipyramids and the organic cations (protonated ethylenediamine molecules) occupy the channels.¹⁴⁴ Due to the specific ion-conducting properties, these compounds can be used as molecular sieves.¹⁴⁵

Hydroxide phosphates with composition $Na_4M^{III}(OH)(PO_4)_2$ ($M^{III} = Al, Ga$) and the ratio $M^I : M^{III} = 4 : 1$ are also known (see Table 15). Let us consider the structures of these compounds using an aluminium compound as an example. The main structural elements of the $Na_4Al(OH)(PO_4)_2$ compound are the infinite $[Al(OH)(PO_4)_2]_{\infty}$ chains extended along the $[001]$ direction (Fig. 27*a*). In these chains, the $AlO_4(OH)_2$ octahedra are *trans*-linked to each other through the bridging oxygen atoms of the hydroxy groups (Fig. 27*b*). The adjacent octahedra in the chains are linked by two PO_4 groups. Each PO_4 group shares two vertices with the adjacent octahedra in the chain. The $[Al(OH)(PO_4)_2]_{\infty}^{4-}$ chains are held together primarily through interactions between two non-shared vertices of the phosphate groups and the sodium atoms located in the channels between the $[Al(OH)(PO_4)_2]_{\infty}^{4-}$ chains. The sodium atoms located between the PO_4 tetrahedra in *cis* positions with respect to the hydroxyl hydrogen atoms have a lesser effect on binding of the chains. The PO_4 tetrahedra and AlO_6 octahedra are only slightly distorted.

In the structure of $Na_4Al(OH)(PO_4)_2$, the sodium atoms have different coordination numbers depending on their positions with respect to the $[Al(OH)(PO_4)_2]_{\infty}^{4-}$ chains. Four of seven independent sodium atoms are involved in the NaO_6 octahedra. One NaO_{4+2} polyhedron is formed by four oxygen atoms located in the first coordination sphere (the $Na-O$ distances are ~ 2.495 Å) and two oxygen atoms at distances of $2.72-2.99$ Å. Finally, the coordination environment about two sodium atoms are five-vertex polyhedra with four short $Na-O$ bonds (~ 2.3 Å) and one abnormally large distance (~ 2.88 Å).

Figure 27. Structure of $Na_4Al(OH)(PO_4)_2$ projected along the $[001]$ direction (*a*) and the $[Al(OH)(PO_4)_2]_{\infty}^{4-}$ chain (*b*).

In the mineral tancoite $LiNa_2HAl(OH)(PO_4)_2$,¹⁴¹ the arrangement of the chains is analogous to that observed in the structure of $Na_4Al(OH)(PO_4)_2$. The slight differences in the positions of the Li and H atoms in the structure of tancoite as compared to the positions of the sodium atoms replacing these atoms in the structure of $Na_4Al(OH)(PO_4)_2$ cause changes in the symmetry of the structure, *viz.*, the parameter *a* is decreased, whereas the parameter *c* is doubled.

Taking into account the similarity of the ionic radii of aluminium, gallium and iron, gallium- and iron-containing analogues of $Na_4Al(OH)(PO_4)_2$ with the same structure would be expected to occur. Actually, we have recently prepared isostructural hydroxide phosphate $Na_4Ga(OH)(PO_4)_2$.

The structures of the $Na_3M^{III}(OH)(HPO_4)(PO_4)$ compounds ($M^{III} = Al, Ga$) are similar to that of $Na_4Al(OH)(PO_4)_2$ with the only difference that the sodium atoms are partially replaced by the hydrogen atoms of the HPO_4 groups (Fig. 28*a*).¹³³ The adjacent octahedra in the $[Al(OH)(HPO_4)(PO_4)_2]_{\infty}^{3-}$ chains are linked through the bridging HO groups and by the HPO_4 and PO_4 groups (Fig. 28*b*). The structure is additionally stabilised by hydrogen bonds involving the HPO_4 groups from the adjacent chains. The sodium atoms in the structure have different coordination environments, *viz.*, NaO_5 , NaO_6 and NaO_8 . The coordination polyhedron about the sodium atom with the coordination number of 8 is a distorted cube with four short, two medium and two long $Na-O$ distances. The average $M^{III}-O$ and $P-O$ bond lengths are comparable with the analogous distances in $Na_4Al(OH)(PO_4)_2$. For $Na_3Al(OH)(HPO_4)(PO_4)_2$, these bond lengths are 1.911 and 1.536 Å, respectively.

The chains consisting of the $[M(EO_4)_2X]$ groups (*X* is a non-specific ligand), which were found in the structures of $M_4^IM^{III}(OH)(PO_4)_2$ and $M_3^IM^{III}(OH)(HPO_4)(PO_4)_2$, are typical of a large group of phosphate, sulfate and silicate minerals.¹³² For example, in the structures of the minerals jahnsite $CaMnMg_2 \cdot [Fe(OH)(PO_4)_2]_2 \cdot 8H_2O$,¹⁴⁶ segelertite $CaMg[Fe(OH)(PO_4)_2] \cdot 4H_2O$ and overite $CaMg[Al(OH)(PO_4)_2] \cdot 4H_2O$ (see Ref. 147), the $[M(EO_4)_2X]$ chains are linked in layers through the $M^{II}O_2(H_2O)_4$ octahedra.

Figure 28. Structure of $Na_3Al(OH)(HPO_4)(PO_4)_2$ projected onto the *ac* plane (*a*) and the $[Al(OH)(HPO_4)(PO_4)_2]_{\infty}^{3-}$ chain (*b*).

Thermal stability of hydroxide phosphates containing mono- and trivalent cations depends on the mode of binding of water molecules in these structures. Thus, hydroxide phosphates $M^I\text{In}(\text{OH})\text{PO}_4$ ($M^I = \text{K}, \text{Rb}$) lose water of crystallisation in the temperature range of 500–700 °C. Decomposition of hydroxide phosphate $\text{KIn}(\text{OH})\text{PO}_4$ affords $\text{K}_3\text{In}(\text{PO}_4)_2$, InPO_4 and In_2O_3 . Hydroxide phosphate $(\text{NH}_4)\text{In}(\text{OH})\text{PO}_4$ decomposes in two steps at 180–490 °C and 535–690 °C. Crystallisation of InPO_4 starts at 620 °C. Dehydration of leucophosphite $\text{KFe}_2(\text{OH})_2(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ occurs in two steps at 300–575 °C. First, the zeolite-type water is removed and then the H_2O molecules located in the first coordination sphere about the iron atoms are eliminated. Dehydration of $\text{NaFe}_3(\text{OH})_4(\text{PO}_4)_2 \cdot n\text{H}_2\text{O}$ proceeds in one step. The temperature ranges of the removal of the zeolite-type water and water of crystallisation overlap (the maximum temperatures corresponding to the removal of these water molecules are 428 and 447 °C, respectively) and complete dehydration is achieved at 600 °C. In the case of the NH_4V analogue of leucophosphite, water of crystallisation is eliminated at a substantially lower temperature (in the range of 45–110 °C) and decomposition of the compound is completed at 320 °C. Dehydration of $\text{Na}_3\text{Al}(\text{OH})(\text{HPO}_4)(\text{PO}_4)$ proceeds in one step with a maximum at ~438 °C and ends in the formation of double aluminium phosphate $\text{Na}_3\text{Al}(\text{PO}_4)_2$.

A comparison of the data on the structures of complex hydroxide phosphates containing mono- and trivalent cations revealed the main structural features of these compounds. The coordination polyhedra about the M^{III} cations are without exception octahedra. The $M^{\text{III}}\text{O}_6$ octahedra are linked in infinite chains through the bridging hydroxy groups. Depending on the ratio between the M^I and M^{III} cations, the chains are either linked to each other through the phosphate tetrahedra or are held together by hydrogen bonds and $M^I \cdots \text{O}$ interactions[†] to form framework, layered or chain structures (Table 16).

For the above-considered compounds, two compositions with the ratios $M^I : M^{\text{III}} = 1 : 2$ or $1 : 1$ (in the case of the medium and large monovalent K^+ , Rb^+ , NH_4^+ cations) are preferential. The compositions with $1 : 3$ or $3 : 1$ (4 : 1), where M^{III} cations are either excessive or deficient with respect to M^I cations, are typical only of sodium-containing aluminium and gallium hydroxide phosphates, both the OH and HPO_4 groups being involved in compounds with the ratio $M^I : M^{\text{III}} = 3 : 1$. It should be noted that water molecules play an important role in the formation of structures containing an excess of M^{III} cations with respect to M^I . The H_2O molecules are involved in the formation of the first coordination sphere about the M^{III} cations and occupy the

channels and cavities in the structures as ‘guests’, which are not bound to any cations.

VI. Other complex phosphates containing mono- and trivalent cations

In addition to fluoride phosphates and hydroxide phosphates containing mono- and trivalent cations, other complex mixed-anion compounds are known. In such compounds, the PO_4^{3-} anion is combined with VO_4^{3-} , MoO_4^{2-} , SO_4^{2-} or $\text{S}_2\text{O}_3^{2-}$. It is expected that mixed-anion phosphates will exhibit improved properties (such as sorption ability, luminescence, *etc.*) as compared to monoanion phases. The replacement of the tetrahedral PO_4 group in the anion sublattices of complex phosphates by other groups enables one to vary not only the total negative charge of the compound, which makes it possible to change the number of cations, but also the size characteristics of the cavities in framework structures and of interlayer spaces in layered phases. Such structural changes may allow one to influence the catalytic properties and ionic mobility of compounds as well as ion exchange processes involving these compounds.^{148–152}

The partial replacement of the PO_4^{3-} anions in compounds with composition $\text{K}_3M^{\text{III}}(\text{PO}_4)_2$ ($M^{\text{III}} = \text{Y}, \text{La}, \text{Eu}, \text{Gd}, \text{Yb}$) by VO_4^{3-} gives rise to continuous or limited solid solutions based on one of the structural types (arcanite or glaserite) typical of non-substituted double phosphates $\text{K}_3M^{\text{III}}(\text{PO}_4)_2$ or vanadates $\text{K}_3M^{\text{III}}(\text{VO}_4)_2$. The lack of new compounds is associated with a small difference in the sizes of the PO_4^{3-} and VO_4^{3-} anions. The formation of limited or continuous solid solutions is determined by the dissimilarity or similarity of the structural types of the starting double phosphates and vanadates.²⁸

Phosphate vanadates $\text{K}_3M^{\text{III}}(\text{PO}_4)_x(\text{VO}_4)_{2-x}$ ($M^{\text{III}} = \text{Sc}, \text{Y}, \text{La} - \text{Lu}; x = 0 - 2$) exhibit sorption properties with respect to H_2O , CO_2 and organic compounds. The degree of sorption of H_2O and CO_2 from the gas phase depends on the $\text{PO}_4^{3-} : \text{VO}_4^{3-}$ ratio whose increase leads to preferential sorption of water molecules from a mixture of H_2O and CO_2 .¹⁵³ The degree of sorption correlates linearly with the conductivity and dielectric characteristics of the water-containing $\text{K}_3M^{\text{III}}(\text{PO}_4)_x(\text{VO}_4)_{2-x}$ phases.

Complex phosphate vanadates $\text{K}_3M^{\text{III}}_{1-y}\text{Eu}_y(\text{PO}_4)_x(\text{VO}_4)_{2-x}$ ($M^{\text{III}} = \text{Sc}, \text{Y}, \text{La}, \text{Gd}; x = 0 - 2; y = 0 - 1$) possess luminescent properties, which depend both on the concentration of the activator Eu^{3+} ions and the $\text{PO}_4^{3-} : \text{VO}_4^{3-}$ ratio. The formation of solid solutions, which crystallise in the same structural type, is evidenced by the similarity of their luminescence spectra. These spectra are characterised by the absence of complete concentration quenching of luminescence as the concentration of activator ions is increased. The maximum intensity of luminescence was observed at the Eu^{3+} concentration corresponding to $y = 0.3$.

[†] Considering the size factor, only sodium can serve as such monovalent cation.

Table 16. Characterisations of the structures of different types of complex hydroxide phosphates with M^I and M^{III} cations.

Type of compound	Ratio $M^I : M^{\text{III}}$	Crystal system	Space group	Building blocks	Structural type
$M^I M^{\text{III}}_3(\text{OH})_4(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ ($M^I = \text{Na}, M^{\text{III}} = \text{Al}, \text{Fe}$)	1 : 3	tetragonal	$P4_12_12$	$[\text{M}^{\text{III}}\text{O}_2(\text{OH})_4] \cup [\text{M}^{\text{III}}\text{O}_3(\text{OH})_2\text{O}_w]$ (chains) + $[\text{PO}_4]$	framework
$M^I M^{\text{III}}_2(\text{OH})(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ ($M^I = \text{K}, \text{NH}_4, M^{\text{III}} = \text{Al}, \text{Fe}, \text{Ga}, \text{V}$)	1 : 2	monoclinic	$P2_1/n$	$[\text{M}^{\text{III}}(\text{OH})_2(\text{H}_2\text{O})_2(\text{PO}_4)_4]_{3\infty}$ (island fragments)	"
$M^I M^{\text{III}}(\text{OH})\text{PO}_4$ ($M^I = \text{Li}, \text{Na}, \text{K}, \text{NH}_4, \text{Rb}; M^{\text{III}} = \text{Al}, \text{Fe}, \text{Mn}, \text{In}$)	1 : 1	triclinic orthorhombic tetragonal	$P\bar{1}, C\bar{1}$ $P2_12_12_1$ $P4_32_12$	$[\text{M}^{\text{III}}\text{O}_4(\text{OH})_2]_{\infty}$ (chains) + $[\text{PO}_4]$	"
$M^I_3 M^{\text{III}}(\text{OH})(\text{HPO}_4)(\text{PO}_4)$ ($M^I = \text{Na}, (\text{Li}, \text{Na}), M^{\text{III}} = \text{Al}, \text{Ga}$)	3 : 1	monoclinic	$C2/m$	$[\text{M}^{\text{III}}\text{O}_4(\text{OH})_2]_{\infty}$ (chains) + $[\text{PO}_4]$ and $[\text{HPO}_4]$	chain
$M^I_4 M^{\text{III}}(\text{OH})(\text{PO}_4)_2$ ($M^I = \text{Na}, M^{\text{III}} = \text{Al}, \text{Ga}$)	4 : 1	orthorhombic	$Pbcm$	$[\text{M}^{\text{III}}\text{O}_4(\text{OH})_2]_{\infty}$ (chains) + $[\text{PO}_4]$	"

Phosphate vanadates $K_3M^{III}_{1-j}Eu_j(PO_4)_x(VO_4)_{2-x}$ ($M^{III} = Sc, Y, Gd$) possessing bright red luminescence are promising photoluminescent and cathode-luminescent materials.^{154–156}

Complex molybdate phosphate $Na_2Y(PO_4)(MoO_4)$ ¹⁵⁷ was prepared by crystallisation from flux in the study of the $Y_2O_3-(NH_4)_2HPO_4-Na_2MoO_4$ system. This compound crystallises in the monoclinic system (space group $C2/c$, $Z = 8$, unit cell parameters $a = 13.928$, $b = 18.016$, $c = 6.847$ Å, $\beta = 119.62^\circ$). The structure of $Na_2Y(PO_4)(MoO_4)$ contains chains (along the c axis) of the edge-sharing YO_8 dodecahedra. The chains are linked in corrugated layers parallel to the ac plane through the PO_4 (shared edges) and MoO_4 (shared vertices) tetrahedra (Fig. 29 *a*). The sodium atoms are located in the interlayer space (Fig. 29 *b*). Molybdate phosphates of this type are unknown for REE.

Figure 29. Structure of $Na_2Y(PO_4)(MoO_4)$ projected onto the ac plane (*a*) (MoO_4 tetrahedra are omitted) and the arrangement of the Na atoms in the structure (*b*).

Quite recently, sodium lanthanum phosphate thiosulfate with composition $Na_2La(PO_4)(S_2O_3)$ was prepared by the reaction of La_2O_3 with Na_3PO_3S in an excess of Na_2S_4 .¹⁵⁸ This compound crystallises in the monoclinic system (space group $P2_1/c$, $Z = 4$, unit cell parameters $a = 13.779$, $b = 5.336$, $c = 9.356$ Å, $\beta = 89.97^\circ$). In the crystal structure of $Na_2La(PO_4)(S_2O_3)$, the LaO_7S_2 polyhedra are linked in chains through the apical sulfur atoms of the thiosulfate groups. The chains are linked in layers by the PO_4 and S_2O_3 tetrahedra (Fig. 30 *a, b*). The negatively charged $[La(PO_4)(S_2O_3)]^{2-}$ fragment is the major building block of each layer. The $[La(PO_4)(S_2O_3)]_n$ layers are parallel to the bc plane. The terminal sulfur atoms of the thiosulfate ions are located within these layers. The structure contains three types of sodium atoms. The Na(1) and Na(2) atoms are located in the interlayer space occupying the centres of the octahedra, which are formed by the oxygen atoms belonging only either to the phosphate $[Na(1)]$ or

Figure 30. Structure of $Na_2La(PO_4)(S_2O_3)$ projected onto the bc plane (*a*) and the chains of the LaO_7S_2 polyhedra linked through the PO_4 and S_2O_3 tetrahedra (*b*).

thiosulfate $[Na(2)]$ groups. The Na(3) atoms are in an octahedral environment formed by the oxygen atoms belonging to four $S_2O_3^{2-}$ anions and one PO_4^{3-} anion.

A new structural type for the $Na_2La(PO_4)(S_2O_3)$ compound would be expected to occur by analogy with the $Na_2Y(PO_4)(MoO_4)$ compound combining the PO_4^{3-} and MoO_4^{2-} anions. However, analysis of the polyhedra demonstrated that the structure of $Na_2La(PO_4)(S_2O_3)$ is derived from glaserite $K_3Na(SO_4)_2$. The difference is that one-half of positions, which are occupied by the alkali-metal cations in the structures of glaserite-like double phosphates [for example, in $K_3M^{III}(PO_4)_2$, where $M^{III} = Lu, Sc$], are vacant in the structure of $Na_2La(PO_4)(S_2O_3)$. These changes in the cation composition lead to the appearance of a superstructure in $Na_2La(PO_4)(S_2O_3)$ resulted from doubling of the unit cell parameter a corresponding to the parameter c in the glaserite structure. In addition, the incorporation of the $S_2O_3^{2-}$ ion into complex phosphate has a substantial effect on thermal stability of the $Na_2La(PO_4)(S_2O_3)$ compound. Thus, the decomposition temperature of the $Na_2La(PO_4)(S_2O_3)$ compound is $313^\circ C$, whereas this temperature for $Na_3La(PO_4)_2$ is much higher ($1000^\circ C$). The data from powder X-ray diffraction analysis and the results of IR and Raman spectroscopy for the decomposition product of $Na_2La(PO_4)(S_2O_3)$ (after TGA) demonstrated that sodium lanthanum phosphate thiosulfate decomposes to form a compound of unknown composition containing the PO_4^{3-} and SO_4^{2-} ions in the anion sublattice.

Recently, a series of new phases with composition $Li_{3-x}Fe_2(PO_4)(SO_4)_2$ were prepared.¹⁵⁹ In these compounds, x depends on the content of iron in oxidation states 2+ and 3+. The redox potential of the $LiFe_2(PO_4)(SO_4)_2$ compound (3.4 eV) is higher than that of its monoanion precursor $Li_3Fe_2(PO_4)_3$

(2.8 eV), and this compound is a promising electrodic material for recharging lithium batteries.

The above-considered examples demonstrate that the $M^I M^{III}(\text{PO}_4)(\text{EO}_4)_2$ compounds possess new or improved properties (important for technical applications) as compared to monoanion complex phosphates. The total negative charge of the anionic portion of the compound can be changed by replacing the PO_4 groups in the anion sublattices of complex phosphates by the tetrahedral EO_4 groups ($E = \text{V}, \text{Mo}, \text{S}$), which allows one to change the number of cations and size characteristics of the cavities of framework structures and of the interlayer spaces in layered phases.

VII. Conclusion

A comparison of the crystal structures of different groups of complex phosphates containing mono- and trivalent cations not only reveals the similarity of formal characteristics (composition, simplest structural polyhedra) among these compounds but also enables one to establish their structural features depending on the size factors (ionic radii of the M^I and M^{III} cations), nature of the cations and anions, combinations of different anions, presence of water molecules and OH groups and hydrogen bonding.

Compositions with the ratio $M^{III}:\text{PO}_4^{3-}$ or $M^{III}:(\text{PO}_4^{3-} + \text{EO}_4^{2-})$ equal to 1:2, for example, $M^I M^{III}(\text{PO}_4)_2$, $M^I M^{III}(\text{HPO}_4)_2$ and $M^I M^{III}(\text{PO}_4)(\text{EO}_4)$, are typical of simple double phosphates, hydrogen phosphates and phosphates whose anionic portions contain the PO_4 groups together with other EO_4 tetrahedra ($\text{EO}_4 = \text{MoO}_4, \text{S}_2\text{O}_3$). Simple hydroxide phosphates and fluoride phosphates have related structures corresponding to the formulas $M^I M^{III}(\text{OH})\text{PO}_4$ and $M^I M^{III}\text{FPO}_4$. A limited number of compositions and structural types are known for simple double phosphates. A complication of the anionic portion of double phosphates and the presence of water molecules in these compounds lead to the formation of complex phosphates of different types (fluoride phosphates, hydrogen phosphates containing different $\text{H}_n\text{PO}_4^{3-n}$ anions and hydroxide phosphates), which differ both in composition and structure. In most representatives of complex phosphates containing mono- and trivalent cations, the ionic radius of the M^{III} cation is no larger than 0.8 Å (Al, V, Fe, Cr, Sc, Ga, In). Compounds containing REE or Y are known only for double phosphates and fluoride phosphates.

Changes in the ionic radii of the M^I and M^{III} cations (particularly, in the REE series) both in compositionally different and analogous groups of compounds are accompanied by a change in the structural type. In the case of sodium derivatives, which are most prone to polymorphism, the structural changes associated with a change in the size of the M^{III} cation and synthesis conditions are most pronounced (see Fig. 1 and Table 3).

The structures of complex phosphates of all the above-considered types are built from the $M^{III}\text{O}_x$, $M^{III}\text{O}_x(\text{H}_2\text{O})_y$ or $M^{III}\text{O}_{x-y}[\text{F},(\text{OH})]_y$ polyhedra ($x = 6-8$ and $y = 2-4$) and the PO_4 or H_nPO_4 polyhedra (the EO_4 tetrahedra can partially replace the PO_4 tetrahedra). The polyhedra about the M^{III} cations with the ionic radii $r \leq 0.8$ Å are octahedra distorted to a greater or lesser extent. The vertices of the octahedra are occupied by the oxygen atoms of the PO_4 , H_nPO_4 , EO_4 or OH groups or water molecules. In the case of fluoride phosphates, the F atoms can also be involved in the coordination polyhedra. In the structures of double REE phosphates and fluoride phosphates, the REE atoms adopt the coordination numbers of 7, 8 and 9.

The partial replacement of the PO_4^{3-} anions by the $\text{H}_n\text{PO}_4^{3-n}$ ($n = 1, 2$), EO_4^{2-} , F^- or OH^- anions and changes in the ratios $r(M^I):r(M^{III})$, $M^I:M^{III}$ and $M^{III}:\text{PO}_4$ ($\text{H}_n\text{PO}_4^{3-n}$, $n = 0-2$) lead to the formation of more complex structural ensembles based on either framework or layered constructions. Layered structures are typical of compounds with a high content of the M^I (or $M^I + \text{H}^+$) cations with respect to the M^{III} cations. This relationship is observed in most of the group of compounds considered above, viz., in double phosphates $M^I M^{III}(\text{PO}_4)_2$, fluoride phosphates

$M^I M^{III}\text{F}_2(\text{PO}_4)_2$, hydrogen phosphates $M^I M^{III}(\text{H}_2\text{PO}_4)_6 \cdot (\text{HPO}_4)_2$ and phosphates containing an EO_4 tetrahedron along with the PO_4 tetrahedron, for example, in $\text{Na}_2\text{Y}(\text{PO}_4)(\text{MoO}_4)$ and $\text{Na}_2\text{La}(\text{PO}_4)(\text{S}_2\text{O}_3)$. One-dimensional motifs are observed in compounds characterised by a high content of alkali-metal cations and the presence of hydroxy groups, for example, in $M^I M^{III}(\text{OH})(\text{HPO}_4)(\text{PO}_4)$ and $M^I M^{III}(\text{OH})(\text{PO}_4)_2$.

A decrease in the $M^I:M^{III}$ ratio results in the formation of framework structures typical of most of representatives of these groups of compounds, in particular, of $M^I M^{III}(\text{PO}_4)_3$, $M^I M^{III}(\text{HPO}_4)_2$, $M^I M^{III}(\text{OH})(\text{PO}_4)$, $M^I M^{III}\text{FPO}_4$ and $M^I M^{III}\text{F}_3(\text{PO}_4)_2$. In framework structures, the $M^{III}\text{O}_x$ or $M^{III}\text{O}_{x-y}[\text{F},(\text{OH})]_y$ polyhedra are linked to each other through either tetrahedral groups (in double and hydrogen phosphates) or fluoride and hydroxy groups (in fluoride phosphates and hydroxide phosphates, respectively).

The character of the structures depends substantially on the presence of the $\text{H}_n\text{PO}_4^{3-n}$ cations, OH groups and H_2O molecules in the coordination sphere about the M^{III} cation, which is associated with the involvement of these groups and molecules in the formation of rather strong hydrogen bonds.

Complex phosphates can be used in the design of polyfunctional materials. Compounds of REE and Sc containing the PO_4^{3-} anions together with the VO_4^{3-} anions are of particular interest. The formation of solid solutions based of double REE- and Sc-containing phosphates and vanadates allows one to vary the luminescent, sorption and other properties of the materials rather accurately by changing the $\text{PO}_4^{3-}:\text{VO}_4^{3-}$ ratio. Phosphate vanadates selective absorb H_2O , CO_2 and various organic molecules from the gas phase. Europium-doped compounds of this type containing Sc, Y and REE possess luminescent properties. It is also highly probable that REE fluoride phosphates and phosphate vanadates will exhibit catalytic properties. Phosphate vanadates of REE can be used also in the construction of nonlinear optical materials.

Phosphates with composition $M^I M^{III}_2(\text{PO}_4)_3$ ($M^I = \text{Li}, \text{Na}$; $M^{III} = \text{Sc}, \text{In}, \text{Fe}$) are ionic conductors. Some representatives of hydrogen phosphates possess proton conductivity. A number of these compounds (with zeolite-type structures) are of interest as new ion exchange phases. The fact that most of the complex phosphates belong to dielectric compounds provides the basis for the preparation of dielectric materials for different purposes.

* * *

When this review was already in preparation, new data on the synthesis, crystal structures and properties of two groups of complex phosphates, viz., $M^I M^{III}(\text{HPO}_4)_2$ and $M^I M^{III}(\text{OH})(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$, were reported. Thus, we have expected that indium hydrogen phosphates $M^I\text{In}(\text{HPO}_4)_2$ ($M^I = \text{Li}, \text{Na}, \text{Ag}, \text{Rb}$),¹⁶⁰ scandium hydrogen phosphates $M^I\text{Sc}(\text{HPO}_4)_2$ ($M^I = \text{K}, \text{Rb}, \text{NH}_4$) and iron hydrogen phosphate $\beta\text{-RbFe}(\text{HPO}_4)_2$ would occur, and this assumption was confirmed. All these compounds, except for $\text{KSc}(\text{HPO}_4)_2$ (space group $Pnma$), crystallise in the monoclinic system (space group $P2_1/c$). The above-listed hydrogen phosphates either widen the range of representatives of the known structural type $\beta\text{-RbV}(\text{HPO}_4)_2$ (see Ref. 62), for example, $\beta_1\text{-RbIn}(\text{HPO}_4)_2$, $\beta\text{-RbFe}(\text{HPO}_4)_2$ and $M^I\text{Sc}(\text{HPO}_4)_2$, where $M^I = \text{K}, \text{Rb}, \text{NH}_4$, or form unique framework structures, for example, $M^I\text{In}(\text{HPO}_4)_2$, where $M^I = \text{Li}, \text{Na}, \text{Ag}$. Our assumption that the structural group of the mineral leucophosphate must involve also rubidium hydroxide phosphate $\text{RbGa}_2(\text{OH})(\text{PO}_4)_2 \cdot 2\text{H}_2\text{O}$ was also confirmed.¹⁶¹

Abstract. Data on the structure, polymorphism, phase equilibria, growth techniques, properties and applications of single crystals of the low-temperature modification of barium borate are analysed. The bibliography includes 201 references.

I. Introduction

Barium borates possess many interesting and valuable properties. Interest in these compounds is due to not only pure research aspects, but also the possibility of modern technological applications. Currently, barium borates are used in production of ceramic glazes, luminophors, oxide cathodes as well as additives to pigments for aqueous emulsion paints.^{1–8} The BaO–B₂O₃ system (a constituent of the BaO–B₂O₃–SiO₂ system) serves as the basis when synthesising special optical glasses.^{9–14}

The history of studies of barium borate, BaB₂O₄, can be divided into two periods. The pioneering communication concerning the synthesis of BaB₂O₄ single crystals dates back to the 19th century.^{1,2} The structure of anions in crystalline borates was established by X-ray structural analysis in the 1950s.^{3,4,15} The crystal structures of a number of barium borates including the high-temperature modification of BaB₂O₄ were established in the 1960s;^{16–18} however, these results were of low reliability.

Two crystalline modifications[†] of BaB₂O₄, *viz.*, the high-temperature (α) and the low-temperature (β) forms were described and characterised by X-ray diffraction analysis by Levin and McMurdie.¹²

In the anions, oxygen atoms surrounding borons can form two types of coordination environment, *viz.*, a tetrahedral and a trigonal coordination environment corresponding to the *sp*³- and *sp*²-hybridisation of the electron orbitals of the B atom, respectively.¹⁹ As a rule, both of them are realised in borate ions. Both the BO₃ triangles and BO₄ tetrahedra can form fused structures by sharing their vertices (bridging oxygen atoms), thus forming polyanions. The presence of polymeric anions in borate melts is responsible for hysteresis of properties (in particular, viscosity) and the glass-forming ability.⁸

The second period of studies of BaB₂O₄ dates back to the 1980s and is associated with the discovery of nonlinear optical properties in the single crystals of the low-temperature modification of barium borate, β -BaB₂O₄ (BBO)[‡] (see Refs 20–25). Its crystals are non-centrosymmetric, which is responsible for a number of specific properties of the compound.^{26,27} This form of barium borate combines excellent nonlinear optical characteristics [large effective second harmonic generation (SHG) coefficient, which is nearly 6 times higher than that of potassium dihydrophosphate crystals; large birefringence; wide transparency region (190–3500 nm), high laser damage threshold], good mechanical properties and very low hygroscopicity. Comparison of the properties of BBO with those of other optically active nonlinear crystals shows that barium borate is the best candidate for fabrication of solid-state UV lasers operating at a wavelength of 200 nm. BBO single crystals are used in optoelectronics for laser radiation-to-radiation frequency conversion (in particular, visible-to-UV frequency upconversion) by the SHG and higher harmonic generation (up to the fifth harmonic) mechanisms.

Received 14 March 2002

Uspekhi Khimii 71 (8) 741–763 (2002); translated by A M Raevsky

[†] In the literature, the high-temperature and the low-temperature modifications of barium borate are, as a rule, designated as α -BaB₂O₄ and β -BaB₂O₄, respectively (in this review, we also use these notations). However, quite the reverse notations are sometimes used.

[‡] The terminology is somewhat ambiguous. The compound having a composition BaO·B₂O₃ is usually treated as a salt, Ba(BO₂)₂, of metaboric acid (HBO₂) and called barium metaborate;² sometimes, the same compound is called barium diborate (see, *e.g.*, Ref. 4). However, barium diborate has another composition, namely, BaO·2 B₂O₃.² To match the crystal structure of BBO, it is more correct to represent its composition as Ba₃(B₃O₆)₂.

Recently, frequency conversion by the stimulated Raman scattering (SRS) mechanism using BBO-crystal oscillators has been studied.^{28–30}

In the last decade, new crystals possessing nonlinear optical properties (including borates) were synthesised.^{31–39} These are, *e.g.*, LiB_3O_5 (LBO)⁸ (see Ref. 31), $\text{KBe}_2\text{B}_3\text{O}_7\text{F}_2$ (KBBF),³² $\text{Sr}_2\text{Be}_2\text{B}_2\text{O}_7$ (SBBO),³³ $\text{LiCsB}_6\text{O}_{10}$ (CLBO),³⁴ $\text{Ba}_2\text{Be}_2\text{B}_2\text{O}_7$ (TBO) and $\text{K}_2\text{Al}_2\text{B}_2\text{O}_7$ (KABO)³⁵ and BiBO_3 (BIBO);³⁶ however, BBO remains of considerable value.

Nonlinear optical properties of various borate single crystals are due to electron delocalisation^{37,38,40–43} in complex boron–oxygen anions. The simplest examples of such anions are provided by the $[\text{BO}_3]^{3-}$ triangles and by two types of ring trimers, *viz.*, the $[\text{B}_3\text{O}_6]^{3-}$ units constructed of three BO_3 triangles with two of the three vertices shared and the $[\text{B}_3\text{O}_7]^{5-}$ units (two BO_4 tetrahedron). They are shown in Fig. 1. Peculiarities of the electronic structure of borate crystals determine high polarisability of these compounds, which is comparable to that of aromatics. These crystals also have good mechanical properties and high laser damage threshold, which is typical of inorganic crystals.⁴⁴

Figure 1. Structural units present in borate crystals. BO_3 (a); BO_4 (b); B_3O_6 (c) and B_3O_7 (d).

Solid-state optoelectronics (photonics) requires high-quality crystals that contain no inclusions, twins and inhomogeneities, are free from thermal strain and variations of the refractive index, have a definite crystallographic orientation and are, as a rule, rather large (of the order of a centimetre). BBO single crystals can be grown by melt-solution (high-temperature flux) technique using the modified Kyropoulos and Czochralski methods^{45,46} or by direct crystallisation from supercooled melts. Crystal growth is complicated by high viscosity and glass-forming ability of melts. The polymeric structure of borate melts can be to some extent controlled by shifting the acid–base equilibria.^{47,48} Low yield of materials suitable for practical applications, undesired variations of the properties of BBO crystals and high cost of optical elements are due to the fact that growing such crystals is a technologically sophisticated procedure.

Recently, interest to centrosymmetric single crystals of the high-temperature α -modification of BaB_2O_4 has quickened.⁴⁹ These crystals are characterised by large birefringence, broad optical transparency region (190–3500 nm) and can compete with calcite crystals that are widely used in linear optics.

An extensive literature on BBO crystals has evolved. Despite this fact, a number of topical problems concerning both the basic

(nonstoichiometry, polymorphism, phase equilibria, thermodynamics) and applied (elucidation of the reasons responsible for characteristic optical and structural inhomogeneities of BBO crystals, optimisation of crystal growth conditions) aspects of the investigation and growth of these crystals are still to be solved.

II. Barium borates. The $\text{BaO} - \text{B}_2\text{O}_3$ system

Studies of the phase equilibria in the $\text{BaO} - \text{B}_2\text{O}_3 - \text{H}_2\text{O}$ system at 30 °C (Fig. 2) revealed the existence of barium metaborate tetrahydrate, $\text{BaO} \cdot \text{B}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$, and barium triborate heptahydrate, $\text{BaO} \cdot 3\text{B}_2\text{O}_3 \cdot 7\text{H}_2\text{O}$.^{2,50} Some other hydrated barium borates were reported in the early studies.² More recently,⁴ $\text{BaO} \cdot \text{B}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ was synthesised, which is formed in dilute solutions and is thought to be metastable,⁵ as well as $\text{BaB}_2\text{O}_4 \cdot 1.67\text{H}_2\text{O}$.⁵¹ Determination of the crystal structures of $\text{BaO} \cdot \text{B}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$ (see Ref. 52) and $\text{BaO} \cdot \text{B}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ (see Refs 53 and 54) revealed the presence of isolated tetrahedral $\text{B}(\text{OH})_4$ groups in these crystals; therefore, the formulae of the compounds can be written as $\text{Ba}[\text{B}(\text{OH})_4]_2$ and $\text{Ba}[\text{B}(\text{OH})_4]_2 \cdot \text{H}_2\text{O}$, respectively.

The crystalline compounds $\text{Ba}_2[\text{B}_5\text{O}_{18}(\text{OH})_2]\text{OH}$, $\text{Ba}[\text{B}_5\text{O}_{18}(\text{OH})] \cdot \text{H}_2\text{O}$ and $\text{Ba}_5[\text{B}_{20}\text{O}_{33}(\text{OH})_4] \cdot \text{H}_2\text{O}$ were hydrothermally synthesised in the $\text{BaO} - \text{B}_2\text{O}_3 - \text{M}_2\text{O} - \text{H}_2\text{O}$ ($\text{M} = \text{K}, \text{Rb}, \text{Cs}$) systems at 280 °C under a pressure of 70 atm.^{55–58}

The melting diagram of the $\text{BaO} - \text{B}_2\text{O}_3$ system was studied by thermal analysis.^{59,60} Using the ‘composition–property’ curve, six congruently melting compounds were found. These are $3\text{BaO} \cdot \text{B}_2\text{O}_3$, $2\text{BaO} \cdot \text{B}_2\text{O}_3$, $\text{BaO} \cdot \text{B}_2\text{O}_3$, $\text{BaO} \cdot 2\text{B}_2\text{O}_3$,

Figure 2. Phase equilibria in the $\text{BaO} - \text{B}_2\text{O}_3 - \text{H}_2\text{O}$ system at 30 °C (a)^{2,50} and crystallisation field of $\text{BaB}_2\text{O}_4 \cdot n\text{H}_2\text{O}$ (open circles) in sodium borate solutions at 25 °C (b).⁵ Points B, C and D denote eutonics (a); the dashed line designates the boundary between the tetrahydrate and pentahydrate regions (b).

§ The notations widely used in the literature are given in parentheses.

BaO $\cdot$ 3 B₂O₃ and BaO $\cdot$ 4 B₂O₃ (for the generalised phase diagram of the BaO–B₂O₃ system, see Ref. 2). It is believed that super-cooling of melts occurred in these studies.

Phase equilibria in the BaO–B₂O₃ system have been studied in detail¹² by annealing and quenching techniques and by the X-ray phase and thermal analyses. Only four congruently melting compounds were found, namely, 3 BaO $\cdot$ B₂O₃, BaO $\cdot$ B₂O₃, BaO $\cdot$ 2 B₂O₃ and BaO $\cdot$ 4 B₂O₃. A melt immiscibility region was observed near the boron oxide composition.

Barium metaborate, BaO $\cdot$ B₂O₃, melts congruently at 1095 °C and forms eutectics at 905 and 889 °C.¹² In addition to the high-temperature α -modification of BaO $\cdot$ B₂O₃, the low-temperature β -modification was found and characterised by X-ray powder diffraction. No transition temperature was reported;¹² it was only assumed to lie between 100 and 400 °C. More recently, in studies of the BaO–B₂O₃–SiO₂ ternary system¹³ the temperatures of a number of phase transformations in the BaO–B₂O₃ system were corrected (increased by ~ 10 °C) while the melting temperature of BaO $\cdot$ B₂O₃ was found to be 1105 °C.

The generalised phase diagram of the BaO–B₂O₃ system (Fig. 3), which was proposed by Levin and reported in a handbook,¹⁰ has been commonly accepted by crystal growth researchers (see, e.g., Refs 11, 27, 46). Following Feigelson *et al.*,⁴⁶ in Fig. 3 we added a horizontal line (dash-and-dot line) corresponding to the polymorphic transformation of BaO $\cdot$ B₂O₃ at 925 °C (see below). It should be noted that the boundaries of the immiscibility region (dashed line) do not match those reported earlier.¹² The coordinates of the upper critical point of the immiscibility dome (1931 °C, 6.6 mol.% BaO) were determined in a thorough study by Hageman and Oonk.⁶¹

Figure 3. Phase diagram of the BaO–B₂O₃ system.¹⁰

The middle part of the phase diagram of the BaO–B₂O₃ system was revised by Hübner⁶² who showed that not only the above-mentioned compounds, but also 2 BaO $\cdot$ 5 B₂O₃, 2 BaO $\cdot$ B₂O₃ and 4 BaO $\cdot$ B₂O₃ are formed in the system. All of the newly found compounds were characterised by X-ray powder diffraction. The congruent melting temperature of 2 BaO $\cdot$ B₂O₃ (920 ± 5 °C) is close to the temperature of the eutectic between BaO $\cdot$ B₂O₃ and 3 BaO $\cdot$ B₂O₃.^{12,13} The temperature of the polymorphic transformation of BaO $\cdot$ B₂O₃ is 925 ± 5 °C. Hübner proposed the existence of homogeneity regions for both modifications of BaO $\cdot$ B₂O₃ and suggested that this region for the high-temperature form is especially broad (Fig. 4). According to this

Figure 4. Middle part of the phase diagram of the BaO–B₂O₃ system.⁶²

version of the phase diagram, the low-temperature modification of β -BaB₂O₄ is not in the equilibrium with the B₂O₃-enriched melt; however, this contradicts the results obtained more recently.^{63,64}

Hübner⁶⁵ also studied the phase equilibria in the BaO–B₂O₃–Al₂O₃ system and reported the formation of continuous solid solutions in the composition range between 2 BaO $\cdot$ B₂O₃ and the low-temperature modification of BaO $\cdot$ B₂O₃ at 700 °C (Fig. 5). The formation of individual compound 2 BaO $\cdot$ B₂O₃ was established based on the X-ray diffraction data obtained in melt crystallisation studies in a number of ternary systems.⁶⁶ Compound 2 BaO $\cdot$ B₂O₃ crystallises in the monoclinic crystal system (Table 1) and its unit cell parameters are close to those of β -BaB₂O₄ in the monoclinic setting (the difference consists in doubling the parameter *c*). This structural type is possible only if barium and oxygen ions are inserted into the β -BaB₂O₄ lattice, which is accompanied by a dramatic increase in density.

Single crystals of the 2 BaO $\cdot$ 5 B₂O₃ (Ba₂B₁₀O₁₇) phase found by Hübner⁶² were grown by Stone *et al.*⁶⁸ by slowly cooling a stoichiometric melt. The solid-phase synthesis was carried out at 750 °C and the melting temperature of the compound was reported to be 901 °C. The melt undergoes a glass transition on cooling with ease.

The crystal structures of compounds BaO $\cdot$ 2 B₂O₃ (Ba₄O₇), BaO $\cdot$ 4 B₂O₃ (Ba₈O₁₃) and 2 BaO $\cdot$ 5 B₂O₃ (Ba₂B₁₀O₁₇) were established (see Table 1).^{16,18,68} At 700 °C, compound BaO $\cdot$ 4 B₂O₃ undergoes a phase transition from the low-temperature orthorhombic to the high-temperature tetragonal modification which is stable up to the congruent melting temperature (889 °C).⁶⁷ The heat of the transition is 2100 J mol^{–1}. The phase transition is accompanied by twinning of crystals.

An IR spectroscopic study⁷⁵ revealed the presence of isolated BO₃ triangles in the structure of compound 3 BaO $\cdot$ B₂O₃ which is thus an orthoborate.

The generalised phase diagram of the BaO–B₂O₃ system is shown in Fig. 6. Since the melting temperature of compound Ba₂B₁₀O₁₇ (see Ref. 68) is somewhat higher than the liquidus temperature for this composition (see Ref. 12), this compound seems to be stable. According to the version of the phase diagram proposed by Levin and McMurdie,¹² an eutectic corresponding to the crystallisation of BaO $\cdot$ 2 B₂O₃ and BaO $\cdot$ 4 B₂O₃ should occur in this concentration range; however, no eutectic effects were observed. Probably, they simply overlooked the compound 2 BaO $\cdot$ 5 B₂O₃. Earlier,⁶⁰ a congruently melting compound of other stoichiometric composition was found in this concentration range.

The ‘interrelation’ between compounds 2 BaO $\cdot$ B₂O₃ and BaO $\cdot$ B₂O₃ is still a moot question. The melting temperature of 2 BaO $\cdot$ B₂O₃ reported by Hübner is much lower than the liquidus

Figure 5. Phase equilibria in the BaO–B₂O₃–Al₂O₃ system at 700 °C.⁶⁵

Open circles denote the compositions studied; full circles denote compounds; SSI and SSII designate the regions of solid solutions; 2 BaO·4 B₂O₃·Al₂O₃ (1), BaO·2 B₂O₃·Al₂O₃ (2), BaO·B₂O₃·Al₂O₃ (3), 3 BaO·2 B₂O₃·2 Al₂O₃ (4) and 5 BaO·6 B₂O₃·2 Al₂O₃ (5).

temperatures determined earlier^{12,59} and, hence, cannot correspond to the equilibrium congruent melting of this compound. However, it is rather close to the eutectic temperature. The authors of this review suggest incongruent melting of 2 BaO·B₂O₃ following a peritectic reaction (see Fig. 6).

Hübner's assumption⁶² of the presence of the homogeneity region based on BaO·B₂O₃ is in agreement with the absence of eutectic effect in this concentration range.¹² Figure 6 presents a version of the phase diagram containing the regions of solid solutions based on α -BaB₂O₄ and β -BaB₂O₄ shown according to Hübner. The presence of these regions suggests a strong non-stoichiometry of BaB₂O₄. If this is the case, the maximum on the liquidus curve should not coincide with the point corresponding to the 1:1 composition. It should also be noted that the densities of both the α - and β -modifications of BaB₂O₄ are much lower than the average density obtained by linear approximation of the data for compounds in the BaO–B₂O₃ system. This anomaly can be to some extent compensated for by the formation of interstitial solid solutions. This issue as well as the thermal stability of 4 BaO·B₂O₃ call for further investigation.

III. Glass formation in the BaO–B₂O₃ system

Melt cooling in the BaO–B₂O₃ system causes glass formation.^{9,11,14} The most stable glasses (ingots up to 50 g by mass) are fabricated by solidification of melts containing from 16 mol.% to 40 mol.% BaO, *i.e.*, in the region of existence of the low-melting compounds BaO·2 B₂O₃, 2 BaO·5 B₂O₃ and BaO·4 B₂O₃ (see Fig. 6). As the cooling rate increases, the region of glass formation extends (up to 60.5 mol.% BaO for ingots of mass 0.1 g) and includes the composition BaB₂O₄. No transparent homogeneous glasses are formed on cooling of B₂O₃-enriched melts. At temperatures that are somewhat higher than the liquidus temperature, the equilibrium melt represents two immiscible liquids of different compositions. Similarly to the melt, on cooling each of the liquids can undergo a glass transition.

Boron oxide can undergo a spontaneous glass transition.⁹ Glassy boron oxide can be readily obtained from boracic acid which melts at 176 °C. Long-term heating is accompanied by slow removal of water from the melt; however, trace amounts of water are hard to remove. The content of the residual water after heating

at 1200 °C for 19 h is 0.127 mass %. Pumping anhydrous dinitrogen through the melt over a period of 5 h reduces the content of water down to 0.025 mass %. A nearly completely dehydrated material was prepared by long-term heating at a pressure of 1 Torr in a platinum crucible and then in a graphite crucible. The viscosity of the melt depends on the content of water; as this parameter decreases from 0.248 mass % down to 0.025 mass %, the temperature corresponding to a viscosity of 10⁴ P increases from 537 to 550 °C.

It is noteworthy that the viscosity of B₂O₃ at 450 °C (melting temperature) is much lower than that of silica at 1710 °C; however, glassy boron oxide is much more hard to crystallise compared to glassy silica. This was assumed to be due to abnormally high ratio of the bond energy to the melting temperature of glassy B₂O₃. No spontaneous devitrification of B₂O₃ at an atmospheric pressure was observed. Crystallisation of boron oxide requires heating at 225–250 °C over a period of several days in a loosely plugged vessel. The sample slowly loses water and is transformed into a solid finely crystalline aggregate characterised by a density of 2.42 g cm^{−3} and a melting temperature lying between 460 and 470 °C. The content of B₂O₃ in the material thus obtained is 99.4% while the rest seems to be the bound water.

An X-ray study of glassy B₂O₃ showed that its structure is a disordered network of [BO₃]^{3−} triangles (in which each oxygen atom is linked to two boron atoms) or distorted [BO₄] tetrahedra.

Glass formation is also typical of the systems comprising B₂O₃ and alkali metal oxides. The Na₂O–B₂O₃ system is characterised by two glass formation regions¹⁴ corresponding to the concentration ranges 0 mol.%–8 mol.% (or 0 mol.%–30 mol.%) and 66.5 mol.%–71.5 mol.% Na₂O. The second glass formation region coincides with the region of existence of low-melting compositions in the vicinity of the NaBO₂–Na₄B₂O₅ eutectic. A 'belt'-like glass formation region was found in the Na₂O–BaO–B₂O₃ system at the B₂O₃ concentration of greater than 60 mol.%.⁷⁶

IV. Methods of preparation of BaB₂O₄

There are four groups of methods for preparation of BaB₂O₄. These are precipitation of crystal hydrates from aqueous solutions followed by dehydration; hydrolysis of alkoxides; anhydrous solid-phase syntheses (possibly) followed by melting and melt-solution syntheses. The last-named group also includes various single-crystal growth techniques which can be considered as specific methods of synthesis.

1. Precipitation of BaB₂O₄·*n* H₂O from aqueous solutions

Methods for the synthesis of barium borate based on precipitation of crystal hydrates BaB₂O₄·*n* H₂O from aqueous solutions (aqueous methods) have been known for long.^{2–8} However, they are rarely employed for the preparation of charge that is used as raw material for the crystal growth.

Aqueous methods for the synthesis of different metal borates share a number of features. During precipitation from aqueous solutions the borates are isolated as crystal hydrates. The content of the bound water depends on the reaction conditions. In addition, metal borates can be isolated in the amorphous state. Such borates are intermediate products of many syntheses; nevertheless, they can undergo a transition into the crystalline state under particular conditions. Amorphous borates are, as a rule, highly reactive.

Borates can contain water in the form of both hydroxyl ion and solvate molecules. This allows one to rationalise a complex process of dehydration of borates at elevated temperatures which involves elimination of individual solvate water molecules and hydroxyl groups, which is due to association of boron-containing anions. Usually, removal of water occurs in a stepwise manner in the temperature range from 100 to 200 °C. The residual water can be removed only at very high temperatures (~1000 °C and above). Often, dehydration of borates is accompanied by a specific

effect of borate rearrangement⁷⁷ which was first reported by Nikolaev.⁷⁸ Namely, dehydration causes a complete destruction of the crystal lattice and transition of the compound under study into the amorphous state; further heating leads to crystallisation accompanied by exothermic effect, which can be detected on thermograms.

The synthesis of BaB_2O_4 by precipitation from aqueous solutions should be carried out in a strongly basic medium ($\text{pH} > 11$) provided that variations of the pH value during crystallisation are small. This can be done by performing a reaction between a solution of boric acid and a solution of $\text{Ba}(\text{OH})_2$ (see Ref. 4) or BaCl_2 .⁵¹ However, it is more convenient to use barium chloride and a mixture of sodium tetraborate and sodium hydroxide.

To maintain the pH value at the desired level, a nearly twofold excess of the precipitating agent is required. The reaction results in a flaky precipitate which is transformed into crystalline $\text{BaB}_2\text{O}_4 \cdot 4\text{H}_2\text{O}$ after several hours.

The crystallisation fields of $\text{BaB}_2\text{O}_4 \cdot 4\text{H}_2\text{O}$ and $\text{BaB}_2\text{O}_4 \cdot 5\text{H}_2\text{O}$ in sodium borate solutions at 25 °C for the reaction presented above were studied by Gode.⁵ The possibility of nearly complete precipitation of boron (in the form of barium borate) from solutions was demonstrated (see Fig. 2b). A drawback of this method consists in poisoning the precipitate by sodium and chlorine impurities.

The synthesis of barium borate from barium nitrate was proposed⁸

It was proposed to remove the chloride (impurity in NaOH) and sodium ions using an ammonia solution (to prevent transformation into polyborates). Drying at 400–650 °C for 30 min resulted in an anhydrous product.

To transform non-crystalline barium borate into the crystalline $\text{BaO} \cdot \text{B}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$, it was recommended⁶ to grind the material in a boric acid solution in the presence of KOH. The yield of the desired product was low (~20%).

Dehydration of the tetrahydrate $\text{BaO} \cdot \text{B}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$ begins at 70 and is completed at 140 °C, while dehydration of the pentahydrate $\text{BaO} \cdot \text{B}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ occurs in the temperature range from 50 to 450 °C.⁴ It should be noted that the melting temperatures of the dehydrated products (1015 and 925 °C, respectively)⁴ are much lower than the equilibrium melting temperatures. Probably, this is due to the influence of the residual water. According to Lehmann *et al.*,⁵¹ dehydration of $\text{BaO} \cdot \text{B}_2\text{O}_3 \cdot 1.67\text{H}_2\text{O}$ occurs in the temperature range 90–170 °C.

Precipitation of the tetrahydrate $\text{BaB}_2\text{O}_4 \cdot 4\text{H}_2\text{O}$ from solution followed by thermal decomposition following the reactions

was employed^{79–82} for the synthesis of BaB_2O_4 that is used as raw material (charge) for the melt growth of β - BaB_2O_4 crystals (the so-called chloride technique). Remelting or sintering BaB_2O_4 at 1095 °C for 3 h results in a coarse-grained material of higher purity grade compared to the charge obtained by solid-phase synthesis from barium carbonate. A thermogram exhibiting a clearly seen peak corresponding to the melting at 1100 °C has been reported.⁸²

It should be noted that the synthesis of BaB_2O_4 by thermolysis of crystal hydrates allows reliable preparation of a product of stoichiometric composition. In addition, it seems that aqueous solutions favour purification of barium-containing reagents

(removal of impurities including strontium and calcium that strongly affect the stability of the crystalline modifications of BaB_2O_4).

2. Syntheses using ‘soft chemistry’ methods

Recently, the so-called ‘soft chemistry’ methods have been used for the synthesis of inorganic materials (see, *e.g.*, Ref. 83). These methods can also be employed to synthesise barium borate. For instance, a stoichiometric mixture of boron triethoxide and barium isopropoxide was slowly hydrolysed with distilled water.⁸⁴ The powder dried *in vacuo* at 60 °C was found to be a new γ -modification of BaB_2O_4 .

3. Anhydrous high-temperature syntheses

Compound BaB_2O_4 can be directly synthesised by melting BaO and B_2O_3 at 1150 °C for 1 to 2 h.⁸⁵ According to the results of differential thermal analysis (DTA) study, the reaction begins at 1060 °C.

Barium borate (the starting material for the synthesis of single crystals) is usually prepared from a mixture of BaCO_3 and B_2O_3 (see Refs 86–89) or H_3BO_3 .^{64, 80, 90–92} The syntheses are conducted using the following reaction equations

Powder mixtures taken in the stoichiometric ratios are mechanically mixed and then heated until sintering and melting. In the case of reaction (3) the powders are sintered at 800 °C for 10 h, melted at 1200 °C for 10 min and then zone melted (both processes are carried out in a graphite boat in an argon atmosphere)⁸⁸ or are melted in air at 1150 °C for 5 h. For the reaction with H_3BO_3 it was recommended⁹² to use a stepwise synthesis with allowance for the reaction mixture to stay at 150 and 700 °C.

Usually, syntheses are performed in platinum crucibles; however, graphite crucibles can also be used in an inert atmosphere (argon).⁸⁸

It seems likely that one can synthesise BBO from barium carbonate according to Berzelius by boiling a barium carbonate suspension in an aqueous boric acid (analogously to the synthesis of lead borate⁴). However, this synthetic route was not studied experimentally.

Barium borate BaB_2O_4 is also synthesised using other barium compounds (*e.g.*, barium oxide,⁷⁹ barium acetate^{90, 91} and barium nitrate^{12, 82}) as starting reagents.

The reaction with barium acetate was carried out in a platinum crucible using stepwise heating;^{91, 92} finally, the product was kept at 1150 °C for 50 h. The reaction proceeds in air; however, it does not always happen that the reaction goes to completion under the crystal growth conditions. This leads to poisoning the growing crystals with carbon. In the reaction with barium nitrate the ground mixture of reagents was heated to 700 °C for 2 h and then repeatedly heated above this temperature.¹²

The following reaction was conducted⁸²

A ground mixture of reagents was repeatedly heated from 700 to 850 °C. It was also found that the reactions of BaCO_3 or BaO with H_3BO_3 do not result in products that are suitable for the Czochralski growth of β - BaB_2O_4 .

4. Melt-solution crystallisation

Barium borate can be synthesised by exchange reactions in melts. The first successful synthesis dates back to 1874.^{1,79} The following reaction was used

Sodium chloride having a lower melting temperature acts as solvent that is removed with water after cooling.

Reactions analogous to the processes underlying the aqueous methods of synthesis^{93,94} can also be used for the synthesis of β -BaB₂O₄

The excess barium chloride acts as flux. The reaction was carried out in a platinum crucible at 1000 °C for 2 h.⁹³ The driving force of the synthesis of BaB₂O₄ is the difference between the heat of reaction and the energy of pyrohydrolysis of barium chloride (~ 78 kcal).

A method of fabrication of a seed rod necessary for melt-solution growth of single crystals is as follows.⁹⁴ BaB₂O₄ polycrystals precipitated in the reaction with boric acid are ground, moulded, sintered in an oxygen atmosphere at 730–850 °C, re-ground and then re-sintered at 850–1095 °C.

An extensive literature on the synthesis of single crystals using the systems of the BaB₂O₄–S or, more generally, BaO–B₂O₃–S types (S is the melt playing the role of solvent) has evolved. Both equilibrium and nonequilibrium melt crystallisations are possible (the former corresponding to the primary crystallisation region of β -BaB₂O₄ in the phase diagrams). Among various solvents, Na₂O is most widely used at present (see below).

Melt-solution growth of single crystals is strongly affected by the impurities coming into the crystal from the solvent. These are the melt components (first of all, sodium), impurities contained in the starting reagents and accumulated within the growing crystal (*e.g.*, potassium or strontium) and ‘extra’ impurities that come from the material the crucible is made of (platinum).

V. Polymorphism and the crystal structure

In addition to the high- and low-temperature modifications of BaB₂O₄ (these two were mentioned above) there are some indications of the existence of at least one unstable low-temperature modification designated as T-BaB₂O₄ (see Ref. 51), or γ -BaB₂O₄.^{84,95} The X-ray diffraction patterns of the samples reported in Refs 51, 84 and 95 are close but not identical. The samples of this phase were obtained by dehydration of BaB₂O₄ · 1.67 H₂O (see Ref. 51) and by the interaction of boron triethoxide and barium isopropoxide. According to Yamaguchi *et al.*,⁸⁴ γ -BaB₂O₄ undergoes an irreversible transformation into α -BaB₂O₄ on heating to ~ 600 °C. An IR spectroscopic study of γ -BaB₂O₄ showed that, in contrast to the structure of the α - and β -forms of BaB₂O₄ (see below), the structure of this modification comprises infinite anionic chains constructed of [BO₄] tetrahedra with their vertices shared (calcium, strontium and lithium metaborates have an analogous structure).[†]

The crystal structure of α -BaB₂O₄ was established by Mighell and Perloff.¹⁷ It was found that the crystal is characterised by the trigonal system and centrosymmetric space group $R\bar{3}c$ (Fig. 7).

According to Hübner,⁶² β -BaB₂O₄ single crystals have a monoclinic unit cell with the parameters $a = 11.133$, $b = 12.67$, $c = 8.381$ Å and $\beta = 100.04^\circ$; the space group is $C2/c$ and $Z = 12$. Coincidence of the results of X-ray powder diffraction studies^{12,62} indicates that the same modification of barium borate was investigated in both cases.

However, Hübner's⁶² choice of the unit cell was questioned.⁶⁹ According to Liebertz and Stahr,⁶⁹ β -BaB₂O₄ crystals are uniaxial and trigonal (the crystallographic parameters are listed in Table 1). This discrepancy is of fundamental nature, since the space group $C2/c$ is centrosymmetric while the space group $R\bar{3}c$ is non-centrosymmetric. Frohlich⁷⁰ established the crystal structure of β -BaB₂O₄ and confirmed the results obtained by Liebertz and Stahr.⁶⁹ Lu *et al.*²² also reported similar results; however, they believed that the β -BaB₂O₄ crystal is characterised by the space group $R\bar{3}$. The results obtained by Lu *et al.*²² were used in the interpretation of the Raman spectra of β -BaB₂O₄ crystals.⁹⁷ Re-determination of the crystal structure^{44,71} and the results of piezoelectric and electro-optical measurements^{38,98} and Raman spectroscopy studies^{99,100} confirmed that the low-temperature modification of barium borate is characterised by the space group $R\bar{3}c$.

A thorough study⁸⁵ of BaB₂O₄ single crystals confirmed the lack of central symmetry and revealed a slight monoclinic distortion of the trigonal lattice. The parameters of the trigonal lattice of β -BaB₂O₄ obtained by different authors are slightly different (see Table 1).

The high- and low-temperature modifications of barium borate exhibit pronounced structural similarity, *viz.*, both of them have layered structures, contain nearly planar boron–oxygen [B₃O₆]^{3–} ring groups arranged perpendicular to the three-fold axis while their lattice parameters are related by simple formulae $a_\alpha \approx \sqrt{3}a_\beta$, $c_\alpha \approx (1/3)c_\beta$, $Z_\alpha = Z_\beta$.

The [B₃O₆]^{3–} groups are constituents of the structure of only one out of the three known crystalline modifications of metaboric acid, namely, metastable orthorhombic HBO₂-III with a melting temperature of 176 °C.³ Therefore, the α - and β -modifications of BaB₂O₄ are salts of this acid.

High-temperature Raman spectroscopy studies^{99,100} of the α - and β -forms of BaB₂O₄ revealed a change in the number of spectral lines in the frequency range of internal vibrations of the [B₃O₆]^{3–} anions corresponding to the D_{3h}^6 and C_{3v}^6 symmetry, respectively. The B–O distances in and out of the ring are ~ 1.40 and 1.32 Å, respectively.

The structures of the α - and β -modifications of BaB₂O₄ are characterised by different types of coordination environment of barium ions. In the high-temperature α -modification there are two types of barium atoms. The coordination number of barium atoms occupying the first position is 6 while for Ba atoms in the second position it equals 9. In the low-temperature β -modification the Ba atoms are in irregular environment of eight oxygen atoms shared by three ring borate anions. The Ba–O distances, $d(\text{Ba–O})$, lie between 2.613 and 3.025 Å. The X-ray powder diffraction patterns of the α - and β -modifications of BaB₂O₄ are presented in Fig. 8.

Investigation of the nonlinear optical properties of BBO is a topical problem. In this connection it is appropriate to briefly outline the nature of chemical bonding in this compound.^{38,40–43,97} In the [B₃O₆]^{3–} ring anions, the sp^2 -hybridised boron atoms form σ -bonds with oxygen atoms. The filled orbitals of the oxygen atoms and the vacant orbitals of the boron atoms involved in the rings interact with one another, thus forming the π -bonds. Positively charged Ba²⁺ ions and negatively charged [B₃O₆]^{3–} groups interact electrostatically. In addition, the intermolecular interaction occurs between electrically neutral layers. A number of the first-principle studies of the electronic structure and nonlinear optical susceptibilities of BBO have been reported.^{42,43} The results of calculations are in good agreement with the experimental data. The energy states of the atoms constituting the [B₃O₆]^{3–} anions contribute to both the upper part and the bottom of the conduction band.

Different temperatures of the phase transition between the β - and α -modifications of BaB₂O₄ have been reported (100–400 °C,¹² 880 °C,¹⁰³ ~ 900 °C⁴⁴ and 917 °C¹⁰⁴). Currently, a value of 925 ± 5 °C reported by Hübner⁶² and confirmed

[†] In addition, two unstable modifications of BaB₂O₄ were obtained during crystallisation of glasses in the BaO–B₂O₃–Al₂O₃ system.⁶⁵

in the annealing and quenching studies^{23, 105} has been commonly accepted.

The phase transition in question is strongly hindered. An X-ray diffraction pattern obtained after annealing of coarse-grained (40–50 μm), single-phase (β -phase) crystalline BBO at 940 °C for 4 h exhibited only traces of the α -phase.⁸⁷ Annealing at higher temperatures is accompanied by gradual decrease in the intensity of the reflections of the β -phase and by simultaneous increase in the intensity of the reflections of the α -phase. After annealing at 960 °C for 2 h nearly ~50% of the initial β -phase transformed into the α -phase. Analogous studies were carried out using single-phase (α -phase) crystalline BBO. After annealing at ~800 °C for 7 h nearly ~30% of the initial α -phase transformed

into the β -phase. At lower temperatures, the phase transformation occurred very slowly.

During measurements¹⁰⁶ of the thermal expansion coefficients the BBO single crystals were overheated up to 983 °C at a heating rate of 1 deg min⁻¹ and to 1010 °C at a heating rate of 0.1 deg min⁻¹. Transition into the α -phase occurred after reaching these temperatures.

According to Kimura and Feigelson,¹⁰⁷ the $\beta \rightarrow \alpha$ transformation takes only 5 min on heating above 1000 °C. It should be noted that the samples studied contained Sr (~0.05%) and Ca (~0.03%); it is thought that Ca impurity causes stabilisation of the α -phase.¹⁰⁸

Figure 8. X-Ray powder diffraction patterns (CuK α radiation) of α -BaB₂O₄ (a), β -BaB₂O₄ (b) and NaBaBO₃ (c).^{101, 102}

A number of *in situ* studies of the $\beta \rightleftharpoons \alpha$ transformation by high-temperature X-ray powder diffraction have been reported.^{82, 84, 106} Kozuki and Itoh¹⁰⁶ heated BBO powder to 1050 °C but no phase transition was observed. Yoshimoto and Kimura⁸² also did not observe the $\beta \rightarrow \alpha$ and $\alpha \rightarrow \beta$ phase transitions upon heating to 1000 °C. According to Yamaguchi *et al.*,⁸⁴ transformation of β -BaB₂O₄ prepared by heating from the γ -modification into α -BaB₂O₄ begins at 870 °C and is completed at 940 °C. The kinetics of this transformation have been studied.

The most surprising results were reported by Kouta *et al.*⁸⁰ who studied the transition in question and did not observe even minor indications of the phase transformation after heating β -BaB₂O₄ powder at 1090 °C for 5 h and subsequent cooling of the sample. The results of DTA study⁸⁰ showed that both modifications of BaB₂O₄ melt at nearly the same temperature, namely, 1100 ± 0.5 °C (α -phase) and 1099 ± 0.5 °C (β -phase).

A special study concerning the influence of the heating and cooling rates ($v = 3.75, 5.0, 7.5, 10.0, 15.0$ deg min⁻¹) on both the transition temperatures and reversibility of the phase transformations has been reported.¹⁰⁴ It was shown that the temperatures of the polymorphic transition of the low-temperature modification of BaB₂O₄ into the high-temperature form (917 °C) and the melting temperature of the latter (1092 °C) are virtually independent of the heating rate, whereas the reverse is observed on cooling.

VI. Peculiarities of crystallisation of BaB₂O₄ melts

BBO melts are characterised by high viscosity, tendency to supercooling and by hysteresis of properties. The physical properties of BBO have been studied recently.^{81, 109} The viscosity of the melt

monotonically increases from 20 to 61 mPa cm⁻¹ as the temperature decreases from 1463 to 1271 K and is ~ 30 mPa cm⁻¹ at the melting temperature. The activation energy of the viscous flow for the melt is 0.95 eV. The time taken to achieve the equilibrium viscosity of the melt at 1463 K is nearly 10 h. The density of the melt is a linear function of the temperature in the range between 1463 and 1271 K; it is described by the following equation

$$\rho = (4.453 - 0.000545)T$$

It was found that $\rho = 3.707$ g cm⁻³ at the melting temperature. The thermal expansion coefficient of the melt is 1.5×10^{-4} K⁻¹. The surface tension at the melting temperature is 0.35 N m⁻¹ (see Ref. 89).

According to the results of our experiments data and to Itoh *et al.*⁷⁹, the degree of supercooling of the melt (ΔT) in a platinum crucible can be as high as 250 °C at cooling rates spanning the range from 4 to 15 deg min⁻¹. In this case crystallisation of β -BaB₂O₄ can occur at temperatures that are much higher than the temperature of the polymorphic transition. Crystallisation occurs randomly; there is a wide spread of the melt crystallisation temperature values but no correlations between this temperature and the cooling rate are observed. Mention has been made that the degree of supercooling of the melt can be as high as 300 °C.¹¹⁰ The problem of crystallisation of BBO (spontaneous crystallisation, seed crystallisation using α -BaB₂O₄ and β -BaB₂O₄ and crystallisation on a platinum wire) has been the subject of numerous studies.

In a study¹⁰⁴ the degree of supercooling of the melt was 170–200 °C. On cooling ($v = 3.75, 5.0, 7.5, 10.0, 15.0$ deg min⁻¹), crystallisation occurred only at the temperature of the polymorphic transition or at lower temperatures and resulted in the low-temperature modification of BaB₂O₄. The crystallisation temperatures were found to be $T_c = 917$ °C at $v = 3.75$ and 5 deg min⁻¹, $T_c = 887$ °C at $v = 7.5$ deg min⁻¹ and $T_c = 857$ °C at $v = 15$ deg min⁻¹.

BBO melts can exist without any changes in the metastable state for long at temperatures that are higher than the temperature of the polymorphic transition and lower than the melting temperature. However, seeding causes rapid crystallisation the rate of which increases with temperature. If α -BaB₂O₄ is used as seed, the same modification of barium borate crystallises. Seeding with β -BaB₂O₄ causes crystallisation of the β -modification despite its instability under these conditions.

Experiments on platinum seeded crystal growth showed⁸⁷ that co-crystallisation of β -BaB₂O₄ and α -BaB₂O₄ begins if $\Delta T \geq 40$ °C. At smaller ΔT values, crystallisation of the α -phase occurs, whereas β -BaB₂O₄ mainly crystallises at temperatures below 1030 °C (*i.e.*, at $\Delta T \geq 70$ °C).⁸²

The degree of supercooling achievable using graphite crucibles is substantially lower compared to platinum crucibles; in addition, crystallisation of both the α - and β -modifications of BaB₂O₄ in graphite crucibles is possible.¹⁰⁷ This is thought to be due to some similarity between the trigonal structures of graphite and BBO.

Thermodynamically, the possibility of direct melt crystallisation of the low-temperature phase can be rationalised by taking into account strong supercooling of the melt and the existence of the temperature of metastable melting of the low-temperature phase (at this temperature the curves of the temperature dependences of the Gibbs thermodynamic potentials of the low-temperature phase and the melt intersect). The corresponding scheme is presented in Fig. 9. The temperature of metastable melting, T_β , of the low-temperature modification lies between the temperature of equilibrium melting, T_α , of the high-temperature modification and the temperature of polymorphic transformation, T_l . For the crystallisation of the β -phase to begin the melt temperature should be lower than T_β .

Ignoring the difference between the heat capacities of the α - and β -modifications of BaB₂O₄, the following relationship is valid:¹¹⁰

Figure 9. Temperature dependences of the Gibbs thermodynamic potentials (G) of the melt (1) and of the α - (2) and β -modifications (3) of BaB_2O_4 .¹⁰⁶

T_t is the temperature of polymorphic transformation, T_β is the temperature of metastable melting of the low-temperature modification and T_α is the temperature of the equilibrium melting of the high-temperature modification.

$$T_\beta = \frac{\Delta H_t + \Delta H_\alpha}{\Delta S_t + \Delta S_\alpha} = \frac{\Delta H_\beta}{\Delta S_\beta},$$

where ΔH and ΔS are the enthalpies and entropies of the reactions. By denoting

$$\delta = \frac{\Delta H_t}{\Delta H_\alpha},$$

one gets¹¹¹

$$T_\beta = \frac{(\delta + 1)T_\alpha T_t}{\delta T_\alpha + T_t}.$$

The estimates of the T_β value are strongly different (Table 2).

From the standpoint of polymorphism, BaB_2O_4 presents a unique phenomenon, since both modifications (α and β) of this compound have virtually equal melting enthalpies and melting temperatures, while the enthalpy (and, correspondingly, entropy) of the $\alpha \rightleftharpoons \beta$ transition is very low.^{80, 82} On the other hand, here we deal with the first-order phase transition characterised by significantly different crystal structures, volumes and densities (in the temperature range from 20 to 1000 °C) of both phases. In this case, a correct thermodynamic description of the phase transformations requires that the heat capacities be taken into account (they must be measured) and, hence, the approximate relationships listed above cannot be used. Under the conditions in question the mutual stability of the polymorphous modifications strongly depends on the presence of impurities, defects, as well as on the mechanical strain and surface energy, so that the possibility of melt crystallisation of a particular modification is first of all determined by the kinetic considerations.

Table 2. Melting temperatures (°C) and enthalpies (kJ mol^{-1}) of the α - and β -modifications of BaB_2O_4 .

T_α	T_β	ΔH_α	ΔH_β	Ref.
1095	1078	67.784	74.562	111
1100	1050	—	—	106
1100 ± 0.5	1099 ± 0.5	—	—	80
—	—	109.45	110.00	82

Hindered melt crystallisation of BBO can be rationalised based on structural considerations. The results of high-temperature Raman spectroscopy studies^{99, 100, 112} of barium borate point to a dramatic difference between the spectra of the melt and crystalline $\beta\text{-BaB}_2\text{O}_4$. The spectrum of supercooled melt exhibited not only narrow lines of $[\text{B}_3\text{O}_6]^{3-}$ anions, but also a number of broad bands corresponding to internal vibrations of long-chain $[\text{BO}_2]_n^{n-}$ anions. The contribution of the $[\text{B}_3\text{O}_6]^{3-}$ anions near the melting temperature is small; however, it increases as the degree of supercooling of the melt increases. Probably, melting of BBO is accompanied by rearrangement of the boron–oxygen complexes (transformation of the $[\text{B}_3\text{O}_6]^{3-}$ ring anions into long anionic chains). Crystallisation is accompanied by the reverse rearrangement.

High viscosity of barium borate melts and their tendency to glass formation are due to the presence of long anionic chains. The hysteresis of viscosity (see above)^{81, 109} seems to be associated with polymerisation–depolymerisation of $[\text{B}_3\text{O}_6]^{3-}$ anions.

Structural rearrangement of the melt on heating was studied experimentally (by X-ray powder diffraction) and theoretically (by the molecular dynamics method).^{113, 114}

It was found⁸² that self-melt crystallisation of $\beta\text{-BaB}_2\text{O}_4$ single crystals is possible if the starting material used for the preparation of the melt corresponded to the β -phase and no melt overheating occurred. The character of crystallisation of the melt can be affected by the presence of fine particles and structural fragments of crystalline phases that play the role of nucleation and crystallisation centres.⁸⁷ Overheating causes destruction of these centres. Graphite particles present in the melt can also play the role of crystallisation centres.¹⁰⁷

Information on the influence of atmosphere on the character of crystallisation of BBO melts was questioned by some authors. However, an increase in the degree of supercooling of the melt in the case of crystallisation in an argon atmosphere compared to the crystallisation in air has been reported recently.¹¹⁵

VII. Growth of $\beta\text{-BaB}_2\text{O}_4$ single crystals

Peculiarities of crystallisation of BBO melts determine two most widely used methods for the growth of $\beta\text{-BaB}_2\text{O}_4$ single crystals. These are the supercooled self-melt growth (under nonequilibrium conditions) and melt-solution growth techniques. In the latter case, both single crystal growth from the equilibrium primary crystallisation region and nonequilibrium crystallisation are possible. The schemes of a number of most widely used single crystal growth techniques are presented in Fig. 10.

1. Self-melt growth of single crystals

Self-melt growth techniques of $\beta\text{-BaB}_2\text{O}_4$ single crystals have the advantages that the growing crystals are not poisoned with flux and the crystallisation rates are high (by an order of magnitude higher compared to melt-solution crystal growth). However, in these cases crystallisation occurs under nonequilibrium conditions at large temperature gradients, which causes development of mechanical strain in and cracking of the crystal. In addition, the crystal quality strongly depends on the procedure employed for the preparation of the starting reagents and on the crystallisation conditions. These methods have not received wide application so far.

Single crystals of $\beta\text{-BaB}_2\text{O}_4$ were Czochralski grown using a platinum wire seed.^{79, 80} Noteworthy is that only the α -modification was melt crystallised if the starting reagents were prepared by the carbonate technique [see reactions (3) and (4)]. The process using the starting reagents synthesised by the chloride method [see reactions (1) and (2)] led to direct crystallisation of the β -phase in a narrow range of the temperature gradient (G) values at the crystallisation front ($G = 150\text{--}125 \text{ deg cm}^{-1}$). Variation of G (an increase up to 175 deg cm^{-1} and a decrease down to 50 deg cm^{-1}) resulted in the crystallisation of the α -phase. A cracked single-crystal boule 7 mm in diameter and 18 mm

Figure 10. Schematic illustrations of the most widely used experimental techniques for the melt and melt-solution growth of single crystals. Czochralski technique, $T = \text{const}$ (a); Kyropoulos technique (immersion-seeded solution growth, ISSG), T decreases (b); top-seeded solution growth (TSSG) technique, T decreases (c); melt feed Czochralski technique (d); Stepanov technique, $T = \text{const}$ (e); zone melting technique (f) and laser assisted pulling from pedestal (g). Crystal (1); melt (2); heater (3); crucible (4); seed (5); feeding charge (6); shape-forming element (7); laser heating (8) and polycrystal (9).

long was obtained at a seed rotation rate of 20 rpm and a pulling speed of 0.6 mm h^{-1} .⁷⁹ Improvement of the growth technique allowed obtaining single crystals 15 mm in diameter and 40 mm long without cracks at a seed rotation rate of 14 rpm and a pulling speed of 4 mm h^{-1} .⁸⁰

According to Kozuki and Itoh,¹⁰⁶ the upper critical temperature for stable Czochralski self-melt growth of β -BaB₂O₄ crystals is 1050°C . The starting material (charge) is prepared from barium nitrate and boron oxide. A single crystal 15 mm in diameter and 7 mm long was grown at a seed rotation rate of 10 rpm and a pulling speed of 3 mm h^{-1} . The vertical temperature gradient was only 10 deg cm^{-1} ; however, a strong influence of the radial temperature gradient was revealed (in this case, the optimum value was 77 deg cm^{-1} , see Ref. 116).

Yet another example of the Czochralski growth of β -BaB₂O₄ crystals has been reported.⁸⁹ A β -BaB₂O₄ seed of specified orientation was placed in a platinum pipe 2 or 4 mm in diameter. The charge was prepared from barium carbonate. The predominant impurity was platinum (30 ppm). The temperature gradient was 300 deg cm^{-1} . Crystals 7 mm in diameter and 20 mm long were grown at a seed rotation rate of 15 rpm and a pulling speed of 5 mm h^{-1} . The same technique was also used for the crystallisa-

tion of solid solutions β -Ba(B_{1-x}R_x)₂O₄ ($R = \text{Al, Ga}$, $0 \leq x \leq 0.1$).¹¹⁶

2. Melt-solution growth of single crystals[†]

a. Choice of solvent

An appropriate solvent (flux) must provide a rather extended primary crystallisation region of the low-temperature modification of BaB₂O₄ and reduce the viscosity and glass-forming ability of the melt. As a consequence, the melts should exhibit a lower degree of polymerisation of the boron–oxygen chains and an increased proportion of the $[\text{B}_3\text{O}_6]^{3-}$ ring anions. The solvent must be of low volatility, possess stable properties and provide very weak interaction with the crystal to exclude the possibility of poisoning. The melt should also not be an aggressive medium towards the material the crucible is made of.

A melt growth technique of β -BaB₂O₄ single crystals from the starting reagents using a shift from the stoichiometric composition towards an excess of BaO or B₂O₃ (the so-called self-flux) has been reported.^{63,103} However, the temperature ranges suitable for crystal growth in this manner are narrow (less than 20°C). More often, an excess of B₂O₃ is used;^{120,121} however, in this case the crystal growth is hampered due to high viscosity of the melt.

A large number of compounds and their combinations have been considered as candidates for solvents. These are, e.g., Li₂O,^{62,103} BaCl₂,^{103,121} BaF₂,^{66,103,121,122} NaF,^{66,90,91,123} LiF,⁶⁶ NaCl,^{66,124–126} NaCl–Na₂O,¹²⁵ PbO,¹²⁷ Na₂O–Nd₂O₃,^{72,120} LiNbO₃,¹²⁰ PbF₂–B₂O₃,¹²⁰ CaF₂¹²⁴ and Na₂SO₄.¹²⁴

Usually, the solvent is chosen based on the phase diagrams of corresponding systems. Some known regions of the phase diagrams are presented in Fig. 11. The BaB₂O₄–NaCl, BaB₂O₄–

[†] For basic principles of the methods for melt-solution (flux) crystal growth, see Refs 117–119.

Figure 11. Phase equilibria in the systems BaB₂O₄–NaCl (see Ref. 124) (a) and BaB₂O₄–BaF₂ (see Ref. 122) (b).

NaF and BaB_2O_4 – BaF_2 sections seem to be quasi-binary. The BaB_2O_4 – Na_2SO_4 section is unstable, since in this case an exchange reaction occurs

The temperatures of the eutectic in the BaB_2O_4 – NaCl system, determined by different authors,^{124,125} virtually coincide (see Fig. 11 a); however, the compositions of the eutectic are appreciably different. Correspondingly, the concentration ranges of the growth of β - BaB_2O_4 crystals in this system are also different. Data on the phase equilibria along the BaB_2O_4 – NaF (see Refs 66 and 123) and BaB_2O_4 – BaF_2 sections (see Refs 103 and 122) are contradictory.

All solvents studied have certain drawbacks. The systems containing Li_2O (see Ref. 103) and BaF_2 (see Ref. 122) exhibit very narrow crystallisation regions of β - BaB_2O_4 , while no such region at all was found in the system containing CaF_2 .¹²⁴ The system with BaCl_2 is characterised by fast hydrolysis. If fluoride melts are used, pyrohydrolysis also occurs in air,¹²⁸ either relatively fast (BaF_2) or slow (NaF). A number of additives (e.g., MgF_2 and BaF_2) do not favour reduction of the melt viscosity; besides, the melt containing MgF_2 is prone to glass formation.⁶⁶ The use of lead-containing compounds^{120,127} favours stabilisation of the α -modification of BaB_2O_4 .⁴⁹ Potassium fluoride additives cause significant changes in the lattice parameters of BBO crystals, which seems to be due to isomorphous incorporation of potassium.⁶⁶

The BaO – B_2O_3 – BaF_2 system is used as flux in the growth of rare-earth ferrite single crystals.¹²⁹

Sodium fluoride is considered as candidate for flux. The BaB_2O_4 – NaF section and the BaO – B_2O_3 – NaF system are characterised by broad regions of primary crystallisation of β - BaB_2O_4 ⁶⁶ and by substantial reduction of the viscosity of the melt, which permits crystallisation at higher rates. However, to make the best use of these advantages, the crystals should be grown in an inert gas atmosphere. Slow pyrohydrolysis of NaF in air during crystallisation causes a gradual transformation of the BaB_2O_4 – NaF system into the BaB_2O_4 – Na_2O system.

Na_2O ^{45,46,64,86,90,91,101–103,105,121,124,130–146} is, at present, most widely used for melt-solution growth of β - BaB_2O_4 single crystals. Melt-solution growth of single crystals in the BaB_2O_4 – $\text{Na}_2\text{B}_2\text{O}_4$ system has also been reported.¹⁰³ The process is complicated by high viscosity of the melt and its tendency to supercooling. A number of studies concerning variation of the melt composition in the BaO – B_2O_3 – Na_2O system are available.^{64,134–137,143,144}

Phase equilibria in the BaB_2O_4 – Na_2O system were first studied by DTA¹⁰⁵ (cited according to Refs 46 and 130). A compound $\text{Na}_2\text{BaB}_2\text{O}_5$ was identified, which congruently melts at 846 °C. The temperatures of the eutectics are 755 and 573 °C. The phase diagram constructed by Huang and Liang¹⁰⁵ was used for the choice and ‘tuning’ of the growth regimes of BBO crystals.

Kaplun *et al.*¹³³ proposed yet another version of the phase diagram of the BaB_2O_4 – Na_2O system. In this case, the liquidus curve in the BBO crystallisation region and the eutectic position match those reported by Huang and Liang;¹⁰⁵ however, the compound $\text{Na}_2\text{O} \cdot \text{BaB}_2\text{O}_4$ was assumed to be incongruently melting at 830 ± 3 °C following a peritectic reaction resulting in a refractory compound that melts at temperatures above 1300 °C (this compound was assumed¹³³ to have a composition $3 \text{ BaO} \cdot \text{B}_2\text{O}_3$). An analogous interpretation of the phase equilibria in this system was reported in other studies.^{143,144} The generalised phase diagram of the BaB_2O_4 – Na_2O system is shown in Fig. 12.

The region of primary crystallisation of β - BaB_2O_4 in the BaO – B_2O_3 – Na_2O ternary system (Fig. 13) has been thoroughly studied by Nikolov and Peshev.⁶⁴

The contradiction between the results of studies^{105,133} was solved recently.¹⁰² In an investigation of the BaB_2O_4 – Na_2O section by DTA and visual-polythermal analysis (VPA) it was found (see Fig. 12) that both strong thermal effects (ascribed¹⁰⁵ to

Figure 12. Phase equilibria along the BaB_2O_4 – Na_2O section.¹⁰²

The data were obtained by DTA, the mixtures were prepared by successive addition of Na_2CO_3 to remelted BaB_2O_4 (1); the data were obtained by DTA, the samples were prepared by solid-phase synthesis (2); the data were obtained by visual-polythermal analysis (3); other data were taken from Ref. 133 (4), Ref. 105 (5), Ref. 64 (6) and Ref. 72 (7).

Figure 13. Primary crystallisation region of the α - and β -modifications of BaB_2O_4 in the BaO – B_2O_3 – Na_2O ternary system.⁶⁴

Primarily crystallising phases: $\text{Na}_2\text{BaB}_2\text{O}_5$ (1), NaBO_2 (2), $\text{Na}_2\text{BaB}_2\text{O}_5$ (3), $\text{Ba}_3\text{B}_2\text{O}_6$ (4), α - BaB_2O_4 (5) and β - BaB_2O_4 (6). The dashed lines denote isotherms.

the melting of $\text{Na}_2\text{BaB}_2\text{O}_5$) and high-temperature equilibrium crystallisation (liquidus curve) manifest themselves in the concentration range from 30 mol.% to 50 mol.% Na_2O . These results are in agreement with those reported by Kaplun *et al.*¹³³ The medium-temperature effects were found¹⁰² to be concentration dependent (this contradicts the results reported earlier¹³³), which is impossible in the case of stable quasi-binary section.

X-Ray diffraction and Raman spectroscopy studies showed that the reaction of BaB_2O_4 with Na_2O results in barium orthoborate, NaBaBO_3 , whose structure comprises isolated $[\text{BO}_3]$ triangles and that compound $\text{Na}_2\text{O} \cdot \text{BaB}_2\text{O}_4$ does not exist. Single crystals of compound NaBaBO_3 were grown by spontaneous crystallisation from melts of different compositions including a melt containing 62 mol.% BaB_2O_4 and 38 mol.% Na_2O using a platinum loop seed. The compound melts at 1270 °C and undergoes a rapid degradation in air, being a good absorbent of water and carbon dioxide. The X-ray diffraction pattern of NaBaBO_3 is

Figure 14. Raman spectra of a NaBaBO₃ single crystal (*a*), Na₃BO₃ powder (*b*) and 3 Na₂O · B₂O₃ melt (*c*).¹⁰² The fundamental vibration of the impurity carbonate ion is asterisked.

shown in Fig. 8*c* and its Raman spectrum is presented in Fig. 14*a*.

Both the α - and β -modifications of BaB₂O₄ have nearly identical thermodynamic characteristics.^{80, 82} This means that the liquidus curve (surface) corresponding to the polymorphic transformation of BaB₂O₄ should exhibit no kinks.

The projection of the liquidus surfaces of a part of the BaO–B₂O₃–Na₂O system on the concentration triangle is shown in Fig. 15. In this system, compound NaBaBO₃ is assumed to be congruently melting and the BaB₂O₄–NaBO₂, NaBaBO₃–NaBO₂ and, probably, BaB₂O₄–NaBaBO₃ sections are thought to be of eutectic character (the eutectics lie at 28 mol.% BaO, 50 mol.% B₂O₃, 22 mol.% Na₂O, 826 °C and at 22 mol.% BaO, 39 mol.% B₂O₃, 39 mol.% Na₂O, 830 °C). The region of primary crystallisation of NaBaBO₃ can be determined by analysing the morphology of the primary (spontaneously grown) crystals. The primary crystals are isometric individuals in contrast to needle-shaped BaB₂O₄ and NaBO₂ crystals. The ternary eutectic occurs at 745 °C and lies at 41 mol.% BaO, 41 mol.% B₂O₃, 18 mol.% Na₂O (or 70 mol.% BaB₂O₄, 30 mol.% Na₂O). The results obtained by different authors^{64, 102} are in good agreement.

By chance, the BaB₂O₄–Na₂O section passes nearly exactly through the ternary eutectic in the BaB₂O₄–NaBaBO₃–NaBO₂ ternary system. Therefore, the left part of the BaB₂O₄–Na₂O section looks like a binary system. It seems likely that weak high-temperature effects were overlooked¹⁰⁵ and that the non-variant effect of the L + NaBaBO₃ + NaBO₂ binary eutectic was interpreted to be the melting of a compound BaB₂O₄ · Na₂O, while the co-crystallisation (co-melting) curve of NaBaBO₃ + NaBO₂ was considered to be the liquidus curve.

Studies of the phase diagram of the BaO–B₂O₃–Na₂O system are complicated by high reactivity and hygroscopicity of melts, by their ability to absorb carbon dioxide and by the

Figure 15. Projections of the liquidus surfaces in the BaB₂O₄–NaBaBO₃–NaBO₂ system on the concentration triangle.¹⁰² The eutectics are labelled *e*₁–*e*₃ and the ternary eutectic is labelled *E*.

corroding action of the melts on the platinum crucibles. High viscosity of the melts and their tendency to supercooling, glass formation and appearance of metastable equilibria present a particular problem.^{102, 143–145}

According to the phase diagram of the BaB₂O₄–Na₂O section (see Fig. 12), the temperature range of crystallisation of β -BaB₂O₄ is ~ 170 °C. The compositions suitable for growth of the low-temperature phase lie in the range 22 mol.%–30 mol.% Na₂O. Usually, the composition with the Na₂O content between 20 mol.% and 22 mol.% is used as charge. However, supercooling of the melt allows growth of large β -BaB₂O₄ crystals at a Na₂O content of less than 5 mol.% at ~ 1050 °C.¹²¹

The volatility of the melt increases along the BaB₂O₄–Na₂O section, whereas its viscosity decreases as the concentration of Na₂O increases.^{121, 132, 145}

b. Crystal growth techniques

The driving force of the melt-solution growth of BBO crystals is due to temperature reduction. Usually, vaporisation of the solvent is not used as a method for the preparation of a supersaturated solution.^{117–119} The process can be performed using various equipment.

Schematic illustrations of a number of crystal growth techniques are shown in Fig. 10.

Only a few studies are concerned with the growth of (i) BBO single crystals by the travelling solvent method (a version of zone melting technique),¹³¹ (ii) single-crystal filaments by laser-assisted pulling from pedestal¹²⁰ and (iii) plates using the Stepanov technique.^{85, 92}

The so-called top-seeded solution growth (TSSG) technique is most widely used.^{45, 46, 66, 86, 121, 130, 137–140, 146} It allows bulk BBO crystals (up to 60 mm in diameter and more than 10–15 mm long) to be grown (Fig. 16). Several versions of this method are known. If crystal growth occurs on slow cooling of the melt without pulling the seed, one deals with the Kyropoulos technique. The Czochralski method involves pulling of the seed-growing crystal under isothermal conditions (see Fig. 10).

In the case of melt-solution crystallisation the composition of the crystal differs from that of the melt; therefore, a feature of the Czochralski technique is continuous change in the composition of the melt and, correspondingly, in the crystallisation conditions. To avoid variations of the melt composition and other parameters and to maintain steady-state growth conditions, a method involving melt feed with BBO charge was proposed.¹³²

Often, a combination of the two above-mentioned growth techniques is employed. In this case, a slow pulling of the crystal is

Figure 16. Photographs of a BBO crystal (*a*), axial slice 8 mm thick (*b*) and a nonlinear optical element of dimensions $8 \times 8 \times 15 \text{ mm}^3$ (*c*). Paper cell size is $5 \times 5 \text{ mm}$. The crystal was grown by the authors of this review at the Crystal Growth Laboratory, Institute of Mineralogy and Petrography, Siberian Branch of the Russian Academy of Sciences.

combined with slow cooling of the melt. The major advantages of the TSSG technique with pulling of the crystal compared to analogous technique without pulling are as follows:

- higher crystal growth rate;
- the possibility of growing thick crystals in smaller crucibles;
- prevention the crucible walls from touching with the growing crystal, which causes seed failure.

Seed growth of bulk $\beta\text{-BaB}_2\text{O}_4$ crystals of good quality with and without pulling from Na_2O flux has been reported.¹²¹ The seed rotation rate varied from 2 to 60 rpm while the pulling speed was $0.01\text{--}0.02 \text{ mm h}^{-1}$. The high seed rotation and crystal pulling rates cause undesired changes in the shape of the interface from a convex interface to a concave one. Inclusion-free BBO crystals were grown at low pulling rates (of the order of 0.5 to 1.0 mm per day).

As a rule, a melt of composition 75 mol.% BBO–25 mol.% Na_2O was used. The liquidus temperature for this composition is $\sim 886^\circ\text{C}$. The starting reagents (BaCO_3 , H_3BO_3 and Na_2CO_3) were weighed, mixed and placed in a platinum crucible 75 mm in diameter. Then the crucible was heated to $\sim 1110^\circ\text{C}$ over a period of several hours until complete decomposition of carbonates. Seed crystals with different orientations were used for crystal growth. Orientation of the seed crystal affects not only the rate and quality of growth, but also the shape of the BBO crystal. A high

anisotropy of the growth rate of BBO crystals was reported. The rates of growth along the *a* and *b* axes were found to be higher than the rate of growth parallel to the *c* optical axis. Crystals grown parallel to the *a* and *b* axes or in other directions that strongly deviate from the *c* axis usually undergo spontaneous cracking in the (001) cleavage plane. This is due to anisotropy of the thermal expansion. The thermal expansion and thermal conductivity coefficient of BBO crystals measured along the *c* axis are by nearly an order of magnitude larger than those measured in the perpendicular direction.³⁹

The radial and axial temperature gradients and the shape of the liquid–solid interface are important parameters that define quality of the crystal. Crystals of the best quality are usually grown if the interface is flat or slightly convex. The shape of the interface depends on both the pulling speed and the seed rotation rate. Obtaining a flat or slightly concave interface requires that the pulling speed and the seed rotation rate be 0.5–1.0 mm per day and 4–8 rpm, respectively. As the seed rotation rate increases, the contribution of forced convection gradually becomes much larger than that of natural convection. If the pulling speed seed is too high, the growing crystals can lose contact with the solution.

Search for methods of control of convective heat and mass transfer always has received considerable attention, since it is these processes that in most cases provide the possibility of growing particular types of crystals with preset properties. All methods of control can be divided into contact methods and contactless ones. The former are based on the action of a physical body placed in contact with the melt, solution or another crystallisation medium. Most of these methods involve mechanical rotation of the crystal and/or crucible, the use of various diaphragms, stirrers, shape-forming elements, *etc.* A number of contact methods have been applied to the growth of BBO crystals.^{139, 147, 148} Extreme sophistication of the mechanical devices gave an impetus to search for simpler methods of control of the heat and mass transfer processes. This approach had some success.

Contactless techniques are based on the action of physical fields (gravitational, electromagnetic and thermal) on the heat and mass transfer processes.

In practice, all crystal growth techniques include (sometimes, unconsciously) a certain pattern of the heat field. In most cases these are static heat fields characterised by the symmetry axis of an infinite order, L_∞ , and particular values of the axial and radial temperature gradients. Traditionally, crystals are grown in tube heating furnaces with cylindrical heat field symmetry L_∞ (excluding the edge effects). With the advent of precision heating furnaces (PHF),¹⁴⁹ the possibility of controlling the heat field and the heat and mass transfer during the crystal growth appeared. This is achieved by changing the heat field symmetry and by rotating the heat field. A version of dynamic control of the heating elements (HE) in such a furnace has been reported.^{150–153} In practice, the growth of crystals under conditions of static, azimuthally distributed heat field in the PHF is also of considerable interest.¹⁴⁰ These conditions are created by either commutation or regular arrangement of the HE around the PHF muffle, which provides a radially distributed pattern for power delivered to the muffle walls and, hence, to the walls of the growth crucible.

Experiments on the growth of BBO crystals¹⁴⁰ were carried out using a heating furnace with a total of 18 HE arranged evenly around the quartz muffle 110 mm in diameter with walls 4 mm thick. Switching on all series-connected HE in the furnace produced a heat field of cylindrical symmetry L_∞ . Strictly speaking, in this case the heat field symmetry should be L_{18} ; however, it was considered as L_∞ (within the limits of experimental error) due to the choice of an optimum distance between the HE and taking into account the effect of the heat field smoothing by the muffle and the crucible walls. Switching off each third HE changed the heat field symmetry in the furnace to six-fold symmetry L_6 . If three HE arranged at an angle of 120° with respect to one another were switched off, the heat field symmetry reduced to L_3 . In

Figure 17. Polar diagrams of the heat fields of symmetry L_∞ (a), L_6 (b) and L_3 (c) used for the growth of BBO crystals (at the top) and the corresponding convective patterns (at the bottom). The open circles denote the switched off heating elements.

Fig. 17, we present the horizontal sections of the growth furnace and the polar diagrams of the heat fields of symmetry L_∞ , L_6 and L_3 , as well as the typical convective patterns on the melt-solution surface, formed under the action of the heat fields of different symmetry.

BBO crystals were grown on a 4×4 mm seed oriented parallel to the optical axis c . The growth procedure consisted in search for an equilibrium temperature by seed touching the melt-solution surface in the place where the rays of the convective star are brought to a point. After the seed started to spontaneously dissolve, the temperature in the furnace was lowered by 1–2 degrees. The next touching of the melt surface was performed after 2–3 h. After prolonged (12–24 h) liquid–seed contact the crystal was allowed to grow on cooling the furnace at a rate of 1–3 degrees per day. The seed was rotated at 1–2 rpm and moved upward at a rate of 0.3–0.4 mm per day. The growth process continued until the crystal became visually much less transparent. This was interpreted as an indication of the constitutional supercooling, which induced a cellular crystal growth.

The experimental data on the growth of BBO crystals under the action of steady-state heat fields of different symmetry are listed in Table 3. As can be seen, a change in the heat field symmetry from L_∞ to L_6 led to a slight increase in the ‘yield’ coefficient (from 1.22 ± 0.02 to 1.27). However, the ‘yield’ coefficient increased by a factor of 1.7 to 2.07 g (kg deg)^{−1} on going to L_3 symmetry [cf. a theoretical value of ~ 2.52 g (kg deg)^{−1} obtained according to the liquidus equilibria in the BaB₂O₄–Na₂O system].

Table 3. Experimental data on BBO crystals grown in a crucible 100 mm in diameter at initial charge of 1.5 kg in heat fields of different symmetry.¹⁴⁰

Run No.	Heat field symmetry	ΔT /°C	Pulling /mm	Crystal mass /g	‘Yield’ coefficient ^a /g (kg deg) ^{−1}
1	L_∞	117.5	12.6	212	1.20
2	L_∞	122.9	10.3	227	1.23
3	L_∞	106.4	16.7	198	1.24
4	L_6	94.2	14.2	179	1.27
5	L_3	103.0	14.4	319	2.07

^a The ‘yield’ (or ‘mass production’) coefficient is an increase in the mass of a crystal grown upon 1 °C temperature reduction at initial crucible charge of 1 kg.

The changes in the ‘yield’ coefficient as function of the heat field symmetry and the observed character and evolution of convective flows on the melt surface were interpreted as follows.¹⁴⁰ As the heat field with L_3 symmetry was created in the growth furnace, the convective regime in the bulk of the melt changed fundamentally. The fluid body divided into three azimuthally distributed convective cells in which the thermal-gravitational flows moved up and down, thus ‘enveloping’ nearly the whole bulk of the liquid phase and forming three intense surface flows merging at the centre. This convective regime provided a permanent renewal of the melt in the region near the crystallisation interface, thus substantially delaying the onset of constitutional supercooling. In this case the ‘yield’ coefficient amounted to 82% of its maximum theoretical value. This, in a way, characterises the extent of involvement of the fluid body in the convection.

BBO crystals thus obtained were found to have a very small central defect region. These crystals can be used for fabrication of relatively large (up to 20 mm and more) nonlinear optical elements and electro-optical cells oriented parallel to the optical axis c .

Feigelson *et al.*¹³⁰ reported the ‘yield’ coefficients of 2.01 and 2.13 g (kg deg)^{−1} obtained in the growth of BBO crystals from a crucible 55 mm in diameter with the corresponding initial charges of 380 and 290 g. An increase in the charge to 470 g caused reduction of the ‘yield’ coefficient to 1.6 g (kg deg)^{−1}. This points to significant difference between the convective regimes in the crucibles 55 and 100 mm in diameter at comparable temperature gradients in the growth furnace.

Recently,¹⁵⁴ pioneering results concerning the growth of BBO crystals in rotating heat fields of different symmetry have been reported.

VIII. Defects and impurities in crystals

Information on intrinsic nonstoichiometry and impurity defects in BBO crystals is scarce.¹⁵⁵ Three types of radiation defects that exhibit UV absorption at 210, 250 and 310 nm were identified in γ -irradiated BBO crystals. The formation of these defects is assumed to be associated with both cleavage of the B–O bonds and atomic displacements from the equilibrium positions.¹⁵⁶

Growth defects were studied by chemical etching, optical microscopy, microprobe technique, X-ray topography and laser scanning tomography.^{46, 86, 121, 130, 157, 158} The main types of defects found in BBO crystals were inclusions (usually, they are interpreted as flux inclusions) and inclusion-induced dislocations. The appearance of gas bubbles is associated with the presence of trace amounts of non-decomposed carbonates in the charge.⁸⁶ High density of dislocations due to solvent trapping was pointed out.¹²¹ It is assumed that removal of inclusions must favour a substantial improvement of the quality and optical characteristics of BBO crystals.

The content of sodium in β -BaB₂O₄ crystals grown under different conditions (from melt-solution and from a stoichiometric melt according to Czochralski) can vary from 120 to 680 ppm (0.012 mass %–0.068 mass %).¹⁵⁹ Transparent inclusion-free crystals contain from 0.012 mass % to 0.023 mass % Na. At a sodium content of greater than 0.035 mass %, the crystals are semi-transparent until becoming opal. Sodium impurity was found to be responsible for thermoluminescence of BBO crystals.^{159, 160}

Among other impurities, an increased concentration of strontium was pointed out.¹⁶¹ Probably, this impurity incorporates into the BBO crystals from barium-containing starting reagents. Lead impurity causes stabilisation of the α -modification of BaB₂O₄.⁴⁹

A feature of BBO crystals is accumulation of sodium and potassium impurities.¹⁰¹ The critical concentration of sodium is 0.021 mass %. As the content of sodium exceeded this value, inclusions of the second phase and the scattering centers appear.¹⁰¹ The effective distribution coefficient of sodium between the crystal and melt is $(2.5–4.4) \times 10^{-3}$.

From crystal chemical considerations it follows that alkali metal impurities can incorporate into the structure of β -BaB₂O₄. As can be seen in Fig. 7, BaB₂O₄ and a sodium compound NaBO₂ are structurally similar. They contain identical structural fragments (boron – oxygen [B₃O₆]³⁻ anions) stacked perpendicular to the *c* axis of the trigonal lattice and exhibit a similar packing motif. The difference is in the arrangement of cations; the number of sodium ions that provide electrostatic compensation of charge is twice as large as the number of barium ions. The trigonal unit cells also have close parameters (see Table 1). This suggests the possibility of heterovalent isomorphism simply described as Ba $\rightleftharpoons$ 2Na and incorporation of extra sodium ions into the β -BaB₂O₄ lattice. The authors of this review also assume that the major type of intrinsic point defects in β -BaB₂O₄ crystals are Frenkel pairs characterised by displacement of Ba ions from the equilibrium positions to the interstitial ones. Close values of the unit cell parameters allow epitaxial growth of NaBO₂ on the β -BaB₂O₄ crystals.

Even better is agreement between the lattice parameters of β -BaB₂O₄ and potassium metaborate, KBO₂, which is isostructural to the sodium-containing analogue. Potassium ions are readily incorporated into the BBO lattice (potassium fluoride melt was used as flux).⁶⁶

The distribution coefficient of sodium in BBO crystals is small, therefore this impurity can be removed by zone melting with ease.⁸⁸ Low efficiency of this technique in the removal of strontium impurity from BBO crystals¹⁰⁷ indicates that the corresponding distribution coefficient approaches a unity.

Inclusions in BBO crystals were found to be sodium enriched.^{46, 130} Identification of the phase that is formed at the crystallisation interface, thus blocking the process of crystal growth, by X-ray powder diffraction failed.⁶⁶ However, a recent X-ray powder diffraction study of the particles with inclusions, picked up with a microscope, showed¹⁰² that this phase has a composition NaBaBO₃.

IX. Constitutional supercooling

Morphological instability of the crystallisation front (Fig. 18) occurs in a certain stage of melt-solution growth of BBO crystals (usually, as the crystal becomes ~ 15 mm thick). It involves the development of a characteristic cellular substructure with quasi-hexagonal cells, which is accompanied by trapping of inclusions and the formation of a protrusion.^{46, 66, 130} The appearance of cellular substructure is the major reason for forced termination of the process of crystal growth. This phenomenon is associated with specific features of heat transfer during the growth process.^{130, 143} However, usually the morphological instability is due to the

Figure 18. Qualitative picture of the development of morphological instability of the crystallisation front and the formation of cellular substructure.

constitutional supercooling which has been studied in detail for binary systems.^{162–166}

Consider the growth of BBO crystals from a Na₂O melt-solution. In this case, sodium piles up near the solidification front, thus causing the loss of its stability. Figure 19 presents a scheme illustrating the distribution of the melt components in the region adjacent to the solidification front for a steady-state growth of BBO crystals from Na₂O melt-solution at the rate *R*. Since the amount of sodium incorporated into the crystal is very small, it is displaced by the growing crystal and is accumulated near the liquid – solid interface. The sodium concentration jump appeared at the crystallisation front induces a diffusion flow of sodium ions in the melt, which is directed away from the liquid – solid interface. The content of barium and boron in the melt is somewhat lower than in the crystal; therefore, these components are trapped by the crystal. This leads to the appearance of a region depleted of Ba and

Figure 19. Schemes illustrating the distributions of the B, Ba, Na and [B₃O₆]³⁻ ring ion concentrations in the crystal – melt system for a steady-state directional crystallisation occurring at a rate *R* (a), of the equilibrium crystallisation temperature of β -BaB₂O₄ (solid line) and of actual change in the temperature (dashed line) (b), and the hypothetical change in the melt composition with the distance from the solidification front (diffusion path) during the growth of BBO crystals (c).¹⁰⁴

Shown are the constitutional supercooling region (b, hatched), the melt composition at the solidification front (c, 1) and the starting composition of the melt (c, 2).

B near the crystallisation front and induces diffusion flows directed from the bulk of the melt towards the interface. Accumulation of the excess sodium should reduce the equilibrium liquidus temperature. The integrated distribution curve of the equilibrium crystallisation temperature is presented in Fig. 19b while the possible shift of the figurative point corresponding to the melt composition for actual crystallisation is shown in Fig. 19c. Since the BaB₂O₄–Na₂O section is unstable, the line corresponding to the change in the melt concentration with distance from the solidification front (diffusion path) should deviate from this section, thus forming a zig-zag curve on the concentration triangle.¹⁶⁷

More detailed analysis of the situation requires a consideration of different forms of boron present in the melt. As mentioned above, melting of BaB₂O₄ causes destruction of the [B₃O₆]^{3–} ring anions (*i.e.*, this crystal is a typical example of compound which nearly completely dissociates on melting).^{99, 100, 112} According to the molecular dynamics calculations,¹⁶⁸ the addition of Na₂O to the melt leads to shortening of the [BO₂]_{*n*}[–] polymer chains formed by [BO₃]^{3–} triangles and to an increase in the proportion of isolated [BO₃]^{3–} triangles, dimeric [B₂O₅]^{4–} units, three-membered [B₃O₇]^{5–} fragments and [B₃O₆]^{3–} ring anions. Nevertheless, one can state that it is the low concentration of the [B₃O₆]^{3–} ring anions near the crystallisation front that is the limiting factor for the growth of BBO crystals.

It should be noted that steady-state melt-solution growth of BBO crystals can be performed using the Czochralski method with melt feed¹³² or by floating zone technique.¹³¹ Experiments carried out according to Kyropoulos (with slow cooling of the system) represent a kind of non-steady-state processes characterised by accumulation of sodium near the solidification front (Fig. 20).

The simplest constitutional supercooling criterion for solidification front stability is provided by the Tiller–Chalmers criterion

$$\frac{GD}{R} < \frac{mC_0(1-k)}{k},$$

where G is the temperature gradient in the melt at the solidification front, D is the diffusion coefficient of the solute, R is the crystal growth rate, m is the slope of the liquidus curve, C_0 is the concentration of the solute in the solution and k is the partition coefficient. This criterion was proposed for steady-state processes in dilute binary systems^{162, 163} and cannot be applied to the crystallisation of BBO. This criterion is equivalent to the boundary condition at the crystallisation interface while the integrated curve describing the increase in the equilibrium crystallisation temperature (liquidus temperature) with the distance from the solidification front of BBO follows the same pattern as in the case of binary systems. Therefore, the criterion for morphological stability of the solidification front of BBO (heat transfer is assumed negligible) can be written as follows

$$\frac{G}{R} D^* < m\Delta C,$$

where D^* is the function of the diffusion coefficients of the components of the system in the melt (it varies from one composition to another), m is the directional derivative of the liquidus temperature taken along the tangent to the diffusion path at the point corresponding to the melt composition at the solidification front (this point is labelled l in Fig. 19c) and ΔC is the change in the composition at the interface. An analogous expression proposed¹⁶⁶ for binary systems can also be used for non-steady-state processes.

In any case the most important factors improving the stability of the solidification front against constitutional supercooling are an increase in the temperature gradient at the crystallisation front and a decrease in the crystal growth rate.

Figure 20. Schemes illustrating successive accumulation of sodium ahead of the crystallisation front for a non-steady-state growth of BBO crystal (a) and the change in the sodium content in the crystal (l) and in the melt (2) (b).

There are two reasons for deterioration of the optical quality of flux grown BBO crystals. These are (i) the attainment of critical supersaturation with respect to sodium near the crystallisation front and (as a consequence) the appearance of a cellular structure with trapped inclusions and (ii) accumulation of sodium impurity above the equilibrium solubility (limiting concentration) in BBO followed by crystallisation of the second phase on cooling of the crystal. In both cases mixing of the melt for not only control of the heat convection, but also homogenisation of the melt composition is of paramount importance.

X. Properties and fields of application of β -BaB₂O₄ crystals

Crystals of the non-centrosymmetric low-temperature modification, β -BaB₂O₄, are widely used in nonlinear optics as nonlinear-optical crystals possessing large birefringence for the generation of optical harmonics and sum frequencies of laser radiation in the visible and UV regions. Widespread use of this material in quantum electronics is to a great extent due to relatively high optical damage threshold. Numerous applied^{30, 169–195} and materials science studies^{156, 157, 196–201} of BBO were reported in the last decade.

Development of compact solid-state sources of tunable UV, visible and IR radiation is topical. Currently, BBO-crystal para-

metric light oscillators (OPOs) pumped by the second and third harmonics of Nd:YAG lasers are most widely used. These devices generate tunable radiation in the 2628 and 3036 nm regions, respectively.¹⁹² The tuning range of BBO-crystal OPOs is limited to strong absorption of the idler wave radiation in the spectral region from 2200 to 3000 nm.⁴⁴ The pioneering study of the characteristics of a BBO-crystal OPO pumped by the fourth harmonic of a Nd:YAG laser ($\lambda = 266$ nm) was reported by Bosenberg *et al.*¹⁹³ A BBO-crystal OPO 25 mm long generated radiation in the spectral region between 330 and 1370 nm at a pulsed pump intensity exceeding 23 MW cm^{-2} . Another BBO-crystal OPO pumped by the fourth harmonic of a single-mode Nd:YAG laser generated radiation in the region 302–2248 nm at a pulsed pump energy of 20 mJ with a conversion efficiency of 6.3% at a wavelength of 340.2 nm at quadruple the oscillation threshold.¹⁹²

The characteristics of a BBO-crystal Type-I OPO pumped by the fourth harmonic of a multimode Nd:YAG laser have been studied.¹⁹⁴ The output was tunable over the region 300–2340 nm. The efficiency ranged up to 15% near the peak of the tunability curve at double the oscillation threshold. The OPO configuration was based on a BBO crystal (aperture 6×8 mm, length 14 mm) cut for Type-I phase matching at an angle (θ) of 38.3° with respect to the optical axis of the crystal.

The above-mentioned applications of BBO crystals were based on the second-order optical nonlinearity. However, $\beta\text{-BaB}_2\text{O}_4$ also possesses third-order optical nonlinearity.³⁰ In particular, it was found that picosecond laser pump of BBO at 1 μm excites efficient Stokes and anti-Stokes Raman parametric generation (RPG) and allows simultaneous SHG and multicomponent RPG in the visible and near IR regions. In particular, a BBO-crystal active element 15 mm long [excitation configuration $a(cc)a$] pumped at 1 μm re-emitted to all RPG components more than 35% of the energy (~ 1 mJ), the first Stokes line ($\lambda = 1.1414 \mu\text{m}$) accounting for $\sim 20\%$. The efficiency of picosecond RPG from $\beta\text{-BaB}_2\text{O}_4$ was also illustrated by an extended (up to the thirteenth component with $\lambda = 0.5661 \mu\text{m}$) wing of the multicomponent anti-Stokes spectral region. Based on high SHG efficiency of BBO crystals, an SRS experiment with the optically active element oriented parallel to the Type-I phase matching direction ($ee-o$) was carried out.³⁰ The experiments showed the possibility of simultaneous conversion of the 1 μm pump of BBO into both the Stokes and anti-Stokes components and the second harmonic. It was found that excitation of the multicomponent RPG induced by the second harmonic generated by the BBO crystal occurs at a lower pump power, which is due to high SHG efficiency from BBO crystals and to dispersion of the Raman amplification coefficient of BBO. This discovery — simultaneous manifestation of the second- and third-order optical nonlinearities in BBO crystals — can be used for creation of novel types of $\beta\text{-BaB}_2\text{O}_4$ -based laser frequency converters.

Electro-optical application of BBO crystals as Pockels cells in the UV spectral region should be emphasised.¹⁹⁵

Recently, BBO crystals have been on the commercial market. A large body of valuable information on the physicochemical properties of BBO crystals can be found in the Internet at URLs <http://www.crystaux.com/betabbo.htm> (website of DLK Crystal) and <http://www.clevelandcrystals.com/BBOLOBO.shtml> (website of Cleveland Crystals, Inc.). The principal properties of BBO crystals are listed in Table 4.

XI. Conclusion

Based on the aforesaid, the following conclusions can be drawn.

Polymorphism of BaB_2O_4 is a unique phenomenon. On the one hand, the high- and low-temperature modifications of this compound have substantially different structures. On the other hand, their thermodynamic characteristics are nearly identical. Studies of the mutual stability of these modifications and of the influence of different factors on their crystallisation and kinetics

Resistivity / $\Omega \text{ cm}$	$> 10^{11}$
Relative static dielectric constants ^k	6.7; 8.1

^a The n_o and n_e values are respectively given. ^b e -Ray. ^c o -Ray. ^d The d_{22} value. ^e The d_{15} value. ^f Given are the θ and Φ values, respectively. ^g Listed are the r_{22} , r_{31} and r_6 values, respectively. ⁱ Given are the α_a and α_c values, respectively. ^k Given are the ϵ_{11}/ϵ_0 and ϵ_{33}/ϵ_0 values, respectively.

of transformations are of great importance. In this connection, investigations of the heat capacities of both modifications of BaB_2O_4 over a wide temperature range are also required.

Hübner's data^{62, 65} on the stability of compound $\text{Ba}_2\text{B}_2\text{O}_5$ and on the formation of BaB_2O_4 -based solid solutions strongly contradict the phase diagram of the $\text{BaO}-\text{B}_2\text{O}_3$ system proposed by Levin *et al.*^{12, 13} An indirect proof of variable composition of BBO is provided by small but, at the same time, noticeable variations of the lattice parameters of single crystals, determined by different authors. Both nonstoichiometry of BaB_2O_4 and the $\text{BaO}-\text{B}_2\text{O}_3-\text{Na}_2\text{O}$ system in the BaO -enriched region (in particular, in the $\text{Ba}_3\text{B}_2\text{O}_6-\text{NaBaBO}_3-\text{BaB}_2\text{O}_4$ concentration triangle) call for further investigation.

Studies of the phase equilibria in the BaO–B₂O₃–Na₂O ternary system showed that the BaB₂O₄–Na₂O section, which is most often used for growth of β -BaB₂O₄ single crystals from Na₂O, is unstable and that compound Na₂BaB₂O₅ does not exist. Compound NaBaBO₃ was identified and structurally characterised. The BaB₂O₄–Na₂O section passes nearly exactly through the eutectic in the BaB₂O₄–NaBaBO₃–NaBO₂ ternary system.

The BaB₂O₄–Na₂O melt used for growth of BaB₂O₄ crystals is multicomponent and unstable. Further search for optimum growth conditions and better solvents seems to be appropriate.

Improvement of methods of control of the heat and mass transfer during crystal growth including those involving variation of the heat field patterns is also topical.

This review has been performed as part of the Research Project 'Investigations of the Phase Diagrams, Search for Solvents and Growth of Nonlinear Optical Crystals in Heat Fields of Different Symmetry' carried out in the framework of the Integration Programme 'Novel Principles and Methods of Design and Targeted Synthesis of Chemical Compounds with Preset Properties' in accord with the Decision of the Presidium of the Siberian Branch of the Russian Academy of Sciences signed on 09.04.2002.

The authors express their gratitude to P Peshev (Institute of General and Inorganic Chemistry, Bulgarian Academy of Sciences, Sophia) for providing access to valuable information, to R M Zakalyukin, E A Tkachenko (A V Shubnikov Institute of Crystallography, Russian Academy of Sciences, Moscow) and S V Kuznetsov (M V Lomonosov Moscow State Academy of Fine Chemical Technology) for technical support and to Yu V Pisarevskij (A V Shubnikov Institute of Crystallography, Russian Academy of Sciences) and A M Yurkin (Institute of Mineralogy and Petrography, Siberian Branch of the Russian Academy of Sciences) for valuable help.
