VII. Reactions of alkenes with NO ⁺	338

Abstract. Reactions of alkenes with nitrogen oxides and other nitrosating and nitrating reagents are considered. The bibliography includes 134 references.

I. Introduction

Reactions of alkenes with nitrogen oxides and other nitrosating and nitrating reagents have attracted attention during the entire history of contemporary organic chemistry. The fundamental studies carried out in this area are of independent significance and have contributed considerably to the arsenal of organic synthesis by providing new preparative methods and accessible highly reactive synthetic blocks.

In this review, we consider the transformations of alkenes in reactions with NO, NO₂, their synthetic equivalents and sources of NO⁺, NO₂⁺ and NO₂⁻ ions. Aside from differences originating from the specific nature of each of these reagents, their reactions with alkenes have certain common features which manifest themselves in the similarity of the intermediates and products formed. Particular attention is paid to reactions which result in aliphatic and alicyclic nitro compounds, since the uses of these compounds in organic synthesis are the most diverse (see., *e.g.*, the reviews ^{1–8}).

The transformations discussed here have been reported in the last 10–15 years. Earlier examples can be found in other reviews.^{9–12} In particular, reactions of alkenes with N₂O₃, N₂O₅ and HNO₃ have been considered in detail in those reviews; however, there have been few publications on these reagents recently,^{13,14} since, as a rule, their reactions have only limited application in preparative synthesis. One should note, however, a recently developed original solid-phase method for the synthesis of 2-arylnitroethenes from styrenes under microwave radiation in the presence of Fe(NO₃)₃ · 9 H₂O or an NH₄NO₃–clay system.¹⁵

Likewise, we do not consider reactions of alkenes with NOCl discussed in detail previously,¹⁶ since this reagent has rarely been used for alkene functionalisation in recent years.¹⁷

II. Reactions of alkenes with NO

Although the NO molecule has an unpaired electron, it is characterised by its low activity toward potential acceptors of free radicals.¹⁸

At present, evidence is available that NO cannot add directly to alkenes. It was reported back in 1957 that meticulously purified NO can be kept in contact with liquid alkenes for a few days without noticeable interactions.¹⁹ It was reported later that pure NO did not react with functionally substituted alkenes (allyl benzyl ether, acetylcyclohexene) or with 1,4-diphenylbuta-1,3-diene.²⁰ It was also found that alkenes with electron-donating substituents at a double bond (butyl vinyl ether and silyloxycyclohexene) undergo changes in the presence of NO but no nitrogen-containing compounds are formed.

On the other hand, there are rather many examples where nitrogen-containing products are obtained in NO–alkene systems. In the study mentioned above,¹⁹ isobutene reacted with NO (from a gas cylinder) containing an admixture of NO₂ to give nitroisobutene **1** and a labile compound with unknown structure, which decomposed during high-vacuum distillation to give nitroalkene **2**.

Brown¹⁹ emphasised that traces of NO₂ in NO are a prerequisite for the reaction. It was assumed that it is NO₂ that triggers the free radical process which continuously regenerates NO₂. This hypothesis was confirmed by the well-known ability of free radicals (including alkyl radicals) to convert NO into NO₂.²¹ According to more accurate data reported later,²² the reaction in the NO–isobutene system yields a very labile hydroxylamine **3** as the main product. The latter is presumably formed as a result of successive reaction of NO with three nitro-*tert*-butyl radicals **4** (which result from the addition of NO₂ present in NO to the alkene) *via* the nitro nitroso compound **5** and the iminoxyl radical **6**.

A V Stepanov, V V Veselovsky N D Zelinsky Institute of Organic Chemistry, Russian Academy of Sciences, Leninsky prosp. 47, 19991 Moscow, Russian Federation. Fax (7-095) 135 53 28. Tel. (7-095) 135 88 54. E-mail: step@ioc.ac.ru (A V Stepanov), ves@ioc.ac.ru (V V Veselovsky)

Received 24 September 2002

Uspekhi Khimii 72 (4) 363–378 (2003); translated by S S Veselyi

$\text{R} = \text{CMe}_2\text{CH}_2\text{NO}_2$.

It should be noted that the radical **6** was detected in an ESR study of this reaction.²³ In addition, nitro-*tert*-butyl radicals **4** were also identified. It was noted that the addition of oxygen to the reaction medium accelerated the process considerably; this confirms the activating role of NO_2 , the concentration of which in the reaction mixture increases due to the oxidation of NO.

On moderate heating, hydroxylamine **3** gives a mixture of nitroisobutenes **1** and **2** in the ratio 1 : 4 and in an overall yield of 85%. It is assumed that the reaction occurs *via* a six-membered transition state.²²

The relatively stable 1-nitro-2-nitroso-1,1,2,2-tetrafluoroethane **7**, which is akin to the intermediate **5** postulated by Phillips and Coyne,²² is the major product formed in the NO – tetrafluoroethylene system.²⁴

The suggested reaction mechanism also involves initiation of the chain process by NO_2 radicals, which are more reactive than NO. The resulting radical **8** is subsequently recombined with NO to give the nitro nitroso compound **7**. This mechanism is confirmed by the fact that no 1,2-dinitrosotetrafluoroethylene was present in the reaction products; the presence of the latter would have meant that the process was initiated by direct addition of NO to the alkene. The authors noted that the reaction was accelerated considerably on addition of NO_2 to the reaction mixture and suggested the possible ways of its formation. In particular, the reaction of perfluoronitronitrosoethane **7** with an excess of NO may give two NO_2 molecules per molecule of the nitroso compound.

When the concentrations of NO_2 and NO become comparable, the recombination of NO_2 with the radical **8**, which terminates the chain process and gives the side dinitro compound **9**, acquires a progressively significant role.

The formation of NO_2 is also possible as a result of disproportionation $3\text{NO} \rightarrow \text{NO}_2 + \text{N}_2\text{O}$, which is favoured by an increase in pressure.

For example, it was found²⁵ that thoroughly purified NO reacted at a noticeable rate with cyclohexene or styrene only at pressures above 5 atm; a GC/MS study of the gaseous reaction products revealed the presence of N_2O . At 7 atm, the corresponding dimeric nitro nitroso compounds **10** and **11** were isolated as the main reaction products; their structures were established by X-ray diffraction analysis. However, when this reaction was carried out with raw NO under atmospheric pressure, analysis of the gas mixture also showed that a small amount of N_2O was present.²⁶

The fact that the presence of NO_2 plays a key role in the reaction of NO with alkenes is also confirmed by results of other studies^{27,28} where linoleic and arachidonic acids and their esters were used as substrates (as models of unsaturated lipids). The air equilibrated reactions were carried out in cyclohexane or benzene. Complex product mixtures were obtained; based on spectroscopic data, nitroalkenes and nitro nitrates were the main components of these mixtures. It was noted that this process was virtually not observed if the reaction mixture did not contact air.

$\text{R}^1 = (\text{CH}_2)_3\text{Me}$, $\text{R}^2 = (\text{CH}_2)_6\text{CO}_2\text{Et}$; $\text{R}^1 = (\text{CH}_2)_6\text{CO}_2\text{Et}$, $\text{R}^2 = (\text{CH}_2)_3\text{Me}$.

It is evident from the examples described above that reactions in alkene – NO systems are not straightforward; as a rule, they give mixtures of products. What is more, their results depend on the purity of nitrogen oxide used. However, studies of the nature of processes in this system have made it possible to develop an efficient method for converting mono- and disubstituted alkenes of the type **12** – **15** into conjugated nitro derivatives.^{29–31}

According to the standard procedure, a solution of an alkene in dichloroethane is stirred under NO, then acidic alumina is added to the reaction mixture, which is refluxed for a short time. The yields of the corresponding vinylnitro compounds **16** – **19** reach 90%. It was found later that treatment with Al_2O_3 can be excluded by performing the reaction in the presence of H-zeolites.³²

$\text{R} = \text{Alk}, \text{Ar}, (\text{CH}_2)_3\text{X}$; $\text{X} = \text{CH}_2\text{Ac}, \text{OSiMe}_2\text{Bu}^t, \text{OAlk}$.

A detailed study of the characteristic features of this process using 4-phenylbut-1-ene as an example made it possible to reveal certain regularities. It was found that complete conversion of the alkene requires four equivalents of NO. A mixture ($\sim 4:1$) of the vinylnitro compound **20** and the nitro alcohol **21** is formed initially (Al_2O_3 is used for the dehydration of the latter). Analysis of the reaction products revealed its stoichiometry:

Using a lesser amount of NO, Hata *et al.*³⁰ isolated the dimer of an intermediate nitro nitroso compound **22**, which reacts with NO to give nitroalkene **20** with liberation of one equivalent of N_2 .

As noted above, there is evidence that thoroughly purified NO does not react with 1,4-diphenylbuta-1,3-diene.²⁰ This observation contradicts earlier data,³³ according to which the reaction of NO with 1,4-diphenylbuta-1,3-diene gives the nitro nitrate **23**. However, it was assumed that the chain radical process is initiated by direct addition of NO to the diene to give an allyl radical, which then recombined with another NO molecule.

The accumulation of NO_2 , which gives rise to the dinitro derivative **23**, is rationalised as follows: the nitroso compound formed initially can sequentially add two NO molecules to give the $\cdot\text{ONO}_2$ radical. The latter reacts with NO to give two molecules of nitrogen dioxide, which competes with NO as the initiator of the radical chain process.

The suggested mechanism also offers an explanation of the formation of dimeric nitroso compound **24a,b** from 2-chloro- (**25a**) and 2,3-dichlorobuta-1,3-diene (**25b**) under similar conditions. In addition, this reaction gives polymers which, according to IR spectroscopic data, contain NO_2 and ONO_2 functional groups. Complete conversion of 2,5-dimethylhexa-2,4-diene afforded a quite stable dinitro compound **26** and a polymeric product.³³

$\text{X} = \text{H} \text{ (a, 15\%)}, \text{Cl} \text{ (b, 40\%)}$.

It should be noted that the reactions of NO with di(poly)enes are currently considered as a promising way to solve the problem of *in vivo* monitoring of this biologically important molecule³⁴ using the ESR method. In particular, it was found³⁵ that absorption of NO with such conjugated polyenes as vitamins A and D₃, as well as β -carotene, results in the appearance of distinct signals of iminoxyl radicals in ESR spectra. It was noted that NO_2 addition products could not be detected in the reaction mixtures.

Treatment of 2,5-dimethylhexa-2,4-diene with nitrogen(II) oxide also resulted in the appearance, in the ESR spectrum, of signals of an iminoxyl radical,^{36,37} which is assumed to have the cyclic structure **27**. However, attempts to isolate it failed.³⁸

However, as was shown later,²⁰ the signals in the ESR spectrum recorded in this case are due to the presence of the iminoxyl radical **28**, which is formed upon initiation of the process by nitrogen(IV) oxide present in NO as an admixture, and the formation of a nitroallyl radical intermediate.

The idea of using dienes as efficient NO traps in biological objects was implemented using *o*-quinodimethanes, which can be obtained by photolysis of the corresponding indanones.^{39,40}

$\text{R} = \text{CO}_2\text{H}, \text{Et}_3\text{N}^+\text{CH}_2.$

Stable iminoxyl radicals **29** formed upon reactions of quinodimethanes with NO can be reliably detected by ESR. Hydrophilic properties required for the use of these compounds in biological systems are provided by incorporation of substituents ($\text{R} = \text{CO}_2\text{H}, \text{Et}_3\text{N}^+\text{CH}_2$). It is of interest that the ESR spectra of reaction mixtures also contain traces of radicals **30** resulting from the addition of NO_2 to dienes.

In conclusion, let us note certain special methods that make it possible to obtain NO addition products of alkenes.

For example, the addition of the NO-containing cobalt(II) complex **31** to mono- and disubstituted alkenes has been reported.⁴¹ The resulting adducts **32** can be reduced to the corresponding diamines.

$R^1, R^2 = \text{H, Alk, Ar}; R^1 - R^2 = (\text{CH}_2)_n; n = 3, 4.$

The ability of NO to add to alkenes by catalysis with Co(II) complexes is well known. The method involves the initial addition of the hydride complex **A** generated *in situ* to an alkene, dissociation of the resulting metal–carbene adduct **B** to release the alkyl radical **C** and recombination of the latter with NO. The resulting nitroso compound quickly rearranges into an oxime.⁴² In this case, the involvement of coordination-bound NO in the process can be ruled out,⁴³ since the addition of a stronger ligand, *viz.*, pyridine, does not inhibit the reaction.

$R = \text{Alk, OAlk, Hal}; \text{Co(eobe)} = \text{EtO}_2\text{C}-\text{C}_6\text{H}_4-\text{Co}(\text{O})_2-\text{C}_6\text{H}_4-\text{CO}_2\text{Et}.$

The efficiency of this approach was first demonstrated with the transformation of substituted styrenes into the corresponding oximes as an example.^{42, 43} In polar aprotic solvents, the reaction occurs slowly and in moderate yields (40%–60%). The best results were obtained in a mixture of dimethoxyethane and Pr^iOH . In this case, acetophenone oxime was obtained in 83% yield.

The method also proved to be efficient for the nitrosation of α, β -unsaturated amides. In this case, the Co(II) hydride complex was generated using Et_3SiH . The resulting nitroso compounds **33** can be transformed into oximes **34** or reduced with Raney nickel into amino acid derivatives **35**.⁴⁴

$R^1 = \text{H, Alk}; R^2, R^3 = \text{Alk, Ar, ArCH}_2.$

III. Reactions of alkenes with alkyl nitrites

Alkyl nitrites react only with double bonds incorporated in readily polarisable conjugated systems. In particular, it was found that dithiafulvenes react with *n*-pentyl nitrite in CH_2Cl_2 to give the

corresponding nitroso compounds **36** in 60%–70% yields.^{45–47} Diselenafulvenes react with alkyl nitrites in a similar way.⁴⁸

$R^1 = \text{CO}_2\text{Me, Ar, Me, SMe}; R^2 = \text{Ar, COMe, CHO}.$

The proposed reaction mechanism⁴⁵ involves the generation of the NO^+ cation from nitrite; however, owing to the low electrophilicity of the cation, it can only participate in electron transfer; in such a case, it is oxidised into NO. The alkene is converted into the radical cation **37**. Recombination of the latter with NO followed by the reaction of the resulting cation **38** with a second nitrite molecule gives the nitro compound **36** and pentanol; the nitronium ion is regenerated.

Dithiafulvene derivatives **39** are even more reactive with respect to nitrites; under mild conditions, they give unstable nitroso compounds **40a**, which are readily oxidised with atmospheric oxygen into the corresponding nitro derivatives **40b**.⁴⁹

$R = \text{Me, CF}_3, \text{CN}.$

Nitrosation of less reactive substrates with alkyl nitrites can only be carried out under catalysis with Co(II) complexes; this method turned out to be more efficient and more convenient in preparative synthesis than the Co(II)-catalysed reaction of alkenes with NO (see Section II). This is obviously due to the higher electrophilicity of the NO^+ cation in comparison with NO and also due to the fact that this reaction is carried out under homogeneous conditions. For example, nitrosation of substituted styrenes in the presence of catalytic amounts of a porphyrin–Co(II) complex and Et_3SiH as a reducing agent gives oximes **41** with an admixture of the corresponding acetophenones.⁵⁰

$R = \text{H, Me, Cl, CO}_2\text{Me, NO}_2.$

The use of Fe(III) acetylacetonate as a catalyst has also been reported.⁵¹ In this case, mono- and dialkyl-substituted alkenes

gave dimers of the corresponding nitroso compounds in ~ 50% yields.

The use of Co(II)-based catalysts for the nitrosation of linear alkenes **42** with electron-withdrawing substituents by alkyl nitrites was found to be very efficient. The reaction gives oximes **43** in high yields.⁵⁰ Dienes **44** as substrates give the corresponding conjugated oximes.⁵⁰ It was noted that the yields of oximes **43** can be increased noticeably using PhSiH₃ as the reducing agent.^{52, 53}

R¹ = H, Alk; R² = H, Alk, OAlk.

R¹ = H, Bu^t, NR₂², OAlk, OAr; R² = Alk.

Styrenes probably react with nitrites according to a mechanism similar to that suggested for the reaction with NO, whereas the conversions of α,β-unsaturated carbonyl compounds presumably involve cobalt enolate **45**.⁵³

R¹ = H, Alk; R² = Alk, Ph, NMePh, OAlk, OBn; R³ = Et, Ph; R⁴ = Alk.

There is yet another method for using alkyl nitrites for the nitrosation of alkenes.^{54, 55} Thus, a highly reactive intermediate is generated from EtONO upon treatment with SO₃; it is believed to have an ionic structure, viz., EtOSO₂O[−]NO⁺ (**46**). The reaction of an excess of the reagent **46** with various alkenes affords sulfates of α-hydroxy aldehydes (**47**) or ketones (**48–50**).

R = H, Alk.

n = 1, 2, 4.

The reagent **46** also serves as an oxidant which converts the intermediate oximes **51** into the corresponding carbonyl compounds. The proposed reaction mechanism is confirmed by the fact that it is possible to isolate dimers of nitroso intermediates using one equivalent of the reagent **46** with respect to the alkene. This reaction was found to be chemoselective. In particular, only the least hindered double bond is involved in the cyclopentadiene dimer; in the case of cyclooctadiene, the monoadduct **50** can be obtained in high yield.

The reaction of isoprene (**52a**) or dimethylbutadiene (**52b**) with a stoichiometric amount of the reagent **46** ends in the formation of the corresponding oxazonium salts **53a,b**. The reaction of the salt **53a** with an excess of the reagent affords hydroxyaldehyde **54**.

R = H (a), Me (b).

In conclusion, we would like to note the ability of alkyl nitrites to generate reactive species in acidic media, which react with alkenes. For example, treatment of acyclic di-, tri- and tetrasubstituted alkenes with pentyl or butyl nitrite in AcOH gives mixtures of products **55–57**, the composition of which varies depending on the substrate structure.⁵⁶

R ¹	R ²	R ³	R ⁴	Yield (%)		
				55	56	57
Ph	Ph	H	H	27	25	—
Ph	Me	H	H	—	33	—
Me	CO ₂ Me	H	H	—	20	—
Et	Et	Me	H	—	23	43
Me	Me	Me	Me	—	6	30

IV. Reactions involving nitrous acid salts

Nitrous acid salts can serve as sources of various neutral species (NO, NO₂, N₂O₃, N₂O₄) and ions (NO₂[−], NO₂⁺) resulting from disproportionation of unstable nitrous acid formed.⁵⁷ Each of these species can, in one way or another, react with alkenes.

For example, the NO₂[−] anion can undergo Michael-type addition to vinyl ketones on treatment of the latter with NaNO₂ in AcOH, giving β-nitro derivatives in satisfactory yields.⁵⁸

R = Me (82%), Et (46%), Prⁱ (42%), Prⁿ (57%), Buⁿ (65%), n-C₅H₁₁ (68%).

Furthermore, procedures based on the reaction of NO₂[−] and a carbocation generated from an alkene are also known. For example, chloromercuriation of mono- and disubstituted alkenes in the presence of NaNO₂ gives adducts of the type **58**, which can be transformed without isolation into the corresponding nitroalkenes **59a–f** in ~80% yields upon treatment with a base.⁵⁹ Mercury perchlorate can be used instead of HgCl₂.⁶⁰ It should be noted that reactions with hex-3-enes stereoselectively give the *E*-nitro derivative **59f** irrespective of the configuration of the starting alkene.

X = CN (**c**), CO₂Me (**d**).

B: is a base

The conversion of conjugated oximes **60a–d** into nitro acetates **61a–d** on treatment with NaNO₂ in acetic acid was explained by reactions of allylic cations of the types **62** and **63** with NO₂[−] (see Ref. 61). In this case, the system NaNO₂–AcOH (HNO₂) plays a double role, *viz.*, it also cleaves oximes to give carbenium intermediates.

Oxime **60a** gave, in addition to the main product **61a**, the minor cyclopentene **64** corresponding to the carbocation **63**. The predominant pathway of the reaction with the carene derivative **60c** results in the nitro derivative **61c**.

In 1985, Abidi⁶² reported an unusual transformation of the isopropylidene fragment of linear monoisoprenoid derivatives into a methylethynyl fragment, which occurred upon treatment with NaNO₂ in aqueous acetic acid (see also the subsequent papers by Abidi^{63,64}). It should be noted here that later studies of this reaction (formal methane elimination) with the same and related substrates^{65,66} could not reproduce the previously reported^{62–64} high yields (60%–90%) of the corresponding methylacetylenes **65a–g**. For example, the yield of the acetylene **65e** from geraniol was no higher than 35%.⁶⁵

R¹ = H, R² = (CH₂)₂OH (**a**), CH₂CHO (**b**); R¹ = CH=CH₂, R² = OH, OAc, OMe (**c**); R¹, R² = (*E*)-CHCHO (**d**), (*E*)-CHCH₂OH (**e**), (*E*)-CHCH₂CH₂C(O)Me (**f**), (*E,E*)-CHCH₂CH₂C(Me)=CH₂CH₂OH (**g**) *etc.*

It was found that this reaction initially yields the nitro derivative **66**. Its treatment with sodium nitrite in acetic acid affords acetylene **65e** with evolution of an equivalent amount of CO₂.

Attempts to rationalise the mechanism of this process^{65,66} led to the assumption that oximes of the type **67** are precursors of acetylenes **65**. It is well known that nitrosation of oximes of conjugated aliphatic ketones can give pyrazole derivatives that can subsequently undergo conversions indicated in the scheme.⁶⁷ In fact, oximes **67** (obtained by an independent synthesis) gave the corresponding alkynes **68** in up to 20% yields upon treatment with NaNO₂ in acetic acid.⁶⁶

R = CH₂Ph, (CH₂)₉Me, CH₂CH(Me)CH₂CH₂OAc,
CH₂CH(Me)OCOPh.

Although the conversion of isoprenoids into methylacetylenes of the type **65** on treatment with NaNO_2 in acetic acid occurs in low yields, this was used in the synthesis of a natural lactone **69**, the key stage of which involves the conversion of a butanolide **70** into acetylene **71**.⁶⁸

Of particular interest is the conversion of geraniol into a nitro derivative **66**, because there is only a limited number of ways for the selective functionalisation of linear isoprenoids.⁶⁹ As was shown later, this reaction is of rather general character and can involve various isoprenoids **72**, including those with additional functional groups.^{70–74} The nitro derivatives **73** obtained by this method have a large synthetic potential and can be used in directed syntheses of natural terpenes.^{70, 72–75}

[illegible]

It is of note that the mechanisms of reactions of alkenes under the action of metal nitrites in acidic media are still a matter of discussion. This is due to the diversity of the reactive species formed. Presumably, the pathway which the process follows, and hence the decisive role of a particular species in conversions of specific olefins, depends on the nature of the unsaturated substrate as well. For instance, unlike the trisubstituted alkenes **72**, ethyl linoleate gives a mixture of diverse products upon treatment with NaNO_2 in an acidic medium.⁷⁶ Their formation is explained by the simultaneous occurrence of at least three processes: a free-radical process involving NO_2 , an ionic process involving NO^+ or NO_2^+ and a direct reaction with N_2O_3 or

N₂O₄.⁷⁶ It was also assumed that nitric acid present in the system in a small concentration can serve as a nitrosating or nitrating agent under these conditions.⁷⁷

$$\begin{aligned} \text{R}^1 &= (\text{CH}_2)_3\text{Me}, \text{R}^2 = (\text{CH}_2)_6\text{CO}_2\text{Et}; \\ \text{R}^1 &= (\text{CH}_2)_6\text{CO}_2\text{Et}, \text{R}^2 = (\text{CH}_2)_3\text{Me}. \end{aligned}$$

Conversions of alkenes upon treatment with the $\text{NaNO}_2\text{--AcOH}$ system in the presence of cerium(IV) ammonium nitrate (CAN) is of interest from the viewpoint of preparative synthesis.^{78,79} The reaction occurs particularly efficiently under sonication.⁷⁹ α,β -Unsaturated nitro compounds **74** were obtained in high yields by this method. A scheme explaining the conversions of linear alkenes, taking the regio- and stereoselectivity of the reactions into account, was suggested. Initially, NO_2 adds to double bonds in alkenes to give alkyl radicals **75**; the latter are oxidised with cerium(IV) ammonium nitrate into carbocations **76**, which eliminate a proton to give more thermodynamically favourable α,β -unsaturated nitro compounds **74** with a *trans*-configuration. Under these conditions, cycloalkenes **77a,b** give nitro derivatives **78a,b**.

$$R = n\text{-C}_6\text{H}_{13}, \text{Ph}, \text{CH}_2\text{SiPr}_3^i$$
 $n = 1$ (**a**), 2 (**b**).

The formation of the carbocation intermediate **76** is confirmed by the fact that the reaction of cycloalkenes **77a–c** in acetonitrile gives nitroacetamides **79a–c**, which are presumably

$n = 1$ (a), 2 (b), 3 (c).

formed due to the stabilisation of the carbocation **80** upon the addition of MeCN.⁸⁰

Quite an unexpected result was obtained under similar conditions with cyclopentenecarbaldehyde as the substrate: the reaction yielded dinitrooxime **81**. It was shown using labelled $\text{Na}^{15}\text{NO}_2$ that the latter is the only source of nitrogen atoms incorporated into compound **81**.⁸¹

There is yet another approach to the use of nitrous acid salts as sources of reactive intermediates: nitrile halides, *e.g.*, nitrile iodide, are generated *in situ* from the salts under the action of halogens. Nitrile iodide was first generated using the reaction of AgNO_2 with I_2 .^{82,83} Theoretically, it may be assumed that the heterolysis of nitrile iodide occurs with formation of either NO_2^+ ions and I^- , or NO^+ and I^- ; furthermore, homolysis into free radicals is also possible (see Ref. 82 and references cited therein).

The reaction of AgNO_2 with I_2 in the presence of an alkene, *e.g.*, styrene, results in the labile nitro iodide **82**, which readily undergoes dehydroiodination on treatment with a base to give ω -nitrostyrene.⁸² This regioselectivity of the process suggests that the reagent formed cannot react with the alkene as iodonium nitrite INO_2 .

With methyl acrylate as the substrate, a terminal nitro derivative **83** was obtained after treatment of the reaction mixture with a base; it may be concluded on this basis that INO_2 in this process is not an equivalent of NO_2^+ but rather a source of NO_2 radicals.

The use of more accessible sodium and potassium nitrites instead of AgNO_2 was a further development of this method.^{84–86} For example, treatment of a series of mono- and disubstituted alkenes with NaNO_2 and I_2 in an $\text{EtOAc}-(\text{CH}_2\text{OH})_2-\text{H}_2\text{O}$ mixture afforded the corresponding α,β -unsaturated nitro compounds in high yields.⁸⁴ The use of phase-transfer catalysis in order to intensify the process was also described. In particular, dihydronaphthalene derivatives **84** reacted with potassium nitrite and iodine in the presence of a crown ether (18-C-6) to give (after treatment with pyridine) nitro derivatives **85** in 50%–90% yields.⁸⁵ It was noted that the reaction occurred much faster under sonication.

$\text{R}^1 = \text{H}, \text{Ph}; \text{R}^2 = \text{H}, \text{OMe}.$

It is also of note that nitro derivatives can be obtained using the $\text{NaNO}_2-\text{I}_2-\text{CuO}-\text{HBF}_4$ system. The efficiency of this approach was demonstrated by the conversion of substituted

styrenes into nitrostyrenes; additional treatment with a base was not required under these conditions.⁸⁶

V. Reactions of NO_2 with alkenes

The reactions of NO_2 with alkenes have mostly been considered in the reviews published previously;^{8–12} therefore, this chapter only discusses the latest publications not included in those reviews.

To date, a number of mechanisms have been suggested for reactions of NO_2 with alkenes. Which one predominates depends on the reaction conditions. In fact, according to kinetic data, if the process is carried out in non-polar solvents, the reaction becomes second-order with respect to NO_2 with an increase in its concentration.⁸⁷ At low NO_2 concentrations, the formation of the alkyl radical **86** (pathway *a*) is the rate-determining step. Subsequently, the radical **86** recombines with the second NO_2 molecule to give dinitro compound **87** and nitro nitrite **88**. In more concentrated solutions, dimerisation of NO_2 increases the concentration of N_2O_4 , which obviously can also add to the alkene to give the radical **86** (pathway *b*), thus increasing the reaction order. Furthermore, one may not rule out the possibility that the alkyl radical **86** reacts with N_2O_4 to give the same products, *viz.*, **87** and **88**.⁸⁸

Pathway *a*

Pathway *b*

If the reaction is carried out in a more polar medium, another process starts to play a considerable role; it occurs by a heterolytic mechanism due to the presence of nitrosyl nitrate (NO^+NO_3^-) in solutions of NO_2 or N_2O_4 .^{89,90} The possibility of the existence of this compound was substantiated by calculations.^{91,92} The fact that alkenes can react with nitrosyl nitrate by a heterolytic mechanism follows from the formation of the corresponding nitro nitroso compounds.^{93,94} For example, treatment of 2,4-dimethylhexene with a solution of NO_2 in CHCl_3 results only in the nitro nitroso adduct **89**, whereas in hexane, this alkene gives a mixture of compounds **90**–**93**, which are formed in the reaction occurring by a homolytic mechanism.⁹⁴ The formation of the dinitro alcohol **93** results from the ability of nitrogen dioxide to abstract hydrogen from the carbon atom adjacent to the double bond to give an allylic radical. This process starts to play a significant role at very low NO_2 concentrations.⁹⁵ For example, a study of reactions of NO_2 with unsaturated fatty acids mainly

revealed allylic nitration products and the corresponding allyl hydroperoxides.^{96, 97}

It should be noted that treatment of hexa-1,5-diene with a dilute solution of NO_2 in hexane gives not only the dinitro compound **94** and the nitro alcohol **95** but also the isomeric 1,2-dinitrocyclopentanes **96**.⁹⁸ The formation of the latter suggests that two NO_2 molecules can add to the diene independently; this is accompanied by intramolecular recombination of the biradical which is formed.

Conjugated dienes mostly give dinitro derivatives **26**, **97–99** under these conditions.⁹⁸ A small amount of compound **26** is also formed in the reaction of 2,5-dimethylhexa-2,4-diene with NO_2 .³³

NO_2 manifests considerable oxidising properties with respect to some substrates. For example, (*Z*)-stilbene reacts with NO_2 in CCl_4 to give benzaldehyde as the main reaction product formed due to oxidative fragmentation.⁹⁹

One should also note the interesting version of epoxidation of the sterically hindered tetrasubstituted alkene **100** on treatment with NO_2 .¹⁰⁰ The latter is reduced to NO . Using the smooth oxidation of NO to NO_2 , this reaction can be carried out either with a stoichiometric or a catalytic amount of NO_2 in the presence of oxygen.

VI. Reactions of the NO_2^+ cation and its equivalents with alkenes

The NO_2^+ cation is generated from acetyl nitrate, which is usually obtained *in situ* from Ac_2O and concentrated nitric acid. It should be noted that the previously suggested mechanism of electrophilic

addition of NO_2^+ to a double bond to give a classical carbocation does not often allow one to explain the diversity of the resulting products and their structures (see, *e.g.*, Ref. 92 and references cited therein).

For example, the reaction of cyclopentene with AcONO_2 results in a mixture of at least six compounds. This mixture does not contain conjugated 1-nitrocyclopent-1-ene, the most thermodynamically favourable compound, the formation of which, due to deprotonation of the corresponding α -nitrocarbocation, could be expected.⁹² Analysis of these results made it possible to assume that this process can occur through initial [2 + 2]-cycloaddition of NO_2^+ to the double bond to give the cyclic cationoid intermediate **101**. Its subsequent reaction with the acetate anion, rearrangement and deprotonation of the intermediates result in a wide range of products. This hypothesis was also confirmed by semiempirical calculations for the ethylene- NO_2^+ system, according to which the cyclic ion of the type **101** corresponds to one of the potential energy minima.^{92, 101–103}

In fact, reactions of various alkenes with NO_2^+ generally yield allylic rather than conjugated nitro compounds. In particular, allylic nitro derivatives were isolated from a mixture of products obtained upon treatment of a derivative of an antibiotic milbemycin with acetyl nitrate.¹⁰⁴

Nitration of 4-methylidenetetrahydropyran **102** with nitric acid in Ac_2O gave the nitro acetate **103** as the major product; the ratio of the allylic (**104**) and vinylic (**105**) regioisomers in the reaction mixture was 2 : 1.¹⁰⁵ The reaction of acetyl nitrate with isoprene afforded a mixture of 1,2- (**106**) and 1,4-addition (**107**) products; the tertiary acetate **106** smoothly isomerises into the primary acetate **107** on treatment with a catalytic amount of H_2SO_4 .^{106, 107}

One of the most convincing confirmations of the four-centred addition mechanism of NO_2^+ to alkenes was obtained in a study of the reaction of acetyl nitrate with 1-trimethylsilylcycloalkenes **108a–c**, which resulted in different products depending on the ring size.¹⁰⁸ For instance, cyclopentene, cyclohexene and cycloheptene derivatives **108a** only give unsaturated nitro compounds **109a** in good yields (50%–70%). Under similar conditions, 1-trimethylsilylcyclooctene (**108b**) gives the dinitro nitrate **110b**;

the cyclododecadecene derivative **108c** gave the dinitro nitrate **110c** and the ketone **111c**.

In these reactions, the trimethylsilyl substituent serves as the directing group in the addition of NO_2^+ to the double bond. The trimethylsilyl group is a better leaving group than hydrogen; this ensures the eventual formation of the conjugated nitro alkene **109a** (pathway *a*). It is believed¹⁰⁸ that the spatial arrangement of the trimethylsilyl substituent in large rings is unfavourable for the E_2 elimination. As a result, it is eliminated by the E_1 mechanism; the resulting carbanion is then converted to the products **110b,c** and **111c** (pathway *b*) on treatment with acetyl nitrate.

More examples are known in which acetyl nitrate reacts selectively with unsaturated substrates containing functional substituents at the double bond.

For example, the reaction of AcONO_2 with alkyl-substituted 1-acetoxycyclohexenes **112**, which occurs through deacetylation of the cation **113**, affords α -nitrocyclohexanones **114** in 70%–90% yields.¹⁰⁹ The yields of the corresponding ketones were subsequently increased to 80%–100% using trifluoroacetyl nitrate.¹¹⁰

$\text{R}^1 = \text{Alk}, \text{R}^2 = \text{H}, \text{Me}.$

A similar reaction of enol acetates **115** and **116** was used for the regio- and stereoselective incorporation of a nitro group into isomeric ketosteroids **117** and **118**,¹¹¹ the direction of their enolisation is governed by the type of fusion of rings A and B.

a — $\text{Ac}_2\text{O}, 4\text{-MeC}_6\text{H}_4\text{SO}_3\text{H}$; *b* — $\text{CF}_3\text{CO}_2\text{NO}_2, \text{CH}_2\text{Cl}_2.$

In enamides of the steroid series, the AcHN group directs the attack of the nitronium cation to the β -position with respect to the double bond, giving the nitro enamides **119** and **120**.¹¹² The enamide **121** gives the nitro acetate **122** under the same conditions.¹¹³

The nitration of the enamides **123a,b** gives different products, depending on the substituent R at the nitrogen atom.¹¹⁴ The unsubstituted amide **123a** yields the nitro alkene **124a** as the main product (55%), whereas the methylated derivative **123b** gives a mixture of the nitro alcohol **125b** and hydroxy ketone **126b** in moderate yield (20%). The difference between the reactivities of the amides **123a,b** is explained by the fact that the nitro compound **124a** can be stabilised due to the formation of an intramolecular hydrogen bond. The methyl derivative **124b** is unstable and undergoes further conversions as a result of the Nef reaction and allylic oxidation. In the case of the amide **124a**, both of the processes also occur, but the yield of the minor products is no higher than 15%.

R = H (a), Me (b).

Probably, a unique example of a reaction of acetyl nitrate with a diene system conjugated with a carbonyl group has been reported by German chemists.¹¹⁵ The nitration of a pregnane ketosteroid, *viz.*, a canrenone derivative, unexpectedly resulted in a 4-nitro compound **127**, whereas the 6,7-double bond in the original dienone remained intact.

Furthermore, the unusual behaviour of cycloheptatriene is also noteworthy. Its conjugated system is oxidised on treatment with CF_3CONO_2 to give a tropylium cation.¹¹⁶ On the other hand, the reaction of cycloheptatriene with copper nitrate in Ac_2O gives

the 1-nitro derivative **128** in low yield.¹¹⁷ The role of copper ions is probably to inhibit the oxidation process. Subsequent nitration of the mononitro derivative **128** with acetyl nitrate gave the dinitro compound **129**.

Nitronium tetrafluoroborate is yet another source of NO_2^+ known for a long time. As noted in an earlier review,¹¹⁸ its reaction with alkyl-substituted alkenes is not straightforward due to the formation of very reactive cationoid intermediates and can be accompanied by polymerisation. We will consider certain examples of reactions of alkenes with NO_2BF_4 which have not been covered in the review by Guk *et al.*¹¹⁸ or in later reviews.

Obviously, the nature of the products formed in the reactions of alkenes with NO_2BF_4 depends on the structure and environment of the cationoid centre, which appears in a reacting molecule in the first step of the process. For example, the reaction of 1-chlorocyclohexene with NO_2BF_4 yields exclusively products of the formal NO_2F addition, *viz.*, compound **130** (with the ratio of the *cis* and *trans* isomers equal to 4:1).¹¹⁹

Isopropenyl derivatives of cyclopropanecarboxylic acid **131** react with NO_2BF_4 in a similar way.¹²⁰ Surprisingly, this does not cause a skeletal rearrangement typical of carbocations with the cyclopropyl substituent.

R = H, Me.

A different pattern is observed in the reaction of nitronium tetrafluoroborate with the isopropenylacetylene–octacarbonyl–dicobalt complex **132**. The alkynedicobaltoctacarbonyl residue in this compound stabilises the carbenium ion formed due to the NO_2^+ attack on the double bond.¹²¹ Subsequent hydrolysis of the reaction mixture and oxidation of the cobalt carbonyl complex gives the nitro alcohol **133**.

Furthermore, reactions of allylic esters (**134a–d**)¹²² and homoallylic esters (**134e–g**)¹²³ with nitronium tetrafluoroborates followed by hydrolysis have been reported; they gave mixtures of 2-fluoro nitro alkane (X = F) and β -nitro alcohol (X = OH) derivatives **135a–g**. In this case, the overall yield and composition of the products depend on the bulk of the acyl substituent R. The reaction presumably occurs *via* cyclic cationoid intermediates **136a–g**, which are split by fluoride or hydroxide ions to give the

final products. The formation of these intermediates was detected using low-temperature NMR spectroscopy.¹²³

Compound 134	R	n	Product ratio 135a–g (X = F/X = OH)
a	Me	1	95/5
b	Et	1	70/30
c	Pr ⁿ	1	65/35
d	Pr ⁱ	1	75/25
e	Me	2	95/5
f	Pr ⁿ	2	75/25
g	Pr ⁱ	2	55/45

Acetonitrile may serve as the nucleophile which completes the reaction of alkenes with NO_2BF_4 . For example, low-temperature treatment of substituted styrenes with nitronium tetrafluoroborate in MeCN followed by decomposition with saturated aqueous NaHCO_3 afforded the corresponding nitro acetamides **137** obviously formed by the Ritter reaction.¹²⁴

Conjugated dienes undergo similar conversions to give 1,2- (**138**) and 1,4-addition (**139**) products in approximately 1 : 1 ratios (the overall yield is 70%–90%). In this case, nitronium tetrafluoroborate was generated by *in situ* anodic oxidation of N_2O_4 in the presence of LiBF_4 .¹²⁵

R = H, Me.

Finally, the reaction of NO_2BF_4 with allylsilanes deserves attention. In particular, it was found that treatment of *trans*-but-2-enyltrimethylsilane with nitronium tetrafluoroborate results in the allylic nitro compound **140**, which is formally a reaction product by the S_{E}' mechanism.¹²⁶ It is believed that compound **140** is formed by electrophilic addition of the NO_2^+ cation to the double bond followed by elimination of the trimethylsilyl group from the carbenium intermediate.

Subsequently,¹²⁷ potential synthetic applications of this approach were demonstrated. It was found that treatment of chiral (*E*)-crotylsilanes **141** with NO_2BF_4 converts them to allylic nitro derivatives **142**. The reaction occurs with high diastereoselectivity (*de* > 90%), since the stereochemistry of the forming chiral centre is controlled by the configuration of the asymmetric centre with the silyl substituent.

$\text{R}^1 = \text{Alk}$; $\text{R}^2 = \text{H}, \text{Me}, \text{All}, \text{OMe}$.

The NO_2^+ cation can also be generated from $\text{Me}_3\text{SiONO}_2$, which reacts with linear or cyclic alkenes in the presence of CrO_3 or DMSO to give α -nitro ketones in high yields.^{128, 129}

$n = 2, 3, 7$.

It is believed that the reaction of $\text{Me}_3\text{SiONO}_2$ with CrO_3 generates $\text{NO}_2\text{OCrO}_2\text{SiMe}_3$ *in situ*; the latter is a source of NO_2^+ and of an oxidant, *viz.*, the $^-\text{OCrO}_2\text{SiMe}_3$ anion. The latter reacts with the carbenium ion **143**, which is originally formed upon the attack of the NO_2^+ cation on the double bond to give intermediate **144**. A similar intermediate was postulated in the oxidation of alcohols with chromium-containing reagents. An analogous role is played by DMSO, which reacts with the carbocation **143** *via* an oxysulfonium salt to give the ylide **145**, a well-known intermediate in the Moffatt–Swern oxidations.

VII. Reactions of alkenes with NO^+

Reactions of NO^+ with alkenes are accompanied by further transformations of reactive β -nitroso carbocations formed initially, and the nature of the products depends on the structure of the substrate. For example, reactions of terminal and internal alkenes with nitrosonium tetrafluoroborate in acetonitrile give *N*-hydroxyimidazolium tetrafluoroborates **146a–d**.¹³⁰ Substi-

$\text{R}^1 = \text{Me}, \text{R}^2 = \text{H}$ (**a**); $\text{R}^1 = \text{R}^2 = \text{Me}$ (**b**);

$\text{R}^1 = \text{Ph}, \text{R}^2 = \text{H}$ (**c**); $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_4$ (**d**).

tuted imidazoles **147a–d** can be obtained in high yields by hydride reduction of the tetrafluoroborates **146**.

Arylalkenes react with nitrosonium tetrafluoroborate or hexafluorophosphate in a different way. In particular, 1-(4-methoxyphenyl)-1-phenylethylene (**148**) gave substituted 1,2-oxazine **149** in acetonitrile in high yield.¹³¹ It is assumed that the reaction occurs *via* carbocationic intermediates **150–152**.

Ar = 4-MeOC₆H₄.

Vinylpyridines react with NOBF₄ in an unusual way to give nitrolic acids **153**,¹³² the mechanism of their formation under these conditions has not been elucidated so far.

R = 2-, 3-, 4-pyridyl.

The reaction of allylic esters with NOBF₄ turned out to be a convenient method for the preparation of substituted 4,5-dihydroisoxazoles **154**.¹³³ The process occurs *via* the β-nitroso carbocation **155**, which is subsequently stabilised due to involvement of the arenecarboxylate residue.

R = H, Me, CH₂Br.

The transformation of the substituted crotylsilane **156** on treatment with NOBF₄ results in 4,5-dihydroisoxazole derivatives **157**.¹³⁴ Presumably, the reaction is stereocontrolled by the formation of a bridged cation **158** (σ,π-C–Si-conjugation), which is opened with total reversal of the configuration of the chiral centre at C(3) [C(5) in the product]. Heterocyclisation of the intermediate **158** gives the oxonium salt **159**, which is then deprotonated and protodesilylated by a base. The process occurs with high enantioselectivity and has high synthetic potential.

Thus, the results considered above demonstrate the wide prospects of nitrosation and nitration of alkenes for the synthesis of diverse functional derivatives, many of which are of interest as building blocks in organic synthesis.

of specific receptors of aspartic and glutamic acids may have therapeutic significance.

Studies of metabotropic glutamate receptors (mGluRs) which control the transmission of electrical signals from nerve cells mediated by interacting membrane proteins suggest that they are activated by L-glutamic acid in an 'extended' conformation.¹⁷ An analysis of the biological role of these receptors is complicated due to insufficient activity, selectivity and bioaccessibility of presently known agonists and antagonists of mGluRs. Carbo- and heterocyclic compounds containing a fragment of the acid **2** are potential selective antagonists of glutamate receptors and interesting subjects for the study of structure–activity relationships.^{18–22}

It is known also that (±)-*cis*-1-aminocyclopropane-1,2-dicarboxylic acid is an agonist of the *N*-methyl-D-aspartate receptor.²³

The present review is devoted to surveying the methods for the synthesis of derivatives of 1-aminocyclopropane-1,2-dicarboxylic acid including miscellaneous carbo- and heterocyclic compounds and peptides. Special attention is given to the methods for the preparation of individual stereoisomers of these compounds, some of which possess pharmacological activity.

II. Methods for the synthesis of 1-aminocyclopropane-1,2-dicarboxylic acid derivatives

A problem in the synthesis of compound **2** is associated with the fact that the acid itself and its esters, which contain a free amino group, are unstable compounds.¹ The data from the first synthesis of acid **2** (see Ref. 24) were not confirmed by the results of subsequent investigations.^{2, 25–27}

The ability of the cyclopropane fragment to be involved in conjugation and to transfer the effects of the attached functional groups²⁸ favours push–pull reactions in 2-aminocyclopropane-carboxylic acid. Acid **2** undergoes spontaneous ring-opening as a result of which the unshared electron pair of the nitrogen atom takes part in the formation of a double bond giving rise to imines.^{29, 30}

Thus an attempt to synthesise amino acid **2** by reaction of triphenylphosphine with a mixture of *cis*- and *trans*-1-azidocyclopropane-1,2-dicarboxylates (**4**) obtained by cycloaddition of ethyl diazoacetate to α -azidoacrylate resulted in diethyl 2-triphenylphosphiniminopent-2-ene-1,5-dioate (**5**).²⁵

However, recently a series of stable compounds containing a functionalised cyclopropane ring were successfully prepared. The known methods for the synthesis of acid **2** and its derivatives can be divided into several groups, viz., 1,3-dipolar cycloaddition of

diazo compounds at unsaturated bonds, syntheses based on reactions of acetylenedicarboxylates with nitrogen-containing compounds, addition of sulfur ylides to dipolarophiles and intramolecular cyclisation.

1. 1,3-Dipolar cycloaddition of diazo compounds to unsaturated bonds

Addition of diazo compounds to alkenes, alkynes and heterocycles is a classical approach³¹ widely employed in the synthesis of cyclopropane-containing amino acids.^{3, 13, 32–38} This reaction first yields dihydropyrazoles which are decomposed upon heating or irradiation with evolution of nitrogen and closure of the cyclopropane ring.

The possibility of preparing acid **2** derivatives by addition of diazoacetates to protected α,β -dehydroalanine has been demonstrated.³⁹ *N*-Acetyl- α,β -dehydroalanine ethyl ester reacts with ethyl diazoacetate to give diethyl *N*-acetyl cycloaspartate (**6**) (yield 12.5%); however, the attempts to establish the configuration of the resulting stereoisomer failed.

Cycloaddition of diazoacetates to a dehydroalanine derivative with subsequent deprotection has been undertaken by Stammer,¹ but acid **2** could not be isolated in a free state.

The low yields of acid **2** derivatives and difficulties in the isolation of the target product have stimulated further studies of reactions of alkyl diazoacetate with *N*-protected α -aminoacrylates.⁴⁰

It was found⁴¹ that methyl diazoacetate reacts with methyl 2-acetylaminocrylate in dichloromethane at room temperature to give dihydropyrazole **7** (yield 60%) and a mixture of *Z* and *E* isomers of dimethyl 1-acetylaminocyclopropane-1,2-dicarboxylates (**8**) (total yield 30%). Presumably, the ring closure occurs *via* the zwitterion **9**.

When the reaction is carried out in chloroform, the yields of cyclopropane derivatives increase to 70%.⁴² With a twofold excess of methyl diazoacetate, the ratio of *Z*- and *E*-isomers was 1 : 3 in dichloromethane and 1 : 1 in chloroform.

It has been shown⁴³ that hydrolysis of the *Z* isomer **8** with 3 M HCl is accompanied by the formation of 2-ketoglutaric acid (**10**) (yield 60%) and (*Z*)-1-aminocyclopropane-1,2-dicarboxylic acid hydrochloride (**2**) (yield 8%). The *E* isomer **8** gives the more stable hydrochloride of anhydride **11** and the hydrochloride of the *E* isomer of acid **2** (yields 60% and 6%, respectively) under identical conditions.

Removal of methyl protective groups in *Z* and *E* isomers of compound **8** by treatment with 1 M NaOH (22 °C, 10 h) and subsequent acidification of disodium salts to pH 5–6 give (*Z*)-1-acetylamino-cyclopropane-1,2-dicarboxylic acid (**12**) and (*E*)-1-acetylamino-cyclopropane-1,2-dicarboxylic acid (**13**) anhydride, respectively.

Further acidification to pH 2 and boiling of the *Z* isomer **12** affords compound (*Z*)-**2** (yield 15%) and an acyclic product **10**, whereas anhydride **11** hydrochloride is the only hydrolysis product of the *E* isomer under identical conditions.

Dihydropyrazoles **7** and **14** decompose on boiling in DMF for 40–60 min to give the corresponding *N*-acetylamino-cyclopropane-1,2-dicarboxylates **8** and **15** in 50% and 40% yields, respectively.⁴⁴

R = H (**8**), Ph (**15**).

Cycloaddition of diazo compounds to *N*-*tert*-butoxycarbonyl- α,β -dehydroalanine *p*-nitrobenzyl ester yields dihydropyrazoles **16**. Decomposition of compounds **16** and subsequent removal of protective groups gave cyclopropane-containing amino acids that were further used for the preparation of peptides which are of interest for their use as renin inhibitors, analgetics and sweeteners.⁴⁵

R¹, R² = H, Alk, Ar; Boc = CO₂Bu^t.

Heterocyclic compounds containing a fragment of 1-amino-cyclopropane-1,2-dicarboxylic acid provide illustrative examples of systems with a stabilised cyclopropane fragment. In addition, their rearrangements afford products manifesting useful properties. Therefore, the development of methods for the synthesis of these compounds is attracting the attention of investigators.

Reaction of 2-diazopropane with dimethyl acetylenedicarboxylate (**17**) gives the adduct **18** in high yield; photoirradiation of the latter results in the evolution of nitrogen and its conversion into dihydropyrazole **19**, a bicyclic derivative of the acid **2**, which represents a convenient synthon for the synthesis of cyclopropenes and dienes.⁴⁶

1,2-Bis(methoxycarbonyl)-3,3-dimethylcyclopropene (**21**) obtained by photolysis of 3*H*-pyrazole **20** reacts with α -diazocyclohexanone in benzene to give isomeric tricyclic adducts **22a** and **22b** in a 3 : 1 ratio (total yield 70%).⁴⁷

A reaction of cyclopropene **21** with diazocyclopropane generated *in situ* from *N*-nitroso-*N*-cyclopropylurea under the action of sodium methoxide in methanol afforded a spirocyclic adduct **23** in 48% yield.⁴⁸

Diazoindeno[2,3-*b*]benzothiophene **24** adds to acetylenedicarboxylate **17** to give a stable polycyclic dihydropyrazole **25**; its stereoconfiguration was not determined.⁴⁹

Cycloaddition of ethyl diazoacetate to 3-nitrocoumarin in the presence of silica gel yields a mixture of ethyl 4,5-benzo-1-nitro-2-oxo-3-oxabicyclo[4.1.0]hept-4-ene-7-carboxylate (**26**) and chromeno[3,4-*c*]pyrazolecarboxylate **27**.

According to the ^1H NMR spectroscopic data, compound **26** is an *endo*-isomer with a *cis*-arrangement of the two protons in the cyclopropane ring and incorporates a nitro analogue of compound **2**.⁵⁰

Spirocyclopropene **28** obtained by addition of diazoindene to dimethyl acetylenedicarboxylate (**17**) with subsequent elimination of a nitrogen molecule and cyclisation of the vinylcarbenium intermediate **29** reacts with 2-diazopropane to give a spiro derivative **30**.⁵¹

The reaction of substituted spirocyclopropenefluorenes **31** with 1-(3,5-dinitrophenyl)-3,4-dihydroisoquinoline (**32**) in anhydrous diethyl ether was studied.⁵² In addition to the expected products (tetrahydroindolizines **33**), this reaction gave novel spiroazanorenefluorenes **34** formed upon intramolecular 1,6-cyclisation of the intermediate **35** (Scheme 1).

Scheme 1

$\text{R}^1 = \text{H}; \text{R}^2 = \text{Me, Et, Pr}^i, \text{Bu}^t, \text{C}_6\text{H}_{13}; \text{R}^1 = \text{Br}, \text{R}^2 = \text{Me}; \text{R}^1 = \text{Cl}, \text{R}^2 = \text{Et}.$

The structure of compounds **34** was established using X-ray diffraction analysis and NMR spectroscopy. Azanorcarene **34** ($R^1 = H$, $R^2 = Me$) was found to possess acidochromic properties. Its ethanolic solution has a green colour which changes to bright violet on addition of aqueous NaOH.

The addition of diazomethane to alkene fragments of heterocyclic systems was studied in the course of synthesis of substituted tricyclic nitrogen-containing compounds.^{53–55} Condensation of keto acid derivatives **36** with 5-aminopyrazoles **37a–c** gave pyrazolo[1,5-*a*]pyrimidines **38a–c** which react with diazomethane at 0 °C to give 6*H*-cyclopropa[*e*]pyrazolo[1,5-*a*]dihydropyrimidines **39a–c** in 61%–100% yields. At room temperature, this reaction gives exclusively 5-methylated derivatives **40a–c**.⁵³

$R^1 = Ac, CO_2Et$; $R^2 = CN$ (a), $CONH_2$ (b), $CONHMe$ (c).

Compound **38a** ($R^1 = Ac$) reacts with ethyl diazoacetate in dioxane at 70 °C in the presence of copper as a catalyst to give 6-ethoxycarbonyl-6*H*-cyclopropa[*e*]pyrazolo[1,5-*a*]dihydropyrimidine **41**; its stereoconfiguration was assigned as *trans* based on the ^1H NMR spectroscopic data.⁵³

Cyclopropane derivatives of partially hydrogenated pyrrolo[1,2-*a*]pyrimidines, which can be used as catalysts in the synthesis of polyurethanes, have been synthesised. For example, diethyl 6,7-dimethyl-8-cyanopyrrolo[1,2-*a*]pyrimidine-3,4-dicarboxylate (**42**) reacts with an excess of diazomethane at room temperature to give the corresponding cyclopropane derivative of pyrrolopyrimidine **43** (yield 40%).⁵⁴

The cyclopropane derivative of imidazo[1,2-*a*]pyrimidine **44** was obtained analogously. This is representative of an interesting class of compounds which includes substances manifesting analgetic, antiinflammatory, antipyretic and anticonvulsive activities.⁵⁵

Selective irradiation ($\lambda = 250–350$ nm) of a spiro-fused diazirine **45** and of dimethyl acetylenedicarboxylate (**17**) in dry toluene gives pyrazole **46** which is further converted into a spiro-fused cyclopropane **47** with liberation of nitrogen. The addition of a second molecule of diazirine **45** to the product formed gives cyclopropadihydropyrazole **48** (yield 12%) after column chromatography on silica gel. Further irradiation is accompanied by the cyclopropane ring opening and elimination of nitrogen, as a result of which compound **48** is converted into diene **49**.⁵⁶

Reaction of cyclopropane **21** with morpholine in anhydrous diethyl ether under irradiation with a mercury lamp afforded morpholinocyclopropane **50**, a potential pyrethroid, as a mixture of two diastereomers as can be judged from ^1H NMR spectroscopic data (total yield 54%).⁵⁷

2. Reactions of acetylenedicarboxylates with other nitrogen-containing compounds

The 1-amino-1,2-dicarboxycyclopropane system can be formed as a result of reactions of electrophilic alkynes with bisdiazines.

The reactivities of cyclic bisdiazines in nucleophilic cycloaddition reactions were studied in the reaction of compound **51** with acetylenedicarboxylate **17** in CH_2Cl_2 in a nitrogen atmosphere.^{58, 59} In addition to a non-symmetrical 1 : 3 adduct **52**, this reaction yields a symmetrical 1 : 2 adduct **53** which incorporates 1,2-diaminocyclopropane-1,2,3-tricarboxylic acid.

Pyrimido[1,2-*e*]purines **54** were prepared by the reaction of 7-alkyl-8-amino-1,3-dimethylxanthines (**55**) with acetylenedicarboxylate **17**. Along with compounds **54**, this reaction yields xanthines **56**, the addition products of two molecules of the alkyne **17** to the amino group of xanthine **55** followed by intramolecular cyclisation involving an additional molecule of compound **17**. The structure of compounds **56** was established by mass spectrometry and X-ray diffraction analysis.⁶⁰

Reaction of allyl amines **57** with acetylenedicarboxylate **17** in chloroform gives 3,3-dichloro derivatives of 1-aminocyclopropane-1,2-dicarboxylic acid **58** as side products formed in low yields as a result of addition of dichlorocarbene, generated from chloroform, to the double bond of the enamine fragment of compound **59**.⁶¹

$\text{R} = \text{H}$ (18%), Me (10%).

3. Addition of stabilised sulfur ylides to dipolarophiles

Phenacylidenesulfuranes **60a** react with acyl azides **61** in benzene at 20 °C to give 2:1 adducts **62** and azido analogues of 1-aminocyclopropane-1,2-dicarboxylic acid **63**. Reaction of ethyl azidoformate (**61**, $\text{R}^2 = \text{OEt}$) with ethoxycarbonylmethylidenedimethylsulfurane (**60b**) gives exclusively the derivative **64** ($\text{R} = \text{OEt}$) with a *trans*-configuration of the cyclopropane ring protons and an intramolecular hydrogen bond (¹H NMR spectroscopic data). Reactions of compound **60b** with benzoyl azides **61** also yield the cyclopropane derivatives **64** rather than the 2:1 adducts.⁶²

$\text{R}^1 = \text{Me, Ph; R}^2 = \text{OEt, 4-MeOC}_6\text{H}_4, 4\text{-MeC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4.$

$\text{R} = \text{OEt}$ (60%), 4-MeOC₆H₄ (25%), 4-MeC₆H₄ (57%), 4-ClC₆H₄ (32%).

Reaction of dihydrooxazolones with sulfur methylides was studied in order to prepare functionalised spirocyclopropanes that can be rearranged into non-natural amino acid derivatives upon heating.⁶³ 4-Cyclohexylidene- and 4-cycloheptylidene-2-phenyl-4,5-dihydrooxazol-5-ones **65a,b** react with phenacylidenedimethylsulfurane (**60a**, $\text{R}^1 = \text{Me}$) in dry THF at 0 °C to give spirofused cyclopropanes **66a,b** in 84% and 35% yields, respectively. ¹H NMR spectroscopic data suggest that in both cases the major isomer has a *trans*-configuration of the carbonyl groups.

$n = 1$ (**a**), 2 (**b**).

Under identical conditions, reaction of dihydrooxazolone **65a** with ethoxycarbonylmethylidenedimethylsulfurane (**60b**) gives a

mixture of diastereomers (3 : 1) (^1H and ^{13}C NMR spectroscopic data) in a total yield of 97%.⁶³

4. Intramolecular cyclisation reactions

Substituted imines undergo [2+1]-cycloaddition at the C=C bond to give cyclopropanes. The derivatives **67** synthesised from *ortho*-substituted anilines by diazotisation and condensation with ethyl chloroacetate were used to prepare cyclopropacinnolines **68**. The *endo*-position of the R group in the resulting compounds was established by ^1H NMR spectroscopy.⁶⁴

R = Me, Et.

Compounds **68** are interesting in that they undergo rearrangements upon boiling to give heterocyclic structures with potential biological activity.^{65, 66}

Easily accessible azo-substituted phosphorus ylides are also subject to intramolecular cycloaddition at the double bond. Phosphorane **69** loses a PPh_3 group upon heating in toluene to give cyclopropacinnoline **68** (R = Me) and the product of its thermal rearrangement **70** (yields 10% and 43%, respectively).⁶⁷

III. Methods for the synthesis of individual stereoisomers of 1-aminocyclopropane-1,2-dicarboxylic acid

The current demand for all four cycloaspartic acid **2** diastereomers is explained by the fact that their incorporation into peptide structures changes the conformations and, as a consequence, biological activities of the peptides as regards their binding to receptors. However, the methods for the synthesis of individual stereoisomers of derivatives of compound **2** are very few in number. Some recently developed procedures for their synthesis based on diastereoselective reactions using chiral starting compounds and catalysts are considered below.

1. Syntheses based on diastereoselective reactions

The preparation of a *trans*-isomer of an *N-tert*-butoxycarbonyl derivative of acid **2** has been described.⁶⁸ Methyl (1*RS*, 5*SR*)-2-

oxo-3-oxabicyclo[3.1.0]hexane-1-carboxylate (**71**) was synthesised by condensation of epichlorohydrin with dimethyl malonate in the presence of freshly prepared sodium methoxide as a catalyst. Ammonolysis of bicyclic lactone **71**, protection of the free hydroxy group by reaction with *tert*-butyldimethylsilyl chloride in the presence of imidazole and subsequent Hoffmann rearrangement with lead tetraacetate in *tert*-butyl alcohol yielded *N*-Boc-protected cyclopropane **72**; selective deprotection of its hydroxy group gave alcohol **73** in 85% yield. The next step included mild oxidation of the primary alcohol in a neutral medium by *in situ* generated RuO_4 with retention of the cyclopropane ring and the protected amino group. The monomethyl ester **74** with *trans*-configuration of the carboxy groups was obtained in 60% yield. This method can also be used for the preparation of isomers with definite absolute configuration starting from optically active epichlorohydrin.

TBDMS = $\text{Bu}^t\text{Me}_2\text{Si}$, ImH is imidazole.

Dialkyl 1-phthalimidocyclopropane-1,2-dicarboxylates **75a,b** having a *trans*-configuration were prepared starting from dialkyl *N*-phthaloyl-4-bromoglutamates **76a,b** upon boiling in ethanol in the presence of triethylamine.⁶⁹ Under the action of 1 or 2 equiv. of AlCl_3 in the presence of NaI, esters **75a,b** are converted either into monoalkyl esters of 1-phthalimidocyclopropane-1,2-dicarboxylic acid or into a free diacid. According to X-ray diffraction analysis,⁶⁹ ^1H NMR and ^{13}C NMR spectroscopic and GC/MS data,⁷⁰ dialkyl esters **75a,b** represent individual isomers with a *trans*-configuration of ester groups relative to the cyclopropane ring, although the starting bromo derivatives **76a,b** were used as a mixture of diastereomers.

R = Me (a), Et (b); Pht =

HPLC studies have shown⁷⁰ that (2*S*,4*S*)-isomers of compounds **76** react with bases much more slowly than (2*S*,4*R*)-isomers. This reaction is accompanied by epimerisation at the C(4) atom of glutamic acid. It was suggested that the abstraction of the proton and the bromide ion follows a concerted mechanism and is similar to the E_2 mechanism. The reaction begins with an attack of the base on the proton at C(2) and the formation of a

transition state. As this reaction requires that the C(1)–C(5) atoms are coplanar in the transition state and that the *anti*-abstraction of the proton and bromide ion occur, the activation energies of the reactions of *threo*-isomers (2*S*,4*S*)-**76a,b** markedly exceed those of the *erythro*-isomers, presumably due to forced shielded positions of C(5)-carboxy and phthalimide groups in the transition state of *threo*-isomers. Therefore, the transformation of a mixture of diastereomers of compounds **76a,b** into derivatives of acid **2** is stereospecific and gives exclusively *trans*-isomers.

B = Et₃N, KOH.

An original method for the synthesis of derivatives of acid **2** based on diastereoselective cycloaddition of stabilised sulfur

ylides to substituted 4-methylideneoxazolidin-5-ones was proposed.²⁶

Treatment of compound **77** with ethyl dimethylsulfonioacetate in THF at 0 °C gives a mixture of three diastereomeric cyclopropane adducts separated by column chromatography. (1*R*,3*R*,6*R*)- and (1*S*,3*R*,6*R*)-isomers of 7-benzoyl-1-ethoxycarbonyl-4-oxo-6-phenyl-5-oxa-7-azaspiro[2.4]heptane (**78a** and **78b**) were isolated as a 9 : 1 mixture in a total yield of 55%, the yield of the diastereomerically pure product **78c** was 6%. The assignment of the stereoconfiguration of the isomers formed was carried out based on X-ray diffraction analysis and NMR spectroscopic data (Scheme 2).

Treatment of a mixture of isomers **78a,b** with sodium borohydride in ethanol results in the oxazolidinone ring opening, as a result of which a mixture of diastereomers of 1-aminocyclopropane-1,2-dicarboxylic acid derivatives **79a** and **79b** is formed in a 9 : 1 ratio.

Attempts to hydrolyse the ester groups of the isomers **78a** and **78b** by treatment with 6 M HCl were unsuccessful, since this led to cyclopropane ring opening.²⁶

A method for the synthesis of (*E*)-2,3-methanoaspartic acid derivatives⁷¹ (Scheme 3) is based on the use of a chiral cyclopropane with substituents which can readily be converted into amino and carboxy functional groups. Reaction of 1-phenylseleno-2-triethylsilyl ethene (**80**) with di-*tert*-butyl methylidene-

Scheme 2

Scheme 3

DPPA = (PhO)₂P(O)N₃.

malonate (**81**) in the presence of ZnBr_2 in CH_2Cl_2 at $-30-0^\circ\text{C}$ gives a mixture of di-*tert*-butyl 2-[(phenylseleno)(triethylsilyl)methyl]cyclopropane-1,1-dicarboxylate (**82**) and protected cyclobutane **83** (7:3) in high yield. Presumably,⁷² the cycloaddition mechanism is similar to that proposed⁷³ for vinyl ketones. The nucleophilic selenide **80** attacks the electrophilic alkene **81** activated by a Lewis acid to give the zwitterion **A**; its cyclisation gives substituted cyclobutane **83**. Intermediate **A** undergoes rearrangement to the zwitterion **B**, which can be converted into an electron-stabilised intermediate **C** containing a selenium bridge. The latter is cyclised to compound **82**; its stereochemistry was established as (*S,S*) or (*R,R*) using ^1H and ^{13}C NMR spectroscopy (Scheme 3).

Stereoselective reduction of a less shielded ester group in compound **82**, which is in the *trans*-position relative to the substituent at C(2), gave an alcohol **84**. The product **85** formed after protection of the hydroxy group in the alcohol **84** was oxidised using the $\text{RuCl}_3\text{--NaIO}_4$ system. Treatment of the acid formed with diazomethane in ether resulted in compound **86**. Removal of the protective *tert*-butyldimethylsilyl group, oxidation of the primary alcohol to an acid and its subsequent reaction with diphenyl phosphorazidate accompanied by the Curtius rearrangement and addition of *tert*-butyl alcohol to the isocyanate formed afforded dialkyl ($\pm$)-(*E*)-1-[(*N*-*tert*-butoxycarbonyl)amino]cyclopropane-1,2-dicarboxylate (**87**); its stereochemistry was established by NMR.

The diastereoselective addition of diketopiperazine **88** to the double bond of methyl 2-bromoacrylate has been described.⁷⁴ Elimination of hydrogen bromide yields the cyclic dipeptide **89** incorporating protected acid **2**.

2. Syntheses based on the use of chiral compounds

The methods for the synthesis of individual stereoisomers of cyclopropane-containing amino acids from optically active starting compounds are often more efficient than those based on stereoselective reactions. The use of commercially available optically active synthons allows one to reduce the number of synthetic

steps and to increase the yield and optical purity of the final product.

A method for the synthesis of methyl-(2*S*,3*R*)-*N*-benzyloxycarbonyl cycloasparaginate from chiral diols was proposed.^{75,76} The Wittig–Horner condensation of phosphonates **90a–c** with isopropylidene-D-glyceraldehyde (**91**) synthesised from D-mannitol yielded (*Z*)-dehydroamino acid derivatives **92a–c** containing one chiral centre (Scheme 4).

Addition of diazomethane to the double bond of intermediates **92a–c** gives dihydropyrazoles **93a–c**; their photochemical degradation affords optically pure cyclopropane derivatives **94a–c** in a quantitative yield (data from ^1H and ^{13}C NMR spectroscopy).

The diastereoselectivity of 1,3-dipolar cycloaddition at the double bond is explained⁷⁵ by the fact that diazomethane attacks preferably from the less shielded *re*-side of the C(2) atom of compound **93**.

Removal of the isopropylidene protective group in compounds **94a–c** is carried out under mild conditions in order to prevent cyclopropane ring opening and epimerisation of the diols formed. Treatment of derivatives **94a–c** with 5% HCl in methanol for 4–4.5 h at room temperature affords chiral diols **95a–c** in quantitative yields; the assignment of their stereoconfigurations was made based on ^1H NMR spectroscopic data. Hydrolysis performed for a longer time caused epimerisation of chiral centres of cyclopropane to yield (2*R*,3*S*)-enantiomers of the diols **95**.

Oxidation of the diol **95a** with sodium periodate in the presence of ruthenium oxide at room temperature gives a dicarboxylic acid monoester (2*S*,3*R*)-**96** in 63% yield.^{75,76}

Reaction of compound **95a** with thiocarbonyldiimidazole gave (2*S*,3*R*)-thiocarbonate **97**; its absolute configuration was established unambiguously using X-ray diffraction analysis.

Other cyclopropane-containing amino acids, *viz.*, (–)-allo-coronamic and (–)-allonorcoronamic acids and (–)-(*Z*)-2,3-methanohomoserine,^{75,76} were synthesised starting from the diols **95**, which demonstrates the efficiency of the latter as enantiomeric synthons in the stereocontrolled synthesis of natural compounds containing a cyclopropane fragment and methano analogues of proteinogenic amino acids.

R = Cbz (**a**), Boc (**b**), Ac (**c**); Cbz = $\text{C}_6\text{H}_5\text{CH}_2\text{OC(O)}$;

Scheme 5

Enantiomerically pure amino acids, which can undergo chemical transformations without loss of their optical activities, can be used as the starting compounds in the synthesis of 2,3-methano amino acid derivatives.

Thus the 2,3-cyclohomoserine derivative **98** with protected amino and carboxy groups was oxidised with $\text{RuCl}_3\text{--NaIO}_4$ to give compound **99** (yield 51%). However, attempts at deprotection of the amino group led to the destruction of the cyclopropane ring.²

3. The use of metal complexes

Chiral metal complexes are widely used for the preparation of enantiomerically pure substituted cyclopropanes⁷⁷ including amino cyclopropanecarboxylic acids. This approach was used, in particular, for the synthesis of stereoisomers of cycloaspartic acid derivatives.

Reaction of methyl *N*-protected 2-aminoacrylate (**100**) prepared by dehydration of serine methyl ester with ethyl diazoacetate yields a mixture of four cyclopropanes which represent addition products of ethoxycarbonylcarbene at the double bond [(*E*)- and (*Z*)-**101**] and incorporation products into the *N*–*H* bond of the amino group [(*E*)- and (*Z*)-**102**] (Scheme 5).⁷⁸

An achiral complex, copper acetylacetonate (**A**), and a chiral copper complex of hemicorrine (the Pfalz complex, **B**) were used as catalysts. *Z* Isomers of the reaction products were predominant; the use of the Pfalz complex made it possible to increase their content. The yields of substituted cyclopropanes **101** and **102** depend on both the amount of ethyl diazoacetate and the nature of the catalyst. Thus reaction of compound **100** with 1.3 equiv. of ethyl diazoacetate in the presence of catalyst **A** afforded a mixture of *E* and *Z* isomers of compounds **101** (**101a** : **101b** = 45 : 55, total yield 15%) and **102** (**102a** : **102b** = 41 : 59, total yield 8%). The reaction performed in the presence of 2.5 equiv. of ethyl diazoacetate and the Pfalz catalyst gave a mixture of *E* and *Z* isomers of compounds **101** and **102** in a 1 : 4 ratio (total yields 40% and 20%, respectively).

The methyl ester of dehydroalanine **103** with two *tert*-butoxycarbonyl groups at the nitrogen atom was synthesised in order to prevent the formation of products **102**; its treatment with an eightfold excess of ethyl diazoacetate in the presence of the Pfalz catalyst gave only the *Z* isomer of 1-[bis(*tert*-butoxycarbonyl)-amino]-2-ethoxycarbonyl-1-methoxycarbonylcyclopropane (**104**)

(yield 85%). Removal of one Boc-group from compound **104** was performed by treatment with trimethylsilyl chloride in methanol–dichloromethane or with a fourfold excess of trifluoroacetic acid in the presence of triethylsilane, which gave the *Z* isomer of the derivative **101**. The same conditions were used for the cleavage of two Boc-groups from compound **104** in the presence of 13 equiv. of trifluoroacetic acid to give trifluoroacetate **105**. Saponification of the diester **104** with an alkali gave consecutively compound **106** with a free α -carboxy group and a dicarboxylic acid **107**.

1-Ethoxycarbonyl-4,5-bis(methoxycarbonyl)-6,6-dimethyl-2,3-diphenyl-2-azabicyclo[3.1.0]hex-3-ene (**108**), a chiral derivative of the acid (*E*)-**2**, was prepared in 62% yield using a photo-induced reaction of the *N*-vinylaminocarbene iron complex **109** with acetylenedicarboxylate **17**.⁷⁹

IV. Properties of 1-aminocyclopropane-1,2-dicarboxylic acid derivatives

Rearrangements of compounds **40** and **41**, which yield diazepines with potential biological activities, have been studied.^{80,81}

Thus compound **41** is converted into diazepine **110** in the presence of silica gel in chloroform; this reaction is accompanied

by the cleavage of one ethoxycarbonyl group (^1H and ^{13}C NMR data).⁸⁰

Treatment of diethyl ester **40b** ($\text{R}^1 = \text{CO}_2\text{Et}$) with ethanolic KOH leads to profound rearrangement of the molecule and the formation of substituted pyrazolopyrrole **111** by cyclopropane ring opening.⁸¹

Boiling of 1,1a-bis(ethoxycarbonyl)-1-methyl-1a,7b-dihydro-cyclopropa[c]cinnoline (**68**, $\text{R} = \text{Me}$) in xylene affords a 1,4-dihydrocinnoline derivative **112** in 60% yield,⁶⁵ while boiling in acetic acid gives an individual isomer of an acetoxydiazepine derivative **113** (yield 60%) with a non-established spatial structure.⁶⁶

Thermolysis of spirocyclopropane **114** in boiling xylene and subsequent alkaline hydrolysis yield a mixture of stereoisomers of amino acid **115** of unknown configuration.⁶³

Protected (*Z*)-cycloaspartic acid (*2S,3R*)-**96** was used as an optically pure starting compound in enantioselective synthesis of (–)-(*Z*)-2,3-methano-L-glutamic acid.⁸²

The reaction of acid **96** with thionyl chloride in toluene gives acid chloride **116**; treatment of the latter with diazomethane in

ether afforded the corresponding diazo ketone **117**. Photolysis of compound **117** in methanol was accompanied by the Wolff rearrangement resulting in methyl ester **118**. Subsequent hydrolysis of the ester **118** with 6 M HCl in the presence of several drops of glacial acetic acid (90 °C, 6 h) and treatment with propylene oxide at 35 °C gave a free amino acid **119** in quantitative yield.

V. Peptides containing 1-aminocyclopropane-1,2-dicarboxylic acid

The synthesis of peptides containing 1-aminocyclopropane-1,2-dicarboxylic acid having a sweet taste has been described.⁸³

The yields of di- and tripeptides containing a residue of acid **2** prepared by oxidation of peptides containing (±)-(*Z*)-2,3-methanohomoserine with sodium periodate in the presence of RuCl_3 are given below.⁸⁴

Peptide	Yield (%)
Boc-Val-Asp-L-Phe-OMe	8
Bz-Val-Asp-L-Phe-OMe	59
$\text{CF}_3\text{CO-Val-Asp-L-Phe-OMe}$	82
Ac-Val-Asp-L-Phe-OMe	36
Boc-Gly-Val-Asp-OMe	45
Bz-Gly-Val-Asp	51
Bz-Gly-Val-Asp-Gly-OMe	42
Bz-Gly-Val-Asp-L-Phe-OMe	62

The possibility of removal of *N*-protective groups from peptides where cycloaspartic acid is not terminal and the presence of free carboxy groups in the side chain allow incorporation of these short fragments into more complex peptides.

Condensation of the (*2S,3R*)-isomer of acid **96** with amine **120** in the presence of 1-(3-dimethylaminopropyl)-3-ethylcarbodi-

imide (DEC) as an activating reagent and 1-hydroxybenzotriazole (HOBT) as a catalyst affords a conformationally rigid dipeptide **121** (yield 64%).⁸⁵

Dipeptide analogues **122a,b** were synthesised⁸⁶ by a reaction of enantiomers of acid **96** with chiral α -substituted isoserine derivatives **123a,b**.

Reaction of (1*S*,2*R*,4'*S*)-1-[*N*-(benzyloxycarbonyl)amino]-2-(2,2-dimethyl-1,3-dioxolan-4-yl)cyclopropanecarboxylic acid (**124**), obtained by saponification of the ester **95a** with 1 M methanolic NaOH, with the methyl ester of (*R*)-phenylglycine yields the dipeptide **125**. Removal of isopropylidene protection in the peptide **125** with 5% HCl in methanol and subsequent oxidation of the diol affords product **126**. Condensation of compound **126** with α -substituted isoserine derivative **123a** afforded the tripeptide **127**.⁸⁶

In addition to conformational rigidity, incorporation of a cycloaspartic fragment into a peptide chain results in the introduction of an additional lateral carboxy group, which may affect the binding of the peptide to the active site of an enzyme or a receptor. Some peptides containing cycloaspartic acid act as analgesics and renin inhibitors and manifest antiviral activities against the hepatitis C virus.⁸⁷ They can also be used as sweeteners.⁴⁵

* * *

1-Aminocyclopropane-1,2-dicarboxylic acid occupies a special place in the series of 2,3-methano amino acids, firstly because it represents a structural analogue of glutamic and aspartic acids which play a crucial role in various metabolic processes occurring in living organisms. Despite the instability of this amino acid, original approaches to the synthesis of its numerous derivatives some of which possess physiological activity have been developed. The use of modern synthetic approaches has made it possible to develop elegant procedures for the synthesis of individual stereoisomers of 1-aminocyclopropane-1,2-dicarboxylic acid derivatives based on diastereoselective reactions and the use of readily available enantiomeric starting compounds. Conformationally rigid peptides containing 1-aminocyclopropane-1,2-dicarboxylic acid play the role of molecular 'probes' in the study of biochemical processes. At the same time, the potentialities of 1-aminocyclopropane-1,2-dicarboxylic acid derivatives in the study of mechanisms of biochemical reactions and the synthesis of physiologically active compounds have not been completely exhausted. Further progress in this branch of amino acid chemistry is expected in the near future.

Fluorine-containing alkyl(aryl) vinyl sulfides

A Yu Sizov, A N Kovregin, A F Ermolov

Contents

I. Introduction	357
II. Methods of synthesis	357
III. Chemical properties	365

Abstract. Approaches to the synthesis of fluorine-containing alkyl(aryl) vinyl sulfides, their reactions with electrophilic and nucleophilic reagents and the behaviour in cycloaddition and oxidation reactions are considered systematically. The bibliography includes 136 references.

I. Introduction

The first data concerning fluorine-containing vinyl sulfides appeared in the early 1950s;^{1,2} however, no reviews considering the chemistry of these compounds have been published so far. The interest in this type of compound is due to their high reactivity and the possibility of converting them into biologically active preparations and materials for engineering. In addition, researchers keep an eye on the theoretical aspects of the chemistry of fluorine-containing vinyl sulfides. The presence of the sulfur atom, possessing p electrons and vacant d orbitals, together with a multiple bond within the same molecule stipulates the occurrence of intramolecular p π -interactions, which have a substantial influence on the properties of vinyl sulfides. Recent studies discuss fundamental problems such as the ability of the sulfur atom to stabilise carbocations, carbanions and radicals and the possibility of migration of substituents in the carbon–carbon–sulfur triad. The influence of the fluorine atoms rich in 2p electrons and the electron-withdrawing polyfluoroalkyl groups on the properties of α,β -unsaturated sulfides are under investigation.

This review covers the most important data on methods of synthesis and chemical properties of alkyl(aryl) vinyl sulfides containing fluorine atoms and/or fluorinated substituents both at the double bond and at the sulfur atom. The scope of consideration includes compounds with several heteroatoms at the double bond having a high preparative value, for example, ketene thioacetals and their O- and N-analogues, whose chemical properties are similar to those of vinyl sulfides.

II. Methods of synthesis

Fluorinated α,β -unsaturated sulfides are synthesised by means of electrophilic and nucleophilic substitution, addition, elimination and condensation reactions usual for organic chemistry.

1. α,β -Elimination in fluorine-containing sulfides

Elimination reactions, first of all, dehydrohalogenation, are employed most widely to prepare fluorine-substituted vinyl sulfides, because sulfides are readily produced upon the addition of thiols to fluoroalkenes. Various organic and inorganic bases are used as dehydrohalogenating agents. Examples of such reactions are listed in Table 1.

Anodic oxidation of ethyl 3,3,3-trifluoro-2-phenylthiomethylpropionate in the presence of $\text{Et}_3\text{N} \cdot 3 \text{ HF}$ in acetonitrile results in β -phenylthio- α -(trifluoromethyl)acrylate **1**.³⁰

Presumably, this reaction proceeds *via* a radical cation, which reacts with the fluoride ion. The β -fluorinated sulfide formed in the first step is unstable under the reaction conditions and is readily dehydrofluorinated to give sulfide **1**.

Vinyl sulfides can be efficiently purified from saturated sulfides by halogenation of the reaction mixture, separation of the resulting high-boiling dihalides and the subsequent dehalogenation with zinc in dioxane.^{5,6}

X = Cl, Br; Y = F, Cl, CF_3 .

Vinyl sulfides **2** with a terminal difluoromethylidene group were prepared by dehalogenation of the corresponding sulfides on treatment with magnesium in the presence of catalytic amounts of iodine and 1,2-dibromoethane.³¹

$\text{R}^1 = \text{H, F, Cl, EtS}$; $\text{R}^2 = \text{Ph, Et}$; X = F, Cl.

Dehalogenation takes place also in the reaction of n-butyl 2,2,3,3,4,4,5,5-octafluoro-1,1-dichloropentyl sulfide (**3**) with triphenylphosphine.³²

Distillation of 1,1,1-triethoxy-2,2-bis(trifluoromethylthio)ethane, prepared by the reaction of trifluoromethanesulfonyl chloride with ethyl orthoacetate, is accompanied by elimination of an ethanol molecule to give 1,1-diethoxy-2,2-bis(trifluoromethylthio)ethylene (**4**).³³

Dehydration of bis(trifluoromethylthio)acetic acid on heating with P_2O_5 gives bis(trifluoromethylthio)ketene (**5**).³⁴

Perfluorinated isobutyryl(isopropylthio)ketene is formed on heating of the methyl ester **6** in SO₃ at 50 °C.³⁵

An efficient method which allows one to prepare tetrasubstituted phenylthioalkenes **7** in high yields has been developed.³⁶

R = Me, Prⁿ, cyclo-C₆H₁₁, Ph; R_f = F, F₃C, F₅C₂.

R = Ph, 2-MeOC₆H₄, 4-MeOC₆H₄; X = F, Cl.

2. The introduction of alkyl(aryl)thio groups into unsaturated compounds using nucleophilic substitution reactions

Fluorinated vinyl sulfides were first prepared¹ by the reaction of perfluorocyclobutene with thiols in the presence of organic bases (NEt₃, Triton B). This gave a mixture of products resulting from replacement of one or two vinylic fluorine atoms.

R = Buⁿ, HO₂CCH₂, .

Subsequently, this reaction was extended to various fluoroalkenes of both aliphatic and alicyclic series with an internal double bond.^{37–39} For example, the reaction of fluoroalkenes with α -toluenethiol in the presence of triethylamine gives vinyl sulfides **8** in 40%–65% yields.³⁷

R¹ = R² = CF₃, R³ = Cl; R¹–R² = (CF₂)₃, R³ = CF₃;
R¹–R² = (CF₂)₂, R³ = F; R¹–R² = (CF₂)₄, R³ = Cl;
R¹ = R² = CF₃, R³ = C₂F₅.

Unlike internal alkenes, fluoroalkenes with a terminal double bond are usually converted into addition products at the C=C bond when they react with thiols in the presence of organic bases; in some cases, the reaction mixtures contain vinylic substitution products as impurities (up to 20%).^{3,4,40,41} An exception to this rule is the dimethylamide of perfluoromethacrylic acid (**9**), which reacts with PhSH and PhCH₂SH to give products of replacement of the fluorine atom **10** (as a mixture of *cis*- and *trans*-isomers according to ¹⁹F NMR data) apart from hexafluoroisobutyric dimethylamide.⁴²

R = Ph, Bn.

This outcome was explained in the study cited by the noticeable basicity of the dimethylamide group, which can trap the eliminated proton thus preventing its addition to the carbanion centre. As a consequence, the intermediate carbanions are stabilised by giving off a fluoride ion to afford vinyl sulfides.

It has been shown recently that perfluoroisobutylene and its chlorinated analogue, *viz.*, 1,1-dichloro-2-trifluoromethyl-3,3,3-trifluoropropene, react with aromatic thiols in THF in the presence of equimolar amounts of diisopropylethylamine giving rise to bis(trifluoromethyl)ketene dithioacetals **11**.⁴³ When the stoichiometry is strictly maintained, monosubstitution products can also be isolated in these reactions.

The reactions of thiols with α -trifluoromethyl-substituted CH-acids such as compounds **12a–d** in the presence of BF₃·NEt₃ represent a convenient method for the synthesis of β -functionally substituted vinyl sulfides and ketene dithioacetals.⁴⁴

R = Me, Bu^t, Bn, CH₂CO₂Me; X = CF₃; Y = CO₂Me (**a**), CN (**b**);
X = Y = CO₂Me (**c**); X = F, Y = CN (**d**).

Undoubtedly, the first step of this reaction involves dehydrofluorination of the CH-acid to give fluoroalkene, which is attacked *in situ* by the anion generated upon the action of BF₃·NEt₃ on the thiol. The intermediate thus formed is stabilised through β -elimination of the fluoride ion, which is bound irreversibly by the BF₃·NEt₃ complex. This is why the reaction mixture contains no addition products. The ratio of mono- to di-substituted products depends on the CH-acidity of the substrate, on the reactant ratio, and on the structure of the starting thiol. When sterically hindered 2-methylpropane-2-thiol was used, no even traces of the corresponding ketene dithioacetals were detected in the reaction mixture. By using three equivalents of BF₃·NEt₃ and two equivalents of the thiol, one can deliberately obtain disubstituted products. In particular, bifunctional thiols such as ethane-1,2-dithiol and mercaptoethanol are converted into cyclic thioacetals **13** in high yields.⁴⁴

X = F, CF₃; Y = CO₂Me, CN; Z = O, S.

A method for the synthesis of vinyl sulfides by the reaction of perfluoropropylene with thiols in the presence of a solution of potassium carbonate in aqueous acetone has been patented.⁴⁵

R = Alk, Ar.

When fluoroalkenes are made to react with sodium or lithium thiolates, fluorinated vinyl sulfides mixed with the addition products are formed.^{5,6,46,47} In some cases, these reactions do not give saturated thioethers.^{48,49} In the case of tetrafluoroethylene, further reaction takes place resulting in symmetrical bis(ethylthio)alkene **14**.⁴⁸

The order of mixing of the reactants is significant in the reactions of fluoroalkenes with thiolates. Indeed, the addition of perfluoroisobutylene to a suspension of RNa in ether gives rise to double substitution products, namely, ketene dithioacetals **11**, whereas the reverse order of reactant mixing results in the predominant formation of monosubstituted compounds **15**.^{50, 51}

R = Et, Buⁿ, Ph.

A similar nucleophilic displacement of fluorine on treatment with sodium ethanethiolate takes place for perfluoroalkenyl ethers **16**. The reaction affords mixed ketene acetals **17**.⁵⁰

R = Me, Et.

When perfluoroisobutylene reacts with potassium diethyl phosphorodithioate, one fluorine atom is replaced in the first stage to give compound **18**, which cannot be isolated because it spontaneously decomposes. The resulting thioketene **19** dimerises to give dithiacyclobutane derivative **20**.⁵²

The dimer **20** is also formed in the reaction of perfluoroisobutylene with salts of other thiol acids.^{52–55}

Heating of copper trifluoromethanethiolate with 1,2-dibromoethylene in *N*-methylpyrrolidone furnishes 1,2-bis(trifluoromethylthio)ethylene (**21**).⁵⁶

On treatment with the ethanethiolate anion, the chlorine atom in β-functionally substituted α-trifluoromethyl-α-chloroethylenes **22** is substituted. The reaction affords a mixture of *Z* and *E* isomers of vinyl sulfides **23** where the *Z* isomer markedly predominates.⁵⁷ Unfortunately, the method of generation of the thiolate anion is not indicated in the study cited.

R¹ = H, R² = Ph; R¹ = Ph, 4-ClC₆H₄, ; R² = H.

Successive treatment of 3-chloro-2-phenyl-3-trifluoromethylacrolein with sodium sulfide and benzyl bromide yields vinyl sulfide **24** resulting from substitution of the benzylthio group for the chlorine atom.⁵⁸

1-Chloro-2,2-dicyano-1-polyfluoroalkylethylenes react with thiols on heating in the absence of bases. The reaction can be followed by monitoring the evolution of hydrogen chloride.⁵⁹

R = Bn, CH₂CO₂Me; R_f = CF₃, C₂F₅.

When bases, for example, triethylamine, are added as HCl acceptors, resinification of the reaction mixture takes place.

3. The addition of sulfur-containing reagents to alkynes and allenes

Nucleophilic and radical addition of sulfur-containing reagents to alkynes, which allows one-step synthesis of vinyl sulfides, has been thoroughly studied.⁶⁰ Both fluorine-containing alkynes and fluorinated thiols can be used to prepare fluorine-containing vinyl sulfides.

The addition of PhSH to trifluoromethyl(phenyl)acetylene (**25**) proceeds in the presence of potassium *tert*-butoxide in ethanol; the product yield is nearly quantitative.⁶¹

Under kinetically controlled conditions, this reaction gives only *Z* isomer of vinyl sulfide **26**, while under conditions of thermodynamic control, a mixture of products is formed with substantial predominance of the *E* isomer (*Z*:*E* = 23:64). At 150 °C, vinyl sulfide (*Z*)-**26** isomerises to give the *E* isomer. It is noteworthy that the oxygen analogue of sulfide **26** does not tend to undergo such *Z,E* isomerisation. The easy isomerisation of vinyl sulfide (*Z*)-**26** was explained by orbital interaction between the sulfur atom and the trifluoromethyl group. A similar situation is observed for the addition of thiols to trifluoromethyl-containing alkynes activated by an aldehyde or a keto group.⁶²

The reaction of 1,1,1-trifluoropropyne with bifunctional thiols proceeds in good yields under mild conditions; in the case, of 2-mercaptoethanol, the reaction proceeds selectively involving the sulfur atom.⁶³

Nucleophilic addition of methanol (in the presence of sodium methoxide) or morpholine to bis(trifluoromethylthio)acetylene gives rise to mixtures of *cis*- and *trans*-isomers of the corresponding vinyl sulfides **27**, **28**.¹²

The addition of morpholine to benzylthiopolyfluoroalkylacetylenes also gives products in high yields.⁶⁴

Carbon disulfide reacts with activated alkynes at $\sim 100^\circ\text{C}$ in methanol to give mixtures of products.⁶⁵ The initial stage of the reaction is cycloaddition of the alkyne to carbon disulfide to give intermediate carbene **29**; it can either dimerise to give adduct **30** or participate in other reactions.

Carbonyl sulfide reacts with hexafluorobutyne in methanol to give *O*-methyl *S*-vinyl thiocarbonate **31**.⁶⁵

Radical addition of trifluoromethanethiol to methyl propiolate affords a mixture of *cis*- and *trans*-isomers of methyl β -trifluoromethylthioacrylate **32** in good yield.²⁰ Ester **32** was converted by standard procedures into the corresponding acid, acyl chloride, amide and nitrile.

Under free radical reaction conditions, trifluoromethanethiol or trifluoromethanesulfonyl chloride add to bis(trifluoromethylthio)acetylene.¹²

X = H (39%), Cl (47%).

The reaction of dimethyl disulfide with hexafluorobutyne occurs on irradiation and heating.⁶⁶

When trifluoroacetic anhydride and the dimethyl sulfide–BF₃ complex react with alkynes, conjugate addition of the CF₃CO group and dimethyl sulfide takes place to give sulfonium salts. In

the reaction with excess dimethyl sulfide, they are demethylated yielding β -methylthio-substituted α,β -unsaturated trifluoromethyl ketones.⁶⁷

R = H, Me, Et.

Tetrakis(trifluoromethyl)allene reacts with thiols on heating with the formation of α,β -unsaturated sulfides **33a,b**.⁶⁸

R = Et (**a**, 48%), Ph (**b**, 81%).

The substantially lower yield of compound **33a** is due to the fact that ethanethiol is able to efficiently reduce the multiple bond in the allene, which gives (F₃C)₂CHCH=C(CF₃)₂ and Et₂S₂.

The reaction of 1,1-difluoroallene with α -toluenethiol in the presence of KOH gives initially the addition product; this is followed by vinylic replacement of the fluorine atom in this product.⁶⁹

4. C-Sulfonylation involving fluorine-containing sulfonyl chlorides

The reactions of β -diketones, β -ketoesters and their anilides with polyfluoroalkanesulfonyl chlorides afford compounds that exist almost completely, according to ¹H NMR spectra of CDCl₃ solutions, as enols, *i.e.*, β -hydroxyvinyl sulfides **34**.^{21, 70–72}

R¹ = Me, Ph; R² = Me, Ph, OEt, NH₂, NHPh; R_f = CF₃, ClCH₂CH(CF₃), MeO₂CCF₂, MeO₂CCF(CF₃), MeO₂CC(CF₃)₂.

These reactions usually proceed under mild conditions without a solvent and give products in high yields.

Similarly to enolisable ketones, enamines react with polyfluoroalkanesulfonyl chlorides to give monosubstituted products.^{73, 74}

R = C(O)NH₂, CN.

α -Fluoro- α,β -unsaturated sulfonyl chlorides easily form C-sulfonylated products with π -donor aromatic and hetero-aromatic compounds, various enolisable carbonyl compounds, and some enamines.^{25, 75–77} For example, the reaction with acetone affords monosulfonylation product.

X = CF₃, Y = CF₃, CO₂Me, CN; X = Y = CO₂Me.

The reaction of 1,3,3,3-tetrafluoro-2-methoxycarbonylpropenesulfenyl chloride with esters of 3-(arylamino)crotonic acid takes place under mild conditions. The reaction is accompanied by intramolecular dehydrofluorination and cyclisation giving rise to substituted *N*-aryl-2-(1-methoxycarbonyltrifluoroethylidene)-2,3-dihydrothiazoles.⁷⁶

The reactions of chlorofluoromethanesulfenyl chlorides with triethylamine furnish vinyl sulfides **35**. This can be a result of electrophilic replacement of hydrogen in enamine **36**.⁷⁸

R_f = CF₃, CF₂Cl, CFCl₂.

In the first step, sulfenyl chloride acts as a chlorinating agent, as indicated by the presence of disulfide in the reaction mixture. Consecutive chlorination–dehydrochlorination of triethylamine results in enamine **36**, which reacts with two sulfenyl chloride molecules. The reaction with dicyclohexylethylamine proceeds in a similar way.⁷⁹

Aliphatic and alicyclic α,β-unsaturated perfluorosulfenyl chlorides readily enter into electrophilic addition to a double bond; this is a way of introducing fluorine- and sulfur-containing unsaturated fragments into diverse alkenes. When activated alkenes, polar solvents and salt additives are used, replacement of vinylic hydrogen atoms and skeletal rearrangement of alkenes become possible apart from the addition reactions. For example, the reaction of perfluoro-3-chloro-2-methylsulfenylphenylpent-2-ene (**37**) with styrene gives vinylic substitution product **38** in a yield of up to 20%.⁸⁰

The reactions of fluorine-containing α,β-unsaturated sulfenyl chlorides with triethyl phosphite give the corresponding alkenyl-ethyl sulfides.³

R¹ = R² = CF₃, R³ = F; R¹ = CF₃, R²–R³ = (F₂C)₃.

Presumably, the attack is directed at the chlorine atom rather than at sulfur (in saturated nonfluorinated sulfenyl chlorides, nucleophiles attack the sulfur atom). As a consequence, the formally positively charged halogen is transferred to the phosphorus atom.

5. Trifluoroacylation of α,β-unsaturated sulfides

Trifluoroacetylation of alkyl(aryl)thioalkenes with trifluoroacetic anhydride at 20 °C or with cooling affords α,β-unsaturated β-alkyl(aryl)thio trifluoromethyl ketones.^{81–83} In the presence of pyridine, the yields of reaction products increase. As the sulfur-containing alkenes, one can use vinyl sulfides, ketene dithioacetals and activated dienes such as 1,1-di(alkylthio)alka-1,3-dienes. In the last-mentioned case, the reaction proceeds stereoselectively to give the *E* isomers of enones.

Using ¹H NMR spectra and kinetic measurements, it was found that the reaction follows an addition–elimination mechanism.⁸⁴ Vinyl sulfides are trifluoroacylated non-stereoselectively.

R¹ = H, Alk, Ar, SAlk, SAR; R² = Alk, Ar.

R¹ = Alk; R² = H, Et.

Aryl orthothioacetates react with excess trifluoroacetic anhydride with elimination of aryltrifluorothioacetate to give trifluoromethyl-α,β-enones, which are precursors of the corresponding ketene dithioacetals.⁸⁵

In the case of divinyl sulfide, one vinyl group is trifluoroacylated.⁸⁶

The unexpected reaction selectivity was explained⁸⁶ by assuming that the lone electron pair of sulfur occurs in strong p,π-conjugation with the trifluoroacetyl group, which substantially decreases the nucleophilicity of the second vinylthio group.

6. Condensation

α -Trifluoromethylthio-substituted acrylonitriles are produced according to the Knoevenagel reaction from trifluoromethylthioacetonitrile and carbonyl compounds.²⁰ This reaction can be carried out for aliphatic, alicyclic and aromatic aldehydes and ketones.

Ethyl(2-trifluoromethylthio)acetate, which has a lower CH-acidity, reacts with aldehydes under similar conditions but does not react with ketones.⁸⁷

In some cases, aldehydes are replaced by their dimethyl acetals in condensations with CH-acids. For example, reactions of malondialdehyde bis(dimethyl acetal) with trifluoromethylthioacetonitrile⁸⁸ and *N,N*-dimethylformamide dimethylacetal with ketones^{39,89} have resulted in the formation of functionally substituted vinyl sulfides **40–42**, which are used in the syntheses of heterocyclic compounds.

$\text{R}_f = \text{CF}_3, \text{CF}_2\text{Cl}$; $\text{R} = \text{Me}, \text{Pr}^n$.

Due to the high CH acidity caused by the presence of two electron-withdrawing groups, the nitrile and trifluoromethylthio ones, trifluoromethylthioacetonitrile enters into ester condensation with methyl trifluoroacetate. Chlorination of the resulting enol sodium salt leads to 3-chloro-3-trifluoromethyl-2-trifluoromethylthioacrylonitrile.⁹⁰

7. Syntheses based on phosphonium ylides

Bis(trifluoromethyl)vinyl sulfides were prepared by heating triphenyl-2,2-bis(trifluoromethyl)vinylidenephosphorane with thiols.⁹¹

$\text{R} = \text{Et}, \text{C}_6\text{Cl}_5$.

Methods for the synthesis of diverse trisubstituted alkenes containing the alkyl(aryl)sulfonyl group have been developed on the basis of the Wittig reaction. The reaction involves various carbonyl compounds: ketones,⁹² aldehydes,⁹³ esters,⁹⁴ and thioesters.^{94–96}

$\text{R} = \text{Me}, \text{Bn}, \text{Ph}$.

$\text{R}^1, \text{R}^2 = \text{Alk}, \text{Ph}$.

$\text{R}^1 = \text{Alk}, \text{Ph}, \text{SMe}, \text{SPh}, \text{CO}_2\text{Et}, \text{CN}$; $\text{R}^2 = \text{Et}, \text{C}_6\text{H}_{13}$; $\text{Y} = \text{S}, \text{O}$.

Butyllithium or sodium hydride is used as the base to generate ylides from the corresponding phosphonium salts.

8. Syntheses based on fluoro-containing thioketenes

Bis(trifluoromethyl)thioketene (**19**) adds to *N,N*-dimethylaniline at 10 °C by attacking one of the methyl groups.⁹² The process is interpreted as the electrophilic attack of the nitrogen atom by the sulfur atom followed by proton migration.

N,N-Dimethyl-*p*-toluidine and *N,N,N',N'*-tetramethylbenzidine also enter into this reaction (in the latter case, the bisadduct is formed). *N*-Ethyl-*N*-methylaniline and *N,N*-dimethyl-1-naphthylamine function as bases catalysing dimerisation of thioketene **19**.

Diethyl ether and methyl benzyl ether react with bis(trifluoromethyl)thioketene (**19**) by a similar mechanism. In the latter case, 3,3,3-trifluoro-2-trifluoromethylpropenyl sulfide is produced.⁹²

The ability of bis(trifluoromethyl)thioketene (**19**) to enter into ene reactions with some alkenes giving the corresponding propenyl sulfides and with allene and dialkylketenes was demonstrated using a large number of examples.⁹²

For example, ketene **19** reacts with propylene to afford compound **43** in 61% yield.

The reactions of bis(trifluoromethyl)thioketene **19** with unsaturated substrates such as thiocarbonyl compounds, alkenes unable to form the products of ene reactions, carbodiimides, *etc.* follow the [2 + 2]-cycloaddition pattern.⁹⁷

When made to react with dienes such as 2,3-dimethylbuta-1,3-diene,⁹⁷ cyclopentadiene and its derivatives, bis(trifluoromethyl)thioketene (**19**) is converted into [4 + 2]-cycloaddition products.⁹⁸ The adduct with cyclopentadiene was obtained in 96% yield.

Disulfide **44** reacts with 1,4-diazabicyclo[2.2.2]octane with intermediate formation of chloro(trifluoromethyl)thioketene **45**, which was isolated as the adduct with cyclopentadiene. Along with bicyclic compound **46**, this reaction produces chloro(trifluoromethyl)thioketene **47**.⁹⁹

9. Other methods of synthesis

The addition of chlorotrimethylsilane to *S*-phenyl chlorodifluorothioacetate followed by dehydrochlorination on treatment with zinc was used to prepare a mixed acetal of difluoroketene.¹⁰⁰

The reaction of benzyl polyfluoroalkenyl disulfides **48a,b** with phosphorous hexaethyltriimide is accompanied by desulfurisation and gives vinyl sulfides **49a,b**.^{101, 102}

$\text{R}^1 = \text{R}^2 = \text{CF}_3$, $\text{R}^3 = \text{C}_2\text{F}_5$ (**a**, 72%);
 $\text{R}^1 = \text{R}^2 = \text{H}$, $\text{R}^3 = \text{CF}_3$ (**b**, 81%).

An interesting example of ring opening in ethylene sulfide on treatment with the perfluoro-*tert*-butyl carbanion, which is formed from perfluoroisobutylene in the presence of KF or CsF, has been reported.¹⁰³ Nucleophilic substitution of the resulting thiolate anion **50** for one or two fluorine atoms in perfluoroisobutylene results in a mixture of vinyl sulfides.

The reaction of hexafluoropropylene with potassium fluoride and sulfur in dimethylformamide leads to hexafluorothioacetone dimer **51**. The subsequent reaction of compound **51** with hexafluoropropylene leads to a mixture of *E* and *Z* isomers of perfluoro-2,4,6-tris(trifluoromethyl)-5-thiahept-3-ene (**52**).³⁵

Heating of tetraethyl 1,3-dithiethanediylienedimalonate with SF_4 in the presence of HF results in the formation of 2,4-bis[2,2,2-trifluoro-1-(trifluoromethyl)ethylidene]-1,3-dithiethane (**20**), which is the dimer of bis(trifluoromethyl)thioketene **19**.⁹⁷

Depending on the amount of hydrogen fluoride used, it is possible to isolate also the products of transformation of two or three ester groups into trifluoromethyl groups.

Dimer **20** is also obtained by the reaction of bis(trifluoromethyl)ketene (**19**) with triphenylphosphine sulfide at 200 °C.^{104–106}

When reacting with organometallic reagents, esters of perfluoroalkanedithiocarboxylic acids are subjected to a thiophilic attack. The intermediate carbanion is stabilised by elimination of the α -fluorine atom. This reaction yields dithioacetals **53**.¹⁰⁷

$\text{R}_f = \text{F}, \text{CF}_3, \text{H}(\text{CF}_2)_3$; $\text{R}^1 = \text{Et, Pr, Bn}$; $\text{R}^2 = \text{Et, Pr, Bu}$;
 $\text{M} = \text{MgBr, Li}$.

The electron-withdrawing properties of the polyfluoroalkyl substituent are favourable for the 1,3-shift of the methylthio group in *S*-methyl β -polyfluoroalkylthiopropiolates on treatment with the hydroxide anion.¹⁰⁸ β -Polyfluoroalkyl- β -methylthioacrylic acids containing more than 90% *Z* isomer are formed in these reactions in high yields.

Pyrolysis of tetrakis(trifluoromethylthio)methane at 400 °C and at atmospheric pressure affords tetrakis(trifluoromethylthio)ethylene **54**.¹²

Presumably,¹² this reaction follows a radical mechanism. Two pathways to the reaction product **54** are possible. The radical **A** formed initially can dimerise to give adduct **B**, which loses two trifluoromethylthiyl radicals being transformed into compound **54**. Radical **A** can be converted into bis(trifluoromethylthio)carbene **C**, which dimerises to give product **54**.

III. Chemical properties

Fluorine-containing vinyl sulfides behave both as alkenes and as sulfides. The reactivity of these compounds depends on the nature and position of substituents. If the fluorinated substituent occurs at the sulfur atom, the double bond differs little in properties from the usual double bond if one takes into account the electron-withdrawing influence of the substituent. Meanwhile, vinyl sulfides with fluorine-containing substituents at the double bond resemble to a larger extent electron-deficient fluoroalkenes, which exhibit a low reactivity toward electrophilic reagents. The behaviour of fluorine-containing vinyl sulfides depends appreciably on a number of factors including the presence of other electron-donating or electron-withdrawing substituents, the positive mesomeric effect of fluorine atoms at the multiple bond, the presence of a good leaving group in the molecule, and the degree of p, π -interaction between the sulfur atom and the double bond, which also depends on the electronic effects of the substituents. The diversity of factors influencing the reactivity of fluorine-containing vinyl sulfides markedly extends the synthetic potential of these compounds. In view of these considerations, the description of chemical properties of fluorinated vinyl sulfides is classified in this review in terms of the nature of the active reagent, irrespective of the reaction route.

1. Reactions with electrophilic reagents

a. Halogenation

Alkyl(aryl)thiochloropolyfluoroethylenes are readily halogenated on treatment with equimolar amounts of chlorine or bromine.^{3, 5, 6, 9}

R = Me, Bn, Ph; X, Y = F, Cl, F₃C; Hal = Cl, Br.

The use of sulfuryl chloride in this reaction gave a mixture of products, although SO₂Cl₂ chlorinates the double bond in benzyltrifluoroisopropenyl sulfide under very mild conditions.¹⁰¹

On treatment with excess chlorine, dithioacetals of fluorine-containing ketenes are chlorinated at the double bond with

simultaneous replacement of one alkylthio group.¹⁸ In the case where the sulfur atom carries a good leaving group, for example, a benzyl group, chlorolysis proceeds further to give sulfenyl chlorides.^{18, 77}

Bromination of 2,2-difluoro-1,1-diphenylthioethylene in methanol is accompanied by conjugate electrophilic addition, as indicated by the formation of methyl bromodifluoroacetate after hydrolysis of the intermediate compound formed.¹⁰⁹

Some perfluoroalkenyl and perfluorocycloalkenyl benzyl sulfides having an electron-deficient multiple bond undergo chlorolysis at the S–Bn bond with retention of the vinyl fragment.³

R¹–R² = (CF₂)₄, R³ = Cl; R¹–R² = (CF₂)₃, R³ = CF₃;
R¹ = R³ = CF₃, R² = F.

A number of β -functionally substituted polyfluoroalkenesulfenyl chlorides have been prepared by chlorolysis of *tert*-butyl sulfides by chlorine⁷⁷ or sulfuryl chloride.²⁵

X = CF₃, Y = CO₂Me, CN; X = Y = CO₂Me.

2-Cyano-1,3,3,3-tetrafluoropropenesulfenyl chloride synthesised in this reaction is a labile compound; on heating, it undergoes intramolecular cyclisation involving the nitrile group to give isothiazole.⁷⁷

A similar intramolecular cyclisation of the intermediate sulfenyl chloride involving the nitrile group is observed in the chlorolysis of *tert*-butyl (2-cyano-1,2-difluorovinyl) sulfide.⁷⁷ Simultaneously, the double bond is chlorinated.

Chlorination of 1-benzylthio-2,2-dicyano-1-trifluoromethylethylene does not yield the expected sulfenyl chloride because both C–S bonds are immediately cleaved to give sulfur disulfide and 1-chloro-2,2-dicyano-1-trifluoromethylethylene.⁷⁷

When 1-benzylthioperfluorocyclobutene (**55**) reacts with molecular chlorine, the replacement of the benzyl group is accompanied by chlorination of the double bond; as a result, saturated sulfenyl chloride **56** is formed as the final reaction product. Perfluorocyclobut-1-enesulfenyl chloride (**57**) was prepared by the reaction of benzyl sulfide **55** with SO_2Cl_2 .³

Vinyl sulfide **58** reacts with chlorine at 20 °C to give the corresponding unsaturated sulfenyl chloride **59**,¹⁰² while at higher temperature, the product of further chlorination **60** was obtained together with sulfenyl chloride.

The formation of compound **60** was interpreted¹⁰² as being due to chlorotropy in the carbon–carbon–sulfur triad.

3-(Hexafluoroisopropylidene)-2-thiabicyclo[2.2.1]hept-5-ene and its derivatives are halogenated at the endocyclic double bond giving rise to the Wagner–Meerwein rearrangement products. The exocyclic double bond is not halogenated in this reaction.⁹⁸

Hal = Cl, Br.

b. Acid hydrolysis

Acid hydrolysis of alkyl perfluorovinyl sulfide carried out under mild conditions affords *S*-esters of α -*H*-thiocarboxylic acids.¹¹⁰

R = F, CF_3 .

On treatment of *S,S*- or *S,O*-acetals of fluorine-containing ketenes with sulfuric acid, esters of dithiocarboxylic acids or thiocarboxylic *O*-acids, and esters of thiocarboxylic *O*-acids or carboxylic acids are formed successively, depending on temperature. Fluorine-containing carboxylic acids are the final reaction products.^{18, 26, 27, 110, 111}

$\text{R}^1 = \text{CF}_3, \text{F}, \text{CHF}_2$; $\text{R}^2 = \text{F}, \text{CF}_3, \text{H}, \text{Alk}, \text{OMe}$;
 $\text{R}^3 = \text{Alk}, \text{Ar}$; X = O, S.

1,1,1-Trifluoroacetone was obtained by acid hydrolysis of benzyl 1,1,1-trifluoroisopropenyl sulfide.¹⁰¹

This reaction is assumed to give first enethiol, which isomerises to give a thioketone and is subsequently oxidised to a ketone.

A general method for the synthesis of polyfluorinated enethiols **61** of the aliphatic and alicyclic series has been described.³⁷ Polyfluoroalkenyl(cycloalkenyl) benzyl sulfides are heated under conditions of kinetic control in the presence of fluorosulfonic acid or concentrated sulfuric acid with simultaneous removal of volatile products by evaporation.

$\text{R}^1 = \text{R}^2 = \text{CF}_3, \text{R}^3 = \text{Cl}$; $\text{R}^1 = \text{R}^3 = \text{CF}_3, \text{R}^2 = \text{C}_2\text{F}_5$;
 $\text{R}^1 = \text{R}^3 = (\text{F}_3\text{C})_2\text{CF}, \text{R}^2 = \text{CF}_3$; $\text{R}^1-\text{R}^2 = (\text{CF}_2)_2, \text{R}^3 = \text{F}$;
 $\text{R}^1-\text{R}^2 = (\text{CF}_2)_3, \text{R}^3 = \text{CF}_3$; $\text{R}^1-\text{R}^2 = (\text{CF}_2)_4, \text{R}^3 = \text{Cl}$.

Enethiols **61** are colourless liquids stable on storage; they do not isomerise spontaneously into the corresponding thioketones. The enethiol to thioketone isomerisation was accomplished only for perfluoro-2-methylpent-2-ene-3-thiol on heating (150 °C, 20 h) or in the presence of catalysts (HSO_3F , Et_2O , $\text{BF}_3 \cdot \text{NEt}_3$). The back transformation of the thioketone into enethiol does not take place.

In the case where the α -position with respect to the sulfur atom is occupied by a fluorine atom instead of the perfluoroalkyl group, the acid-induced cleavage of the corresponding perhaloalkenyl benzyl sulfides gives fluorides of fluorine-containing α -hydrothionic acids rather than enethiols as the final products.⁴

$\text{R}^1 = \text{R}^2 = \text{CF}_3$; $\text{R}^1 = \text{CF}_3, \text{R}^2 = \text{F}$; $\text{R}^1 = \text{F}, \text{R}^2 = \text{Cl}$.

It is reasonable to assume that this transformation involves the intermediate formation of enethiols, which are unstable under the reaction conditions (due to the substantial positive mesomeric effect of the vinylic fluorine atom) and isomerise to thermodynamically more stable forms.

Hydrolysis of the enamine, prepared from trifluoromethanesulfonyl chloride and triethylamine, furnishes bis(trifluoromethylthio)acetaldehyde, which mainly exists as the enol form.¹¹²

A similar reaction carried out for β -alkyl(aryl)thio- α -polyfluoroalkyl-containing enamines readily gives the corresponding ketones.^{64, 74}

c. Other reactions

Electrophilic elimination of ethyl fluoride from bis(trifluoromethyl)ketene *O*-ethyl-*S*-alkyl acetals takes place on heating with boron trifluoride etherate.¹¹³

The reaction mechanism is similar to the mechanism of elimination of alkyl fluorides from bis(trifluoromethyl)ketene *O,O*-di- and *O,N,N*-trialkyl acetals in the presence of Lewis acids. On treatment with the Lewis acid, the allylic fluorine atom is eliminated from alkoxyalkene to give the mesomeric carbenium ion.¹¹⁴ A similar reaction for *S,S*-dialkyl dithioacetals of bis(trifluoromethyl)ketene could not be performed.¹¹³

Acetals of α,β -unsaturated trifluoromethyl ketones containing an α -methylthio or α -phenylthio group do not undergo Lewis acid-catalysed intermolecular allylation. The products of intramolecular cyclisation are formed instead.¹¹⁵

Some trifluoroisopropenyl sulfides enter into acid-catalysed intramolecular cyclisation. Thus heating of 2-(1-trifluoromethylvinylthio)acetic acid in F_3CCO_2H in the presence of fluorosulfonic acid as the catalyst is accompanied by lactonisation giving thialactone **62** in a preparative yield.²¹

The intramolecular cyclisation of 3-(1-trifluoromethylvinylthio)pentane-2,4-dione occurs under more rigorous conditions.²¹ The reaction is accompanied by resinification, the yield of compound **63** being not higher than 30%.

Cyclisation of *o*-(1-trifluoromethylvinylthio)phenols **64** occurs when this compound is heated to 120 °C in trifluoroacetic acid in a sealed tube.¹¹⁶

R = H, Me, Et.

The intramolecular cyclisation of 5-methoxy-2-trifluoromethylthiopenta-2,4-dienonitrile (**41**) induced by HBr and AcOH involves the nitrile group. This reaction was patented as a method of synthesis of 3-trifluoromethylthio-substituted pyridines.¹¹⁷

In the reaction of *tert*-butyl 2-trifluoromethyl-1,2-dichlorovinyl sulfide with *o*-nitrophenylsulfenyl chloride, the *tert*-butyl group at the sulfur atom is replaced, which results in an asymmetric disulfide.⁹⁹

The reaction of 3-(hexafluoroisopropylidene)-1,4-diphenyl-2-thiabicyclo[2.2.1]hept-5-ene with *p*-methylbenzenesulfonyl chloride yields the Wagner–Meerwein rearrangement product, which is spontaneously dehydrochlorinated.⁹⁸

An important feature of sulfur compounds is the ability to stabilise both carbanionic and carbocationic centres.

The ability of sulfur atoms to stabilise α -carbanions has been used in the alkylation of β -polyfluoroalkyl- α -hydrovinyl sulfides **65**. Successive treatment of compounds **65** with butyllithium and alkyl halides⁹⁴ or with non-ionisable aldehydes leads to alkylation products **66** and **67**.¹¹⁵

R¹ = Me, Ph; R² = Me, All, Bn; X = Br, I; Y = O, S.

$\text{R}_f = \text{CF}_3, \text{C}_2\text{F}_5$; $\text{R}^1 = \text{Me}, \text{Ph}$;

$\text{R}^2 = \text{Ph}, \text{Bu}^t, \text{PhCH}=\text{CH}, \text{PhC}\equiv\text{C}, \text{Bu}^t\text{C}\equiv\text{C}, 2\text{-furyl}$.

The adducts **67**, formed in the reactions with aldehydes, are converted into α,β -unsaturated perfluoroalkylvinyl ketones **68** on treatment with *p*-toluenesulfonic acid. This reaction is stereoselective, giving rise to *Z* isomers of alkenes **68**.

The electrophilic addition of chlorodiphenylmethane to 1,1-difluoro-2,2-di(phenylthio)ethylene involves the difluoromethylene fragment; thus, the sulfur atom stabilises a positive charge more efficiently than a fluorine atom.¹⁰⁹

2. Reactions with nucleophilic reagents

a. Reactions with O-nucleophiles

Vinyl sulfides^{32,52} and ketene *S,S*-acetals^{18,26} with a fluorine atom at a multiple bond are prone to react with aliphatic alcohols to give vinylic substitution products.

$\text{R}^1 = \text{F}, \text{H}(\text{F}_2\text{C})_3$; $\text{R}^2 = \text{Alk}$.

The exothermic reaction of 2-(methylthio)pentafluoropropene with allyl alcohol in the presence of a catalytic amount of KOH produces a mixture of three products, namely, sulfide **69**, allyl ether **70**, and allyl 2-methylthio-2-trifluoromethylpent-4-enoate (**71**), the last compound being the product of a [3,3]-sigmatropic rearrangement.²⁴

The reaction of 2-bromo-1,1,1-trifluoro-3-phenylthiopropene with substituted allylic alcohols in the presence of sodium hydride leads to the products of bromine replacement.¹¹⁸ The intermediate formation of 1,1,1-trifluoro-3-phenylthiopropyne was assumed for these reactions.

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{H}, \text{Alk}, \text{Ph}$.

Unsaturated ethers **72** have been used in the Claisen rearrangement for stereocontrolled synthesis of trifluoromethyl ketones.

The final product formed in the reaction of tetrakis(trifluoromethylthio)ethylene with methanol in the presence of sodium methoxide is trimethyl bis(trifluoromethylthio)orthoacetate. This reaction is assumed to occur in several steps that include successive addition of the methoxy anion and elimination of the trifluoromethoxy anion.¹²

On heating to 70–80 °C with an aqueous solution of sodium hydroxide, *o*-(1-trifluoromethylvinylthio)phenols are converted into 3-trifluoromethylbenzo-1,4-oxathianes **73** upon an intramolecular cyclisation.¹¹⁶ When this reaction is carried out under more rigorous conditions with excess NaOH, 2,2-difluoro-3-hydroxymethylbenzo-1,4-oxathianes are formed along with 1,4-oxathianes.¹¹⁹

$\text{R} = \text{Alk}, \text{OMe}, \text{F}$.

Apparently, the reaction mechanism includes the attack of the hydroxide anion on the $\text{C}=\text{C}$ bond of the initial compound, stabilisation of the resulting carbanion due to elimination of the fluoride ion and cyclisation of the intermediate difluoromethylene compound.

The products of sulfenylation of enolising carbonyl compounds with α -fluoro- α,β -unsaturated sulfonyl chlorides in the presence of the $\text{BF}_3 \cdot \text{NEt}_3$ complex are prone to undergo intramolecular cyclisation with elimination of HF and the formation of alkyliden-1,3-oxathioles.¹²⁰

$\text{R}^1 = \text{Alk}, \text{Ar}$; $\text{R}^2 = \text{H}, \text{CO}_2\text{Et}, \text{C}(\text{O})\text{Me}, \text{C}(\text{O})\text{CF}_3$;
 $\text{X} = \text{CF}_3, \text{CO}_2\text{Me}, \text{CN}$.

The reaction conditions are determined by the ability of the carbonyl compound to undergo enolisation. In the case of β -dicarbonyl compounds, cyclisation takes place even in the

absence of $\text{BF}_3 \cdot \text{NEt}_3$ on moderate heating. A similar reaction is also typical of *o*-sulfenylated phenols.⁷⁵

When reacting with potassium hydroxide, ethyl 2-(1-trifluoromethylvinylthio)acetoacetates **74a,b** are deacetylated to give the corresponding acids.²¹ The vinylthio group does not participate in the reaction.

$\text{R} = \text{H}$ (**a**, 57%), Me (**b**, 52%).

The decarbonylation of vinyl sulfides containing an aldehyde group at the multiple bond takes place on treatment with KOH in dichloromethane⁵⁷ or potassium *tert*-butoxide in toluene.⁹⁶

$\text{R}^1 = \text{Et, Ph; R}^2 = \text{Ph, 4-ClC}_6\text{H}_4, \text{furan-2-yl}$.

The *Z* isomer markedly predominates in the reaction products, the *Z* to *E* isomer ratio being changed with respect to the initial compounds in favour of the *Z* isomer.

b. Reactions with N-nucleophiles

In reactions with N-nucleophiles, the replacement of various good leaving groups at the multiple bond is most typical of fluorinated vinyl sulfides containing strong electron-withdrawing substituents (including functional ones). For instance, the chlorine atom in 2-chloro-1-cyano-2-trifluoromethyl-1-trifluoromethylthioethylene can be easily replaced by a phenylamino group.⁹⁰

The replacement of the vinylic fluorine atom in β -alkylthio derivatives of perfluoromethacrylic acid on treatment with ammonia and primary or secondary amines proceeds equally smoothly.¹²¹

$\text{R}^1 = \text{Bu}^t, \text{Bn; R}^2, \text{R}^3 = \text{H, Alk, Ar; X} = \text{CO}_2\text{Me, CN.}$

Meanwhile, 3-benzylthio-2,3-difluoroacrylonitrile not activated by the trifluoromethyl group does not react with primary arylamines even on heating.

β -Functionalised alkyl(aryl)polyfluoroalkenyl sulfides react with acid amidines and arylhydrazines to form substituted pyrimidines and pyrazoles. Intramolecular cyclisation involves the functional group in the products of replacement of the fluorine atom formed initially.¹²¹

$\text{R}^1 = \text{Bu}^t, \text{Bn, Ar, Het; R}^2 = \text{Me, Ph; X} = \text{CO}_2\text{Me, Z} = \text{OH; X} = \text{CN, Z} = \text{NH}_2.$

2-Chloro-1-cyano-2-trifluoromethyl-1-trifluoromethylthioethylene¹²² and 3-benzylthio-2,3-difluoroacrylonitrile¹²¹ enter into analogous reactions with acid amidines to give aminopyrimidines.

The reaction of 1-polyfluoroalkylthio-2-dimethylaminovinyl methyl ketones with arylhydrazines is also accompanied by heterocyclisation. 4-Polyfluoroalkylthiopyrazoles **75** thus formed have been patented as pesticides.⁸⁹

The alkylthio group in β -alkylthio- α,β -unsaturated trifluoromethyl ketones is easily substituted by amines. This affords enamines in yields of 56% to 100%.¹²³

$\text{R}^1 = \text{Me, Et; R}^2 = \text{H, Me, Ph; R}^3, \text{R}^4 = \text{H, Me, Et, Bn.}$

Bis(trifluoromethylthio)acetaldehyde, which mainly exists as the corresponding enol, reacts with amines to give the products of replacement of the hydroxy group.¹¹²

The reaction of perfluoro-2-isopropylthio-4-methylpent-2-ene, which isomerises to the terminal fluoroalkene, with anhydrous ammonia affords cyano-containing enamine.¹²⁴

Hexamethyldisilazane adds to 2-methylthiopentafluoropropene under rigorous conditions. The reaction is accompanied by elimination of trimethylfluorosilane to give 2-methylthio-3,3,3-trifluoropropionitrile.²⁴

The double bond in 2-benzylthio-1,1,1-trifluoropropene exhibits diphilic properties being able to add both electrophilic (for example, Cl_2) and nucleophilic reagents. The reaction with diethylamine proceeds with a yield of 66%.¹⁰¹

However, the reaction of ethyl 2-(1-trifluoromethylvinylthio)acetoacetate **74a** with phenylhydrazine leads to substituted pyrazoline, the vinylthio group remaining intact.²¹

The reaction of 2,2,2-trifluoroethyl phenyl sulfide with lithium diisopropylamide (LDA) affords (phenylthio)ynamine.²⁶ The first step involves dehydrofluorination to give 2,2-difluorovinyl phenyl sulfide.

Unexpectedly, 2-diethylamino-2-fluoro-1,1-bis(trifluoromethylthio)ethylene was found to be the major product in the reaction of tetrakis(trifluoromethylthio)ethylene with excess diethylamine.¹²

The reaction mechanism proposed in the study¹² includes the addition of diethylamine to the double bond and elimination of trifluoromethanethiol from adduct **A** yielding the product of replacement of one trifluoromethylthio group **B**. Compound **B** reacts with the fluoride ion, which is produced in the reaction mixture upon decomposition of the trifluoromethylthio anion, and is stabilised due to elimination of the second trifluoromethylthio group from intermediate **C**.

c. Reactions with C-nucleophiles

Difluoroketene *S,S*- and *S,O*-acetals react with C-nucleophiles such as organolithium compounds or Grignard reagents to give products of replacement of the fluorine atom.^{17, 26, 27}

In reactions with enolates, generated by treatment of methyl ketones with potassium hydride, fluoro(trifluoromethyl)ketene diethyl dithioacetal also forms the products of replacement of the vinylic fluorine atom.¹²⁵

R = Me (78%), Ph (83%).

1,1,1-Trifluoroisopropenyl phenyl sulfide adds butyllithium at the double bond.¹⁰ The carbanion **A** thus produced is stabilised by elimination of a fluoride ion being converted into difluoromethylidene compound **B**. This reacts subsequently with BuLi leading to monofluorine-containing vinyl sulfide **76**.

The reaction of the same 1,1,1-trifluoroisopropenyl phenyl sulfide with the anion generated from ethylacetoacetate on treatment with diazabicycloundecene (DBU) proceeds by a similar mechanism. Heterocyclisation takes place to give substituted 4*H*-pyran.¹⁰

The replacement of the phenylsulfo group in phenyl vinyl sulfone takes place in the presence of phenyllithium.⁴⁹

Sulfides containing conjugated double and triple bonds have been prepared by reactions of α -bromovinyl sulfide **77** with alkynes catalysed by palladium complexes.¹²⁶

R = Bu, Bu^t, Ph, SiMe₃, CH₂OH.

Treatment of 2-ethylthiopentafluoropropene with caesium fluoride results in a carbanion, which reacts with a second molecule of the initial vinyl sulfide to give dimer **78** and other products.¹⁴

Alkoxy carbonylmethyl polyfluoroalkenyl sulfides containing a functional group in the β -position readily cyclise to thiophenes under the action of bases.^{59, 127, 128} Thus on treatment with sodium methoxide, methoxycarbonylmethyl 1,3,3,3-tetrafluoro-2-methoxycarbonylpropenyl sulfide generates a carbanion with participation of the methylene group and undergoes intramolecular cyclisation, which affords 5-fluoro-3-hydroxythiophene **79**. The vinylic fluorine atom remains intact. When an excess of sodium methoxide is used, the vinylic fluorine atom in the cyclic structure **79** is substituted by the methoxy group, which yields 3-hydroxy-5-methoxythiophene **80**.⁵⁹

3-(Methoxycarbonylmethylthio)acrylates with different structures readily enter into a similar reaction. In this case, substituted acrylonitriles are converted into 3-aminothiophenes. The reaction is catalysed more efficiently by triethylamine. With this catalyst, the yields of the reaction products are nearly quantitative.⁵⁹

3. Cycloaddition

Published data on cycloaddition involving fluorine-containing vinyl sulfides are scarce. For example, [2 + 2]-cycloaddition of 2,2-difluorovinyl phenyl sulfide and its 1-halogenated analogues to α -*tert*-butylthioacrylonitrile has been reported.¹²⁹

R = H (47%), F (57%), Cl (88%).

α -Substituted acrylic acid derivatives react with difluoroketene *S,S*-diethyl acetal to give cyclobutanes in up to 100% yields.¹²⁹

R¹ = CN, CO₂Me; R² = OMe, SePh, SBu^t, SPh, $-\text{N} \begin{array}{c} \diagup \quad \diagdown \\ \text{O} \end{array}$.

1,1,1-Trifluoroisopropenyl sulfides enter into the Diels–Alder reaction with cyclopentadiene on heating to 100 °C being thus converted into mixtures of *endo*- and *exo*-adducts.^{21, 130}

R = CH₂CH₂Cl, CH₂C(O)Me.

Cycloaddition of trifluoromethylthioethylene to 2,3-dimethylbuta-1,3-diene occurs under drastic conditions.⁶²

4. Oxidation

Hydrogen peroxide in acetic acid was the first reagent to be used to oxidise vinyl sulfides to α,β -unsaturated sulfoxes.^{5, 6, 8, 16, 67}

R = Et, Prⁱ, Ph; X, Y = F, Cl, F₃C, SPh.

However, lately, organic oxidants have been used most often. For example, 2 equivalents of *m*-chloroperbenzoic acid (MCBA) in dichloromethane ensure oxidation of fluorine-containing vinyl sulfides to sulfoxes at 20 °C.^{49, 93, 96, 126, 131, 132}

R¹ = Alk, Ar, CO₂Et, CN; R² = Et, C₆H₁₃, Ph; R_f = F, CF₃, C₂F₅

When 1 equivalent of MCBA is used, the reactions normally produce mixtures of oxidation products; however, in the case of α -fluorovinyl sulfides, selective preparation of sulfoxides in 79%–83% yields is possible.⁹³

R = Alk, Ar.

By oxidation of *n*-butyl 1-chloro-2,3,3,4,4,5,5-heptafluoropent-1-enyl sulfide with excess trifluoroperacetic acid at 20 °C, the corresponding sulfoxide was obtained in 70% yield.³² On treatment of a mixture of *cis*- and *trans*-1,2-di(trifluoromethylthio)ethylenes with trifluoroperacetic acid in dichloromethane at 20 °C, a mixture of disulfoxide **81** isomers was obtained in a high yield. The racemic modification of the *trans*-isomer was isolated from this mixture in 8% yield.¹⁵

The reaction of β -trifluoroacetylated vinyl sulfides with H₂O₂ in CF₃CO₂H involves not only oxidation of the sulfur atom but also transformation of the carbonyl group, giving rise to diols stable up to 40 °C.¹³³

R = Me, Ph.

An efficient method for selective oxidation of 1-trifluoromethylvinyl sulfides to sulfoxides consists of treatment of the compounds with 30% hydrogen peroxide in hexafluoroisopropyl alcohol.¹³⁴

$\text{R}^1 = \text{Bu}^i, \text{Ph}, \text{CO}_2\text{Et}, \text{HC}=\text{CHPh}, \text{CH}_2\text{CH}_2\text{Ph}; \text{R}^2 = \text{Et}, \text{C}_7\text{H}_{15}.$

The selective formation of sulfoxides in this reaction is due to the effect of the solvent, *i.e.*, hexafluoroisopropyl alcohol ($\text{p}K_a = 9.3$), which activates H_2O_2 through the formation of a hydrogen bond. Simultaneously, hexafluoroisopropyl alcohol forms a hydrogen bond with the oxygen atom of the sulfoxide obtained in the reaction; this markedly changes the nucleophilicity of the sulfur atom and prevents oxidation to sulfone. With a more basic solvent, trifluoroethanol ($\text{p}K_a = 12.8$), the reaction is very slow.

Vinyl sulfides can be oxidised using perfluoro-*cis*-2,3-dialkyl-oxaziridines. They oxidise α -trifluoromethylvinyl sulfides to the corresponding sulfoxides in the $\text{CHCl}_3\text{--CFCl}_3$ solvent system at -50°C .¹³¹ Further oxidation of sulfoxides at 20°C leads to sulfones.

$\text{R}^1 = \text{Alk}, \text{Ar}, \text{CO}_2\text{Et}; \text{R}^2 = \text{Et}, \text{C}_6\text{H}_{13}; \text{R}_f^1, \text{R}_f^2 = \text{C}_4\text{F}_9, \text{C}_3\text{F}_7, \text{C}_6\text{F}_{13}, \text{C}_5\text{F}_{11}.$

5. Other reactions

On exposure to UV radiation, trifluoromethylthioethylene reacts with bromine and trifluoromethanethiol by a free radical mechanism.¹²

Meanwhile, the radical addition of trifluoromethanesulphenyl chloride to trifluoromethylthioethylene affords several products.¹² The major product is 2-chloro-1,1-bis(trifluoromethylthio)ethane (**82**).

Enantioselective hydrogenation of vinyl sulfide **83** in the presence of catalytic amounts of ruthenium complexes gives saturated sulfide **84** in 83% yield and with an enantiomeric purity of 89%.¹³⁵

Esters of β -bromo- and β -chloro-perfluorodithiocrotonic acid have been prepared in high yields by heating fluoro(pentafluoroethyl)ketene with anhydrous magnesium halides.¹³⁶

$\text{X} = \text{Cl}, \text{Br}.$

Cyclisation involving the trifluoromethyl group occurs on heating of cyano(trifluoromethyl)ketene *N,S*-acetals in diphenyl oxide. At 180°C , the reaction was found to be accompanied by evolution of hydrogen fluoride and intramolecular cyclisation to form an aromatic nucleus.¹²¹

$\text{R} = \text{H}, \text{F}, \text{Me}, \text{PhO}.$

Evidently, the first step of the reaction is proton migration from the nitrogen atom to the α -carbon atom and thermal dehydrofluorination of the CH -acid thus formed. On alkaline hydrolysis of the reaction products, 3-cyanoquinolin-4-ones **85** were obtained and characterised.

* * *

To summarise the information covered in this review, one can state that fluorine-containing alkyl(aryl) vinyl sulfides are fairly reactive compounds with great synthetic potential. Numerous convenient methods for the synthesis of fluorinated vinyl sulfides based on readily available starting compounds have now been developed. Therefore, the problems of synthetic applications of these compounds come to the forefront, because until recently, they have been mainly used in reactions where the alkyl(aryl)thio group functioned as a leaving fragment. However, lately, the reactions with retention of the sulfur atom in the molecule as well as regio- and stereo-selective processes have attracted increasing attention.

The preparative accessibility of fluorine-containing alkyl(aryl) vinyl sulfides in combination with high reactivity creates prerequisites for the use of these compounds in the synthesis of diverse organic and heterocyclic products that present both theoretical and practical interest.

Nanochemistry: a direct route to high technologies of the new century

A L Buchachenko

Contents

I. Nanochemistry: a science about the 'nanoworld'	375
II. Nanoclusters	377
III. Nanotubes	379
IV. Nanowires	384
V. Nanomechanics	386
VI. Technologies for handling nanoobjects	388

Abstract. This review deals with problems involved in creating and handling nanoparticles, as well as the integration of nanoparticles into various systems and the operation of such systems. The review analyses the chemical, electrical and magnetic properties of the three main elements of nanotechnologies, *viz.*, clusters, nanotubes and nanowires. The bibliography includes 77 references.

I. Nanochemistry: a science about the 'nanoworld'

Chemistry celebrated the end of the 20th century with a remarkable result of strategic importance: it has approached the threshold of being able to detect a single molecule and identify its physical and chemical behaviour. As a result, a new field of chemistry has appeared, *viz.*, the chemistry of single molecules. A molecule acquires identity and becomes a 'person'.^{1–3}

This new field defines precisely the upper boundary of yet another field of chemistry, called nanochemistry, which studies small ensembles of molecules (or atoms) comprising more than one species. However, there is no strict quantitative criterion for defining the lower boundary of this region; furthermore, setting any artificial limits (*e.g.*, size in nanometres or number of molecules or atoms in hundreds or thousands) is harmful.

The world of nanochemistry is a vast world from individual molecules to continual systems that constitute a phase. Nanoparticles are characterised by intermolecular interactions that deprive molecules of their personality; the properties and behaviour of molecules in ensembles differ from those of single molecules (social communities of people and animals show some similar features).

The main and fundamental problem of nanochemistry around which all interests of researchers are concentrated is the problem of dimensional effects. The intriguing questions are: how the properties of single molecules evolve into the properties of a phase when molecules are united; how bridges between the world of single molecules and the macroscopic world of substance are built; how the hierarchy of quantity is converted into the hierarchy

of properties. Dimensional effects are so diverse and unexpected that there is no general solution to the problem. The methods of quantum chemistry and molecular dynamics succeed in answering specific questions only. They can explain almost everything but cannot provide reliable predictions. However, science only then becomes real science when it can foresee. In this sense, nanochemistry altogether is still ahead of us; nanoparticles will long remain our 'employers'.

The lower boundary of nanochemistry (with the adjoining colloid chemistry and chemistry of highly dispersed systems) is rather vague and is determined by common sense, which appeals to two important considerations: first, the relationship between the concepts 'nanoparticle' and 'nanoreactor' (*vide infra*); second, the extent to which nanoparticles lose their individual properties when materials or colloid systems are formed from them, *i.e.*, how much they lose their identity as 'chemical persons'.⁴

1. The structural-chemical contours of nanochemistry

The simplest nanoreactors in which reagents are arranged spatially are van der Waals molecules, *i.e.*, weakly bound complexes of atoms, radicals, ions and molecules; the partners in such complexes are held by intermolecular non-valence interactions. The van der Waals molecules have been observed in supersonic molecular beams and studied by laser and microwave spectroscopy and by mass spectrometry. Very many molecules of this kind are known: He_2 , $(\text{H}_2)_2$, $\text{C}_6\text{H}_6 \cdot \text{CH}_4$, $\text{C}_2\text{H}_4 \cdot \text{Ar}$, $\text{HCl} \cdot \text{Xe}$, $\text{Ar} \cdot \text{I}_2$, CaMg , $(\text{C}_2\text{H}_2)_2$, $\text{He} \cdot \text{NH}_3$, *etc.* Various physical parameters have been determined for the majority of these molecules: symmetry and geometry (bond angles and lengths), dipole moments, rotation and oscillation frequencies, lifetimes and dissociation energies, magnetic susceptibilities and ionisation potentials, quadrupole and coupling constants and many others.

But why are van der Waals molecules so interesting to physicists and chemists and what are they good for? First, they are a reliable source of atom–atom potentials; it is due to them that interatomic potentials have acquired spectroscopic precision and are now widely used as the key parameters in calculations of chemical and molecular dynamics of liquids, glasses and macromolecules; they are used in calculations of intermolecular energy transfer and energy relaxation. Atomic potentials are responsible for the molecular organisation of crystals and macromolecules, polymorphism of crystals, self-organisation of molecular ensembles, self-replication of biomolecules, *etc.*

Second, van der Waals molecules are responsible for the macroscopic properties of gases (*PVT* diagrams, viscosity, second virial coefficient, *etc.*); they induce condensation, crystallisation

A L Buchachenko N N Semenov Institute of Chemical Physics, Russian Academy of Sciences, ul. Kosygina 4, 119991 Moscow, Russian Federation. Fax: (7-095) 938 24 84. Tel. (7-095) 939 71 28

Uspekhi Khimii 7 (5) 419–437 (2003); translated by S S Veselyi

and other phase transitions; they also define the critical points of substances and the density fluctuations and correlation radii in these points.

Do the van der Waals molecules play any role in chemical reactions? At first glance, the answer should be 'no', since the bond energy between the partners in these molecules is low, *viz.*, about kT or sometimes even lower. However, a partner in such a molecule may act as a 'rider', *i.e.*, as a third body that acts as a drain for the excess of energy evolved in the reaction, and eliminate reaction prohibition as regards the orbital symmetry or angular momentum. Here is a good example:

The cross-section of this reaction is negligibly small due to an orbital symmetry forbiddenness. However, the same reaction between $(\text{Cl}_2)_2$ (a van der Waals molecule) and Br_2 occurs in almost each collision, since orbital symmetry forbiddenness is eliminated by the third particle.

It is known that the angular distribution of products in reacting molecular beams suggests unambiguously that many reactions (even $\text{H} + \text{D}_2 \rightarrow \text{HD} + \text{D}$) are preceded by the formation of short-lived complexes between the reagents, *i.e.*, the van der Waals molecules, which can often be observed spectroscopically.

The interest in complexes between metal atoms and small molecules (H_2 , CO , CH_4 , C_2H_4 , N_2 , *etc.*) is increasing continuously; many complexes of this kind have already been studied to date: $\text{Al} \cdot \text{N}_2$, $\text{Ca}^+ \cdot \text{N}_2$, $\text{Hg} \cdot \text{N}_2$, $\text{Cr}^+ \cdot \text{N}_2$, *etc.* Pair non-valence interactions of atoms and molecules are at the upper boundary of nanochemistry.

In addition to the van der Waals molecules, there is an enormous number of other nano- and microreactors of diverse nature, scale and molecular ordering: complexes; crystal solvates; nanohydrates (*e.g.*, that of methane); clathrate compounds (*e.g.*, with cyclodextrins, semispherands and calixarenes as 'hosts' which interact with guest molecules); macromolecules (helices or rigid rods); cavities in zeolites and porous materials. Many characteristics are different in microreactors: molecular dynamics of reagents, mechanisms and rates of chemical transformations, pK values of acids and bases, local charges and their distribution, potentials and electron affinity, conformations and reactivity; new 'forced' reactions appear, and many other anomalies are found.

The area of nanochemistry which aims at the creation of closed or semiclosed nano- and microreactors is being developed rapidly. Methods to obtain polymers in which 75% of the volume is occupied with monodisperse empty spheres have been developed; the volumes of these spheres can be varied from 10 to 10^3 nm. Molecular 'vases' have been created, *i.e.*, calixarenes which can reversibly 'captive' guest molecules and release them (depending on the solvent, solution pH and calixarene structure);⁵ molecular traps have been synthesised, *i.e.*, carseplexes that can trap molecules like certain predacious insect-catching flowers. Unlike endofullerenes, they can release their molecular 'preys' after a change in the solvent, pH, *etc.* All these structures belong to the class of molecular containers or self-folding cavitands which can trap predefined molecules and release them as the conditions are changed.

'Empty' tubular silicon fibres, *viz.*, unidimensional nanoreactors, have been created. They are obtained by deposition of tetramethyl orthosilicate dissolved in supercritical CO_2 onto carbon fibres. Carbon is removed by thermal treatment in O_2 or by plasma etching to give nanotubular silicon fibres ready for various uses, *e.g.*, as nanoreactors or nanocontainers. The diameter of such fibres is determined by the diameter of the carbon fibre and is an order of magnitude larger than that of carbon nanotubes.

The interest in such well-known nanoreactors as micelles has not slackened, either. Dendrimeric megamolecules are also widely used as nanoreactors and nanocontainers.

Novel unusual quasi-bidimensional nanoreactors have recently been synthesised, *viz.*, rigid graphite-like planes connected by flexible-chain bridges ('columns') consisting of carbon (polymethylene) chains. The distances between the graphite-like planes in such reactors can be varied by changing the number of atoms in a 'column' (*e.g.*, C_{10} , C_{16} , *etc.*); the lateral distances between the columns can be changed by varying the number of columns (the thickness of the column 'forest'). The reversible and continuous contraction–expansion of the interplanar distance is achieved by the stimulation of conformation transitions in polymethylene chains, *viz.*, from a coil conformation (the planes are spaced most closely) to a stretched chain (the most widely spaced planes).⁶ These transitions can be smoothly controlled by adjusting the nanoreactor to a given volume by filling it with solvents. Such a system is similar to a 'bellows' system; its reversible contraction–expansion mimics muscular contraction. It may be considered as an ideal reversible mechanochemical molecular machine. It can be used as a nanoreactor by loading with catalysts and carrying out catalytic reactions; it can also serve as a versatile and reversible molecular container, *etc.* The first system of this kind was based on a decane-1,10-diphosphonate derivative of γ -zirconium phosphate.

A 'contour' analysis of nanochemistry reveals two facets: on the one hand, nanochemistry produces its own objects, *viz.*, nanoparticles, nanoreactors, nanocontainers; on the other hand, it employs the numerous advantages of nanoparticles and their unusual and flexibly adjustable properties for its own needs, such as the development of new materials, reagents and elements for use in nanotechnologies.

2. A nanoparticle and a nanoreactor

Every year, nanochemistry becomes an increasingly structured science with strictly defined concepts and formulated terminology, the language as 'the dress of thought'. In view of this, it is necessary to define two key concepts, *viz.*, the nanoparticle and the nanoreactor. The former concept characterises the dimensional parameters, while the latter defines the nanoparticle function. For example, an iron cluster loses its specific functional properties (ionisation potential, magnetism) almost completely and approaches the properties of metallic iron when the number of atoms in the cluster (n) equals 15. At $n > 15$, it remains a cluster in terms of dimension, but it loses the properties of a 'nanoreactor' in which the properties become a function of the size. In those clusters where an α -naphthol molecule is surrounded by n water molecules, a cluster behaves as a nanoreactor at $n \leq 20$; its properties depend on its size. At $n > 20$, this dependence disappears and the cluster behaves as a macroscopic aqueous 'reactor' in which the reagent is localised; however, it does not display any chemical anomalies. For example, at $n > 20$, acid dissociation of α -naphthol and proton transfer to water molecules occur.

In clusters of monovalent magnesium (and calcium) with $(\text{H}_2\text{O})_n$ and $(\text{CH}_3\text{OH})_n$, the electron transfer and hydrogen reduction occur according to the reactions

only in the range $6 \leq n \leq 15$; no hydrogen evolution occurs for any other n values.⁷

Hence, the cluster demonstrates its dimensional effects and 'works' as a nanoreactor only at $n \leq 15$; at $n > 15$, the cluster behaves as a small reaction vessel without dimension-related anomalies in its reactivity.

Nanocavities in various porous materials may be considered as nanoreactors as long as the properties of the reagents which they incorporate (pK , ionisation potential), their structures (conformations) and properties of the reacting systems (rate constant, 'forced' reactions, molecular dynamics, *etc.*) depend on the cavity size. When these dependences do not exist any more, nanocavities

become just nanosized containers in which the trapped particles behave as if they were located in an infinite volume.

Of course, the nonequivalence of the concepts 'nanoparticle' and 'nanoreactor' is not always obvious; in many cases, it is impossible to distinguish them. However, it is important to perceive clearly the two aspects of the dimensional effect, both as a purely scale- and space-related effect and as a physicochemical phenomenon where the size affects the properties of trapped atoms and molecules. It is this second aspect that is the most attractive feature of nanochemistry.

3. Nanoclusters, nanowire and nanotubes: three key objects of nanotechnologies

The diversity of nanoobjects studied by nanochemistry is enormous (see the section about the contours of nanochemistry); the chemistry of these nanoobjects is equally diverse. However, we will consider only those nanoobjects which either already show real promise for the high technologies of the new century or which may ensure serious breakthroughs in the future, *viz.*, in the creation of nanolasers, nanocables, optical nanoconverters and nanosources, nanoelements of integrated circuits, nanocatalysts, nanomechanical devices, nanoresonators, nanowave guides, nanodiodes, *etc.* These objects include three-dimensional clusters, quasi-unidimensional clusters (nanowires) and nanopipes. It is these objects that may ensure extreme, almost on the molecular scale, miniaturisation of diodes, transistors and other elements of nanoelectronics, nanomechanics, nanophysics, nanoinformatics (nanocomputers, nanosensors), *etc.*

II. Nanoclusters

1. A cluster as a nanoreactor

The diversity of nanoclusters is infinite, and therefore they are inexhaustible. They can be neutral (atomic and molecular) or charged (ionic and molecular ionic). They are obtained and studied in gases (*e.g.*, in expanding supersonic molecular atomic beams), in zeolite channels (*e.g.*, the In_8 cluster), in liquids (including liquid helium), on solid surfaces, in solid matrices, *etc.* Clusters are extremely important in chemical materials science (cluster materials with unusual physics and mechanics), in chemical analysis and in diagnostics (detectors and sensors).

Clusters are relatively new objects in chemistry; they are studied by organoelement and organometallic chemistry and by chemical physics (atomic and molecular clusters). Many studies have dealt with the methods of their synthesis, their structures and properties. Their role in condensation, evaporation and crystallisation processes is also critical; they serve as precursors of new phases ('protophases'). However, it is the chemistry of these species, their reactivities, catalytic 'potential' and direct use in materials science that attracts the greatest interest. Cluster chemistry belongs to the future.

The rate of photoinduced isomerisation of a *trans*-stilbene molecule in a (hexane) $_n$ cluster was measured by picosecond spectroscopy in molecular beams.⁸ The isomerisation rate constant decreases with an increase in n in the order: 9.7×10^9 ($n = 0$, free molecule); 3×10^9 ($n = 1$); 1×10^9 ($n = 2$); 0.8×10^9 ($n = 3$); $0.5 \times 10^9 \text{ s}^{-1}$ ($n = 4$) to reach a limit at $n \geq 5$. Unexpectedly, all of these constants turned out to be smaller than the observed isomerisation constant of *trans*-stilbene in pure liquid hexane at the same temperatures and energies ($11.5 \times 10^9 \text{ s}^{-1}$). Thus, incorporation of a *trans*-stilbene molecule in a cluster decreases its reactivity. The cluster shell traps the molecule more strongly than the 'liquid-phase' shell: the former anomalously increases the kinetic (Kramers') friction, *i.e.*, the movement of a reacting molecule on the potential surface along the reaction coordinate.

The abundance and hence importance of clusters may turn out to be even greater than it seems now. It has recently been discovered experimentally (by cold neutron scattering and XRD) that liquid ammonia consists of $(\text{NH}_3)_7$ clusters where one molecule is located in the centre while the remaining molecules

are located at the periphery. The cluster structure of water is well known: water molecules are combined into hexa-, penta- and tetramers to give structures with similar energies resembling a prism, a cage, an 'open book', adamantane, as well as dodecahedra and other large clusters. Even liquid solutions of ethanol in water are inhomogeneous: they consist of coexisting water and alcohol clusters;⁹ the fractions of these clusters become equal when the alcohol content in water is about 40%. It is possible that the particular qualities of this water-alcohol solution originate from this fact. Liquid benzene was also found to have a cluster structure. It looks like this is a general phenomenon; in such cases, all liquid-phase reactions should be interpreted as reactions in nanoreactors.

What is more, a chemical reaction itself may favour the organisation of molecules into nanoreactors. For example, a colourless spiropyran with a long hydrocarbon 'tail' is converted photochemically into a coloured bipolar compound with separated charges; it is the molecules of this compound that are combined into micelles. Here, the photochemical reaction works as a trigger that switches micelling on.

A new trend in cluster chemistry is the study of the reactions of clusters with solids as a function of cluster energy. The elasticity of a cluster upon collision with a surface turns out to be very high. As is exemplified with $\text{H}^+(\text{H}_2\text{O})_n$, $\text{H}^+(\text{CH}_3\text{OH})_8$, $(\text{C}_6\text{H}_5\text{CH}_3)_5^+$ and $\text{H}^+(\text{NH}_3)_{10}$ ionic clusters and the diamond surface, clusters are reflected elastically from the surface and retain about 75% of their initial energy. The high elasticity of a cluster is explained by its high entropy (owing to the participation of different isomers in the molecular structure of the cluster).

However, when cluster ions acquire a high energy above a certain threshold, they disintegrate (mainly into monomeric fragments). In particular, $\text{H}^+(\text{NH}_3)_{10}$ disintegrates into NH_3 molecules faster than 80 ps. This suggests that fast energy redistribution occurs in such a 'superheated' cluster. Yet another remarkable phenomenon is the impact-induced chemical reactions in clusters [*e.g.*, the formation of I_2^- from the cluster ions $(\text{CH}_3\text{I})_n^+$ and F_2^- from $(\text{CH}_3\text{F})_8^+$]. This new direction is called the femtosecond cluster mechanochemistry.¹⁰

2. Clusters in catalysis

The importance of cluster materials in catalysis was recognized long ago, and intense development in this field is continuing.¹¹ However, the technological capabilities of cluster catalysis are much greater than the achievements: this is an iceberg the major part of which has not yet been explored.

There are two main circumstances that are promising for the technological application of cluster catalysis: the high surface area of catalysts (which is related to productivity) and dimensional effects, which manifest themselves in the properties of clusters as nanoreactors (this is related to the selectivity and possibility of 'tuning' a cluster for a specific reaction). As indicated above, a general solution to the 'dimensional' problem is unknown; because of that, clusters continue to remain mysterious objects. Their route to catalysis starts from testing their reactivities in model experiments. In particular, any cluster of any size can be prepared in molecular beams, and reactions of these clusters with added molecules can then be studied by mass spectrometry.

It was shown using this method that the Re atom does not react with CH_4 , whereas the Re_3 cluster is reactive. Linear three-atom Cu_3 and Ni_3 molecules do not react with H_2 and CH_4 , whereas triangular molecules are highly reactive (the Ni_{13} cluster is also very reactive). The Co_n clusters react with H_2 in a dissociative way upon virtually each collision if $n = 3, 4, 5$ or $10-18$, whereas clusters with $n = 6-9$ are completely inert.¹²

Figure 1 shows the dependence of rate constants on the cluster size n for the reactions $\text{Nb}_n + \text{D}_2$ and $\text{Nd}_n + \text{N}_2$. One can see a distinct stepwise dependence of reaction rates (dissociative adsorption of N_2 and D_2 molecules on an Nd_n cluster is the rate-determining step) on the size of the cluster; it is almost the same for both reactions and is insensitive to temperature. On the other

Figure 1. Dependence of the rate constants of dissociative adsorption of D_2 (a) and N_2 (b) on the size of a niobium cluster (n is the number of atoms in the cluster).

Temperature /K: (1) 280, (2) 300, (3) 370.

hand, the rate constant for the reaction of Nb_n with O_2 [$(3-7) \times 10^{-10} \text{ cm}^3 \text{s}^{-1}$] is similar to the constant of bimolecular collisions and does not depend on n (the dimer Nb_2 is an exception).¹³

Figure 2. Dependence of the probability of the reactions $\text{Nb}_n + \text{D}_2$ (1) and $\text{Nb}_n + \text{N}_2$ (2) at 300 K (a) and of the ionisation potential of the Nb_n cluster (b) on the size of the cluster.

Figure 2 displays two relationships: the probability of the reactions $\text{Nb}_n + \text{D}_2$ and $\text{Nb}_n + \text{N}_2$ and the ionisation potential of the Nb_n cluster as functions of n . A pronounced and unambiguous ‘antiphase’ relationship between the reactivity of clusters and their ionisation potentials is observed: the lower the ionisation potential IP_{eff} of a cluster the higher its reactivity. It was concluded on this basis that charge transfer between a cluster and an adsorbed molecule is the main factor that governs the cluster reactivity; it is this factor that is responsible for the dimensional effects in Nb_n clusters.¹³ It is noteworthy that only the clusters with $n = 5, 6$ and 11 are reactive in the dehydrogenation of benzene.

The Mo_n clusters are highly reactive in the reaction with N_2 (dissociative adsorption). At $n = 16$ and 23, the reaction constant is close to the gas-kinetic threshold; at any other n values, the rate constants are two orders of magnitude lower.¹⁴ The W_n clusters react similarly: the maximum reactivity is observed for clusters with $n = 16$ and 23.¹⁵

Even gold loses its chemical ‘nobleness’ in clusters. Figure 3 demonstrates the catalytic activity of Au_n clusters in the reaction

One can see that clusters with $n = 8, 11, 15$ and 18 are the most active.¹⁶

Figure 3. Yield of CO_2 molecules per cluster in the catalytic reaction $\text{CO} + \text{O}_2 \rightarrow \text{CO}_2$ as a function of the size of the Au_n cluster.

The MoO^+ ion does not react with NH_3 ; however, the ionic clusters Mo_3O_8^+ and Mo_3O_9^+ vigorously dehydrogenate ammonia to give a complex with the dehydrogenation product, *viz.*, nitrogen; they also oxidise CO into CO_2 .¹⁷ The V_3O_7^+ cluster is very efficient in the dehydrogenation and cracking of butane, butene and butadiene; the $\text{V}_3\text{O}_{12}^+$ cluster has low activity, whereas $\text{V}_3\text{O}_{17}^+$ is totally inert. The V_3O_6^+ and $\text{V}_3\text{O}_{11}^+$ clusters are inefficient in these reactions but are actively involved in oxidative condensation and cyclisation, *i.e.*, removal of only one oxygen atom from the cluster completely changes the type of the reaction involving the cluster.¹⁸

Studies on the use of titanium dioxide (TiO_2) as a photocatalyst for water and air purification from organic pollutants are under way. The drawback of TiO_2 is that its optical absorption band lies in the UV region (shorter than 390 nm), which decreases considerably its potential as a photocatalyst. Doping of TiO_2 with nitrogen (both in films and in clusters) shifts the $\text{TiO}_{2-x}\text{N}_x$ absorption band to the region of 520 nm, thus increasing considerably the efficiency of photocatalysis.

The dependence of the catalytic activity and reactivity of clusters on the dimensional effect follows, first, from the energetic parameters (the role of the ionisation potential in the reactivity of Nb_n clusters has already been noted above) and, second, from the structural changes in the atomic surfaces of clusters (exit of elements of different faces, edges and terraces on the surface). It

is the second reason that determines the difference in the reactivity of different faces of a single crystal in heterogeneous catalytic processes.

It has become clear now that the dimensional effects in catalysis are second in importance (the chemical nature of the catalyst is the most important). They can control both the rate (which can be changed by a few orders of magnitude) and the direction of a reaction.¹⁹

It should however be admitted that clusters as such are not catalysts yet. The use of high technologies in catalysis implies that clusters are tested for reactivity in specific reactions chosen with respect to reactivity and selectivity and finally combined in a macroscopic catalytic ensemble without losing the individuality of the clusters. The latter problem is not easy; many research groups are working towards its solution. Although it is unlikely that a general solution to this problem can be found, it can, in principle, be solved in each particular case.

A new strategy in heterogeneous catalysis involves a combination of catalysis with tunnelling scanning microscopy. The tip of a tunnelling microscope can deposit any number of atoms (including single atoms) onto any topological element of a surface (face, edge, terrace), thus creating catalytic nanoreactors and making it possible to test any reactions on them. The creation of an 'atomic pump', *i.e.*, prototype of a machine that deposits single atoms which drift through a nanotube, is a brilliant breakthrough that may occur in this nanotechnology. The drift of atoms is controlled by a laser (see Section IV.3). This is a new direction in the fundamental science of catalysis and a direct route to the use of high technologies in catalysis.

3. Optical converters

Particularly impressive are dimensional effects in semiconducting nanocrystals with sizes smaller than the Bohr exciton radius. In such nanoclusters (called quantum points), the quantum trapping of an electron-hole pair (photochemically or radiation-induced) in a restricted volume results in the expansion of the forbidden band as the cluster size decreases. This means that recombination luminescence shifts to the blue region (high energies) with a decrease in the cluster size. The CdSe nanocrystals 'dressed' in one or two ZnS monolayers represent a good example. If the diameter of the internal CdSe nucleus is changed stepwise from 23 to 55 Å, the bright blue luminescence changes to green, yellow, orange and finally bright red.²⁰ Upon coherent excitation of the electronic gas, gold clusters (nanorods) fluoresce with a quantum yield 10^6 times higher than metallic gold; furthermore, the quantum yield is proportional to l^2 (where l is the nanorod length), while the maximum of the luminescence band is proportional to l . It has been shown recently that a carbon nanotube is also a quantum point.²¹

Quantum points are mainly studied by physicists. The creation of quantum points doped by admixture ions is a subject of nanochemistry. In doped quantum points, the excitation energy 'mounts' the admixture site and is emitted by it. For instance, high-quality nanocrystals of ZnSe doped with Mn^{2+} ions were obtained by a reaction of a solution of selenium in trioctylphosphine with diethylzinc and dimethylmanganese.²² In this case, each nanocrystal contained one Mn^{2+} ion. Using the magnetic circular dichroism and electron spin resonance, it was proved that the Mn^{2+} ion is located inside the nanocrystal, replacing the Zn^{2+} ion in the cubic lattice of ZnSe. It should be noted that such perfect doped nanocrystals could not be obtained when diethylmagnesium was used instead of diethylmanganese; the Mg^{2+} ions were partially located on the surface and distorted the optical conversion.

The blue fluorescence characteristic of undoped crystals is suppressed almost totally in manganese-doped ZnSe nanocrystals and is changed for red fluorescence (2.12 eV, 585 nm); the quantum yield of luminescence at 293 K is 22% and reaches 75% below 50 K. Thus, the admixture Mn^{2+} ion in semiconduc-

tor crystals is a collector of the electron-hole recombination energy and its efficient monochromatic emitter.

Of light-converting organic nanoclusters, J-aggregates are very popular, *i.e.*, ensembles of molecules of organic dyes which efficiently collect the electron excitation energy (directly or through electron-hole recombination) and emit it with a high quantum yield (as a rule, in a narrow spectral region). In fact, they act like molecular antennae in photosynthetic centres.

4. Magnetism and spintronics

Because the ratio of the surface and bulk atoms in ferromagnetic metal clusters is infinitesimal, the mutual compensation of the atomic magnetic moments of clusters is incomplete. Furthermore, the crystal lattice of the cluster can differ from that of the metal. For this reason, the magnetization and magnetic atomic moment in clusters depend on the cluster size and differ from the macroscopic characteristics of the metal. Based on this, new nanocluster magnetic materials with new attractive properties are created. This field of research has been successfully developed for a long time; good books and reviews on the topic are available (see, *e.g.*, Refs 23 and 24), which allows us to refrain from discussing it here.

Over the past three years, a new field of electronics, *viz.*, spintronics (spin electronics), has developed rapidly. Spintronics opens up new horizons for developers of new-generation electronic devices and instruments using high technology.²⁵ Unlike classical electronics, which controls the movement of electrons and holes (negative and positive charges) by means of potentials (both biasing and stopping potentials), spin electronics controls both charges and spins (magnetic moments) of current carriers. Two controlling factors work in spintronics, *viz.*, electric potentials and magnetic fields.

The main material of spintronics is represented by either a film of a conducting metal (copper, ruthenium) enclosed between layers of ferromagnetic metals or a semiconductor nanometre-thick film separating ferromagnetic layers. Owing to the magnetic resistance effect, the electric current in a film of a non-magnetic metal or the tunneling current in a semiconductor film (tunnel barrier) depends not only on the controlling electric potentials but also on the magnetic field created by the ferromagnetic layers and the external field. Clearly, this circumstance increases considerably the number of methods to monitor and control electric currents by both selecting ferromagnetic films (with different hysteresis loops and different magnetisations) and by applying an external magnetic field. In combination with controlling potentials, this creates a flexible and multiparameter system for the control of electric currents.

Currently, there is a race to create new technologies and devices using spintronics; the tension of this race is only comparable to that of the 'cold cheminuclear synthesis' race at the end of the 1980s. However, unlike cold cheminuclear synthesis, spintronics is realistic. The development of many devices is underway, including spin-dependent field transistors, spin-dependent light-emitting diodes, spin tunnel diodes and optical switches in the terahertz frequency range, spin modulators, coders and decoders, spin-dependent sensors and elements of computer and communication memory, *etc.* Practical Americans estimate the new technology market to be worth multi-trillion dollars;²⁵ certainly, nanochemistry is the main paradigm of these new developments.

III. Nanotubes

The chemistry and physics of nanotubes are under rapid development. Many methods and technologies for the synthesis of these species have been developed, *viz.*, electric-arc discharge, laser-thermal ablation, flame synthesis and pyrolysis of hydrocarbons.²⁶ As of today, the best one is the pyrolytic method for the synthesis of nanotubes from CO, CH₄, C₂H₄ or C₂H₂ on a surface with a deposited catalyst or with a volatile catalyst precursor [like Fe(CO)₅]; in the latter case, the synthesis of the catalyst (*e.g.*, Fe

atoms and clusters) and the synthesis of the nanotubes are coupled. The combination of these diverse methods is the essence of the technology of chemical deposition from a gas (or vapour) phase on a solid surface (support), the technology which is considered the most efficient today. Methods for the continuous and large-scale production of nanotubes with controlled growth rate and adjustable diameters and lengths have already been developed.²⁶

1. Architecture of nanotubes

For nanotubes as technological objects, the architecture of their ensembles and the possibility of controlling it, adjusting it and combining objects into integrated circuits are important factors; the latter factor makes the problem of nanocontacts particularly important.

Considerable success has been achieved in the creation of controlled architecture. Multilayered tubes with preset architecture were obtained using a porous silicon support with submicron pores electrochemically pretreated (electrocutting) in an HF–MeOH solution. This treatment has made it possible to create a thin nanosized layer with nanopores (diameter about 3 nm) on silicon. Atop this nanolayer, a catalyst (iron film 5 nm thick) was sputtered through a shading mask. Subsequently, nanotubes were synthesised from ethylene at 700 °C by chemical deposition onto catalytic islands. The multilayered nanotubes formed on these islands looked like a thick forest of perfect ‘towers’ oriented strictly vertically. The length of the nanotubes (height of the ‘towers’) was controlled in the range 10–240 nm; the square of a ‘tower’ depended on the mask selected.²⁷

The reason for the architectural perfectness of the ‘nanopipe’ ensemble (and the advantage of the technology) is that the catalyst is strongly retained in the nanopores of the support, while the strong van der Waals interaction of the outer spheres of the growing nanotubes precludes their distortion and ensures the rigid fixation of the entire bunch of nanotubes growing on a single catalytic island. It was found that the growth of nanotubes on nanoporous silicon occurs much faster than on ‘non-cut’ planar silicon. The reason for the fast growth of nanotubes is that ethylene arrives at the catalytic islands not only from the gas phase but also through the nanopores of the support, ‘feeding’ the growing nanotubes with carbon from the inside. Finally, yet another remarkable result of this technology is the synthesis of nanotubes with monodisperse diameters.²⁸

Monolayer nanotubes are usually grown by arc discharge or laser ablation. In these cases, the evaporation of carbon atoms occurs at 3000 °C or higher, which restricts the growth of nanotubes; they bend and get entangled, and it is difficult to purify them and build ensembles from them. High-quality monolayer nanotubes are obtained by chemical deposition of carbon from methane. The advantage of methane is that its stability precludes the formation of amorphous carbon that contaminates the catalyst on which nanotubes grow.

A bimetallic Fe/Mo catalyst deposited on an aluminium–silicon material prepared by sol–gel technology was found to be the best catalyst for the synthesis of monolayer nanotubes. The diameters of the nanotubes grown on this catalyst range from 0.7 to 1.5 nm (this is their disadvantage); the tubes with a diameter of 1.4 nm are obtained in a maximum yield. Again, the main condition required to obtain high-quality nanotubes is a strong bond between the metal and the support. The high porosity of the support ensures a high density of catalytic sites on the surface and the easy access of methane to these sites. The latter circumstance is particularly important, since the growth rate of nanotubes is limited by gas diffusion.

It is important for nanotechnology that oriented nanotubes can be grown. The first steps in this direction have already been made. Lithographic methods are used to create islands (elevations with deposited catalyst ‘chips’) on supports. Nanotubes grow on such chips; many of them start from one chip and reach another one thus creating a network of suspended ‘bridges’ between the

islands. The architecture and density of the network is set by the initial architecture of the deposited chips. This may already be regarded as a prototype for integrated circuits.²⁸

The diameters of nanotubes obtained by chemical deposition are determined by the size of the catalytic cluster or the nanopore in which the catalyst is ‘sitting’, whereas those of the nanotubes obtained in an arc discharge are determined by the pressure of the inert gas (helium). It has recently been shown²⁹ that the mean diameter of nanotubes formed in an arc discharge increases proportionally to the logarithm of pressure. This result may prove to be useful.

2. Architecture of nanocontacts

Nanocontacts are the trouble spot of nanotechnologies. Based on current experience, two approaches to the formation of nanocontact architecture seem possible: by different growth mechanisms of nanotubes and by handling nanotubes (this will be explained below).

The growth mechanism may be judged from the state of the nanotube ends (they are usually visible under an electron microscope). When catalyst species are strongly fixed on a support, the ends of the growing nanotubes are free of catalyst species, hollow and covered with hemispheres (fullerene caps). In such cases, tubes grow from their bases: through adsorption and decomposition of methane (or some other carbon source) on the surface of the metal catalyst, dissolution of carbon and diffusion of carbon atoms to the metal surface layer, oversaturation of the solution with carbon and deposition of carbon on the lower part of a tube. A tube grows from its bottom (base); carbon arriving from the catalyst builds the ground floor of the tube and ‘pushes’ it upwards. In this case, a strong nanocontact of the tube with the prepared support, where the required architecture of nanotube chips has been preset, is formed at once.

It is possible to update this technology by feeding the catalyst from the gas phase; in such a case, catalyst nanoclusters ‘mount’ the top of the tube and growth continues on them.

A brilliant version of this technology has been implemented recently.³⁰ Nanotubes were grown on a quartz surface at 800 °C in a stream of an Ar/H₂ mixture to which drops of a solution of ferrocene in xylene were injected at regular intervals. Pyrolysis of ferrocene was accompanied by the formation of iron clusters which were deposited on quartz at the very beginning of the process. Xylene decomposed on these nanocontacts and carbon tubes started to grow there. New clusters formed on the tops of the nanotubes from subsequent portions of ferrocene and xylene, and the tubes continued to grow on these clusters. This process gives rise to a colony of nanotubes. It resembles a multistorey building: there are catalyst clusters in the base and between the storeys, whereas the distance between the storeys determined by the intervals between the injection of ferrocene + xylene portions is occupied by nanotubes.

Figure 4 demonstrates the architecture of the resulting nanotubes. The image on the left, obtained using a scanning electron

Figure 4. An electron-microscopic image of colonies of nanotubes grown on iron clusters (a) and a schematic drawing of tubes with incorporated iron clusters (b).

microscope, shows a colony of vertical nanotubes. The horizontal parallel lines (bridges between the storeys) correspond to the iron clusters which are formed at the moments when the solution of ferrocene in xylene is injected. If the intervals between the injections are constant, the 'storeys' grow strictly uniformly and have equal heights. Furthermore, the height of a storey depends on the ferrocene:xylene ratio in the solution which feeds the growth of the nanotubes. This ratio also affects the tube growth rate, because in fact it is the catalyst:carbon ratio.

This technology is remarkable because in this case iron clusters are included in the growing tube so that the catalyst is captured inside the tube and is in a strong contact with the tube wall from the inside (this is sketched in Fig. 4*b*). The growing tube shapes the cluster in such a way that it becomes oblong; the cross-section of the cluster exactly matches the inner diameter of the tube (this has been proven by transmission electron microscopy³⁰). What is more, the nanotube reliably protects the trapped iron clusters from oxidation. The nanotubes obtained by this method have ferromagnetic properties, which allows one to handle them using magnetic fields and magnetic manipulators. The architecture of such an ensemble of nanotubes resembles that of a macroscopic crystal in which the lattice points are occupied by iron clusters included in nanotubes with a preset space periodicity.

Clearly, this technology offers ways to create nanocontacts at both ends of nanotubes; it is flexible and controllable and may be combined with other technologies. It is also obvious that this technology can be used as a method to fill nanotubes with other metals.

3. Nanowires in nanotubes

A nanotube is a one-dimensional nanocontainer that can be filled with various compounds: metal oxides (PbO₂, CoO, PbO, V₂O₅, Bi₂O₃, MoO₃), salts and acids (KI, AgNO₃, HAuCl₄, H₂PtCl₆, ZrCl₄, CsCl, UCl₄, ThCl₄, HNO₃, PdCl₂, *etc.*), elements (S, Se, Sb, Ge, B) and metal carbides (Mg, Ni, Mn, Nd, Mo, Ta, Co, Cu, *etc.*). Filling can occur both during the synthesis of nanotubes and after the isolation and purification of the preformed nanotubes. The latter way is virtually always more reliable, controllable and target-oriented. Filling can be performed from a gas or vapour phase, from solutions and melts. In nanotubes, as in nanoreactors, chemical synthesis can be carried out (see the review by Rakov²⁶).

Of considerable interest is the filling of nanotubes with metals in order to obtain metallic conductors, *i.e.*, nanowires coated with a carbon 'cloth'. In this case, the nanotube not only shapes a nanowire but also protects it from oxidation and deteriorating effects of other corrosive media. It is clear that such nanoobjects are of particular importance from the viewpoint of high technologies.

In early studies on the synthesis of nanotubes containing Cu, Ni, Fe, Ag, Au, Pd and Pt, nanotubes were filled with metal oxides or chlorides which were subsequently reduced with hydrogen into the corresponding metals.³¹ Nanowires of β -Sn were obtained by electrolysis of a LiCl–SnCl₂ melt that filled a nanotube.³² Electrolysis was also used to obtain 40–90 nm-long nanowires of a Sn/Pb alloy.³³

The nanowires formed are usually polycrystalline; however, single-crystal wires were obtained in certain cases. For example, reduction with hydrogen of Bi(NO₃)₃ introduced into a single-layer nanotube from a solution in nitric acid gave single crystals of Bi hundreds of nanometers long and with a diameter of about 1 nm in high yield.³⁴ Unlike a macrocrystal, the nanocrystal obtained in a nanotube was slightly skewed (the planes are inclined). It is of interest that the diameter of a Bi-nanowire is considerably smaller than the diameter of a nanotube; on average, there are five Bi atoms in the tube cross-section. Filling nanotubes (~ 10 nm diameter) with gaseous Ni(C₅H₅)₂ results in a Ni wire with a diameter of 4 nm and a length up to 500 nm.³⁵ It has not yet

been understood why the diameter of the wire formed is so small, especially as the nanowire and nanotube diameters often coincide.

The incorporation of C₆₀ fullerene molecules in nanotubes is an exotic event.³⁶ Such structures resemble 'pods' filled with 'peas', *i.e.*, C₆₀ molecules from the gas phase. They are clearly visible under an electron microscope. If filling is incomplete, the fullerene molecules are grouped in twos, threes, *etc.*; they readily move along the tube jumpwise (the jump length ranges from 1 to 10 nm). A jump occurs almost instantaneously (in fractions of a second); the interval between the jumps is 10–20 s. The jumps are induced by electrons emitted by the electron microscope used for observation.

If a 'fullerene-in-a-nanotube' system (C₆₀@NT) is externally doped with metallic potassium, it acquires metallic conductivity owing to the chemical transfer of electrons from potassium to the nanotube and then to C₆₀. As a result, each C₆₀ molecule acquires the 6– charge, and a compact chain of such molecules inside the nanotube constitutes a nanowire of an organic metal.³⁷ It is hard to predict the place of such wires in nanotechnologies, but one of its advantages is obvious: it is possible to control charges and their mobilities by the Coulomb fields of external ions (outside the nanotube).

Even more interesting are nanotubes filled with endofullerenes. For example, the La@C₈₀@NT and Gd@C₈₂@NT systems have already been obtained.³⁸ In these structures, metal ions carry positive charges, whereas the surfaces of the nanotubes are most likely negatively charged.[†] These are new one-dimensional crystals, the properties and technological 'capabilities' of which are far from being studied completely and are therefore not yet recognized.

A new type of nanowire has recently been obtained. This is a nanocable in which the internal conductor is an iron rod about 10 nm thick and about a micron long 'dressed' with a boron nitride tube with a diameter of about 50 nm.³⁹ The BN ceramic is an excellent electric insulator, which reliably protects the inserted iron rod from oxygen and other corrosive media. A remarkable feature of these nanocables is that there is a carbon layer between the BN shell and the iron rod; this layer keeps iron in its reduced state and ensures a strong bond between the metal and the ceramic shell. The 'mediation' of carbon is particularly important, considering that BN ceramics are very poorly wetted with iron and their direct contact is very unstable.

The BN nanocables were obtained in an induction graphite furnace from B₄N₃O₂H and an aqueous solution of Fe(NO₃)₃ through which a stream of N₂ was passed. Upon heating, B₄N₃O₂H decomposed to give the boron oxides B₂O₃ and B₂O₂. Furthermore, synthesis of CO occurred in the graphite furnace according to the reaction

The resulting boron oxides entered the reaction zone at 1700 °C and reacted with the gas mixture N₂ + CO + H₂, whereas the Fe(NO₃)₃ that was present decomposed to give α -Fe. These reactions resulted in BNFe nanotubes. An electron-microscopic image of one of them is shown in Fig. 5.

It was shown by electron energy loss spectroscopy (EELS) that the outer shell of a nanocable contains only B and N atoms; carbon appears nearer to the centre and its concentration in the B–N–C system is higher nearer the α -Fe nanowire. Such high-conductivity ferromagnetic nanowires that are well protected by ceramics may find a well-deserved application in future nanotechnologies. It should be noted that this technology makes it possible to obtain nanocables containing not only Fe nanowire but also other metals.

[†] It should be noted that negative charges in C₆₀@HT structures are concentrated inside the tube (on C₆₀^{6–}).

Figure 5. An electron-microscopic image of an iron nanowire (black band) inside a BN nanotube.

4. Nanotube as a field emitter

Perhaps the use of nanotubes as field emitters is their most widespread application. Field emission is emission of electrons from high-curvature surfaces (edges, blades, undulations) under applied voltage. The advantages of field emitters over thermal emission cathodes are well known: these are their small size, low energy consumption, high current density and a possibility of miniaturisation. No wonder that their small radius of curvature, high length/radius ratio, high conductivity and thermal stability make nanotubes a promising emitting material.

The first studies on emission from nanotubes were carried out by Chernozatonskii *et al.*⁴⁰ in 1995. Over the short time that has passed since then, working colour displays with diagonal axes of 10–20 cm, high luminosity (up to 800 cd cm⁻²) and long service life have been created. The working elements in such displays consist of nanotubes grown on porous silicon, mesoporous aluminosilicate or quartz using the technologies described above (in the section devoted to the architecture of nanotubes).⁴¹ Displays based on nanotubes will shortly become a market product; this will be the first breakthrough of nanotechnologies in the economy.

Using electron holography, the electric field of a nanotube was studied as a function of potential. This method is based on the interferometry of electrons that have passed through the electric field of a nanotube.[‡]

A scheme showing the instrumented set up is shown in Fig. 6. A nanotube was mounted on the holder in the electron microscope chamber using a conductive epoxy resin. A current-collecting gold

[‡] This brilliant technique is used to measure internal potentials, electrostatic and magnetostatic fields, contact potentials, *etc.*

Figure 6. A scheme for the measurement of the electric potential of a nanotube using electron interference.

plate was placed opposite the nanotube at a distance of 6 μm from it. A piezoelectric handling device was designed specially for mounting nanotubes.⁴² The nanotube and the plate formed an electric circuit to which a voltage V_b was applied. The current in the chain was recorded continuously.

In the centre of the microscope electron beam, a biprism was placed, which divided the beam into two parts that were later brought together on a display screen at the bottom. The electron field emission of the nanotube manifested itself at a bias voltage of $V_b = 70$ V; the current between the nanotube and the plate was 40 pA. At $V_b = 120$ V, the current was already considerable, *viz.*, 0.54 μA , and a holographic picture of the nanotube electric field appeared on the display screen (Fig. 7). The holographic picture shows distinct interference bands along the nanotube (especially in the lower, increased image).

Figure 7. A holographic image of the nanotube potential (a) and an enlarged image of the portion marked by the square (b).

The observed interference bands appear because the phase of the coherent electron beam which passes near the tube is changed in the electric field of the tube. Superposition of this beam with the other beam which was not exposed to the field of the nanotube results in interference. By analysing the phase shift as a function of the voltage V_b , it is possible to reconstruct the electric field maps around the nanotube (see Fig. 8). Based on these maps, one can find the electric field strength at the tube end (H).⁴² The results of this experiment are shown below.

V_b / B	120	90	70
$H / \text{B nm}^{-1}$	1.22	0.82	0.64

It is remarkable that almost the entire electric field is concentrated at the tube end, whereas no other possible sources contribute to the field emission of the nanotube. Given a constant potential V_b , the local electric field at the top of a tube is inversely

Figure 8. Images of the phase shifts (a) and phase gradients (b) of the electric potential at the end of a nanotube.

proportional to its radius and almost does not depend on the magnetic field. What is more, the holographic picture confirms that there is no potential drop along the tube even in a strong emission mode. Both of these circumstances, *viz.*, localisation of the electric field at the top of the tube and the absence of field gradient along the tube, make nanotubes a perfect material for field displays.

It should be noted that the advantages of the nanotechnological experiments involve not only the gathering of direct information about the properties and behaviour of nanoobjects but also acquiring experience in handling these objects and creating new, sometimes sophisticated, technologies for operating with such objects.

The emission properties of nanotubes can be tuned. For example, filling tubes with cesium decreases the work function by 2 eV; as a result, the emission current increases by an order of magnitude.⁴³

Recently, the thermal conductivity of carbon tubes was measured: it is $250 \text{ W m}^{-1} \text{ K}^{-1}$ at room temperature for one-layer tubes and about $3000 \text{ W m}^{-1} \text{ K}^{-1}$ for multilayer tubes. Since the dependence of thermal conductivity on temperature has the form $f(T^2)$, this means that 'two-dimensional' phonons are responsible for thermal conductivity; the free-pathlength of these phonons was estimated to be 500 nm.⁴⁴

The thermostimulated electromotive force (thermo-EMF) generated by a single multilayer nanotube linearly increases with temperature, with a constant gradient of $80 \mu\text{V K}^{-1}$; its sign is positive, *i.e.*, the thermo-EMF is created by 'holes'.⁴⁴

5. Nanotubes as molecular diodes

Electric conductivity is the key property of nanotubes as elements of nanoelectronics. It is measured by the four-probe method as

follows: four conductors [*e.g.*, consisting of tungsten obtained from $\text{W}(\text{CO})_6$ in a gas phase] are deposited on a nanotube lying on a support in such a way that the distances between the contacts are tens of nanometers. After that, the current–voltage characteristics of the nanotube are measured.

One-layer tubes with the indices (n,n) are metallic. Perfect tubes (without defects and admixture atoms) have ballistic conductivity: at low resistances of the metal–tube contacts, the resistance of the tube should approach half of the quantum limit of resistance h/e^2 (where h is the Planck constant and e is the electron charge), *i.e.*, reach 6500Ω . However, this limit could not be reached because of the high resistance of the contacts (several megaohms), which creates a Coulombic blockage. Of the metals tested, the best results were obtained for Ti: the Ti–tube nanocontacts have the lowest resistances.²⁸ At 2 K and nanotube length of $\geq 3 \mu\text{m}$, the resistance was about $12 \text{ k}\Omega$.

The resistance of such tubes is almost independent of temperature. Similarly, there is no explicit dependence on the bias voltage: when the blocking voltage changes from -100 to 100 V , the nanotube resistance changes only 2–4-fold and the tubes remain conductive. All of these are reliable indications of the 'metallic' behaviour of nanotubes.

Chiral nanotubes with indices (m,n) are semiconductors with the band gap $E \sim d^{-1}$, where d is the nanotube diameter. For nanotubes with diameters of 0.7 to 3 nm obtained by chemical deposition onto catalytic islands (see Sections III.1 and III.2), the band gap was from 1 to 0.25 eV, respectively. Dai *et al.*²⁸ thoroughly measured the electron transport properties of one-layer nanotubes obtained by this method. Their resistances at room temperature were 200–500 $\text{k}\Omega$ for tubes with $d > 2.0 \text{ nm}$; the resistances were higher (about megaohms) for tubes with smaller diameters ($d < 1.5 \text{ nm}$). Semiconductor tubes are hole-doped; their conductances decrease when a positive blocking voltage is applied. At 4 K, tubes with $d > 2.0 \text{ nm}$ become insulators in the range from ± 10 to $\pm 1000 \text{ mV}$. For tubes with smaller diameters, this range is broader.

A remarkable feature of all I – V -dependences for semiconductor tubes is that these characteristics are asymmetrical with respect to the bias voltage and its polarity: at a constant blocking voltage, the absolute current is higher at a positive bias than at a negative bias. The asymmetry increases abruptly as the blocking voltage increases, a feature that is known to characterise a semiconductor diode (rectifier).

Unambiguous evidence that a doped nanotube is a diode was obtained.⁴⁵ A one-layer nanotube contaminated with an admixture deposit on certain areas was provided with three Au electrodes (A, B and C, Fig. 9) in such a way that the tube segment between the electrodes B and C is clean, whereas the region between the electrodes A and B contains the impurity deposit (it is clearly visible near the electrode A). The entire device was arranged on a silicon substrate filled with an insulating SiO_2 layer 100 nm thick in such a way that the substrate worked as a capacitive blocking electrode. Resistances were measured in the range from 0.5 $\text{M}\Omega$ (for metallic tubes) to 10 $\text{M}\Omega$ (for semiconductor tubes). The contact resistances measured using the four-probe method were $\sim 0.5 \text{ M}\Omega$.

Figure 9b shows the I – V -characteristics of the electronic circuit shown in Fig. 9a. The inset shows the I – V -dependence for the 'non-contaminated' region of the tube (BC): it is symmetrical with respect to the bias potential, *i.e.*, the conductivity does not depend on the sign of the bias voltage, which is a feature of a homogeneous semiconductor with distributed *p*- and *n*-carriers. The I – V -dependence for the 'contaminated' region AB is strongly asymmetric and depends on the sign of the bias voltage, which is typical of diodes. Thus, the AB region of a nanotube is a molecular diode where the admixture acts as an *n*-type dopant and where an electron–hole junction with a junction potential appears. If the blocking voltage is positive, the current passing through the nanotube decreases. This suggests that holes dominate in the charge transport through the diode.

Figure 9. Image of a one-layer nanotube with attached electrodes A, B, C in an atomic force microscope (a) and dependence of current in the tube on the bias potential (b).

What is more, it turned out that current depends on the blocking voltage in a stepwise manner, *i.e.*, there are discrete zones in a doped nanotube. The following dopant types are possible: admixtures (like amorphous carbon or catalyst clusters), topologic defects (five- or seven-membered rings in the structure of a tube), incorporated atoms (N, B, *etc.*), contacts between tubes with different diameters, mechanical strain of a pipe where it is bent, *etc.*

Of great interest is the controlled doping of nanotubes using the tip of a tunnelling microscope or an atomic pump. It allows one to design flexible hetero-junctions (diodes, transistors) with controlled band structures. Diodes with a slope of $\partial I / \partial V \approx 200 \text{ nA V}^{-1}$ have already been obtained. The slope normalised with respect to the tube diameter (*i.e.*, to the channel width) is $\sim 0.1 \text{ mS } \mu\text{m}^{-1}$, which is comparable with the slope for a silicon diode.²⁸ Certainly, we do not speak of immediate replacement of the comprehensively developed silicon electronics by nanoelectronics; however, one can speak of a new direction, *viz.*, nanoelectronics (or molecular electronics) with its new advantages. The results of the studies described above allow ways to bring these potential capabilities into reality to be explored.

6. Superconductivity of nanotubes and cryoelectronics

Superconductivity of a bunch of one-layer nanotubes arranged in parallel (about 350 pipes with 1.4 nm diameter each) connected to an electric circuit by ordinary (non-superconducting) $\text{Al}_2\text{O}_3/\text{Pt}/\text{Au}$ contacts with layer thicknesses of 5, 3 and 200 nm, respectively, was first discovered by Kociak *et al.*⁴⁶ The resistance of such a bunch at 300 K was $\sim 10 \text{ k}\Omega$ and increased with a decrease in temperature from 300 K to 1 K; after that, an abrupt decrease in resistance occurred (by two orders of magnitude) to a limiting value of 74Ω at 100 mK. For an electric chain with normal (non-superconducting) contacts, the minimum resistance should not be smaller than half the quantum resistance limit h/e^2 ; it follows that about 25% of the total number of the tubes (350 tubes) participate in superconductivity. (As expected, a magnetic field of about 1 T destroys superconductivity.)

Taking into consideration the miniature size of electronic nanodevices and the moderate cost of cooling such devices, it can be considered that the superconductivity of nanotubes, nanocontacts and nanowires, even if it appears only at very low temperatures, can be introduced in practical nanoelectronics.

This is one of the advantages of cryoelectronics. Yet another advantage of cryoelectronics is the infinitely low noise level.

The discovered superconductivity is similar to that observed in graphite intercalated with alkali metals or in alkaline salts of fullerenes. However, the superconductivity temperature in nanotubes is much lower, which may be attributed to lower-frequency phonons in nanotubes (it is assumed that these phonons correspond to deformation oscillations of nanotubes).⁴⁷

Later,⁴⁸ the superconductivity of a single one-layer tube bridging two Au–Ti contacts was discovered. Figure 10 shows how the resistance of such a tube depends on temperature and how superconductivity is destroyed by magnetic fields.

Figure 10. Arrangement of a single nanotube between Ti- and Au-contacts (a) and dependence of resistance on temperature in different magnetic fields at $I = 1 \text{ mA}$ (b).

Magnetic field strength /G: (1) 0, (2) 500, (3) 1000, (4) 2000, (5) 3000, (6) 5000, (7) 7000, (8) 10 000, (9) 12 000, (10) 15 000, (11) 20 000.

IV. Nanowires

Below, we consider ‘free’ (not enclosed in a carbon nanotube), conducting or light-emitting (metallic or semiconducting) nanowires.

1. Metallic wire

The most developed technique is drawing the wire from nanorods fastened between the cantilever and the tip of a tunnelling microscope.

Figure 11 a displays the scheme of a device for drawing nanowires. Gold nanorods (cylinders 0.125 μm in diameter and 2 μm long) were fastened between the gold tip of a tunnel scanning microscope and the tip of an auxiliary microscope. This arrangement enables the simultaneous detection of the electric conductivity and deformation force as a function of the stretch (length) of the nanowire.⁴⁹ The dependence of the conductivity and deformation force on the displacement (wire stretching) is shown in Figs 11 b,c, respectively.

It is interesting to note that electric conductivity and force change in a jump-wise manner: with an increase in length, the former decreases to a limiting value which corresponds to the quantum limit of conductivity.[§] The jump-wise behaviour of force means that the wire cross-section changes in a discontinuous manner; jumps occur when atoms rearrange and ‘jump into’ the final monoatomic chain. The molecular dynamics simulation of an atomic cluster during its stretching (Fig. 11 d) perfectly repro-

§ The quantum limit of conductivity is the conductivity of one (monoatomic) tunnelling channel.

Figure 11. A scheme of a device for drawing nanowires (a) and dependence of electric conductivity (b) and deformation force (c) on displacement. The lower drawing (d) shows the results of a molecular dynamics simulation of force as a function of displacement and a scheme of the arrangement of atoms in a nanowire.

duces the experimental dependences. Quantum-chemical calculations within the framework of the density functional theory confirmed the stability of monoatomic chains.[¶] It follows from dynamic and quantum-chemical calculations that the degradation occurs in a five-atom linear chain⁵⁰ and requires a force of 1.5 ± 0.3 nN. It follows that the energy of an atom–atom bond in a monoatomic chain is twice as high as the atomic bond energy in the bulk metal. This is a reasonable result as a metal features multi-centred bonds and each of such bonds is weaker than a localised and isolated bond.

2. Semiconducting wires and nanolasers

Semiconducting nanowires are usually grown on clusters of metal catalysts. For example, GaP wires with controlled diameters (10,

20 and 30 nm) and > 10 μm long were obtained on gold clusters.⁵¹ Both types of clusters (GaP and Au) were obtained by laser ablation; a direct relationship between the Au cluster size and the diameter of GaP wires was observed, *i.e.*, the wire diameter ‘tuned’ to fit the size of the catalytic cluster.⁵²

Nanowires of GaN,⁵³ SiC,⁵⁴ Ga₂O₃,⁵⁵ *etc.* have been obtained to date. A simple technology has been developed to synthesise Ga₂O₃ by heating GaAs with sputter-deposited Au at 1240 °C in a stream of dry O₂; nanowires or nanostrips were obtained, depending on the technology used.⁵⁶ Nanowires are single-crystalline; they grow in a direction perpendicular to the (102) plane and display good photoluminescence characteristics. Wu *et al.*⁵⁷ synthesised GeO₂ nanowires with 50–120 nm diameters and hundreds of micrometres long. They luminesce upon photoexcitation; the quantum yield of their radiation is an order of magnitude higher than that for GeO₂ powders. A few other types of nanoobjects have recently been obtained, *viz.*, SnO₂ nanowires and nanotubes,⁵⁸ silicon nanowire ‘wrapped’ in a monolayer of gold atoms,⁵⁹ nanowires with the composition Mo_{1-x}W_xS₂ ($x < 0.1$) (one- and multilayer) with a bamboo trunk-type tubular architecture.⁶⁰

The high yield of optical radiation in semiconductor nanowires stimulated the search for strong nanoemitters that would work as coherent light sources (nanolasers and optical nanowaveguides). The first success was achieved with ZnO nanowires: excitation of densely packed nanowires resulted in laser emission (from the entire set of wires).⁶¹ A more detailed analysis of laser emission from individual nanowires was made by Johnson *et al.*⁶² ZnO nanowires were grown on the sapphire (110) surface. This plane is well compatible with the ZnO (0001) plane. ZnO nanowires grown vertically on sapphire were ultrasonically removed from the support and deposited on quartz from an ethanolic solution; their packing density on a horizontal surface was about 300 wires per 1 mm².

The wire diameters could be varied from 40 to 150 nm, and their lengths, from 4 to 10 μm . Each wire was detected separately. The laser emission was monitored using a near-field scanning optical microscope combined with fiberglass detection.

The majority of nanowires demonstrated intense light emission localised at their ends; however, they did not show the main sign of laser generation: the generation threshold was not reached even at very high excitation power (above 1 MW cm⁻²). However, certain nanowires behaved as ‘honest’ nanolasers: they gave high quantum yields and generation thresholds even at low pumping strength (Fig. 12).

To explain this laser-related ‘personality’ of nanowires, Johnson *et al.*⁶² devised a very plausible explanation: when the wires are ultrasonically detached from the sapphire, their end surfaces are formed in an arbitrary manner, hence light reflecting properties are poor (strong diffusion, phase detuning). This means that the Q value of such ‘maimed’ nanowires is low. Only part of the wires have well-reflecting ends (*e.g.*, if a nanowire is ‘torn out’ with

Figure 12. Generation intensity of ZnO nanolasers as a function of pumping energy.

¶ In this context, one has to remember G A Razuvaev who, as early as in the 1970s–80s, synthesised polyatomic metal chains using organometallic chemistry methods.

a nanopiece of sapphire) and hence behave as optical resonators. This is an important result that clearly shows the weaknesses in the technology and suggests ways to overcome them in order to make nanolasers with a low lasing threshold.

3. Ferromagnetic wires

It is considered that ferromagnetic nanowires may become the main elements of quantum magnetic disks, which are the subject of intense development by researchers in the field of nanochemistry. Discrete one-domain elements with high length/diameter ratios, arranged like columns and incorporated in a non-magnetic support, may serve as building blocks for a big information and operation system. Each such block carries one bit of information, and their density reaches hundreds of gigabytes per square centimetre.⁶³

The first steps in this direction have already been made:⁶⁴ cobalt was electrochemically deposited on anodised aluminium with high pore density (pore diameter 60 nm, density 10^{10} – 10^{11} cm⁻²); it filled all the pores to form a regular hexagonal surface 'lattice' of nanowires (columns ~ 60 nm in diameter and 1.6 µm high). This system is essentially a prototype of a quantum magnetic disk. Studies of this system by magnetic force spectroscopy confirmed that each nanowire incorporated in a pore is a one-domain magnet with strong magnetisation anisotropy (Fig. 13). The easy magnetisation axis is oriented along the nanowire. In this direction, the Co wire is a soft ferromagnet, while in the transverse direction, it is a hard ferromagnet as the hysteresis loops suggest.

Figure 13. Hysteresis loops of magnetization of a Co nanowire parallel to the long axis (1) and perpendicular to it (2).

It was shown by magnetic force spectroscopy that the topography of the ferromagnetic columns matches exactly the topography of pores in the starting anodised aluminium, *i.e.*, one nanowire is trapped in each pore. The number of south magnetic poles exactly equals the number of north poles, and all the poles are arranged in a strictly regular manner: each south domain is surrounded by north domains, and vice versa. Magnetic field (1 T) causes complete magnetic orientation of all domains. Such a device is almost ready for recording and reading information (*e.g.*, using the tip of a magnetic force microscope).

It should be noted that the porous structure and hence the topology of ferromagnetic domains are sensitive to electrochemical anodisation and deposition modes, *i.e.*, the quality of nanomagnetic materials can be controlled technologically. There is no doubt that this area of nanochemistry has a great future.

V. Nanomechanics

Handling nanoobjects requires that their mechanical properties are known. The interest in nanomechanics stems from the possibility of creating nanopistons, nanosyringes, nanopumps

(*e.g.*, for cell biology), variable capacitance nanocapacitors, nanotweezers and other devices.

1. Internal friction in nanotubes

The first device in which the inner part of a multilayer carbon nanotube moved along an external part (as a piston in a cylinder) was created in 2000.⁶⁵ The authors opened the end of a multilayer nanotube and attached a nanomanipulator to the inner tubes. After that, they partially pulled the inner part out while observing this action under an electron microscope.

The first significant result of this work was the creation of a new nanomanipulator. Another result is the observation that, after the pulled-out part of the tube was released by the manipulator, it was instantly retracted back by the restoring force of the van der Waals interaction. It follows from this observation that nanotubes enclosed in each other move relative to each other with almost no friction and thus make an ideal wear-resistant molecular plain bearing.

Direct measurements of the force of cohesion between two coaxial nanotubes were carried out using an atomic force microscope.⁶⁶ An individual multilayer nanotube was fixed between the rigid cantilever of a spectrometer and the tip of the upper cantilever of an atomic force microscope (the latter served to measure the length and force). The distance between the cantilevers after stretching the nanotube and the stretching force were recorded.

The experiment was designed to consist of two stages. It was anticipated that disruption of the outer tubes would occur in the first stage due to stretching and that intact inner tubes would slide from under this 'wreckage' upon subsequent stretching.

However, of the 16 experiments that have been carried out, only the first stage, *i.e.*, total destruction of the outer tubes, was observed in 14 cases; it was only in two cases that 'sliding' of inner tubes from outer ones was observed after disruption of the outer tubes. The entire experiment (the measurement of the force F as a function of elongation L) was recorded on video. Analysis of the $F(L)$ relationship gave the cohesion force of sliding nanotubes.⁶⁶

The cohesion force per unit length of the contact was 0.45 and 0.67 N m⁻¹ for the two 'successful' experiments (the cohesion force expressed in N m⁻¹ corresponds to the cohesion energy expressed in J m⁻²). It is of note that the interplanar adhesion force in pure graphite is as small as 0.11–0.12 N m⁻¹. However, it should be taken into account that the values of 0.45 and 0.67 N m⁻¹ are overestimated, as they include not only surface cohesion but also cohesion due to boundary effects, *i.e.*, hindrance of the movement of the inner tube by the broken edges of the outer tube.

2. A nanotube as a high-frequency mechanical oscillator

The negligibly small friction between moving nanotubes opens up a route to nanomechanical oscillators. The mechanical scheme of such an oscillator is shown in Fig. 14.⁶⁷

A block of inner nanotubes that has been drawn out of outer tubes is then drawn back in due to the potential energy $U(x)$ of the van der Waals interaction between the atoms of two sliding tubes,

Figure 14. A scheme of movement of inner and outer nanotubes (see the text for comments relating to A–C).

viz., a cylinder and a piston (position A, Fig. 14). When the inner tubes return, the potential energy decreases, whereas the kinetic energy increases: in the equilibrium position B, the former equals zero, whereas the latter has a maximum value. Subsequently, the inner tube is drawn out on the other side because of momentum, until the kinetic energy decreases to zero. At this point (position C), the potential energy acquires a maximum value and draws the tube back in. In fact, this is a typical nanopendulum the oscillation frequency of which can be calculated if the van der Waals restoring force is known. The latter is a function of the displacement of the piston relative to the cylinder.

The van der Waals energy $U(x)$ of the cylinder–piston system was evaluated quantitatively using the Lennard–Jones potential and the structural parameters of the nanotubes (in particular, the gap between the tubes was considered to be 0.34 nm). The oscillation frequency was determined by solving the Newton equation

$$Mx(t) = F_{\text{vdW}} + F_{\text{fr}},$$

where M is the piston mass; $x(t)$ is the acceleration (the second derivative of the piston coordinate with respect to time); F_{vdW} is the force of the van der Waals cohesion between the piston and the cylinder, which equals $F_{\text{vdW}} = -dU(x)/dx$; F_{fr} is the friction force which was considered negligibly small, *i.e.*, $F_{\text{fr}} \ll F_{\text{vdW}}$.

Numerical estimates of the oscillation frequency for conditions similar to those used in the experiment by Yu *et al.*⁶⁶ gave values of $\sim 10^9$ Hz.

However, it is clear that an external impact is required to start such a gigahertz oscillator (mechanical pendulum). An alternating electric field can serve as the launching system; however, this requires that the piston be electrically charged (this can be achieved, *e.g.*, by chemical doping of the nanotubes). In any case, this appears to be a reasonable and promising direction of nanomechanics.

3. A nanopendulum as an electronic shuttle

There is a device known in classical physics, which consists of two big capacitor plates and a metal ball hung between the plates. By applying a DC voltage of several hundred volts to the plates, it is possible to make the ball rock between the plates and transfer charges. The charge carried by the ball in each oscillation is about 10^{10} electrons; the current in the circuit is 1–10 μA at an oscillation frequency of about 10 Hz.

In a nanoversion, such a device might work at frequencies of about 100 MHz and carry single electrons. It is quite obvious and realistic that such a device can serve as an element of a quantum computer or a current interrupter in nanocircuits. The first example of a nanopendulum (electronic shuttle) has been reported by Erbe *et al.*⁶⁸

The central part of the device (a) (it may be called a quantum bell) and its electrical scheme (b) are shown in Fig. 15. Its main part is the turning anchor C, which is (clamped and grounded) fastened in the upper part of a silicon plate. A metal island insulated from the rest of the turning anchor is deposited on its end. The control electrodes G_1 and G_2 carry a voltage (about 3 V) which controls the movement of the anchor-pendulum. The element S supplies electrons, whereas the element D is an electron receiver and plays the role of a FET drain. All the elements are deposited by nanolithography onto a silicon substrate.

The pendulum is brought into motion by an alternating voltage on the electrodes G_1 and G_2 with a frequency f . While moving, the metal island at the pendulum end regularly touches the S and D elements (the space between an element and an island is about 300 nm). The tunnelling of electrons from the element S to the island, and from the island to the element D, occurs during the short moments of contact. The electric capacitance of the contact under static conditions is 84 aF (attoFarads), which corresponds to ± 527 electrons at a voltage of ± 1 V.

At room temperature, the direct current between the elements S and D is about 20 nA; however, it increases or decreases

Figure 15. A scheme of a the nanopendulum (a, b) and the frequency dependence of current transferred by the pendulum at 300 K (c) (see text).

abruptly at certain resonance frequencies (see Fig. 15 c). Resonance appears at those instants when the frequency of the control current at the electrodes G_1 and G_2 coincides with the intrinsic mechanical frequency of the pendulum. One can see that the range 40–120 MHz contains several resonances of this kind, *i.e.*, there are several intrinsic frequencies of the pendulum, corresponding to different modes of high-frequency mechanical movement (bending, torsion, oscillation). The anti-resonances (current dips at certain frequencies) appear when the pendulum stops due to non-coincidence between the control frequency and the intrinsic frequency. In total, this mode may be called the ‘irregular movement’ of a pendulum.

However, as the temperature is decreased, the irregular mechanical modes start to ‘freeze out’, and only one intrinsic frequency of 120 MHz remains at 4.2 K; the current at this frequency corresponds to the transfer of 0.11 ± 0.001 electrons per pendulum oscillation. This is a pure mode in which the pendulum works as a discrete electron shuttle, transferring one electron on each ninth oscillation from S to D.

VI. Technologies for handling nanoobjects

Nanotechnology comprises two main constituents: (1) creating nanoobjects for nanodevices; (2) operations with these objects and mechanisms for handling them. And although studies along both directions are being carried out astonishingly quickly (similar development rates in the history of science have only been observed in relation to the discovery of superconducting ceramics and ‘cold thermonuclear fusion’), the second constituent still remains a weak, limiting point.

In the previous sections, we have already discussed some operating devices and nanomanipulators. Presently, the employment of the scanning tunnelling microscope (STM) and atomic force microscope (AFM) seem the most promising technologies. As Rakov has aptly noted in his paper,²⁶ ‘after the invention of STM and AFM molecular nanotechnology is no longer only a scientific concept’; it may be added that it has moved to the stage of acquiring practical experience.

1. Study of nanotubes and nanorods lying on a surface

The tip of an AFM reveals that nanotubes lying on a surface possess folds, bends, loops and even foldovers. The latter are changes in the lower tube occurring due to the compression force from the upper tube: it deforms markedly (by about 30%), its cross-section becomes elliptic, and the crossing point of the tubes is displaced downwards. By measuring this displacement and using the known Young modulus (about 1.5 TPa), one can evaluate the compression force and the energy of ‘adhesion’ of the pipe to the surface. For a multilayer nanotube with a diameter of 100 Å that lies on the surface of passivated silicon, the binding energy to the surface is 0.08 eV nm⁻¹ (per unit length of the tube). The compression force at the point of contact of two crossing tubes is about 35 nN; this corresponds to a pressure of about 10 GPa.⁶⁹ The compression of a one-layer tube with a diameter of 1.3 nm by 30% requires a force of ~10 nN.

The interaction between a nanotube and a surface determines both the normal force and the force of horizontal displacement (pinning), which is responsible for the friction of a tube moving along a support. The pinning force for a nanotube (10–30 nN) is comparable to the force with which the AFM tip affects an object. This possibility of moving nanotubes along the surface by means of an AFM tip has been implemented brilliantly.⁶⁹ It is possible to manipulate nanotubes in many ways: they can be moved, bent, twisted, oriented, turned around the normal line relative to the surface and shaped (in particular, Hertel *et al.*⁶⁹ shaped nanotubes as the contour of the Greek letter θ). Even an attempt to dissect a nanotube with an AFM tip succeeded, though after prolonged ‘dragging’ of the tube along the surface.

The mastering of the technology for manipulating nanotubes by means of an atomic force microscope is an important breakthrough in nanotechnology, as it removes barriers (including psychological ones) to the design of systems and ensembles from nanotubes with subsequent ‘welding’ of the ends with an electron or laser beam. An atomic force microscope was also used to move (rotate and displace) gold nanorods (10 nm in diameter, 70 nm long) on a SiO₂ surface;⁷⁰ it was shown that the ease of manipulation depends on the point of application of the force on a nanorod.

An interesting and seemingly promising technology for manipulating nanotubes has been proposed by Kim and Lieber.⁷¹ They ‘equipped’ a scanning probe microscope with nanotweezers, which are made of two gold leaflets with nanotubes and an insulating glass spacer. By applying a controlled electric field to the plates, it is possible to manipulate the nanotubes and grip nanoobjects with them. By varying the diameters of the nanotubes, it is possible to adapt the nanotweezers for gripping nanoobjects of various sizes.

2. Magnetic field as a manipulator

The spatial orientation and lining up of extended nanoparticles, as well as assembling them into ensembles can be performed by a magnetic field. For example, nanotubes are oriented in a magnetic field in such a way that their long axes are directed along the magnetic field (Fig. 16). The orientational probability (the fraction of nanotubes directed along the field) increases with an increase in the magnetic field.

Figure 16. Dependence of the degree of nanotube orientation on the magnetic field strength (H).

(a) 0, (b) 5, (c) 10, (d) 16, (e) 20, (f) 30, (g) 40, (h) 60, (i) 80 kG.

For multilayer nanotubes (the number of layers is 23 ± 7 , the inner diameter is 2.8 nm, the outer diameter is 17.9 nm, the length is 1.5 μ m), the anisotropy of magnetic susceptibility measured from the dependence of orientation on the field (see Fig. 16) is $\chi_{\parallel} - \chi_{\perp} = (9 \pm 5) \times 10^{-6}$ cm³ K per mole of carbon atoms contained in a nanotube.⁷²

The anisotropy evaluated theoretically (under the assumption that the atomic magnetic susceptibility is the same as that in graphite) is 124×10^{-6} cm³ K mol⁻¹, which is much higher than that measured experimentally. This discrepancy is convincing proof that there are circular diamagnetic currents induced by the external magnetic field along the axis of the nanotube.

A remarkable (and unexpected) result is the dependence of the susceptibility anisotropy on temperature: at 231 and 314 K, it is 4×10^{-6} and 45×10^{-6} cm³ K mol⁻¹, respectively.⁷³ This dependence cannot be ascribed to kinetic effects in orientation mobility: the arrangement of nanoparticles in a magnetic field was always performed under the same conditions, *viz.*, in a CCl₄ solution, at prolonged exposure to the field and with the sub-

sequent fixation of the resulting orientation distribution by removal of the solvent. The origin of this effect remains unclear. It is possibly due to the internal coaxial rotation of tubes relative to each other. The high-frequency rotation of tubes (see the section on nanomechanics) may be the source of extra current and contributes to the anisotropy of magnetic susceptibility.

3. Atomic-molecular pump

A project has been proposed (and there are grounds to consider it highly realistic) involving a laser-controlled atomic-molecular pump in which a nanotube is used as a container for transporting atoms, ions or molecules (e.g., Li^+ or C_{60}^{6-}); these electrons will 'carry' atoms and ions along the tube. Usual direct excitation is not suitable for these purposes as a nanotube is a molecule with a centrally symmetric potential. In these molecules, the number of hot electrons that move in opposite directions (to the left and to the right) along the tube is the same, i.e., there is no electronic current. Asymmetry in the distribution of 'left' and 'right' electrons can be created by quantum interference of one- and two-photon excitation by coherent light at frequencies of $2\omega_0$ and ω_0 . Under such coherent two-frequency excitation, the electronic current appears in the tube, the direction of which is defined by the phase offset between the two laser sources and can be phase-controlled. Such laser-stimulated electronic current was called 'electronic wind' (Fig. 17).

Figure 17. A scheme of a laser-controlled atomic-molecular pump (see text).

If the tube contains neutral (uncharged) atoms or molecules, the elastic scattering of hot electrons on these species will move the latter in the direction of the electronic wind. However, if the tube is filled with partially charged atoms or molecules, then the elastic scattering of hot electrons will create an electrostatic field the potential of which is directed against the electronic wind (see Fig. 17). This occurs because the number of electrons moving along the electronic wind (from the left to the right) is larger than that of electrons moving in the opposite direction. Hence, the number of electrons reflected to the left will be greater than the number of electrons reflected to the right. Thus, the electric charges $\pm\Delta Q$ created by reflection generate a field in which atoms move against the electronic wind.

Theoretical estimates of the operation of such a pump are very optimistic. In fact, for lithium with an effective charge of +0.6, the motive force F_d is $-0.8 \mu\text{eV}$; for a neutral Li atom carried by the electronic wind, the mean rate F_w is $25 \text{ nm } \mu\text{s}^{-1}$ (see Ref. 74).

An atomic-molecular pump can be easily controlled by light through phase ratios and intensities. There is no doubt that such a pump will be implemented in the near future. Following that, new breakthroughs in cluster chemistry and nanoelectronics should be expected.

4. Magnetic-resonance atomic-force spectroscopy as a new nanotechnology

The magnetic-resonance atomic-force spectroscopy combines the principles of atomic force microscopy and magnetic resonance. The areas of its application are obvious even now: these include the visualisation of magnetic nanostructures on the atomic scale, measurement of the density of electron magnetic moments and magnetic relaxation in nanostructures, use in spintronics devices (see Section II.4) and in reader elements of quantum computers, etc.

The typical elements of a magnetic-resonance atomic-force spectrometer are shown in Fig. 18. A micron-size ferromagnetic tip (made of an SmCo_5 or Pr-Fe-B alloy) is fastened at the end of an atomic-force cantilever. The sample to be studied is placed under the tip in a non-uniform field B_z with a vertical gradient dB_z/dz . The external field B_z and the magnetic field of the ferromagnetic tip create concentric surfaces with equal magnetic field strengths (isomagnetic surfaces) in the sample.[†] A microwave coil is placed aside of the sample; the purpose of the coil is to irradiate the sample at a frequency ω corresponding to the electron paramagnetic resonance.

Figure 18. A scheme of a magnetic-resonance atomic-force spectrometer.

Because the magnetic field in the sample is non-uniform, only a small fraction of the spins (only those located on the isomagnetic surface with a field strength B_z) respond to the microwave frequency ω :

$$\omega = \gamma B_z,$$

where γ is the gyromagnetic ratio for the electron spin. On two neighbouring isomagnetic surfaces separated by a distance Δz , the resonance conditions have the form:

$$\omega_1 = \gamma (B_z)_1,$$

$$\omega_2 = \gamma (B_z)_2.$$

Then, the difference between the resonance frequencies $\Delta\omega = \omega_1 - \omega_2$ is expressed through the field gradient:

$$\Delta\omega = \gamma [(B_z)_1 - (B_z)_2] = \frac{dB_z}{dz} \Delta z.$$

If the resonance bandwidth for electron spins in the sample is $\Delta\omega$, then, at a given field gradient, all the electron spins in the Δz layer undergo microwave resonance.

In a few experiments using magnetic-resonance atomic-force spectroscopy, field gradients (dB_z/dz) of $300-2200 \text{ T m}^{-1}$ were used (see Refs 75 and 76); the largest gradient value was

[†]Note that isomagnetic surfaces are not necessarily spherical (more exactly, hemispherical). The surface shape is defined by the shape of the nanotip and the profile of its magnetic field. A ferromagnetic nanocrystal of any shape can serve as a nanotip.

250 000 T m⁻¹ (see Ref. 77). Given a resonance band width of $\Delta\omega = 1$ Hz (this band corresponds to an ESR line width of 1 Hz) and a field gradient of 2000 T m⁻¹ (i.e., 2×10^{-2} Hz nm⁻¹), we obtain $\Delta z = 50$ nm. This means that microwave irradiation with the band $\Delta\omega = 1$ Hz can affect the spins of the electrons located in a layer 50 nm thick. At the record gradient of 250 000 T m⁻¹ (this is 25 Hz nm⁻¹), the layer thickness is 0.4 nm. It is clear that the stronger the gradient of a non-uniform magnetic field the thinner the layer that is probed magnetically.

Unlike the electron spin resonance technology which detects and measures the microwave power absorbed by an electron spin system, magnetic-resonance atomic-force spectroscopy detects and measures the magnetic force on the cantilever. In this case, microwave irradiation results in reorientation of electron spins (transitions between Zeeman levels occur) and a change in the spin magnetisation of the probed layer in the sample being studied. As a result, the magnetic force on the cantilever changes.

As an elastic system, a cantilever has its own frequency of mechanical oscillations f (about 1–10 kHz, depending on its shape and mass) and elastic constant k (about 10^{-2} N m⁻¹). The oscillation frequency of the cantilever is maintained constant by a piezoelectric element which controls the cantilever movement. The electric field at the control piezoelectric element is created by a fibre-optic interferometer that monitors the position of the cantilever and generates a control signal, which maintains the cantilever's own frequency.

When an external gradient magnetic field B_z is applied, the spin system is polarised (the spins are oriented) and the magnetisation acquires a steady-state value. The magnitude of this magnetisation is determined by two factors: first, the external constant field B_z , and second, the magnetic field of the tip. The magnetic field of the cantilever with a ferromagnetic tip, which oscillates along the coordinate z , varies as a function of the tip's field; simultaneously, the sample layer with thickness Δz also undergoes height-oscillation along this coordinate.

At the instant when the cantilever is at its amplitude maximum, the microwave field is turned on (phase synchronisation). The spin system and spin magnetisation now change for two reasons: first, due to the microwave field that inverts the spins, and second, due to the movement of the cantilever, which changes the positions of the resonance layers in such a way that the spins are either affected by the resonance microwave field or come out of resonance.

In the new steady state (in the presence of a microwave field) a new value of magnetisation is established and the oscillating magnetic force F between the cantilever and the sample changes; as a result, the elastic constant of the cantilever changes and its new own frequency is established. The change in the elastic constant Δk is defined by the relationship

$$\Delta k = \frac{F}{\Delta a},$$

where Δa is the cantilever's oscillation amplitude (normally about 20 nm) and

$$\frac{\Delta f}{f} = 0.5 \frac{\Delta k}{k}.$$

This allows one to determine the oscillation part of the magnetic force F , which is a function of the number of spins being detected, the amplitude of the microwave excitation and the relaxation time of spin magnetisation. The sensitivity of this technology is as high as a hundred electron spins in a nanometre layer.⁷⁷

Thus, a magnetic-resonance atomic-force spectrometer is a superdynamic system that analyses the behaviour of two dynamic interacting subsystems: (i) a spin subsystem in a microwave field and in an oscillating field of a cantilever and (ii) a mechanical oscillating subsystem of the cantilever, which modulates the spin subsystem.

Of course, this new technology is still in its infancy; it operates under high vacuum conditions and at cryogenic temperatures and is still 'aristocratic'. However, its potential for studying the 'nanoworld' is huge.

* * *

Being the chemistry of nanoobjects, nanochemistry is inseparable from nanotechnologies as a combination of methods for handling nanoobjects. This field of chemistry has tempting prospects; some of these are already being implemented, while others are on the 'waiting list'. And, though making predictions is the same as writing memoirs for a person who has just been born and then making that person live according to those memoirs, it may be stated with certainty that nanochemistry and nanotechnologies will some day become as important as life chemistry.

Abstract. Modern concepts of mass transport in solids are considered. Essential information on the structure of organic and inorganic ion-exchange materials and on defect formation processes is presented. The key methods of investigations of ion transfer are described. The results of studies on the transfer processes in membrane systems induced by various driving forces including the concentration, electric potential and electrochemical potential gradients are generalised. The bibliography includes 530 references.

I. Introduction

Mass transport in solids and across their surfaces is of importance for separation and purification of liquids (including water treatment),^{1–5} for fuel cell operation,⁶ catalytic reactions,⁴ as well as for numerous solid-phase,^{7–9} sorption^{4, 10} and many other processes. Therefore, the problem of description of the kinetics of ion and molecular transfer has attracted the attention of researchers. However, no general approach to the solution of this problem has been proposed as yet notwithstanding its obvious importance and topicality. For each particular case there are specific relations, methods and terminology. As a consequence, researchers who study the mass transport problem in a certain field often have almost no information on the studies carried out by their colleagues in allied sciences. Narrow specialisation is also determined by the extreme complexity of phenomena accompanying the ion and molecular transport, *e.g.*, sorption and desorption of substances, defect formation in the interior and on the surface of ion-exchange materials (ion exchangers) and occurrence of chemical reactions. Mass transport can also be affected by the dimension of the system under study and by the possibility for transfer to follow alternative routes.^{11, 12} Therefore, often the kinetic laws that are successfully used for description of ion transport in a

particular system can appear to be inapplicable to its close analogues. Nevertheless, the existence of some general regularities of the transfer processes occurring in solid systems of various nature seems not to be improbable. This requires the development of general approaches to the description of the chemical kinetics of ion transfer. Solving this problem has been the focus of considerable research involving a wide use of modern experimental equipment, theoretical concepts and various methods of numerical analysis.

The main goal of this review is to generalise approaches to the description of transfer processes in ion-exchange and membrane materials of various nature and to outline the main methods of investigations of ion transfer in such systems. In presenting the material the authors of this review tried to avoid the use of complicated mathematics. The emphasis is placed on consideration of relatively simple approaches and relations, on interpretation of the results obtained and on the description of regularities of transport processes in both organic high-molecular-mass and inorganic materials including systems possessing ion-exchange properties and ionic conduction.

II. Structure of ion-exchange and membrane materials

1. Structure of organic ion-exchange materials

Currently, organic ion-exchange and membrane materials are used much more widely than their inorganic analogues. Therefore, most of the modern models of transfer and structure of ion-exchangers have been developed for organic materials. In this connection it is appropriate to consider first the structure of polymer-based materials. Ion-exchange materials of different nature including the so-called homogeneous membranes and gel ion exchangers are in fact inhomogeneous.^{1, 11–13} There are different forms of inhomogeneity, *e.g.*, a structural, chemical and physical one, which can manifest themselves on both the macro- and microscopic level. Sometimes, such inhomogeneities are created in a targeted manner in the course of synthesis procedures (macroporous ion exchangers, granulates, heterogeneous membranes). In other cases they appear spontaneously. Inhomogeneity of a material strongly affects the transfer mechanism and many physicochemical properties of ion exchangers, as well as the operating characteristics of membrane systems.

An ion exchanger, which is in equilibrium with atmosphere, is called dry (air-dry). However, even in this case the material contains some amount of water (nearly two water molecules per

ionogenic group for sulfonated cation exchanger and 3 mass % or about 2%–3% of the maximum water uptake for perfluorocarbon membranes).^{13, 14} The structure of the dry ion exchanger is determined by conditions of the polymer synthesis and by structural rearrangement of the polymer due to the presence of ionogenic groups.

If ion exchangers are obtained by polymerisation and polycondensation, small highly cross-linked nuclei are first formed. Then nuclei merge together, thus forming an island structure;¹¹ the process can be accompanied by entanglement of polymer chains.¹² As a consequence, the polymer contains a large number of defects of various nature and size. These defects impart different levels of heterogeneity, from microscopic (atomic groups and molecules) to macroscopic (macropores, clusters of size 100 nm and larger), to the polymer structure.

In numerous studies carried out since the mid-1950s pores and other features of the heterogeneous structure of polymer matrices were detected both by direct observations (by electron microscopy, scanning electron microscopy,¹² small-angle X-ray scattering,^{13–16} Mössbauer spectroscopy,^{13, 17, 18} NMR spectroscopy^{19–22} and other methods^{13, 20, 21, 23–28}) as well as by indirect measurements (by mercury porosimetry,²⁹ reference porosimetry,^{30–32} differential scanning calorimetry,^{33, 34} etc.^{1, 34–37}).

Among the pioneering studies on the effect of charged ions on the ionomer structure was that reported by Eisenberg.³⁸ He chose an ion pair (an ionogenic group, *i.e.*, a partially or completely dehydrated fixed ion–counterion pair) as the main structural unit and showed that the dipole–dipole interaction causes association of the ion pairs to form the so-called multiplets containing no polymer chain segments. Due to steric hindrances the number of ion pairs in a multiplet is small, at most 6–8 according to Weiss *et al.*³⁹ and 2 according to Dreyfus.⁴⁰ The dipole–dipole attraction leads to aggregation of multiplets to yield larger associates (clusters). However, clustering induces a strong stretch of the elastic polymer matrix. The possibility for such a transformation to occur depends on several factors, *e.g.*, elasticity and degree of cross-linking of the polymer chains, concentration of ionogenic groups, etc. Ponomarev and Ionova⁴¹ studied changes in the strain energy, the energy of hydrophobic interactions between polymer chains and the Coulombic interaction energy upon clustering of ionogenic groups and showed that the process is energetically favourable if the concentration of ionogenic groups is not too low and the polymer network is sufficiently elastic. The newly formed cluster acts as an additional cross-link, thus making the polymer matrix more rigid.

Dreyfus⁴⁰ considered a simple model, which allows assessment of the structure and estimation of the size of dry clusters, as well as determination of their arrangement in membrane (Fig. 1). The model assumes an ideal flexibility of polymer chains. The only factor which limits an increase in the density of ionogenic groups is

Figure 1. Schematic representation of a dry cluster in an ion-exchange membrane containing elastic hydrophobic polymer chains.⁴⁰ Multiplets (1), polymer chain segments or bundles (2) and approximate cluster boundary (3).

the size of the polymer chains. For perfluorocarbon membranes the radius of the dry ionic cluster is 1–2 nm.⁴⁰ This is in agreement with the results of the small-angle X-ray scattering experiments.¹⁵

Hydration of ion exchangers causes essential changes in their structure. A consequence of hydration of ions and hydrophilic regions of the polymer matrix is swelling of the ion exchanger. This leads to an increase in the mobility of polymer chains, which, in line with the formation of a network of hydrogen bonds, facilitates additional aggregation and brings about clustering and formation of other structural elements with more or less homogeneous structure and composition. Because of this in studies on membrane systems such aggregates are called 'phases'. In spite of the fact that this term is not rigorous, we will use it in the text below. One phase is the hydrophilic 'gel' phase, which comprises the system of micropores formed by the rather closely spaced fixed and mobile ions and hydrophilic segments of the polymer chains. The second, hydrophobic, phase includes aggregated hydrophobic polymer chains and their bundles, as well as segments of an inert binder (*e.g.*, polyethylene), which is added to increase a membrane's mechanical strength. The electrically neutral solution, which fills voids, mesopores and macropores upon swelling, can be treated as the third phase.

As perfluorocarbon sulfonated cation-exchange membranes pass from the dry state to the swollen state with a water content of 20 mass %, the intensity of small-angle X-ray scattering by clusters increases by nearly an order of magnitude.¹³ The inter-cluster distance increases from 2–3 to 4–5 nm.^{13, 15, 42–44} Analogous results were obtained¹⁶ for polyphosphazene membranes (a promising material for fuel cell applications).⁴⁵ As water penetrates into the cluster, its volume increases, thus causing a stretch of the elastic matrix. In this case hydrophobic segments of polymer chains can be displaced from the cluster volume, thus forming the hydrophobic phase. Equilibrium is attained when the energy liberated upon hydration of ions becomes equal to the energy required to stretch the matrix.^{42–44, 46} As a result, the hydrated cluster looks like an inversed micelle.

The cluster–network model proposed by Gierke *et al.*⁴² treats spherical clusters. The fixed ions are at the cluster's periphery, which provides a minimum value of the surface energy and excludes contact of the polymer with water. Counterions neutralise the charge of the fixed ions, thus forming an electrical double layer (Fig. 2). The interior of the cluster is filled with aqueous electrolyte solution. For simplicity, Hsu and Gierke⁴² assumed that, depending on the energy state, there are two kinds of water, the 'inner' water and the 'surface' water. The latter fills the first and second outer layers of the cluster and constitutes the hydration shells of the fixed ions and counterions. The state of the inner water does not differ from the state of water in free solution.

The cluster diameter can be evaluated from the water uptake of the membrane. Assuming that clusters occupy the sites of a cubic lattice separated by 5 nm, the number of clusters per cubic centimetre of the membrane is 8×10^{18} while the number of water molecules per cluster at a water content of 15 vol. % is nearly 10^3 . At a membrane capacity of 1 mmol cm^{-3} , the number of fixed ions in the cluster approaches a value of 70. The cluster diameter is

Figure 2. Schematic representation of the structure of a swollen perfluorinated membrane according to the cluster–network model of Gierke.⁴²

~ 4 nm.⁴² It increases as the membrane's exchange capacity increases and as the degree of cross-linking of the polymer matrix decreases.^{15, 16}

This model also permits consideration of channels connecting adjacent clusters (see Fig. 2). Such channels were shown to be thermodynamically stable.⁴² However, the free energy of the system changes only slightly upon channel formation (-11 J cm⁻³); therefore, channels continuously appear and disappear. According to Timashev's figure of speech,¹³ they are 'scintillating'. The calculated channel diameter (1.4 ± 0.2 nm) is consistent with the experimental data ($1.2-1.3$ nm).⁴⁶

As the concentration of fixed ions and the water content in the membrane increases, the cluster diameter increases while the intercluster distance decreases. A feature of this situation is a marked trend to a 'collapse' of the system of hydrated clusters to form a through pore network.⁴⁰ A fraction of clusters 'merge' together, the channels connecting adjacent clusters are shortened, their diameters increase and the membrane structure becomes less regular. The transport properties of highly hydrated perfluorocarbon membranes with relatively high concentrations of fixed ionogenic groups are similar to those of the 'gel' hydrocarbon membranes. At a low content of water the properties of the two types of membranes differ appreciably in, *e.g.*, the character of dependence of the specific conductivity and diffusion permeability on the electrolyte concentration, *etc.*⁴⁷

The cluster-network model by Gierke was subjected to criticism^{13, 48, 49} because it provides no explanation for new results obtained by X-ray diffraction, Mössbauer spectroscopy, *etc.* To interpret these results, a channel model of the structure of the amorphous part of a perfluorocarbon membrane was proposed.¹³ This model assumes the presence of a comb-like periodic layered system of conducting pores (channels) with a wall-to-wall distance of 3–4 nm. Tovbin, Vasyutkin and Dyakonov^{48, 49} modified this model and developed a three-dimensional structural model of a perfluorinated membrane, which treats two kinds of pores, *viz.*, slit-like and cylindrical ones. The larger slit-like pores with a wall-to-wall distance of 3–5 nm are formed by close-packed polymer chains, are 10–17 nm long and 5–10 nm wide. Regular packing of polymer chains that form the 'walls' of the slit-like pores is periodically distorted by transient regions characterised by chain bending and entanglement. Such transient regions can be represented as sets of cylindrical pores formed by segments of bending polymer chains; the characteristic pore diameter and pore length are 1.5 and 2.5 nm, respectively. The role of these pores is analogous to that of the cluster-connecting channels in the Gierke model. The characteristic sizes of the structural elements in the models by Gierke and by Tovbin–Vasyutkin are in good agreement while the models themselves differ in interpretation of the cluster and channel shape.

The results obtained in a large number of experimental studies carried out to date allow definite conclusions about the structure of swollen hydrocarbon membranes. One of the pioneering works was reported by Gnusin⁵⁰ who studied inhomogeneous distribution of the concentration of ionogenic groups by microscopic observations. Similar results were also obtained by spectroscopic methods,^{13, 17, 22, 51, 52} contact reference porosimetry^{30–32} as well as by other methods.^{34–37} Figure 3 presents the results obtained for a heterogeneous cation-exchange membrane MK-40 by contact reference porosimetry^{31, 53} and mercury porosimetry.³⁴ The pore radius distribution curve is bimodal. Its maxima correspond to two types of pores, that is, the micropores and mesopores of radius about 10 nm and macropores of radius of the order of nearly 1000 nm. The first type of pores is localised within particles of the KU-2 cation-exchange resin employed for the preparation of the membrane, while the second type of pores represents the space between the resin and binder (polyethylene) particles.

According to Vol'fkovich *et al.*,³¹ micropores (of radius 1–2 nm) and mesopores (of radius 2–10 nm) in the structure of hydrocarbon membranes involve the space between individual polymer chains and their bundles. The volume of macropores (of

Figure 3. Pore radius distribution curves for a MK-40 membrane obtained by contact reference porosimetry (1),⁵³ mercury porosimetry (2),³¹ (3)³⁴ and sorption technique (4);³⁴ V is the total volume of the pores of radius r .

radius exceeding 10 nm) is the space between large bundles of polymer chains and between these bundles and polyethylene binder particles. Large pores have puckered walls, the relative fraction of such pores can serve as a measure of inhomogeneity of ion exchangers. However, the total volume of large pores is much smaller (sometimes by an order of magnitude³¹) than that of the small pores, which determine the ion-exchange and sorption properties of an ion exchanger. For instance, more than 80% of pores in the MA-100 homogeneous membrane have radii less than 10 nm, while the maximum volume fraction falls to the pores of radius 4.5 nm.³¹

2. Structure of inorganic ion-exchange materials

The major distinction between inorganic systems and the polymeric systems considered above is a higher degree of structural ordering in the former material. Exchange of a particular type of ion by another one usually occurs with retention of the lattice framework. A feature of the structure of ion-exchange materials with a rigid three-dimensional framework is the high degree of retention of the type of coordination polyhedra characteristic of a certain sort of ion. Most inorganic ion-exchange materials possess cation-exchange or bifunctional properties. The latter group is mostly represented by hydrated oxides of polyvalent elements.

Among inorganic ion-exchange compounds, it is possible to identify the following classes: complex and hydrated oxides and salts of polyvalent metals. Detailed description of each class has been documented.^{2, 54, 55} In this Section we will consider the structure of some of the most widely used inorganic ion exchangers. From this point on for more systematic presentation it is convenient to divide the ion exchangers into nanomaterials, layered materials and materials with a three-dimensional framework.

A strong impetus to the development of research on nanomaterials has been noted recently. This is mainly due to the specific properties of such materials^{56–60} and to advances in the synthesis, investigation and applications of fullerenes.^{61–64} The geometry of small particles is to a great extent determined by the condition for a minimum surface tension energy. Therefore, a nearly spherical shape is the most typical. The developed surface of nanoparticles contains numerous uncompensated bonds, which can be stabilised upon sorption of various ions and molecules.⁵⁵ However, these species are weakly bound to the nanoparticle cage, which makes possible reversible dissociation and surface migration.⁵⁵ In combination with high surface diffusion coefficients this determines good transport properties of such materials.^{60, 65, 66}

Figure 4. Schematic representation of the structure of hydrated zirconia.^{54, 55}

This type of ion-exchange material is often called a globular hydrate.⁵⁵ Typical representatives of such materials are hydrated oxides of polyvalent metals. Ion transport in them mainly occurs within the intergrain space containing a large number of water molecules (Fig. 4). These compounds are characterised by relatively low ion-exchange capacity, which can vary by several orders of magnitude on heating or prolonged storage as a result of olation, oxolation and crystallisation processes. In some cases heat treatment at temperatures of up to 400 °C can improve the exchange properties of these compounds due to shortening of distances between hydroxyl groups and particle's surface.⁶⁷

Structural peculiarities of amorphous hydrated oxides are due to the inhomogeneity of the bonds formed by OH groups and, as a consequence, by their ability to dissociate by acid or basic mechanisms with appreciably different dissociation constants. Therefore, the exchange capacity of hydrated oxides, which manifests itself when contacting an aqueous solution, strongly depends on the proton concentration in the solution.^{54, 68} In addition, these materials can change their properties from anion-exchange to cation-exchange with an increase in the pH value of the solution. The relation between cation- and anion-exchange properties of hydrated oxides is determined primarily by the electronegativity of the structure-forming cation. For instance, double hydroxides of divalent and trivalent elements^{69, 70} as well as hydrated yttrium oxide⁷¹ are anionites. Depending on the particular conditions, hydrated zirconium and tin oxides possess both cation- and anion-exchange properties,⁵⁴ while hydrated antimony(V) oxide is a cation exchanger.⁷²

Globular hydrates also comprise tungstophosphates of some monovalent metals, which possess cation-exchange properties. The number of water molecules that form a monolayer on the particle surface usually varies from 7 to 12 per formula unit. Both heteropolyanions and protons are sorbed on the surface of such compounds, which is equivalent to the deposition of acid salts in which the content of hydrogen ions can exceed 1.0 per formula unit.⁷³ According to NMR studies, monovalent cations on the surface of particles at room temperature are in the highly mobile state.^{73, 74} It is these ions that can be exchanged with ease upon contact with aqueous solutions of salts.

The advantage of layered compounds is the high concentration of accessible sorption sites or ion exchange groups. Among this class of inorganic ion-exchange materials, hydrogen phosphates and arsenates of polyvalent elements [$\text{MH}_x(\text{ZO}_4)_2 \cdot n\text{H}_2\text{O}$] ($\text{Z} = \text{P}, \text{As}$) are most widely used. The structure of a typical representative of this group of compounds, zirconium hydrogen phosphate, is presented in Fig. 5. Cations of small radii can migrate in the large interplanar space (interplanar spacing $d = 7-8 \text{ \AA}$) with ease in the direction parallel to that in which layers are aligned.^{76, 77} Because of this the exchange capacity of such compounds is most often much higher than that of globular hydrates. For instance, a typical value of the ion-exchange

Figure 5. Crystal structure of zirconium hydrogen phosphate.⁷⁵

capacity of, *e.g.*, hydrogen phosphates of tetravalent elements is 4–8 mequiv g^{-1} (see Refs 78–83). Due to the nonequivalence of hydrogen atoms and steric hindrances to arrangement of the second cation in the matrix, exchange processes in hydrogen phosphates of tetravalent elements most often involve two stages. Besides, in contrast to most polymeric membrane materials, exchange in these systems often occurs by movement of the interphase boundary, the composition of each phase being changed slightly in the course of exchange.^{55, 84} Hydrogen tantalum phosphate has a somewhat lower exchange capacity (2 mequiv g^{-1}).⁸⁵ At the same time the cation mobility in this compound is much higher than that in the hydrogen phosphates of tetravalent elements.^{86, 87}

Another group of layered compounds possessing ion-exchange properties comprises hydrated oxyphosphates of pentavalent metals $\text{H}_2\text{XO}_2\text{PO}_4 \cdot n\text{H}_2\text{O}$ ($\text{X} = \text{V}, \text{Nb}, \text{Mo}$). For instance, the niobium compound contains two hydroxyl groups;⁸⁸ however, only one proton in them can be replaced by a cation in the reaction with alkali.^{89–92} Exchange processes in uranyl phosphate ($\text{H}_2\text{UO}_2\text{PO}_4 \cdot n\text{H}_2\text{O}$) occur similarly.^{93, 94} No less important is the ability of the compounds under study to be intercalated with alkali metal cations or hydrogen, which is accompanied by reduction of a fraction of the polyvalent cations and the formation of variable-composition compounds $\text{M}_x\text{VOPO}_4 \cdot n\text{H}_2\text{O}$.^{95–97} The latter also possess ion-exchange properties^{98–100} and, in addition, high conductance, which is of great importance for the occurrence of some practically valuable transfer processes.

Layered ion exchangers comprise a giant class of clay materials built of blocks whose composition approximately corresponds to $\text{Si}_2\text{Al}_4\text{O}_{20}^{4-}$. The electroneutrality of the compound is ensured overall by the incorporation in the interplanar space of alkali or alkaline-earth metal cations or protons. A large proportion of cations located within the interplanar space can be readily exchanged. The total ion-exchange capacity of such materials can be as high as 1.5 mequiv g^{-1} . For the H-form of the materials with a nearly ideal composition the ion-exchange capacities with respect to cations and anions are approximately equal.^{2, 101–103} Many layered inorganic ion exchangers are characterised by low solubility and their synthesis is, as a rule, accompanied by the formation of strongly supersaturated solutions. This leads to the formation of small particles, which are less thermodynamically stable; however, the exchange reactions on their surfaces usually occur much faster. Therefore, often researchers restrict themselves to the synthesis of materials built of rather small particles, which makes the 'boundary' between layered ion exchangers and nanomaterials diffuse. An intermediate position between the two above-mentioned classes of compounds is occupied by fibrous materials.^{104, 105}

The exchange processes in the layered compounds considered above are, as a rule, accompanied by substantial changes in the interplanar spacing due to the different radii of the exchanging cations and to the change in the degree of hydration.⁸⁵ However,

not all compounds obey this regularity. In particular, practically valuable inorganic membrane materials are β -aluminates having a composition $M_{1+x}Al_{11}O_{17+x/2}$ (M^+ is a proton or the ammonium, alkali or monovalent metal cation). They also have a layered structure. A peculiar feature of their structure is that the four-layer blocks of composition $(Al_{11}O_{16})_n$ with close-packed oxygen atoms are linked by oxygen atoms of the fifth layer containing a quarter of the oxygen atoms in each of the four above-mentioned layers. Because of this the interplanar spacing varies only slightly in the course of exchange. Besides, cation exchange in such materials occurs relatively slowly at ambient temperatures. Therefore, most often the exchange processes are carried out in nitrate melts of β -aluminates at temperatures of at least 300 °C.^{106–115} These compounds can be considered as a transient form between layered ion exchangers and materials with a three-dimensional framework.

Inorganic ion-exchange materials with a three-dimensional framework demonstrate the largest variety of structures. Transfer in such compounds is due to the presence of long continuous channels. Since ion transfer can occur only through migration of defects (vacancies or interstitial ions), a fraction of sites 'reserved' for the mobile ions should be vacant.⁶ Some examples of these compounds are provided by complex phosphates and silicates $A_xB_2(YO_4)_3$, where A is the univalent cation, B is the trivalent or tetravalent cation and Y = P or Si. Sodium-containing representatives of this type of material[†] are characterised by high cation mobility.¹¹⁶ High cation mobility was also found in other structurally similar compounds containing protons, ammonium, lithium and some other cations (see, e.g., Refs 117 and 118). The three-dimensional crystal lattice of the compounds belonging to the NASICON structural type is formed by the XO_6 octahedra (X is the trivalent or tetravalent metal) and PO_4 tetrahedra linked in such a way that three-dimensional channels extending along the crystallographic axis c are formed in the structure.¹¹⁹ It is these channels where all the atoms of type A are located. However, if they are all occupied in $Na_4Zr_2(SiO_4)_3$, a total of 25% and 75% of sites remain vacant in $Na_3Sc_2(PO_4)_3$ and $NaZr_2(PO_4)_3$, respectively. In this connection at temperatures above the superionic phase transition temperature (320 K) a fraction of lithium atoms in the $LiZr_2(PO_4)_3$ structure cannot be located by the diffraction techniques.¹¹⁹ Besides, it was found that such materials can be doped with heterovalent admixtures. For instance, it is possible to replace a fraction of phosphorus atoms by silicon, vanadium or niobium atoms.^{120, 121} The largest increase in conductivity can be achieved by replacing a fraction of the cations occupying the X sites by trivalent metal cations with a simultaneous increase in the content of the alkali metal cations A (see, e.g., Refs 122–125). The conductivity (cation mobility) of such systems can be several orders of magnitude higher than the conductivity of the initial phases.

Most often cation exchange in the NASICON compounds is carried out by treating the initial phase with salt melts.^{126–128} Compounds with the three-dimensional framework also comprise zeolites that are widely used as sorption materials and catalysts,^{102, 129–135} some complex oxides and many other inorganic materials that have been reviewed.^{2, 54, 55} It should be mentioned that a large number of novel inorganic ion exchangers are synthesised and studied yearly.^{136–142} High selectivity and stability of inorganic ion-exchange materials are prerequisites for the development of investigations in this area.^{2, 102, 143, 144}

Recently, extensive research on the synthesis and properties of mixed ion exchangers based on inorganic matrices with chemically bound organic fragments, which contain functional groups or link individual layers and thus confine the volume of the interplanar space, has been carried out. Such ion exchangers are most often synthesised using hydrogen phosphates of tetravalent elements as

matrices.² This allowed preparation of a large number of cation- (see Refs 145–148) and anion-exchange materials¹⁴⁹ possessing specific properties. Studies on the synthesis of similar materials based on other classes of compounds have also been carried out.¹⁵⁰

Polymer-based composite materials with heterogeneous inorganic admixtures can be considered as a new class of ion-exchange materials. They exhibit specific physical and chemical properties and can be divided into two types, viz., materials with an inert and with an ion-exchange polymer matrix. In the first type of system the mobile cations are generated by the inorganic component.^{151–155} Such materials are formed, e.g., in the reaction of a polymer matrix with alkali metal halides or pseudohalides. The rubbery phase of the polymeric component provides a high ion mobility.^{156, 157} The maximum conductivity of these composites is attained at an optimum ratio between the concentrations of the salt molecules and monomer units (this ratio is usually 0.2 to 0.4). In some cases the optimum value is much smaller.^{151, 158, 159} In the initial stage of doping a sharp increase in the cation mobility is due to an increase in the concentration of charge carriers. Further increases in the cation mobility are accompanied by a substantial increase in the degree of crystallinity of the polymer and reduction of the mobility of charge carriers.¹⁵¹ The effect of various microcrystalline oxides,^{156, 157, 160} phosphates¹⁶¹ and other heterogeneous admixtures to solid polymer electrolytes on the ion-exchange properties of the composite materials under study has been investigated.

The second type of material employs an active ion-exchange membrane capable of sorbing both cations^{162–164} and anions¹⁶⁵ as the polymer component. The list of currently used inorganic dopants includes a variety of compounds, namely, hydrated oxides of polyvalent elements (aluminium, titanium, silicon, antimony),^{162, 166, 167} heteropolyacids^{163, 168, 169} and other compounds.¹⁶⁴ The characteristic size of the dopant species can vary from several to several hundreds of nanometres.¹⁶⁸ Apparently, in most cases they form islands in the membrane. For instance, a small-angle X-ray scattering study¹⁷⁰ revealed that the average distance between the dopant species in the Nafion– SiO_2 system is about 5 nm. The advantages of the composite membranes are mechanical strength, selectivity and the possibility of increasing the ionic conductivity of some systems, which can be as high as 10^{-3} – 0.2 S cm⁻¹ (see Refs 162, 165, 171).

III. Ion diffusion in solids

1. General laws

The rates of diffusion processes in various solids are substantially different. In the vast majority of compounds such processes proceed at relatively low rates; nevertheless, this does not make them less significant. For instance, very slow geochemical processes cause changes in the composition and structure of the Earth's crust.¹⁷² Raising the temperature permits a substantial increase in the ion and molecular mobility. At high temperatures, solid-phase reactions between rather stable (at first glance) oxide phases proceed at a rather high rate.⁵ Ion exchange and membrane processes are due to cation and anion diffusion.⁵⁵ The mechanism and rate of transfer in ion-exchange and membrane materials to a great extent determines the possibility of their practical use. Selective electrotransport of cations and anions through cation- and anion-exchange membranes, respectively, permits, e.g., desalination of liquid mixtures.

Two mechanisms, diffusion and convection, underlie the ion transfer processes. In this review we will mostly consider the first mechanism. The rate of diffusion processes is determined by the product of the charge carrier mobility and their concentration. The first factor depends on the nature of the mobile ion and the matrix (the material in which transfer occurs).^{173–175} In most inorganic compounds it is possible to select one type of ion having high mobility, which allows one to treat them as unipolar electrolytes. The highest mobility is possessed by small ions, which can

[†] They were called NASICON (an abbreviation of Na Super Ion CONductor).

travel with ease through faces of adjacent coordination polyhedra. At the same time, such ions must be capable of forming and cleaving chemical bonds, which implies a relatively low polarising ability. For this reason only small singly charged ions can possess a high mobility in inorganic systems at moderate temperatures (below 700–800 K). Among anions, these are only the fluoride and oxygen (at elevated temperatures) ions. Usually, cations of smaller radius also have a higher mobility. The highest ion mobility is attained for a number of compounds of monovalent metals (copper, silver and sodium).¹⁷³ Having similar radii, the first two cations offer the advantage of high polarisability of their electron shells.

The transport properties of most inorganic compounds are due to (i) the presence of vacant structural sites, in which the energy of the mobile ions is similar to the energy of the structure-forming ions, and (ii) the ratio of the cation size and the face size of the coordination polyhedron through which cation migration occurs.^{174, 175} In the case of proton diffusion (small radius, $\sim 10^{-5}$ Å) the latter factor is insignificant. More important for proton transfer is the system of interatomic distances and the proton-acceptor ability of electronegative lattice-forming atoms.^{176, 177}

Ion transfer in solids occurs through the migration of defects (vacancies or interstices) and the ratio of the number of defects to the number of mobile ions determines the concentration of charge carriers, which is the most important characteristic. All materials possessing high rate of ion transfer are characterised by high concentration of charged point defects.^{173, 177, 178} Such an approach is applicable to a wide range of systems. For instance, water is a poor conductor first of all due to the low concentration of charge carriers (hydrated protons or hydroxide ions). The addition of acids or alkali causes the formation of defects, thus leading to a sharp increase in the conductivity of the system.¹⁷⁹ Analogously, the concentration of defects in the low-temperature modification of silver iodide (β -AgI) is relatively low, while it increases by several orders of magnitude in the superionic phase of this compound.¹⁸⁰ The concentration of defects in superionic compounds can be as high as 10^{18} cm⁻³ (see Refs 172 and 181). It is this parameter whose value determines the ability of a substance to provide fast ion transport.

The reaction of defect formation in an ionic crystal M^+X^- with Frenkel defects can be described by the following equation¹⁸²

where M is the cation, V is the vacancy, the subscripts M and i correspond to the atom occupying the cation site and the interstice, respectively, and the superscripts (a point and a prime) respectively denote the positive and negative charge of the species with respect to the stoichiometric charge of a given lattice site. Let N_i and N_v be the mole fractions of the ion interstices and cation vacancies in the bulk of the crystal. The product of these quantities can be expressed through the equilibrium constant (K_F) or the Gibbs free energy (ΔG_F) of the reaction (1)

$$N_i N_v = CK_F = C \exp\left(-\frac{\Delta G_F}{RT}\right), \quad (2)$$

where C is the number of interstices per site of a regular lattice (e.g., for crystals with the rock salt structure one gets $C = 2$). Since the crystal is electrically neutral, the concentrations of vacancies and interstices in the crystal have equal values. Therefore, we can write

$$N_i = N_v = (CK_F)^{1/2} = C^{1/2} \exp\left(-\frac{\Delta G_F}{2RT}\right). \quad (3)$$

In some materials the energies of the atoms occupying the lattice sites and the defect sites are nearly equal. In particular, the energies of the cations occupying five different sites with the

coordination numbers of 5, 8 and 9 in the structure of sodium β -aluminate are similar.¹⁸³ Because of this at room temperature nearly half the sodium ions are located at sites with a higher energy, which makes the notions 'sites' and 'interstices' undefined. At the same time in the case of $NH_4Al_{11}O_{17}$ arrangement of a large NH_4^+ cation at different sites leads to a larger energy difference. Therefore, in $NH_4Al_{11}O_{17}$ almost all ammonium ions occupy the so-called Beavers–Ross sites. Clearly, in ammonium β' -aluminate, $(NH_4)_{1+x}Al_{11}O_{17+x/2}$, the excess NH_4^+ ions should occupy the interstices. This should lead to a decrease in the concentration of cation vacancies [see Eqn (3)]. However, structural studies point to a sharp increase in the number of cation vacancies with increasing concentration of interstitial ammonium ions. For instance, on average 23% of regular sites in $(NH_4)_{1.2}Al_{11}O_{17.1}$ are vacant, while the interstices are occupied by 0.43 ammonium ions per formula unit.¹⁸⁴ As the ammonium ion arrives at an interstice, it displaces adjacent cations from regular lattice sites to the interstices with similar energies. The formation of relatively large structural domains (clusters) characterised by the predominant population of interstices appears to be energetically favourable. It is these clusters in which the majority of excess cations is located.

The rate of ion transport can also be considerably increased by doping ionic crystals with heterovalent admixtures. Doping causes an increase in the concentration of cation vacancies or interstices. For instance, heterovalent replacement of the phosphorus or tetravalent metal atoms in high-defect solid solutions based on phases with the NASICON structure (see above) by cations of lower valence with simultaneous introduction of an excess of alkali metal results in a sharp increase in the concentration of interstitial mobile ions, which is accompanied by an increase in the ionic conductivity.^{116, 122, 185} A study of a lithium-containing compound revealed the formation of clusters containing cation interstices alternating with the domains of stoichiometric composition, which is similar to β -aluminates of alkali metals. This allowed Abrahams and Bruce¹⁸⁶ to conclude that ion transfer in such materials involves migration of clusters containing a large number of interstices.

Replacement of silicon by phosphorus in a silicate of composition $Li_{4-x}Si_{1-x}P_xO_4$ also results in the formation of one cation vacancy in the lattice. A feature of the Li_4SiO_4 – $LiAlSiO_4$ system is the formation of a continuous series of solid solutions of composition $Li_{4-3x}Al_xSiO_4$ and an individual compound $Li_5AlSi_2O_8$. West *et al.*¹⁸⁷ showed that individual compounds in this system exhibit the lowest conductivity. Interstitial lithium ions are the main type of defects, which determines the conductivity of the Li_4SiO_4 -based solid solutions

In contrast to this, cation vacancies dominate in the solid solutions based on $LiAlSiO_4$

The cooperative phenomena contribute largely to transfer processes in condensed media.¹⁸⁸ They have a particularly strong effect on proton transfer, which always occurs by successive proton jumps from one electronegative atom to another and by rotation of proton-containing groups.¹⁸⁹ Water molecules located near a hydrophobic polymeric ion-exchange matrix form relatively weak hydrogen bonds and readily pass into the rotational mobility state. A rotating water molecule should be treated as a neutral spherical species rather than a dipole. Hydrogen bonds formed by this molecule are cleaved, which facilitates the mobility of the nearest neighbours. Their rotation, in turn, induces the mobility of other surrounding molecules and, finally, of the whole system. For instance, a fraction of the hydrogen bonds formed by water molecules and proton hydrates in $H_3PW_{12}O_{40} \cdot 29H_2O$, in which the anion O atoms having a low proton-acceptor ability act as proton acceptors, are very weak. The high rotational mobility of these fragments, which, in turn, function as acceptors of

protons of other H-bonds, propagates over the whole proton hydrate sublattice due to the cooperative effect. Therefore, its transition to the highly mobile state occurs at low temperatures.¹⁹⁰ A similar transition to the mobile state at low temperatures has been reported for layers of water molecules sorbed on the surface of some inorganic compounds.¹⁷⁶

Vibrations of both solution particles and functional groups of ion exchanger induce alternating weakening of some hydrogen bonds and strengthening of some others in the system. Strengthening of hydrogen bonds brings about a decrease in the activation energy for proton transfer and accelerates proton hopping, whereas the weakening of bonds enhances the rotational mobility. These processes are separated in space, so that proton transfer acquires a cooperative character. The cooperative nature of proton transfer has also been noted for salts of polyfunctional organic acids,^{191, 192} for chains of the acid $-(\text{H}_2\text{O})_n-$ anion type¹⁹³ and for complex biomolecules.^{194, 195} There are grounds to believe that the cooperative mechanism of transfer can also be involved in the case of some alkali metal cations.¹⁹⁶ It should be mentioned that all the systems listed above are characterised by relatively weak binding, which seems to be important for efficient cooperative processes. The higher the structural disorder and the weaker the bonds formed there, the larger the vibrational amplitude and the higher the rate of transfer. It is the weakness of bonds formed and the ease of their rearrangement that result in a large vibrational amplitude and the highest efficiency of cooperative processes.

In this connection we will return to the polymeric membrane materials considered above. A salient feature of such systems is a decrease in the ionic conductivity with a decrease in the mobility of polymer chain segments, which is accompanied by an increase in the viscosity of the polymer.¹⁵¹ Taking into account this fact, Druger *et al.*¹⁹⁷ proposed a percolation model of transfer with allowance for correlation between cation hopping and rotation of segments of polymer chains, which induces reorientation of cation's coordination polyhedra.

Diffusion in polymeric membranes and ion-exchange materials is usually described assuming the three most probable ion transfer mechanisms, *viz.*, the vacancy, relay and solvation ones.^{51, 198, 199} According to the vacancy mechanism, the mobile ions migrate from one fixed (immobile) molecular group to another one. Migration occurs if at least one neighbouring group is unoccupied by an ion. The relay mechanism involves 'displacement' of an ion bound to the fixed group by a 'free' ion present in the channel. The 'displaced' ion goes to the conductive channel or displaces the next bound ion, thus maintaining the relay transmission. The third solvation mechanism deals with the motion of ions in solution and is to a great extent analogous to transfer along interstices in ionic crystals.

The first and third mechanisms can be realized simultaneously, since the counterion having escaped its potential well cannot go beyond the bulk of the ion exchanger (this corresponds to the formation of Schottky defects in crystals²⁰⁰). This relay mechanism occurs in the case of a narrow channel (pore), where the vacancy mechanism is impossible for steric considerations.^{201, 202}

The depth of the potential well is determined by the energy of the coulombic interactions between hydrated ions, by the chemical interaction between the ion and the molecular group it is bound to and by the energy necessary to stretch the polymer network and thus to provide the possibility for an ion to escape.⁵¹ For some transfer mechanisms the barrier height also depends on the energy of formation of ion vacancies and dopant ions.²⁰⁰ According to quantum-mechanical calculations by Shaposhnik *et al.*,^{203, 204} insertion of water molecules between the counterion and the fixed ion leads to substantial weakening of coulombic interactions between them. At the same time one should take into account the energies of the hydrogen bonds formed by water molecules with the counterions and fixed ions, which is responsible for the crucial role of hydrogen bond cleavage in ion trans-

port. The potential barrier is determined by the elementary jump length, λ , of the diffusing ion. In ionic crystals, ion hopping from one interstice to another occurs; therefore, the λ value is determined by the lattice constant.²⁰⁰ For ion-exchange materials, λ is most likely determined by the distance between corresponding molecular groups and depends on the ion-exchange capacity.⁵¹ In conventional ion-exchange membranes the average distance between such groups is 0.5–1.0 nm.^{13, 51} Probably, ion transfer from one fixed group to another involves a number of elementary jumps. In this case, at least in systems with a high concentration of ionic salts in channels, the role of transfer agent can be played by the mobile ions likely charged with the fixed groups (coions) or by the solvent molecules.

When estimating the self-diffusion coefficient of multiply charged ions, Shaposhnik *et al.*^{203, 204} pointed out that the probability of a fluctuation, which makes possible simultaneous abstraction of an ion from several fixed groups it is bound to, is very low. Assuming that the ion escapes from the potential well in several steps, they concluded that the diffusion coefficients of the doubly charged ions must be nearly 4 times lower than those of the corresponding singly charged ions.

2. Transfer processes and interfaces

Most of the membrane and sorption processes are heterogeneous, so interfacial phenomena are of great importance in this case.²⁰⁵ Frenkel²⁰⁶ and Chebotin and Perfil'yev²⁰⁷ pointed out that the grain boundaries and the surfaces of solid particles are sources of excess point defects, the concentration of which for ionic crystals is determined by the surface potential. Most often cations and anions are located on the surface of crystals under different conditions. Apparently, that is why cation vacancies or interstices are mainly sorbed on the surface, while defects of the opposite sign are concentrated within a thin near-surface layer. Because of this the so-called 'surface' charge appears within the Debye layer (~ 1 – 3 nm thick). The volume density of the 'surface' charge tends to zero with the distance from the interface to the interior of the crystal.^{208–210} The magnitude of the charge is determined by the morphology, crystal chemistry considerations and sorption properties of the surface. The electrical double layer at the organic ion exchanger–solution interface is formed analogously.^{11, 173}

The concentration of defects and the surface potential of silver chloride polycrystals were estimated by Maier²¹¹ from the ionic conductivity of this compound. The results of calculations are in good agreement with the data obtained using independent methods. In particular, the surface potential of silver chloride and silver bromide changed from -0.1 to -0.25 eV on heating from 298 to 550 K.^{212, 213} According to calculations, at room temperature the concentration of cation interstices in these compounds must be three orders of magnitude higher than in the bulk of the crystal.²¹² Enhancement of the translational mobility of ions and intensification of the diffusion processes on the surfaces of crystals are due to weak binding of the surface atoms and high imperfection of the surface.^{65, 66, 214}

The contribution of the surface component to transfer processes is most significant for nanomaterials, since the linear size of nanoparticles can be comparable with the thickness of the Debye layer. In this case the bulk of the particle is characterised by an increased concentration of defects and the material as such must possess an abnormally high conductivity.²¹⁵ A detailed description of ion transfer in nanomaterials can be found in reviews.^{60, 216}

In the early 1970s Liang²¹⁷ discovered that the ionic conductivity of the low-temperature modification of silver iodide placed in contact with finely dispersed alumina increases by several orders of magnitude despite the fact that the latter compound did not possess conducting properties. This appeared to be of increasing interest due to the potential use of composite electrolytes in compact power sources with high capacity.²¹⁸ A number of experimental studies were carried out, aimed at increasing the ionic conductivity of silver, mercury, lithium and monovalent copper halides by doping them with finely dispersed

powder of an inert phase, for the most part finely dispersed alumina, silica and titania.^{219–227} At about that time Shahi and Wagner^{228, 229} and Hartwig and Weppner²³⁰ reported an increase in the ionic conductivity of two-phase solid electrolyte mixtures (AgI–AgBr, LiI–NH₄I). In succeeding years the number of studies in this research area increased significantly.

An increase in the conductivity upon heterogeneous doping of ionic compounds is primarily determined by a substantial increase in the contribution of the surface component. Numerous attempts to explain this phenomenon have been undertaken. For instance, Stoneham *et al.*²³¹ postulated that the formation of the highly conducting phase is due to the presence of trace amounts of water. However, experimental data supported the assumption that an increase in the conductivity of binary systems of the AgI–Al₂O₃ type is first of all determined by an increase in the concentration of defects in ionic salts containing mobile ions.²²⁰

Suppose that the admixture (phase B) possesses the properties of a base, is chemically inert towards the ionic compound M⁺X[–] and forms no solid solutions with M⁺X[–]. It is known that two phases are in equilibrium if the chemical potentials of all components (including ions) in each phase are equal to one another. Therefore, sorption of the M⁺ and X[–] ions on the surface of B is possible until the ion activities are equal to those in the bulk of M⁺X[–]. For instance, only silver ions incapable of penetrating alumina particles are in the mobile state in the AgI–Al₂O₃ system; however, these ions can be efficiently sorbed at the interface. Because of this, cation vacancies are concentrated in the adjacent layer of the solid electrolyte, thus imparting a negative charge to it (Fig. 6a). By analogy with the situation which takes place when a solid contacts an electrolyte solution,^{232, 233} an electrical double layer is formed at the AgI/Al₂O₃ interface. A theory for this phenomenon has been developed by Maier *et al.*^{208, 234–248} Defect formation can be described by the following equations:²⁰⁸

$$M_M + V_B = M_B + V'_M, \quad (6)$$

$$M'_B + V_i = M'_i + V_B, \quad (7)$$

where the subscript B denotes the interfacial sorption site.

To describe the thermodynamics of interfacial processes, the functions ΔG_{VB} and ΔG_{iB} were introduced. The difference between the values of these functions at the interface and at the surface of a pure crystal equals the Gibbs free energy of migration of a metal ion from MX to the surface of the B phase. If $\Delta G_{VB} < \Delta G_{iB}$, a fraction of ions escape from the bulk and appear at the interface due to sorption. This causes a sharp increase in the concentration of vacancies within the Debye layer. The change in the concen-

Figure 6. Scheme of defect formation at the AgI/Al₂O₃ interface (a) and changes in the defect concentration (c_d) within the boundary layer (b);⁹ x is the distance from the surface of the Al₂O₃ particles (phase B) into the interior of the AgI particle.

tration of cations along the normal to the interface is analogous to that shown in Fig. 6b. If the phase B possesses the properties of a weak base, it does not possess the ability to sorb cations and can tear them away (adsorb anions), which leads to an increase in the concentration of interstices in the near-surface layer. In both cases for a rather strong interaction the concentration of a particular sort of defect increases, which affects the physical and chemical properties of composite systems.

Various types of interactions at solid/solid interfaces have been reported.^{181, 240} In particular, the systems comprised of alumina and lithium iodide (or silver chloride, or a divalent metal fluoride) are characterised by sorption of mobile monovalent ions (Li⁺, Ag⁺, F[–]) at the interface. As a consequence, the concentration of vacancies within the Debye layer sharply increases.^{208, 243, 249} The interaction of the silver chloride surface with ammonia vapour causes an increase in the concentration of cation vacancies due to the formation of relatively strong cationic complexes at the interface.²⁴⁰ In contrast to this, interaction of silver chloride or calcium fluoride with Lewis acids (BF₃ or AsF₅) results in the formation of strong surface anionic complexes. In this case the concentration of interstitial silver ions or fluoride ion vacancies within the Debye layer increases sharply.^{240, 242, 244} The interaction of silver iodide with silver bromide or silver chloride also causes a substantial increase in the conductivity of the system^{225, 250, 251} due to the formation of heterogeneous (AgI/AgCl) contacts, which is accompanied by an increase in the concentration of cation vacancies and interstices in the near-interface region. This kind of interphase interaction is analogous to the formation of an electrical double layer near the surface of solids immersed in electrolyte solutions.^{232, 233} Sorption of oxygen atoms on the oxide surfaces also causes the formation of cation vacancies in the near-surface layer.²⁴⁵

As mentioned above, ion exchangers and membrane materials can be represented as multicomponent and multiphase systems comprised of very thin interlayers, channels or voids filled with a charged solution (micro-, meso- and macropores) and an inorganic or polymer matrix containing functional groups. Due to the interaction between the solution and matrix, spatially separated charges appear. Most often, the size of channels and pores, in which ion transfer occurs, is of the order of several nanometres (see Fig. 3). Since this size is comparable to the characteristic thickness of the Debye layer, rather intense sorption–desorption processes occur involving the overall pore system. Even in the case of contact with neat solvent the concentration of charged particles formed as a result of dissociation of functional groups or sorption of one sort of ions (solvent constituents; in the case of water these are the H⁺ or OH[–] groups) in the conducting channels is high. Therefore, transfer processes in these channels can be highly efficient. Besides, since changes in the concentration of charged species are most pronounced within the grain boundary Debye layer (Fig. 7), the ion distribution over the channel thickness is nonuniform. The rate of ion transport differs correspondingly.

Figure 7. Counterion and coion distribution in the membrane channel (a) and changes in their concentrations near the channel wall (b); counterions (1), coions (2) and ionogenic groups (3).

The electric potential and ion concentration distributions in the pores of ion-exchange materials are described in the framework of the Gouy–Chapman theory and related models based on it.^{252–255}

The effect of homogeneous and heterogeneous contacts on the rate of chemical transport is ambiguous. On the one hand, a considerable increase in the concentration of charge carriers within the Debye layer accelerates transfer along the boundary. On the other hand, ion transfer between two phases can be complicated because of the low concentration of charge carriers at the interface.^{9, 248, 256} Besides, interfacial phenomena strongly affect the kinetics of various processes that occur involving the solid phase. Nonlinear phenomena, such as oscillating catalytic processes,²⁵⁷ oscillations of the electrochemical potential on the surface of metallic electrodes,^{258, 259} *etc.*, can be observed at the gas–solid and liquid–solid interfaces. Therefore, it is of importance to allow for all interactions between the membrane material and the environment in the course of ion transfer.

Let us consider transfer of the component M through an ionic compound $M^{z+}X^{y-}$ through which both ionic and electronic conduction can occur. If the driving force is weak, one can assume that the flux of the component M is proportional to the electrochemical potential gradient ($\Delta\mu_M$). Directed transfer of only one sort of ions would lead to charge separation in the membrane bulk, which requires a large expenditure of energy. Therefore, chemical transport usually involves unidirectional diffusion of differently charged ions including electrons or counterdiffusion of likely charged ions. Generally, the flux of any sort of ions can be calculated from stoichiometric ratios. For instance, the flux of metal ions is given by the Wagner equation²⁶⁰

$$J_M = -\frac{\sigma \Delta\mu_M}{(ze n_M)^2}, \quad (8)$$

where σ is the ambipolar conductivity of the crystal

$$\sigma = \frac{\sigma_M \sigma_B}{\sigma_M + \sigma_B} \quad (9)$$

(σ_M and σ_B are the ionic conductivity of the material with respect to a given sort of ion and the electronic conductivity, respectively), e is the electron charge and n_M is the stoichiometric coefficient. Equation (8) is also applicable to calculations of transport through grain boundaries.²⁵⁶

Analysis of the relations listed above suggests that the rate of mass transfer is controlled by the concentration of defects possessing a lower mobility. If the limiting factor is ion transfer, chemical transport in systems with multiple boundaries characterised by an increased concentration of defects occurs at a higher rate. Acceleration of transfer involves more intense chemical transport along grain boundaries (Fig. 8 *a*).

In some cases mass transfer along grain boundaries accelerates due to the specific interaction between them. In particular, a study²⁶¹ of electrotransport of multiply charged cations across the

interface between two oxide phases revealed that the properties of ceramics obtained in the synthesis of some molybdates and tungstates of divalent metals in an electric field are significantly different from the properties of ceramics obtained by sintering of oxide powders. This first of all manifests itself as a change in the adhesive properties of the interfaces between the initial reagent and product, as well as an increased concentration of diffusant on the product surface. Besides, it was shown that diffusion of molybdenum and tungsten in such systems occurs faster compared to diffusion of calcium, strontium and lead, which contradicts the commonly accepted electrotransport models. Neiman and Guseva²⁶¹ assumed that molybdenum and tungsten diffuse as constituents of ‘multiparticle defect complexes’ and pointed to a marked dependence of the transfer rate on the substrate porosity. Based on the aforesaid, it was concluded that MoO_3 (WO_3) interact with the reaction product as wetting agents, thus forming a thin layer of the ‘surface phase’, which accelerates ion transfer.

Studies on the synthesis of tungstates and molybdates in an electric field involving unidirectional diffusion of MoO_3 and WO_3 revealed an abnormally strong effect of the electric field on the reaction kinetics, as well as a ‘non-Faraday behaviour’ of the reaction and a nonmonotonic dependence of the reaction rate on the voltage applied.^{262–264} Similar phenomena were also observed in studies of the interaction of (i) molybdenum and tungsten oxides with trivalent bismuth oxide²⁶⁵ and vanadium and niobium oxides,^{266, 267} (ii) V_2O_5 and Nb_2O_5 with rare-earth element oxides,²⁶⁸ (iii) Bi_2O_3 with transition-metal oxides²⁶⁹ and (iv) indium, gallium and chromium oxides with Al_2O_3 and ZrO_2 .^{270, 271}

Following a parallel between transfer in solids and fluids, it is appropriate to discuss the interrelation between anomalous transport properties of grain boundaries (see above) and high ionic mobility in globular hydrates whose structure was described above.

Water molecules filling the intergrain space of these compounds are bound to the surface only by weak coordination and hydrogen bonds. Therefore, water molecules are in a highly mobile state.^{66, 71, 74, 189} At the same time, defect formation occurs on the surface of the hydrated particle (see above). This process is accompanied by passage of a fraction of the surface cations and anions into the newly formed solution, which, under some assumptions, can be treated as an individual phase. Ionic constituents of this phase also possess high mobility. Therefore, they can exchange with ease, as solid particles contact the surrounding real solution. (This is also the reason for the conducting properties of such compounds.^{54, 71, 101}) For instance, the following process is to some extent possible:

since hydroxyl groups in $\text{SnO}_2 \cdot n\text{H}_2\text{O}$ can undergo dissociation by the acid mechanism.

The intergrain space of a globular hydrate is filled with a solution of composition $y\text{H}^+ \cdot n\text{H}_2\text{O}$, which is responsible for high proton conductivity of this compound (it can be as high as $3 \times 10^{-4} \text{ S cm}^{-1}$ at room temperature). This solution is an analogue of the charged defect layer near the surface of the oxide phase. Proton transfer in the solution filling the intergrain space of globular hydrates is similar to that occurring in aqueous solutions and proceeds by the Grotthus mechanism.¹⁷⁵ Related phenomena are also responsible for the conductivity of finely dispersed zirconium hydrogen phosphate (proton mobility on the surface of this compound is four orders of magnitude higher than in the bulk phase⁶⁶) and insoluble alkali metal tungstophosphates.^{74, 120}

The above-mentioned structural features of globular hydrates determine fast ion transport and the occurrence of chemical reactions involving only active surface groups. For the most part the exchanging ions migrate in the intergrain space along grain boundaries. Typical examples of chemical transport in globular hydrates are provided by numerous ion-exchange reactions occur-

Figure 8. Schemes of mass transport along (*a*) and normal to (*b*) the interface.²⁵⁶

ring in hydrated oxides^{54, 55, 71, 101} and hydrates of heteropolyacids.^{74, 120, 272}

Similar reactions are also observed in the course of chemical transport in the case of conventional polymeric membrane materials.^{9, 273} Defect formation in them occurs mostly at the interface between the polymer matrix and solution filling the conducting channels.

If a transport process involves mass transfer across the interface between two crystals (Fig. 8b), an additional potential difference is produced, which hinders the process. This phenomenon is analogous to the *p-n*-junction in semiconductors. Jamnik and Maier²⁵⁶ showed that, all things being equal, diffusion through the system containing an interface oriented normal to the flow direction is substantially hindered. A large proportion of the transferred mass is concentrated at the interface between two crystals.

However, real processes involving chemical transport along the normal to the interface are much more diverse. The interphase interaction can also cause an acceleration of mass transfer in this direction. In particular, studies on the proton/alkali-metal-cation exchange reactions in titanium and zirconium hydrogen phosphates revealed a strong dependence of the reaction kinetics on pH value of the solution contacting the solid phase. The exchange rate is limited by two-dimensional counterdiffusion of the exchanging cations through the newly formed product layer.²⁷⁴ The second stage of exchange is controlled by proton diffusion. Changes in the pH value in the course of the exchange reaction

cause a decrease in the calculated cation diffusion coefficient (*D*) in the $\text{Na}_2\text{Zr(PO}_4)_2 \cdot 3\text{H}_2\text{O}$ layer by three orders of magnitude and more (Fig. 9).^{275, 276} For alkali solutions this is due to defect formation on the surface of crystals,²⁷⁵ which to a first approximation can be described by the following quasi-chemical reactions:

The former process is predominant in weak alkaline solutions. It is accompanied by the formation of a negatively charged surface layer with a high concentration of proton vacancies. The charge of the layer can be compensated upon sorption of cations on the surface of the solid phase. At higher pH ($9 < \text{pH} < 11$), the concentration of vacancies increases and this charge compensation mechanism is no longer efficient. Therefore, insertion of sodium ions into the interstices or abstraction of anions from the

Figure 9. Calculated coefficient of cation diffusion in a $\text{Na}_2\text{Zr(PO}_4)_2 \cdot 3\text{H}_2\text{O}$ layer plotted vs. the pH value of the contacting solution.

surface occur simultaneously. The change in the main mechanism of defect formation is accompanied by changes in the slope of the plot of the logarithm of the diffusion coefficient vs. the pH value (see Fig. 9). Proton vacancies formed in the course of the process migrate into the interior of the crystal along with the oppositely charged sodium cations. In this case the concentration of proton defects in the bulk of the solid phase is related to their concentration on the surface.⁷⁶ In turn an increase in the concentration of charge carriers causes an increase in the diffusion coefficient.

At $\text{pH} < 7$, the slope of the plot of the logarithm of the diffusion coefficient vs. the pH value changes its sign (see Fig. 9). This means that proton interstices become the main type of defects in this range of pH values. They can be formed in the reaction

As we approach the equilibrium position in the second stage of the H^+/Na^+ exchange on zirconium hydrogen phosphate (it is attained in the region $4 < \text{pH} < 6$ ⁷⁶), the proportion of proton interstices increases and approaches the equilibrium value when two phases, $\text{NaHZr(PO}_4)_2 \cdot 5\text{H}_2\text{O}$ and $\text{Na}_2\text{Zr(PO}_4)_2 \cdot 3\text{H}_2\text{O}$, contact each other. Thus, defect formation occurs mainly at the interface between two solid phases while the proton interstices diffuse into solution through the $\text{Na}_2\text{Zr(PO}_4)_2 \cdot 3\text{H}_2\text{O}$ layer.^{76, 275}

Using a relation proposed⁷⁶ for nonlinear diffusion allowed a description of the defect distribution throughout the sample bulk (excluding the electrical double layer) in different stages of ion exchange (Fig. 10). Proton interstices are the main type of defects in acid media (Fig. 10a). The exchange process is determined by counterdiffusion of proton interstices and sodium ions. In the case of alkali solutions the diffusion layer can be divided into two regions (Fig. 10b). In the region adjacent to the unsubstituted $\text{NaHZr(PO}_4)_2 \cdot 5\text{H}_2\text{O}$ phase, counterdiffusion of proton interstices and sodium ions predominates, whereas counterdiffusion of proton vacancies dominates in the region near the alkali solution. In the latter case the exchange is determined by parallel diffusion of sodium ions and proton vacancies. At a point characterised by equal concentrations of proton vacancies and interstices, they annihilate and the main type of charge carriers changes.

A significant effect of anions present in solution on the kinetics of H^+/Na^+ ion exchange on zirconium hydrogen phosphate has

Figure 10. Change in the defect concentration (*c*) with the length of the diffusion layer of $\text{Na}_2\text{Zr(PO}_4)_2 \cdot 3\text{H}_2\text{O}$ (*l*) contacting a solution with pH 4 (a) and 11 (b):⁷⁶ interstitial sites (1) and vacancies (2).

been reported.^{277,278} The rate of exchange increased with an increase in the sorption ability of anions on the surface of zirconium phosphate in the series $\text{NO}_3^- \approx \text{ClO}_4^- < \text{SO}_4^{2-}$ and $\text{I}^- < \text{Br}^- < \text{Cl}^-$. The increase in the rate of exchange is due to the necessity of compensating the charge of proton vacancies on the surface of the double phosphate. A possible mechanism involves desorption of phosphate ions from the surface, which becomes easy because of sorption of anions bearing a smaller charge on the free surface sites.^{277,278}

These effects are much less pronounced in the case of the interaction between exchange products with different degrees of substitution. Such effects were detected in studies of the kinetics of ion exchange and ionic conductivity in the $\text{NaHZr}(\text{PO}_4)_2 \cdot n\text{H}_2\text{O} - \text{H}_2\text{Zr}(\text{PO}_4)_2 \cdot \text{H}_2\text{O}$ and $\text{Na}_2\text{Zr}(\text{PO}_4)_2 \cdot m\text{H}_2\text{O} - \text{NaHZr}(\text{PO}_4)_2 \cdot n\text{H}_2\text{O}$ systems and by analysing the ^{23}Na NMR spectra.^{84,87}

IV. Transport equations

1. The basic systems of equations

In deriving transport equations using the thermodynamics of nonequilibrium processes the membrane material is considered as a 'black box', since initially no information on its thermodynamic, structural and kinetic parameters is available. In the equilibrium state the electrochemical potential, $\tilde{\mu}_i$, of the i th component has a constant value at any point of the system. If the electrochemical potential gradients, $d\tilde{\mu}_i/dx$, differ from zero (for simplicity we consider a one-dimensional transfer along the normal to the membrane surface), fluxes (J_i) of the i th particles appear in the system. At small deviations from the equilibrium, the fluxes and forces inducing them are linearly related.^{279–281} With allowance for the fact that the force $d\tilde{\mu}_j/dx$ exerted on particles of the j component can cause transfer of the particles of the i component (e.g., electromigration of ions causes transfer of water, or electroosmosis), we get the Onsager equation

$$J_i = - \sum_j L_{ij} \frac{d\tilde{\mu}_j}{dx}. \quad (15)$$

Determination of the phenomenological transfer coefficients, L_{ij} , is complicated by the fact that the number of these coefficients is rather large even for simple systems. For instance, for a membrane contacting a binary electrolyte solution one has to know six transfer coefficients. In addition, the local coefficients L_{ij} are functions of the local concentration of the so-called 'virtual solution'. The virtual solution was first introduced by Kedem and Katchalsky²⁸² and was called the 'Corresponding Solution'. This is a hypothetical solution, which is in equilibrium with a certain membrane layer.

The generalised electrochemical potential, $\tilde{\mu}_i$, in Eqn (15) can be represented as a function of the concentration (or activity a_i), electric potential ϕ and pressure p of the virtual solution

$$\tilde{\mu}_i = \mu_i^0 + RT \ln a_i + z_i F \phi + \bar{V}_i p, \quad (16)$$

where z_i is the charge, F is the Faraday number and $\bar{V}_i$ is the partial molar volume of the ions i .

To determine the local L_{ij} values characterising a thin membrane layer of thickness dx from the experimental integral values of the transfer coefficients characterising the whole membrane, the membrane must be macrohomogeneous,^{283,284} i.e., the L_{ij} values must be independent of the layer coordinate dx provided that each layer dx is in equilibrium with the same solution. Figure 11 presents the dependences of the L_{ij} coefficients on the concentration of the equilibrium NaCl solution obtained for a perfluorocarbon membrane Nafion-120 containing sulfonic acid groups. These coefficients were calculated²⁸⁵ using the data reported by Narebska *et al.*^{286,287} who carried out six experiments on measurements of the specific conductivity, apparent transport

Figure 11. Phenomenological coefficients L_{ij} for a Nafion-120 membrane plotted vs. concentration of the equilibrium NaCl solution;²⁸⁵ (a): $10^{10} L_{++}$ (1), $10^9 L_{+w}$ (2), $10^8 L_{ww}$ (3); (b): $10^{11} L_{--}$ (1), $10^{10} L_{-w}$ (2), $10^{11} L_{+-}$ (3), $10^{11} l_1$ (4) ($l_1 = L_{+-} - m M_w L_{-w}$, where m is the molality of the equilibrium solution, M_w is the molecular mass of water); the subscripts '+' and '-' refer to the cation and anion, respectively, and the subscript 'w' refers to water.

numbers, salt diffusion, osmotic and electroosmotic fluid flows, as well as the fluid flow due to the hydrostatic pressure drop.

The choice of fluxes (J_i) and corresponding thermodynamic forces (F_i) in the transfer equations of nonequilibrium thermodynamics is not arbitrary: if J_i and F_i are chosen correctly, the sum of their products must be equal to the dissipative function (product of the absolute temperature and the rate of entropy production per unit volume of the membrane^{279–282})

$$T \frac{ds}{dt} = \sum_i J_i F_i, \quad (17)$$

where $s = S/Ad$, S is the entropy of the adiabatic system comprised of the membrane and two adjacent solutions, A is the surface area and d is the membrane thickness. In our case the thermodynamic force has the form

$$F_i = - \frac{d\tilde{\mu}_i}{dx}.$$

It is of importance that we can choose the forces and fluxes, since this allows an appropriate description of various aspects of membrane transport phenomena. For instance, the Onsager equation, Eqn (15), is convenient for theoretical analysis since the equilibrium condition corresponds to the absence of external forces ($d\tilde{\mu}_i/dx = 0$); the well-known Nernst–Planck equation (see below) also follows from Eqn (15); finally, the contribution of coupled effects can be estimated by comparing the L_{ij} values,²⁸⁶ since these coefficients are of the same dimension. At the same time the L_{ij} coefficients are related in a complex manner to the measurands (membrane conductivity, diffusion permeability, etc.). The use of equations similar to Eqn (15) presents some difficulties in description of transfer phenomena with a pronounced convective component.²⁸⁸

A large number of equations were proposed^{288–292} in addition to the Onsager equation to allow for the coupled effects. For instance, the Stefan–Maxwell equations can be treated as an empirical generalisation of the transfer equations for ideal gases.²⁹³ One can also derive these equations from the statistical mechanics equations in the framework of the microscopic approach. The possibility of using particle velocities instead of the flux densities and applying the pressure gradient in explicit form as the driving force also makes them convenient for the description of convective transfer.^{294–296}

The so-called ‘frictional’ model of mass transport is based on an analogy between the motion of particles (ions, molecules) in a continuous medium and the motion of bodies in a viscous fluid. Spiegler²⁸⁹ was the first who applied this theory to membranes; more recently, it was developed by other researchers.^{297, 298} Other applications (transfer in ionic solutions and melts) were generalised in a monograph.²⁹⁰ Studies by Meares *et al.*²⁹⁷ and by Narebska *et al.*^{286, 287} showed that the friction coefficients, f_{ij} , are also concentration dependent, though to a somewhat lesser extent compared to the L_{ij} coefficients.

2. The Kedem–Katchalsky system of equations

Let us analyse the Kedem–Katchalsky system of equations, which is of prime interest for a practical description of transfer through membranes.^{282, 283, 299} The Kedem–Katchalsky equations are written in the form²⁸⁵

$$J_v = -L_p \left(\frac{dp}{dx} - \sigma_s RT c_s v \frac{d \ln a_{\pm}}{dx} \right) + \beta I, \quad (18)$$

$$J_i = -c_i L_p (1 - \sigma_s) \frac{dp}{dx} - \omega \frac{d\pi}{dx} + \frac{It_i}{z_i F} = \quad (19)$$

$$= -c_i L_p (1 - \sigma_s) \frac{dp}{dx} - P \frac{dc_i}{dx} + \frac{It_i}{z_i F},$$

$$\frac{d\varphi}{dx} = -\frac{I}{\kappa} - \frac{RT}{F} \left(\frac{t_+}{z_+} \frac{d \ln a_+}{dx} + \frac{t_-}{z_-} \frac{d \ln a_-}{dx} - \right. \quad (20)$$

$$\left. -\beta c_s v_i F \frac{d \ln a_{\pm}}{dx} \right) - \beta \frac{dp}{dx}.$$

Here J_v is the volume flux density of the solvent; J_i is the flux density of the ions i ; I is the current density; c_i and c_s are the molar concentrations of the ions i and the salt in the virtual solution within the membrane, respectively; $a_{\pm}$ is the mean ionic activity, π and p are the osmotic and hydrostatic pressures in the virtual solution, respectively; v_i is the stoichiometric number of the ion i and φ is the electric potential.

The conducting properties of a membrane are characterised by six local transport coefficients. These are the specific conductivity, κ ; diffusion permeability, P or ω ; hydraulic permeability, L_p ; the transport number of the counterions, t_+ ; electroosmotic permeability, β ; and the Staverman reflection factor, σ_s , which varies from zero to unity for non-rejecting to perfect membranes, respectively.

The convenience of the practical application of Eqns (18)–(20) can be demonstrated taking Eqn (20) as an example. Here, we can distinguish with certainty between three components of the electric potential gradient, *viz.*, the ohmic (first term), diffusion (second and third terms) and the streaming potentials due to the osmotic and hydrostatic pressure drop driven transfer (fourth and fifth terms, respectively).

It should be noted that the above-mentioned systems of transfer equations including the Onsager and Kedem–Katchalsky equations are mathematically equivalent,¹ since passage from one system to another can be done by simply substituting variables.

3. The Nernst–Planck equation

The Nernst–Planck equation is most widely used in the theory of transport in membranes. This equation has a somewhat simpler form compared to the equations used in theory of nonequilibrium processes but takes into account only two main components of transfer, namely, diffusion and electromigration. It can be derived from the Onsager equation (15) assuming that the cross-coefficients are equal to zero.^{289, 290} It is of interest to consider diffusion on the microscopic level by applying the random walk theory to particular ions or vacancies.³⁰⁰ This permits an alternative examination of the Nernst–Planck equation.

Suppose that hopping occurs by jumps of equal length λ and that the i th ion can execute stochastic jumps in any direction irrespective of the preceding jumps, the hopping probability for any direction being constant. Then, the particle flux density along some direction is described by the Fick equation with the self-diffusion coefficient D

$$D_i = -\frac{\omega \lambda^2}{6}, \quad (21)$$

where ω is the hopping frequency, which depends on the escape frequency of the ion from the potential well (v) and on the number, n , of the nearest potential wells accessible to the ion through a single jump

$$\omega = vn; \quad (22)$$

n is the number of the nearest sites accessible to a given ion in the crystal structure or the number of fixed functional groups in an organic ion exchanger. For the vacancy mechanism of transfer n equals the number of ions in the nearest environment of a vacancy.

In the case of stochastic self-diffusion in a constant external electric field, E , directed along a particular axis x ,

$$E = -\frac{d\varphi}{dx},$$

the resultant flux of the ions i through a unit of area can be defined in the same manner as in Eyring’s theory of absolute reaction rates

$$J = \frac{\lambda}{2\sqrt{3}} nv \left[c_1 \exp\left(-\frac{zF\Delta\varphi}{2RT}\right) - c_2 \exp\left(\frac{zF\Delta\varphi}{2RT}\right) \right], \quad (23)$$

where c_1 and c_2 are the ion concentrations on the left and on the right with respect to the barrier under study. If the electric field is not too strong ($|\Delta\varphi| \ll RT/F \approx 25$ mV at room temperature), by expanding the exponents in Eqn (23) in a series and restricting ourselves to the first two terms of the expansion, we get the Nernst–Planck equation

$$J = -D \left(\frac{dc}{dx} + zc \frac{F}{RT} \frac{d\varphi}{dx} \right). \quad (24)$$

In the absence of the concentration gradient ($dc/dx = 0$) Eqn (24) takes the form

$$J = -Dzc \frac{F}{RT} \frac{d\varphi}{dx}. \quad (25)$$

Using the ion mobility u , the parameter J can be represented in the form

$$J = -cu \frac{d\varphi}{dx}. \quad (26)$$

From Eqns (25) and (26) one can get the Nernst–Einstein relationship

$$u = D \frac{zF}{RT}. \quad (27)$$

The Nernst–Planck equation is of great importance for transport theory; however, it is of limited utility. The most important conclusions reported by Buck³⁰⁰ and other researchers^{13, 51, 301–311} who examined limitations of this equation are as follows.

1. The microscopic approach to the derivation of the Nernst–Planck equation implies averaging over a rather large number of jumps, *i.e.*, from the molecular standpoint a membrane should be a homogeneous medium. Application of the Nernst–Planck equation to thin biomembranes, membranes with narrow (on the molecular scale) conducting channels and mosaic membranes seems to be hardly probable. The energy profile of the ion moving across a biomembrane can exhibit only 3–4 barriers;^{301, 302} therefore, in this case the absolute reaction rate method is more appropriate for description of ion transport.^{300, 303}

2. The Nernst–Planck equation should also not be applied at times shorter than the time necessary for averaging fluctuations of the external force exerted on an ion.³⁰⁰ One of the fastest processes suitable for description by the Nernst–Planck equation is relaxation of the space charge in the electrical double layer at the interface between two electrolyte solutions or at the electrolyte solution/electrode interface.³⁰⁶ The relaxation time

$$\tau = \frac{\lambda^2}{D}$$

(λ is the Debye length) is of the order of 10^{-8} – 10^{-9} s for solutions with an electrolyte concentration of 10^{-2} – 10^{-3} mol litre⁻¹.

3. As mentioned above, transport processes can be controlled by ion diffusion across the interface,^{13, 51, 300, 304, 305} which is associated with a particular chemical reaction, rearrangement of the hydration shell, overcoming of the Coulomb barrier by multiply charged counterions, *etc.* In the last case the potential barrier can be much higher than in the bulk of the corresponding phase, while the potential jump $|\Delta\phi|$ at the interface (overvoltage at the interface) can be comparable with the overall potential jump in the membrane system. In this case the condition

$$|\Delta\phi| \ll \frac{RT}{F},$$

necessary for the approximated expression of the exponents in Eqn (23) is broken and, hence, Eqn (24) is no longer valid.

4. Equation (24) was derived assuming a stochastic motion of ions and that each succeeding jump is independent of the preceding one. However, this assumption is often not true. Particle diffusion in crystals,³⁰⁷ ion exchangers^{51, 301–303, 311} and solutions⁵¹ involves correlated successive jumps of individual species. In the case of low-concentration vacancy diffusion it is more probable for an ion to return to the initial site than to jump in another direction. Due to such a correlation the distance from the initial site travelled by the ion after n jumps will be shorter than the ion displacement caused by stochastic diffusion. In the Nernst–Planck equation the diffusion coefficient depends on the microscopic-scale transfer mechanism (self-diffusion or conduction). It seems plausible that this can be interpreted as a dependence of D on the nature of the driving force of transfer. This dependence, which is sometimes interpreted as violation of the Nernst–Einstein relationship, is taken into account using the apparent correlation coefficient

$$f = \frac{D_{id}}{D_{ie}}, \quad (28)$$

where D_{id} and D_{ie} are the experimental diffusion coefficients determined in the self-diffusion and conduction studies, respectively. The f value primarily depends on structural features and varies for ionic crystals from 0.5 to nearly unity.³⁰⁸ For the relay transfer mechanism the f value can be much less than 0.5. The f

values for a number of ion exchangers have been documented.^{1, 51, 308}

5. Stochastic diffusion and conduction studies revealed some differences between the interaction of an ion with the ionic atmosphere.^{309, 310} Diffusion is accompanied only by the relaxation drag effect, which is due to the finite time of annihilation and creation of the ionic atmosphere (relaxation time). In the case of conduction in an external electric field an ion moves through the ionic atmosphere moving in the opposite direction rather than in an immobile medium. Therefore, the ion experiences the drag effect due to both relaxation and electrophoresis.^{309, 310}

6. A significant drawback of the Nernst–Planck equation is that it does not include the parameters of water transfer and the streaming potential, which are important characteristics of biomembrane processes and electrodialysis of concentrated solutions.³¹¹ In addition, some coupled effects due to the ‘frictional’ interaction between the mobile and fixed ions and molecules are also ignored. In particular, this drawback sometimes precludes the use of the Nernst–Planck equation for characterisation of ion-exchange membranes.²⁸⁵

Notwithstanding the above-mentioned limitations, the Nernst–Planck equation has found a wide field of applications. It is used for the description of transfer in liquids, solids and gels, in the bulk of the corresponding phases and at the phase boundaries. Given the activity coefficients and cross coefficients, the field of applications of this equation is extended even more. If a phase boundary can be considered as a quasi-equilibrium one, the Nernst–Planck equation is transformed into the Boltzmann and Donnan equations. As applied to electric transfer and diffusion, it is transformed into the Ohm and Fick laws, respectively. The Nernst–Planck equation describes both steady-state and non-steady-state processes including such fast phenomena as the space charge relaxation. This equation can be readily combined with other equations, which describe conjugated chemical reactions, ion and molecular association and dissociation, adsorption and the space charge formation. Combining the Nernst–Planck equation and the equations describing the hydrodynamics of a solution adjacent to the membrane permits construction of mathematical models for assessment of the role of concentration polarisation in the membrane transfer processes.

4. Generalisation of the Nernst–Planck equation

Often it is convenient to use the ion transfer equation, which is analogous to the Nernst–Planck equation but includes some coupled effects. Such an equation is obtained by substituting Eqn (20) into Eqn (19) at $dp/dx = 0$ assuming a linear relation between individual ion activity coefficients and the average ion activity coefficient²⁸⁵

$$J_i = -P_i \frac{dc_i}{dx} - \frac{z_i}{|z_i|} u_i c_i \frac{d\phi}{dx}, \quad (29)$$

where P_i is the individual local membrane permeability to diffusion of the ion i and u_i is the mobility of the ion i in the membrane. Both coefficients are explicit functions of the experimentally measurable parameters (transport numbers, conductivity, diffusion permeability and electroosmotic permeability of the membrane). This significantly simplifies the determination of the coefficients in Eqn (29). The advantage of this equation is that it implicitly (through a membrane’s electroosmotic permeability) includes the effect of the streaming potential (and, hence, water transport) on the ion transfer. Finally, when using the virtual solution, there is no need to calculate the potential jumps at the membrane/solution interface and sometimes no need to determine the actual ion concentrations in the membrane.

Comparison of the Onsager and Kedem–Katchalsky equations allows one to relate the corresponding transfer coefficients.²⁸⁵ It is possible to obtain six relations for six pairs of coefficients. Some of the relationships are known. For instance, one of them expresses the specific conductivity of a membrane (the

Kedem–Katchalsky coefficient) through the L_{ij} coefficients in the Onsager equation.^{312–314} The following approximate equation between the Kedem–Katchalsky transport coefficients was obtained²⁸⁵ neglecting the cross-coefficients that describe the interaction of coions with counterions (L_{+-}) and water (mM_wL_{-w}) in one relationship

$$P = \frac{2RT\kappa t_{+ap}\gamma}{F^2c}, \quad (30)$$

where t_{+ap} is the apparent transport number of the counterions and γ is the activity factor.²⁸⁵

Equation (30) is a generalisation of the Nernst–Einstein relationship to osmotic and electroosmotic transport of water across a membrane. To use this equation, one should know the values of all parameters. These values are hard to determine. Nevertheless, many authors^{36,285,312–316} used and tested this equation under different conditions, mainly assuming that $t_w = 0$ and $t_{+ap} = t_+$. A rigorous study²⁸⁵ of the Nafion-120, MF-4SK and MK-40 membranes revealed that the coefficient l_1

$$l_1 = L_{+-} - mM_wL_{-w}$$

has a positive value (see Fig. 11b). This means that the first term (L_{+-}) describing the interaction between differently charged ions is larger than the second term (mM_wL_{-w}), which describes the interaction between coions and water. Following Kedem and Perry,³¹³ these membranes can be considered as hydrophobic. If $l_1 = 0$, both types of interaction are mutually cancelled out and relationship (30) should be exactly fulfilled. The case $l_1 < 0$ has been studied.³¹³

Using relation (30), Eqn (29) can be transformed into a transfer equation, which is even more similar to the Nernst–Planck equation,²⁸⁵

$$J_i = L_i \left(b_i RT \frac{d \ln c_i}{dx} + z_i F \frac{d\phi}{dx} \right), \quad (31)$$

where the L_i and b_i coefficients are explicitly expressed through t_i and κ . Here, the b_i coefficients tend to unity at c_i tending to zero and depend on the transport numbers of the ions and water.²⁸⁵ The distinction between Eqn (31) and the Kedem–Katchalsky equation [Eqn (19)] is that the former ignores the interaction of coions with counterions and water. The advantage of Eqn (31) is its applicability to polyionic systems.

It should be noted that the electric potential gradient in Eqn (31) includes the streaming potential due to convective transfer driven by the hydrostatic and osmotic pressure gradients [see Eqn (20)]. Therefore, Eqn (31) implicitly takes into account the effect of osmotic volume transfer on the ion transport. In the so-called ‘extended’ Nernst–Planck equation these components are included in an explicit form in the convective term^{11,317–320}

$$J_i = -D_i \left(\frac{dc_i}{dx} + c_i \frac{d \ln \gamma_i}{dx} + z_i c_i \frac{F}{RT} \frac{d\phi}{dx} \right) + c_i \vartheta, \quad (32)$$

where γ_i is the ion activity coefficient and ϑ is the linear velocity for transfer of the centre of mass of the fluid, while the concentration and electric potential refer to the whole membrane. In the calculations, ϑ is assumed to be proportional to the electric potential and hydrostatic pressure gradients;¹¹ it can also be found experimentally when determining the volume flux through the membrane.³²⁰

Equation (30) and analogous relations,^{315,316} which generalise the Nernst–Einstein equation, are used for characterisation of ion-exchange membranes;^{285,316,321} it is more easily to calculate the transport number, t_i , from the readily measurable κ and P values than to determine it by directly measuring the ion fluxes.³²²

5. Particle diffusion kinetics of ion exchange

The kinetics of ion exchange in systems containing inorganic ion exchangers are most often studied assuming that the process is controlled by diffusion within the grain, since diffusion in solutions occurs much faster. The quantitative description of diffusion processes is complicated by the necessity of collecting a fraction of particles (crystals) of a prescribed size, which can vary over a wide range in the course of the exchange. The interdiffusion coefficients of the ions involved in the process can also change as the process is developed. This can be due to both a gradual change in the concentration of the ions of different mobility in the material under study and to the change in the characteristic size of channels and pores in the ion exchanger matrix.⁵⁵ Changes in the defect concentration in the bulk of the ion exchanger with consumption of the active component in solution can also appear to be important.⁹ Nevertheless, in most cases the kinetics of exchange are described ignoring these factors.

Among the pioneering studies concerned with generalisation of the equations of transfer to objects of various geometry with inclusion of different boundary conditions was that reported by Barrer.³²³ Most often, the transport phenomena occurring when an ion exchanger contacts external solution are described by the relation proposed by Boyd *et al.*³²⁴ for diffusion in a homogeneous grain. The necessary conditions are as follows: (i) exchange occurs through the formation of a continuous series of solid solutions, *i.e.*, it does not involve any phase transitions and (ii) the grain/solution interface is in local thermodynamic equilibrium. The equation for a spherical grain has the form

$$F = 1 - \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left(-\frac{D t \pi^2 n^2}{R^2}\right), \quad (33)$$

where F is the fractional attainment of equilibrium, D is the interdiffusion coefficient of the ions within the grain, t is the time and R is the radius of the ion exchanger particles. The series in this equation rapidly converges for large values of F . Mention may be made that this relationship can be derived from the Fick law,^{11,325} which is a particular case of Eqn (19).

Formula (33) was used for the determination of the cation diffusion coefficients in various ion exchangers.⁵⁵ A somewhat modified relation in the differential form was proposed,⁸⁶ which includes an additional term to take into account changes in the defect formation conditions upon exchange.

In many inorganic ion exchangers the exchange processes are accompanied by changes in the phase composition. In this case the initial phase coexists with the newly formed one. The process involves a gradual movement of the interface into the interior of the grain. After solving the problem of motion of a particle in the crystal field with a periodic potential in the presence of a chemical potential gradient a relation was proposed for the determination of the diffusion coefficients from the data on the kinetics of ion exchange. In the case of two-dimensional diffusion (cylindrical grain approximation), *e.g.*, ion exchange in layered phosphates of some polyvalent metals, the relation has the form³²⁶

$$J = \frac{2\pi c D h \Delta\mu}{RT} \ln \frac{r_0}{r}, \quad (34)$$

where c is the concentration of the mobile ions, h is the characteristic size of the ionite particle, $\Delta\mu$ is the chemical potential difference of the exchanging ions between the surface of the crystal and the interface between the initial and newly formed phases, r is the grain radius and r_0 is the radius of the domain of the initial phase retained within the grain.

If exchange occurs through a flow of an alkali solution to crystalline α -zirconium hydrogen phosphate, the calculated interdiffusion coefficient varies by three orders of magnitude.⁷⁶ The reason is a dramatic change in the alkali concentration, which causes changes in the defect formation conditions. A relation proposed^{76–84} to describe all processes occurring in the system

and the concentration distribution of various defects in the product layer is more sophisticated than Eqn (34).

It should be noted that systems with organic ion exchangers often exhibit a mixed-diffusion type of exchange. The limiting stage of such a process can change with the solution concentration, namely, transfer in dilute solutions is controlled by the diffusion through the outer diffusion layer, while transfer in concentrated solutions is controlled by intradiffusion.^{11, 327–329} Nevertheless, experimental studies on ion exchange, counterdiffusion across a membrane or diffusion of one electrolyte (dialysis) provide information necessary for the determination of the diffusion coefficients^{330, 331} and selectivity of ion-exchange membranes.³³² In the case of organic membranes characterised by rather high permeability with respect to water one should take into account the osmotic transfer of water and the corresponding streaming potential.^{328, 329, 333}

6. Continuum models

Formal description of transfer processes involving treatment of a membrane as a ‘black box’ prevents the static and kinetic properties of membranes from being related to their structural features. Knowledge of such a relation is necessary to gain a better insight into the selectivity mechanism of membrane transport, dependence of the transport properties on the concentration, electric current, *etc.* This information is also necessary for chemists to obtain membranes with prescribed properties.

A large number of models relating the structural and kinetic properties of membranes have been proposed. These models can be divided into two large groups. These are the heterogeneous models, which treat a membrane as a multiphase system and characterise each phase by specific structural and kinetic parameters, and the continuum models, which concern continuous changes in the membrane properties taking into account only one phase (the membrane material can be multiphase; however, transfer in other phases is usually ignored).

The continuum models can be in turn divided into three groups:

(1) models, which treat a membrane as a single phase (charged gel); the static and kinetic parameters of the membrane (fixed ion concentration, ion diffusion coefficients, *etc.*) can continuously change with the coordinate and exhibit no explicit relation to the structural parameters;^{334, 335}

(2) capillary models,³³⁶ which are also known as the space charge models^{253–255, 337–345} in which transfer is considered to be within capillary pores with charged walls;

(3) models based on percolation theory;^{346–348} in this case the ion transfer is simulated by flow of a fluid through a system of voids connected by narrow channels.^{13, 346}

The capillary models provide the most detailed information on the transport parameters and are based on information on the membrane structure. They were first developed to describe the electrokinetic phenomena in microcapillaries with charged walls.^{254, 336} More recently,^{253–255, 337–345} they were improved and adapted for the description of the membrane transfer phenomena. These models permit the inclusion of rather subtle effects, *viz.*, changes in the dielectric constant with the distance from pore walls,³³⁷ adsorption,^{254, 341–343 *etc.*}^{255, 344, 345} and consideration of various pore geometries (planar, cylindrical and spherical).³⁴⁰

The equation of transport in a pore schematically shown in Fig. 12 is written as the Nernst–Planck equation with the convective term (32) projected on the longitudinal (x) and normal (z) coordinates.^{337, 339} The diffusion coefficient of the ions in the solution confined within the pore is usually assumed to be equal to the diffusion coefficient in free solution. The cross-sectional distribution of the local concentration, $\bar{c}_i$, of the ions i in the pore is described by the Poisson–Boltzmann equation.^{253, 339, 340} The surface density of the electric charge, q , on the pore walls is $110–440 \text{ mC m}^{-2}$,^{42, 252, 349} while the pore radius varies from 0.5 to 5 nm.³³⁹

Figure 12. Schematic representation of the structure of a membrane containing parallel cylindrical pores with charged walls. The hatched area represents the insoluble polymer matrix.

The convective transfer rates, $\mathcal{Q}(r)$, were found by numerical solution to the Navier–Stokes equations.^{253, 255, 337–340, 344, 345} Determination of Onsager’s L_{ij} coefficients for the Nafion-120 membrane allowed^{338, 350} one ‘to bridge the gap’ between the two approaches, irreversible thermodynamics and model description. The parameters of the model (effective pore radius, fixed ion concentration per unit volume of the solution confined inside a pore and tortuosity factor) were chosen based on the results of the porosity, exchange capacity, membrane conductivity and membrane hydraulic permeability measurements.

The percolation theory^{13, 347, 348} is well adapted for the description of transfer in a system with a developed network of channels exhibiting both high and low ion transfer ability (clusters and cluster-connecting channels in perfluorinated membranes, respectively). This theory provides an explanation for the dependence of the membrane conductivity (κ) on the water content (w).^{351, 352} At low water content both clusters and channels are low hydrated and their mass-transfer resistance is so high that the former virtually do not contact one another. As the water content increases, a more and more increasing number of clusters becomes connected by channels, thus forming a network penetrating throughout the whole membrane. There is a threshold water content (percolation threshold, w_0) corresponding to the insulator–conductor transition. At $w < w_0$, the membrane conductivity is zero while at $w > w_0$, it increases exponentially.^{347, 348} A theoretical estimate of the exponent is 1.5 ± 0.2 for the three-dimensional system.³⁴⁸ The pre-exponential factor is determined by peculiarities of the ion–ion and ion–molecule interactions and by diffusion processes between two adjacent clusters.^{42, 351, 352} The percolation models for ion transfer and water transport in ion-exchange materials were developed by Timashev.¹³

7. Heterogeneous models

Analysis of the ion exchanger structure (see above) showed that the material contains more or less homogeneous regions, which are conventionally called phases.³⁵³ One phase comprises the electrically neutral solution, which fills both macroscopic structural defects (macropores, cavities, cracks) and central parts of mesopores (clusters in perfluorinated membranes also belong to this type of defect). The second phase, which is called ‘gel’,^{11, 354–356} is formed by an ensemble of micropores and the outer parts of mesopores containing fixed and mobile ions, water and polymer chains. Sometimes, the third (inert) phase, which is comprised of entangled hydrophobic polymer chains (the case of perfluorinated membranes) or inert binder used to improve the mechanical strength (*e.g.*, heterogeneous membranes MK-40 and MA-40) is taken into consideration.

The aim of simulation of transfer in a multiphase membrane is to determine particular physicochemical properties of each phase

Figure 13. Schematic representation of a two-phase microheterogeneous membrane.

The shaded area is the gel phase; shown are two length scales, a microscopic (δx) and a macroscopic one (dx).

and then to obtain characteristics of the whole membrane as functions of the properties of the individual phases. Let us consider a macroscopic volume, *e.g.*, a layer containing all phases of the membrane, which are in equilibrium with one another. The thickness of this layer, dx , is small as compared to the membrane thickness (Fig. 13). In the framework of the thermodynamics of nonequilibrium processes the equations of transfer for each phase k and for the whole layer of thickness dx can be written in the form

$$J_i^{(k)} = -L_i^{(k)} \frac{\delta \tilde{\mu}_i}{\delta x}, \quad (35)$$

$$J_i = -L_i^* \frac{d\tilde{\mu}_i}{dx},$$

where $\delta \tilde{\mu}_i$ and $d\tilde{\mu}_i$ are the changes in the electrochemical potential between points separated by the distance δx within the phase k and by the layer dx , respectively. The problem can be formulated in the following way: to determine the effective coefficient L_i^* for the membrane layer as a function of the $L_i^{(k)}$ coefficients, which characterise individual phases, and the geometric parameters, which describe the shape and mutual position of the phases.

Search for the functions relating the effective conductivity to the corresponding characteristics of individual phases for various transfer phenomena (conduction, diffusion, heat transfer, *etc.*) has been ongoing for many years. As long ago as 1873 Maxwell³⁵⁷ reported a solution to the problem of conduction in a conducting medium containing widely separated spheres whose specific conductivity differs from that of the medium. Studies by Rayleigh,³⁵⁸ Landau and Lifshitz,³⁵⁹ Bier, Lichnecker and Roter (see references cited in Ref. 360) and other researchers^{361–366} who contributed largely to the solution to this problem should be pointed out. The results obtained were generalised in a hypothesis called the ‘generalised conduction principle’,³⁶¹ according to which the function relating L_i^* to $L_i^{(k)}$ is independent of the nature of both the force exerted on the heterogeneous system and the substance transferred.

The structure of ion-exchange membranes was described using various approaches,^{11, 354–356, 363} which were analysed in some reviews.^{9, 362, 364} In the early stage, heterogeneous structural–kinetic models for the description of the shape and mutual arrangement of phases included a rather large number of parameters, which made their use difficult. Gnusin and Grebenyuk³⁵⁴ proposed the so-called three-channel model for charge transfer in inhomogeneous membranes. They distinguished three types of conducting channels: gel segments, gel-connecting channels and the mixed channel. The model permitted a correct description of

the concentration dependence of a membrane’s specific conductivity; however, it required knowledge of three independent geometric parameters. More recently, Gnusin *et al.*³⁶⁵ developed a two-parameter procedure for description of the geometry of the system. Yet another stride taken towards the development of heterogeneous models was the passage from a particular type of force (electric or diffusion) exerted on the system to the generalised force in the form of the electrochemical potential gradient.³⁶⁶ A so-called ‘microheterogeneous model’, which included both improvements mentioned above, was developed.^{36, 366–369}

The basic principles of the ‘heterogeneous interstitial solution’ model³⁷⁰ are similar to those of the microheterogeneous model described below. For simplicity, let the ion exchanger be a two-phase system comprised of the gel phase and the gel-connecting channels filled with the equilibrium solution, the volume fractions of the phases being f_1 and f_2 , respectively. By writing the equation of transfer for each phase and using the continuity condition for the electrochemical potential at the interface one can obtain the equation in the framework of the microheterogeneous model^{36, 366}

$$L_i = [f_1 \bar{L}_i^\alpha + f_2 (L_i^*)]^{1/\alpha}, \quad (36)$$

where $\bar{L}_i$ and L_i^* correspond to the gel phase and to the solution phase, respectively, and α is the structural parameter. The relation (36) is a generalisation of particular expressions obtained for two limiting cases, *viz.*, parallel ($\alpha = 1$) and series ($\alpha = -1$) arrangement of the phases with respect to the transfer direction; in intermediate situations, the α value lies in the range $-1 < \alpha < 1$.³⁶⁶ The L_i and $\bar{L}_i$ parameters can be expressed through ion diffusion coefficients in the corresponding phases, D_i and $\bar{D}_i$

$$L_i = \frac{D_i c_i}{RT},$$

$$\bar{L}_i = \frac{\bar{D}_i \bar{c}_i}{RT},$$

while the ion concentrations in the gel phase, $\bar{c}_i$, can be found from the corresponding concentrations in the solution phase, c_i , using the Donnan equation.

The diffusion coefficients in the interstitial solution are assumed to be equal to those in free solution. The model permits calculations of the ion concentrations in the gel phase, $\bar{c}_i$, and the effective membrane conductivities, L_i^* , as functions of the electrolyte concentration in the interstitial solution.

The advantage of the model is the possibility of description of the static and transport properties of a membrane using one set of structural and kinetic parameters (see above). In this connection it is of interest to calculate the d.c. and a.c. specific conductivities of the membrane (κ_d and κ_a , respectively). The relation between κ_d and κ_a was studied by Gnusin *et al.*^{366, 367} who derived and experimentally tested the following approximate formula

$$\kappa_d = \bar{\kappa}^{f_1} (\kappa^* t_i)^{f_2} = \kappa_a t_i^{f_2},$$

where $\bar{\kappa}$ and κ^* are the specific conductivities of the gel phase and the interstitial solution, respectively, and t_i is the transport number of the ions i in solution. The κ_a values can be calculated using an approximate relationship, which is valid at $\alpha \rightarrow 0$,³⁶⁶

$$\kappa_a = \bar{\kappa}^{f_1} (\kappa^*)^{f_2}, \quad (37)$$

according to which the $\log \kappa_a - \log \kappa^*$ curve must be linear with a slope of f_2 . Indeed, as can be seen in Fig. 14, Eqn (37) permits the correct description of the experimental data. The f_2 values calculated using Eqn (37) and those determined in the electrolyte sorption, contact reference porosimetry and differential scanning calorimetry studies have been compared.^{34–36} The similar values of this parameter determined by independent methods indicate

Figure 14. Plot of the a.c. specific conductivity of ion-exchange membranes vs. the specific conductivity of solution.³⁶ Membrane in solution: C-60/65 in HCl (1); Amberplex C-1 in NaCl (2) and KCl (3); Amberplex A-1 in NaCl (4); AMF C-103 in NaCl (5); MF-4SK in NaCl (6) and Nepton CR-61 in KCl (7).

that the microheterogeneous model correctly describes the structure of ion-exchange membranes and that the electrically neutral solution characterised by the volume fraction f_2 does exist within the membrane. Equation (37) and the microheterogeneous model has been used by many researchers for estimation of the degree of heterogeneity of organic ion-exchange membranes.^{371–373}

Summing up, mention should be made that capillary and microheterogeneous models considered above use all transport equations and all relations between the transport coefficients, which were obtained in the framework of the thermodynamics of nonequilibrium processes. Additional parameters, which depend on the membrane structure, allow one to relate the transfer coefficients to the structural – kinetic parameters of the membrane and to the concentration of the equilibrium solution.

V. Limiting stages of transfer and diffusion layers

1. Change in the electrochemical potential and limiting stages of transfer

As mentioned above, directed diffusion in membrane materials is driven by the electrochemical potential gradient produced in the system for various reasons.

A peculiar feature of heterogeneous processes is a nonuniform change in the electrochemical potential gradient along the normal to the interfaces. The systems comprised of membrane or ion-exchange materials usually have a multilayer structure. Often, membranes themselves contain some layers; e.g., bipolar organic membranes³⁷⁴ and membranes with a modified surface layer^{375,376} comprise two layers. In any case the membrane is surrounded by two diffusion layers of the solution (see below). Under intense current regimes in solution a macroscopic space charge appears near the membrane surface.^{377,378} This charge can also be considered as a layer which resists mass transfer. The electrochemical potential changes differently on going through different layers of the system; the layers characterised by maximum potential jump exhibit the highest mass-transfer resistance.

Let us consider the interaction between the compounds A and B, which involves the formation of a new phase AB due to the diffusion of A across the product layer and the movement of the AB/B interface. Different types of changes in the chemical potential of the component A, $\Delta\mu_A$, in this system are shown in Fig. 15. If a reaction is controlled by the diffusion across the product layer, it is this layer that contributes predominantly to the change, $\Delta\mu_A$. If the coefficient of diffusion through this layer can be considered constant, the chemical potential of a quasi-stationary process decreases uniformly, since the ion fluxes through any cross-section must be equal (Fig. 15a). However, more often

Figure 15. Change in the chemical potential along the normal to the interface for solid-phase reactions.⁹

The reaction is controlled by: diffusion, $D = \text{const}$ (a); diffusion, $D = \text{var}$ (b); mass transfer through the interface (c); relaxation processes in near-surface layer (d); change in the chemical potential due to diffusion and relaxation processes (e).

(taking into account the phenomena considered above) the interaction between the product and the initial components causes an increase in the defect concentrations at the A/AB and AB/B interfaces. This violates a uniform decrease in the chemical potential. If differently charged defects (e.g., cation interstices and vacancies, as in the ion-exchange process described above) are generated at the oppositely lying interfaces, the chemical potential changes to the greatest extent at a point corresponding to the minimum value of the overall diffusion coefficient with respect to both types of defects (Fig. 15b).⁷⁶

Even higher chemical potential gradients can be achieved for the reactions controlled by interfacial processes (Fig. 15c,d). The rates of such processes are determined by the surface area of the interphase boundary and by the properties of the phases. It is commonly accepted that the surface processes controlling the rates of chemical reactions can proceed by two main mechanisms, that is, activated diffusion across the interface and relaxation resulting in a structural rearrangement. The chemical potential decreases primarily at the moving interface in the former case (see Fig. 15c) and in a narrow near-interface region within a certain initial component in the latter case (see Fig. 15d). Real systems usually exhibit a combination of the case shown in Fig. 15c or Fig. 15d with a decrease in the chemical potential within the product layer (Fig. 15e). It was concluded³⁷⁹ that high activation energies for ion transfer across the interface are hardly probable, since the interface has an increased energy and the diffusion processes in the near-interface region are accelerated. Therefore, in the text below emphasis is placed on the relaxation processes in the region adjacent to the reaction product.

An increase in the chemical potential difference for the ions A at the AB/B interface causes acceleration of their transport across the interface and the formation of a supersaturated solution of A in the near-interface region of the phase B. Passage of the solution to the AB region requires its ordering and a change in the geometry of the environment. In particular, the formation of a large number of linear dislocations and point defects at the interface in the case of interaction between the crystalline phases AB and B and a solid solution is due to different lattice parameters of these phases. For the reasons described above transformation of the A–B solid solution into a chemical compound is accompanied by transfer of the ions A and B within the solution. Such a process inevitably requires the overcoming of some activation

barriers and a time delay (induction period). According to Schmalzried and Janek,³⁷⁹ the average time taken to transfer the silver ions across the α -AgI/ β -Ag₂S interface is five orders of magnitude shorter than the corresponding times of the individual phases. The structural rearrangement region can be as thick as ~ 10 nm,³⁷⁹ which exceeds the thickness of the Debye layer and corresponds to several tens of crystallographic planes.

The flux of the ions A across the AB/B interface (J_A) is given by the Nernst–Planck equation. The J_A value can be determined from electrochemical experiments (e.g., 2.3×10^{-5} mol cm² s⁻¹ for the α -AgI/ β -Ag₂S interface at 260 °C³⁸⁰). Mass-transfer resistance at the interface can be due to some other processes, namely, a chemical reaction (e.g., complexation), rearrangement within the hydration shell, overcoming of the Coulomb barrier by multiply charged counterions, etc.^{13, 51}

As the reaction passes, the thickness of the product layer (L_{AB}) increases, which causes an increase in the diffusion resistance of the AB layer and in the total change in the chemical potential within this layer ($\Delta\mu_A^{AB}$). The overall change in the chemical potential of the system equals the Gibbs free energy of the reaction (ΔG_{AB}); therefore, a change in ΔG_{AB} is accompanied by a change in the potential difference at the AB/A interface (see Fig. 15 e)

$$\Delta\mu_A^b = \Delta G_{AB} - \Delta\mu_A^{AB}.$$

Since we deal with a quasi-stationary process, the fluxes of A through the interface and through the AB layer must be equal to each other

$$J_A = -\frac{J_A^0 \Delta\mu_A^b}{RT} = -\frac{D_A^{AB} c_A^{AB} \Delta\mu_A^{AB}}{RTL_{AB}}, \quad (38)$$

where D_A^{AB} and c_A^{AB} is the diffusion coefficient and concentration of A in the AB layer, respectively. From this one can readily obtain the condition for equality of $\Delta\mu_A^b$ and $\Delta\mu_A^{AB}$, which corresponds to the change in the limiting stage of the reaction from interfacial relaxation to diffusion in the AB layer. This situation occurs as the AB product layer reaches some characteristic thickness at which the dependence of the mass of the product on the duration of the reaction changes from linear to parabolic. The characteristic thickness of this layer for, e.g., the formation of spinels, is of the order of 1 μ m,³⁸⁰ while the time taken to change the type of the limiting stage is of the order of several minutes.³⁸¹

Ion transfer in a complex multilayer system is controlled by those layers for which the electrochemical potential jump is comparable to the overall change in the electrochemical potential in the system. If the potential jump for a particular layer is small compared to the overall change in the potential, the electrochemical potentials at the left and right boundaries of the layer can be considered approximately equal. Then to a first approximation the boundaries can be treated as being in quasi-equilibrium with each other. This assumption essentially simplifies the determination of the fluxes of the solution components through the membrane. Usually the surface layers of a membrane are assumed to be in local thermodynamic equilibrium with the surface layers of the solution, which allows one to relate the boundary concentrations in the membrane to the boundary concentrations in the solution by the Donnan relations.^{1, 11, 327} Timashev and co-workers^{13, 304, 305} examined nonequilibrium boundary conditions applicable to, e.g., membranes with modified surface layers.

2. Diffusion layers

In some cases the rate of transfer across a membrane is controlled by mass delivery to (or rejection from) the membrane surface from the bulk of the solution through the boundary layer adjacent to the membrane (this layer is called the diffusion layer).

The concept of the diffusion layer was proposed by Nernst³⁸² who studied the dissolution of solids and assumed that the rate of

the process is limited by the diffusion across the non-stirring boundary layer of the fluid of thickness δ

$$J = -\frac{D(c_0 - c_s)}{\delta}, \quad (39)$$

where D is the diffusion coefficient of the solute, c_0 is the concentration in the stirring solution and c_s is the concentration of the substance at the interface with the solid.

Levich³⁸³ reported a consistent interpretation of the concept of the diffusion layer in the framework of his theory of convective diffusion. According to this theory, the flux density vector of a substance in a fluid has a diffusive and convective components

$$\vec{J} = -D\text{grad}c + c\vec{v}, \quad (40)$$

where c is the concentration of the substance and $\vec{v}$ is the velocity of the centre of mass.

Convective transfer within the diffusion layer is possible but tends to zero as the solid surface is approached. Nernst's conception of the boundary layer, in which mass transfer occurs by diffusion only, can be considered as a convenient idealisation. The thickness of the diffusion layer is determined by the coordinate of the intersection point of the tangents to the concentration profiles at the solid surface and in the bulk of the stirring solution.

The following expression was derived for calculating the thickness of the diffusion layer in the case of a laminar flow of a fluid in a channel formed by two plane-parallel plates

$$\delta = 1.02 \left(\frac{yDh}{\bar{v}} \right)^{1/3}, \quad (41)$$

where y is the longitudinal coordinate measured from the inlet of the channel, h is the distance between the plates and $\bar{v}$ is the average fluid flow velocity. Numerical test calculations carried out in the framework of the convective-diffusion model of electro-dialysis^{384, 385} showed³⁸⁵ that this formula is valid for relatively short channels ($y \leq 0.02\bar{v}h^2/D$). In this case the thicknesses of the diffusion layers adjacent to membranes are small compared to the intermembrane distance h (Fig. 16). On further increase in the channel length the horizontal plateau in the concentration profile becomes diffuse, the diffusion region fills the entire channel, and the concept of the diffusion boundary layer loses its meaning. According to numerical calculations,^{385, 386} the thickness of the diffusion layer formally determined from the intersection point of the tangents is nearly one third of the intermembrane distance.

Experimental studies on the concentration distributions in the desalination compartments of electrodialysis cells have been reported.^{387–389} When the solution flow hits barriers present in

Figure 16. NaCl-Concentration profile in the desalination channel [combination of an anion-exchange (A) and a cation-exchange (K) membrane] of an electrodialysis apparatus at different values of dimensionless longitudinal coordinate $Y = yD/(\bar{v}h^2)$. Calculated using the convective-diffusion model;³⁸⁴ Y : 0 (1), 0.001 (2), 0.05 (3) and 0.2 (4).

the channel (separator, ionite granules), the diffusion layer is partially interrupted; its local thickness varies periodically.^{386, 390}

In the case of ion exchange and electrolyte diffusion across a membrane the concentration profiles are formed in both the ion-exchange material and the adjacent diffusion layers. The shape of the profiles depends on the dimensionless relative diffusion permeability of the membrane, p (Fig. 17),^{1, 391}

$$p = \frac{Pc^I\delta}{Dd},$$

where P is the diffusion permeability of the membrane, D is the electrolyte diffusion coefficient in the solution and d is the membrane thickness. At small p , the concentration and, hence, the electrochemical potential change primarily within the membrane (particle diffusion kinetics), while at large p this occurs within the diffusion layers of the solution (film diffusion kinetics). For organic membranes, the P/D ratio is of the order of 10^{-1} – 10^{-2} , while the δ/d ratio varies from 0.1 to 1; hence one gets $p \approx 10^{-3}$ – 10^{-1} . For most inorganic membranes $p < 10^{-2}$ and the change in the concentration within the diffusion layers can be neglected. The role of the parameter p is analogous to the role of the Biot or Helfferich criteria^{11, 327} used in ion exchange theory; sometimes, the reciprocal of p , or the relative electrodiffusion resistance of the membrane, is used.^{1, 391}

Figure 17. Concentration profiles obtained for the virtual solution in the membrane and in two diffusion layers (I and II) in the case of a binary electrolyte diffusion ($I = 0$).

Calculated using the microheterogeneous model for the MK-40–NaCl system, $\delta^I = \delta^{II} = \delta$; $p = 0.01$ (1), 0.1 (2), 1 (3) and 10 (4); $c^I = 1$ mol litre⁻¹; $c^{II} = 0$.³⁶⁸

However, a complete analogy between the electrolyte diffusion and ion exchange is possible only at a zero current. Due to the difference between the transport numbers of ions in the solution and in the membrane the flow of a current of density I causes desalination of the solution layer adjacent to one membrane surface (a diffusion layer depleted in electrolyte is formed), while the solution in the layer adjacent to the other membrane surface is concentrated.¹¹ As the potential jump increases, the electrolyte concentration at the depleted-diffusion-layer/membrane interface becomes much lower than in the bulk of the solution and the current density reaches the limiting value, I_{lim} . In an ideal system characterised by a constant thickness of the diffusion layer and local electroneutrality the current density must not exceed the I_{lim} value. However, in real systems, especially in dilute solutions, the current density can be several tens of times higher than I_{lim} .^{392–397} This is due to a number of phenomena^{394–405} involving electrodiffusion transport at high voltages: generation of the H^+ and OH^- ions upon irreversible splitting of water at the membrane/solution interface;³⁹⁴ coupled convection due to the concentration and (or) temperature gradients (gravitational convection)^{394–397} and the space charge density gradient (electroconvection);^{398–404} and the ‘exaltation’ effect.^{394, 405} It should be noted that exper-

imental and theoretical investigations of these phenomena are of importance for understanding and optimising the electrodialysis process under intense current regimes.^{394, 402}

The limiting current density is inversely proportional to the thickness of the diffusion layer δ .^{1, 11} This dependence is often used to determine the δ value from the limiting current density at the membrane surface^{406, 407} or from the limiting flux of a particular component.⁴⁰⁸ For dilute solutions the accompanying effects mentioned above cause a significant distortion of the shape of the current-vs.-voltage curve, thus hampering a correct determination of the limiting current and δ value.^{394, 406, 409} A method involving the use of an auxiliary electrode system to eliminate this problem has been developed.⁴⁰⁶

3. Limiting stages and mathematical description of multistage transfer

Determination of the limiting stages of a transfer process is of considerable importance for an understanding and practical implementation of the process. However, this is a complicated problem. As mentioned above, ion transfer across a membrane is generally a mixed-diffusion process,^{306, 327, 391} i.e., the resultant rate of transfer is determined by transport through both the membrane and the diffusion layers of the solution. As the current strength increases, the role of the depleted diffusion layer in controlling the kinetics of the ion transfer process becomes increasingly important irrespective of the p value and in the limiting case it is transfer through this layer that is the limiting stage of the process. Taking into account this fact, it is possible to explain many experimentally observed regularities of ion transport in membrane systems. For instance, the loss of transport selectivity of a particular type of the competing counterions across the membrane is due to the change from particle diffusion (or mixed-diffusion) kinetics at low currents to film diffusion kinetics at currents close to the limiting current.^{391, 410, 411} Even in the presence of a specially modified surface layer,³⁷⁵ which resists the transfer of two competing counterions in different manners, the transfer permselectivity can be significantly improved only at currents lower than the limiting current.^{410, 412}

Ion transfer is often complicated by the occurrence of chemical reactions, e.g., water splitting at the interface between two layers of a bipolar membrane^{392, 393, 413–417} or near the membrane/solution interface.^{392–394, 414–421} This is possible if currents close to or exceeding the limiting current flow in the system, in the case of association or dissociation of weak electrolyte ions and molecules (amino acids) accompanying the so-called facilitated transfer^{422–426} or in the case of electrodialysis of natural water (carbonates, phosphates).^{427–430} Water splitting in aqueous solutions is a slow process with a rate constant of 2×10^{-5} s⁻¹ (see Ref. 392) and can therefore be the limiting stage of transfer in membrane systems. However, the mechanism of this reaction is rather complicated. In the membrane’s bulk within a thin boundary layer 1–10 nm thick the reaction is accelerated, being catalysed by some functional groups (secondary and tertiary amines, weak acid carboxylic groups), heavy metal ions and by the electric field gradient of the electrical double layer,^{392, 414–417, 431, 432} which can be as high as 5×10^8 V m⁻¹ (see Ref. 392). As a result, the reaction rate can increase by nearly five orders of magnitude. In some cases this is the desired effect (in, e.g., production of acids and alkali from salts using bipolar membranes³⁷⁴), whereas in other cases this significantly complicates the technological process (in, e.g., desalination of solutions by electrodialysis^{356, 433}). The hydrocarbonate ions in the membrane can also catalyse water splitting, thus increasing the generation rate of the H^+ and OH^- ions (see Ref. 429). At the same time dissociation of some weak electrolyte anions at the membrane boundary can to some extent control the rate of electrodialysis.^{356, 433}

Thus, studies of transport inside a membrane only are insufficient for understanding the transfer processes in membrane systems. Transfer across the diffusion layers and interface (more

exactly, matching these processes and transport within the membrane) strongly affects the behaviour of the whole system. The three-layer mathematical models of transfer in membrane systems^{1, 369, 391, 410, 411, 434–441} give an adequate insight into the processes, since transfer is considered both within the membrane and in two diffusion layers adjacent to the membrane. The three-layer mixed-diffusion model was first proposed by Wills and Lightfoot⁴³⁴ for electrodiffusion of a binary electrolyte. Electrodiffusion of binary and ternary electrolytes across a homogeneous^{391, 434–437} and a microheterogeneous membrane^{369, 411} has been studied. Zholkovsky⁴³⁶ and Gnusin⁴²¹ included transfer of the H^+ and OH^- ions appearing due to splitting of water at the membrane/solution interface. The contribution of electroosmotic ion transfer has been reported.³¹⁹ Using a specific numerical procedure, Manzanares *et al.*³⁰⁶ included violation of the electroneutrality conditions within the diffusion layers and the membrane. The role of the modified surface layer was elucidated,⁴¹⁰ the bi-ionic potential was studied^{328, 329} and facilitated diffusion of amino acids across the membrane was investigated.^{422–425}

The authors of all the studies mentioned above used similar formulations of the mathematical problems, the differences being due to the desire for taking into account a particular additional effect. Transfer across both diffusion layers ($0 \leq x < \delta^I$ and $d + \delta^I < x \leq d + \delta^I + \delta^{II}$) and the membrane ($\delta^I \leq x \leq d + \delta^I$) (see Fig. 17) is described by the Nernst–Planck equations^{306, 391, 439} under local electroneutrality. It is also assumed that the membrane boundaries are in local thermodynamic equilibrium and that the continuity conditions hold for the electrochemical potential and fluxes. The concentrations of all types of the ions i at the outer boundaries of the diffusion layers (c_i^I and c_i^{II}) are specified, while the current density is considered known. In this case the problem posed is a boundary-value problem for a three-layer domain. Solving this problem involves determination of the fluxes, concentration and potentials as functions of the coordinate x .

A general analytical solution to the problem for a single-layer domain was proposed by Schlögl.²⁹² The system under study was also divided into three domains (see Fig. 17) and the corresponding solutions were matched.^{391, 435, 439} Garrido *et al.*³¹⁹ and Karlin⁴³⁷ proposed numerical methods suitable for the steady-state and non-steady-state cases. Sistat and Pourcelly⁴³⁹ reported an analytical solution to the problem for a binary electrolyte using the Lambert function. Lebedev *et al.*^{391, 411, 440, 441} modified the known ‘shooting’ method^{442, 443} in order to adapt it to multilayer domains. More detailed reviews of the methods for solving this type of problem can be found in Refs 411 and 438 and in the monograph.¹

The use of the local electroneutrality condition makes the models used rather accurate provided that the current density is lower than I_{lim} . However, many practically important processes (e.g., deionisation of water by electrodialysis^{356, 444} or operation of bipolar membranes³⁷⁴) require intense current regimes when the current density exceeds I_{lim} . Levich⁴⁴⁵ considered the problem of ion transfer across the electrode/solution interface and showed that the concentration of the electrically neutral electrolyte solution near the electrode surface (c_s) varies at low currents. Simultaneously, the thickness of the diffuse part of the electrical double layer changes; however, the Boltzmann equilibrium distribution of the ion concentrations in this part is retained. The thickness of the electrical double layer is inversely proportional to $\sqrt{c_s}$ and, therefore, increases with a decrease in c_s . An analogous conclusion was also drawn by the authors of Refs 446 and 447 who extended the range of the current strengths to $I = I_{lim}$. Rubinstein and Shtilman³⁹⁸ first obtained a numerical solution to the Nernst–Planck–Poisson equations for the overlimiting current flowing across the diffusion layer adjacent to the ion-exchange membrane. They showed that at $I > I_{lim}$ the space charge region goes beyond the quasi-equilibrium electrical double layer at the interface. This causes a decrease in the effective

thickness of the diffusion layer, thus providing the ‘overlimiting’ increase in the salt ion current. The study³⁹⁸ has attracted considerable interest, since it gave a clue to the understanding of the mechanism of the ‘overlimiting’ current phenomenon. It was followed by a large number of studies concerning the role of the space charge in the formation of the ‘overlimiting’ current.^{377, 378, 398–404, 448–452} Considerable progress was achieved due to a rigorous and, at the same time, rather simple solution of the Nernst–Planck–Poisson equations by Urtenov *et al.*^{403, 448, 449} Assuming a quasi-uniform distribution of the space charge^{403, 404} instead of the electroneutrality condition, in some instances the system of differential equations was reduced to a cubic algebraic equation.⁴⁰³ This also permitted significant simplification of the method for solving the problem and studies of a three-layer system with two⁴⁵¹ and three types of ions.⁴⁵²

Simultaneously with the description of the structure of the diffusion layer at $I > I_{lim}$ many researchers^{394, 399–402} attempted to simulate the mechanism of the appearance of convective fluid flows under the action of the electric field on the space charge (these flows destroy the diffusion layer). Currently, the electroosmotic slip mechanism, which was first proposed by Dukhin *et al.*⁴⁰¹ who called it electroosmosis of the second kind (since the space charge responsible for the onset of convection appears as a result of the current flow), is thought to be the most probable. Rubinstein *et al.*^{377, 399, 400} reported a comprehensive analysis of electroconvection and showed that it appears in the near-surface region of both homogeneous and inhomogeneous membranes. The electroosmotic slip of a fluid can cause instability of concentration polarisation at the membrane, which manifests itself as oscillations of the electric potential jump, which transform into a random motion detected as an excess low-frequency electric noise at super-overlimiting currents. Urtenov *et al.*^{394, 449} reported numerical calculations of electroosmotic vortices assuming a constant bulk electric force calculated using the Nernst–Planck–Poisson equations. The results obtained are in good qualitative agreement with those reported by Rubinstein.

Mention should be made that electroconvection is not the only form of a coupled convective motion of a fluid under intense current regimes. Gravitational convection also plays an important role in membrane systems, especially at rather high solution concentrations and large intermembrane distance.^{396, 397} Under these conditions the Grashof¹ (or Rayleigh^{377, 400}) numbers can exceed their critical values and convective flows develop in the system, destroying the diffusion layer. The contribution of electroconvection to the overlimiting current is more significant for dilute solutions at short intermembrane distances.^{1, 394}

In conclusion it should be emphasised that concentration polarisation and transfer across the diffusion layer are of crucial importance for the formation of the properties of the whole membrane system. To follow how the properties of a membrane (in particular, its structure and kinetic parameters) affect the integral properties of the whole membrane system, one must know methods for description of the transfer processes occurring on different levels, namely, in a single membrane and in an assembly comprising a large number of membranes. In this case a hierarchic system of mathematical models⁴⁵³ (some of them were briefly outlined above) may appear to be useful.

VI. Methods of investigations of ion transport in membranes

Conventionally, there are two avenues of research on the ion transfer in membranes. One of them involves comparison and optimum choice of membranes for various processes.^{356, 454} Here, the main problem is the choice of the basic physicochemical (static and transport) characteristics of membranes, which would provide the greatest body of information, have unambiguous and clear physical meaning and be determined in not very time-consuming experiments without using sophisticated equipment.

On the other hand, measurements of physicochemical characteristics of membranes are required for basic research on the mechanism and quantitative description of ion transfer.

Numerous studies on the methods of chemical and thermodynamic research on ion exchange have been reported to date.^{11,327} The diffusion layer characteristics are successfully determined by laser interferometry,^{388,389} voltammetry,^{409,420,455} chronopotentiometry,^{372,409,456} using electrochemical noise^{396,397,457} and impedance measurements,^{416,417,456} *etc.* The electrochemical methods of investigations of the properties of ion-exchange membrane systems were reviewed by Pourcelly *et al.*⁴⁵⁶

In this Section we will dwell only on the methods for measuring the conducting and selectivity properties of membranes, due to which they occupy a special position among a variety of modern materials. These properties include first of all the conductivity, diffusion permeability and transport numbers of ions.^{285–287,458,459} Below we briefly outline the electrochemical, ion exchange and spectroscopic methods used in this field of research.

1. Conductivity and transport numbers

Methods for measuring the ionic conductivity of solids are most often used for the description of the transport properties of various membrane materials, from inorganic salts and oxide systems to polymeric membranes. The area of their application extends from obtaining thorough knowledge of the nature of ionic mobility and its relation to the structure and surface to the practically valuable studies on fabrication of various electrochemical, membrane devices and power sources, in particular, fuel cells that have been the subject of intensive recent research.^{4,460–462} In this connection it will be recalled that the well-known membrane polymeric material Nafion belongs to the proton solid electrolytes exhibiting the best conducting properties.^{463,464}

The ionic conductivity is most often studied by impedance spectroscopy, which involves complex measurements of the ohmic and capacitive resistance of membranes. By plotting the impedance or admittance hodograph for a wide frequency range it is possible to determine the ionic conductivity of the material under study. Now we will outline the methods employed and point to some recent studies. Conduction studies of inorganic membranes,⁴⁶⁵ various polyelectrolytes^{159,461,462,466–469} and composite membranes^{469,470} most often involve measurements of their impedance. Detailed description of the measuring techniques, measuring cells, as well as analysis of the results obtained using different types of equivalent circuits has been documented.^{456–458,471–478} In particular, the use of impedance spectroscopy allows measurements of the diffusion coefficients of electrolyte in the diffusion layer and determination of the rate constants for water splitting in membrane systems.^{414–417,439,479–482}

Since the conductivity of most membrane materials is strongly dependent on the water content,^{351,458,461,462} considerable efforts have been made to control the water vapour pressure and maintain it at a constant level. However, even this approach precludes the choice of conditions identical to those realised in studies of the transport properties in aqueous electrolyte solutions. To ensure such conditions, experiments often involve conductivity measurements of membranes separating two electrolyte solutions containing the working electrodes.^{456,458,477–478} The additional resistance of the solution is included by carrying out measurements for the same cell without the membrane (difference method). In some instances the solution resistance is comparable or higher than the membrane resistance. This causes a marked increase in the measurement error. Besides, interpretation of the results obtained is complicated by an additional contribution of the resistance of the membrane/electrode interfaces to the measured value and by possible deformation of the membranes in the cell.^{458,478} Methods of solving this problem have been documented.^{458,476–478}

A version of the difference method is the probe technique, which involves measurements using a four-electrode cell (two polarising and two working probe electrodes).⁴⁷¹ The use of two additional silver chloride or calomel electrodes permits simultaneous a.c. and d.c. measurements.³⁶⁷

The membrane d.c. frequency spectra measured under non-equilibrium conditions can also serve as a source of valuable information. To this end, a six-electrode cell can be used. One pair of electrodes is employed for the d.c. polarisation of the membrane under study, the other pair is used to induce an alternating sinusoidal electric field, while the third pair of electrodes acts as the potential probes. For simultaneous measurements of the membrane's voltage-vs.-current curve the cell is additionally equipped with two reversible reference electrodes. The use of such a measuring complex allows essential extension of the capabilities of membrane conductometry.⁴⁷⁷

A simple and rather accurate method for measuring the conductivity of ion-exchange materials representing both films and pieces of arbitrary geometry is the isoconductivity point technique.^{354,355,458} It involves conductivity measurements of the solution with and without the ion exchanger in the conductometric cell.

Membrane selectivity depends on the mobility and concentration of ions in a given material. The basic characteristics of the ion-selective properties of a membrane are the transport numbers, which are defined as the electric charge transferred by a given type of ion in the absence of the pressure and concentration gradients. The fundamentals of the method for determination of the transport numbers of various solid and liquid objects were developed by Turbandt.⁴⁸³

The selectivity is often estimated by the e.m.f. method in a cell containing reversible electrodes and a membrane separating two solutions of different concentration.⁴⁸⁴ In practice the so-called effective transport numbers, *i.e.*, the fraction of the charge transferred in the presence of the concentration and pressure gradients, are most often determined.^{485,486} To optimise the experimental design, it was proposed to use strong currents flowing over a short period of time;⁴⁸⁴ closed cells with a concentration drop changing its sign in the course of the experiment;^{444,487} devices for automatically maintaining the component concentrations at the cell inlet at a constant level,^{394,488,489} *etc.*⁴⁴⁴ To calculate the 'true' transport numbers, it was proposed to extrapolate the effective transport numbers to an infinitely strong current, since in this case the diffusion (not convection!) contribution to the flux can be neglected.⁴⁷¹

A more detailed description of methods for measuring the transport numbers can be found in monographs.^{307,308,444,472} It is appropriate to mention that liberation of some substances (*e.g.*, oxygen) at electrodes in the case of volumetric control of the transfer process requires a rather high voltage. This can introduce errors into the results obtained as compared to those obtained under the conditions of impedance spectroscopy measurements.

Other electrochemical methods of investigations of transfer phenomena can also be rather informative. These include thermoelectric measurements, thermally stimulated depolarisation, Hall effect studies, *etc.*^{472,474}

2. Spectroscopic methods

Various spectroscopic methods are often used in studies of transfer phenomena, ion and molecular mobility. One of them is vibrational spectroscopy.^{165,490} However, NMR spectroscopy is the most important and promising. The advantages of this method are a broad range of characteristic frequencies and the possibility of description of the local environment of a given sort of atom. Since the energy of the dipole–dipole interactions is inversely proportional to the cubed distance between the dipoles, the shape and width of the line of a given nucleus are determined by its nearest environment only. This allows one to distinguish between the crystallographically nonequivalent positions in the crystal structure and to characterise the nearest environment of a given

type of nuclei.^{491–494} In the case of a solid the rotation of the interatomic vector about the direction of the magnetic field at a frequency close to or higher than the resonance frequency causes averaging of the internuclear coupling. First of all, this manifests itself as line narrowing in the NMR spectra.⁴⁹⁵ Analysis of changes in the widths or in the second moments of the NMR lines permits information on the rotational mobility in solids to be obtained.^{180, 494} Translational mobility of ions and molecules also leads to line narrowing, though the effect is much more pronounced in this case. The lines of the nonequivalent nuclei involved in the fast exchange merge together. Such studies allow determination of the characteristic frequency and the activation energy for this type of mobility.^{494, 496, 497} The most valuable information on the cation mobility is provided by NMR relaxation in solids. Here, the researcher can immediately determine the frequency of rotational mobility and describe the processes of ion and molecular transfer. It should be noted that the activation energy for mobility extracted from the NMR data is often different from the data of electrochemical (in particular, impedance spectroscopy) measurements. The reason is that NMR spectroscopy gives the description of the local nuclear environment (see above), whereas the conductivity is undoubtedly an integral characteristic of a material. The predominant contribution to the overall process of transfer across the membrane may come from a low fraction of the atoms and ions possessing the highest mobility, *e.g.*, those located on the material's surface. Numerous examples of NMR studies of transfer processes have been documented.^{87, 166, 494, 496–502}

Another promising method for investigation of transfer phenomena in membranes is Raman spectroscopy,^{456, 503–506} which allows measurements of the vibrational spectra of the membrane components. This method provides particularly valuable information when the membrane contacts solutions of weak electrolytes. By Raman spectroscopy one can determine the concentrations of various ions (polychromates,⁵⁰³ sulfates and hydrosulfates⁵⁰⁴), nitric acid and nitrates⁵⁰⁵ in the membrane and in solution, as well as study poisoning of membranes in electroanalysis.⁵⁰⁶

3. Ion exchange rate and diffusion permeability measurements

The pioneering quantitative studies on the kinetics of ion exchange were carried out by Boyd, Adamson and Myers³²⁴ who proposed a model, which treated an ionite grain as a homogeneous sphere. More recently, this model has been extensively used by Barrer and Falconer.^{507, 508} Up to now the results obtained in that time for the diffusion-controlled processes in a grain or film (adjacent diffusion layer) have been widely used in the same form to describe the kinetics of ion exchange. Processes involving diffusion in the ionite grain as the rate-determining stage predominate.

There are processes to which the above-mentioned model is inapplicable. Tunitskii *et al.*⁵⁰⁹ and Helfferich^{510–512} extended this model to the diffusion of ions possessing different mobilities and to the processes complicated by the occurrence of chemical reactions. According to another model proposed for ion exchange in a heterogeneous grain due to the movement of the interface between the initial and the newly formed phases, diffusion across a variable-thickness layer of exchange products occurs.^{76, 274, 513}

A salient feature common to all these models is that the experimental data are obtained after disturbance of the equilibrated system by adding a reagent, which either contains a certain type of exchanging ion or, on the contrary, reduces their concentration due to complexation or formation of a weakly dissociating compound (*e.g.*, water). Then, the system relaxes to the equilibrium state. Here, the measured quantity is the continuously varied concentration of a particular sort of ions in the solution or in the ionite phase. In this connection such methods are called non-steady-state ones. The solution composition can be analysed by various analytical methods including potentiometric, polaro-

graphic and some other techniques.^{161, 273, 274} It is commonly accepted that the drawback of this approach is the variable composition of the solution, which causes the driving force of the process to change and complicates its mathematical description.

To eliminate these problems, either the ratio of the solution volume to the ionite volume is increased or the so-called methods of infinitely large volume are used (a large volume of solution is rapidly passed through a thin ionite layer). The course of the process is assessed by analysing the changes in the composition of the sorbent phase.^{55, 514, 515} This approach permits obtaining exact results but is very labour-consuming, which significantly limits the area of its application. In addition, the need for carrying out a continuous experiment can come into conflict with the necessity of frequent monitoring of the composition of the solid or liquid phase. More detailed studies of diffusion processes are also carried out using the methods based on the layer-by-layer analysis of cylindrical or conical ionite samples.^{516–519}

Much less time-consuming are the isoconcentration methods involving compensation of the changes in the solution composition due to some external action. For instance, Haagen⁵¹⁹ who proposed this method studied the H^+/M^+ exchange reaction resulting in the formation of acid in solution. The acid formation changes the colour of an indicator. By adding the necessary amount of alkali the acid is neutralised and the colour is restored. The exchange rate can be estimated from the amount of alkali, which should be added during some time interval. More recently, this method was improved, namely, it was forced into the regime of automatic compensation of the liberating product and a number of novel methods for detection of disturbance of the system's equilibrium was implemented. Some other techniques were developed, which significantly extended the area of application of this method.^{520, 521}

Using planar membranes, one can investigate the transfer processes induced by various driving forces, namely, the concentration, pressure or electric potential gradients. The method of studying the diffusion processes induced by the concentration or the chemical potential difference of a particular sort of ion is the most similar to those considered above. A membrane is placed between two half-cells containing solutions with different concentrations of the permeate.^{522–524} The method permits studies of the transfer processes proceeding at substantially different rates, as well as the processes occurring under quasi-steady-state or strongly nonequilibrium conditions.⁵²⁴ This is first of all due to the possibility of varying the solution concentrations, cell volumes and the geometric parameters of the membrane (surface area, thickness). Besides, the chemical potential difference of a certain type of ion can be substantially increased by using reagents which react with these ions, thus resulting in the formation of complex, weakly dissociating or insoluble compounds.⁵²⁴ A method for measuring the partial fluxes of particular types of ions through the membrane upon changes in the concentration and electric potential differences on each side of the membrane has been developed.⁵²⁵ To improve the accuracy of the measurements, the pH value and the concentration of ions in the solutions circulating through both half-cells are automatically maintained at a constant level.

Studies of transfer through the membrane volume and elucidation of the role of the membrane surface require reliable data on the diffusion layer adjacent to the surface. Unfortunately, experiments with conventional flow cells are inappropriate for taking into account the role of the diffusion layer, since the layer thickness varies with coordinate and can be calculated only for plane-parallel geometry. Bobreshova *et al.*^{526, 527} developed the rotating membrane disk method, which significantly simplifies the solution to this problem, since it provides uniform accessibility of both sides of the membrane surface to mass transfer and permits calculations of the thickness of the diffusion layer. This method allows one to analyse the polarisation characteristics of the

membrane system and relatively easily distinguish between different stages of mass transfer.

Experimental methods for measuring the diffusion permeability of membranes can be conventionally divided into two groups: methods without and with solution flow. A non-flow cell for the first group of methods comprises two compartments separated by the membrane under study. One compartment is filled with an equilibrium solution with a prescribed electrolyte concentration, while the other compartment is filled with deionised water. The diffusion flow of electrolyte through the membrane can be assessed from, e.g., an increase in the conductivity of the solution in the compartment filled with deionised water.⁵²⁸ A drawback of such cells is that the electrolyte concentrations in both compartments vary with time. This limits the lower bound of the concentration to 0.01 mol litre⁻¹. The flow cell methods make possible extension of the concentration range and reduction of the lower bound of the concentration down to 10⁻⁴ mol litre⁻¹.³⁶⁸

The method for determination of the self-diffusion coefficients of the ions in membranes using radiotracers should be pointed out (for a review of related methods, see Ref. 129). As a rule, the self-diffusion parameters of the labelled ions can be measured with high accuracy.

Studies of the interdiffusion of ions in an external electric field and without it permit the determination of both the diffusion and electromigration mobility of the ions. If the dependence of these ion coefficients on the water content in the membrane is known, it is possible to draw some conclusions about the membrane microstructure. For instance, it was shown^{529, 530} that an increase in the concentration of the solution in which the perfluorocarbon membrane is immersed (or a decrease in the membrane's water uptake) is accompanied by breakdown of large clusters into smaller ones and by shortening of the narrow cluster-connecting channels characterised by unidirectional diffusion of various ions. For cross-linked polystyrene sulfo cation-exchange membranes the above-mentioned coefficients are virtually independent of the solution concentration,⁵³⁰ which is thought to be indicative of a rigid network microstructure of the membrane.

VII. Conclusion

Progress of membrane science is favoured by the wide use of membrane and ion-exchange materials in various industrial processes, water treatment, air cleaning, separation processes and the production of highly efficient power sources, etc. Various practically valuable applications require specific materials, which can operate in various media in different temperature regimes and possess high selectivity and chemical stability and specific mechanical properties. Because of this, a large number of novel membrane materials are synthesised and studied yearly, as well as new avenues and methods of application being proposed. In particular, the synthesis of novel composite membrane materials with prescribed properties has been the subject of considerable recent research. However, in all cases the ability of membranes to provide fast ion or molecular transfer is particularly important. From this standpoint the determining role is played by the methods for description of transfer phenomena.

The greatest body of information on the structure of and transfer processes in membranes can be obtained using complementary experimental methods of investigation. Notwithstanding common patterns of transfer phenomena in various inorganic and high-molecular-mass ion-exchange and membrane materials, it is impossible to correctly describe them without knowledge of the structural peculiarities and properties of these systems as well as phase transformations occurring in the course of exchange. In most cases of crucial importance is the use of different methods for theoretical description of these phenomena. At the same time interpretation of the experimental results and, hence, to a great extent their value are often limited to the existing mathematical models of the phenomenon under study. This particularly concerns the non-steady-state methods of investigation of transfer

phenomena (chronopotentiometry, impedance), which have been rapidly developing recently. Description of these phenomena requires setting up of and solution of sophisticated mathematical problems. However, taking into account impetuous development of computational methods, rapid progress in this field also seems to be possible.

There is a great variety of transfer phenomena in membrane systems. However, the limited size of this review precluded consideration of many important problems in this area of study. Nevertheless, the authors hope that it will attract the attention of researchers to this field of investigation from both theoretical and practical standpoints.

Solid-phase method for tritium labelling of biologically active compounds

V P Shevchenko, I Yu Nagaev, N F Myasoedov

Contents

I. Introduction	423
II. Key information on hydrogen spillover	423
III. Solid-phase reactions in the synthesis of tritium-labelled preparations	425
IV. Characteristics of solid-phase hydrogenolysis by tritium	440
V. Conclusion	444

Abstract. The solid-phase method for conducting hydrogenolysis, hydrogenation and isotope exchange reactions is described. The potential of the solid-phase method for tritium labelling of various organic compounds including lipids, nucleotides, amino acids, peptides, *etc.* is demonstrated. The influence of the reaction conditions on the yield and on the molar radioactivity of the labelled specimens is considered. It is shown that the results obtained can be interpreted by the dependence of tritium spillover on the nature of the initial compound and other factors. The bibliography includes 158 references.

I. Introduction

Organic compounds labelled by tritium (a radioactive isotope of hydrogen) are widely used in research in chemistry and biology, in medicine and agriculture. The range of such compounds manufactured by various companies comprises hundreds of names and is being constantly extended and updated. Among labelled compounds, physiologically active substances are especially abundant, first of all, because of their use in biology and medicine. The structures of labelled products needed for various purposes become more complicated with time. Therefore, labelling procedures have to be modernised not only to prepare each of the main classes of organic compounds but also to introduce a label into various compounds of the same class.

The steadfast attention to the problem of synthesis of tritium-labelled compounds is due to the fact that tritium has an appropriate half-life (12.26 years) and high molar radioactivity. High-performance liquid chromatography allows one to isolate specimens with a radiochemical purity of 96%–98% even in the case where highly rigorous conditions are used for labelling such that the yield of the labelled compound is only several percent. Specific binding to receptors of tritium-labelled preparations is virtually free from isotope effects; this accounts for high sensitivity of this method and permits accurate determination of the rate constants for binding. Tritium-labelled compounds are also used in pharmacokinetic studies to determine the target organ

in which a drug is mainly accumulated and the rates of excretion of this drug from the organism. Tritium compounds are also needed to study metabolism and substrate specificity of enzymes and to search for new efficient enzyme inhibitors. Recalling also the fact that tritium-labelled specimens are at least 10 times less expensive than ^{14}C -labelled ones, one can understand why every aspect of related to the preparation of tritium isotopomers of biologically active compounds arouses considerable interest.

The methods for introduction of a tritium label can be divided into two main groups, namely, various versions of isotope exchange and chemical methods (usually, tritiation, dehalogenation, selective tritiation and dehalogenation).

This review considers the solid-phase method for tritium labelling. In view of the specific nature of solid-phase (without a solvent) synthesis, hydrogenation and isotope exchange are considered as particular cases of hydrogenolysis.¹ According to this method, an organic substance is applied on a support (sorbent) where a metal catalyst has been applied preliminarily, and this system is heated under a tritium gas atmosphere. Solid-phase hydrogenolysis proved to be the process of choice for introducing a tritium label into organic compounds. Using these reactions, tritium-labelled lipids, peptides, proteins, nucleic acids, carbohydrates, glycoproteins, nucleoproteins, lipoproteins, glycolipids, alkaloids, terpenoids and many other classes of biologically active compounds have been obtained rather easily.

Plentiful data on the reactions of various compounds applied on a support with activated hydrogen species formed on the metal catalysts have been reported. The enhanced mobility of activated hydrogen on inert supports has been discovered.² The flow of activated hydrogen species from one phase to another has been called hydrogen spillover. It is hydrogen (tritium) spillover that determines the possibility of solid-phase hydrogenolysis. Therefore, before considering the factual information on solid-phase reactions involved in tritium labelling of organic compounds, we give an account of the main data concerning the spillover of hydrogen, which would be useful for understanding the main features and the mechanism of hydrogenolysis.

II. Key information on hydrogen spillover

In most cases, solid-phase reactions are carried out under rigorous conditions, namely, at temperatures above 200 °C (usually, at 300, 500 °C or higher). For the majority of biologically active substances, the use of high temperatures is inadmissible; these substances are studied at lower temperatures. The regularities of the occurrence of solid-phase reactions established in low- and high-temperature experiments are different. Therefore, the data

available from the literature concerning the nature of activated hydrogen species and the conclusions concerning processes related to hydrogen spillover on supports (high-temperature experiments) require critical analysis to be applied to the introduction of tritium into biologically active compounds (low-temperature experiments).

The activity of metal catalysts in the isotope exchange decreases in the series $\text{Pt} > \text{Pd} > \text{Ni}$.³ The chemisorption of H_2 usually occurs at 200–300 °C.⁴ The products of dissociation of molecular hydrogen on platinum migrate to the support in which a dynamic equilibrium is established between the atomic and protic forms of hydrogen.^{5,6} The number of active species, for example, for silica gel, amounts to $\sim 10^{12} \text{ g}^{-1}$ (see Refs 7–9). It was found that silica gel bearing activated hydrogen species is able to catalyse hydrogenation of alkenes. Under these conditions, hydrogenation mainly takes place on the sites generated owing to hydrogen spillover from the gas phase.^{7–11}

Hydroxy groups, oxides or carbon can act as hydrogen acceptors.¹² For example, a study by FT IR spectroscopy has shown the occurrence of isotope exchange between deuterium and hydrogen of the OH groups on Y zeolite (ZeY).¹³ It has also been shown¹⁴ that the OH groups of the support exchange with tritium under hydrogenation conditions. The reaction between the spillover species and the CH_3O fragments of the substrate molecules has been found to give OH groups and CH_4 .^{15,16}

The destruction products formed in reactions can serve as carriers of the active hydrogen species from the initiator to the acceptor.^{17–20}

The diffusion coefficients of hydrogen are determined using various methods including temperature-programmed desorption²¹ and adsorption²² methods, electron microscopy²³ and NMR.^{24,25} The diffusion over the surface of the support can occur over a distance of up to 90–200 nm from the metal catalyst (platinum) particles.^{24,25}

A mathematical model of spillover has been considered in several publications.^{26–28} This model assumes that the activated species are formed on the source metal and the support conveys these species to the substrate and back. One-, two- and three-dimensional diffusion kinetic models for hydrogenolysis of a supported organic substrate have been constructed.²⁸ The models take into account the concentration gradient of the spillover hydrogen and poisoning of the catalyst during the reaction. It was shown that hydrogenation is almost localised in the reaction areas around the crystallites of the metal catalyst and, hence, there exists some ratio of the catalyst, the support and the substrate optimal for this particular reaction. Data supporting both the atomic and protic natures of the spillover species can be found in the literature. Currently, most researchers hold the opinion that the spillover involves hydrogen atoms.^{18,29,30} It was found¹⁸ that the rate of disappearance of the EPR signal from perylene corresponds to the rate of absorption of H_2 by the Pt/ZrY system. It is noteworthy that direct EPR monitoring of atomic hydrogen on most supports is possible only at temperatures below –170 °C. Thorough analysis of the shape of the peak and the chemical shift in the ^1H NMR spectra has shown³⁰ that hydrogen migrates over the SiO_2 surface as $\text{H}^\bullet$ radicals. The adsorption sites for these radicals may be represented by SiO or Si groups.

It has been shown by EPR that tetravalent cerium is reduced to trivalent on the ZeY + Pt(black) system in the presence of hydrogen.³¹ Using *N-tert*-butyl- α -phenylnitron or 2,4,6-tri-*tert*-butylnitrobenzene, which served as traps for hydrogen, weakly bound hydrogen atoms participating in benzene hydrogenation have been detected.³²

It has been found that the exchange processes of $^2\text{H}_2$ with the OH groups of semiconductor supports do not differ much for *n*- and *p*-type semiconductors with applied platinum;³³ thus it can be concluded that spillover involves uncharged species.

The first step of spillover is homolytic cleavage of the H–H bond on the metal, regardless of whether hydrogen atoms or protons participate in the spillover. The rate-limiting step is either

the surface diffusion on the support or the transfer of particles from the catalyst to the support. Since the activation energies of these elementary steps are different, the limiting step of spillover may change upon temperature variation.⁷ The prevalent opinion is that hydrogen spillover is limited by diffusion over the surface of the support.⁶

The hypothesis according to which spillover proceeds by a proton mechanism has also been reported.^{11,34,35} Using reduction with temperature programming and IR spectroscopy, it was shown that, first, hydrogen quickly dissociates to atoms and then forms H^+ ions, which diffuse into the substrate bulk and slowly react with oxygen atoms of the support material.³⁶ In a number of studies,^{37–39} the increase in the electrical conductivity of TiO_2 in a hydrogen atmosphere was attributed to proton diffusion to the titanium dioxide. The electrical conductivity of TiO_2 attached to platinum is the first to increase and then this also takes place for TiO_2 without platinum.

The proton mechanism of spillover is also indicated by the correlation between the spillover rate and the proton affinity of the promoter,^{11,34} which can solvate the diffusing proton: water > methanol > ethanol > *n*-propanol > *n*-butanol. In the presence of these promoters, the spillover rate does not depend on the surface area of the applied platinum, whereas in the presence of, for example, acetic acid, which has a low proton affinity, this dependence does exist. In the latter case, the reaction rate can be determined by the rate of proton solvation.

Even those who support the atomic nature of hydrogen spillover have to admit⁴⁰ that no unambiguous spectroscopic data indicating that $\text{H}^\bullet$ act as activated hydrogen species have yet been obtained. In some cases, experimental evidence for both mechanisms is found for the same catalyst systems under the same reaction conditions.⁴⁰ Depending on the type of testing or the particular spectroscopic technique used, either atomic hydrogen or protons are identified. The model proposed by Roland *et al.*⁴⁰ describes the spillover as the formation of an electron donor on the surface of the support. In this consideration, weakly chemisorbed hydrogen is regarded as atomic, while strongly chemisorbed hydrogen is taken as protons. Quantitative data obtained by spectroscopic methods do not allow one to identify unequivocally the nature of the activated species in the solid-phase catalytic reactions.

Tritium can also react with a substrate in either atomic or ionic form. However, the results of the hypothetical interactions of the electrons generated in parallel with the formation of protons with either gaseous hydrogen or with the substrate molecules have not been considered in the literature. The latter process could also be interpreted as a specific case of electrochemical reaction. Electrons are free to migrate over the crystallite of the metal catalyst or over the support (for example, graphite). However, if the substrate is an insulator, the electron conductivity may prove to be negligibly low.

It is worth mentioning that the conductivity in the metal crystallite decreases as the temperature rises, because electron scattering is enhanced upon disordering of the motion of atoms caused by their thermal excitation. Metalloids usually have positive temperature coefficients of conductivity.⁴¹ The interaction with electrons might be responsible for the disappearance of the EPR signal of perylene adsorbed on the Pt/ZrY system¹⁸ and for the reduction of tetravalent cerium to trivalent cerium.³¹ It was shown above^{6–10} that hydrogenation can be accomplished by gaseous hydrogen; this may be related to the presence of electrons arising upon the spillover of protons.

Research into the reactions of various organic molecules with atomic tritium formed upon heating of tritium gas to 2000 K on a tungsten filament has shown⁴² that, even when the target is cooled with liquid nitrogen, the degree of replacement of hydrogen in the molecule of an organic compound does not exceed 10%. In this case, the chemical and radiochemical yields of the exchange were exceptionally low compared to the yields of solid-phase reactions. Indeed, even at room temperature, atomic hydrogen reduces

many metal oxides, reacts with sulfur, nitrogen and phosphorus, and also reacts with oxygen to give hydrogen peroxide; in addition, the hydrogen atoms easily recombine. The reactions involving radicals produce a variety of side products. Thus, if the label is introduced *via* a reaction with atomic tritium, the yields of labelled biologically active compounds would be very low. At temperatures used to carry out solid-phase reactions, atomic tritium generated in the reaction of tritium gas with the catalyst is converted into molecular tritium, which does not play any important role in the synthesis of labelled preparations. This seems to account for the stability of organic compounds in these reactions.

Probably, noticeable participation of atomic tritium in reactions could be expected at higher temperatures, which are not normally used in solid-phase labelling. Indeed, only at high temperatures can radical elimination as well as hydrogenation and dehalogenation involving atomic tritium compete with energetically more favourable recombination of tritium atoms.

It is of interest to analyse the data concerning the reactions of radicals with the substrate under conditions more appropriate for the investigation of these systems.⁴³ For example, it was found that radicals are more prone to undergo elimination than addition reactions.⁴³ This is due to the fact that the elimination

involves a linear reaction centre, which ensures the lowest activation barrier. During the addition

the reaction centre is a triangle; this, undoubtedly, increases the activation energy of this reaction. The intramolecular transfer of hydrogen atoms was studied by EPR (although, at low temperatures), and the kinetics of free-radical intramolecular transfer of protium and deuterium atoms was first studied by direct spectral methods using hydrocarbon groups grafted to the solid surface (silica gel) (Table 1).⁴⁴

Table 1. Rate constants for free-radical intramolecular transfer of protium and deuterium atoms.⁴⁴

Process	<i>T</i> / K	$10^{-5} k$ / s ⁻¹

$\begin{array}{c} \diagup \text{Si} \diagdown \\ \quad \\ \text{C}^\bullet\text{H}_2\text{C}^\bullet\text{H}_2 \\ \quad \\ \text{CH}_3 \end{array} \rightleftharpoons \begin{array}{c} \diagup \text{Si} \diagdown \\ \quad \\ \text{CH}_2\text{CH}^\bullet\text{H} \\ \quad \\ \text{CH}_2^\bullet\text{H} \end{array}$	373	20 ± 2

It was shown that the radical centre can migrate; therefore, different polymerisation, isomerisation, *etc.* products can be formed not only at the sites of the initial formation of radicals.

It is of interest to analyse the regularities involved in homolytic and electrophilic substitution of tritium for hydrogen in aromatic compounds⁴⁵ in order to compare them with the regularities of isotope exchange. For electrophilic substitution, where H⁺ acts as the electrophilic species, *ortho*-, *para*- and *meta*-directors are distinguished in the molecule (Table 2). The proton addition is the slow step in this reaction. For example, on treatment of aromatic compounds with a mixture of trifluoroacetic acid and

Table 2. Rate constants for deuterium inclusion (rel.u.) into different positions of the aromatic ring with different substituents.

Position of the substituent	Rate of inclusion for the substituent			
	CH ₃	CH ₃ O	Cl	I
<i>ortho</i>	83	23 000	0.035	0.043
<i>meta</i>	1.9	0.25	0.002	0.003
<i>para</i>	83	55 000	0.160	0.112

heavy water, the rate of deuterium exchange was found to vary in parallel with the equilibrium degree of protonation.

Let us compare electrophilic alkylation of aromatic compounds with the corresponding radical reactions. Methylation of toluene and ethylation of bromo- and fluorobenzene by treatment with R⁺[Al₂Cl₇]⁻ proceed as typical electrophilic substitution reactions (Table 3). Homolytic methylation gives a different ratio of substitution products.

Table 3. Inclusion (%) of the CH₃ and C₂H₅ groups into *ortho*-, *meta*- and *para*-positions during alkylation of aromatic compounds.

Process	Inclusion position

fluorobenzene ^a	43	14	43
bromobenzene ^a	24	22	54

^a Electrophilic substitution. ^b Homolytic methylation.

As will be shown below, this type of specificity is also observed during solid-phase hydrogenolysis by tritium. It is evident that this type of process specificity cannot be interpreted when considering only the source or the mechanism of transport of activated species to the substrate. However, since these species have different properties (a radical and an ion), by investigating the reaction products and/or distribution of a label in them, one can draw conclusions in favour of a particular mechanism of hydrogen spillover.

III. Solid-phase reactions in the synthesis of tritium-labelled preparations

Solid-phase reactions proved to be fairly efficient for the introduction of a tritium label into organic compounds. When selective methods are used, the problem of optimisation of the conditions of introduction becomes especially topical. Highly labelled materials can be prepared in solid-phase processes such as selective isotope exchange, selective hydrogenation of unsaturated carbon–carbon and heteroatom–carbon bonds and selective reductive dehalogenation of one of the several halogen atoms or reductive dehalogenation for organic molecules containing labile unsaturated fragments.

It should be mentioned that the solid-phase reactions listed above are accompanied by side processes, which considerably influence the radiochemical characteristics of labelled specimens. For example, when substances applied on a catalyst are treated with tritium gas, the final molar radioactivity of the products depends appreciably on the isotope effects. The destruction of organic compounds not only hampers purification of labelled materials but also results in isotope dilution of tritium. Evidently, the reactions of organic compounds with the resulting protium –

tritium mixture decrease the degree of inclusion of tritium into the molecules of these compounds. A model has been proposed⁴⁶ that can be used to explain the influence of different factors on the degree of inclusion of tritium into organic molecules.

1. Solid-phase isotope exchange

Isotope exchange is the method of choice for introducing a tritium label, as it does not require the synthesis of precursors. In addition, isotope exchange allows one to prepare a labelled specimen using very small amounts (5–10 mg) of biologically active substances, which are often scarce and expensive. This method is inapplicable only when the starting compound is totally destroyed under experimental conditions.

The solid-phase catalytic isotope exchange is a complex process affected by numerous factors related to the properties of both organic compounds and the catalysts. For example, the efficiency of solid-phase isotope exchange depends appreciably on the melting point of the organic compound. In view of this fact, all compounds can be divided into two groups. The first one includes substances that behave like liquids at the chosen reaction temperature (in this case, the molecules can migrate over the support and with respect to one another); the second group comprises compounds that exist as crystals during the reaction (in this case, direct contact with the catalyst active sites is impossible and the degree of isotope exchange mainly depends on the efficiency of tritium spillover). Naturally, the regularities of insertion of the label into compounds of the first and second groups are dissimilar. Lipid-related compounds usually have low melting points, while nucleotides, nucleosides, amino acids, peptides and their derivatives have high melting points. Therefore, it is expedient to consider the regularities of labelling of compounds with different properties by this procedure and then to present data on the radiochemical characteristics of labelled specimens obtained under the optimal conditions for each class of compound.

a. Study of the dependence of the degree of solid-phase isotope exchange on the nature of organic compounds

Let us consider the results of experimental studies of the influence of the nature of organic compounds on the kinetics of their labelling and the dependence of the molar radioactivity of the resulting preparations on the reaction temperature.

Experiments on introducing a label into crystalline L-valine and L-alanine showed that the degree of isotope exchange smoothly increases with an increase in the temperature and the kinetic curves reach a plateau.^{47, 48}

A similar situation is observed in introduction of the label into adenine, guanine, xanthine, hypoxanthine (Table 4), deazaguanine and 3-indolylacetic acid.⁵¹

Table 4. Relative molar radioactivity of adenine, guanine, xanthine and hypoxanthine (5% Pd/CaCO₃, τ = 60 min) at various temperatures.^{49, 50}

$T/^{\circ}\text{C}$	RMR (%)			
	adenine	guanine	xanthine	hypoxanthine
20	1.4	1.3	0.8	1.7
120	1.8	1.7	2.4	—
140	16.8	6.5	20.9	13.1
150	34.7	16.7	50.0	—
160	54.7	25.7	67.4	16.7
180	100	71.9	96.5	63.0
200	—	91	100	100
220	—	100	—	98.8

Note. Here and in other tables, τ is the experiment duration; RMR is the relative molar radioactivity; the highest molar radioactivity attained in this series of experiments was taken to be 100%.

Figure 1. Degree of labelling of the substrate vs. the temperature of isotope exchange.⁵²

Reaction conditions: τ = 15 min; 5% Pt/C: hexadecane, 10:1 (1); 5% Pt/C: 6-ketopalmitic acid, 10:1 (2); 5% Pt/C: methyl stearate, 10:1 (3); 5% Pd/C: cetyl alcohol, 6:1 (4).

The kinetics of variation of the molar radioactivity of purine bases and amino acids are similar: the kinetic curves and the curves for the temperature dependence of the degree of labelling reach a plateau.

The curves obtained for low-melting compounds of lipid nature look quite different (Fig. 1). Similar types of dependence are also found in the case of other catalysts (Pd/BaSO₄, Rh/C),⁵² which differ in the ability to initiate the isotope exchange and in the temperature at which the highest molar radioactivity is attained. The appearance of maxima on these dependences can be explained in the following way. The molecules of, for example, a low-melting fatty acid, unlike those of high-melting compounds, can create a certain structured system around the active sites of the catalyst;⁵³ a layer of chemisorbed molecules functioning as ligands appears on the catalyst surface.^{54, 55} These systems are more stable against poisoning and deactivation. In view of the foregoing, the processes taking place on the catalyst surface during the solid-phase isotope exchange between tritium gas and low-melting compounds can be described by the following scheme. First, the adsorbed molecules of the substance undergo a redistribution on the catalyst surface to give ordered systems involving some of the substrate molecules and the catalyst active sites. The greater part of the molecules moves freely and comes in contact with these ordered structures. Therefore, the rate and the degree of exchange during labelling of such substances are higher than those in the case of high-melting compounds.^{52, 53} As the temperature and process duration increase, the degree of isotope exchange becomes higher but the rate of side processes also increases. Starting from certain temperatures, the structured chemisorbed layer is destroyed; this stops the isotope exchange and induces decomposition of, first, the fraction of the specimen with the highest degree of labelling.⁵³ This accounts for the appearance of maxima in the plots for the dependence of the molar radioactivity of fatty acids on the temperature and the duration of isotope exchange.^{52, 56}

This type of regularity has been observed when introducing the label into hexadecane, 6-ketopalmitic acid, methyl stearate and cetyl alcohol (see Fig. 1); the positions of the maxima and the patterns of temperature dependences of the molar radioactivity can be substantially different for different compounds.

All attempts to explain the appearance of the maxima by other reasons (for example, by high content of bound hydrogen in the activated carbon,⁵⁷ sublimation of a part of the compound from the catalyst surface, a decrease in the catalytic activity of the metal after thermal treatment^{58, 59}) have not been confirmed experimentally.

Figure 2. Degree of labelling of stearic acid vs. the temperature of isotope exchange (10% Pd/BaSO₄); (1) standard catalyst; (2) catalyst pre-calcined at 240 °C and 0.1 Pa.

Upon degassing and thermal deactivation of the catalyst, the degree of labelling of, for example, stearic acid really decreases but the general extremal pattern of the temperature dependence does not change (Fig. 2).⁶⁰ The proposed interpretation of the pattern of these curves would be confirmed if the maxima disappeared in the case of merely mechanical application of stearic acid onto the sorbent mixed with the standard catalyst. Indeed, with such application, the formation of the structured system of stearic acid molecules around the active sites of the catalyst would be appreciably hampered due to the short reaction time, and, hence, the degree of inclusion of tritium would be more uniform for all molecules of organic acid. Therefore, this modification of the conditions of the solid-phase reaction should entail some decrease in the degree of isotope exchange.

An experiment of this type has been carried out:⁶⁰ a methanol solution of stearic acid was mixed with the Alusorb or Silasorb sorbent in 1 : 10 ratio, the solvent was removed, and the residue was dried. Then the support–substance mixture was thoroughly triturated in a mortar together with the catalyst and the reactions with the aliquot portions of this mixture were carried out at different temperatures (Table 5). As can be seen from the data given in the Table, with an increase in temperature, the molar radioactivity of the specimen first increases, then decreases and subsequently varies insignificantly.

Table 5. Relative molar radioactivity of labelled stearic acid at various temperatures of isotope exchange (5% Pd/BaSO₄, catalyst : substance ratio is 20 : 1, $\tau = 15$ min) on the catalyst without a support and using an additional support.⁶⁰

$T/^{\circ}\text{C}$	RMR (%)		
	no support	Alusorb	Silasorb
190	42	46	47
200	71	76	80
210	82	81	82
220	100	79	81
230	48	75	84
240	36	82	83

Thus, the degree of labelling depends substantially on the aggregative state of the substrate under the solid-phase reaction conditions.^{52, 61}

A study of the dependence of the degree of labelling on the length of the carbon chain in homologues of fatty acids whose melting points are markedly lower than the temperature at which the isotope exchange is carried out showed a linear decrease in the molar radioactivity with a decrease in the chain length. Hence, the isotope exchange for this type of substance is a probability process. Some other features were noted. For example, the temperatures corresponding to the maximum degree of isotope replacement (T_{max}) were different for different homologues. For

example, the T_{max} values for lauric (m.p. = 44 °C), myristic (m.p. = 58 °C), palmitic (m.p. = 64 °C) and stearic (m.p. = 70 °C) acids were 190, 200, 205–210 and 210 °C, respectively.^{52, 62}

Apparently, for representatives of one homologous series (for example, for fatty acids), T_{max} depends on the temperature of phase transition (melting). At a definite temperature, diffusion of these molecules increases so sharply that the efficiency of isotope exchange reaches a maximum and does not depend on the efficiency of hydrogen spillover. The conducting of these reactions at higher temperatures results only in activation of side processes.

However, for high-melting sodium salts of acetic, propionic, and butyric acids, the molar radioactivity did not show this type of unambiguous dependence on the number of carbon atoms.⁶³ Evidently, the accessibility of the substance bulk during the isotope exchange reaction differs appreciably depending on whether the substance occurs on the support surface in the solid (crystalline) or in the liquid state.

b. Introduction of a tritium label into lipophilic compounds and into low-molecular-mass bioregulators by solid-phase isotope exchange

Compounds of lipid nature vary appreciably in thermal stability and in stability against hydrogenolysis; they can be either polar or non-polar and either aliphatic or aromatic. Examples of such compounds are given below.

In this section, in addition to lipophilic compounds, we also consider other substances used in pharmacology. For example,

As a rule, these compounds are polyfunctional and contain fragments that are unstable under solid-phase reaction conditions. Many of these substances (called, for convenience, pharmaceuticals) possess hydrophobic properties, like compounds of a lipid nature.

To optimise the conditions of labelling in compounds of this type, the degree of isotope exchange has been studied as a function of the following variables: temperature (in the 60–240 °C region), the catalyst: substance ratio, the reaction time (in the range of 5–60 min), the nature of the catalyst (5% Pt/C, 5% Pd/C, 5% Rh/C, 5% Pd/BaSO₄) and some others.^{52, 56, 61–71} For example, it was found that the best conditions for introducing a

Table 6. Molar radioactivity (MR) of labelled sodium isobutyrate obtained with solid-phase isotope exchange carried out under various conditions.⁶³

Reaction conditions			MR /PBq mol ^{−1}
catalyst	τ /min	T /°C

label into thermally stable isobutyric acid are as follows: 5% Pd/C, 30 min, 170 °C (Table 6).⁶³ Under more rigorous conditions, the yield of the labelled product decreased.

Study of the influence of the structure of compounds having similar physicochemical properties on the molar radioactivity of labelled specimens has shown⁶³ that the probability of inclusion of tritium, for example, in the methyl group of the isobutyric, propionic and butyric acids, is more than three times higher than the probability of its inclusion into methylene groups (Table 7). The reasons for this difference are considered below.

Table 7. Molar radioactivity of labelled organic acids prepared by solid-phase isotope exchange (5% Pd/C, T = 200 °C).⁶³

^a Expressed in PBq mol⁻¹.

It has been noted above that the nature of the tritium active species can be traced most clearly in reactions with aromatic compounds. The susceptibility to electrophilic substitution is known^{45,72} to be different for different aromatic systems. It depends on the structure of the compound and on the presence of substituents; this was demonstrated, for example, by measuring the rate constants for the isotope exchange during the preparation of [8-³H]nucleotides of the adenine series. The data reported by Sidorov and Myasoedov⁷⁵ allow one to suggest that if the activated hydrogen species that react with an organic compound are represented by positively charged tritium ions, the degree of labelling should decrease in the sequence ribavirin, tiazofurin, zaleplon and alprazolam. Indeed, it was shown^{53,74} that ribavirin was labelled to a 7–8 times higher degree than alprazolam. Apparently, this is due to the fact that the highest probability of the electrophilic substitution is expected for the triazole fragment of ribavirin. Therefore, ribavirin should exhibit the highest molar radioactivity over the given series (see Table 9). Due to the presence of the sulfur atom in the thiazole fragment, tiazofurin is substantially deactivated and the electrophilic substitution is less efficient.

Not every substance withstands the conditions of the solid-phase isotope exchange to the same extent. The chemical yield of hexadecane and cetyl alcohol after the exchange is 80%, whereas labelled compounds containing free amines, neuraminic acid and so on are formed in less than 20% yields.^{61,69,76} The stabilities of the specimens can be sharply different even in the case of compounds with similar structures (see Table 10). For example,

the yield of the sodium salt of *N*-acetylneuraminic acid α -methylglycoside at 200 °C is almost twice as high as that of the derivative of the trisaccharide sialyllactose at 160 °C. It was shown⁷⁶ that the degree of inclusion of the label into the sodium salt of *N*-acetylneuraminic acid α -methylglycoside increases ~4-fold as the temperature rises from 160 to 200 °C (Table 11). If the derivative of the trisaccharide sialyllactose did not decompose at 200 °C, it would be possible to obtain a labelled specimen with a molar radioactivity of > 1 PBq mol⁻¹.

Table 11. Relative molar radioactivity of the labelled sodium salt of *N*-acetylneuraminic acid α -methylglycoside (the ratio catalyst : substance is 25 : 1) for different conditions of solid-phase isotope exchange.

Reaction conditions			Yield (%)	RMR (%)
catalyst	$T/^{\circ}\text{C}$	τ /min		
5% Pd/BaSO ₄	140	40	92	13
	180	5	75	39
5% Pd/CaCO ₃	140	40	95	16
	160	25	91	22
	180	5	74	46
	200	5	25	86
	220	5	8	100

The large scatter in the yields of labelled specimens is also typical of aromatic compounds. The compounds containing triazole, pyrazole and thiazole fragments are more stable during the solid-phase method of labelling than isoxazole derivatives; however, the yields of these compounds under the conditions optimal from the standpoint of higher molar radioactivity were 2 to 80% (see Table 9).

Thus, if the compound is stable, the solid-phase procedure gives labelled specimens with a very high molar radioactivity. For introducing a label into labile compounds, it is necessary to use modified procedures. There are two approaches for increasing the yield of such compounds: (1) organic compounds are applied onto an additional inert support and are mixed mechanically with the catalyst; (2) the catalyst is modified prior to the reaction.

c. The introduction of the tritium label into components of nucleic acids by solid-phase isotope exchange

The best catalyst for introducing a tritium label into purine bases is 5% Pd/CaCO₃ (Table 12). The dependence of the molar radioactivity on the reaction temperature for these compounds shows a gradual increase to 140 °C and a sharp growth in the range of 150–200 °C (see Table 4).⁴⁹ Apparently, the increase is due to the

Table 12. Molar radioactivity of the specimens obtained by tritium labelling of purine bases under various conditions.

^a In all experiments, $\tau = 30$ min. ^b Expressed in PBq mol⁻¹.

fact that tritium atoms start to play a noticeable role in the isotope exchange, instead of the cations.

The introduction of a label into components of nucleic acids with different stabilities has been reported^{75, 78–80} (Table 13). It can be seen from the data presented in the table that high degrees of replacement of protium by tritium were attained in compounds with a rather simple structure. In the case of polymeric derivatives or compounds containing labile fragments, labelling had to be performed at relatively low temperatures, which substantially influenced the molar radioactivities of the labelled preparations. The major side products obtained according to this procedure were those resulting from hydrogenation, isomerisation and destruction processes.

To increase the molar radioactivity of labile compounds, additional supports were used; this made it possible to carry out the reaction at higher temperatures (Table 14).⁵¹ It can be seen from the data given in the table that an increase in the catalyst: compound ratio entails an increase in the degree of tritium inclusion with a simultaneous decrease in the yield of the labelled

specimen. With the use of an additional support and a mixture of 5% Pd/CaCO₃ with indol-3-ylacetic acid supported on Al₂O₃, the yield of the desired product increased to 12.5%. According to ³H NMR data, the distribution of the label at 200 °C is uniform over all the stable positions of tritium in indol-3-ylacetic acid, which is indicative of a considerable contribution of atomic tritium to the labelling process.

The proportion of tritium in purine bases depends on the nature of the initial compound.⁷⁹ As can be seen from the data listed in Table 15, the presence of the phosphate group decreases the content of tritium in the purine moiety of the molecule. Possible interpretations of this finding are discussed below.

Table 15. Molar radioactivity and fraction of tritium (%) in the specimens obtained by labelling of purine bases.

Compound	MR /PBq mol ⁻¹	Fraction of tritium
Adenosine	4.44	48
Guanosine	2.56	30
Acyclovir	4.78	14
AMP	0.46	12
ATP	0.46	13
NAD	4.10	1.3

Note. Here and in other tables, AMP is adenosine 5'-monophosphate, ATP is adenosine 5'-triphosphate, NAD is nicotinamide dinucleotide.

d. The introduction of the tritium label into amino acids and peptides by solid-phase isotope exchange

Many amino acids are thermally more stable than nucleic acids. Data on the solid-phase introduction of the tritium label into some amino acids have been reported (Table 16).⁸¹ At 220 °C, the distribution of the label at the valine carbon atoms (α : β : γ) is described by a 1 : 1 : 6 ratio (τ = 20 min, the 5% Pd/C : compound ratio is 10 : 1). The distribution of the label (%) in [2,3-³H]alanine under the same conditions is given by⁸¹

Compound	<i>n</i> = 0	<i>n</i> = 1	<i>n</i> = 2	<i>n</i> = 3
CH _n ³ H _{3-n} C ³ HNH ₂ CO ₂ H	3	15	22	5
CH _n ³ H _{3-n} CHNH ₂ CO ₂ H	5	17	23	7

At high temperatures, the degree of isotope replacement is of the same order of magnitude at any atom of the amino acid.

Other data have been obtained at lower temperatures.⁸² The distribution of tritium in the (*R*)-4-hydroxy-[G-³H]-L-proline molecule was studied. This compound was synthesised by heating (150 °C) for 60 min of a mixture of 5% Rh/Al₂O₃ with the activated Norit carbon impregnated with an aqueous solution of amino acid and then freeze-dried (the catalyst : Norit : (*R*)-4-hydroxy[G-³H]-L-proline ratio was 10 : 50 : 1). The ratio of the activation energy (*E*_a) of hydrogen exchange at a given carbon

Table 16. Molar radioactivity, yield and optical purity of labelled amino acids prepared by solid-phase isotope exchange (200 °C, 60 min).⁸⁶

Compound	MR /PBq mol ⁻¹	Yield (%)	Optical purity (%)
Glycine	1.8	90	—
Serine	1.4	50	75
Alanine	3.2	65	82
Valine	6.5	85	94
Leucine	7.9	70	85
Isoleucine	8.1	75	88
Histidine	4.5	20	50
Tryptophane	3.6	30	70

atom to the activation energy (E) of hydrogen exchange in methane is as follows:

Position of the label	3 β	3 α	5 α	5 β	2	4
$E_a : E$	0.946	0.856	0.653	0.794	0.852	0.924
Content of the label (%)	1	6	59	21	9	4

When the solid-phase isotope exchange is carried out under relatively mild conditions, the following tendency can be traced: the lower the activation energy for the exchange at a given carbon atom, the higher the degree of replacement of protium by tritium.

In the case of amino acids, the use of an additional support also promoted an increase in the molar radioactivity (Table 17).⁴⁸ Activated carbon, alumina and calcium carbonate are used most often. This procedure made it possible to obtain labelled compounds having various stabilities with a high molar radioactivity.

Table 17. Molar radioactivity of biotin and amino acids prepared by solid phase isotope exchange using various additional supports.⁴⁸

Compound	Reaction conditions				MR /PBq mol ⁻¹
	I ^a	II ^b	III ^c	<i>T</i> /°C

^a The catalyst : substance ratio /mg μmol^{-1} . ^b Additional support. ^c The additional support : substance ratio /mg mg^{-1} .

The influence of the same additional support, in particular, carbon, prepared by different procedures on the degree of labelling has been studied⁸³ (Table 18). In an experiment, phenylalanine was applied on the Norit carbon or on fibrous carbon in a ratio of 1 : 10. The resulting blends were mechanically mixed with 5% Pd/C in 1 : 1 ratio. After treatment with tritium ($T = 130^{\circ}\text{C}$, $\tau = 25$ min), the yield and the molar radioactivity of labelled phenylalanine were determined.

It was found that with the use of 5% Pd/C, the yield was as low as 1% and with a mixture of 5% Pd/C with the Norit carbon, the yield was even lower, 0.1%. A higher yield and a higher molar radioactivity (at 140°C) were attained by using fibrous carbon.

Table 18. Yield and relative molar radioactivity of labelled phenylalanine obtained by solid-phase catalytic isotope exchange under various conditions ($\tau = 25$ min, $T = 130^{\circ}\text{C}$).⁸³

Reaction conditions		Yield (%)	RMR (%)
catalyst	support		
5% Pd/C	—	1	—
	Norit carbon	<0.1	—
5% Pd/CaCO ₃	fibrous carbon	16	100
	Norit carbon	2	29
5% PdO/ Al ₂ O ₃	fibrous carbon	39	44
	Norit carbon	1.5	17
5% PdO/ BaSO ₄	fibrous carbon	41	35
	Norit carbon	2	22
	fibrous carbon	35	47

Similar results were obtained upon mixing fibrous carbon – phenylalanine systems with 5% Pd/CaCO₃, 5% PdO/BaSO₄ and 5% PdO/Al₂O₃ (see Table 18). When fibrous carbon was used, the yields of phenylalanine were 15–20 times and the molar radioactivities were 1.5–2 times as high as those obtained in the presence of the activated Norit carbon, which is used most often in these reactions.

This result was attributed⁸³ to the fact that fibrous carbon consists of very thin graphite layers (30–500 Å thick) laid to form highly ordered structures;⁸⁴ therefore, it adsorbs approximately an order of magnitude more hydrogen than the usual carbon. In addition, the amounts of hydrogen adsorbed on and desorbed from graphite nanofibres at room temperature were substantially different, indicating chemisorption of hydrogen on carbon. This was confirmed by temperature-programmed desorption.⁸⁴ Hence, fibrous carbon as a support has certain advantages over other materials. A higher saturation by tritium molecules of the whole bulk of the reaction mixture should be favourable for the efficiency of its spillover and should lead to a higher concentration of the activated species of tritium directly in the reaction area.

The higher yield of labelled organic compounds makes it possible to obtain a plausible yield of labelled preparations at higher temperatures (35–45 $^{\circ}\text{C}$ higher than in the case of the standard procedure). This, in turn, makes it possible to increase substantially the molar radioactivity of the material; for example, in the case of phenylalanine, this value increases ~ 3 -fold.⁸³

The method according to which a mixture of the substance with the catalyst is treated before the reaction by transition metal salts also proved to be efficient for increasing the molar radioactivity of thermally unstable preparations. For example, rhodium salts were used in the labelling of amino acids.⁸⁵ As noted above, the molar radioactivity of labelled compounds can be increased by creating conditions for more efficient hydrogen spillover under which isotope exchange takes place throughout the whole bulk of the substrate or by increasing the thermal stability of the substance (in this case, the label can be introduced at a higher temperature). In order to elucidate the role of rhodium trichloride during labelling, it was used to impregnate the catalyst and the support both separately and jointly.

It can be seen from the data presented in Table 19 that the key role of RhCl₃ is not to stabilise the amino acid by complex formation but rather to decrease the destructive action of the activated tritium species on the substrate. When the catalyst was treated with rhodium trichloride and then mixed mechanically with the support (fibrous carbon or Al₂O₃) on which phenylalanine had been applied, the yield of the labelled product increased 3–6-fold. On treatment of the support with a solution with RhCl₃ and phenylalanine followed by freeze-drying of the resulting mixture and subsequent mechanical mixing with the catalyst, the yield of the labelled product increased only 2–4-fold. In both experiments, molar radioactivities of the same order were obtained. This fact indicates that in the case of using the conven-

Table 19. Yield and relative molar radioactivity of labelled phenylalanine obtained with different ways of modification of reaction ingredients by rhodium trichloride ($\tau = 20$ min, $T = 190^{\circ}\text{C}$, the ratio support : phenylalanine is 10 : 1, catalyst : support is 1 : 1, phenylalanine : RhCl₃ is 1 : 1).

Catalyst	Support	Yield (%)	RMR (%)
5% PdO/BaSO ₄	fibrous carbon	4.2	100
	fibrous carbon/RhCl ₃	14.8	18
	the same	20.5	21
5% PdO/BaSO ₄ /RhCl ₃	—	31.1	9
	Al ₂ O ₃	1.5	48
5% PdO/BaSO ₄	Al ₂ O ₃	8.9	83
	Al ₂ O ₃ , RhCl ₃	17.2	44
5% PdO/BaSO ₄ /RhCl ₃	Al ₂ O ₃	30.4	42

tional procedure (an aqueous solution of amino acid and RhCl_3 is freeze-dried with the catalyst), RhCl_3 not only stabilises labile compounds but, simultaneously, it modifies the initiator of hydrogen spillover. Apparently, co-precipitation of rhodium salts on palladium with subsequent heating under an atmosphere of tritium gas gives rise to bimetallic active sites, which acquire new properties of both an adsorbent and an initiator of hydrogen spillover. Phenomena of this type have been considered in detail⁸⁶ in a study of the influence of technetium on the efficiency of solid-phase isotope exchange.

Comparison of the catalytic activity of mono- (Pd or Pt) and bimetallic systems (Pd–Tc or Pt–Tc) showed a non-additive increase in the catalytic activity (synergism) in the case of bimetallic catalysts with respect to the activity of metal catalysts used separately under the same conditions.⁸⁷ Some researchers explain the synergistic effect by the fact that hydrogen is activated on one type of active sites and the reactions proceed on another type of active sites.^{88–91} This model assumes that the spillover of hydrogen between these sites is enhanced. Other researchers believe that the synergism is mainly related to the interaction of the atoms of one metal catalyst with the other.^{92–102} In this case, hydrogen becomes activated and reacts in the same phase, *i.e.*, the activated hydrogen species migrate from one metal atom to the other within the bimetallic active site.

In solid-phase experiments, the degree of labelling of amino acids was lower in the presence of bimetallic catalysts than in the presence of monometallic catalysts.⁸⁶ This implies that no activation of tritium spillover takes place on the bimetallic catalysts, and the activated tritium species merely migrate from one metal atom to the other within the common catalytic site. Indeed, the capacity for the sorption of hydrogen is lower for bimetallic catalysts than for monometallic ones,⁸⁷ which is usually related to the decrease in the efficiency of hydrogen spillover.

Thus, the increase in the stability of amino acids resulting from catalyst modification by rhodium salts is mainly due to the fact that the reaction of the molecules of these compounds with activated tritium species proceeds to a lesser extent on bimetallic catalysts than on monometallic ones. Therefore, in the case of solid-phase labelling in the presence of metal catalysts, the degree of decomposition of the initial substance decreases after treatment of the catalysts with rhodium salts, which allows the isotope exchange to be carried out at higher temperatures. Indeed, without rhodium salts, raising the temperature by 60 °C (a 5% PdO/ Al_2O_3 : amino acid ratio of 10:1, $\tau = 30$ min, a tritium pressure of 350 hPa) resulted in a ~20-fold decrease in the yield of glycine and a 5-fold decrease in the yield of ω -aminocaproic acid.⁸⁵

$T/^\circ\text{C}$	160	180	200	220
Yield of glycine (%)	66	21	5	3
Yield of ω -aminocaproic acid (%)	4.8	1.8	1.2	0.9

When the catalyst was treated with rhodium trichloride, the decrease in the yield of labelled amino acids with temperature rise was found to be markedly retarded (Table 20). This made it possible to introduce the label into thermally unstable ω -aminocaproic acid at 180 °C (molar radioactivity of the product was 0.85 PBq mol^{−1}, yield 45%).⁸⁵

Evidently, the degree of isotope exchange can also be increased by creating conditions for more efficient interaction of the activated tritium species with substrate molecules.

The tritium labelling of high-melting compounds can be enhanced using 4-dimethylaminopyridine (Table 21).⁸⁵ Many reactions involving protons can proceed only in the presence of this compound.¹⁰³ Apparently, after co-precipitation with the substrate, this molecule can facilitate the diffusion of tritium cations into the substance bulk and thus increase the probability of isotope exchange. The data presented in Table 21 confirm the legitimacy of this hypothesis. However, it is too early to draw more definite conclusions. Evidently, solid-phase reactions of this type can be carried out only at relatively low temperatures;

otherwise, tritium would be inserted into 4-dimethylaminopyridine, which would reduce the molar radioactivity of the labelled specimen and would markedly complicate isolation and purification of the target product.

As in the case of compounds of a lipid nature, the replacement of protium by tritium is usually higher for the methyl groups of amino acids than for the methylene groups or than the isotope exchange at a tertiary carbon atom (Table 22).¹⁰⁴

Table 22. Relative reactivity of amino acids in solid-phase isotope exchange and tritium distribution in labelled compounds ($T = 150$ °C).¹⁰⁴

Compound	Relative reactivity	Fraction (%) of the label at carbon atoms with different degrees of substitution		
		RCH_3	RR^1CH_2	$\text{RR}^1\text{R}^2\text{CH}$

Valine	1.0	92	—	8

Data on the label distribution in aromatic amino acids and on the relative reactivities of these substrates are summarised in Table 23.¹⁰⁴ It can be seen that the highest degree of isotope exchange is found for histidine, the major amount of the label being concentrated in the aromatic ring. The same is observed for other aromatic amino acids. The degree of isotope substitution depending on the nature of the amino acid varies in the sequence:¹⁰⁴ basic amino acids > aliphatic amino acids without ionic groups > acidic amino acids.

Table 23. Relative reactivities of aromatic and heteroaromatic amino acids and serotonin in the solid-phase isotope exchange and tritium distribution in labelled compounds ($T = 150\text{ }^{\circ}\text{C}$).¹⁰⁴

Compound	Relative reactivity ^a	Fraction (%) of the label at different positions

Thyroxine	0.72	11	35	54
Serotonin	1.2	35	7	58

^a Valine was used as the reference.

Labelling of peptides is often carried out using procedures of liquid-state hydrogenation and dehalogenation of their precursors prepared by multistage synthetic protocols. In most cases, this is done using derivatives whose molecules include dehydroproline, iodophenylalanine or diiodotyrosine.¹⁰⁵ The molar radioactivity of the specimens obtained by this method was $0.77\text{--}2.35\text{ PBq mol}^{-1}$, depending on the precursor.

The synthesis of peptides is usually carried out either in solution or in the solid state. The synthesis of precursors is a very cumbersome and expensive stage. Therefore, solid-phase isotope exchange between the tritium gas and peptide usually proves to be more efficient.

Peptides are more labile compounds than amino acids. In addition, there exists the problem of racemisation of amino acid residues at the α -position during the labelling. Therefore, labelled peptides are obtained by conducting reactions at relatively low temperatures (Table 24).¹⁰⁶ The distribution of the label in the amino acid residues in these peptides was approximately equal but hydrogen at the α -carbon atoms of amino acids proved to be the most reactive in the isotope exchange with tritium. For example, the peptide Met-Gly-His-Phe-Pro-Gly-Pro contained after labelling ($140\text{ }^{\circ}\text{C}$), on average, 1.44 tritium atoms, and 88% of them were in the α -positions of amino acid residues. At $180\text{ }^{\circ}\text{C}$, 4.29 tritium atoms were incorporated in this peptide, and only 76% of tritium occurred in the α -position of the amino acid residues.¹⁰⁶ Thus, the same trend is observed: the higher the reaction temperature, the more uniform the distribution of the label (Table 25).

The influence of the peptide structure on the distribution of the label among amino acid residues was studied using model

Table 24. Molar radioactivity of tritium-labelled peptides ($T = 140\text{ }^{\circ}\text{C}$, labelling was carried out using an additional support or the rhodium complex with the peptide).¹⁰⁶

tripeptides.¹⁰⁴ It can be seen from the data listed in Table 26 that at $150\text{ }^{\circ}\text{C}$, the label is inserted non-uniformly. For example, the amounts of tritium in Gly(I) and Gly(II) in the Gly-Gly-Val peptide differ by a factor of ~ 5 . When tritium is introduced in identical amino acid residues, the label is mainly found in terminal amino acids; in the case where both residues are terminal, the label is inserted predominantly into the amino acid residue located at the N-end of the peptide. The patterns of label distribution in a free amino acid molecule and in the same molecule incorporated in a peptide are similar. At $180\text{ }^{\circ}\text{C}$, the molar radioactivity of Val-Gly-Gly reaches 7.70 PBq mol^{-1} . The overall replacement of protium by tritium amounts to 70%. It should be noted that racemisation did not exceed 1%, which corresponds to the accuracy of the experiment.¹⁰⁴

Interesting results have been obtained during the introduction of a tritium label into dalargin (Tyr-D-Ala-Gly-Phe-Leu-Arg), a synthetic analogue of the endogenous opioid peptide [Leu⁵]enkephalin (Tyr-Gly-Gly-Phe-Leu), which is used as a drug in gastroenterology.¹⁰⁷ In conformity with the temperature dependence of the degree of isotope substitution, the isotope label was incorporated in all amino acid fragments of dalargin (a 5% Rh/Al₂O₃: peptide: Al₂O₃ ratio of 2 : 1 : 20). At $140\text{ }^{\circ}\text{C}$, higher reactivity was found for alanine and glycine residues, while at $190\text{ }^{\circ}\text{C}$, the fraction of tritium that entered the aromatic residues of phenylalanine and tyrosine increased. A temperature of $160\text{ }^{\circ}\text{C}$ and storage in an atmosphere of tritium gas for 40 min were found to be the conditions of choice for labelling, the molar radioactivity of the labelled peptide being 1.93 PBq mol^{-1} . This peptide fully retained the biological activity, which was estimated as the ability to bind to the opioid receptors of the rat brain.

During labelling of more complex amino acid sequences, it may happen that one fragment of the molecule shields another fragment from the reaction with active tritium species. In this case, the distribution of the label along the amino acid chain is no longer uniform.¹⁰⁸

(1.85–2.04 PBq mol⁻¹ per bond). In this case, the solid-phase hydrogenation procedure is more efficient than the standard liquid-phase procedure. This is due to the fact that hydrogenation carried out with heating is accompanied by isotope exchange (see Table 29).

For example, hydrogenation of methacrylic acid by treatment with tritium gas on the 5% Pd/C catalyst at 170 °C gave a labelled specimen with a molar radioactivity ~3 times as high as could be expected upon the reduction of the double bond.⁶³ In addition, by using solid-phase hydrogenation, one can increase the yield of the labelled specimen (with respect to the liquid-phase method). This situation is often observed when hydrogenation affords isomeric products as, for example, in the reduction of 16 α ,17 α -cyclohexanopregn-4-ene-3,20-dione.

R = —H (5 β ,16 α ,17 α -cyclohexanopregnane-3,20-dione),
 $\cdots\text{H}$ (5 α ,16 α ,17 α -cyclohexanopregnane-3,20-dione).

The reaction gives rise to saturated steroids, namely, the 5 α - and 5 β ,16 α ,17 α -cyclohexanopregnane-3,20-dione isomers, in a ratio of 1:14. Only several percent of the 5 α -isomer could be isolated from the reaction mixture; preparative amounts of this compound (a 1:3 ratio in the reaction mixture) have been obtained by using solid-phase hydrogenation.¹¹² This difference can be explained by the fact that the liquid-phase hydrogenation proceeds in the active sites of the catalyst, while in the solid-phase process, atoms of the metal catalyst generate activated tritium species, which react with a steroid molecule. Evidently, when the steroid is adsorbed on the catalyst active sites during hydrogenation in solution, the influence of the steric factors is maximum; however, if the active species of tritium attack the double bonds of the substrate molecule adsorbed on a support, the formation of 5 α -isomers is more likely.

The dependence of the 5 α - to 5 β -isomer ratio on the reaction temperature can be followed using the data of Table 30, which presents also the amounts of isomers in the reaction mixture obtained from 1 mg of the substance introduced in the reaction.

For the solid-phase hydrogenation of unsaturated carbon–heteroatom bonds, thorough selection of the labelling conditions is required. For example, the nitrile of glycolic acid was used as the precursor in the synthesis of labelled ethanolamine. This precursor was reduced in the presence of 5% Pt/C, 5% Pd/C, 5% Rh/Al₂O₃ and 5% Rh/CaCO₃.^{113–115} The 5% Rh/C catalyst (Table 31), a temperature of 100 °C and a reaction time of 20 min were found to be the best conditions as regards the synthesis of a highly labelled specimen (1.04–1.48 PBq mol⁻¹). When palladium catalysts are used, the labelled specimen is

formed in 10%–20% yield and has a molar radioactivity of 0.15–0.22 PBq mol⁻¹ (see Ref. 114). This rather low yield can be explained by assuming that dehydration, deamination and other reactions take place in parallel on the metal catalysts.^{61, 69}

As an example of solid-phase reduction of the keto group, one can consider the synthesis of [2-³H]inositol from *scyllo*-inosose (pentahydroxycyclohexanone) and 2,2,6,6-tetramethyl-4-hydroxypiperidine from 2,2,6,6-tetramethyl-4-oxopiperidine.^{62, 113} To select the optimal conditions for the reduction of *scyllo*-inosose, the 5% Pd/CaCO₃, 5% Rh/Al₂O₃, 5% Pd/BaSO₄, 5% Pt/C and 5% Pd/C catalysts were tested. The best results were attained with the rhodium catalyst (the catalyst: substrate ratio was 10:1) and with heating to 150 °C for 15 min (the molar radioactivity of the labelled specimen was 0.56 PBq mol⁻¹ and the yield was 25%). 2,2,6,6-Tetramethyl-4-oxopiperidine was hydrogenated on 5% Rh/C to give 2,2,6,6-tetramethyl-4-hydroxypiperidine (see Table 29).

The molar radioactivities attained upon labelling in the former and in the latter case differ by a factor of ~9, as the efficiency of isotope exchange depends appreciably on the structure of the compound. In the former case, the keto–enol tautomerism of *scyllo*-inosose is hampered and the label is inserted only *via* ketone hydrogenation. In the latter case, all four α -hydrogen atoms have time to be replaced before the keto group is reduced. This appears to be a weighty reason supporting the formation of ³H⁺ as the activated species in the spillover.

Apart from the reduction of the C $\equiv$ N fragment to C³H₂NH₂ and the C=O fragment to C³(H)OH, data on hydrogenation of C=NOH to C³H₂NH₂ have been reported. For example, reduction of 2,2,6,6-tetramethyl-4-hydroxyiminopiperidine to 2,2,6,6-tetramethyl-4-aminopiperidine has been described;⁶² in this case, the isotope exchange is no less intensive than in the case of reduction of 2,2,6,6-tetramethyl-4-oxopiperidine (see Table 29).

In order to have an apprehension of the mechanism of solid-phase hydrogenation, Zolotarev *et al.* studied¹¹⁶ the reduction of (*R*)-4-*tert*-butoxy-4,5-dihydro-3H-pyrrole-2-carboxylic acid (**2**) prepared from amino acid **3**.

Compound **2** was applied onto alumina, dried and mechanically mixed with 5% Pd/BaSO₄. The mixture was subjected to freeze-drying (at a catalyst:Al₂O₃:substrate ratio of 10:20:1, *T* = 100 °C, τ = 60 min). After the reaction, the *tert*-butyl protection was removed by treating the reaction mixture with hydrochloric acid and the product was purified by the procedure described previously.^{117–119} The yield of (*R*)-4-hydroxy[G-³H]-L-proline (**4**) was 23% and the molar radioactivity was 1.85 PBq mol⁻¹. The isotopomer was isolated in a yield of 4%. The distribution of the label was determined by ³H NMR spectroscopy.

The distribution of the label in proline **4**, obtained by hydrogenation of compound **2** by tritium gas at 100 °C, was as follows:

Position of the label	3 β	3 α	5 α	5 β	2	4
Content of the label (%)	29	20	0	35	16	0

4,5-Dihydro-3H-pyrrole-2-carboxylic acid was used as the reference compound. The distribution of the label in [G-³H]proline (the molar radioactivity was 2.07 PBq mol⁻¹) obtained on hydrogenation of 4,5-dihydro-3H-pyrrole-2-carboxylic acid at 100 °C is given by

Position of the label	3 β	3 α	5	2	4
Content of the label (%)	34	34	6	26	0

Apparently, the first stage of hydrogenation of compound **2** involves the capture of tritium cations by nitrogen and oxygen atoms; as a consequence, the mobility of hydrogen at the third and fifth carbon atoms substantially increases and the carboxy group acquires the ability to occupy the *trans*-position relative to the 4-*tert*-butoxy group. Therefore, hydrogenation of the initial double bond can be accompanied by the addition of tritium into the 2-, 3- and 5-positions. The attack by tritium of the 5-position occurs necessarily from the β -H side; the attack of the 3-position is governed, on the one hand, by shielding of the β -H atom by the carboxy group and, on the other hand, by shielding of the α -H atom by the 4-*tert*-butoxy group. Thus, the contents of tritium in the α - and β -positions at C(3) should be comparable. Indeed, the data presented here on the distribution of the label show that the label is missing from the 5 α -position of proline **4**, while the ratio of the degrees of labelling at C(3) is 29:20 in favour of the 3 β -position. This may be due to the fact that the label in the 2-position of proline **4** appears, in the researchers' opinion,¹¹⁶ upon the intramolecular transfer of tritium from the 3 α -position of the molecule. If hydrogenation of 4,5-dihydro-3H-pyrrole-2-carboxylic acid gives a racemate, no steric restrictions are involved in the labelling of the C(3) atom, and the major portion of tritium is found at the 3-position of the molecule of this amino acid. For the same reason, the content of the label at the 2-position of the proline molecule increases and the probability of tritium insertion into the 5-position decreases ~6-fold.

If the first stage of the solid-phase hydrogenation is the reaction of the substrate with the tritium cations, it is reasonable to assume that the addition of the tritium cations to the molecules of unsaturated amino acid gives two options for the subsequent transformations: (1) capture of an electron to give a radical, which undergoes recombination with atomic tritium; (2) hydrogenation involving tritium gas on the sites arising due to the spillover.⁷⁻¹¹ The observed steric effects may be indicative of a predominant direct participation of tritium gas in the hydrogenation.

As an example, Fig. 3 shows the curves for the time variation of the yield of the labelled amino acid obtained by the reduction of 2-benzoylamino-3,3-dimethylacrylic acid to give *N*-benzoyl[³H]-valine (2.74 PBq mol⁻¹) at different temperatures and different pressures of tritium gas.⁸¹ It can be seen that with an increase in temperature, duration and pressure of tritium gas, the hydrogenation rate increases, but below 100 °C, the reaction does not proceed to completion,⁸¹ although even at 60 °C, isotope equilibration of virtually all the labile hydrogen atoms (attached to nitrogen, oxygen, sulfur and other atoms) takes place as a result of

Figure 3. Yield of the labelled product of solid-phase hydrogenation of 2-benzoylamino-3,3-dimethylacrylic acid ($P = 333$ hPa, 5% Pd/BaSO₄ as the catalyst) vs. reaction time at different temperatures (a) and different pressures (b).

a: $T/^{\circ}\text{C}$: (1) 60, (2) 80, (3) 100, (4) 120, (5) 140;

tritium spillover. Apparently, this is due to the fact that at these temperatures, the metal catalyst is rapidly saturated with hydrogen and deactivated (see Section IV).

The activation energy for hydrogenation of 2-benzoylamino-3,3-dimethylacrylic acid (46.09 kJ mol⁻¹) is close to the activation energy for the isotope exchange between valine and tritium gas (50.28 kJ mol⁻¹).^{81, 120} In the researchers' opinion, this attests that both reactions are limited by the same step of tritium inclusion. These values are in good agreement with the well-known activation energy of the solid-phase hydrogenolysis on platinum metals.⁷ It can be asserted that this step is not isotope exchange because the activation energies for the isotope exchange and hydrogenation depend appreciably on the nature of the substrate and differ even for different fragments of the same molecule. The assumption that a process related to the formation of active tritium species and to the spillover of these species to the reaction area is the limiting step seems doubtful. It has been shown⁸¹ that even at 20 °C, the active hydrogen atoms in the 2-benzoylamino-3,3-dimethylacrylic acid molecule are replaced by tritium over a period of 20 min. Therefore, the most plausible assumption is that the activation energies presented above are due to the fact that the tritium cation has to approach a carbon atom of the organic compound for the formation of the transition state.

The solid-phase hydrogenation technique can be used to reduce uridine derivatives. For example, the reduction of 5-hydroxymethyl-2'-deoxyuridine 5'-monophosphate (7% Pd/BaSO₄, $T = 170^{\circ}\text{C}$, $\tau = 30$ min) yielded thymidine 5'-monophosphate with a molar radioactivity of 2.54 PBq mol⁻¹ in 10% yield.¹²¹ It is of interest that the use of hydrogenation to prepare high-labelled purine and pyrimidine compounds gave no advantages over isotope exchange.⁷⁸ For example, the reduction of 5-formyluracil and 5-hydroxymethyluracil to thymine gave labelled preparations with molar radioactivities of 3.15 and 4.07 PBq mol⁻¹, respectively,^{80, 122, 123} while labelled thymine

obtained by isotope exchange had a molar radioactivity of $4.26 \text{ PBq mol}^{-1}$. In the case of reduction of 5-hydroxymethyl-deoxyuridine to thymidine, the molar radioactivity was even lower ($2.82 \text{ PBq mol}^{-1}$).¹²⁴

3. Solid-phase dehalogenation

Catalytic dehalogenation is the best known hydrogenolysis reaction. If tritium gas is used as the reagent, dehalogenation gives rise to tritium-containing compounds.

Usually, aromatic compounds are dehalogenated by a liquid-phase procedure.¹⁰⁵ This affords labelled specimens with a molar radioactivity of $0.7\text{--}0.9 \text{ PBq mol}^{-1}$. However, the liquid-phase approach cannot be used, as a rule, for labelling of saturated halogen-containing compounds under conditions acceptable for work with tritium gas.

The solid-phase catalytic dehalogenation was first employed to introduce a tritium label into uracil.¹ Characteristic features of this reaction as applied to tritium labelling of nucleic acid components have been studied in detail.¹²⁵

The advantages of the solid-phase approach have been demonstrated in relation to the dehalogenation of aliphatic compounds.⁶⁰ 11-Chloroundecanoic acid was chosen as the model compound for working out the conditions for the labelling of aliphatic compounds by dehalogenation. The dependence of the degree of labelling of both 11-chloroundecanoic acid and undecanoic acid formed in the reaction on the nature of the catalyst and the reaction temperature was studied (Fig. 4). The molar radioactivity of 11-chloroundecanoic acid reached $6.30 \text{ PBq mol}^{-1}$, while that of the undecanoic acid formed from it was $4.20 \text{ PBq mol}^{-1}$. For comparison, debromination of 3-bromo-

propionic acid (10% Pd/C, 1 M NaOH, $\tau = 4 \text{ h}$, $P = 905 \text{ hPa}$) furnishes $[3\text{-}^3\text{H}]$ propionic acid with a molar radioactivity of $0.72 \text{ PBq mol}^{-1}$ (see Ref. 126).

It can be seen from the above data that under the optimal conditions (10% Pd/BaSO₄, $T = 180^\circ\text{C}$), the yield of undecanoic acid reached 25%–30%. If the goal was to label the starting compound, the reaction was carried out at 170°C and the yield of the chlorine-containing precursor was 50%–60% (see Fig. 4). It was found that the isotope exchange in halogen-containing saturated acids proceeded much more readily than dehalogenation. Apparently, this is due to the fact that halogens are nucleophiles and can be removed from the organic molecule under these conditions only as hydrogen halides. Therefore, the solid-phase dehalogenation of aliphatic compounds at relatively low temperatures is less probable than isotope exchange. At high temperatures, a radical mechanism of dehalogenation is most likely.

The introduction of a label *via* solid-phase dehalogenation has been studied in detail for bromo-substituted components of nucleic acids (Table 32).^{75, 127}

It has been shown¹²⁷ that the degree of dehalogenation increases with an increase in the palladium content on carbon or with an increase in the catalyst to substance ratio. This is due to the fact that hydrogen bromide deactivating the catalyst is formed as a side product. When a certain palladium : halogen-containing precursor ratio was reached, the yield increased to 85%–90% and then remained constant. Therefore, the notion of catalytic capacity of the catalyst was introduced for these reactions. This value is defined as the number of moles of the halogen derivative which can be converted into the debrominated compound by a particular amount (weighed portion) of the palladium catalyst. During the study, it was found that these compounds cannot migrate over the support surface; therefore, the catalytic capacity depends on the reaction temperature and the nature of the initial halogen derivative.

Solid-phase dehalogenation of aromatic compounds is less efficient than dehalogenation in solution (Table 33). In the latter case, the experimental procedure is simpler and better reproducible, the reaction products can be more easily purified and often have better radiochemical parameters. Therefore, study of the solid-phase dehalogenation of aromatic compounds makes sense if it is necessary to label a halogen-substituted biologically active compound with retention of its native structure. For example, alprazolam was converted into a labelled preparation with a molar radioactivity of $0.15 \text{ PBq mol}^{-1}$ without loss of chlorine even at 175°C ,¹²⁸ i.e., selective isotope exchange was carried out for an

Note. The following designations are used: UMP is uridine 5'-monophosphate, CMP is cytidine 5'-monophosphate, GMP is guanosine 5'-monophosphate, GTP is guanosine 5'-triphosphate, UTP is uridine 5'-triphosphate, CTP is cytidine 5'-triphosphate.

organic molecule containing fragments labile under a tritium gas atmosphere.

4. Preparation of tritium-containing compounds on the basis of reagents labelled by the solid-phase method

In some cases, it proves to be more difficult to introduce a label into a biologically active compound than into one of its fragments. In these cases, the label is introduced into this fragment and then the structure of the molecule is reconstituted. For example, *N*-oleoyldihydrosphingosine with a high molar radioactivity was synthesised in two stages. First, dihydrosphingosine was labelled by a solid-phase procedure;⁶⁹ then the product was condensed with oleic acid by the method of mixed anhydrides.

2-Hydroxyethylamides of eicosapolyenoic acids were synthesised in a similar way. Evidently, it is impossible to introduce any significant amounts of tritium into the final compound without affecting the double bonds of polyunsaturated fatty acids. Therefore, solid-phase tritiation of glycolic acid nitrile was used to obtain aminoethanol,¹¹⁴ which was then condensed with a fatty acid by the method of mixed anhydrides.

The unlabelled reagent was taken in a tenfold excess.

The condensing agents used in this type of reactions include carbonyldiimidazole, carbonylditriazole and carbodiimides. For example, carbonyldiimidazole was used to prepare labelled (1*R*,2*R*)-*N*-[2-(4-methylpiperidylmethyl)cyclohexyl]-4-amino-5-chloro-2-cyclopropylmethoxybenzamide.⁷⁴

Acetylation of amines by non-labelled reagents presents no problem. Reactions using acetic anhydride, acetyl chloride, *etc.* give high yields of amides. However, synthesis of labelled analogues of these compounds presents a number of difficulties, which make these procedures unattractive. The main difficulty is high volatility of these substances. Work with such compounds (unlike non-volatile compounds) can be carried out only in a specially equipped laboratory. In addition, extensive use of these reagents is hampered by their high cost. Sodium acetate can be labelled by a direct reaction, as it is non-volatile (m.p. = 324 °C);⁶¹ therefore, this compound makes a convenient reagent for the preparation of labelled amides. The method consists of mixing of solutions of labelled sodium acetate¹²⁹ and amine hydrochloride; this gives labelled acetic acid and sodium chloride. After addition of the condensing agent, the tube is sealed and heated. When the reaction has been completed, the contents of the tube are frozen and refrozen to separate non-volatile products, the residue is dissolved in methanol, and the solution is acidified by hydrochloric acid and concentrated to remove traces of labelled acetic acid. Dicyclohexylcarbodiimide and carbonylditriazole were used as condensing agents. The best results were attained with carbonylditriazole (the yield of the labelled preparation reached 15%).

5. The selectivity problems in the solid-phase hydrogenolysis by tritium

It has been shown above that molecules containing halogen atoms can be labelled using selective isotope exchange. As has already been noted, labelling of alprazolam made it possible to obtain a labelled specimen with a molar radioactivity of 0.15 PBq mol⁻¹ (see Ref. 128).

This Section considers approaches designed for solid-phase labelling either by isotope exchange when the substrate molecules contain readily reducible fragments (for example, nitro groups or double bonds) or by selective dehalogenation and hydrogenation (Fig. 5, Table 34).^{130, 131} The selective hydrogenation can involve

Table 34. Molar radioactivities of labile compounds labelled in the presence of heterogeneous platinum group metal catalysts.¹³¹

Methyl ester of <i>N</i> -nitroarginine	180	0.85
Etomidate	160	0.86
Vitamin K ₁	130	2.3

Figure 5. Temperature dependence of the content of hydrogenation products of fusicoccin in the reaction mixture.¹³⁰ (1) Fusicoccin, (2) dihydrofusicoccin (DHF); (3) [³H₄]tetrahydrofusicoccin (THF); (4) [³H₆]hexahydrofusicoccin (HHF).

either hydrogenation of one or several double bonds or hydrogenation of one aromatic fragment in the presence of several other such fragments.

For compounds containing nitro groups, isotope exchange was carried out at temperatures of 180–190 °C and for compounds containing double bonds, at 100–160 °C.

As noted above, stability of a biologically active compound can be increased by using rhodium trichloride, an additional support or a partially deactivated catalyst. For example, in the case of thyroxine and vitamin K₁, palladium catalysts deactivated by lead diacetate were used;¹³⁰ rhodium trichloride was employed for dimethomorpholine⁷³ and an additional support, for etomidate.¹³¹

For selecting the optimal conditions for labelling compounds with double carbon–carbon bonds, a special study has been carried out to establish the temperatures of reduction of double bonds with different degrees of substitution.¹³⁰

Fusicoccin was chosen as the model compound to elucidate the conditions of labelling by selective solid-phase hydrogenation of one double bond,^{132–134} because this compound contains mono-, tri- and tetra-substituted double bonds. Selective solid-phase hydrogenation was studied in the temperature range of 40–220 °C, the reaction time and the pressure of tritium gas being also varied (see Fig. 5, Table 35). The selective hydrogenation of a monosubstituted double bond starts even at 40 °C and proceeds efficiently at 100 °C.

Table 35. Dependence of the content of major hydrogenation products of fusicoccin in the reaction mixture on the pressure of tritium gas and the reaction time ($T = 100$ °C, the Lindlar catalyst: substance ratio is 10:1).¹²⁹

Reaction conditions		Content (%)		
P /hPa	τ /min	fusicoccin	[³ H ₂]DGP	[³ H ₄]TGP
210	20	38	51	2
280	20	32	57	2
350	20	13	60	3
350	60	6	69	4

An increase in the pressure of tritium gas and the reaction time affect to a lesser extent the process selectivity.¹³⁰ If the goal of the experiment is to obtain the highest yield of dihydrofusicoccin, the reaction should be carried out at 130 °C (see Fig. 5).

The results were verified during labelling of vitamin K₁ (Table 36).¹³⁰ The presented data show that trisubstituted double bonds withstood temperatures in the 120–140 °C range; therefore, labelling of vitamin K₁ was carried out at 130 °C (see Table 34).

Table 36. Content of vitamin K₁ in the reaction mixture and degree of isotope exchange at different temperatures of tritium labelling (the Lindlar catalyst: substance ratio is 10:1, $P = 333$ hPa, $\tau = 20$ min).¹³⁰

T /°C	Content (%)	RMR (%)	Radiochemical purity (%) (see ^a)
80	99	9	95
100	68	16	64
120	60	52	21
140	16	100	8

^a Radioactivity of the label in the substance divided by the radioactivity of the reaction mixture.

Thyroxine was used as the halogen-containing compound to study the possibility of labelling by selective dehalogenation. At high temperatures (180–200 °C), liothyronine and *iso*-liothyronine could be isolated from the reaction mixture in a pure state. At 180 °C ($\tau = 10$ min), the yields of these compounds were 3.2% and 0.4%, and at 200 °C ($\tau = 5$ min), they were 5.3% and 1.3%, respectively. The molar radioactivity of the dehalogenated products reached 0.7 PBq mol⁻¹ (see Ref. 130).

Research into solid-phase hydrogenation and dehalogenation is usually necessary for studying the stability of a particular labile fragment in the molecule corresponding to a given class of compounds and to carry out solid-phase isotope exchange with retention of the native state of the initial compound as, for example, in the case of labelling of vitamin K₁.

An absolutely different situation occurs in working out the conditions of selective hydrogenation of one aromatic fragment in the presence of other aromatic fragments (for example, the pyridine and benzene rings). Hydrogenation of aromatic compounds in solution is known to occur only at very low pH.^{68,135} However this results in high isotope dilution of the labelled specimen. For example, in the synthesis of cyclohexylmethylamine from benzylamine using the liquid-phase hydrogenation procedure, the molar radioactivity of the labelled preparation was 1.66 PBq mol⁻¹, while the solid-phase hydrogenation procedure gave a specimen with a molar radioactivity of 7.78 PBq mol⁻¹ (see Ref. 68). In this case, the advantage of the solid-phase approach is obvious. Apparently, the nature of the activated tritium species is largely responsible for whether or not the process can, in principle, be selective. If these species are cations, the process selectivity would be high (the pyridine fragment is protonated much more efficiently than the benzene fragment). The aromatic structure of the pyridine fragment is violated and hydrogenation is thus facilitated. Thus in the case of selective hydrogenation⁵⁰

the labelled molecule contained five tritium atoms (6.44 PBq mol⁻¹). The content of this product in the reaction mixture was 7 times as high as the total content of all other substances, *i.e.*, the process was highly selective. This indicates that tritium cations play an active role in the hydrogen spillover. In other words, the specificity of solid-phase reactions may be largely responsible for the relative stability of organic compounds labile under the conditions of hydrogenolysis. Therefore, below we consider the features of solid-phase reactions that influence not only the retention of the native structure of the initial compounds (including chirality) but the distribution of the label in the molecules.

IV. Characteristics of solid-phase hydrogenolysis by tritium

A leading specialist in the synthesis of tritium-labelled organic compounds, Evans, has noted¹³⁶ that labelling methods in which organic compounds are kept under a tritium atmosphere with process initiation by a Tesla discharge or by UV or γ -radiation or gas exposure of a material applied on a heterogeneous catalyst are nothing but various modifications of the Wilzbach method. Many researchers still adhere to this point of view.¹³⁷ However, back in the 1960s, it was found that the label distribution in the aromatic ring obtained using heterogeneous catalysts differs appreciably from that obtained using other procedures (Tables 37, 38).^{138,139}

It can be seen from these data that electrophilic substitution predominates in the replacement of hydrogen in the aromatic ring by tritium using heterogeneous catalysts, whereas in other cases, radical substitution is the prevailing process. A similar tendency has been noted in another publication.¹⁴⁰ For example, upon labelling of a peptide with N-terminal tyrosine supported on a heterogeneous catalyst at 135 °C, the amount of the label inserted in the *ortho*-position relative to the hydroxy group of tyrosine was ~20 times as high as that in the *meta*-position.

Table 37. Distribution of the label (%) in toluene introduced by the Wilzbach method and by its modifications.¹³⁸

Label position	No activating factor (Wilzbach method)	Activation method		
		γ -radiation	Tesla discharge	UV radiation
<i>ortho</i>	56.5	54.7	39.7	49.8
<i>meta</i>	29.3	29.3	40.8	33.5
<i>para</i>	14.2	16.0	19.5	16.7

Table 38. Distribution of the label in benzoic and salicylic acids introduced by the Wilzbach method (I) and by treatment with tritium gas of the acids applied on the heterogeneous catalyst (II).¹³⁹

Acid	Content of the label (%) in the position		
	<i>ortho</i>	<i>meta</i>	<i>para</i>
Benzoic	58.3	21.3	20.4
	5.0	72.5	22.5
Salicylic	39.0 ^a	48.4 ^a	13.6 ^a
	16.9 ^a	31.7 ^a	51.4 ^a

Note. The value indicated above the bar was obtained using method I and that below the bar was obtained using method II. ^a Relative to the hydroxy group.

Thus, the mechanism of reactions between tritium gas and a substance applied on a heterogeneous catalyst differs from that involved in labelling by the Wilzbach method.

Usually, this is related to the processes taking place when catalysts are saturated with hydrogen.^{141–143} According to a view proposed and substantiated on the basis of a study of the valence state of hydrogen in intermetallic hydrides,¹⁴¹ hydride dispersion can be considered as being due to a redox process giving rise to hydride ions H ^{δ^-} , which takes place when the hydrogen concentration (*c_H*) in the solid hydride is higher than a critical concentration *c_{Hcr}*. The *c_{Hcr}* value is determined by the redox potential of the reaction

where MM is the metallic matrix of the catalyst.

According to this model, hydrogen chemisorbed on the active sites of the catalyst surface donates some of its s-electrons to the conduction band of the metal. Therefore, at low *c_H* values, the behaviour of absorbed hydrogen is described satisfactorily by the Ubbelode model,¹⁴² which implies high diffusional mobility of H ^{$\delta+$} and an increase (or, at least no decrease) in the electrical conductivity of the hydride phase with respect to that of the initial metal. The *c_{Hcr}* value corresponds to a concentration of the oxidant (H ^{$\delta+$}) at which these species oxidise the metallic matrix and become electron density acceptors, being converted into bulky and low-mobility H ^{$\delta-$} ions, and thus deplete the conduction band of the metal. It is evident that at higher degrees of filling of voids by H ^{$\delta-$} ions having a relatively great effective volume, the electron deficiency on the metal atoms that form the metal sublattice in the crystal structure of the catalyst should increase, which may restrict the reversible adsorption of hydrogen. This sharply decreases the concentration of activated species (tritium, in the case of preparation of labelled substances) able to enter into exchange reactions, and hence arrests almost completely the isotope exchange. The *c_{Hcr}* value may not be attained for a long period when hydrogen spillover takes place.

The causes of the transfer of activated species from the metal crystallite to the support are not discussed here in detail, as this has been the subject of numerous publications (see, for example, Refs 144–148) which evaluate how this process is affected by adsorp-

tion of molecular hydrogen, extensive rearrangement of the sorbent surface, relaxation of disordered structures and other factors. The migration of a proton over the oxygen-containing surface of the support follows a relay mechanism. The activation energy of this transfer equals 20.1 kJ mol^{-1} (see Ref. 149). Study of spillover over the support surface revealed both electronic and ionic conduction.³⁵ Therefore, the observed process, unlike those involved in the Wilzbach method, can be described more reliably in terms of the 'capacitor model' proposed by Shevchenko *et al.*¹⁵⁰ According to this model, the $^3\text{H}^+$ ions and the electrons formed in the reaction of tritium gas with the catalyst migrate separately over the surface. The support surface acts as a sort of multilayer capacitor. Depending on the experimental conditions, interaction of tritium cations with electrons (discharge of the neighbouring oppositely charged zones) takes place with one or another probability, giving rise to tritium atoms, which rapidly recombine and pass to the gas phase. When the flux of $^3\text{H}^+$ ions and electrons reaches the substrate, isotope exchange, hydrogenation, dehalogenation and other reactions occur efficiently. If the substrate contains easily protonated groups, the degree of labelling should markedly diminish. It is evident that at higher temperatures, the probability of interaction between neighbouring oppositely charged zones would increase; therefore, the contribution of the reactions of atomic tritium to the processes resulting in the formation of the labelled compound would also increase. Thus, if the substrate contains readily protonated groups, the molar radioactivity of the labelled product should markedly increase with temperature rise (the neutral species of atomic tritium would react more efficiently with these compounds). As an example, one can consider the above-mentioned preparation of labelled peptide with N-terminal tyrosine. Thus at 150°C , the degree of labelling of the *ortho*-position relative to the hydroxy group of tyrosine was only 3 times higher than that of the *meta*-position and the molar radioactivity increased 1.9-fold.¹⁴⁰

The distribution of the label in aromatic amino acids is especially useful for elucidation of the nature of the activated tritium species. This can be illustrated using the distribution of the label in aromatic rings of tyrosine and serotonin as examples. The contents (%) of the label in the aromatic rings (the total amount of the label in the ring was taken to be 100%) were as follows:¹⁰⁴

Position	<i>ortho</i>	<i>meta</i>
Tyrosine	78	22
Serotonin	85	15

As noted in the previous Section, the distribution of the label corresponding to that expected in terms of the electrophilic substitution model can serve as strong evidence supporting the assumption that the tritium cation is the activated species involved in the hydrogen spillover.

The published data provide grounds for two conclusions: (1) inclusion of the label follows predominantly the electrophilic substitution mechanism; (2) the lower the reaction temperature, the higher the predominance of electrophilic substitution. The 'capacitor model' concept is useful for explaining the roles of particular factors in the preparation of tritium-labelled specimens and eliminates many contradictions arising in the study of the theoretical aspects of this problem.

For example, the capacitor model can account for the high yields of labelled specimens obtained *via* solid-phase reactions. This is due to the fact that the participation of atomic tritium in the labelling is insignificant, as the radical detachment of hydrogen followed by recombination of the resulting radical is a more intricate process than the mere recombination of atomic tritium.^{151–153}

As noted above, the mechanism of tritium labelling influences the distribution of the label in organic molecules. For instance, a ^3H NMR study (alanine supported on carbon was labelled in the presence of platinum group catalysts) has shown¹⁴⁰ that at 130°C , the rate of tritium inclusion to the third carbon atom is

7.5 times as high as that to the second carbon atom. In the $70–155^\circ\text{C}$ range, the rate constant for isotope exchange changed by two orders of magnitude (the activation energy was equal to 62.8 kJ mol^{-1}). At 30°C , the isotope label was selectively inserted into the methyl group of alanine, whereas, at 190°C , the label was uniformly distributed throughout the alanine molecules. The activation energy of the isotope exchange in the methyl group of alanine was 58.7 kJ mol^{-1} and that for the alanine methine group was $107.7 \text{ kJ mol}^{-1}$. This sharp difference can be explained in the following way. The amino group is readily protonated, which hampers the reaction of $^3\text{H}^+$ with the carbon atom of the methine group of alanine. The charge that appears on nitrogen induces migration of the electron density in the methyl group (hyperconjugation⁴⁵). As a result, the deficit of electron density on the carbon atom at the 2-position is compensated, the methyl-group hydrogen atoms become more active, and the activation energy of isotope exchange at the third carbon atom decreases. At higher temperatures (190°C), radical elimination reactions become more significant. Therefore, the labelling efficiency at the 2-position sharply increases, which is responsible for the different label distribution.

The validity of this approach is confirmed by the distribution of the label in some other amino acids (Table 39). Only in the case of serine and methionine was the C(2) position labelled to a higher degree. Apparently, this is due to the fact that oxygen and sulfur, like amino groups, are easily protonated and the carboxy group located near the amino group makes the isotope exchange at C(2) prevailing.

Table 39. Distribution of the label (%) in amino acids applied on heterogeneous catalysts and treated with tritium gas at 150°C .¹⁰⁴

Amino acid	Content of the label at the atoms				
	C(2)	C(3)	C(4)	C(5)	C(6)
Alanine	4	96			
Asparagine	40	60			
Aspartic acid	40	60			
Arginine	19	23	14	44	
Proline	9	6	4	81	
Methionine	75		4	21	
Serine	70	30			
Threonine	18	9	73		
Leucine	4	5	5	86	
Lysine	31	10	12	18	29
Valine	4	4	92		

The possibility of introducing a label into organic substances susceptible to hydrolysis is also largely determined by the mechanism of this process. It is known that liquid-phase reactions proceed in the active sites of the catalyst. These sites adsorb, first of all, unsaturated fragments of molecules and, hence, hydrogenolysis and hydrogenation are the predominant types of reactions. Under solid-phase conditions, labelling is due to reactions of molecules of the substance with activated tritium. Apparently, reduction of the $\text{N}-\text{CHR}-\text{C}_6\text{H}_5$ and $\text{O}-\text{CHR}-\text{C}_6\text{H}_5$ fragments to toluene or its derivatives or reduction of the $-\text{NO}_2$, $=\text{N}-\text{OR}$ groups to amino groups, *etc.*, would be hampered under solid-phase reaction conditions, as nitrogen and oxygen atoms are prone to be protonated and isotope exchange can be carried out selectively without disturbing the native structures of biologically active products. An important feature of solid-phase hydrogenolysis is the retention of the initial structure of compounds including chirality. Now we consider the reasons for this fact.

When labelling biologically active compounds, researchers pay considerable attention to the problem of preserving the

optical activity. Only the invariability of the native conformation of compounds can ensure the retention of the initial biological properties of the substrate.

Research into characteristic features of electrophilic substitution in the series of aliphatic compounds⁴⁵ basically ended in the 1960s. Bimolecular (S_E2), monomolecular (S_E1) and intramolecular (S_{EI}) mechanisms of electrophilic substitution were found. Of special interest for our purposes are data concerning the S_{EI} mechanism because it is obvious that upon substitution according to this mechanism, the stereochemical configuration does not change.

The results of calculation of the spatial repulsion forces based on the putative structures of the transition state were consistent with experimental results.⁴⁵ The mechanism of the solid-phase isotope exchange has been studied by quantum-chemical calculations.¹⁵⁴ The water molecule was taken as Y. The results of Dewar AM1 semiempirical calculations of fragments of the potential energy surface for the interaction of alanine carbon atoms with the hydroxonium ion were refined by Hartree–Fock *ab initio* calculations in the 3-21G and 6-31G basis sets using the GAMESS program. According to the results obtained, the activation energy of isotope exchange decreases due to an additional interaction of hydrogen atoms, *i.e.*, this transition state is additionally stabilised by a bond between the exchanging hydrogen ions. In the transition state, tritium attacks the C–H bond from the same side as where the atom being replaced is located, *i.e.*, the S_{EI} mechanism is executed. Thus, if this isotope exchange takes place at a chiral carbon atom, the native configuration of the initial compound will be retained. The transition state involved in the S_{EI} mechanism of electrophilic aliphatic substitution can be represented as follows:¹⁵⁴

Direct evidence for the assumption that the active species of hydrogen react with the substrate without modifying its crystal lattice was obtained in the 1980s.¹⁵⁵ Experiments were carried out with 4-isopropyl-3-methylphenol. This compound is not optically active in solution but it spontaneously forms chiral structures (dextro- and levorotatory crystals) upon crystallisation. The powder obtained from one sort of 4-isopropyl-3-methylphenol crystals was tritiated with 5% Pt/C and kept for 95 min at 80 °C under a hydrogen atmosphere. The reaction product proved to be optically active.

At higher temperatures where the contribution of atomic tritium to the isotope exchange becomes substantial, the absence of racemisation can be explained by the fact that the activation energy for radical elimination reactions is markedly lower than that for the electrophilic isotope exchange (Table 40). Apparently, in this case, the retention of chirality is due to the fact that the rate of recombination of the resulting radicals is incomparable with the rates of radical formation or, all the more, conformational changes.

The possibility of preparing labelled compounds containing trisubstituted unsaturated carbon–carbon bonds depends also on the nature of activated tritium. It is known⁴⁵ that the transfer of $^3H^+$ is the rate-determining step of hydrogenation and that the carbenium ion ($R'-H^3HC-C^+H-CH_2R$) is formed as the intermediate product. This intermediate is reduced to give a saturated compound. Thus, the presence of an easily protonated

Table 40. Kinetic parameters of the radical elimination and addition reactions.¹⁵²

Reaction	E_{c0} /kJ mol ⁻¹	$10^{11}r_c$ /m	$(r^+/r_c)_0$	ΔH /kJ mol ⁻¹
$H^+ + RH \rightarrow H_2 + R^+$	54.6	3.762	0.48	94.5
$H^+ + CH_2=CHX \rightarrow$ $\rightarrow CH_3C^+HX$	101.6	4.563	0.41	227.6
$H^+ + HOR \rightarrow$ $\rightarrow H_2 + RO^+$	38.3	2.812	0.47	33.5
$H^+ + O=CR^1R^2 \rightarrow$ $\rightarrow HOC^+R^1R^2$	102.9	4.401	0.38	149.7

Note. The following designations are used: r_c is the distance equal to the sum of vibration amplitudes of atoms of the reacting bonds in the transition state; r^+ is the parameter characterising the position of the transition state on the section r_c ; the $(r^+/r_c)_0$ ratio characterises the position of the transition state for $\Delta H = 0$.

fragment which has acquired a charge near a C=C bond decreases the probability of protonation of this double bond and thus this bond is additionally strengthened. The formation of carbenium ions during the solid-phase hydrogenation is indirectly confirmed by the possibility of double bond migration ($R'-H^3HC-CH=CHR$). This process is detected most easily if $R = OH$. In this case, migration of the double bond gives an aldehyde stable under the reaction conditions. For example, in hydrogenation of allyl alcohol at room temperature under solid-phase conditions, the yield of aldehyde was $\sim 10\% - 20\%$.¹⁵⁶ Thus, by solid-phase reactions, it is possible to carry out selective isotope exchange and obtain unsaturated labelled preparations.

If the reaction is carried out at a higher temperature, one should bear in mind that double bonds may be reduced by atomic tritium. Comparison of the kinetics of radical addition and elimination reactions has shown that hydrogen elimination always proceeds more easily than hydrogen addition to a double bond. This is due to different geometries of the reaction centre and to stronger repulsion in the non-linear centre, which is formed upon the reaction of activated hydrogen with the double bond (see Table 40).⁴³ Another important parameter is the force constant of the bond being attacked, which is always higher for a multiple bond than for a single bond. Moreover, the activation energy of the addition reaction depends more appreciably on the enthalpy change than the activation energy of elimination. As a result, the major process is recombination of atomic tritium, resulting from coupling of tritium cations with electrons, which increases the stability of unsaturated compounds under these conditions.

Thus, if the organic molecule contains easily protonated fragments, they are the first to react with activated tritium species. If the protonated fragments in the molecule are labile, this may give a series of specific side products. In the labelling of compounds whose melting points are higher than the temperature used to conduct the isotope exchange, the degree of isotope exchange would mainly depend on the efficiency of tritium spillover in the bulk of the organic substance applied on a catalyst. If protonated fragments or charged groups present initially in the molecule prevent electrophilic substitution or tritium spillover to the bulk of the organic compound, the final molar radioactivity of the labelled specimen would substantially diminish.

Indeed, it was noticed long ago¹³⁶ that the exchange of hydrogen isotopes occurs, first of all, in hydroxy, carboxy, amino and other functional groups. When tritium labelling by solid-phase isotope exchange is carried out for amines⁶⁸ (benzylamine, spermine, ethylenediamine and its derivatives) (Table 41), a series of deaminated products are formed; in the case of spermine, it was impossible to isolate the labelled specimen from the reaction mixture.

Table 41. Molar radioactivity and yield of tritium-labelled amines (5% Pd/C, $T = 190\text{ }^{\circ}\text{C}$, $\tau = 15\text{ min}$).^{53,61,74}

Compound	MR /PBq mol ⁻¹	Yield (%)
Ethylenediamine	0.13	50
Piperazine	0.32	23
1,4-Diazabicyclo[2.2.2]octane	0.46	15

In the labelling of high-melting compounds, the physicochemical properties of the starting compound exert a considerable influence on the final molar radioactivity of the labelled compound. For example, whereas in methyl stearate molecules (m.p. = $39\text{ }^{\circ}\text{C}$) hydrogen is replaced almost completely by tritium, in the case of sodium acetate (m.p. = $324\text{ }^{\circ}\text{C}$), according to ^3H NMR spectroscopy,⁶⁸ only some of the molecules occur in the areas where isotope exchange proceeds efficiently.

Analysis of the ^3H NMR spectra of labelled sodium acetate has shown that labelled molecules comprise 74% triply substituted, 24% doubly substituted and 2% monosubstituted isotopomers, *i.e.*, the molar radioactivity should be $\sim 3\text{ PBq mol}^{-1}$. However, in reality, the molar radioactivity of [^3H]CH₃CO₂Na was $1.1\text{--}1.3\text{ PBq mol}^{-1}$. The reason is that the ^3H NMR technique allows one to determine only the ratio of different tritium-containing isotopomers in sodium acetate molecules. The amount of the unlabelled initial substance remaining in the reaction mixture is not detected by ^3H NMR spectroscopy. Therefore, the discrepancy between the results obtained by ^3H NMR and by radioactivity measurements is due to the fact that $\sim 60\%$ of sodium acetate has not entered into the isotope exchange, which markedly decreases the final molar radioactivity of the labelled preparation. Indeed, as shown by micrographic studies,¹⁵⁷ solid-phase hydrogenolysis of another high-melting compound, namely, disodium *trans*-epoxysuccinate (m.p. = $262\text{ }^{\circ}\text{C}$), is not accompanied by a noticeable diffusion of this compound over the surface of the palladium catalyst.

Thus, if the melting point of the compound is comparable with or lower than the temperature at which the isotope exchange is carried out, displacement of substrate molecules relative to one another is possible; each molecule can be subjected to the action of activated tritium with the same probability,⁶⁰ and the effect of the tritium spillover to the bulk of the given substance on the final molar radioactivity of the labelled specimen is moderate. This can be illustrated by the following data on the molar radioactivity obtained upon solid-phase tritium labelling of fatty acids:²⁹

Acid	Stearic	Palmitic	Myristic	Lauric
MR /PBq mol ⁻¹	13.0–13.5	12.5–12.9	12.0–12.1	11.0–11.5

To confirm the statement that solid-phase reactions can involve both tritium cations and atomic tritium whose contributions to the final molar radioactivity of the labelled specimen depend on the nature of the initial compound, it was necessary to choose a model compound that, on the one hand, could serve as a sort of trap for tritium cations and, on the other hand, would be sufficiently thermally stable to ensure favourable conditions for isotope exchange involving atomic tritium.

A series of compounds have been tested,⁵³ but they proved to be either good substrates for tritium cations or insufficiently thermally stable. Sulfobromophthalein satisfied the above-out-

lined conditions to the highest extent.¹⁵⁸ The synthetic route to the tritium-labelled sulfobromophthalein is presented below:

This compound contains easily protonated groups (including sulfo groups), which may give rise to a substantial positive charge; in addition, it withstood heating to $280\text{--}290\text{ }^{\circ}\text{C}$ in the presence of a catalyst in an atmosphere of tritium gas. The label was introduced in the presence of palladium supported on barium sulfate, calcium carbonate, carbon or alumina. The catalyst : substance ratio was 10 : 1 and the temperature range was $150\text{--}290\text{ }^{\circ}\text{C}$. At $150\text{--}180\text{ }^{\circ}\text{C}$, the yield of the specimen was almost quantitative; at $180\text{--}220\text{ }^{\circ}\text{C}$, it gradually decreased to 60%; at $250\text{ }^{\circ}\text{C}$, to 53%; at $270\text{ }^{\circ}\text{C}$, to 46%; and at $285\text{ }^{\circ}\text{C}$, to 34%. Even when the reaction

was carried out at 210 °C for 0.5 h, the molar radioactivity of the labelled specimen did not exceed 0.08 PBq mol⁻¹. Only at temperatures higher than 285 °C did the radioactivity reach 0.5–0.6 PBq mol⁻¹. The fact that the aromatic compound containing four bromine atoms can be isolated in 30%–50% yield after the reaction with tritium gas at these high temperatures attests to the lack of interaction between tritium cations and protonated sulfobromophthalein molecules.

The observed phenomenon supports the view that labelling proceeds in this case by the mechanism of radical elimination of hydrogen with subsequent recombination of the resulting radical. Indeed, the reaction of atomic tritium with the phenolic fragment of the sulfobromophthalein yields the aryloxy radical, which then undergoes recombination with the abstraction of hydrogen from the *ortho*-position. This gives a radical which can be stabilised upon conjugation with the radical centre delocalised over three positions of the benzene ring.⁴⁵ This is followed by the reaction with atomic tritium to give the labelled specimen. It is clear that the spillover of electrically neutral atomic tritium into the bulk of the substrate crystallite would take place even if the molecules of the substance contain easily protonated groups.

Thus, labelling in solid-phase reactions involves both tritium cations and tritium atoms. The molar radioactivity of labelled specimens at relatively low temperatures (usually below 180 °C) is mainly determined by reactions of the organic compound with tritium cations. The degree of isotope exchange depends mainly on the efficiency of tritium spillover to the bulk of the organic compound applied on the catalyst. At higher temperatures, the contribution of atomic tritium in the labelling increases.

V. Conclusion

This review covers the results of synthesis of labelled specimens using solid-phase hydrogenolysis reactions including hydrogenation and isotope exchange with tritium. The regularities of these reactions were studied, in particular, the effects of the nature of the substrate and the catalyst, the pressure of tritium gas, the process duration, temperature, *etc.* on the yield and molar radioactivity of the resulting specimens. Examples of preparation of labelled biologically active compounds are cited.

It was found that at temperatures below 180 °C used most often for solid-phase labelling, the key radiochemical parameters of labelled specimens (yield, molar radioactivity, tritium distribution) are governed by the reaction of ³H⁺ with the substrate. At higher temperatures, the concentration of atomic tritium increases. In this case, especially for substrates containing easily protonated groups, the molar radioactivity of the product should markedly increase (non-charged species of atomic tritium react more efficiently with these compounds).

The service life of the catalyst depends on the time it takes to reach a certain threshold concentration of hydrogen in the crystallites of the metal catalyst, c_{H_2} . The time required to reach this value is dictated by the relationship between the rate of saturation of metal crystallites with tritium gas and the efficiency of its spillover. The efficiency of tritium spillover as applied to the synthesis of labelled organic compounds is determined by the time period tritium exists as a system of cations and electrons solvated on the support surface and in the substrate bulk.

If the goal is to prepare a labelled specimen in a high yield and with the distribution of the label corresponding most closely to that obtained upon electrophilic substitution, the solid-phase reaction should be carried out at the lowest temperature that would ensure the required molar radioactivity. The reaction time is determined by the period of catalyst deactivation. If the aim is to obtain the labelled specimen with the highest possible molar radioactivity, the reaction is carried out in the temperature range in which the required [³H]-labelled compound can be isolated in a yield of at least 5%–10%. The reaction time is usually 5–15 min.

Judging by the data reported in the literature, a promising expedient is to combine various catalysts (palladium–rhodium or

palladium–technetium mixed catalyst), supports (separate application of the catalyst and the substrate followed by mechanical mixing) or substrates (consecutive application of several substrates). These approaches increase the yield of the labelled specimen and in some cases, the synthesis of such substances would be otherwise impossible.

Contents

I. Introduction	447
II. Synthesis of naphthaldehydes	447
III. Structures and physicochemical properties of naphthaldehydes	459
IV. Reactions	466

Abstract. Data on methods for the preparation of naphthaldehydes, their physicochemical properties, structural characteristics and reactivities are generalised. Particular attention is given to procedures for formylation of naphthalenes and *peri*-interactions involving the aldehyde group in the α -position. The bibliography includes 201 references.

I. Introduction

Naphthaldehydes^{1–3} play a very important role in naphthalene chemistry, much as other aldehydes play a significant part in the chemistry of other classes of organic compounds, which is associated primarily with the diversity of reactions involving these compounds. The high reactivity of the formyl group is widely utilised in the synthesis of complex natural compounds containing the naphthalene fragment. In addition, naphthaldehydes and, primarily, α -naphthaldehydes possess specific features, which receive the continuing attention of both synthetic and theoretical chemists. Among these features are, in particular, different manifestations of *peri*-interactions^{4–6} and the possibility of performing *peri*-cyclisation.⁷ Interest in naphthaldehydes has increased substantially after isolation of gossypol (**1**), *viz.*, 2,2'-binaphthyl polyphenol dialdehyde, from cotton seeds. This compound appeared to be the first efficient contraceptive pill for men.⁸

Gossypol also exhibits antitumor and antiviral activity and, in spite of substantial toxicity, is registered in some countries for use as a pharmaceutical. It was established that the toxicity of

gossypol is associated with the presence of aldehyde groups. However, all attempts to replace these groups by other functionalities led only to the disappearance of biological activity (the history of the discovery of gossypol and its chemical and pharmacological properties were surveyed in a review).⁸

The published data on the chemistry of naphthaldehydes are voluminous and scattered throughout various sources. These data have not been generalised, except for outdated information summarised in the monographs,^{9,10} which causes great inconvenience for researchers. This fact gave impetus to the present review. Since it is practically impossible to cite all studies concerning naphthaldehydes, emphasis is given to main trends associated with the synthesis, reactions and physicochemical characteristics of these compounds. Most attention is concentrated on the preparation of naphthaldehydes by direct formylation of naphthalenes or naphthalene carbanions (organometallic compounds), *peri*-interactions, *peri*-cyclisation reactions involving the α -formyl group, characteristic features of the molecular structures of these compounds and their relationship with physicochemical properties and reactivity. Other aspects of the chemistry of naphthaldehydes are considered as necessary.

II. Synthesis of naphthaldehydes

Naphthaldehydes can be prepared according to virtually all procedures generally used in the synthesis of aromatic aldehydes.^{1–3,11} In addition to direct formylation, these methods involve oxidation of methyl-, hydroxymethyl- and halomethyl-substituted naphthalenes, reduction of nitriles and naphthalene-carboxylic acid chlorides, *etc.* Data on these methods published up to the mid-1950s are generalised in the monograph.⁹ Since then, almost all the above-mentioned synthesis methods have been improved primarily due to the use of new reagents. Generally, this enables one to use milder conditions of reactions and enhance their selectivity. The most typical examples are considered below.

1. Formylation of naphthalenes

a. Naphthalene and alkynaphthalenes

Gattermann formylation (under the action of a mixture of HCN and HCl in the presence of AlCl_3 , CuCl_2 or other Lewis acids) of naphthalene¹² and α -methylnaphthalene¹³ afforded α -naphthaldehyde (**2**) and its 4-methyl derivative **3**. The modification of this reaction consists in replacing HCN by less toxic $\text{Zn}(\text{CN})_2$ (Adams method)¹⁴ or *sym*-triazine.¹⁵ Thus, the synthesis with the use of *sym*-triazine afforded aldehyde **2** in 57% yield.

Received 25 October 2002

Uspekhi Khimii 72 (5) 498–523 (2002); translated by T N Safonova

Under the conditions of the Gattermann reaction, 1,6- and 2,6-dimethylnaphthalenes gave aldehydes **4** and **5**, respectively.¹²

Formylation of 2,3-dimethylnaphthalene should be carried out with thorough control over the reaction temperature. Thus, 'normal' product **6** was generated in good yield only at a temperature below 55 °C, whereas it was transformed into 2,4-dimethyl-1-naphthaldehyde (**7**) at a temperature above 65 °C.^{16, 17}

Naphthalene is readily subjected to formylation by dichloromethyl *n*-butyl ether in the presence of TiCl₄ (Rieche method).¹⁸ Apparently, this procedure is among the simplest approaches to α -naphthaldehyde **2** (79% yield).

Naphthalene does not react with the milder formylating Vilsmeier reagent^{19, 20} (a mixture of POCl₃ with *N,N*-dimethylformamide or other formamide derivatives, for example, with *N*-methylformanilide). However, the reaction of acenaphthene performed under these conditions afforded acenaphthene-5-carbaldehyde (**8**) (81% yield).^{21, 22}

Recently, a convenient procedure was proposed for the preparation of aldehyde **8** by microwave irradiation of a mixture of acenaphthene and the Vilsmeier complex on a support (DMF-POCl₃-SiO₂, 300 W, 2 min, 89% yield).²³ Naphthalene, like acenaphthene, is formylated by the modified Vilsmeier complex in which phosphorus oxychloride is replaced by trifluorome-

thanesulfonic anhydride.²⁰ The reaction proceeded under very severe conditions (130 °C, 48 h) to give aldehydes **2** and **8** in 50% and 90% yields, respectively.

Under standard conditions of the Gattermann-Koch reaction (CO-HCl, AlCl₃), naphthalene does not undergo formylation.²⁴ However, aldehyde **2** was prepared with the use of the CO-HF-BF₃ system under high pressure.²⁵ It was demonstrated that formyl fluoride served as the true formylating agent in this reaction.²⁶ In the presence of BF₃, the latter compound reacted (CS₂, 0–10 °C, 3–5 h) with naphthalene to form a mixture of α - and β -naphthaldehydes in 20% and 67% yields, respectively. Considering the traditionally higher reactivity of the α positions in naphthalene compared to the β positions, the formation of β -naphthaldehyde as the major product under such mild conditions seems to be surprising. However, this fact was not commented in the study²⁶ and the review.²⁷

The modified Gattermann-Koch reaction with the use of the stronger Lewis catalyst SbF₅ instead of BF₃ can lead to diformylation of naphthalene.²⁸ This reaction afforded a mixture of 1,5- (**9**), 1,6- (**10**), 1,7- (**11**) and 1,8-diformylnaphthalenes (**12**) in a total yield of 80% in a ratio of **9**:**10**:**11**:**12** = 51:6:27:16. It should be noted that the positions of substituents in formylation products of naphthalene differ substantially from those in nitration products. It is known that nitration gives rise to 1,8- and 1,5-dinitronaphthalenes in a ratio of ~7:3.⁹ By contrast, 1,5-dialdehyde prevails among diformylation products, the second highest yield was observed for the 1,7-isomer. Apparently, the first step of this reaction affords β -naphthaldehyde in a noticeable amount and further formylation of the latter at the free α positions of the unsubstituted ring gives dialdehydes **10** and **11**.

When studying Gattermann-Koch (CO-HF-SbF₅) and Friedel-Crafts (HCOF-HF-SbF₅) formylation of α -methyl-naphthalene, Tanaka and co-workers^{29, 30} found that the rate and regioselectivity of the Gattermann-Koch reaction depend on the SbF₅: α -methyl-naphthalene molar ratio (Table 1). The authors attributed this fact to a superposition of two mechanisms

Table 1. Results of Gattermann-Koch (GK) and Friedel-Crafts (FC) formylation of α -methyl-naphthalene.³⁰

Molar ratio SbF ₅ : α -methyl-naphthalene	Reagent	Temperature /°C	Time /h	Product ratio 3 : 13	Reaction type
1:1	CO	0	2	100:0	GK
1.25:1.00	CO	0	0.15	68:32	ditto
1.25:1.00	CO	-40	2	64:36	"
1:1	HCOF	0	1	93:7	FC
1.25:1.00	HCOF	0	1	94:6	ditto
1.25:1.00	HCOF	-40	1	94:6	"
2:1	HCOF	-40	1	94:6	"

Note. Reaction conditions: 10 mmol of 1-methylnaphthalene, 500 mmol of HF; CO pressure was 20 atm (GK reaction); 80 mmol of HCOF (FC reaction).

of electrophilic substitution, *viz.*, conventional and non-conventional (intracomplex). In the course of formylation by a conventional mechanism, the electrophilic species (HCO^+), which is generated through the reaction of the reagent acting as a protoelectrophile (CO or HCOF) with protic (HF) or Lewis (SbF_5) acid, attacks the aromatic substrate at the *ortho* or *para* positions with respect to the methyl group to form the corresponding σ -complexes, which give aldehydes **3** and **13**.

In the naphthalene series, σ -complexes corresponding to α substitution are more stable than σ -complexes corresponding to β substitution. Hence, *para* isomer **3** is generally produced in higher yield than *ortho* isomer **13**.

The first step of formylation according to an alternative mechanism involves protonation of the substrate giving rise exclusively to methylnaphthenium cation **14**. The latter donates a proton to the protoelectrophile (CO) thus transforming it into the active electrophile. If the electrophile and substrate in the *para*-oriented π -complex **15** thus produced have no time to move apart, their interaction gives rise to the *para*- σ -complex and finally (after proton elimination) to *para*-aldehyde **3**.

If the substrate and electrophile in complex **15** are separated, the reaction mechanism consists of the usual electrophilic attack.

The highest regioselectivity of the Gattermann–Koch reaction is observed at the SbF_5 : α -methylnaphthalene molar ratio of 1:1. Since the HF – SbF_5 system acts as a superacid, this reagent ratio allows the substrate to be completely protonated to give methylnaphthenium cation **14**. As a result, the reaction proceeds by an intracomplex mechanism to give *para* isomer **3** as the only product. In the presence of a larger amount of SbF_5 and, consequently, a larger amount of the superacid, carbon monoxide molecules are also subjected to protonation to give the HCO^+ cations. Since the reaction of the latter with cation **14** is unlikely, the contribution of the conventional mechanism of formylation increases and, as a consequence, the yield of *ortho* isomer **13** increases.

Since the basicity of formyl fluoride is lower than that of carbon monoxide, the dependence of the Friedel–Crafts reaction on the amount of SbF_5 is less pronounced and the constancy of the *para/ortho* regioselectivity most likely indicates that the reaction proceeds predominantly by the intracomplex mechanism.

Formylation of naphthalene and its 1- and 2-methyl derivatives was also performed with the use of triformamide $\text{N}(\text{CHO})_3$ in the presence of AlCl_3 . However, these reactions afforded aldehydes **2** and **3** and 2-methyl-1-naphthaldehyde in low yields (18%–30%).³¹

b. Naphthols and alkoxy- and alkylthionaphthalenes

Depending on the nature of the formylating agent, α -naphthol (**16**) is formylated at either *ortho* or *para* position with respect to the hydroxy group. For example, the reaction of compound **16** with the HCN – AlCl_3 system (Gattermann reaction) afforded 4-hydroxy-1-naphthaldehyde (**17**) in high yield,^{14, 32, 33} whereas the Reimer–Tiemann reaction (70–80 °C, CHCl_3 – NaOH) gave rise to its *ortho* isomer **18** in ~40% yield.³⁴ Apparently, one of the best methods for the synthesis of the latter compound involves the reaction of α -naphthol with orthoformic ester in the presence of AlCl_3 producing aldehyde **18** in almost quantitative yield.³⁵ The reaction of α -naphthol with α, α -dichlorodimethyl ether in the presence of TiCl_4 (Rieche method) afforded a mixture of aldehydes **17** and **18** in 68% and 10% yields, respectively.³⁵

(a) HCN – AlCl_3 (>90%); (b) CHCl_3 – NaOH (38%–48%); (c) $\text{HC}(\text{OEt})_3$ – AlCl_3 (97%).

Formylation of β -naphthol (**19**) gave rise to 2-hydroxy-1-naphthaldehyde (**20**) regardless of the method used. The Gattermann reaction with the use of the HCN – ZnCl_2 system³³ or the $\text{Zn}(\text{CN})_2$ – HCl system¹⁴ produced aldehyde **20** in virtually quantitative yield. However, even in spite of lower yields, this hydroxy aldehyde is much more convenient to prepare by the Duff³⁶ (with the use of urotopine and acetic acid), Rieche,³⁵ Vilsmeier³⁷ and, particularly, Reimer–Tiemann reactions.³⁸

(a) $(\text{CH}_2)_6\text{N}_4$ – AcOH (76%); (b) CHCl_3 – NaOH (40%).

Recently, the $(\text{CH}_2\text{O})_n$ – MgCl_2 – Et_3N system in acetonitrile was proposed for *ortho*-formylation of phenols.³⁹ In this reaction, β -naphthol gave aldehyde **20** (72%) and 1-methoxymethyl-2-naphthol (9%).

Gattermann formylation (HCN – ZnCl_2 , ether, 20 °C) of 1,2-dihydroxy-, 1,3-dihydroxy-, 1,4-dihydroxy-, 2,3-dihydroxy-, 1,5-dihydroxy-, 2,6-dihydroxy- and 2,7-dihydroxynaphthalenes

afforded aldehydes **21**–**27**, respectively, as the only products.^{40, 41} Aldehyde **25** can also be synthesised by Rieche formylation of 1,5-dihydroxynaphthalene. However, the latter reaction is accompanied by the formation of impurities, which are difficult to separate.⁴²

Unlike the above-mentioned dihydroxy derivatives of naphthalene, Gattermann formylation of 1,6-, 1,7- and 1,8-dihydroxynaphthalenes afforded two isomeric aldehydes in all cases.⁴⁰

3-Hydroxy-2-naphthoic acid is subjected to Vilsmeier formylation at position 4.¹⁹

Formylation of alkoxy-naphthalenes proceeds much as that of naphthols, although there are some exceptions. For example, Gattermann⁴³ or Vilsmeier⁴⁴ formylation of 1-methoxynaphthalene gave 4-methoxy-1-naphthaldehyde (**28**) in nearly quantitative yield (the reaction with the use of triformamide as the formylating agent, aldehyde **28** was prepared in only 42% yield).³¹ If position 4 is occupied by the methyl group, the aldehyde group is added at the α position with respect to the more electron-donating methoxy substituent to form compound **29**.

2-Alkoxy-naphthalenes were smoothly formylated at position 1 to give aldehydes **30a,b** in good yields.^{45–47}

Compound	R	Yield (%)	Ref.
a	Me	90	45, 46
b	Et	74–84	46, 47

Under the same conditions, 6-alkyl-2-methoxynaphthalenes produced aldehydes **31**.^{48–50}

Vilsmeier formylation of dimethoxynaphthalenes giving rise to aldehydes **32–36** was carried out in the studies.^{44, 51–55}

The Vilsmeier reaction of 1,5-dimethoxynaphthalene afforded 4,8-dimethoxy-1-naphthaldehyde (**37**) with a small impurity of dialdehyde **38**.⁵⁶ It was demonstrated⁴² that the latter can also be synthesised by Rieche formylation of monoaldehyde **37** (93% yield).

Vilsmeier formylation of 1,4,5,8-tetramethoxynaphthalene gave aldehyde **39** in quantitative yield. The latter was used as the starting compound in the synthesis of natural compounds.^{57–59} Formylation of 2-methylthionaphthalene produced aldehyde **40**, which is one of a few known sulfur-containing naphthaldehydes.⁶⁰

A rare example of *ipso*-formylation with the substitution of the isopropyl group was observed in attempting to subject 2,2'-binaphthyl derivative **41** to the Rieche reaction in the presence of TiCl_4 . Dialdehyde **42** was obtained in 79% yield.⁶¹

Interestingly, the reaction of monomeric substrate **43** performed under analogous conditions afforded 'normal' formylation product **44** in quantitative yield.⁶²

Formylation of compounds **45a** (apogossypol) and **45b** giving rise to gossypol **1**^{61,63} and its ethyl analogue **46**, respectively,⁶¹ follows another pathway compared to the above-mentioned reactions involving polymethoxy derivatives **41** and **43**. Apparently, the hydroxy groups, which can form hydrogen bonds with an electrophile, efficiently stabilise the transition state corresponding to aldehydes **1** and **46**.

R = Pr^i (**45a**, **1**), Et (**45b**, **46**).

c. Aminonaphthalenes and aminonaphthols

Aminonaphthalenes exhibit much higher reactivity in formylation compared to naphthols and alkoxy-naphthalenes. However, the orientation effects in both series of compounds are virtually identical. For example, the Vilsmeier reactions of 1-dimethylamino- (**47**)^{64,65} and 1-diethylaminonaphthalenes (**48**)⁶⁶ afforded the corresponding 4-dialkylamino-1-naphthaldehydes **49** and **50**.

R = Me (**47**, **49**), Et (**48**, **50**).

2-Anilinonaphthalene was formylated at position 1 to give aldehyde **51** (48% yield).⁶⁷ 2-Diethylaminonaphthalene was formylated at the *amphi* position with respect to the NEt_2 group to form aldehyde **52**.⁶⁶

1,8-Bis(dimethylamino)naphthalene (**53**) known under the name of 'proton sponge' exhibits high reactivity with respect to formylating agents. This diamine reacts with the Vilsmeier reagent (DMF-POCl_3) already at $-50\text{ }^\circ\text{C}$.⁶⁸ The results of this reaction depend substantially on the diamine **53**: Vilsmeier reagent molar ratio. Apparently, the proton abstracted upon formylation is bound by a highly basic ($\text{p}K_a$ 12.1) compound **53** to form a cation, which is not involved in formylation. Hence, 2 equiv. of diamine **53** per equivalent of the DMF-POCl_3 mixture should be used for the preparation of monoaldehyde **54**. As a result, more than 50% of the starting compound is regenerated and aldehyde **54** is produced in 70% yield with respect to bis(dimethylamino)naphthalene **53** consumed. In the reaction of diamine **53** with the Vilsmeier reagent taken in a ratio of 1:1, the yield of monoaldehyde **54** decreased to 16.5%, *peri*-dialdehyde **55** was produced as the main reaction product (50%), and unsymmetrical dialdehyde **56** was generated as an impurity (all yields are given with respect to

compound **53** consumed). Diamine **53** was also subjected to formylation by chloral in pyridine, but aldehyde **54** was obtained in a yield of no higher than 7%.⁶⁸ Unlike compound **53**, its tetraethyl analogue is difficult to formylate and 4,5-bis(diethylamino)-1-naphthaldehyde was isolated in only 13% yield.⁶⁹ Apparently, due to strong steric hindrances in the 4,5-bis(diethylamino)-1-naphthaldehyde molecule, the electron-donating effect of two *peri*-NEt₂ groups with respect to the naphthalene system is much weaker than that in the 'proton sponge.'

1-Methoxy-8-dimethylaminonaphthalene **57** exhibits reactivity as high as that of diamine **53**.⁷⁰ This compound readily reacts with the Vilsmeier reagent at $-50\text{ }^{\circ}\text{C}$ to form monoaldehyde **58** in 85% yield with an insignificant (2.5%) impurity of dialdehyde **59** (the yields are given with respect to amine **57** consumed in the reaction, about one-half of the latter being involved in the formation of inert cations and regenerated). The formation of compound **59** is the first example of the introduction of two aldehyde groups into the same ring of the naphthalene system. Interestingly, the yield of dialdehyde increased substantially when the reaction was performed at $-10\text{ }^{\circ}\text{C}$ and the **58**:**59** product ratio was 3 : 1.

In 1-methoxy-5-(*N*-methylacetamido)naphthalene, the methoxy group exhibits a stronger activating effect in contrast to compound **57**. Formylation (Rieche method) afforded aldehyde **60** as the only product (yield 60%).⁷¹

d. Naphthalene-based heterocyclic systems

Formylation of *peri*-fused heterocyclic systems based on naphthalene was carried out in a series of studies. These systems are of interest because the heterocycle in these compounds serves as a special kind of substituent exerting a substantial effect on the

degree of activation of the naphthalene system with respect to the electrophilic substitution as well as on the orientation effects. It was demonstrated⁷² that 6-methoxy-1,3-dimethyl-1*H*-1,2-diazaphenylene (**61**) rapidly reacted with the Vilsmeier reagent even at $0\text{ }^{\circ}\text{C}$ to give 7-carbaldehyde **62** as the only product (87% yield). In this experiment, intermediate immonium salt **63** was isolated as a perchlorate. The ease of formylation results from π -excessiveness of the heterocycle in diazaphenylene **61**, which formally contains 7 π electrons. The partial shift of the excessive Hückel electron from the heterocycle in molecule **61** induces substantial negative π -charges in the *ortho* and *para* positions of the naphthalene fragment.

Formylation of 1,2-diazaphenylene **64** containing the unsubstituted NH group proceeds less selectively. In this reaction, the sterically non-hindered *ortho* position and the pyrrole nitrogen atom are subjected to electrophilic attack along with the *para* position with respect to the NH group. The reaction afforded aldehyde **65** and dialdehyde **66** as the major products. In addition, formyl derivatives **67** and **68** were isolated in low yields (Scheme 1).

Since heterocyclic 1,2-diazaphenolens are characterised by very low basicity ($\text{p}K_{\text{a}} < 3$), they are present in reaction mixtures predominantly as bases, which, evidently, undergo formylation. A different situation occurs in the case of much more basic ($\text{p}K_{\text{a}} > 5.5$) 1,3-diazaphenolens (perimidines). Perimidine (**69**) and 2-methylperimidine (**70**) are very difficult to formylate. A large excess of the Vilsmeier reagent and prolonged heating at $80\text{--}90\text{ }^{\circ}\text{C}$ are required for the latter reactions to proceed. However, the yields of 4(9)- (**71**) and 6(7)-formylperimidines (**72**) produced under these conditions were also no higher than 10%. Aldehydes **73** and **74** derived from 2-methylperimidine were

Scheme 1

prepared in only 1%–2% yields.⁷³ Since the 1,3-dimethylperimidinium cation does not undergo formylation at all, it can be concluded that perimidines **69** and **70** are virtually completely protonated under the conditions of the Vilsmeier reaction and the reaction proceeds through formation of the free base, which is present in the reaction mixture in a low equilibrium concentration.

R = H (**69**, **71**, **72**), Me (**70**, **73**, **74**).

An important role of the basicity of the substrate is evidenced by the fact that 2-trifluoromethylperimidine (**75**) of low basicity is readily subjected to formylation.⁷⁴ This reaction afforded 4(9)-carbaldehyde **76** (yield 42%) and 6(7)-carbaldehyde **77** (22%) as the major products along with small amounts of dialdehydes **78**–**80**. It should be noted that formation of the latter product is the only example of diformylation of the naphthalene ring at two β positions.

It should be noted that 1-methyl-2-trifluoromethylperimidine (**81**) is much more difficult to formylate than its non-methylated analogue **75**.⁷⁴ For example, the reaction of compound **81** proceeded at a noticeable rate only at 80 °C, and the total yield of aldehydes **82**–**84** was 46% after 3.5 h, whereas formylation of perimidine **75** was completed within 2.5 h even at 35 °C. In

addition, perimidines containing the unsubstituted NH group were formylated predominantly at positions 4(9), whereas an analogous reaction of *N*-methylated derivative **81** gave rise predominantly to 6- and 7-carbaldehydes (product ratio **82**:**83**:**84** = 22:20:58). It can be hypothesised that the NH group in molecule **75** is efficiently involved in stabilisation of the transition complex corresponding to *ortho*-formylation (this is, to a large extent, true also for 1,2-diazaphenylene **64** and other analogous compounds).

1,3-Dialkylperimidones **85a,b**, which are less basic than 2-trifluoromethylperimidines, were smoothly formylated at position 6 to form aldehydes **86a,b** in 85% yield.⁷⁴ In attempting to perform further formylation, compound **86a** underwent isomerisation to 4-carbaldehyde **87**. The fact that the second formyl group is difficult to introduce can be attributed to the lower π -donating ability of the heterocycle in perimidones due to the electron-withdrawing effect of the carbonyl group. This is also evidenced by the fact that formylation requires high temperature.

85, 86: R = Me (**a**), Et (**b**).

The electronic structure of 1,2,2,3-tetramethyl-2,3-dihydroperimidine (**88**) is more similar to that of 1,8-bis(dimethylamino)-naphthalene (**53**) rather than to that of perimidines **69** and **70**. Being in addition a weak base, compound **88** is readily formylated (Scheme 2) to give monoaldehydes **89** and **90** and dialdehydes **91**

Scheme 2

and **92**.⁷⁴ These results are very similar to those observed upon formylation of 'proton sponge' **53**, with the only difference that the formation of mono-*ortho*-aldehyde was not observed in the latter case.

2. Organometallic syntheses

Not all aldehydes of the naphthalene series can be prepared by electrophilic formylation of naphthalenes. One of the typical limitations concerns compounds in which the CHO group and an electron-donating substituent are present in different benzene rings. In such cases, the problem can be solved by performing formylation of organometallic compounds of the naphthalene series with the use of DMF, *N*-methylformanilide or *N*-formylpiperidine. These organometallic compounds are synthesised by either direct metallation of the corresponding naphthalenes or replacement of the halogen atom by metal.

Direct metallation of C–H bonds in naphthalenes generally gives good results for molecules containing a group with a lone electron pair. Due to preliminary coordination with a metallating reagent, this group directs metallation and subsequent formylation at the *ortho* or *peri* position. A characteristic example is 1-dimethylaminonaphthalene (**47**) from which 8-dimethylamino-1-naphthaldehyde (**93**) was prepared as the only product (67% yield) according to the following scheme.^{75,76}

Apparently, metallation at position 8 (rather than at position 2) of the naphthalene system can be explained as follows. Due to steric hindrances, the NMe_2 group is twisted so that the lone electron pair of the nitrogen atom is oriented toward the *peri*-proton. Consequently, after coordination of this pair to the lithium ion, the Bu^- anion appears to be adjacent to the hydrogen atom at position 8, which is eliminated first to form 8-lithium derivative **94**.

In the case of 1-methoxynaphthalene (**95**) in which the MeO group is conformationally more labile, the situation is not so unambiguous. This compound is lithiated by *n*-butyllithium at both positions 8 and 2, the contribution of *ortho*-metallation being much higher. Treatment of the resulting mixture of lithium derivatives **96** and **97** with *N*-methylformanilide afforded 8-methoxy-1-naphthaldehyde (**98**) in only 9% yield and 1-methoxy-2-naphthaldehyde (**99**) in 38% yield.^{77,78} Nevertheless, in spite of such a low yield, this procedure for the preparation of *peri*-aldehyde **98** is preferable to alternative multistep syntheses. It was demonstrated that metallation of compound **95** depends substantially on the nature of both the metallating agent and solvent.⁷⁹ Thus, the addition of tetramethylethylenediamine completely shifted the reaction toward *ortho*-metallation, whereas the use of *tert*-butyllithium instead of *n*-butyllithium led to the predominant formation of *peri*-metallation product **96**.⁷⁹ (The latter observation is consistent with the data on the reaction of *tert*-butyllithium with 1,4-dimethoxynaphthalene.⁸⁰) Treatment of 8- and 2-lithium derivatives thus prepared with dimethylformamide afforded *peri*- and *ortho*-naphthaldehydes **98** and **99** in a ratio of 2 : 1.

Neither of the two accessible *peri* positions was subjected to metallation upon treatment of 1,2,4-trimethoxynaphthalene (**100**) with *n*-butyllithium. The reaction proceeded at position 3 with high selectivity due, apparently, to its activation simultaneously by two methoxy groups. Treatment of the 3-lithium derivative with dimethylformamide gave aldehyde **101** as the only product.⁵⁵

Interestingly, 2-methoxynaphthalene was also metallated at position 3 rather than at position 1. Subsequent formylation afforded aldehyde **102**.⁷⁷ Analogously, dialdehyde **103a** was generated from 2,2'-dimethoxy-1,1'-binaphthyl. Demethylation of **103a** with BCl_3 gave rise to dialdehyde **103b**.⁸¹

The dimethylamino group exerts a stronger orienting action in the course of metallation compared to the alkoxy group. Treatment of 4-dimethylamino-1-tributylsilyloxynaphthalene with *tert*-butyllithium followed by the addition of DMF produced aldehyde **104** as the only product.⁸⁰

The carbamoyl group possesses an even higher metal-orienting ability than the NMe_2 , CH_2NMe_2 or OMe groups. This is

evidenced by the transformation of compounds **105a–c** into aldehydes **106a–c**.⁸²

R = NMe₂ (a), CH₂NMe₂ (b), OMe (c).

If metallation of C–H bonds in naphthalenes is either hindered or does not provide the required reaction pathway, naphthaldehydes are synthesised with replacement of the halogen atom by metal followed by formylation. For example, treatment of α -naphthylmagnesium bromide with dimethylformamide, *N*-formylpiperidine, *N*-formylmorpholine or 2-(*N*-formyl-*N*-methyl)aminopyridine afforded α -naphthaldehyde **2** in good yields (Table 2). For this purpose, 1-tributylstannyl naphthalene was also used. The latter was transformed into α -naphthaldehyde under the action of α,α -dichlorodimethyl ether in the presence of anhydrous AlCl₃. Analogously, β -naphthaldehyde was generated from 2-tributylstannyl naphthalene.⁸⁷ The reaction of 6-methoxy-2-naphthylmagnesium bromide with DMF gave 6-methoxy-2-naphthaldehyde in 80% yield.⁸⁸

Table 2. Organometallic syntheses of α -naphthaldehyde.

M	Formylating agent ^a	Reaction conditions	Yield (%)	Ref.
MgBr	DMF	Et ₂ O, 0–20 °C	87	83
MgBr	NFP	Et ₂ O, 0 °C	94	84
MgBr	NFM	Et ₂ O, 0 °C	92	85
MgBr	NMFAP	THF, 0 °C	76	86
SnBu ₃	Cl ₂ CHOMe	AlCl ₃ , –78 to 20 °C	80	87

Note. The following notations are used: NFP is *N*-formylpiperidine, NFM is *N*-formylmorpholine, NMFAP is 2-(*N*-methyl-*N*-formyl)aminopyridine.

Lithiated naphthalenes, which are generated upon treatment of bromonaphthalenes with butyllithium, have found wide use in the synthesis of naphthaldehydes. The synthesis of 3,6-di-*tert*-butyl-1-naphthaldehyde (**107**) from bromide **108**⁸⁹ is a typical example.

Aldehydes **49**,⁹⁰ **109a,b**⁹¹ and **110**^{91,92} were prepared analogously. In these reactions, DMF or *N*-formylpiperidine generally serve as the formylating agents. However, the synthesis of aldehyde **111** was carried out with the use of *N*-methoxy-*N*-methylformamide.⁹³

109: R = CH₂OH (a), CH(OMe)₂ (b).

3. Oxidation of alcohols and alkyl naphthalenes

Various oxidising agents are presently used for the preparation of aldehydes from alcohols. These oxidising agents provide good yields, high selectivity and rather mild reaction conditions preventing further oxidation of aldehydes to carboxylic acids. In addition to a traditional oxidising agent (manganese dioxide), *N*-chlorosuccinimide, pyridinium chlorochromate, pyridinium dichromate, methylammonium chlorochromate deposited on silica gel,⁹⁴ the DMSO–oxalyl chloride–Et₃N system (Swern oxidation) and some other reagents also meet these requirements. Examples of their use in the synthesis of substituted α -naphthaldehydes are given in Table 3.

Catalytic procedures were developed for oxidation of alcohols of the naphthalene series to aldehydes. Thus, good results were obtained in oxidation of 1-hydroxymethylnaphthalene by molecular oxygen in the presence of heterogeneous catalysts based on transition metal salts (Ru, Co).⁹⁹ Bis(pentafluorophenyl)borinic acid (C₆F₅)₂BOH–Bu^tCHO–MgSO₄ was proposed as an efficient catalyst for homogeneous Oppenauer oxidation of the same alcohol to 1-naphthaldehyde.¹⁰⁰

Table 3. Synthesis of selected naphthaldehydes by oxidation of alcohols.

Aldehyde	R ¹	R ²	Oxidant [O] ^a	Yield (%)	Ref.
98	H	MeO	MnO ₂	88	95
112	H	Br	NCS	85	96
113	H	I	NCS	70	96
114	Cl	Cl	NCS	78	96
115	Cl	Me	PDC	83	97
116	Br	Me	PDC	88	97
117	PhS	Me	DMSO–OxCl–Et ₃ N	88	97
118	PhSO ₂	Me	DMSO–OxCl–Et ₃ N	78	97
1 (<i>S</i> -gossypol)	–	–	DMSO–OxCl–Pr ₂ NEt	81	63
119	Br	–	PCC	79	91
120	OMe	–	PCC	–	98

Note. The following notations are used: NCS is *N*-chlorosuccinimide; PDC is pyridinium dichromate; PCC is pyridinium chlorochromate; DMSO is dimethyl sulfoxide; OxCl is oxalyl chloride.

Many studies, including patents,^{100–103} were devoted to the synthesis of naphthaldehydes by catalytic oxidation of methyl-naphthalenes. Scheme 3 gives an insight into the mechanism of these transformations. This scheme shows photochemical oxidation of 1-methyl- and 1,3-dimethylnaphthalenes to aldehydes **2** and **121**, respectively.

The reaction proceeds by the following mechanism:

The process is carried out in the presence of 9,10-dicyanoanthracene (DCA) serving as a sensitising agent (S), methyl viologen (MV^{2+}) and divalent iron ions.¹⁰⁴ These reactions often afford naphthalenecarboxylic acid as a by-product. However, this drawback can be remedied by using modern reagents, such as *o*-iodoxybenzoic acid, as an oxidising agent.¹⁰⁵

Vinylnaphthalenes¹⁰⁶ and acenaphthylene were also proposed as the starting compounds for the preparation of naphthaldehydes. Ozonolysis of acenaphthylene afforded 1,8-diformylnaphthalene (**12**) in 73% yield.¹⁰⁷ Due, apparently, to Coulombic repulsions between two closely spaced carbonyl groups, this dialdehyde is very readily hydrated and transformed into cyclic hydrate **122** under normal conditions. The latter exists as two stereoisomers with melting points (T_m) of 140.0–141.5 °C and 106–107 °C (its *cis-meso* form is shown below). Upon sublimation in hard vacuum, this hydrate loses the water molecule and is transformed into non-hydrated form **12** ($T_m = 124$ –125 °C).¹⁰⁸

Interestingly, an attempt to prepare dialdehyde **12** by oxidation of 1,8-dihydroxymethylnaphthalene with manganese dioxide¹⁰⁸ led only to the formation of naphthopyranone.

4. Syntheses from naphthalenecarboxylic acid derivatives

First data on syntheses of naphthaldehydes by reduction of naphthalenecarboxylic acid derivatives date back to the beginning of the 20th century. For example, 5-methoxy-1-naphthaldehyde (**123**) was prepared by the Rosenmund reaction.¹⁰⁹ Since that time, new more efficient reagents for reducing carboxylic acid chlorides were found. In our opinion, sodium tris(*tert*-butoxy)-

aluminium hydride (STBA) is a reagent of choice. This reagent allows one to perform the reaction at low temperature and prepare 1- and 2-naphthaldehydes (in particular, aldehyde **124**) in nearly quantitative yields.¹¹⁰ The lithium analogue of STBA can also be used, for example, in the synthesis of dialdehyde **103b**.¹¹¹ However, the reactions with the use of the latter reagent generally afford aldehydes in lower yields.¹¹⁰

Recently, Korean chemists have developed an original procedure for the redox transformation of aroyl chlorides into aldehydes.¹¹² First, the reaction of aroyl chloride with aluminium chloride was carried out to obtain the corresponding aluminium alkoxide, which was immediately oxidised with pyridinium chlorochromate or pyridinium dichromate to prepare aldehyde. This method made it possible to synthesise 1- and 2-naphthaldehydes in virtually quantitative yields.

This approach was also extended to the synthesis of aldehydes from carboxylic acids,¹¹³ esters¹¹⁴ and directly from primary alcohols.¹¹⁵

Reduction of acid nitriles is yet another procedure widely used for the preparation of naphthaldehydes. The list¹¹⁶ of reducing reagents used for this purpose consists of more than ten compounds, including tin dichloride and a number of complex hydrides. For example, the use of lithium diisobutylaluminium hydride (DIBAL) as the reducing agent gave good results in the synthesis of aldehydes **125a,b** from nitriles **126a,b**.^{117, 118}

R = H (a), Br (b).

In recent years, high requirements have been imposed upon the selectivity of the process. For instance, potassium 9-(pentan-2-yl)-9-boratabicyclo[3.3.1]nonane¹¹⁹ and lithium tris(diethylamino)aluminium hydride¹¹⁶ were proposed as reagents for reduction of aryl cyanides in the presence of aliphatic acid nitriles. These reducing reagents were also successfully used for the synthesis of naphthaldehydes.

Reduction of 1,8-naphthalic anhydride in the presence of the $\text{Na}_2\text{Fe}(\text{CO})_4$ complex¹²⁰ or treatment of acenaphthenequinone with alkali in DMSO¹²¹ afforded 8-formylnaphthalene-1-carboxylic acid (existing in cyclic form **127**) in good yields.

5. Syntheses based on halomethylnaphthalenes

The use of bromomethyl- and dibromomethylnaphthalenes in the synthesis of naphthaldehydes seems to be very attractive because they are readily accessible reagents prepared by free-radical bromination of methylnaphthalenes with *N*-bromosuccinimide (NBS). For example, 8-methyl-1-naphthaldehyde (**128**) was synthesised in two steps from commercial 1,8-dimethylnaphthalene. The bromomethyl group was oxidised with 2-nitropropane.¹²²

1,4-Naphthodialdehyde was prepared from 1,4-bis(bromomethyl)naphthalene by the Sommelet reaction.¹²³

Isomeric 1,3-, 1,5-, 1,6-, 1,7-, 2,6- and 2,7-dialdehydes as well as 1,3,5-, 1,3,6-, 1,3,7- and 1,4,6-trialdehydes of the naphthalene series were synthesised according to the Kröhnke method.¹²³ This method involves the preliminary transformation of halomethyl derivatives of naphthalene into pyridinium salts and then into nitrones, which are subjected to acid hydrolysis, as exemplified by the synthesis of 1,3-naphthodialdehyde (**129**).

Kochergin and co-workers¹²⁴ developed a procedure for the preparation of aromatic aldehydes, including naphthaldehydes, based on transformations of chloromethylarenes into nitrates and decomposition of the latter under the action of sodium ethoxide.

In some cases, naphthaldehydes were synthesised with the use of dibromomethylnaphthalenes as the starting compounds, which

were subjected to hydrolysis. In particular, this method was used for the preparation of *peri*-dialdehyde **12**,¹⁰⁸ 1,1'-binaphthyl-2,2'-dicarbaldehyde¹¹¹ and naphthalene-2,3-dicarbaldehyde (**130**).¹²⁵

6. Functionalisation of substituents in naphthaldehydes

Functionalisation of substituents in naphthaldehyde molecules as well as the introduction of new groups (for example, by electrophilic substitution) is used when target compounds are difficult to prepare according to other methods. For example, demethylation of 8-methoxy-1-naphthaldehyde (**98**) with aluminium chloride afforded aldehyde **131**,^{77,95} which is a very valuable reagent from the preparative standpoint. This compound can also be synthesised by reduction of naphtholactone **132** with lithium tri(*tert*-butoxy)aluminium hydride (75% yield)¹²⁶ or by oxidation of 2*H*-naphtho[1,8-*b*,*c*]furan (**133**) with lead tetraacetate (30% yield).^{95,127} However, the latter reaction is complicated by the formation of by-products. Compound **133** and its 2- and 4-methoxy derivatives are slowly transformed into *peri*-hydroxynaphthaldehydes even in air.^{95,127}

Heating of 4,8-dimethoxy-1-naphthaldehyde **37** with 1 equiv. of anhydrous AlCl_3 in benzene⁴² or with BBr_3 in dichloromethane⁵⁶ led to selective demethylation of the methoxy group at position 8 to give *peri*-hydroxyaldehyde **134** in good yield. The reaction with the use of 2 equiv. of AlCl_3 afforded dinaphthol **25**.⁴² This method was used also for the synthesis of hemigossypol and its analogues from methoxy precursors⁸ (see also the transformation **103a** $\rightarrow$ **103b**).⁸¹

Bromination of aldehyde **131** produced its bromo derivatives **135** and **136**.¹²⁸

Nitration of aldehyde **131** with nitric acid ($\rho = 1.35 \text{ g cm}^{-3}$) afforded nitro derivatives **137a,b**.¹²⁸ Analogously, the reaction of *peri*-methoxynaphthaldehyde **98** gave rise to 8-methoxy-5-nitro-1-naphthaldehyde (**138**), whose treatment with aqueous alkali produced 8-hydroxy-5-nitro-1-naphthaldehyde (**137b**).¹²⁸

R = NO_2 (a), H (b).

The synthesis of 8-methylthio-1-naphthaldehyde (**139**) from bromide **112** (72% yield)⁹⁶ provides an example of functionalisation based on the nucleophilic substitution.

7. Other methods

The synthesis of aldehydes based on formylation of radical anions of polycyclic arenes was described. Thus, the reactions of sodium naphthalenide with ethyl formate or *N,N*-dibutylformamide afforded naphthaldehyde **2** in 55% yield.¹²⁹ Aromatic aldehydes can also be synthesised by formylation of aryl iodides under homogeneous catalysis conditions.¹³⁰

In some cases, naphthaldehydes are synthesised by the Poldovski reaction in spite of the fact that the products are generally

obtained in low yields. The preparation of 8-formyl-1-naphthamides **140a,b** from *N*-oxides **141a,b**⁸² provides a typical example.

Compounds 140, 141	R	Yield 140 (%)
a	Et	19
b	Pr ⁱ	40

Treatment of benzylamines with phenyl dichlorophosphate and DMSO followed by the successive addition of triethylamine and oxalic acid made it possible to prepare both aromatic ketones and aldehydes.¹³¹ For example, 1-aminomethylnaphthalene was transformed under these conditions into α -naphthaldehyde in 78% yield. This reaction is a modification of the Pfizner–Moffat oxidation and involves preliminary activation with DMSO.

In several studies, naphthaldehydes were prepared by cyclisation. Recently, Italian chemists have developed a procedure for the synthesis of fluorinated 2-naphthaldehydes **142a–c** based on oxidative annelation of the benzene ring to *O*-trimethylsilyl 2-benzylvinyl ethers **143** (Scheme 4).¹³² In addition to the organometallic synthesis of the ethers (**144** $\rightarrow$ **143**), the procedure involves carbon–carbon chain growth through the addition of ethyl vinyl ether to compounds **143** and acid-oxidative cyclisation of isomeric acetals **145** and **146** under the action of dichlorodicyanobenzoquinone (DDQ). The former reaction requires the use of cerium ammonium nitrate (CAN) and proceeds, most likely, by a radical mechanism. Aldehydes **142** were prepared in satisfactory total yield ($\sim 40\%$) with respect to the starting fluorophenylmagnesium bromide.

Tetralones were proposed as the starting compounds for the synthesis of substituted 1-hydroxy-2-naphthaldehydes, in particular, of compound **147**. Tetralones are subjected to successive formylation (through the formation of enolates) and aromatisation under the action of DDQ.¹³³

III. Structures and physicochemical properties of naphthaldehydes

In this section, attention is focused on such physicochemical properties that allow one to obtain information on the conformation of the aldehyde group and the character of its electronic interactions with the core and other substituents.

1. Infrared, ultraviolet and mass spectra

Based on the stretching absorption band of the C=O bond ($\nu_{\text{C=O}}$) as the characteristic band in the IR spectra of unsubstituted α - and β -naphthaldehydes **124** (1700 cm^{-1} in CCl_4), it can be seen from Table 4 that the low-frequency shift of this band ($\Delta\nu_{\text{C=O}}$) is favoured by the involvement of the aldehyde group in intramolecular hydrogen bonding, different electronic interactions of this group with other substituents and steric factors. For example, $\Delta\nu_{\text{C=O}}$ in the spectra of *o*-hydroxynaphthaldehydes **18** and **20** is -50 cm^{-1} due, apparently, to intramolecular hydrogen bonding. In the spectrum of 3-hydroxy-2-naphthaldehyde (**148**), this shift is smaller ($\Delta\nu_{\text{C=O}} = -32\text{ cm}^{-1}$). Apparently, the intramolecular hydrogen bond in the latter compound is weaker due to the larger C(β)–C(β) bond length and, consequently, to the larger distance between the CHO group in position 2 and the OH group in position 3 of the naphthalene ring. Interactions between the

substituents in *peri*-hydroxynaphthaldehyde **131** are of particular interest. Formally, the OH and CHO groups are not conjugated and the intramolecular hydrogen bond cannot be as strong as those in aldehydes **18** and **20** because the seven-membered chelate ring rather than the six-membered ring is closed in **131**. Actually, $\Delta\nu_{\text{C=O}}$ in the IR spectrum (in CHCl_3) of compound **131** (-30 cm^{-1}) is even smaller than that in the spectrum of aldehyde **148**. In a solution of compound **131** in THF, the hydrogen bridge is, apparently, partially broken and the IR spectrum has two $\nu_{\text{C=O}}$ bands one of which (at 1660 cm^{-1}) can be assigned to the form containing an intramolecular hydrogen bond and another band (at 1680 cm^{-1}) can be attributed to the form without an intramolecular hydrogen bond.

A record decrease in $\nu_{\text{C=O}}$ (to 1610 cm^{-1}) is observed in the IR spectra of gossypol **1** and its analogue **46**.^{61,135} This fact suggests that the aldehyde group in compounds **1** and **46** is chelated with the *o*-OH group rather than with the *peri*-OH group (*cf.* ^1H NMR spectra and results of X-ray diffraction analysis discussed in Sections III.2 and III.6). In the IR spectrum of aldehyde **149**, $\Delta\nu_{\text{C=O}}$ is -60 cm^{-1} .

A decrease in the frequency of absorption of the carbonyl group due to its conjugation with the electron-donating substituents is smaller than one would expect (see, for example, Table 4, compounds **2**, **49** and **54**). A small value of $\Delta\nu_{\text{C=O}}$ for *peri*-dialdehyde **55** prepared from the 'proton sponge' is particularly surprising, the more so that other physicochemical characteristics of this compound, in particular, the dipole moments (see below), are indicative of very strong conjugation in its molecule.

Substituents facilitating the twist of the CHO group with respect to the plane of the naphthalene system cause a decrease in conjugation as a result of which $\nu_{\text{C=O}}$ increases [see Table 4, aldehyde **35** and its 3-methyl- (**150**) and 3-bromo derivatives (**151**)].

α -Naphthaldehyde **2** and *peri*-dialdehyde **12** are colourless compounds, and the long-wavelength absorption band in their UV spectra is observed at 300 nm (Table 5). However, the presence of even one electron-donating substituent in the *para* position with respect to the formyl group causes a strong bathochromic shift of this band and the corresponding compounds become coloured. Aldehydes **49** and **54–56** containing the NMe_2 groups are typical examples. The conjugation is particularly pronounced in *peri*-dialdehyde **55**, which occurs as dark-orange crystals with metallic lustre. α -Naphthaldehyde derivatives containing substituents with the lone electron pair (OH, OMe, NAlk_2) in position 8 are also yellow or orange in colour. The fact that aldehyde **93** is coloured was attributed to *peri*-interactions between the substituents (see Section III.6) resulting in an increase in the energy of the highest occupied molecular orbital (HOMO) involving the lone electron pair of the O or N atoms of the electron-donating group.⁷⁶ In our opinion, an alternative explanation can be put forward, according to which the electron-donating (NMe_2) and electron-withdrawing (CHO) substituents are independently conjugated with the π -system of the ring, which facilitates an increase in the energy of the HOMO and a decrease in the energy of the lowest unoccupied molecular orbital

^a Shoulder.

(LUMO). A narrowing of the energy gap between these orbitals leads to a shift of the absorption band to the visible region. To study this problem in more detail, it would be of interest to record the UV spectra of 5-methoxy- and 5-dimethylamino-1-naphthaldehydes.

It should be noted that UV spectra played a large role in the determination of the structure of gossypol yellow in colour ($\lambda_{\text{max}} = 277, 289$ and 364 nm).¹³⁷

Mass-spectrometric data for naphthaldehydes are scarce. Mezheritskii and co-workers⁴² studied the fragmentation pathways of 4,8-dihydroxy-1,5-naphthodialdehyde in detail. In the mass spectrum of this compound, the molecular ion peak is most intense (100%). The character of fragmentation led the authors of the cited study⁴² to the conclusion that both cyclic and acyclic forms of this dialdehyde are present in the gas phase, and decomposition of each form follows its own pathway. In particular, the fragmentation of the molecular ion of the dialdehyde form begins with elimination of the $\cdot\text{CHO}$ radical followed by liberation of two CO molecules. By contrast, the intensity of the molecular ion peak in the mass spectrum of 8-dimethylamino-1-naphthaldehyde is 60%, whereas the $[\text{M}^{+\cdot} - \text{CO}]$ peak is most intense.⁷⁶

The electron affinities (*EA*) of 1- and 2-naphthaldehydes, which were measured by high-pressure pulse mass spectrometry, are 0.68 and 0.64 eV, respectively (for comparison, *EA* of naphthalene, 1-nitronaphthalene and 2-nitronaphthalene are -1.12 , $+1.23$ and $+1.18$ eV, respectively; the negative electron affinity of naphthalene reflects the instability of its radical anion).¹³⁸

2. NMR spectra

The most useful information on conformations of the formyl group, which can be obtained from ^1H NMR spectra of naphthaldehydes, involves chemical shifts of the protons of the CHO group and also of the nearest-neighbourhood protons, primarily, of *peri*-H. The chemical shifts of the proton of the CHO group for selected naphthaldehydes, which do not contain intramolecular hydrogen bonds, are given in Table 6.

If a molecule contains no bulky substituents adjacent to the formyl group, the latter can be located virtually in the ring plane (see Section III.6). In this case, the signal for the proton of the CHO group is generally observed at δ 10 (see Table 6). If the aldehyde group is twisted with respect to the naphthalene system, its proton is in the region of the diamagnetic component of the ring current and the corresponding signal shifts downfield. In addition, the chemical shift of the proton of the formyl group depends substantially on the anisotropic effect of the adjacent group, particularly, if it contains the lone electron pair. These phenomena can be observed in the ^1H NMR spectra of 8-substituted naphthaldehydes in which the chemical shifts of the proton of the CHO group reach 11 ppm and can be even higher (see Table 6). The rotation of the CHO group can be caused by both steric factors and electronic interactions between the substituents. For example, if a substituent in position 8 of the naphthalene system contains an

Table 6. Chemical shifts of the proton of the CHO group (δ_{CHO}) in the ^1H NMR spectra of selected naphthaldehydes.

^a 2H.

atom with the lone electron pair (NMe₂, OMe, SMe), the latter tends to attack nucleophilically the carbonyl carbon atom, which requires rotation of the CHO group with respect to the ring plane by a large angle τ (see Section III.6). Apparently, when τ is close to 90° , the signal for the proton of the CHO group is observed at $\delta \sim 11.0$. The arrangement of the ring and formyl group in a single plane is apparently characterised by the chemical shift $\delta_{\text{CHO}} \sim 9.8$.

It is known that the carbonyl group possesses a substantial anisotropic effect. The protons located in the magnetic cone in the vicinity of the oxygen atom are subjected to strong deshielding and their signal shifts substantially downfield. This effect influences also the protons adjacent to the carbonyl carbon atom (however, to a much lesser degree). α -Naphthaldehyde **2** and its 2-hydroxy derivative **20** are characteristic examples. Taking into account the presence of an intramolecular hydrogen bond in compound **20**, the orientation of the CHO group is beyond question. Hence, a substantially larger downfield shift of the signal for the H(8) proton in the ^1H NMR spectra of α -naphthaldehyde indicates that its carbonyl group is directed toward the *peri*-proton (*Z* conformation). The occupancy of the *Z* conforma-

tion in 2-methoxy-1-naphthaldehyde (**30a**) is even higher due, apparently, to the supporting effect of the methoxy group.

According to estimates made in the studies^{141, 142} based, in particular, on a comparison of the chemical shifts of the signal for the H(8) proton in the spectra of α -naphthaldehyde (δ 9.23) and model compound **152** (δ 9.51), the CHO group in molecule **2** is non-coplanar with the ring (the corresponding angle is 22°). Judging from the data for cyclic ketones **152** and **153**, the formyl group in molecule **154** containing the even bulkier acetyl group should be even more non-coplanar. For a series of carbonyl derivatives of naphthalene,¹³⁹ the diamagnetic shifts of the signal for the proton at the *peri* position with respect to the aldehyde group (relative to the corresponding signal in the ^1H NMR spectrum of naphthalene) under the influence of the anisotropic effect of the C=O group are shown below.

Data on deshielding of the *ortho*- and *peri*-protons in naphthaldehydes containing the NMe_2 groups in their cores are presented in Table 7. The downfield shifts of the signals for the *peri*- and *ortho*-protons in the ^1H NMR spectra of dimethylaminonaphthaldehydes relative to the corresponding signals for compounds **47** (for **49**) and **53** (for **54–56**) are shown below.^{65, 68} (The atomic numbering scheme for the hydrogen atoms in compounds **47** and **53** used here and in Table 7 is arbitrary.)

Table 7. Chemical shifts (δ) of the protons experienced the anisotropic effect of the carbonyl group in the ^1H NMR spectra (in CDCl_3) of dimethylaminonaphthaldehydes.^{65, 68}

Compound	δ		
	H(2)	H(7)	H(8)
47	7.50	—	7.60
53	7.33	—	7.39
49	7.78	—	9.35
54	7.55	—	8.85
55	7.83	7.83	—
56	7.83	7.85	8.85

Conclusions about the orientations of the groups in dialdehydes **55** and **56** were made based on the results of X-ray diffraction analysis (see Section III.6). The degree of deshielding of the H(8) proton in monoaldehyde **54** is equal to that in dialdehyde **56**. This indicates that the carbonyl oxygen atom in molecule **54** is also directed toward the *peri*-proton. The same is true for monoaldehyde **49** in which the deshielding of the *peri*-proton is even more substantial. It should be noted that weak deshielding of the *ortho*-protons is observed even if the carbonyl oxygen atom is oriented toward these protons, the more so that this deshielding is, undoubtedly, associated with the electron-withdrawing ability of the CHO group.

Analysis of the ^1H NMR (see Ref. 142) and ^{13}C NMR (see Ref. 92) spectra and the nuclear Overhauser effect in combination with theoretical MM2 calculations¹⁴³ demonstrated that the occupancy of the *Z* conformation in α -naphthaldehyde is, on the average, 80%–90% regardless of the conditions, whereas the *E* conformer is more favourable for β -naphthaldehyde to the same extent (Table 8). It was believed¹⁴⁴ that both conformers are stabilised through a more efficient conjugation between the *trans*-arranged C=O group and the $\text{C}(1)=\text{C}(2)$ bond characterised by a higher multiplicity. In addition, a weak intramolecular hydrogen bond can occur between the carbonyl oxygen atom and the H(8) proton in 1-naphthaldehyde.¹⁴⁵

The free activation energies of rotation of the CHO group in α - and β -naphthaldehydes determined by dynamic ^{13}C NMR spectroscopy are 26.8 and 34.4 kJ mol^{-1} , respectively. The introduction of the methoxy substituent at position 4 of molecule **2** and at

position 6 of molecule **124** increases the rotation barrier by 4.6 and 2.9 kJ mol^{-1} , respectively.⁹²

The ^1H NMR spectra of naphthaldehydes in which the CHO group is involved in intramolecular hydrogen bonding have some characteristic features. Among these compounds are *peri*- and *ortho*-hydroxynaphthaldehydes (Table 9). Evidently, the formyl group in 8-hydroxy-1-naphthaldehyde (**131**) is virtually coplanar with its aromatic core, and the carbonyl oxygen atom is directed toward the hydroxy substituent. This is evidenced primarily by the chemical shift of the proton of CHO (δ 9.76) and the position of the signal of OH (δ 11.60) characteristic of the hydroxy group involved in intramolecular hydrogen bonding. Analogous patterns are observed in the spectra of 5-methoxy (**155**), 7-methoxy (**156**), 5-bromo (**135**), 5,7-dibromo (**136**) and 5-nitro derivatives (**137b**) of *peri*-hydroxyaldehyde.

The spectrum of 8-hydroxy-4-methoxy-1-naphthaldehyde (**134**) differs substantially from those mentioned above. The unexpectedly large (δ 11.16) chemical shift of the proton of CHO in the spectrum of this compound can be attributed only to a sharp change in the conformation of the formyl group (for example, to its substantial rotation about the $\text{C}_{\text{Ar}}-\text{CHO}$ bond) necessary for the nucleophilic attack of the hydroxy group on the carbonyl carbon atom (see Section III.6) or its transformation into the *E* form. In the latter case, the proton of the CHO group is located in the diamagnetic field of simultaneously two benzene rings and its signal should be shifted substantially downfield, as was observed for the α -protons of naphthalene (δ 7.81) compared to the β -protons (δ 7.46). However, the role of the 4-methoxy group remains unclear.

As a result of the transformation into the *E* form, the signal for the proton of the CHO group in 2-hydroxy-1-naphthaldehyde (**20**) also undergoes a substantial diatropic shift (δ 10.78). The presence of an intramolecular hydrogen bond in this compound leads

to closure of the more stable six-membered ring, as evidenced by the position of the signal for the proton of OH in the ^1H NMR spectrum of aldehyde **20** (δ 13.15) compared to that in the spectrum of aldehyde **131** (δ 11.60) containing the seven-membered chelate ring. In this connection, gossypol (**1**) and hemigossypol (**157**) are of interest. In these compounds, intramolecular hydrogen bonds can occur between the 1-CHO and OH groups both in positions 2 and 8. The data from Table 9 provide unambiguous evidence in favour of the former type of hydrogen bonding, *i.e.*, in favour of the six-membered ring closure and *E* conformation of the aldehyde functional group in molecules **1** and **157**. The record chemical shift of the proton of CHO in the spectrum of hemigossypol suggests that the aldehyde proton in this compound is, presumably, also involved in intramolecular hydrogen bonding with the oxygen atom of the OH group in position 8 (the assumption that the formyl group can act as an H donor in hydrogen bonding has been made recently in the study¹⁴⁸).

On the whole, the same is true for the signals of the formyl group in the NMR spectra of aldehydes based on naphthalene-containing heterocyclic systems, but there are some specific features associated with annular tautomerism and the presence of heteroatoms. Thus, the ^1H NMR spectrum of 6(7)-formyl-2-trifluoromethylperimidin (**77**) in CDCl_3 has signals of both annular tautomers **A** and **B**, the aldehyde group occurring in the *Z* form in both tautomers.^{149, 150} This is evidenced by a substantial deshielding of the adjacent *peri*-proton whose signal is observed at δ 8.77 and 8.82 for the tautomers **A** and **B**, respectively. The signals for the aldehyde proton are observed at δ 10.04 and 9.97, respectively. This is characteristic of the *Z* conformation of the CHO group, which is virtually coplanar with the naphthalene core (see Section III.6).

Due to the formation of a strong intramolecular hydrogen bond between the proton of the NH group and the oxygen atom of the formyl group, perimidine-4(9)-carbaldehydes, in particular, compound **76**, occur in non-polar solvents and in the solid state exclusively in the chelated 9-CHO-form **A**.⁷³ However, in polar media, for example, in DMSO, the solvent competes with the aldehyde group for the proton of the NH group, an intramolecular hydrogen bond is partially cleaved and different conformers and tautomers, including the forms **B** and **C**, can either coexist or undergo rapid interconversions. For example, the ¹H NMR spectrum of aldehyde **76** in DMSO-*d*₆ at 25 °C has two signals for the proton of CHO at δ 9.90 and 10.45 with the intensity ratio of ~1 : 3. The former signal belongs, apparently, to the chelated 9-CHO group and the latter signal can be assigned to the 4-CHO group in the tautomer **C**. Upon heating, both peaks coalesce into one signal at δ 10.20, whereas the peak of the proton of NH disappears, which is indicative of the rapid interconversion of the tautomers

The spectra of 1-*R*-4-formylperimidines, for example, of compound **82**, have a signal for the proton of the CHO group at abnormally low field ($\delta_{\text{CHO}} \sim 10.8$). Since the aldehyde group in these compounds does not experience steric hindrances and its non-coplanarity with the ring is unlikely, this position of the signal indicates that compounds of type **82** adopt the *E* conformation **A** in which the hydrogen atom of the formyl group is deshielded by the adjacent nitrogen atom of the pyridine type. In addition, the *Z* conformation **B** can be destabilised due to repulsion between the lone electron pairs of the oxygen and nitrogen atoms.

Interesting conformational transitions were observed for 2-trifluoromethylperimidine-4,9-dicarbaldehyde (**80**).⁷³ Judging from the ¹H NMR spectrum in CDCl₃, under these conditions the CHO group in position 9 is fixed in the *Z* conformation (δ_{CHO} 9.93), whereas the 4-formyl substituent occurs in the *E* conformation (δ_{CHO} 10.83). In DMSO-*d*₆, the spectral pattern changes sharply. This spectrum has only two two-proton doublets corresponding to aromatic protons and one singlet of two equivalent CHO groups. Symmetrisation of the spectrum indicates that the polar solvent easily cleaves the intramolecular hydrogen bond resulting in rapid prototropism between the degenerate tautomers **A** and **B**.

The conformers of naphthaldehydes can be reliably identified based on the long-range spin–spin coupling constants between the formyl proton and the *meta*-proton of the ring, $^5J_{\text{H-CHO}}$,^{73, 142} whose values are given below. Generally, these constants are not observed in the spectra of the *Z* forms, but are pronounced in the spectra of the *E* conformations. Their values are generally in the range of 0.4–0.9 Hz. It can be readily seen that the necessary condition for the manifestation of the constants $^5J_{\text{H-CHO}}$ is the *trans*-arrangement of the coupling hydrogen atoms with respect to the C_{Ar}–CHO bond.

In principle, the conformations of naphthaldehydes can also be established based on analysis of the ¹³C NMR spectra. For example, it was noted that the ¹³C signal of the *ortho*-carbon atom in the *cis* position with respect to the carbonyl carbon atom shifts downfield, on the average, by ~8 ppm compared to the signal for another *ortho*-carbon atom.⁹² (The detailed data on the ¹³C NMR spectra of naphthaldehydes were reported in the studies.^{63, 140, 144, 151, 152}) The ¹⁷O NMR spectrum of 4-methoxy-1-naphthaldehyde was studied.¹⁴⁰ This spectrum has a signal for the carbonyl oxygen atom at δ 552.3 and a signal for the oxygen atom of the methoxy group at δ 66.0.

The above-considered data lead to the following important conclusion. Naphthalenes have four types of formyl groups, which are subjected to different action of the diamagnetic component of the ring current. These groups correspond to the *E* and *Z* conformations of α - and β -naphthaldehydes. Each group in the planar form is characterised by different chemical shifts of the proton of the formyl group. The proton of CHO in the *E* form of α -naphthaldehyde is characterised by the most substantial deshielding, whereas the chemical shifts for the remaining three forms are much smaller and differ only slightly from each other. In

substituted naphthaldehydes, the situation is complicated because the chemical shifts of the proton of the CHO group are influenced by steric and electronic factors.

3. Dipole moments

To estimate the polarity and degree of conjugation between the CHO and NMe₂ groups in aldehydes **49**, **54** and **55**, their dipole moments were measured (Table 10). A comparison of the dipole moments of α -naphthaldehyde (**2**), 1-dimethylaminonaphthalene (**47**) and 4-dimethylamino-1-naphthaldehyde (**49**) demonstrated that the additional dipole π moment (μ_{π}^{π}) in compound **49** induced by the so-called 'through-conjugation' is 0.35 D, which is almost three times smaller than that in 4-dimethylaminobenzaldehyde ($\mu_{\pi}^{\pi} \approx 1$ D). Presumably, this is a consequence of steric hindrances to the planar arrangement of the CHO and NMe₂ groups, on the one hand, and the naphthalene π -system, on the other, caused by the *peri*-protons. However, the situation sharply changes on going to 4,5-bis(dimethylamino)-1-naphthalene-1,8-dialdehyde (**54**) and, particularly, to 4,5-bis(dimethylamino)-1,8-naphthodialdehyde (**55**). The unexpectedly large dipole moments of these compounds indicate that the conjugation between the CHO and NMe₂ groups becomes at least as efficient as that in 4-dimethylaminobenzaldehyde. The additional π moments in monoaldehyde **54** and *peri*-dialdehyde **55** are ~ 1.4 and 2.3 D, respectively. This is consistent with the X-ray diffraction data for dialdehyde **55**. These data are indicative of a sharp increase in the distance between the NMe₂ groups compared to the corresponding distance in 'proton sponge' **53**, which is favourable for the strong through-conjugation. Considering the dipole moment (9.21 D), *peri*-dialdehyde **55** is similar to ionic substances. Actually, unlike most of 'proton sponge' derivatives, dialdehyde **55** is noticeably water-soluble, has a rather high melting point (162–164 °C) and exhibits metallic lustre. Strong conjugation decreases the positive charges on the carbon atoms of the formyl groups, pushes them apart and is favourable for stabilisation of the molecule. This is a fundamental difference between *peri*-dialdehyde **55** and dialdehyde **12**, which exists as a cyclic hydrate **122** under ordinary conditions.

Table 10. Dipole moments (μ) of selected naphthaldehydes and model compounds.¹³⁶

Compound	μ /D	Compound	μ /D
2	2.87	53	1.19
47	1.19	54	5.44
49	4.41	55	9.21

The Kerr constants and dipole moments of 1- and 2-naphthaldehydes **2** and **124** were determined and compared with those of 1- and 2-acetylnaphthalenes.¹⁵³ The Kerr constants for aldehyde **2** indicate that the CHO group is rotated with respect to the plane of the naphthalene system by 15°. However, these data do not allow one to make a conclusion as to which conformation (*Z* or *E*) is more favourable. The Kerr constants for aldehyde **124** are consistent with the planar *E* form.

Quantum-chemical calculations in the π approximation of dipole moments of two planar conformers of α - and β -naphthaldehydes and a comparison of these values with the experimental values μ did not lead to reliable conclusions about which form is favourable because of the similarity of the experimental and theoretical values.^{154, 155} The dipole moment of 2-naphthaldehyde (**124**) in CCl₄ (3.26 D) is smaller than that of its 1 : 1 complex with phenol (4.6 D).¹⁵⁶

4. Basicity

Like other carbonyl compounds, naphthaldehydes belong to bases and can be protonated by strong acids at the oxygen atom of the carbonyl group. The ionisation constants (pK_a) of 1- and 2-naphthaldehydes determined by spectrophotometry in aqueous

H₂SO₄ are -6.34 and -6.68 , respectively.¹⁵⁷ Therefore, both these aldehydes are somewhat more basic than benzaldehyde ($pK_a -6.99$) but less basic than 1- and 2-acetylnaphthalenes ($pK_a -5.86$ and -6.04 , respectively). The basicities of aromatic aldehydes, including naphthaldehydes, can also be measured by IR and ¹H NMR spectroscopy.¹⁵⁸

5. Electrochemical reduction

Electroreduction of 1- and 2-naphthaldehydes in DMF and acetonitrile was studied by cyclic voltammetry.¹⁵⁹ Radical anions were generated as primary reduction products, which rapidly disappeared due to subsequent dimerisation. It was found that the reactivity of the radical anions decreases in the series benzaldehyde > 2-naphthaldehyde > 1-naphthaldehyde.

6. Results of X-ray diffraction studies

The structural data for the crystal structures of more than 20 derivatives of 1- and 2-naphthaldehydes, including gossypol (**1**) and its numerous crystal solvates, are available in the Cambridge Structural Database (April 2002). These data were used primarily for studying the conformational effects and *peri*-interactions involving the α -formyl group. There are three main types of displacements of the *peri*-substituents.

If one substituent is an electrophile (among which is the CHO group), whereas another substituent is a nucleophile, their interaction can cause these substituents to either approach each other (type **A**) or incline in the same direction (type **B**). If both substituents are either electrophiles or nucleophiles, they are pushed apart (type **C**). The type of interaction in each particular case can be judged from the distance (d) between the atoms of the substituents directly bound to the naphthalene ring and from the angles (θ) between the C–Nu and C–E bonds, on the one hand, and the adjoining bonds of the naphthalene ring, on the other (Table 11). It is very important to take into account the angle of rotation (τ) of the aldehyde group with respect to the ring plane.

The interaction of type **A** leads finally to the formation of covalent bonds. For naphthaldehydes existing in the aldehyde rather than cyclic form, such interactions have not been observed so far. All interactions of the CHO group with nucleophilic substituents in position 8 belong to type **B** (see Table 11). The type **B** displacement is most pronounced in 8-dimethylamino-1-naphthaldehyde (**93**). This is evidenced by the bond angles $\theta_1 - \theta_4$ and a shortened distance between the nitrogen atom and the carbon atom of the carbonyl group. Although both substituents in molecule **93** are inclined in the same direction, the angle of inclination of the NMe₂ group is larger than that of the CHO group due to which the distance between these substituents decreases. In addition, noteworthy is the large angle τ , which is a prerequisite to the attack of the lone electron pair of the amine nitrogen atom on the carbonyl carbon atom. One can conclude that this is the initial phase of the nucleophile–electrophile interaction and covalent binding.^{5, 6}

In spite of the fact that both *peri*-substituents in 8-methoxy-1-naphthaldehydes **159** and **160** are also inclined in the same direction, the distances between these substituents are substantially larger and the angle of rotation of the formyl group with respect to the ring plane is too small to provide the necessary trajectory of attack of the methoxy oxygen atom on the carbonyl carbon atom. It is believed that the leaning effect in molecules **159** and **160** is associated with weak Coulombic attraction between the oxygen atom of the OMe group and the hydrogen atom of the aldehyde group. Apparently, it is this interaction that is responsible for the *E* conformation of the CHO group in both aldehydes.

Table 11. Geometric parameters characterising *peri*-interactions between the formyl and nucleophilic (Nu) groups in 8-substituted 1-naphthaldehydes.

Compound	Nu	R ¹	R ²	<i>d</i> / Å	τ / deg	θ_1 / deg	θ_2 / deg	θ_3 / deg	θ_4 / deg	Ref.
93	NMe ₂	H	H	2.489	65.8	124.3	116.0	122.2	118.5	160
159	OMe	OMe	OTs	2.628	23.9	123.4	115.1	126.4	114.9	5
160	OMe	H	OTs	2.644	32.9	123.5	115.3	124.7	115.8	5
161	OCOPh	OMe	H	2.823	12.8	117.6	118.8	125.5	115.9	5

In molecule **161**, the benzyloxy group is too bulky and the nucleophilicity of the oxygen atom of the ester group is too small to be attracted to the formyl group. That is the reason why this aldehyde is characterised by a large distance (*d*) between the *peri*-substituents, and the plane of the aldehyde group is nearly coplanar with the ring plane. As a consequence, the arrangement of the *peri*-substituents in this compound corresponds to type C. This structural type is even more pronounced in *peri*-dialdehyde **55** based on a 'proton sponge'.¹³⁶ The distance between the carbonyl carbon atoms (2.99 Å) in its molecule is much larger than the distance between the carbon atoms of the methyl groups in 1,8-dimethylnaphthalene (2.56 Å). Both aldehyde groups in molecule **55** exist in the sterically less strained *E* conformation and the angles of their rotation with respect to the plane of the naphthalene ring are relatively small ($\tau = 20.1^\circ$ and -27.3°). All these geometric features are favourable for conjugation between the CHO and NMe₂ groups in this *peri*-dialdehyde.

According to the results of X-ray diffraction analysis, the conformations of the *para*- and *ortho*-aldehyde groups in the 2,5-diformyl derivative of 'proton sponge' **56** are virtually identical with those in 1- and 2-naphthaldehydes, respectively. The former group occurs in the *Z* conformation and is located virtually in the plane of the ring ($\tau = 6.8^\circ$). The latter group occurs in the *E* conformation and the angle of its rotation ($\tau = 32.9^\circ$) is substantially larger due to the presence of the adjacent NMe₂ group.¹³⁶ The *Z* form is typical also of the CHO group in trifluoromethyl-perimidine-6(7)-carbaldehyde (**77**).¹⁴⁹ Hence, it can be concluded that if there are no substituents adjacent to the α -formyl group in the naphthalene ring, the oxygen atom of this group is always directed toward the *peri*-proton.

X-Ray diffraction studies, as well as ¹H NMR spectra, demonstrated that an intramolecular hydrogen bond involving the β -hydroxy group in 2-hydroxy-1-naphthaldehyde (**20**),¹⁶¹ hemigossypolone (**162a**),¹⁶² gossypolone (**162b**)¹⁶² and gossypol (**1**)^{163–166} stabilises the CHO group in the *E* conformation not only in solution but also in crystals. The geometric parameters of this intramolecular hydrogen bond are given in Table 12.

X-Ray diffraction studies of dialdehyde **56** and compounds **148**,¹⁶⁷ **163a**,¹⁶⁸ **163b**,¹⁶⁹ **164**¹⁷⁰ and **165**¹⁷¹ showed that the β -formyl group tends to adopt the *E* conformation not only in solution (see Table 8) but in the crystalline state as well. The exception is binaphthyl dialdehyde **166** for which the *Z* form was observed.¹⁷² Apparently, this is attributed to destabilisation of the *Z* conformer due to Coulombic repulsion between the oxygen carbon atom and the oxygen atoms of the substituent in position 3. Evidently, one CHO group in naphthalene-2,3-dicarbaldehyde (**167**) occurs in the *E* conformation, whereas another CHO group exists in the *Z* form for the same reason.¹⁷³

Table 12. Geometric parameters of an intramolecular hydrogen bond in naphthaldehyde derivatives **20**, **162a** and **162b**.

Compound	<i>d</i> / Å			Angle O–H...O / deg	Ref.
	O...O	O–H	H...O		
20	2.567	1.070	1.59	148.9	161
162a	2.55	0.73	1.89	150.4	162
162b	2.54	1.03	1.71	134.7	162

7. Ring-chain tautomerism

If a naphthaldehyde molecule has the OH-, NH- or SH-containing substituent adjacent to the aldehyde group, ring-chain tautomerism can take place due to the intramolecular nucleophilic addition of the O, N or S atoms of this substituent to the carbonyl group. 1,8-Naphthaldehydic acid existing under ordinary conditions in the naphthopyran form **127** serves as an example. Analogously, 2-hydroxymethyl-1-naphthaldehyde (**168**) occurs in the cyclic form **B** both in solution and in the solid state, whereas 1-hydroxymethyl-2-naphthaldehyde exists in form **169**.⁹¹ Crystalline 3-hydroxymethyl-2-naphthaldehyde (**170**) also occurs in the cyclic form **B** (the $\nu_{C=O}$ band is absent in the IR spectrum), but its tautomers **A** and **B** in CDCl₃ co-exist in equilibrium, in which the

acyclic form **A** prevails (77%). It is this form of aldehyde **170** that is involved in reactions as evidenced by the formation of 3-bromomethyl derivative **171** upon treatment of compound **170** with hydrobromic acid.⁹¹

8-Hydroxy-1-naphthaldehyde (**131**) and its derivatives with electron-donating substituents in the naphthalene core are not prone to conversion into the cyclic form in neutral or acidic media although the presence of small amounts of this form in solutions cannot be ruled out.⁷ Heating of 8-hydroxy-5,7-dinitro-1-naphthaldehyde in ethanol afforded cyclic acetal **172**.¹²⁸

Unstable 8-mercapto-1-naphthaldehyde (**173**) prepared by reduction of 2-oxo-2*H*-naphtho[1,8-*b,c*]thiophene (**174**) with lithium aluminium hydride or diborane exists exclusively in the cyclic form **A**.¹⁷⁴

As mentioned above (see Section III.6), there are pronounced attractions between the substituents in 8-dimethylamino-1-naphthaldehyde (**93**). Treatment of this aldehyde with acids led to its partial cyclisation, both forms of hydrate **93H⁺** (**A** and **B**) being clearly seen in the ¹H NMR spectrum.⁷⁶

Catalytic reduction of 8-nitro-1-naphthaldehyde (**175**) followed by treatment of the reaction mixture with acetic anhydride afforded 1-acetyl-1,2-dihydrobenzo[*c,d*]indole (**176**).¹⁷⁵ Apparently, the initially formed *peri*-aminonaphthaldehyde **177** immediately underwent cyclisation to give compound **178**, which was subjected to further hydrogenation to form unstable benzoin-doline **179**. The latter can be isolated only as the more stable acetylated derivative **176**.

IV. Reactions

Naphthaldehydes are involved in all reactions typical of aromatic aldehydes. In addition, *peri*-substituted α -naphthaldehydes undergo specific transformations, primarily, cyclisations, due to the presence of closely spaced *peri*-substituents. For this series of compounds, the formation of thiosemicarbazones,⁴⁴ 2,4-dinitrophenylhydrazones,⁶⁸ oximes (which are then transformed into nitriles)^{68, 176, 177} and azomethines,⁶⁸ including polydentate ligands based on 1,1'-binaphthyl dialdehydes of type **103a,b**,^{81, 111, 178, 179} was described. Reduction of naphthaldehydes with complex metal hydrides afforded primary alcohols.^{65, 69, 70, 180} These reactions with the use of lithium tritide and lithium trimethoxyborotritide gave rise to tritium-labelled alcohols.¹⁸¹ Reduction of 2-naphthaldehyde with the TiCl₄–Bu₄N⁺I[–] system afforded 1,2-binaphthylethanediol.¹⁸² Procedures were developed for the enantioselective addition of diethylzinc¹⁸³ and other organometallic compounds¹⁸⁴ to 2-naphthaldehyde with the participation of chiral catalysts or auxiliary groups involved in the substrate. For other naphthaldehydes, analogous reactions were documented.^{58, 185} Naphthaldehydes gave condensation products with compounds containing the active methylene group, *viz.*, diethyl malonate ester,^{122, 186} malononitrile,^{186–188} esters of cyanoacetic¹⁸⁶ and other carboxylic acids,⁸⁹ benzyl cyanides,^{52, 187} γ -picoline,⁹⁸ barbituric acid,¹⁸⁹ trinitrotoluene,⁶⁰ *etc.*

The transformation of 4,8-difluoro-1-naphthaldehyde into the corresponding naphthalenecarboxylic acid under the action of KMnO₄ or the Jones reagent¹¹⁸ can serve as an example of oxidation of naphthaldehydes. The Angeli's salt (sodium tri-oxodinitrate, Na₂N₂O₃) can be used as an oxidising agent. In the latter case, the reaction proceeds by a very complex mechanism involving [2 + 2]-cycloaddition between the N=N bond of the oxidising agent and the C=O group of the aldehyde.¹⁹⁰ Milder reagents can oxidise other groups, the aldehyde group remaining intact. For example, gossypol was converted into gossypolone **162b** (47%–69% yield) under the action of an aqueous solution of FeCl₃.¹⁹¹

Attempts to prepare hydrazones by treating naphthaldehydes with hydrazine were often unsuccessful and led to the formation of the corresponding azines.^{68, 192} Nevertheless, the *in situ* formation of hydrazones was used for the conversion of naphthaldehydes into methylnaphthalenes (Kishner–Wolff reaction)^{44, 52} and *peri*-heterocyclic compounds.¹⁷⁶

p-Toluenesulfonylhydrazones of α -naphthaldehydes were synthesised and then treated with alkali to prepare naphthyldiazomethanes.^{96,97} Naphthaldehydes are involved in the Baeyer–Villiger reaction accompanied by the replacement of the formyl group by the hydroxy group.⁵³ Examples of such transformations were given in the Refs 55, 56, 117.

The tandem reactions of 2-trimethylsilyloxy-1-naphthaldehyde (**180**) with various trimethylsilyldialkylamines and nucleophiles afforded naphthols **181**.¹⁹³

$\text{Nu} = \text{Me}, \text{CH}_2\text{CO}_2\text{Et}, \text{CH}_2\text{CH}=\text{CH}_2, \text{AlkC}\equiv\text{C}; \text{R} = \text{Alk}.$

Under the conditions of acid catalysis, naphthaldehydes react with aromatic CH-nucleophiles, for example, with arylamines. This reaction was used, in particular, for the preparation of the dye Victoria Blue (**182**) from 4-dimethylamino-1-naphthaldehyde (**49**) and 1-dimethylaminonaphthalene (**47**).⁹⁰

The Wittig^{75,77,78,107,160,194} and Wittig–Horner reactions^{133,195} of naphthaldehydes were studied in detail. These reactions afford alkenes, which are generally used for subsequent cyclisations, including the synthesis of natural compounds,¹⁹⁶ biologically active substances¹³³ and synthetic precursors of fullerene.¹⁹⁷ The syntheses of 6,7-bis(dimethylamino)phenalene (**183**),¹⁸⁶ naphtho[1,8-*b,c*]pyran (**184**)⁷⁸ (a modification of this synthesis was described in the study¹⁹⁸), 1-methylbenzo[*d,e*]quinoline (**185**)¹⁶⁰ and benzo[*d,e*]isoquinoline (**186**)¹²² provide only a few examples of such transformations. An analogous approach was used for the synthesis of linear and angular naphthofurans and benzocoumarins.⁷⁷

PPA is polyphosphoric acid.

peri-Dialdehyde **55** derived from the ‘proton sponge’ underwent the intramolecular Cannizzaro reaction upon refluxing in water to form 6,7-bis(dimethylamino)naphtho[1,8-*c,d*]pyran-1-one (**187**).⁶⁸ Interestingly, this process, unlike the classical procedure, does not require the use of alkali. Apparently, the necessary alkalinity of the medium is provided by the high alkalinity of the ‘proton sponge’ by itself.

Naphthalene-1,8-dicarbaldehyde is also involved in the analogous reaction with the only difference that the latter reaction does require alkali.¹⁹⁹

Buu-Hoi *et al.*¹⁸⁷ and then Mezheritskii and co-workers^{7, 71, 200} demonstrated that the seven-membered heterocycles can be built up based on *peri*-hydroxy- and *peri*-aminonaphthaldehydes to form naphtho[1,8-*b,c*]oxepine and naphtho[1,8-*b,c*]azepine derivatives **188**–**190**.

In some studies, heterocyclisation was carried out with the use of 2-hydroxy-1-naphthaldehydes.^{188, 201}

* * *

The data surveyed in the present review provide evidence that naphthaldehydes play a very important role in the chemistry of naphthalene. These compounds serve as important starting reagents for the preparation of complex organic compounds, including biologically active and natural substances. Substituted naphthaldehydes are used for studying the effects of *peri*-interactions, in particular, these compounds model the transition state of the nucleophilic addition to the carbonyl group. This gives insight into the action of enzymes in living organisms. Studies of direct formylation of naphthalene derivatives are not only of great preparative importance but also provide a better understanding of the factors responsible for the reactivity of polynuclear arenes. Undoubtedly, these lines of investigation will be extensively developed in the coming years.

This review was financially supported in part by the Russian Foundation for Basic Research (Project No. 02-03-32080).

Abstract. The review concerns the photorefractive effect in polymeric systems, which involves the creation, upon a primary photochemical reaction, of a phase grating shifted in space relative to the fringe pattern. The interaction of interfering laser beams accompanied by energy transfer from one beam to the other as well as salient features of the refractive index modulation in polymeric systems with low and high glass transition temperatures are considered. Particular attention is given to the photorefractive polymers with high glass transition temperatures containing nanocrystalline J-aggregates of cyanine dyes, which are characterised by high third-order nonlinear electric susceptibilities and induce modulation of the refractive index due to the Kerr electro-optic effect. The prospects for application of polymeric photorefractive materials are outlined. The bibliography includes 113 references.

I. Introduction

The photorefractive (PR) effect is induced by two interfering laser beams (a pump beam and a signal beam) and consists in reversible creation of a phase grating, which is shifted in space relative to the bright fringes. As a consequence, the pump beam reflected from the grating travels parallel to and is in phase with the signal beam. After passing the PR system the intensity of the signal beam is amplified at the attenuation of the reflected pump beam. The reflected signal beam is out of phase with the pump beam; therefore, the intensity of the latter decreases.

The photorefractive effect arises in polymeric media possessing specific properties. First, they must exhibit photoelectric sensitivity and provide the possibility of photogeneration of charge carriers of both signs in bright regions of the interference pattern as a result of a primary photochemical reaction and subsequent charge separation and transport. In most polymeric systems electrons are trapped by deep traps near the generation sites in bright regions of the interference pattern, while holes drift in the applied electric field E_0 towards the dark regions of the

interference pattern until trapping. As a result, a periodic space-charge field E_{sc} is induced, which is shifted in space relative to the fringe pattern. Second, polymeric systems must contain some compounds (chromophores) possessing second- or third-order nonlinear optical properties and/or anisotropy of the linear polarisability (e.g., dipole molecules of organic compounds with electron-donor and electron-acceptor substituents). The orientational or electronic polarisation of chromophores in the periodic field E_{sc} is responsible for periodic modulation of the refractive index, i.e., creation of a phase grating whose maxima coincide with those of the periodic field E_{sc} and, hence, are shifted in space relative to the interference fringes.

Photorefraction was first observed in inorganic crystals LiNbO_3 and LiTaO_3 in 1966.¹ In 1990, the phenomenon was reported for organic crystals² and in 1991 for polymeric composites.^{3,4} Recently, interest in photorefraction in the polymeric materials has increased due to the possibility of using them as highly efficient active optical elements for data transmission and controlling coherent radiation in various electro-optical and optical communication devices. Pioneering attempts to employ photorefractive polymeric materials for writing holograms of moving objects were due to the high writing and erasing speed of such materials. Polymeric systems are also of considerable interest because their spectral properties can be smoothly varied by changing the structure of polymers and polymeric composites. There is a great potential of doping such systems; in addition, they are cheap, readily processable and allow fabrication of parts of any shape and size which are compatible with modern micro-electronic and optoelectronic devices, etc.

Recently, various types of photorefractive polymeric materials have been designed. These are polymers in which functional groups (namely, sensitisers responsible for the photoelectric sensitivity, charge transport sites and nonlinear optical chromophores) are constituents of the main polymer chain or bound to it as side substituents; 'guest–host' composites (functionally doped polymers possessing the charge transport properties); and polymer layers modified in one or another manner (e.g., photochemically). Often, bifunctional polymeric systems are prepared, in which the same chain fragment or dopant simultaneously exhibits the properties of sensitiser and a chromophore or a charge transport site.

In preparing the manuscript the authors of this review focussed on the most interesting, from their viewpoint, results rather than comprehensive consideration of numerous available studies on the title problem.

II. Nature of the photorefractive effect in polymers

The most informative method for studying the PR effect is the two-beam method (Fig. 1). It involves splitting of a laser beam into two beams, which reflect from mirrors and then intersect inside a polymer layer. Each beam is characterised by the

Figure 1. A scheme for measuring the PR effect.

Laser (1), reflecting mirrors (2), beam splitter (3), shutters for beams 1 and 2 (4), sample (5), constant voltage source (6), photodiodes (7), computer (8); 2θ is the angle between beam 1 and beam 2; ϕ is the angle between the z axis (bisectrix of the 2θ angle) and the normal to the surface of the sample.

amplitude, $E_{1,2}(\omega)$, or intensity, $I_{1,2} \sim E_{1,2}^2$, of the electric component of the electromagnetic field. Interference causes a periodic distribution of the light intensity (I) in space

$$\frac{I}{I_1 + I_2} = 1 + 2 \frac{(I_1 I_2)^{0.5}}{I_1 + I_2} \cos\left(\frac{2\pi x}{\Lambda}\right). \quad (1)$$

Here x is the coordinate along the x axis directed normal to the bisectrix of the 2θ angle between the beams (Fig. 2a); Λ is the spatial period (Fig. 2b), *i.e.*, the distance between the bright fringes [or constructive interference fringes, where $\cos(2\pi x/\Lambda) = 1$] along the x axis

$$\Lambda = \frac{\lambda}{\sin \theta},$$

$\lambda = \lambda_0/n$ is the optical wavelength in the polymer; λ_0 is the free-space wavelength; and n is the refractive index of the polymer.

A feature of systems exhibiting photoelectric sensitivity is photogeneration of charge carriers in the constructive interference regions. The number of charge carriers generated is proportional to the light intensity modulation, m (Ref. 5)

$$m = 2 \frac{(I_1 I_2)^{0.5}}{I_1 + I_2}.$$

The necessary condition for the PR effect is considerable difference between the mobilities of photochemically generated electrons and holes. For most polymeric media the mobility of electrons is much lower than that of holes. Electrons are trapped in the regions of bright fringes, while holes drift in the constant electric field E_0 towards the dark regions [or the destructive interference regions, where $\cos(2\pi x/\Lambda) = -1$]. This leads to separation of charge carriers in space and to the appearance of a periodic space-charge electric field E_{sc} , which is directed perpendicular to the bisectrix of the angle between the incident beams and shifted in phase by ψ relative to the fringe pattern (see Fig. 2b)

$$E_{sc} = E_{sc}^0 \cos\left(\frac{2\pi x}{\Lambda} - \psi\right). \quad (2)$$

The E_{sc}^0 field is proportional to the concentration of charge carriers generated in bright regions or, ultimately, to the light intensity modulation

Figure 2. Measuring cell geometry (a) and a scheme illustrating the nature of the PR effect in polymeric systems (b);

(a) polymer layer (1), electrodes made of transparent conducting $\text{In}_2\text{O}_3:\text{Sn}$ film supported by glass slides; regions of constructive and destructive interference in the polymer layer are denoted by the solid and dashed lines, respectively; (b) the fringe pattern and photogeneration of charge carriers, the E_{sc} field distribution along the x axis and the distribution of the total field, $E_t = E_{sc} + E_0$, in the polymer layer (thick arrows); the ‘-’ signs in the interference-maximum regions denote trapped electrons; the ‘+’ signs denote holes migrated to the interference-minimum regions in the E_0 field; ψ is the shift in space of the phase of the E_{sc} field relative to the fringe pattern; the E_{sc} vector is parallel to the x axis and the E_0 vector is directed from the anode to the cathode.

$$E_{sc}^0 \sim 2 \frac{(I_1 I_2)^{0.5}}{I_1 + I_2}. \quad (2a)$$

If positive charges are located at the midpoints of dark regions, the E_{sc} field has maxima at the midpoints between bright and dark fringes, *i.e.*, these maxima are shifted by $x = \Lambda/4$ or by a phase of $\psi \approx \pi/2$ in space relative to the bright fringes. However, the phase shift is usually less than $\pi/2$.

If a composite contains chromophores possessing nonlinear optical properties or anisotropy of the linear polarisability, the E_{sc} field induces a periodic distribution of the refractive index. Indeed, the refractive index is related to the linear electric susceptibility of a unit volume of a polymeric composite $[\chi^{(1)}]$ as follows:

$$n^2 = 1 + 4\pi\chi^{(1)}. \quad (3)$$

The electric susceptibility,

$$\chi^{(1)} = \frac{P(\omega)}{E(\omega)},$$

characterises the linear polarisation, $P(\omega)$, of a unit volume of a substance, induced by the electric component, $E(\omega)$, of the electromagnetic field vector of the light wave. As will be shown below, $\chi^{(1)}$ becomes a variable quantity in a constant electric field.

A feature of non-centrosymmetric chromophores (dipole molecules containing electron-donor and electron-acceptor groups) is that displacement of the electron density from the donor group to the acceptor group induced by the $E(\omega)$ field is larger than in the opposite direction. If the dipole chromophores in the bulk of a substance are aligned in some way during the preparation of a polymer layer, stimulated radiation of an ensemble of such chromophores is anharmonic and can be represented by a set of Fourier components with frequencies ω , 2ω , *etc.*^{6–9} Otherwise, the dipole chromophores are disordered. The second-order susceptibility is given by the formula

$$\chi^{(2)} = Nf(\omega)\beta\langle\cos^3\varphi\rangle,$$

where N is the number of chromophores per unit volume; $f(\omega) = (n^2 + 2)/3$ is the correlation factor relating the external electric field of electromagnetic wave to the field in the medium; β is the second-order molecular polarisability; and $\langle\cos^3\varphi\rangle$ is a parameter characterising the averaged value of the angle of rotation of the dipole moments of chromophores about a specified axis.

For centrosymmetric media (random distribution of the dipole moments of N chromophores), $\langle\cos^3\varphi\rangle = 0$ and the second-order nonlinear susceptibility vanishes. If rotational diffusion of chromophores is possible in a medium, they are aligned in the electric field E_0 . Rotational diffusion of chromophores in polymeric systems is efficient only at temperatures above the glass transition temperature (T_g); therefore, experiments with high- T_g polymers require preliminary alignment in the polarising electric field E_p at $T_p > T_g$. Such an alignment is retained on subsequent cooling ('freezing') of the system in the field E_p down to temperatures below T_g . According to the Langevin formula,

$$\langle\cos^3\varphi\rangle = \frac{f(0)E_p\mu_g}{5kT},$$

where $f(0)$ is the correlation factor relating the external applied field E_p to the field in the polymer layer,

$$f(0) = \varepsilon \frac{n^2 + 2}{2\varepsilon + n^2}$$

(ε is the dielectric constant); and μ_g is the ground-state dipole moment of the chromophore. The formula for the second-order nonlinear volume susceptibility of high- T_g polymers has the form

$$\chi^{(2)} = \frac{Nf(\omega)f(0)\beta E_p\mu_g}{5kT}. \quad (4)$$

At room temperature, chromophores in plasticised polymers (T_g is below the temperature of the experiment, $\sim 20^\circ\text{C}$) are in the mobile state and their alignment makes no sense, since they again become randomly distributed after switching the E_p field off. In such polymers the second-order susceptibility arises only in a constant field. Taking into account the fact that the $\chi^{(2)}$ value is determined by the total field

$$E_t = E_{sc} + E_0,$$

we get

$$\chi^{(2)} = \frac{Nf(\omega)f(0)\beta E_t\mu_g}{5kT}. \quad (4a)$$

The distributions of the E_t field and the E_{sc} and E_0 components along the x axis are shown in Fig. 2b.

The E_t field is involved in the electronic polarisation of a molecule along with the light wave field, $E(\omega)$; therefore, the expression for the volume polarisation, $P(E)$, can be written as follows:

$$\begin{aligned} P(E) = & [\chi_E^{(1)}(-\omega, \omega) + \chi^{(2)}(-\omega, \omega, 0)f(0)E_t + \\ & + \chi^{(3)}(-\omega, \omega, 0, 0)f^2(0)E_t^2]f(\omega)f(-\omega)E(\omega) + \\ & + [\chi^{(2)}(-2\omega, \omega, \omega) + \\ & + \chi^{(3)}(-2\omega, \omega, \omega, 0)f(0)E_t]f^2(\omega)f(-2\omega)E^2(\omega) + \\ & + \chi^{(3)}(-3\omega, \omega, \omega, \omega)f^3(\omega)f(-3\omega)E^3(\omega). \end{aligned} \quad (5)$$

Here $\chi_E^{(1)}$ is the linear volume susceptibility in the constant field; $\chi^{(2)}$ and $\chi^{(3)}$ are the second- and third-order nonlinear volume susceptibilities, respectively; $(-\omega)$, (-2ω) and (-3ω) are the frequencies of the first, second and third harmonics of stimulated radiation of the ensemble of oscillating dipoles when the laser operates at the fundamental frequency ω .

Taking into account formula (5), the linear electric susceptibility in the presence of a constant field E_0 and the E_{sc} field is

$$\chi^{(1)} = \chi_E^{(1)} + f(0)E_t[\chi^{(2)} + \chi^{(3)}f(0)E_t],$$

while relationship (3) takes the form

$$n_E^2 = 1 + 4\pi[\chi_E^{(1)} + E_t(\chi^{(2)} + \chi^{(3)}E_t)]. \quad (5a)$$

[hereafter the $f(0)$ factor is omitted].

The refractive index modulation (grating amplitude) is determined by the difference between expression (5a) in the presence of the E_t field and expression (3) in the presence of the E_0 field, when $\chi^{(1)} = \chi_0^{(1)}$,

$$\Delta n = \frac{n_E^2 - n^2}{n_E + n}.$$

Assuming $n_E + n = 2n$, we get

$$\Delta n = \frac{2\pi}{n} [E_{sc}(\chi^{(2)} + \chi^{(3)}E_t) + \chi_E^{(1)} - \chi_0^{(1)}]. \quad (6)$$

This relation demonstrates that generally three effects contribute to the creation of the phase grating. The first and second effects (the first two terms) are the refractive index modulations due to the Pockels electro-optic effect (PEO) and the quadratic Kerr electro-optic effect (KEO)

$$\Delta n_1 = \Delta n_{PEO} + \Delta n_{KEO}, \quad (7)$$

where

$$\Delta n_{PEO} = \frac{2\pi}{n} \chi^{(2)} E_{sc},$$

$$\Delta n_{KEO} = \frac{2\pi}{n} \chi^{(3)} E_{sc} E_t.$$

According to the known formula⁶ of the electro-optic effect,

$$\Delta n_1 = \frac{n^3}{2} E_t(r + sE_t)$$

the linear Pockels electro-optical coefficient r is proportional to the susceptibility, $\chi^{(2)}$, while the quadratic Kerr electro-optical coefficient s is related to the $\chi^{(3)}$ susceptibility.

The other terms in formula (6)

$$\Delta n_2 = \frac{2\pi(\chi_E^{(1)} - \chi_0^{(1)})}{n}$$

are the refractive index modulations due to alignment of dipole chromophores along the E_t field. This effect is characteristic of plasticised layers only and is not observed in high- T_g polymeric

systems. Due to orientational birefringence, OB, the refractive index modulation is described as follows:^{10–13}

$$\Delta n_{OB} = \frac{2\pi}{n} (\chi_E^{(1)} - \chi_0^{(1)}) = \frac{2\pi}{n} N \Delta \alpha \left(\langle \cos^2 \varphi \rangle - \frac{1}{3} \right) \approx \quad (8)$$

$$\approx \frac{2\pi}{n} \frac{4Nf^2(0)f(\omega)}{45} \Delta \alpha(-\omega, \omega) \left(\frac{\mu_g E_t}{kT} \right)^2,$$

where $\Delta \alpha$ is the anisotropy of the linear polarisability

$$\Delta \alpha = \alpha_{||} - \alpha_{\perp},$$

and $\alpha_{||}$ and $\alpha_{\perp}$ are the molecular polarisabilities along and normal to the principal axis of a dipole chromophore, respectively.

For an isotropic medium, $\langle \cos^2 \varphi \rangle = 1/3$; therefore, the volume anisotropy of the linear polarisability vanishes [see formula (8)]. A two-level model of polarisation¹⁴ describes the anisotropy of polarisability, $\Delta \alpha(-\omega, \omega)$, by the relationship

$$\Delta \alpha(-\omega, \omega) = \Delta \alpha(0) \frac{E_{ge}^2}{E_{ge}^2 - (\hbar\omega)^2},$$

where $\Delta \alpha(0) = 2\mu_{ge}^2/E_{ge}$ and μ_{ge} and E_{ge} are the dipole moment and energy of transition from the ground state to the excited state, respectively. Since the OB is due to rotational diffusion of a dipole chromophore during the formation of the E_t field, the parameter Δn_{OB} significantly contributes to the refractive index modulation of those liquid crystals or plasticised polymers whose glass transition temperatures are low (close to room temperature).^{10, 12, 15} Creation of orientational grating was established in liquid-crystalline media^{16–18} and polymeric composites.¹⁰ Liquid crystals are characterised by the largest orientational refractive index modulation due to strong dielectric anisotropy.^{11, 13, 17–19}

The photorefractive effect in nonlinear optical materials is determined by the spatial modulation of the refractive index (see above).⁴

Creation of a grating in polymer layers of thickness d meeting the following criterion

$$Q = \frac{\pi d \lambda}{\Lambda^2 n} > 1,$$

(more preferable, $Q > 5$, see Ref. 12) is accompanied by self-diffraction of beams due to the Bragg scattering (reflection). Beam 1 is reflected towards beam 2, while beam 2 is reflected towards beam 1. For the measuring cell geometry shown in Fig. 2a the reflected beam 1 is in phase with beam 2. Beam mixing causes an increase in the intensity of the output beam 2 and a decrease in the intensity of the output beam 1 because the reflected beam 2 and beam 1 are out of phase.

The main formulae suitable for estimation of the PR parameters (e.g., the two-beam coupling gain Γ , phase shift of the grating, etc.), were obtained by solving the Kogelnik coupled-wave equations,²⁰ according to which a change in the amplitude (or $I^{0.5}$) of each beam along the z axis is proportional to the amplitude of the other beam and the refractive index modulation, Δn (see Refs 5, 20–23)

$$\frac{\partial(I_1)^{0.5}}{\partial z} = -\left(\frac{\pi \Delta n}{\lambda}\right) (I_2)^{0.5}, \quad (9)$$

$$\frac{\partial(I_2)^{0.5}}{\partial z} = -\left(\frac{\pi \Delta n}{\lambda}\right) (I_1)^{0.5}. \quad (10)$$

The most important relationships were obtained for the PR effect in inorganic crystals assuming that $\Delta n \sim E_{sc}$.^{5, 21, 22} Taking into account formulae (2) and (2a), in this case one can write^{5, 22–28}

$$\Delta n = \Delta n_{\max} \frac{2(I_1 I_2)^{0.5}}{I_1 + I_2} \cos\left(\frac{2\pi x}{\Lambda} - \psi\right).$$

Beam 2 reflected from the PR grating in the $\Delta n_{\max}$ region travels now in the same direction as does beam 1 (the angle of incidence equals the angle of reflection), i.e., towards positive x values (see Fig. 2b). Therefore Eqn (9) can be rewritten as follows:²²

$$\frac{\partial(I_1)^{0.5}}{\partial z} = -2\left(\frac{\pi \Delta n_{\max}}{\lambda}\right) \frac{(I_2)^{0.5} (I_1 I_2)^{0.5}}{I_1 + I_2} \cos\left(\frac{2\pi x}{\Lambda} - \psi\right). \quad (9a)$$

Simultaneously the reflected beam 1 propagates in the same direction as does beam 2 (towards negative x values). Then, formula (10) takes the form²²

$$\frac{\partial(I_2)^{0.5}}{\partial z} = -2\left(\frac{\pi \Delta n_{\max}}{\lambda}\right) \frac{(I_1)^{0.5} (I_1 I_2)^{0.5}}{I_1 + I_2} \cos\left(-\frac{2\pi x}{\Lambda} - \psi\right). \quad (10a)$$

In accord with the energy conservation law

$$I_1(0) + I_2(0) = \frac{I_1(z) + I_2(z)}{\exp(-\alpha z)} = \frac{I_1(L) + I_2(L)}{\exp(-\alpha L)}.$$

Here $I_1(z) \equiv I_1$ and $I_2(z) \equiv I_2$; $\alpha = 2.3A/d$ is the absorption coefficient (A is the optical absorption at the laser wavelength and d is the layer thickness); $I_1(0)$, $I_2(0)$ and $I_1(L)$, $I_2(L)$ are the intensities of the input and output beams, respectively; $L = d/\cos(\phi - \theta)$ is the optical path of beam 2 (see Fig. 2a). Let us denote $I_1(0) + I_2(0) = I_0$. To simplify the solutions, suppose that $\alpha = 0$; then, after replacing I_2 by $(I_0 - I_1)$ in Eqn (9a) we get

$$\frac{\partial(I_1)^{0.5}}{I_1^{0.5}(I_0 - I_1)} = -2 \frac{\pi \Delta n_{\max}}{\lambda I_0} \partial z \times \left[\cos\left(\frac{2\pi x}{\Lambda}\right) \cos \psi + \sin\left(\frac{2\pi x}{\Lambda}\right) \sin \psi \right]. \quad (11)$$

Analogous substitution into Eqn (10a) for beam 2 ($I_1 = I_0 - I_2$) gives

$$\frac{\partial(I_2)^{0.5}}{I_2^{0.5}(I_0 - I_2)} = -2 \frac{\pi \Delta n_{\max}}{\lambda I_0} \partial z \times \left[\cos\left(\frac{2\pi x}{\Lambda}\right) \cos \psi - \sin\left(\frac{2\pi x}{\Lambda}\right) \sin \psi \right]. \quad (11a)$$

Relationships (11) and (11a) thus obtained are unsymmetric, namely, the second terms on the right-hand sides of the equations (they are responsible for energy transfer from beam 1 to beam 2) have opposite signs (negative sign for beam 1 and positive sign for beam 2).²² The energy transfer coefficient, or the two-beam coupling gain, can be found by subtracting relationship (11) from Eqn (11a). After integration of this difference at a particular x value (e.g., at $x = \Lambda/4$), one gets⁵

$$\ln \frac{I_2(L)\beta}{I_1(L)} = \Gamma L, \quad (12)$$

where $\beta = I_1(0)/I_2(0)$,

$$\Gamma = \frac{4\pi \Delta n_{\max} \sin \psi}{\lambda}. \quad (12a)$$

From Eqn (12) it follows that

$$I_1(L) = I_2(L)\beta e^{-\Gamma L}.$$

Hence

$$I_1(L) + I_2(L) = I_2(L)\beta e^{-\Gamma L} + I_2(L) = I_2(L)(1 + \beta e^{-\Gamma L}).$$

At the same time, in accord with the energy conservation law one has

$$I_2(L) + I_1(L) = [I_2(0) + I_1(0)]e^{-\alpha L} = I_2(0)(1 + \beta)e^{-\alpha L},$$

i.e.,

$$I_2(L)(1 + \beta e^{-\Gamma L}) = I_2(0)(1 + \beta)e^{-\alpha L}$$

or

$$\frac{I_2(L)}{I_2(0)} = \frac{(1 + \beta)e^{-\alpha L}}{1 + \beta e^{-\Gamma L}}. \quad (13)$$

Formula (13) serves for estimation of the amplification of the information beam 2 at different β , Γ and α . Experimental estimation of the gain involves measurements of the beam coupling ratio (γ_0)

$$\gamma_0 = \frac{I_2(L)_t}{I_2(L)_{t=0}}. \quad (14)$$

Here the $I_2(L)_t$ value (beam 1 is on) is determined by relationship (13). If beam 1 is switched off [$I_1(0) = 0$ and $\beta = 0$], one gets $I_2(L)_{t=0} = I_2(0)\exp(-\alpha L)$. Thus, the formula (14) for the beam coupling ratio takes the form

$$\gamma_0 = \frac{1 + \beta}{1 + \beta \exp(-\Gamma L)}.$$

From here the two-beam coupling gain, Γ , can be calculated using the formula

$$\Gamma L = \ln \frac{\gamma_0 \beta}{1 + \beta - \gamma_0}. \quad (15)$$

The γ_0 value is estimated from that portion of the kinetic curve, which corresponds to saturation of the beam coupling ratio.

Thus, a shift of the phase grating in space relative to the constructive interference fringes provides amplification of beam 2 due to attenuation of beam 1. As the polarity of the applied voltage (i.e., the E_0 sign) changes (see Fig. 2a), photogenerated mobile holes migrate in the opposite direction relative to that shown in Fig. 2b and the grating is shifted by a phase of ψ towards positive x values

$$\Delta n = \Delta n_{\max} \left[\frac{2(I_1 I_2)^{0.5}}{I_1 + I_2} \right] \cos \left(\frac{2\pi x}{A} + \psi \right).$$

In this case beam 1 is amplified, while beam 2 becomes the pump beam. The beam directed from the fringe to the grating is amplified (see Fig. 2a).

As will be shown below, polymeric composites containing nanocrystalline J-aggregates of cyanine dyes (dipole molecules aligned to form the 'head-to-tail' chains) occupy a special position among photorefractive polymeric materials. Figure 3 presents the kinetic curves for two-beam coupling measured for aromatic polyimide (API) containing J-aggregates of thiacyanine dyes (Dye 1 and Dye 2, respectively).^{29, 30}

Measurements were carried out at $\beta = I_1(0)/I_2(0) = 1$. The experimental design was as follows. The first experiment involved measurements of the beam 1 intensity. First, beam 1 was switched on. At $t = 0$, the E_0 field was applied to the sample and then beam 2 was switched on (upward arrow). This resulted in a decrease in the beam 1 intensity (curve 1). The intensities of the output beam 1 with beam 2 off and on are denoted as $I_1(L)_{t=0}$ and $I_1(L)_t$, respectively. After the curve reached saturation, beam 2 was switched off (downward arrow) and, as can be seen, the initial beam 1 intensity, $I_1(L)_{t=0}$, was restored. Then the same operations were repeated for beam 2. First, beam 2 was switched on and then the E_0 field was applied, the $I_2(L)_{t=0}$ value was measured and beam 1 was switched on. This led to an increase

Figure 3. Kinetic curves for two-beam coupling in a polymeric composite [API containing J-aggregates of Dye 1 (a) and Dye 2 (b)].^{29, 30} Experimental conditions: an Ar-Kr laser (647 nm), $I_1(0) = I_2(0) = 0.03 \text{ W cm}^{-2}$, $E_0 = 16 \text{ V } \mu\text{m}^{-1}$. Changes in the beam 1 intensity upon switching beam 2 on (upward arrow) and off (downward arrow) (1) and changes in the beam 2 intensity upon switching beam 1 on (upward arrow) and off (downward arrow) (2).

in the beam 2 intensity, $I_2(L)_t$ (curve 2). After switching beam 1 off the intensity of beam 2 took its initial value $I_2(L)_t = 0$. The $I_2(L)_t/I_2(L)_{t=0}$ ratio is the beam coupling ratio, γ_0 , at saturation [see Eqn (14)]. As the refractive index modulation is created, the intensity of beam 1 (pump beam) decreases, while the intensity of beam 2 (signal beam) increases to nearly the same extent (see Fig. 3). This unambiguously points to writing of a phase grating, which is shifted in space relative to the fringe pattern (see Fig. 2b).

The most important characteristics of the PR effect are the two-beam coupling gain, Γ (more rigorously, the net internal gain, $\Gamma - \alpha$), $\Delta n_{\max}$, the diffraction efficiency, η , and the response time, τ , of the polymeric composite to the two-beam coupling. The last-mentioned parameter is 3 s for the API/Dye 1 composite (see Fig. 3a) and less than 20 ms (the temporal resolution of the experimental setup) for the API/Dye 2 composite (see Fig. 3b).

The diffraction efficiency (in %) is defined by the following relation:²¹

$$\eta = 100 \sin^2 \left(\frac{\pi \Delta n_{\max} d}{\lambda \cos \theta} \right). \quad (16)$$

Experiments on determination of the diffraction efficiency involve the use of two writing beams to create a grating which is read out with the third beam (readout beam of intensity I_3) propagating parallel to beam 1 (or 2). Beam 3 diffracts towards beam 2 (or 1) with an intensity of I_{01} . The diffraction efficiency is determined as follows:

$$\eta = 100 \frac{I_{01}}{I_{01} + I'_3},$$

where I'_3 is the intensity of the non-distorted readout beam passed through the photorefractive layer under diffraction. A salient feature of the PR media is the possibility of fast writing dynamical holograms with $\eta \approx 100\%$ (the writing time is of the order of several milliseconds).^{31–34} It should be noted that the diffraction efficiency contains no information on the phase shift of the grating relative to the fringe pattern. Below we will consider creation of a grating with a zero phase shift in the system exhibiting both photoelectric and nonlinear optical properties.³⁴ Therefore, only analysis of the kinetic curves for two-beam coupling with amplification of one beam at the attenuation of the other beam (see Fig. 3) provides an unambiguous proof of the PR effect.

III. The figure of merit of nonlinear optical chromophores

Choosing a chromophore involves estimation of its Figure of Merit (FOM), which characterises the ability of the chromophore to generate the PR effect.^{15,35–41} Criteria for choosing chromophores with high FOM have been reviewed.¹⁵ Photorefraction in inorganic crystals is primarily due to the Pockels electro-optic effect; therefore, in this case one deals with the FOM_{PEO} .⁴ As to the polymeric media, the Δn_{PEO} and Δn_{KEO} and Δn_{OB} parameters can contribute largely to the refractive index modulation. In the case of non-plasticised high- T_g polymeric systems containing low-molecular-mass chromophores with small FOM_{KEO} after alignment of the chromophores in the field E_p the refractive index modulation Δn is due to the Pockels electro-optic effect only and here we have to deal with

$$\text{FOM}_{\text{PEO}} = \frac{\beta \mu_g}{M},$$

where M is the molecular mass. Generally, various polarisation mechanisms of nonlinear optical chromophores^{35–40} contribute to the refractive index modulation

$$[\text{FOM}] = \text{FOM}_{\text{OB}} + \text{FOM}_{\text{PEO}} + \text{FOM}_{\text{KEO}}.$$

Combining different contributions of the polarisation to the overall FOM requires the appearance of some constants in

addition to the corresponding molecular characteristics; therefore, the FOM in the case of low-molecular-mass chromophores (FOM_{KEO} is negligible) is given by the following relationship^{15,16,39,40}

$$[\text{FOM}] = \frac{1}{M} \left[2\Delta\alpha(0) \frac{\mu_g^2}{kT} + 9\mu_g \beta(0) \right].$$

The figure of merit depends on the degree of charge transfer δ in the nonlinear optical chromophore.^{35–41} Indeed, the molecule of such a chromophore incorporates an electron-donor (D) and an electron-acceptor (A) group linked by a system of conjugated bonds, $\text{D}^{+\delta} - \text{Sp} - \text{A}^{-\delta}$ (Sp is a spacer). The structural formulae of some of the most widely used chromophores are presented below. The degree of charge transfer is determined by the contributions of two resonance structures, without $(\text{D} - \text{Sp} - \text{A})$ and with full charge transfer $(\text{D}^{+1} - \text{Sp} - \text{A}^{-1})$, to the ground state⁴²

$$\text{D}^{+\delta} - \text{Sp} - \text{A}^{-\delta} = a(\text{D} - \text{Sp} - \text{A}) + b(\text{D}^{+1} - \text{Sp} - \text{A}^{-1}), \quad (17)$$

where

$$\delta = \frac{b^2}{a^2 + b^2} = c^2.$$

When choosing an optimum chromophore, one should study how the contributions of various FOMs depend on the mixing parameter (c^2 parameter, MIX) of these two structures.^{38,40,41} As parameter is also given the bond length alternation in the conjugated molecule^{35,43–46} (namely, the difference, Δr , between the average lengths, r , of the single and double carbon-carbon bonds, which in turn depends on the degree of charge transfer in the chromophore). The orientational polarisability is positive at any Δr value. According to Marder *et al.*,⁴⁴ the bond lengths in polyenes ($c^2 = 0$) are as follows: $r(\text{C} - \text{C}) = 1.45$, $r(\text{C} = \text{C}) = 1.34$ and $\Delta r = 0.11$ Å. Introduction of the D and A groups causes an increase in c^2 and a decrease in the Δr value; in this case β and the third-order molecular polarisability (γ) are positive. At $c^2 = 0.5$, the bond lengths equilibrate ($\Delta r = 0$); i.e., the molecular structures become symmetric (the so-called cyanine limit). At this degree of charge transfer, $\beta = 0$ while γ reaches its maximum negative value. On going to zwitterionic structures at $c^2 > 0.5$ the Δr and β values become negative. As a consequence, the Δn_{OB} and Δn_{PEO} parameters of this type of chromophore have opposite signs.

Photoexcitation of a chromophore containing the D and A groups causes a change in the degree of charge transfer from δ to $1 - \delta$ due to electron transfer (see Ref. 42)

Here $h\nu = E_{\text{ge}}$. The ground-state and excited-state dipole moments of the chromophore are respectively

$$\mu_g = e\delta r_{\text{DA}},$$

$$\mu_e = e(1 - \delta)r_{\text{DA}},$$

where e is the charge of an electron and r_{DA} is the distance between the D and A groups. Thus, the difference

$$\Delta\mu = \mu_e - \mu_g$$

approaches μ_e at $\delta \approx 0$, decreases down to zero for centrosymmetric chromophores ($\delta = 0.5$) and becomes negative at $\delta > 0.5$.

Numerous studies on the 'guest-host' photorefractive polymeric systems containing dipole chromophores have been reported.^{4,12} As mentioned above, alignment of chromophores in the bulk of high- T_g polymers requires the prepoling in a constant field E_p at a temperature T_p , which is 2 to 20 °C higher than T_g .⁴¹ On subsequent cooling of the system below T_g in the presence of the polarising field E_p the chromophore alignment is 'frozen'.

It should be noted that, depending on the properties of the polymer matrix, ‘unfreezing’ of rotational diffusion can occur at temperatures much below T_g . For instance, the intensity of the second laser harmonic generated in a poly(methyl methacrylate) (PMMA) layer doped with poly(ethylene oxide) and nonlinear optical chromophore 4-anilino-4'-nitroazobenzene (DO-3 dye) substantially increases after heating of the system at 52–57 °C and reaches the same values as those obtained after heating at temperatures above T_g (92–95 °C).⁴⁷ This effect is due to an increase in the volume expansion coefficient of the polymer blend in the temperature range 52–57 °C.⁴⁸

After alignment of the oligomeric chromophores in the E_p field the refractive index modulation is due to the Pockels and Kerr electro-optic effects. If we go to the molecular polarisabilities, formula (7) takes the form⁴¹

$$\Delta n_1 = \Delta n_{PEO} + \Delta n_{KEO} = \frac{2\pi}{n} \frac{N f^2(0) f(\omega) E_{sc}}{5} \left[\beta(-\omega, \omega, 0) \frac{\mu_g E_p}{k T_p} + \gamma(-\omega, \omega, 0, 0) E_0 \right], \quad (18)$$

where

$$\beta(-\omega, \omega, 0) = \beta(0) \frac{E_{ge}^2 [3E_{ge}^2 - (h\omega)^2]}{3[E_{ge}^2 - (h\omega)^2]^2},$$

$\omega = 2\pi/\lambda$, λ is the laser wavelength at which the PR effect is measured and $\beta(0)$ is the static contribution to the second-order molecular polarisability extrapolated to $h\omega = 0$.^{7, 16–19} The two-level polarisation model¹⁴ defines the molecular polarisabilities as follows:

$$\beta(0) = \frac{6\mu_{ge}^2 \Delta\mu}{E_{ge}^2}, \quad (19)$$

$$\gamma(0) = \frac{24(\Delta\mu^2 - \mu_{ge}^2)\mu_{ge}^2}{E_{ge}^3} + \frac{24\mu_{ge}^2 \mu_{ce'}^2}{E_{ge'} E_{ge}^2},$$

where $\Delta\mu = \mu_e - \mu_g$, $\mu_{ce'}$ is the dipole moment of the transition from the first to the second excited level and $E_{ge'}$ is the energy of transition from the ground state to the second excited state.^{43–46, 49}

Taking into account the net FOM, formula (18) can be written as follows:

$$\Delta n_1 = \Delta n_{PEO} + \Delta n_{KEO} = \frac{2\pi}{n} \frac{N f^2(0) f(\omega) E_p}{5k T_p} [\text{FOM}],$$

where

$$[\text{FOM}] = \text{FOM}_{PEO} + \text{FOM}_{KEO} = \mu_g \beta(0) + \frac{E_0 k T_p}{E_p} \gamma(0), \quad (20)$$

where $E_0 k T_p / E_p$ is a constant.

At room temperature, anisotropic chromophores in low- T_g polymers are in the mobile state and can be aligned during measurements of the PR effect in the E_t field, which changes both its direction and amplitude (see Fig. 2b). In this case a doubled FOM_{PEO} value is introduced into Eqn (20) (see Refs 35, 40, 41, 45)

$$[\text{FOM}] = \text{FOM}_{PEO} + \text{FOM}_{KEO} = 2\mu_g \beta(0) + k T \gamma(0). \quad (20a)$$

As mentioned above, the refractive index modulation arises in the low- T_g polymeric composites due to the linear orientation polarisation of a dipole chromophore in the E_t field. Therefore, the expression for the net refractive index modulation must contain an additional term Δn_{OB} [see formula (8)]

$$\Delta n = \Delta n_{OB} + \Delta n_{PEO} + \Delta n_{KEO} = \frac{4\pi}{n} \frac{N f^2(0) f(\omega) E_t^2}{45k T} [\text{FOM}], \quad (21)$$

where

$$[\text{FOM}] = \text{FOM}_{OB} + \text{FOM}_{PEO} + \text{FOM}_{KEO},$$

$$\text{FOM}_{OB} = \frac{\Delta\alpha(0)\mu_g^2}{k T}.$$

Since the net modulation, Δn , is quadratically dependent on E_t , it was assumed^{15, 16, 39, 40} that creation of a grating in low- T_g composites is due to the Kerr electro-optic effect only. By substituting Eqn (20a) into relationship (21) we get

$$[\text{FOM}] = \text{FOM}_{OB} + \text{FOM}_{PEO} + \text{FOM}_{KEO} = \Delta\alpha(0) \frac{\mu_g^2}{k T} + 9\mu_g \beta(0) + \frac{9}{2} k T \gamma(0). \quad (21a)$$

This expression is, as a rule, used when comparing the contributions of various polarisation mechanisms to the amplitude of the refractive index modulation.⁴¹

To prepare photorefractive polymeric systems, chromophores possessing the maximum net FOM are chosen. The parameters in formula (21a) are determined from ellipsometric measurements, by analysing the optical and electro-optical absorption spectra in solution^{15, 16, 39–41} and from quantum-chemical calculations.^{35–38, 43–46}

1. Photorefractive polymeric systems with low glass transition temperatures

The FOM values of typical chromophores used in studies of the PR effect are listed in Table 1. When choosing nonlinear optical chromophores for photorefractive composites based on both low- and high- T_g polymers, these data allow estimation of the relative contributions of various polarisation mechanisms to the creation of a phase grating using formulae (20) and (21a). As can be seen, for all chromophores

$$\text{FOM}_{OB} \gg \text{FOM}_{PEO} + \text{FOM}_{KEO},$$

i.e., low- T_g polymers must have a much higher refractive index modulation and, hence, PR-characteristics than the samples with high T_g .

Analysis of the data listed in Table 1 also reveals that if chromophores incorporated into high- T_g polymers (in this case $[\text{FOM}] = \text{FOM}_{PEO} + \text{FOM}_{KEO}$) are preliminarily aligned in the E_p field at $T_p \gg T_g$, the Pockels electro-optic effect makes major contribution to the creation of a grating. Otherwise the phase grating amplitude in high- T_g polymeric systems is determined only by the Kerr electro-optical coefficient whose contribution to the net FOM allows one to assume that the PR-characteristics, e.g., Γ [see formula (12)] should be much lower than the corresponding characteristics obtained for polymer composites with low T_g .

Since 1994 (see Ref. 10), the vast majority of photorefractive materials were synthesised using polymers with glass transition temperatures close to room temperature. Most of them are based on plasticised poly(vinylcarbazole) (PVCz),^{12, 19, 31–33, 50–54} carbazoyl-substituted polysiloxanes (PSX-Cz)^{55–57} and polyethers.^{58, 59} In such polymeric media the major contribution to the creation of a phase grating comes from the linear orientation polarisation. Under these conditions, the diffraction efficiency buildup rate is determined by rotational diffusion of the chromophore and is described as follows:^{60, 61}

$$\eta(t) \sim \sin^2 \left[A_1 \left(1 - e^{-D_1 t} \right) + A_2 \left(1 - e^{-D_2 t} \right) \right],$$

where

$$A_1 + A_2 = \frac{\pi}{2},$$

and D_1 and D_2 are coefficients: $D_n = n(n+1)D$ at $n = 1$ and 2 ; and D is the rate constant for rotational diffusion.

^a FOM_{PFO} = $9\mu_g\beta(0)$, FOM_{KFO} = $9kT\gamma(0)/2$ and FOM_{OB} = $\Delta\alpha(0)\mu_g^2/kT$ [see formula (21a)]. ^b Obtained from quantum-chemical calculations.

The determining role of plasticiser was demonstrated taking composites prepared from carbazolyl-substituted polysiloxane, 2,4,7-trinitro-9-fluorenone (TNF) and indole derivatives (chromophores) as examples. The major contribution (97%) to the net FOM of this system comes from the FOM_{OB}.⁵⁷ In the absence of plasticiser this composite has $T_g = 34^\circ\text{C}$ and the net internal gain ($\Gamma - \alpha$) is close to 2 cm^{-1} . Doping with a small amount of plasticiser (ethylcarbazole, ECz) causes lowering of the T_g value down to 23°C and an increase in ($\Gamma - \alpha$) to 25 cm^{-1} (see Ref. 57). The steady-state value of the net internal gain is achieved about 1 s after the start of two-beam coupling, which is believed to correspond to the reorientation time of nonlinear optical chromophores in the E_t field. It was also pointed out⁶² that nonlinear optical chromophores form aggregates, which cannot be oriented in the applied field E_0 ; as a consequence, the PR effect is weakened. For this reason, the side butyl groups are introduced into the chromophore molecule (see Table 1, compound 8) to preclude dimerisation.

2. Photorefractive polymeric systems with high glass transition temperatures

The data for compound 2 (see Table 1) show that an increase in the number of conjugated bonds from 1 to 5 causes a respective increase in the FOM_{PFO} and FOM_{KFO} values by a factor of 19.6 and 42. The third-order molecular polarisability of acetylene oligomers with the number of conjugated bonds varying from $n = 1$ to 31 increases with an increase in the length of the conjugated system as follows:^{49, 63–65}

$$\gamma(0) = \gamma_1(0)n^{2.5 \pm 0.2}. \quad (22)$$

J-Aggregates of cyanine dyes are known to have a very high third-order susceptibility.^{66–69} The corresponding dependence

$$\chi^{(3)} \sim n^{2.36},$$

coincides with relationship (22) within the limits of experimental error. The third-order volume susceptibility, $\chi^{(3)}$, of J-aggregates of dyes can be as high as nearly $2.7 \times 10^{-13}\text{ C m J}^{-3}$ (in SI units).⁶⁶ This value is due to co-operative electronic excitation of molecules and delocalisation of the excitation along the whole length of the J-aggregate, which comprises n conjugated bonds.^{66–69} Orientational diffusion of dipole chromophores in high- T_g polymers is restricted; therefore, after application of the field E_t the major contribution to the refractive index modulation [see Eqns (21) and (21a)] should be expected only from the third-

order electronic polarisation. It is the use of J-aggregates of cyanine dyes as nonlinear optical chromophores that allowed the obtention of high PR-characteristics of composites based on aromatic polyimide with $T_g \approx 230^\circ\text{C}$,^{29, 30} which are comparable with the corresponding parameters of plasticised composites based on PVCz.

Poly(diacetylenes)^{49, 70–72} and polyenes of various structures⁷³ are also characterised by rather high $\chi^{(3)}$ values; however, they are several orders of magnitude lower than those of J-aggregates.

IV. Interrelation between the photorefractive effect and the photoelectric and electron transport properties

Depending on the composition of a system, the PR-characteristics can be related in a different manner to the rate of charge photo-generation, charge carrier mobility or to the rate of rotational diffusion of a nonlinear optical chromophore in the field E_t . When creating dynamical holograms, it is essential to achieve a short response time of the polymer layer to the two-beam coupling. Therefore, it seems likely that polymeric systems with electronic polarisation rather than orientational effects, which are limited to rotational diffusion of the chromophore in the matrix, should be more promising in this case.

Note that the ionisation potential of the chromophore (I_D) influences the high two-beam coupling gain coefficients and diffraction efficiency more strongly than the nonlinear optical characteristics responsible for the FOM values.^{33, 74} This was established taking composites prepared from PVCz containing the donor carbazolyl groups (Cz), acceptor (2,4,7-trinitro-9-fluorenylidene)malonodinitrile (TNFDM) and the chromophores **14–16** as examples.

The donor–acceptor complex PVCz·TNFDM is responsible for the photoelectric sensitivity of these composites. The ionisation potentials of the carbazolyl group, Cz, and chromophores **14–16**, their FOM values, and the most important PR-characteristics of the composites are listed in Table 2. The refractive index modulation $\Delta n_{\max}$ was estimated from the η values measured in the presence of chromophores **14–16** using formula (16), which was modified to include the sample geometry and had the form^{33, 74}

$$\eta = \sin^2(586 \Delta n_{\max}).$$

The product $\Delta n_{\max} \sin \psi$ was calculated using the measured two-beam coupling gain coefficients Γ and formulae (15) and (12a). Therefore, by comparing η and Γ it is possible to determine the phase shift ψ (see Table 2), which decreases in the series of the chromophores **14–16**. Analysis of the measured η values showed that the $\Delta n_{\max}$ values increase by a factor of 1.6 and 2.2 if the chromophore **14** is replaced by **15** and the chromophore **15** is replaced by **16**, respectively. Taking into account the fact that these replacements cause a much smaller increase in the FOM value (by a factor of 1.06 and 1.2, respectively), it was concluded that the $\Delta n_{\max}$ value is primarily determined by the space-charge field E_{sc} rather than FOM (the larger the ionisation potential difference between the carbazolyl group and the nonlinear optical chromophore, the stronger the E_{sc} field). It was hypothesised^{33, 74, 75} that the increase in E_{sc} is due to an increase in the quantum yield of holes, which can be related to the hole jump to chromophore (Ch) during the reactions

Hole jump to chromophore by reaction (23a) precludes its disappearance *via* recombination of the radical ion pair following reaction (23), thus increasing the quantum yield of holes. The molecules of acceptor, TNFDM, act as deep electron traps; therefore they persist in the region of bright fringes. When present in low concentrations, chromophores act as hole traps; however, at high concentrations (28.5% of the composite mass) they serve as charge transport agents^{33, 74, 75}

Table 2. Ionisation potentials and FOM values for chromophores **14–16** and the most important characteristics of polymeric photorefractive composites based on PVCz,^a TNFDM and chromophores **14–16** at 60 V μm^{-1} (see Refs 33 and 74).

Chromophore	I_D / eV	FOM (rel.u.)	Composite characteristics		
			η (%)	Γ / cm^{-1}	ψ / deg
14	5.59	1.0	25	70	37
15	5.46	1.06	40	88	29
16	5.40	1.27	85	167	25

^a The ionisation potential of the carbazolyl group is 5.90 eV.

The photoconductivity and the quantum yield of mobile holes in the composite prepared from PVCz, sensitiser (TNFDM), plasticiser (ECz) and a nonlinear optical chromophore were shown⁷⁵ to increase by nearly an order of magnitude upon replacement of TNFDM by C₆₀ fullerene. This is due to the corresponding decrease in the probability of recombination of charge carriers by reaction (23).

The larger the difference

$$\Delta I_D = I_D(\text{Cz}) - I_D(\text{Ch}),$$

the higher the probability that efficient deep hole traps will be formed.^{33, 74, 75} Therefore, a decrease in $I_D(\text{Ch})$ causes shortening of the hole path length and a corresponding decrease in the phase shift ψ (see Table 2). The limiting case, *viz.*, a decrease in phase ψ down to zero was found for a composite prepared from PVCz, TNF (acceptor) and nonlinear optical chromophore 2-(4-nitro-phenyl)-4,5-bis(4-methoxyphenyl)imidazole (Lophine-1, 33 mass %) (see Ref. 34). The effect is due to the fact that, similarly to an electron, a hole trapped by the chromophore by reaction (23a) remains immobile in the region of bright fringes and, hence, no PR effect occurs. The formation of a Lophine-1⁺...TNF^{−•} radical ion pair is accompanied by the appearance of the corresponding band in the optical absorption spectrum and changes the layer composition, thus causing creation of the amplitude and phase gratings with zero phase shift ($\psi = 0$), similarly to conventional photochemical writing of a hologram.

In poly(methyl methacrylate) with carbazolyl-containing side groups and the chromophores **17–19**,

the T_g value was changed by introduction of different amounts of liquid-crystalline plasticiser 4-C₇H₁₅C₆H₄C(O)OC₆H₄CN-4. It was found that the larger the $T_e - T_g$ difference (T_e is the temperature of the experiment), the higher the photoconductivity and the phase shift ψ . It was concluded that raising the temperature causes an increase in the hole path length (until trapping by deep traps), which in turn leads to an increase in ψ . If at a constant temperature of the experiment ($T_e = 21^\circ\text{C}$) the $(T_e - T_g)$ difference increased due to a decrease in T_g caused by an increase in the concentration of plasticiser, Γ increased more slowly than η .⁷⁶ This is due to a decrease in the phase shift ψ as a result of reduction of the mobility of charge carriers on dilution of carbazolyl transport groups with neutral plasticiser molecules. Experiments with a composite prepared from PVCz, TNF and the nonlinear optical chromophore *N,N*-diethyl-*p*-nitroaniline (EPNA) and doped with 4-(diethylamino)benzaldehyde diphenylhydrazone (DEH) showed that the phase shift depends on the dopant concentration in a complex manner. The ionisation potential of DEH is somewhat lower than that of PVCz.⁷⁷ Comparison of the Γ and η values obtained at 633 nm revealed that $\psi = 32^\circ$ for the undoped material, decreases to 8° upon doping with about 2×10^{-3} mass % of DEH and down to nearly zero at 2 mass % of DEH but then increases and reaches a value of 45° at a DEH

concentration of 20 mass %. The effect is due to the fact that photogenerated holes, which did not undergo recombination by reaction (23), migrate from one carbazolyl group of PVCz to another by the hopping mechanism

When present in low concentrations, the DEH molecules act as traps of mobile holes

and thus restrict the free path of charge carriers. However, as the DEH content increases to ~ 8 mass % and the average distance between neighbouring molecules is correspondingly shortened, they provide hole transportation by the hopping mechanism

In a composite prepared from PVCz, TNF and the nonlinear chromophore 1-(2'-ethylhexyloxy)-2,5-dimethyl-4-(4''-nitrophenylazo)benzene the chromophore molecules also play the role of hole traps at low concentrations but become responsible for hole transportation in the PR layers if the chromophore concentration reaches 47.5 mass %. Under these conditions the hole mobility ($2 \times 10^{-6} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$) remains unchanged upon replacement of the PVCz matrix by the dielectric polycarbonate matrix.⁷⁸

The grating buildup speed can be related to the quantum yield of charge carriers (φ) and to the time it takes for a charge carrier (t_{tr}) to travel the distance $\Lambda/2\cos\phi$ as follows:

$$\frac{\partial E_{sc}}{\partial t} \sim \frac{\partial N_h}{\partial t} = \frac{\varphi I_0 (1 - 10^{-A}) \lambda^2 \cos\theta}{A h c} - \frac{N_h}{t_{tr}}, \quad (24)$$

where $\Lambda/2\cos\phi$ is the distance from the bright fringe to the midpoint between the interference-maximum regions along the direction of the E_0 field (see Fig. 2a); N_h is the concentration of the photogenerated holes determining the photocurrent j_{ph} ; I_0 is the laser light intensity; $(1 - 10^{-A})$ is the fraction of light energy absorbed within the layer (A is the optical absorption); and hc/λ is the light quantum energy. Formula (24) was derived assuming $\psi = \pi/2$; i.e., the hole distribution in Fig. 2b is centred at the midpoint between the bright fringes.

In the API-based composites containing J-aggregates of carbocyanine dyes the free carrier generation rate determines the kinetic characteristics of photorefraction, as demonstrated by analogy between the kinetic curves for the growth of photocurrent (Fig. 4) and the kinetic curves for two-beam coupling (see Fig. 3).^{29, 30, 79, 80} The curve for the growth of photocurrent measured for the API/Dye 1 composite (see Fig. 4a) is described by a biexponential dependence

$$\frac{j_{ph} + j_d}{j_d} = 14 - 7 \exp\left(-\frac{t}{3}\right) - 6 \exp\left(-\frac{t}{45}\right)$$

with the time constants $\tau = 3$ and 45 s. In the case of two-beam coupling (see Fig. 3a) the intensity $I_2(L)$, increases synchronously with the fast component of photocurrent

$$\frac{I_2(L)_t}{I_2(L)_{t=0}} = 1 + 0.125 \left[1 - \exp\left(-\frac{t}{3}\right) \right]$$

(time constant $\tau = 3$ s). The diffraction efficiency also increases with the time constant $\tau = 3$ s. Thus, in these composites the rate of hole accumulation, $\partial N_h/\partial t$, determines the time constant for the growth of the intensity $I_2(L)_t$. This is additionally confirmed by the correspondence between the rapid increase in the gain coefficient $I_2(L)_t/I_2(L)_{t=0}$ for the API/Dye 2 composite, for which $\tau < 20$ ms (see Fig. 3b), and the equally rapid appearance of a steady-state photocurrent as the laser is switched on (see Fig. 4b). In this case the speed of writing of the grating can be limited by the mobility of charge carriers μ . The available data on the mobility of charge carriers in composites of close compositions show that

Figure 4. Changes in the $(j_{ph} + j_d)/j_d$ ratio (j_d is the dark current) for the API/Dye 1 (a) and API/Dye 2 (b) composites upon switching an Ar–Kr-laser beam (647 nm, $I_0 = 0.06 \text{ W cm}^{-2}$) on (upward arrow) and off (downward arrow).^{79, 80}

$\mu \approx 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ (see Refs 81 and 82); this allows one to conclude that the time a charge carrier takes to travel a distance $\Lambda/2\cos\phi$ ($\Lambda = 1653 \text{ nm}$) is

$$t_{tr} = \frac{\Lambda}{2E_0\mu\cos\phi}. \quad (25)$$

At $E_0 = 16 \text{ V } \mu\text{m}^{-1}$, the time t_{tr} is $\sim 6 \times 10^{-6} \text{ s}$, which is much shorter than the response time ($\tau = 3 \text{ s}$) to the two-beam coupling (see Fig. 3a).

It should be noted that if the photocurrent is measured under conditions corresponding to attainment of the steady-state value $(j_{ph} + j_d)/j_d$, i.e., when $\partial N_h/\partial t = 0$ in Eqn (24), deep traps are filled and the lifetime of the photogenerated charge carriers is not trap-limited. Since the photoconductivity is related to the photocurrent as follows

$$\sigma_{ph} = \frac{j_{ph}}{E_0} = N_h e \mu,$$

at $\partial N_h/\partial t = 0$ formula (24) can be rewritten so that it allows estimation of the quantum yield of mobile charge carriers (photo-generation efficiency)

$$\varphi = \frac{j_{ph} h c}{e \lambda I_0 (1 - 10^{-A})}. \quad (26)$$

The efficiency of photogeneration of transportation centres, measured using the field dependence of the photocurrent, coincided with the efficiency estimated using the xerographic discharge curves. In the latter case no negative electrode was available and φ was determined from the rate of discharge of the surface potential, V_0 , which appeared upon deposition of negatively charged CO_3^- ions formed in the corona discharge in air near the surface of the layer on the free surface of the polymer

layer. The parameter $(dV/dt)|_{V_0}$ was estimated at different V_0 values from the difference

$$\left. \frac{dV}{dt} \right|_{V_0} = \left. \frac{dV}{dt} \right|_{V_0(\text{light})} - \left. \frac{dV}{dt} \right|_{V_0(\text{dark})},$$

where $(dV/dt)|_{V_0(\text{light})}$ and $(dV/dt)|_{V_0(\text{dark})}$ are the initial fall-off rates of the surface potential upon switching on the light and in the dark, respectively. In contrast to the method involving measurements of the field dependence of the photocurrent (the steady-state photocurrent value is attained after full occupation of deep traps, see above), xerography allows measurements of φ with empty traps. The quantum yield of charge carriers is proportional to the initial potential drop $(dV/dt)|_{V_0}$

$$\varphi(V) = \frac{\varepsilon \varepsilon_0 h c}{e \lambda I_0 (1 - 10^{-4}) d} \left. \frac{dV}{dt} \right|_{V_0}. \quad (26a)$$

The $j_{\text{ph}}(E_0)$ dependence measured in the API/Dye 1 composites has the form^{79,80}

$$j_{\text{ph}} = a (E_0)^{3.5}, \quad (27)$$

where a is a constant. In accordance with this relationship the photoconductivity,

$$\sigma_{\text{ph}} = \frac{j_{\text{ph}}}{E_0},$$

and the photoelectric sensitivity (photoconductivity per unit of light intensity),

$$S = \frac{\sigma_{\text{ph}}}{I_0},$$

depend on the field E_0

$$\sigma_{\text{ph}} = a(E_0)^{2.5},$$

$$S = \frac{a(E_0)^{2.5}}{I_0}.$$

The field dependence of the quantum yield of mobile charge carriers [see Eqn (26)] is also described by a power function

$$\varphi = b \varphi_0 (E_0)^{3.5}. \quad (28)$$

Here b is a constant and φ_0 is the quantum yield of the bound, isolated and thermalised electron–hole pairs with the initial electron–hole distance r_0 . To estimate the φ_0 and r_0 values, the probability that the electron–hole pair escapes recombination was calculated using the Onsager equations for Brownian motion of charges in the field E_0 with inclusion of the Coulombic attraction. Since the experimental field dependence of φ is linear in the $\varphi - (E_0)^{3.5}$ coordinates, a method for solving the Onsager equations expanded of up to the $(E_0)^4$ term⁸³ was employed.

Figure 5a presents the quantum yield, φ , of mobile charge carriers plotted vs. the applied field E_0 determined from the photocurrent for the API/Dye 1 composite. The curve calculated using the Onsager equation at $\varphi_0 = 0.2$ and $r_0 = 12 \text{ \AA}$ fits well the experimental points. As can be seen in Fig. 5b, the experimental φ values estimated both from the photocurrent [see Eqn (26)] and xerographically [see Eqn (26a)] virtually coincide. This is due to the fact that for both experimental methods trapping by deep traps imposes no limitations on the lifetime of photogenerated charge carriers, since, as mentioned above, in the former case they are fully occupied while in the latter they are empty and the measurement time is shorter than the trapping time of the charge carriers. It should be noted that Melz⁸⁴ related the parameter r_0 to the exponent, m , in the formula

$$\varphi = b \varphi_0 (E_0)^m$$

Figure 5. Quantum yield (φ) vs. E_0 plot for the API/Dye 1 composite: overall curve (a) and its initial portion (b).^{79,80}

(a) φ values were estimated from photocurrent using formula (26) (points); (b) φ values were estimated from the photocurrent using formula (26) (1) and from xerographic curves using formula (26a) (2); solid lines were obtained from calculations using the Onsager formula with $\varphi_0 = 0.2$ and $r_0 = 12 \text{ \AA}$.

at $\varepsilon = 3$ and $T = 23 \text{ }^\circ\text{C}$ using the Onsager theory. He also found that if the distance between charge carriers is $\sim 12\text{--}13 \text{ \AA}$, $m = 3.5$. Thus, the r_0 value obtained^{79,80} with this m coincides with the calculated value.

Detailed analysis of the studies on charge photogeneration and transport in polymeric systems can be found in some monographs (see, e.g., Refs 85 and 86).

The linear dependence φ on the applied field was obtained for the polysiloxane PR layers bearing side carbazolyl groups (PSCz) and doped with trinitrofluorenone and the chromophores FDEANST or DTNBI.⁸⁷ The hole mobility in these layers is nearly $2 \times 10^{-7} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at $E_0 = 16 \text{ V } \mu\text{m}^{-1}$. Estimation using formula (25) showed that the time taken to travel the distance $\lambda/(2\cos\phi)$ is $1\text{--}2 \text{ ms}$, which is nearly 100 times shorter than the experimentally determined time constant for the growth of the signal beam intensity.⁸⁸ It seems likely that in this polymeric system the rate of photogeneration charge also determines the speed of writing of the grating.

The mobility of charge carriers in the PR composites comprised of a polystyrene matrix, the nonlinear optical chromophore 2,2-dimethyl-4-(4-nitrophenylazo)phenol and various low-molecular-mass transport dopants is reduced by more than two orders of magnitude as the dipole moment of the dopant molecules increases from 1 to 4 D.⁸⁸ The highest mobility ($4 \times 10^{-6} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$) at $16 \text{ V } \mu\text{m}^{-1}$ was obtained for hole transport with 1,1-bis(di-4-tolylaminophenyl)cyclohexane while the lowest one ($2 \times 10^{-8} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$) was obtained for electron transport along the 1,1'-dioxo-2-(4-methylphenyl)-6-phenyl-4-(dicyanomethylidene)thiopyran molecules. Such a change in the mobility corresponds to extension of the t_{tr} time from 1 to 200 ms; in the latter case the speed of writing of the grating can be limited

by transport of charge carriers. To identify the stage responsible for the speed of writing, the kinetic curves of the growth of the diffraction efficiency in the PVCz/TNF/DMNPAA system doped with high concentration of plasticiser (ethylcarbazole, $T_g = 10^\circ\text{C}$) were measured under different writing conditions.⁸⁹ The efficiency $\eta = 0.85\eta_{\text{max}}$ was observed after 73.2 s if both beams were switched on and then the E_0 field was switched on and after 2.18–5.54 s if the E_0 field was switched on 30 min before switching on both beams. Such a shortening of the response time was associated with the fact that chromophores pre-oriented in the E_0 field are only slightly reoriented as E_{sc} increases and that this reorientation occurs much faster than reorientation from the disordered state.

The dependence $j_{\text{ph}} \sim E_0^m$ corresponding to the Onsager theory is masked in the presence of ionic components. Indeed, in contrast to the systems considered above experiments with poly(phenylenevinylene) containing sensitisers, tri(bipyridyl)ruthenium complexes $\text{Ru}(\text{bipy})_3^{2+}(\text{PF}_6^-)_2$, and fragments with nonlinear optical chromophores ($T_g = 16^\circ\text{C}$) in the main chain the photocurrent initially increases with increasing E_0 but substantially slows down at $E_0 > 40 \text{ V } \mu\text{m}^{-1}$.⁹⁰ In this E_0 range the two-beam coupling gain coefficient and the diffraction efficiency reach saturation and become equal to $\Gamma = 25 \text{ cm}^{-1}$ and $\eta = 0.5\%$, respectively. This was explained by peculiar features of reorientation of the $\text{Ru}(\text{bipy})_3^{2+}(\text{PF}_6^-)_2$ dipole in the E_t field. As E_t increases, the PF_6^- anion changes its position relative to the cation and the direction of the dipole moment of this ion group changes. The dipole induces an internal local electric field. The stronger the E_0 field, the better the dipole alignment along the E_t direction and the stronger the internal local field. The local field is directed oppositely to the E_t field; therefore, the growth of the effective field E_t' responsible for the creation of a grating is restricted.⁹⁰

V. The gain coefficient and diffraction efficiency in photorefractive polymeric systems

The most important characteristics of recently developed photorefractive polymeric systems are listed in Table 3. The two-beam coupling gain coefficients of these composites were measured both at equal beam intensities [$\beta = I_1(0)/I_2(0) = 1$, see formula (15)] and at $\beta > 1$ to avoid 'depletion' of the pump beam.

Taking the PVCz/TNF-composites containing the chromophores *N,N*-diethyl-*p*-nitroaniline or 4-(hexyloxy)nitrobenzene as examples, it was shown⁹¹ that the two-beam coupling gain coefficient in the PR layers is independent of β and close to 10 or 3 cm^{-1} , respectively, in the range of β variation from 0.8 to 81. A very weak dependence of Γ on β (Γ increases from 5 to 10 cm^{-1} as β increases from 1 to ~ 500) was found for inorganic crystals.⁵

Currently, PR-materials with low glass transition temperatures (*i.e.*, close to room temperature or below it) have been the subject of intensive research and development. The T_g values were lowered by introducing plasticisers. In such composites the grating is created due to the orientation polarisation of chromophores in the E_t field.^{10, 12, 31–33, 52, 56, 62, 73, 74, 76, 87, 92–105} The composites listed in Table 3 (except for the composite No. 14 with triphenylamino transport groups incorporated into the main chain¹⁰⁰) include polymers such as PVCz, polysiloxanes or polyacrylates with the carbazolyl transport groups in the side chains. In these systems phototransfer of an electron by reaction (23) is followed by hole hopping from bright fringes to the dark regions in the E_0 field (see Fig. 2*b*). Fullerene C_{60} and a charge transfer complex between the donor carbazolyl group of the polymer and the acceptors, TNF or its derivative TNFDM, are used as sensitisers. The composites sensitised with C_{60} fullerene are characterised by high quantum yields of charge carriers, since the recombination stage of reaction (23) is impeded due to the long distance between the charges owing to electron delocalisation over the bulky C_{60} molecule.¹⁰³ A feature of the composite No. 12 is the possibility of simultaneously writing the PR-grating and a

local photochemical grating.⁹⁹ The creation of the latter is due to energy transfer from the triply excited fullerene to the nonlinear optical chromophore, which occurs simultaneously with the process (23). The excited chromophore enters into the [2+2]-cycloaddition reaction with the non-excited chromophore, thus creating a photochemical phase grating which is not shifted in phase relative to the bright fringes. Simultaneous creation of two gratings was also found in the composite comprised of neutral PMMA, DEH and a nonlinear optical chromophore (DO-3 dye).¹⁰⁴ Laser-induced photoexcitation of the dye at 514 nm is followed by phototransfer of an electron, its trapping by the acceptor group of the dye (NO_2^-), generation of a mobile hole (DEH^+)

thus causing the appearance of photocurrent and the refractive index modulation.

The γ_0 value at an external field strength of $8 \text{ V } \mu\text{m}^{-1}$ is 1.065. The PR effect is masked by the effect of a reversible increase in the intensities of both beams by 12%. The latter effect is due to *trans*–*cis*-photoisomerisation of the DO-3, which is accompanied by a nearly seven-fold decrease in the absorption coefficient.¹⁰⁵

A single-component photorefractive polymer layer was obtained by photochemical modification (PM) of poly(hydroxy-aminoether), PHAE (see Table 3, compound No. 22).^{106–109} The layers comprised of PHAE with donor amino groups (AM) incorporated into the main chain and the CBr_4 acceptor groups were photochemically modified. The amino group and CBr_4 form photosensitive charge-transfer complexes characterised by optical absorption in the region 330–500 nm. Exposure to light in this spectral region results in the formation of chromophores of the Michler hydrol (MHB^+) type due to phototransfer of charge.

Here R is the hydroxyether fragment responsible for the adhesive and other properties.

After removal of CBr_4 from the layer by heating, the exposed areas of the polymer layer consisted of the PHAE with the modified main chain containing conjugated MHB^+Br^- fragments that absorb light in the region 560–700 nm and are responsible for the photoelectric sensitivity of PM PHAE¹¹⁰ and for the second-order nonlinear optical properties.¹¹¹ When writing a PR-grating using two beams of an Ar–Kr laser ($\lambda = 647 \text{ nm}$), photoexcitation of MHB^+Br^- in the region of bright fringes is followed by phototransfer

which is accompanied by trapping of electrons (MHB^+Br^-) and the formation of mobile holes

which migrate in the E_0 field and are trapped in the dark regions, thus forming the space-charge field E_{sc} .

Note. BBP is butyl benzyl phthalate; PDCST is 4-piperidinodicyanostyrene-malononitrile; BDMNPAB is 1-*n*-butoxy-2,5-dimethyl-4-(4'-nitrophenylazo)benzene; DHADC-MPN is 2-*N,N*-dihexylamino-7-dicyanomethylidenyl-3,4,5,6,10-pentahydronaphthalene; DCST is dicyanostyrene; APSS is 4-[*N*-(2-hydroxyethyl)-*N*-methylamino]-4'-(6-hydroxyhexylsulfonyl)stilbene; TCP is tricresyl phosphate; AODCST is aminodicyanostyrene; Lemke-e is (3-{2-[4-(*N,N*-diethylamino)phenyl]vinyl}-5,5-dimethylcyclohex-2-enylidene)malonodinitrile; MHADC-MPN is *N,N*-methylhexylamino-7-dicyanomethylidenyl-3,4,5,6,10-pentahydronaphthalene; DB-IP-DC is 3-{(E)-2-dibutylaminovinyl}-5,5-dimethylcyclohex-2-enylidene)malononitrile; CPA is a copolymer of carbazoyl acrylate and 1-(acryloxyethoxy)-2,5-dimethyl-4-(nitrophenylazo)benzene;

The PM PHAE layers generate the second harmonic at 532 nm under the action of pulses of a Nd–YAG laser ($\lambda = 1064$ nm).¹¹¹ This is due to the fact that in Ch^+X^- compounds the outer anion X^- causes a displacement of the electron density in the cationic fragment.⁴³ The dipole moment thus induced interacts with the E_0 field. This interaction is responsible for the appearance of a predominant orientation of the dipole moments of the MHB^+ cations in the bulk of the polymer layer, and, hence, for the volume susceptibility $\chi^{(2)}$. The second- and third-order volume susceptibilities provide the refractive index modulation

$$\Delta n_1 = \Delta n_{\text{PEO}} + \Delta n_{\text{KEO}} = \frac{2\pi E_{\text{sc}}(\chi^{(2)} + \chi^{(3)} E_{\text{t}})}{n}.$$

The MHB^+ cation can exhibit orientational polarisability despite the fact that this nonlinear optical chromophore is incorporated into the polymer chain of PM PHAE and its diffusive motion is restricted. The polarisability is due to the interaction between the cation and the mobile Br^- anion, which is displaced relative to the cation during the formation of the E_{t} field and changes the direction of the induced dipole moment of the MHB^+ cation, thus contributing of Δn_{OB} to the refractive index modulation.

A peculiarity of PM PHAE is that the transport centres and the photogeneration and nonlinear optical fragments formed upon exposure are embedded into the main chain. This substantially decreases the probability of the formation of dimers, which are deep hole traps. Besides, as mentioned above, compensation of dipole moments in the case of dimerisation of low-molecular-mass chromophores reduces the orientational polarisability.⁶²

Table 3 lists the most important characteristics of a photorefractive polymeric material (API containing nanocrystalline J-aggregates of carbocyanine dyes) with a high glass transition temperature ($T_{\text{g}} = 230$ °C). J-Aggregates form a centrosymmetric structure in the polymer matrix. As mentioned above, this structure is characterised by a very high third-order susceptibility,⁶⁶ so the refractive index modulation is governed by the contribution of the Kerr electro-optic effect, Δn_{KEO} [see Eqn (7)]. Therefore, in contrast to most polymer composites listed in Table 3, in this case there is no need for pre-poling of J-aggregates in the electric field or use of viscous low- T_{g} polymers. As can be seen in Table 3, the PR-polymeric material with J-aggregates has a large two-beam coupling gain coefficient, the net internal gain having a record value of 361 cm^{-1} .

VI. Practical applications of polymeric photorefractive materials

Organic (in particular, polymeric) materials have long been thought as inefficient, unstable and insufficiently pure for electronic and photonic applications. Because of this the emphasis was placed on inorganic crystalline and amorphous semiconductors and dielectrics. However, considerable advances in the synthesis of and research on new organic compounds achieved during the last two decades have introduced radical changes in the situation. Suffice it to say that currently nearly 90% of photoreceptors for copiers, laser printers and digital presses are made of organic polymeric materials. What is more, novel polymers, organic compounds and materials based on them possessing photoelectric and optical properties are considered as rather promising for use in electroluminescent devices, solar energy converters, etc.

Such characteristics of photorefractive polymeric materials as high photoelectric sensitivity, beam coupling ratio, refractive index modulation, diffraction efficiency and short (millisecond range) hologram writing times, as well as the possibility of repeated real-time hologram writing/erasure cycles make these materials promising for photonic applications. In particular, dynamical holograms can be written with a diffraction efficiency

of nearly 100% and erased by illuminating the PR-layer in the absorption band of a photogenerator. Some other applications include, e.g., a unique image amplification effect, a laser-based method for detection of ultrasonic oscillations of various media⁹³ and a method for storage of digital information by one- and two-photon excitation of a photorefractive polymeric material.¹¹² It is of interest to consider the prospects for use of these materials in everyday life, which go beyond the scope of the photonics area, in more detail.

Protection of documents and goods from forgery and counterfeit is a topical problem. Current holographic techniques are no longer a solution to this problem, since holograms can be readily copied. Peyghambarian *et al.*¹¹³ proposed a photorefractive method for security verification of objects of various nature, which is based on the ability of photorefractive polymeric materials to write dynamical holograms. A transparent phase mask of size 5×5 mm and thickness $1\text{--}2 \mu\text{m}$ is placed on an object to be verified. The mask is an array of a rather large number of pixels, the pixel size being of the order of several tens of micrometres. Such pixels are photolithographically or in another manner formed in an initial mask material in a specified order or randomly and differ from the latter in refractive index value. Using a simple optical laser correlator, the mask with a secret code is compared with the reference mask encoded exactly in the same way as the test mask. The main element of such a device is the photorefractive polymer layer (for the layer composition, see Table 3, No. 1). First, a photorefractive hologram of the test phase mask is written on the polymer by the interference of the pump beam and the signal beam and serves as a holographic filter. Then the laser beam transmitted through the reference mask passes through the polymer layer from the opposite side. This beam undergoes diffraction towards the pump beam. If the images of the reference mask and the test mask in the photorefractive polymer layer match each other, the intensity of the diffracted beam increases dramatically. The advantages of this system are low cost, nearly full protection from copying information recorded on the mask, real-time operation (response time is about 1 s), confident verification (even if 90% of information recorded on the mask is erased) and the possibility of using a small-size semiconductor laser diode for writing dynamic holograms.

Energy transfer between interfering beams in photorefractive polymer layers is used for image amplification in video-rate optical processing applications.⁹² Using a conventional optical scheme with the pump and the signal beams interfering in a photorefractive polymer layer (beam intensity ratio $\beta = 2000$ at a signal beam intensity of 0.5 mW cm^{-2}), a net increase in image intensity by a factor of 37 was observed within a video frame at a $E_0 = 77 \text{ V } \mu\text{m}^{-1}$ field applied to the layer. The frame exposure time is determined by the time taken to reach the maximum net intensity gain during creation of a phase hologram in the PR layer (the layer composition is listed in Table 3, No. 11) and is 33 ms, which nearly coincides with the frame illumination time when watching a movie. As the polarity of the external field applied to the photorefractive polymer layer changes, energy is transferred from the signal beam to the pump beam. As a consequence, only moving objects can be visualised using the image-bearing laser beam. Indeed, by imaging static objects a hologram is created in the photorefractive layer and the signal beam energy is transferred to the pump beam, thus diminishing the image. If objects move faster than the photorefractive response time, the hologram has no time to be created, so no energy transfer from the signal beam occurs and the moving object can be clearly seen on a screen. Clearly, by varying the hologram writing speed in the PR layer it is possible to change the speed threshold necessary for visualisation of moving objects.

A photorefractive method of medical diagnosis has been proposed.⁹⁶ It is known that biological tissues strongly scatter radiation over the whole optical region and at the same time are transparent in the near-IR region (700 to 900 nm). Hence, tissue diagnosis requires separation of the scattered radiation from the

unscattered radiation carrying useful information about absorption centres in the medium. In addition, the material for writing dynamic holograms must be near-IR sensitive. This problem can be solved using a photorefractive polymeric material (for the composition, see Table 3, No. 6). The technique employs a time delay of the scattered radiation with respect to the unscattered radiation in the signal beam due to extension of the optical path in the scattering medium. The source of IR radiation was either a pulsed femtosecond Ti:sapphire laser ($\lambda = 830$ nm) or a semiconductor laser diode capable of generating a continuous-wave (cw) low-coherence beam. The hologram is formed only when the unscattered radiation of the signal beam overlaps with the pump beam. When using a pulsed laser, the delayed scattered radiation reaches the PR layer after the pump beam pulse; when using a cw laser, coherent portions of the unscattered beam and the pump beam interfere, while the delayed scattered radiation reaches the PR layer simultaneously with the non-coherent radiation of the signal beam. In both cases the hologram is formed only when the signal and the pump beams overlap within the coherence length of a laser source. The hologram can be reconstructed using the probe laser beam counterpropagating with the pump beam and a conventional optical scheme.

In all the systems considered above, low- T_g photorefractive polymers were used. In addition to their advantages (see above) photorefractive polymeric systems have a fundamental drawback, which precludes wide industrial applications of such materials and consists in a relatively short lifetime of stable photorefractive parameters (about six months at room temperature even when encapsulated and protected from moisture).^{11,3} This is due to crystallisation of chromophore and phase separation within the layer. A possible solution to this problem is to work with high- T_g polymeric systems. This is of course associated with loss of alignment of the dipole chromophores in the modulated space-charge field responsible for additional increase in Δn . Therefore, search for new polymeric systems with high nonlinear susceptibilities is required. A promising avenue of investigations is the incorporation of chromophores with high third-order susceptibility into photorefractive polymeric systems. For instance, J-aggregates of carbocyanine dyes have been used.^{29, 30, 80} As mentioned above, during the synthesis of a PR material J-aggregates form a centrosymmetric structure, which has a very high third-order susceptibility $\chi^{(3)}$. Hence there is no need for alignment of J-aggregates in the electric field, which is necessary if one operates with photorefractive polymers possessing linear orientational polarisability and second-order nonlinearity. The refractive index modulation, Δn , is determined by the Kerr electro-optic effect and is proportional to $E_1^2 \chi^{(3)}$; hence, there is no need to use low- T_g polymers.

Besides, the electronic nature of optical nonlinearity allows one to expect a substantial shortening of the writing time of dynamical holograms, which in this case is not related to the orientational motion of bulky chromophores. It should also be noted that, depending on their structure, carbocyanine dyes absorb in the whole visible region and in the near IR region. J-Aggregates of carbocyanine dyes are nanocrystalline particles, which absorb the electromagnetic radiation at wavelengths that are 100–300 nm longer than the absorption wavelengths of the corresponding monomeric dye molecules. Thus, in principle the long-wavelength limit of the sensitivity of photorefractive polymeric materials can be estimated at 1550 nm. The fact that optical fibre communication operates at this wavelength significantly extends the range of practical applications of such materials. Oligomeric triacetylene and diacetylene compounds characterised by high third-order susceptibility (see above) can also be used as chromophores.

This review has been written with the financial support of the International Scientific and Technological Centre (Grant 2207) and the Russian Foundation for Basic Research (Project No. 02-03-33052).

Abstract. Published data on the synthesis and reactivity of halogen-containing chromones, flavones, thiochromones and furochromones are generalised. The bibliography includes 220 references.

I. Introduction

Chromone (4*H*-chromen-4-one, 4*H*-1-benzopyran-4-one, **1a**) is a parent compound for an important class of oxygen-containing heterocyclic compounds with a benzoannulated γ -pyrone ring. This heterocyclic system is frequently encountered in the vegetable world, most often as flavone (2-phenylchromone, **1b**), flavonol (3-hydroxy-2-phenylchromone, **1c**) and isoflavone (3-phenylchromone, **1d**) derivatives, which form the group of flavonoids — flower and fruit pigments.¹ These compounds exhibit various types of biological activities² and find use as substrates in the preparation of many pharmaceuticals including some antitumour drugs.³ Alkylchromones are less naturally abundant; nevertheless, some of them are also known to be biologically active. For example, of therapeutic interest are 3-methyl- and 2,5,8-trimethylchromones.² The natural furochromones khellin (**2a**) and visnagin (**2b**) are the active substances of the plant *Ammi visnaga* L., known for its therapeutic properties since antiquity.^{4,5}

$R^1 = R^2 = H$ (**a**);
 $R^1 = H, R^2 = Ph$ (**b**);
 $R^1 = OH, R^2 = Ph$ (**c**);
 $R^1 = Ph, R^2 = H$ (**d**).

$R = MeO$ (**a**), H (**b**).

Among halogen derivatives of chromone **1a**, compounds acting as stimulators for the central nervous system^{6,7} and exhibiting high antiviral,⁸ antimicrobial,^{9,10} antimycotic,^{9,10} anti-allergic^{11–13} and neuroleptic¹⁴ activities have been found. The enhanced interest in the chromone chemistry is indicated by publication of a series of reviews^{15–18} and monographs.² However, halogenated chromone derivatives (halochromones and haloalkylchromones) are the subjects of only one chapter in the book² published in 1977. In recent years, a fairly large number of studies dealing with the chemistry of halochromones containing halogen atoms attached directly to the carbon atoms of the chromone system and haloalkylchromones in which halogen atoms occur in the side chains have been reported. However these data have not yet been reviewed or analysed. This review is meant to fill this gap. Here we consider chromones **3–5**, where R^1 , R^2 are any substituents containing no halogen atoms.

$X = Hal, CH_2Hal, COCH_2Hal.$

$X = Hal, R^F, CCl_3, CH_2Hal.$

$X = Hal, CH_2Hal.$

Derivatives **5**, containing a halogen or a halomethyl group in the benzene ring, differ little in methods of synthesis and reactivity from the appropriate halogenated benzene derivatives and are of secondary importance for the chromone chemistry, which is mainly determined by the γ -pyrone ring having two electrophilic centres, the C(2) and C(4) atoms. Therefore, attention will be focused on halo- and haloalkylchromones **3** and **4**, containing a halogen-containing substituent in the γ -pyrone ring. The presence in the ring of a halogen atom, which is a good leaving group, or a 2-polyhaloalkyl group, which increases the electrophilicity of the C(2) atom, extends appreciably the synthetic potential of chromones and makes them valuable substrates for the synthesis of new heterocyclic compounds with a broad range of useful properties.

To complete the picture, the review covers the most important publications of the 1960s–1970s not included in the monograph² and also the sparse data available on halo-containing thiochromones and furochromones. The methods of synthesis and chemical properties of chromones with the perfluorinated benzene ring have been covered in a number of reviews;^{2,18,19} therefore, we do not consider them here. The reactions of heteroanalogues of

isoflavones containing a trifluoromethyl group at the 2-position with alkalis, hydrazines, amidines and hydroxylamine have been described in a review published previously.¹⁵

II. Methods for the synthesis of halochromones

The most convenient methods for the formation of the chromone system include the Claisen condensation of 2-hydroxyacetophenones with esters,²⁰ the Baker–Venkataraman rearrangement of *O*-acyl derivatives of 2-hydroxyacetophenones²¹ and the Kostanecki–Robinson method, consisting of the reaction of the same ketones with carboxylic acid anhydrides.¹⁴ This gives rise to compounds that exist either in the open β -diketone form or in the cyclic 2-hydroxychromanone form, depending on the conditions and the nature of the substituents. Upon dehydration in an acid medium, they yield the corresponding chromones. The introduction of halogen atoms into the pyrone and benzene rings and into the side chains can be performed both during the synthesis of chromones (by using halo-containing ketones and esters) and by treatment of chromones or their precursors (β -diketones) with halogenating agents.

1. Synthesis of 2-halochromones

2-Halochromones represent a group of halo-derivatives of chromone difficult to access, as the introduction of the halogen atom into the 2-position of the chromone system is usually a more complicated synthetic task than halogenation of the benzene ring activated by electron-donating groups.

The first representatives of chromones containing a halogen atom at the 2-position [2-chloro- (**6a**) and 6-methyl-2-chlorochromones (**6b**)] were prepared in 1960 from β,β -dichloroacrolein and the corresponding phenols.²² The key step of the synthesis is the Fries rearrangement of aryl dichloroacrylate on treatment with AlCl_3 at 130 °C followed by cyclisation of *o*-hydroxyketones in an alkaline medium to give 2-chlorochromones **6**.

R = H (**a**), Me (**b**).

Subsequently, α,β,β -trichloro- and α -bromo- β,β -dichloroacroleins^{23,24} and also α,β,β -trichloro- and α,β -dichloroacryloyl chlorides²⁵ have been involved in this reaction. The intra- and intermolecular acylation of phenols with these reagents resulted in the synthesis of 2- and 3-halo- and 2,3-dihalochromones. For example, 2,3-dichloro-7-methoxy- or 3-chloro-7-methoxychromones were prepared from 1,3-dimethoxybenzene and α,β,β -trichloro- or α,β -dichloroacryloyl chloride.²⁵

Other methods for the introduction of a halogen atom into the 2-position are also known. The presence of the 3-hydroxy group facilitates the electrophilic attack on the C(2) atom; as a result, bromination of 3-hydroxychromone affords 2-bromo-3-hydroxychromone in a good yield,² while its nitration furnishes 3-hydroxy-2-nitrochromone. By treatment with acetyl halides, the latter product can be converted into 2-chloro- and 2-bromo-3-acetoxychromones (**7**).²⁶ The reactions of chromane-3,4-dione 3-oximes and thiochromane-3,4-dione 3-oximes with hydrogen halides yield 3-amino-2-chloro- and 3-amino-2-bromochromones and -thiochromones (**8**).²⁷

It is noteworthy that all the known methods for the synthesis of 2-halochromones proposed 30–40 years ago were based on initial compounds difficult to prepare and in most cases, the methods were not generally applicable. In recent years, no significant progress in the development of new approaches to the preparation of these compounds has been made either. Only in one study,²⁸ was the Fries rearrangement used to prepare 2-chloro-6-methylchromone,²² which was then introduced in reactions with α -amino ketones and α -aminoacetals (see Section III.1).

2. Synthesis of 3-halochromones

Due to the vigorous development of transition metal-catalysed cross-coupling reactions giving C–C bonds, which open up the way to complex natural molecules, the interest in the synthesis of 3-halochromones has been enhanced and they have become available compounds. 3-Halochromones can be prepared by halogenation of either chromones or their precursors, *i.e.*, β -diketones and β -aminovinyl ketones containing 2-hydroxyaryl substituents at the carbonyl group (in most cases, the latter route is preferred).

The reaction of chromones with halogens or some halogenating reagents usually starts with the halogen addition to the double bond of the pyrone ring, which is followed by dehydrohalogenation (either spontaneous or base-induced), resulting in the target 3-halochromones. For instance, the reaction of chromone **1a** with bromine in CCl_4 gives 2,3-dibromochroman-4-one, which is readily converted into 3-bromochromone (**9**).²⁹ Chromanone reacts with bromine in CHCl_3 to give 3,3-dibromochromanone; however, this product could not be converted into chromone **9** in a plausible yield.³⁰

Treatment of chromone **1a** with sulfonyl chloride with cooling gives rise to 2,3-dichlorochroman-4-one, which is smoothly converted into 3-chlorochromone (**10a**) on treatment with triethylamine.³¹ Interestingly, chromones **1a** and **10a** react with thionyl chloride to give 4,4-dichloro- (**11a**) and 3,4,4-trichloro-4*H*-chromenes (**11b**), whose reaction with 4-nitroaniline affords the corresponding *N*-(4*H*-chromen-4-ylidene)anilines (**12a, b**), the first representatives of the chromeneimine series.³¹

X = H (**1a**, **11a**, **12a**), Cl (**10a**, **11b**, **12b**).

The reaction of 6-nitrochromone with a potent electrophilic brominating agent, in particular, the dibromoisocyanuric acid–sulfuric acid system, results in the formation of 3,8-dibromo-6-nitrochromone, whereas chromone **1a** gives only 6-bromochromone under similar conditions due to protonation of the pyrone ring. With a greater amount of dibromoisocyanuric acid, the transformation of chromone **1a** yielded 5,6,8-tribromo- and 3,5,6,8-tetrabromochromones.³²

Treatment of chromone-3-carbaldehyde (**13a**) or chromone-3-carboxylic acid (**13b**) with sodium hypochlorite in acetic acid gives 3-chlorochromone **10a** with a 2-acetoxy-3,3-dichlorochroman-4-one impurity.

R = CHO (**13a**), CO₂H (**13b**).

Under similar conditions, 3-formylchromones substituted in the benzene ring form the corresponding 3-chlorochromones in 43%–82% yields.^{33, 34}

The transformation of 3-acetylchromone (**13c**) and chromone-3-carbonitrile (**13d**) under the same conditions gives 2-acetoxy-3-acetyl- (**14a**) and 2-acetoxy-3-cyano-3-chlorochroman-4-ones (**14b**). On treatment with HCl, the acetyl derivative **14a** furnishes chromone **10a**, while nitrile **14b** is converted into 2-amino-3-chlorochromone (**15**) in aqueous acetic acid in the presence of AcONa. In this case, the reaction is accompanied by opening of the pyrone ring followed by cyclisation involving the cyano group.³⁴

R = COMe (**13c**, **14a**), CN (**13d**, **14b**).

Chromone-3-carbaldehyde (**13a**) reacts with sodium hypobromite in the light to give a mixture of three products where 2,2,3',5'-tetrabromo-2'-hydroxyacetophenone (**16**) is the major

product (30%), while the expected 3-bromochromone **9** is formed in a low yield (8%). The researchers believe³⁴ that tetrabromoacetophenone results from radical opening of the pyrone ring, because the same reaction carried out in the dark gave only bromo-derivatives **9** and **17** in 32% and 29% yields, respectively (Scheme 1). The reaction mechanism includes the addition of acetyl hypobromite and subsequent elimination of the formyl group under the action of a base. The elimination of molecule AcOH from intermediate **A** affords chromone **9**, while its bromination leads to chromanone **17**.

Scheme 1

B is base.

The reduction of 3,4-dichlorocoumarins, prepared by treatment of phenols with perchloropropylene in the presence of aluminium chloride,³⁵ with lithium tri(*tert*-butoxy)aluminium hydride produces lactols, which are easily transformed into 3-chlorochromones **10a–c** when heated in acetic acid in the presence of catalytic amounts of H₂SO₄.^{36, 37}

R = H (**a**), Me (**b**), Cl (**c**).

When chromone **1a** is subjected to oxidative chlorination (*m*-chloroperbenzoic acid, HCl, DMF, ~20 °C), 3-chlorochromone **10a** is formed in 96% yield.³⁸ This method is suitable for introducing chlorine into the α-position of both cyclic and acyclic α,β-enones.

Electrolysis of chromone (**1a**) and 2-methylchromone (**1e**) in a methanol–water mixture (4:1) containing potassium halide yields 3-halo-2-methoxychroman-4-ones **18**, which are unstable during storage. On treatment with K₂CO₃ in methanol, they pass almost quantitatively into the corresponding 3-chloro- (**10a**, **19a**) and 3-bromochromones (**9**, **19b**).³⁹

$\text{R} = \text{H, Me; X} = \text{Cl, Br}$.

The most general protocol used to prepare 3-halochromones (which also appears most attractive from the preparative standpoint) is halogenation of β -aminovinyl ketones containing a 2-hydroxyaryl group at the carbonyl carbon atom.⁴⁰ To prepare 3-halochromones containing no substituents at the 2-position, 2-hydroxyacetophenones are condensed with excess dimethylformamide dimethyl acetal. The 1-(2-hydroxyaryl)-3-dimethylaminoprop-2-en-1-ones thus formed are halogenated with *tert*-butyl hypochlorite, bromine or iodine in CHCl_3 ⁴⁰ or with *N*-fluoro-2,4,6-trimethylpyridinium triflate in a $\text{CH}_2\text{Cl}_2 - \text{MeCN}$ mixture.¹⁴

$\text{R} = \text{H, Me, Cl, MeO; X} = \text{F, Cl, Br, I}$.

When electrophiles with good leaving groups such as iodine chloride or trifluoro- and trichloroacetic anhydrides are used in the reaction with aminovinyl ketones, 3-chloro- and 3-trihaloacetylchromones are formed.⁴¹ The use of expensive dimethylformamide dimethyl acetal can be avoided by preparing aminovinyl ketones in two steps *via* chromone-3-carbaldehydes,⁴² which are readily deformylated by opening the heterocycle under the action of piperidine.⁴³

$\text{R} = \text{H, Me, Cl}$.

The reaction of 5,8-dimethoxy-2-methylchromone with piperidine in boiling methanol yields aminovinyl ketone **20**, which reacts with bromine in CHCl_3 being converted into 3-bromo-5,8-dimethoxy-2-methylchromone.⁴⁰

This reaction was used as an example to demonstrate that halogenation of enamines of 2-hydroxyacetophenones can be employed to obtain 2-substituted 3-halochromones.

3-Bromo-2-methylchromone (**19b**) was prepared in a relatively low yield, as a mixture with 2-methylchromone (**1e**) from β -diketone **21** under similar conditions (treatment with bromine in CHCl_3).⁴⁴ The outcome of this reaction proved to be substantially dependent on the nature of the solvent in which bromination took place. Indeed, when chloroform was replaced by ethanol, the yield of chromone **19b** increased to 90%, while the reaction performed in acetic acid in the presence of excess bromine led to 3-bromo-2-dibromomethylchromone.⁴⁵

In the reaction of 2-methylchromone (**1e**) with bromine in AcOH , chromone **19b** is formed in a low yield (25%).² Upon an attempt to prepare compound **19b** from 2-methylchromone (**1e**) and *N*-bromosuccinimide in CCl_4 , as described in an earlier publication,⁴⁶ three products were isolated, namely, chromone **19b**, 2-(bromomethyl)chromone and 3,6,8-tribromo-2-methylchromone.⁴⁷

NBS is *N*-bromosuccinimide.

In the case of 6-methyl- and 6-methoxy-2-methylchromones, the reaction proceeds more unambiguously giving rise to 6-substituted 3-bromo-2-methylchromones (yields 90%–92%), together with small amounts of 2-(bromomethyl)chromones (5%–8%).⁴⁷ The reaction of 6-hydroxy-2-methylchromone with bromine in concentrated H_2SO_4 (25°C , 6 h) gives 5-bromo-6-hydroxy-2-methylchromone (yield 73%). In acetic acid ($45 - 50^\circ\text{C}$, 8 h) and in the presence of excess bromine, 3,5-dibromo-6-hydroxy-2-methylchromone is formed (yield 53%).⁴⁸

Ziegler bromination of 2-methylthiochromone gives 3-bromo-2-methylthiochromone, which is oxidised at sulfur on treatment with H_2O_2 to yield 3-bromo-2-methylthiochromone 1,1-dioxide.⁴⁹

Treatment of 6-substituted 2-methylchromone and chromone-2-carbaldehyde with an aqueous solution of sodium hypochlorite in the presence of AcOH gives the corresponding 3-chlorochromones[†] in 61%–93% yield.⁵⁰ *N*-Trichloroacetyl- and *N*-ethoxycarbonyl-2-aminochromones are selectively chlorinated at the C(3) atom on treatment with SO_2Cl_2 in CHCl_3 at $\sim 20^\circ\text{C}$.⁵¹ In the I_2 – HIO_4 system, *N*-ethoxycarbonyl-2-aminochromone affords the 3-iodo-derivative in a yield of 78%.⁵²

Refluxing a solution of ethyl chromone-2-carboxylate in sulfuryl chloride in the presence of benzoyl peroxide for 10 h gives a mixture consisting of approximately equal amounts of mono- (**22**) and di-chloro (**23**, **24**) derivatives.⁵³ Chromanone **24**, which is a product of free radical addition of chlorine at the double bond, easily loses an HCl molecule on treatment with pyridine, being thus converted into 3-chloro derivative **22**.

Under similar conditions, methyl chromone-2-carboxylate yields only methyl 3-chlorochromone-2-carboxylate (yield 69%)⁵⁴ and chromone-2-carbonitrile is converted into 3-chlorochromone-2-carbonitrile (yield 63%), which was used to prepare 3-chloro-2-(5-tetrazolyl)chromone, exhibiting an antiallergic activity.⁵⁵

3-Bromochromone-2-carboxylic acid (**25**) and its ethyl ester (**26**) have been synthesised by two procedures.⁵⁴ According to one procedure, the condensation product obtained from 2-hydroxyacetophenone and diethyl oxalate and existing in the cyclic chromanone form **27** is made to react with bromine in chloroform in the presence of pyridine at -3°C . This yields a mixture of *cis*- and *trans*-isomers of 3-bromochromanone **28** in 72:28 ratio. When compound **28** is refluxed in an EtOH–HBr mixture, ethyl 3-bromochromone-2-carboxylate (**26**) is formed in 49% yield, while refluxing of **28** in an AcOH–HBr mixture gives the acid **25**. The ester **26** can also be obtained by the above-described method⁴⁰ from ethyl chromone-2-carboxylate and pyrrolidine via aminovinyl ketone but in a lower yield.⁵⁴

Bromination of ethyl 7-hydroxychromone-2-carboxylate with bromine in acetic acid (75 – 80°C , 5 h) furnishes a mixture of 8-bromo-, 6,8-dibromo- and 3,6,8-tribromo-7-hydroxychromone-2-carboxylate, whereas bromination of the corresponding acid stops after the formation of 8-bromo-7-hydroxychromone-2-carboxylic acid under the same conditions (yield 94%).⁵⁶

3. Synthesis of 3-halo flavones

Interestingly, 3-chloroflavones were first obtained⁵⁷ by the reaction of 3,4-dichlorocoumarins³⁵ with phenylmagnesium bromide rather than by chlorination of flavones. The key intermediate in this reaction is benzopyrylium salt **A**, which is hydrolysed at the 4-position to give 3-chloroflavones **29a–c**. This was the first example of direct transformation of the coumarin system into the chromone one.

R = H (**a**), Me (**b**), Cl (**c**).

A modification of this method is treatment of the benzopyrylium salts formed *in situ* from phenols, perchloropropene and AlCl_3 with substituted phenols. This procedure was used to prepare 2'-hydroxy-3-chloroflavones **30**.⁵⁸

[†] In the case of 6-substituted chromone-2-carbaldehyde (unlike chromone-3-carbaldehyde³⁴), the 2-formyl group is retained.

$R^1, R^2 = \text{Me, Cl.}$

Acetylsalicylic acid and *O*-aroylsalicylic acids cyclise in the $\text{PPh}_3\text{--NEt}_3\text{--CCl}_4\text{--CH}_2\text{Cl}_2$ system at $\sim 20^\circ\text{C}$ over a period of several hours to give 3-chloroflavone (**29a**) and its derivatives **19a** and **31a,b** (yields 43%–60%). In the researchers' opinion,⁵⁹ these products are formed *via* ylide type intermediate **A**. This reaction allows one to obtain 3-chlorochromone compounds in one step.

$R = \text{Me (19a), Ph (29a), 4-ClC}_6\text{H}_4 \text{ (31a), 3-C}_5\text{H}_4\text{N (31b).}$

3-Chloroflavone (**29a**) is also formed on refluxing flavone (**1b**) with suluryl chloride (CHCl_3 , 1 h, 65%)³¹ or thionyl chloride (PhH , 15 h, 70%).⁶⁰ With excess SO_2Cl_2 in the presence of benzoyl peroxide (16 h, $\sim 20^\circ\text{C}$), flavone (**1b**) is converted into 2,3,3-trichloroflavanone **32** (67%).³¹

Compound **32** can also be prepared without benzoyl peroxide by refluxing flavone **1b** or **29a** with excess SO_2Cl_2 in benzene for 15 h.⁶¹

6- and 7-Chloroflavones react with thionyl chloride to give 3,6- and 3,7-dichloroflavones. 6-Chloroflavone reacts with suluryl chloride giving rise to 2,3,3,6-tetrachloroflavanone. The reaction of 7-hydroxyflavone with SOCl_2 in boiling benzene affords a mixture of 7-chloro- and 3,7-dichloroflavones, while its reaction with SO_2Cl_2 leads to 3,6,8-trichloro-7-hydroxyflavone.⁶² When 6-methylflavone is refluxed with SO_2Cl_2 in CCl_4 for 15 h, 3-chloro-6-dichloromethylflavone is the major reaction product. 2,3,3-Trichloro-6-dichloromethylflavanone is formed as a minor product. The reaction of SO_2Cl_2 with 6-methoxyflavone results in a complex mixture of four chloro derivatives of flavone and flavanone.⁶³ A general and an efficient method for the synthesis

of 3-chlorinated derivatives of flavone, chromone and thioflavone has been proposed. The procedure implies treatment with SO_2Cl_2 ⁶⁴ and the use of montmorillonite K10 as the catalyst.

Oxidative chlorination of flavones has been carried out using LiCl as a source of chloride ions and $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ ^{65,66} or $\text{Mn}(\text{OAc})_3 \cdot 2\text{H}_2\text{O}$ ⁶⁷ as the oxidant. The process afforded 3,3-dichloroflavanones **33**, which are readily dehydrogenated yielding 3-chloroflavones.

$\text{Ar} = \text{Ph}; R = \text{H, Me, OMe, Cl, Br}; \text{Ar} = 4\text{-MeOC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4; R = \text{H.}$

On refluxing in the $\text{CuCl}_2\text{--DMSO}$ system, flavanones and their linear isomers, 2'-hydroxychalcones, are immediately converted into 3-chloroflavones **29** in 80%–85% yields. Dichloro derivatives are not formed under these conditions.⁶⁸

Treatment of flavone **1b** with bromine in chloroform in the presence of silver acetate produces 2-acetoxy-3-bromoflavanone, which is easily transformed into 3-bromoflavone (**34b**) on treatment with KOH in aqueous alcohol.⁶⁹

Upon direct bromination of flavone **1b** with bromine in boiling acetic acid, 3-bromoflavone **34b** (75%) and 3,8-dibromoflavone (10%) were isolated.⁷⁰ However, attempts to prepare substituted 3-bromoflavones and their heteroanalogues have not met with success.⁷¹ During bromination of flavones in the $\text{Br}_2\text{--AcOH}$ system, the addition of $\text{Hg}(\text{OAc})_2$ is recommended.⁷² Preparation of 3-bromoflavones by the reaction of flavone with bromine in pyridine has been reported;⁷³ the product yields were not given in the publication.

Good results have been attained by using *N*-bromosuccinimide as the brominating agent. For instance, 3-bromoflavones **34b,f** were prepared in high yields by the reaction of flavones **1b** and **1f** with *N*-bromosuccinimide in methanol or acetic acid.⁷⁴

$\text{Ar} = \text{Ph (b), 4-MeOC}_6\text{H}_4 \text{ (f).}$

This method was used successfully to prepare 3,8-dibromo-7-butoxy-6-nitroflavones. These compounds were used to demon-

strate that the introduction of a bromine atom in the 3-position of flavones increases their antibacterial activity.⁷⁵

Substituted 3-bromoflavones **35** were prepared by treatment of appropriate flavones with *N*-bromosuccinimide in CHCl_3 or CuBr_2 in an $\text{AcOEt}-\text{CHCl}_3$ mixture (the yield of compounds **35** reached 50%–80%).^{71, 76–78}

$\text{R}^1 = \text{H, Me, MeO, Cl, Br, F}$; $\text{R}^2 = \text{H, Me, Br}$; $\text{Ar} = \text{Ph, 4-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4, 4\text{-FC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4, 4\text{-AcNHC}_6\text{H}_4, 2\text{-MeOC}_6\text{H}_4, 2\text{-C}_4\text{H}_3\text{O, 2-C}_4\text{H}_3\text{S}$; $\text{AX} = \text{NBS, CuBr}_2, \text{C}_5\text{H}_5\text{NH}^+\text{Br}_3^-$, $\text{PhI}(\text{OAc})_2-\text{Me}_3\text{SiX}$ ($\text{X} = \text{Cl, Br}$).

Recently, it was found that the reaction of flavones with pyridinium tribromide in pyridine and CH_2Cl_2 ($\sim 20^\circ\text{C}$, 16–48 h)⁷⁹ or with diacetoxy- λ^3 -iodanylbenzene in the presence of trimethylsilyl halides and pyridine (0°C , 4 h)⁸⁰ provides the corresponding 3-bromo- and 3-chloroflavones **35** in 60%–86% yields. In the latter case, halogenation can be carried out on a polymer substrate.

Bromination of flavones with 2,4,4,6-tetrabromocyclohexa-2,5-dienone proceeds under mild conditions to give the corresponding 3-bromoflavone in good yields.⁸¹

A facile and versatile method for the synthesis of 3-halo-flavones is based on halogenation of flavone precursors, diketones **36**.^{76, 82–86} For example, substituted 3-chloroflavones are formed on treatment of diketones **36** with sulfuryl chloride in dioxane and 3-bromoflavones, on treatment with bromine in dioxane.⁸² The reaction involves intermediates **37**, which undergo cyclodehydration in the presence of the hydrogen halide evolved in the reaction to give 3-halo-flavones in 60%–70% yields. Subsequently, this procedure has been utilised to prepare 2-styryl-,⁸⁴ 2-(α -furyl)- (see Refs 71, 83) and 2-(α -thienyl)-3-halochromones,⁷¹ as the double bond and the heterocyclic ring of 2-substituents are not halogenated under these conditions.

$\text{R} = \text{H, Me, Cl, Br}$; $\text{Ar} = \text{Ph, 4-MeOC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4, 2\text{-C}_4\text{H}_3\text{O, 2-C}_4\text{H}_3\text{S, PhCH=CH, 4-MeOC}_6\text{H}_4\text{CH=CH}$; $\text{X} = \text{Cl, Br}$.

It should be noted that the reaction between 2-styrylchromones and pyridinium tribromide in AcOH at $\sim 20^\circ\text{C}$ starts with bromination of the double bond of the styryl substituent; only after this, does bromination of C(3) take place.⁸⁷

In the bromination of 5-aryl-1-(2-hydroxyaryl)pent-4-ene-1,3-diones in DMF (which traps the HBr evolved), intermediate α -bromodiketones **38**, existing in the linear form in CDCl_3 (according to ^1H NMR data), were isolated.⁸⁴

$\text{R}^1 = \text{H, Me}$; $\text{R}^2 = \text{H, MeO}$.

The same compounds are formed upon bromination of styryl diketones in the $\text{Br}_2-\text{AcOH}-\text{AcONa}$ system, whereas treatment with *N*-bromosuccinimide in CCl_4 yields a mixture of compounds **34** and **38** that are difficult to separate.⁸⁵ It is noteworthy that, unlike diketones **38**, 2-bromo-1-(2-hydroxyphenyl)-3-phenylpropane-1,3-dione (**37a**) produced in the reaction of diketone **36a** ($\text{R} = \text{H, Ar} = \text{Ph}$) with bromine in chloroform in the presence of K_2CO_3 exists in the crystalline state as cyclic semiketal **39a**, while in CDCl_3 , it exists as a mixture of ring-chain tautomers **37a** and **39a** in a 3 : 11 ratio, respectively.⁸⁸

Treatment of flavanone with the complex $[(\text{C}_6\text{H}_7\text{NO})_3 \cdot \text{HBr} \cdot \text{Br}_2]$ in THF is an efficient method for the synthesis of 3-bromoflavanone, which is formed as a mixture of *cis*- and *trans*-isomers. Treatment of 4'-methoxy- and 4',7-dimethoxyflavanones with this complex in DMSO results in product mixtures consisting of the corresponding flavones and 3-bromoflavones.⁸⁹ Pyrolysis of 2'-hydroxy-4-methoxydihydrochalcone dibromide at 150°C yields a mixture of three products, namely, 2'-hydroxy-4-methoxychalcone, 4'-methoxyflavone and 3-bromo-4'-methoxyflavone; the last-mentioned product is formed upon bromination of 4'-methoxyflavone under conditions of pyrolysis.⁹⁰

The reaction of 2'-benzyloxy-6'-hydroxychalcone and 2'-benzyloxy-6'-hydroxy-2-cinnamylideneacetophenone with bromine or iodine (DMSO , Δ , 0.5 h) represents a one-step synthesis of the corresponding flavones and 2-styrylchromones dihalogenated in the benzene ring, which is activated by the hydroxy group at the 5-position; 3-halochromones are not formed under these conditions.⁹¹

Data on the synthesis of 3-iodoflavones (which hold much promise as intermediates in the synthesis of diflavonoids) and 3-fluoroflavones are quite scarce. Unlike chromone **1a**, flavone **1b** is smoothly lithiated at the 3-position on treatment with lithium diisopropylamide (THF , -78°C), which makes it possible to prepare 3-iodoflavone **40** by treating 3-lithioflavone with iodine.⁹²

Recently, the first and still the only one rather general method for the synthesis of 3-iodoflavones **41**, 3-iodothioflavones **42** and 3-iodo-2-(methyl)thiochromones, has been developed.⁹³ The method consists of the treatment of flavones, thioflavones and thiochromones with the $\text{Ce}(\text{NH}_4)(\text{NO}_3)_5$ – I_2 system in anhydrous acetonitrile at 55–60 °C. The yields of 3-iodoflavones **41** vary over broad limits (24%–80%) and reach a maximum (71%–80%) when an electron-donating group occurs at the 4'-position. Thioflavones and 2-(methyl)thiochromones are iodinated under the same conditions almost quantitatively (95%–98%). These results are in good agreement with the mechanism of electrophilic substitution at C(3) involving I^+ .

41: X = O: $\text{R}^1 = \text{H}, 4\text{-MeO}, 4\text{-BnO}, 4\text{-Cl}, 2\text{-MeO}$;

$\text{R}^2 = \text{H}, 6\text{-MeO}, 7\text{-MeO}, 5,7\text{-(MeO)}_2$;

42: X = S: $\text{R}^1 = \text{H}$; $\text{R}^2 = \text{H}, 6\text{-Me}$.

3-Fluoroflavone and its 6-substituted derivatives were prepared from appropriate flavones by electrochemical fluorination using the $\text{Et}_4\text{NF} \cdot 4 \text{HF}$ or $\text{Et}_3\text{N} \cdot 3 \text{HF}$ salts in acetonitrile as the source of fluoride anions.^{94,95} Anodic fluorination of flavones affords mono- (**43**), di- (**44**) and tri- (**45**) fluoro derivatives, whose ratio depends on the type of salt used and the temperature of electrolysis. 3-Fluoroflavones **43** are formed upon dehydrofluorination of compounds **44** under the action of triethylamine, while trifluoro derivatives **45** are the products of further fluorination of flavones **43**.

$\text{R} = \text{H}, \text{Me}, \text{Cl}$.

The yields of 3-fluoroflavones **43** vary over a broad range (25%–63%). Nevertheless, due to high regioselectivity, mild reaction conditions and the absence of toxic reagents, which are normally employed in the chemical fluorination, this method is an efficient tool for the synthesis of various fluorine-containing heterocycles.⁹⁵ By anodic fluorination of thioflavone under similar conditions, 3-fluorothioflavone (22%) and 2,3,3-trifluorothioflavanone (42%) have been synthesised.⁹⁶

The synthesis of 3-bromo- and 2- and 3-fluorokhellins from khellin **2a** and BrF has been reported.⁹⁷ The protocol includes the formation of *trans*-3-bromo-2-fluoro-2,3-dihydrokhellin **46** in a high yield. On treatment with 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) in DMSO, compound **46** is smoothly converted into 3-bromokhellin **47**. The reaction of **46** with KF or CsF gives 2-fluorokhellin **48**, and the reaction with AgF in acetonitrile affords a mixture of *cis*- and *trans*-2,3-difluoro-2,3-dihydro-

khellins **49** (51% and 36%, respectively). When the *cis*-isomer is treated with 1,5-diazabicyclo[5.4.0]undec-5-ene in DMSO, 3-fluorokhellin **50** is formed.

III. Chemical properties of halochromones

1. Reactions of 2-halochromones

As regards the ability of the halogen atom to act as a leaving group, 2- and 3-halochromones markedly surpass chromones halogenated at the benzene ring (except for 5,6,7,8-tetrafluorochromones in which the fluorine atom located in the *para*-position relative to the carbonyl group is susceptible to nucleophilic substitution¹⁸). The halogen atom situated in the β -position with respect to the carbonyl group is the most active; therefore, 2-halochromones surpass 3-halochromones and are similar to acid halides in reactivity.

When 2,3-dibromothiochromone 1,1-dioxide is made to react with primary and secondary aliphatic and aromatic amines,⁹⁸ only one bromine atom is replaced, namely, that located at the

2-position. Tertiary aromatic amines behave in this reaction as C-nucleophiles.⁹⁸

2-Chlorochromones are readily hydrolysed to 4-hydroxycoumarins when treated with water in the presence of acids or bases,²² while 2-chloro-3-hydroxychromone reacts with methylamine, aniline or secondary amines yielding the corresponding 2-amino-3-hydroxychromones (yields 40%–50%).⁹⁹

Recently, chromeno[2,3-*b*]pyrrol-4(1*H*)-ones **51**, analogues of natural products useful for pharmacology, have been prepared from 2-chloro-6-methylchromone and α -aminocarbonyl compounds (as acetals, ketals or hydrochlorides).²⁸ The reaction follows the A_N-E mechanism proceeding through replacement of the chlorine atom by nitrogen giving rise to 2-aminochromone derivatives **52**, which cyclise on heating in a pyrrolidine–acetic acid mixture (1:1). Presumably,²⁸ pyrrolidine activates the carbonyl group through the formation of iminium salt **53** (in the presence of other acids or bases, this reaction does not occur).

The anodic fluorination of (*E*)-3-(4-chlorobenzylidene)-2,3-dihydrochroman-4-one or isomeric 3-(4-chlorobenzyl)chromone yields the same product — (*E*)-3-(4-chlorobenzylidene)-2-fluoro-2,3-dihydrochroman-4-one (**54**). On treatment with piperidine in acetonitrile at ~20 °C, compound **54** is converted into 3-(4-chlorobenzylidene)-2-piperidino-2,3-dihydrochroman-4-one (**55**).¹⁰⁰

2. Reactions of 3-halochromones

3-Halochromones contain a double bond with geminal arrangement of the carbonyl group and the halogen atom; thus, they can be regarded as geminally activated haloalkenes, which are highly reactive and are widely used in the synthesis of heterocycles and analogues of natural compounds.¹⁰¹ The reactions of nucleophilic reagents with 3-halochromones containing two good leaving groups (the halogen atom at the α carbon atom and the phenolic fragment at the β carbon atom) are more diverse than reactions with haloalkenes. Indeed, haloalkenes react with *N*-nucleophiles along three major pathways including the formation of aziridines and aminoalkenes with a vicinal or geminal (*ipso*-substitution) activating group.¹⁰¹ In the case of 3-halochromones, apart from these pathways, reactions associated with opening and transformation of the γ -pyrone ring can also take place. Note in addition that, whereas the reaction pathway with haloalkenes is governed by the nature of the activating group, in the case of 3-halochromones, the most important factor is the type of the nucleophilic species, together with the size and the electronic properties of the 2-substituent.

Among 3-halochromones, 3-halo-2-hetaryl- and their heterocyclic analogues are least reactive, which is due to the presence of the (het)aryl substituent at the 2-position. For example, the most typical reaction of 3-halo-2-hetaryl- is contraction of the γ -pyrone ring on refluxing with an ethanol solution of KOH to give compounds **56**.

$R^1 = Ar, Het, CH=CHAr; R^2 = H, Me, Cl; X = Cl, Br.$

This ring transformation has been repeatedly used to confirm the structures of 3-bromo-2-hetaryl-,⁸² 3-halo-2-hetaryl-⁸³ and 3-halo-2-styrylchromones.⁸⁴ However, in the case of 3-halochromones devoid of substituent at the 2-position, ring transformation occurs only on treatment with amines (see below). Worthy of note is also the possibility of replacement of the chlorine atom in 3-chloro-2-hetaryl- by a cyano group in the presence of copper(I) cyanide,^{57, 102} which cannot be accomplished for other halochromones.

a. Reactions with N- and S-nucleophiles

A very important reaction of 3-halochromones is its amination by secondary cyclic amines (pyrrolidine, piperidine, morpholine and *N*-methylpiperazine), which results in the corresponding 3-aminochromones **57**.^{37, 46, 47, 70, 103, 104} Presumably, the *ipso*-replacement of the halogen atom observed in this case follows the 1,4-addition mechanism involving the formation of the aziridinium intermediate **A**, whose subsequent opening gives an amino group at the C(3) atom.^{37, 105, 106}

$R^1 = H, Me, Ar; R^2 = H, Me, Cl; X = Cl, Br;$

$NHR_2^3 = HN(CH_2)_Z (Z = CH_2, O, NMe), HN(CH_2)_4.$

The presence of a substituent at the 2-position of the chromone system hampers the reaction; amination of 3-haloflavones is carried out under rather drastic conditions. 3-Bromo derivatives are more reactive than analogous 3-chloro derivatives. 3-Bromoflavone is converted into amino derivatives **57** at $\sim 100^\circ\text{C}$ in 60%–80% yields (6–8 h),⁷⁰ while 3-chloroflavone enters into the reaction with morpholine or piperidine only on heating in *N*-methylpyrrolidone in a sealed tube ($200\text{--}220^\circ\text{C}$, 72–80 h) and the yield does not exceed 30%–44%. Flavone **58** cyclises under these conditions to form tetracyclic derivative **59**.¹⁰⁴

3-Chlorochromones,^{37, 103} 3-bromo-2-methylchromone⁴⁶ and 3-bromoflavone⁷⁰ are aminated on heating without a solvent; however, an attempt to use these conditions for amination of 3-bromochromone (**9**) resulted in a complex mixture of products.¹⁰⁶ A study of amination of 3-halochromones devoid of substituents at C(2), which is the site of the initial nucleophilic attack, has shown that the reaction of 3-bromochromone (**9**) with primary amines in acetonitrile in the presence of K_2CO_3 (added for neutralisation of HBr evolved during the reaction) is accompanied by contraction of the γ -pyrone ring giving benzofuran (coumarone) derivatives **60**. The reaction with secondary amines under the same conditions gives the expected 3-aminochromones **61**.¹⁰⁶ The synthesis of compounds **60** proceeds *via* opening of the pyrone ring induced by the attack by the amine on the C(2) atom followed by replacement of the bromine atom under the action of the phenoxide anion (tautomerism and double bond configuration have not been discussed in the study cited¹⁰⁶).

$\text{R}^1 = \text{Bu}, \text{Bn}, \text{cyclo-C}_6\text{H}_{11}$; $\text{R}_2\text{NH} = \text{HN(CH}_2)_4\text{O}, \text{HN(CH}_2)_3\text{CH}_3$.

Note that 6-bromonorkhellin **62** reacts with primary and secondary amines with contraction of the pyrone ring to give furocoumarone derivatives **63**.¹⁰⁶

$\text{R}_2\text{NH} = \text{BuNH}_2, \text{cyclo-C}_6\text{H}_{11}\text{NH}_2, \text{HN(CH}_2)_4\text{O}, \text{HN(CH}_2)_3\text{CH}_3$.

Recently, it was shown¹⁰⁷ that replacement of acetonitrile by DMF changes the reaction pathway between secondary cyclic amines and 3-halochromones unsubstituted at the 2-position. Instead of 3-aminochromones **61**, the reaction affords benzofuranones **60** (yields 72%–96%), *i.e.*, the reaction occurs in the same way as that with primary amines in MeCN.

Of 3-halochromones, 3-iodochromone (**64**) is the most reactive. For reactions of halochromones with imidazole, it was shown that on replacement of 3-iodochromone by 3-bromo- or 3-chlorochromone, the reaction rate and the product yield substantially decrease.¹⁰⁸ The reaction of 3-iodochromone with piperidine has been studied in detail.¹⁰⁷ The reaction carried out in MeCN in the presence of K_2CO_3 was found to yield aminovinyl ketone **65** (63%) and 3-iodo-2-piperidinochromone (**66**) (4%). In DMF in the absence of K_2CO_3 , a mixture consisting of compounds **65** (51%), **66** (11%) and 3-piperidinochromone (**61**, $\text{NR}_2^2 = \text{NC}_5\text{H}_{10}$) (13%) is obtained. The diversity of reaction products is explained by a variety of transformations of the Michael adduct formed initially; in particular, iodine elimination with simultaneous ring opening affords compound **65**, iodination followed by elimination of HI gives chromone **66**, and intramolecular replacement of iodine *via* the aziridinium cation leads to chromone **61**. When 3-chloro- or 3-bromochromone is introduced in this reaction, products of types **65** and **66** are not formed.¹⁰⁷

The reaction of 3-bromo- and 3-bromo-6-chlorochromones with excess imidazole in the presence of its silver salt (80°C , 0.5 h) proceeds by Michael addition followed by dehydrobromination and results in 2-imidazolylchromones **67**.¹⁰⁸ Due to the electron-withdrawing nature of the imidazole ring, the acidity of the H(2) atom increases, and the formation of the aziridinium intermediate becomes impossible due to the reduced nucleophilicity of the imidazole nitrogen; apparently, this contributes to the change in the reaction route.

$\text{R} = \text{H}, \text{Cl}$.

3-Bromothiochromones react with imidazole or 2-alkyl-imidazoles giving rise to 2-imidazolylthiochromones and react with secondary amines (piperidine, morpholine and methylethylamine) to give 3-aminothiochromones, *i.e.*, 3-bromochromones and 3-bromothiochromones are equally reactive towards imidazoles and secondary amines.¹⁰⁹

2-(*N*-Azolyl)chromones are prepared by heating 3-iodochromone (**64**) with azoles (imidazole, pyrazole, pyrrole, 1,2,4-triazole, benzimidazole, indazole) in DMF in the presence of K_2CO_3 (80°C , 56%–89%).¹¹⁰ The reaction of 3-iodochromone (**64**)

with indole carried out under the same conditions leads to a mixture of approximately equal amounts of 2-(1-indolyl)chromone (**68**) and 2-(1-indolyl)methylene-3(2*H*)-benzofuranone (**69**). Substituents in the indole system have a substantial influence on the **68** to **69** product ratio. In the presence of electron-donating groups (Me, MeO), the product ratio changes in favour of benzofuranones **69**, whereas electron-withdrawing substituents (Cl, NO₂) promote the proportion of chromones **68**, because in this case, the indole nitrogen atom is depleted of electrons.¹¹⁰

R = H, 3-Me, 5-Me, 5-MeO, 5-Cl, 5-NO₂, 6-NO₂.

The reactions of chromone **64** with 1-methyl-2-sulfanylimidazole, 3-sulfanyl-1,2,4-triazole or 4-methyl-3-sulfanyl-4*H*-1,2,4-triazole (DMF, K₂CO₃, ~20 °C) proceed differently from the reactions with azoles. In this case, 3-azolylsulfanylchromones **70** are formed instead of 2-substituted chromones or benzofuranones.¹¹¹ An analogous compound has also been obtained in the reaction of chromone **64** with 2-thiocytosine.¹¹² The substitution of a sulfur atom for iodine involves the formation of a three-membered episulfonium cation **A** (similarly to the substitution of nitrogen for halogen). The subsequent opening of the three-membered ring furnishes chromones **70a–c**.

Unexpectedly, the reaction of 3-iodochromone (**64**) with 2-sulfanylimidazole does not stop after the formation of chromone **70d** but proceeds further as an intramolecular ring transformation giving a mixture of products **70d** and **71** in 18% and 62% yields, respectively.¹¹¹

2-Sulfanyl- and 5-methoxy-2-sulfanylbenzimidazoles react with chromone **64** to yield compounds of type **71** as the major products, whereas 5-nitro-2-sulfanylbenzimidazole gives only the corresponding chromone **70**.¹¹¹ When K₂CO₃ is replaced by Bu₄NCl, the reactions with 2-sulfanylimidazole and 2-sulfanylbenzimidazole stop after the formation of 3-substituted chromones **70**.¹¹³

Finally, the reaction of *N,N'*-dimethylthiourea with 3-iodochromone (**64**) produces a mixture of imidazoline **72** and thiazoline **73**; thiourea acts as an N-nucleophile in the first step of the reaction and as either an N- or S-nucleophile in the final step.¹¹⁴

Thus, the transformations of 3-bromo- and 3-iodochromones induced by N- and S-nucleophiles demonstrate the broad synthetic potential of these compounds, the high reactivity of which ensures the existence of several pathways for particular reactions. On the one hand, this diversity of properties complicates prediction of the structures of the final products but, on the other hand, this makes 3-halochromones attractive objects for further investigations.

It should be noted that data on the reactions of 3-halochromones with bisnucleophiles (even with simple ones such as hydroxylamine or hydrazine) are very scarce.

The reaction of 3-bromochromone (**9**) with hydroxylamine has been reported to give the oxime of 3-hydroxy-1-benzofuran-2-carbaldehyde, the structure of which was confirmed by X-ray diffraction data; however, neither the synthetic procedure nor the spectroscopic or physicochemical characteristics were described.¹⁰⁶

Some data on the reactions of alkyl 3-chloro- and 3-bromochromone-2-carboxylates with ammonia and amines have been reported.^{53, 54, 115} Depending on the reaction conditions, methyl ester **74** reacts with ammonia to give products **75–77**; this implies that the reaction first involves the ester group, and then the chlorine atom is replaced by the amino group, which is able to react with acetone to yield Schiff's base **77**.⁵⁴ The yield of amide **76** increases to 66% when the ethyl ester is used as the starting compound instead of the methyl ester, which is due to different solubilities of these compounds in methanol.⁵³

Attempts to replace chlorine in 3-chlorochromone-2-carboxylate by an amino group on treatment with ammonia have failed. In 3-chlorochromone-2-carbonitrile, the group to be replaced is the cyano group; this gives 2-amino-3-chlorochromone, which is hydrolysed in an acid medium to 3-chloro-4-hydroxycoumarin.⁵³ On the basis of these data, it was concluded⁵³ that the reactivity of 2-substituted 3-chlorochromones decreases in the sequence 2-Me < 2-CO₂Et < 2-CN < 2-CO₂H.

The reactions of ethyl ester **78** with methylamine, 2-aminoethanol, piperidine, aniline and *o*-phenylenediamine proceed with replacement of the bromine atom and with retention of the pyrone ring, yielding products **79–83**.^{54, 115}

Ester **78** reacts with ammonia giving rise to amide **76** (yield 74%). Due to steric hindrance in the ester group, *tert*-butyl 3-bromochromone-2-carboxylate reacts only at the C(3) atom with replacement of bromine yielding *tert*-butyl 3-aminochromone-2-carboxylate (yield 55%).¹¹⁵

Thus, neither primary nor secondary amines react with 3-halochromone-2-carboxylate with contraction of the pyrone ring to form the furan ring. When secondary amines react with 3-bromo-2-methylchromone and 3-haloflavones, the pyrone ring is also retained.

b. Reactions with C-nucleophiles

The reactions of bromochromone (**9**) with C-nucleophiles are highly significant, in particular, for the preparation of pharmaceutically valuable products. Thus the reactions of chromone **9** with β -diketones and β -ketoesters {1,5-diazabicyclo[4.3.0]non-5-ene (DBN) or DBU, CHCl₃, ~20 °C, 0.5–1 h} lead to highly functionalised furans **84**.¹¹⁶ Completion of this reaction requires two equivalents of a base, while replacement of DBN or DBU by Et₃N results in the recovery of the starting compounds. The mechanism of this transformation involves 1,4-addition of the β -dicarbonyl compound to chromone **9** followed by intramolecular *O*-alkylation and opening of the pyrone ring to give 2-salicyloylfurans **84**.¹¹⁶

$R^1 = R^2 = \text{Me}$; $R^2 = \text{OEt}$; $R^1 = \text{Me, Ph, CH}_2\text{SPh, CH}_2\text{CO}_2\text{Et}$;
 $R^1 - R^2 = \text{CH}_2\text{CMe}_2\text{CH}_2$.

The reaction of 3-bromochromone (**9**) with nitro enamines resulting in 2-salicyloylpyrroles **85**¹¹⁷ is carried out in the MeCN–K₂CO₃ system (previously, this system was used in reactions with amines¹⁰⁶).

$R = \text{Me, Ph}$.

Heating of chromone **9** with 4-hydroxy-6-methyl-2*H*-pyran-2-one in pyridine for 4–5 h gives furopyrone **86**.¹¹⁷

Unlike β -diketones and β -ketoesters, derivatives of malonic acid, more susceptible for C-alkylation, react with 3-bromochromone (DBU, MeCN, 20 °C) *via* the formation of the cyclopropane intermediate **A**. Owing to the anchimeric assistance from the neighbouring oxygen atom, the cyclopropane ring in compound **A** is easily cleaved to give 3-substituted chromones **87**.

$R^1 = R^2 = \text{CO}_2\text{Et}$; $R^1 = \text{CO}_2\text{Et}$, $R^2 = \text{CN}$;
 $R^1 = \text{CO}_2\text{Bu}^t$, $R^2 = \text{CN}$; $R^1 = \text{CN}$, $R^2 = \text{SO}_2\text{Me}$.

The reaction of 3-bromochromone (**9**) with Meldrum's acid affords chromone **88**, which is converted into acid **89**.¹¹⁸

3-Bromo-2-methylchromone (**19b**) reacts with diethyl malonate in the presence of Et₃N in acetone being converted into diethyl (2-methylchromon-3-yl)malonate.⁴⁵ However, the reaction pathway between 3-bromochromone (**9**) and ethyl *N*-(diphenylmethylidene)glycinate changes (apparently, for steric reasons). In this case, elimination of hydrogen bromide from the

protonated Michael adduct **90** results in the formation of 2-substituted chromone **91**.¹¹⁸

Notably, as in the reactions with amines, 6-bromonorkhellin **62** shows a specific behaviour in reactions with C-nucleophiles; in particular, it reacts with ethyl acetoacetate and ethyl *tert*-butyl cyanoacetates in the same way as 3-bromochromone (**9**), *i.e.*, to give furan **92** and 6-substituted norkhellins **93**, whereas the reaction with diethyl malonate produces furocoumarone derivative **94**.¹¹⁸ Thus, the pyrone fragment of compound **62** is also prone to contraction in reactions with C-nucleophiles.¹⁰⁶

In reactions with the ambident nitronate anions generated from the corresponding nitro compounds, 3-bromochromone (**9**) and 6-bromonorkhellin (**62**) behave in the same way to give chromones **95** (yields 49%–74%) and **96** (yields 39%–90%) containing the oxime function at 2(7)-positions and the hydroxy group instead of the bromine atom.¹¹⁹ As in the case of β -diketones and β -ketoesters, the reactions of nitronate anions with chromones start with the Michael addition, which is accompanied by intramolecular *O*-alkylation and gives intermediate **A**. Subsequently, under the action of the *N*-oxide fragment, the isoxazole (rather than the pyrone) ring in the intermediate **A** is opened, which gives oximes **95** and **96**.

R = Me, Et, CO₂Me, Ph.

The khellin derivative **96** (R = Me) cyclises on heating with dimethylformamide dimethyl acetal at 100 °C for 0.5 h being thus converted into 5,9-dimethoxy-3-methyl-10*H*-furo[3',2':6,7]chromeno[2,3-*d*]isoxazol-10-one (**97**). Similar products were also obtained under the same conditions from chromones **95** (yields 49%–83%).¹¹⁹

c. Cross-coupling and cycloaddition reactions

In recent years, studies dealing with the use of 3-halochromones in homo- and cross-coupling reactions catalysed by transition metal complexes have been appearing more and more often. These reactions open up a new route to the synthesis of complex molecules incorporating a chromone fragment. For example, derivatives **98**, otherwise difficult to prepare, have been synthesised by vinylation of 3-bromochromone (**9**) with methyl acrylate or styrene in the presence of catalytic amounts of palladium acetate and triphenylphosphine (DMF, Et₃N, 120 °C, 6 h).¹²⁰

R = CO₂Me, Ph.

Cross-coupling of 3,6-dibromochromone with methyl acrylate involves both bromine atoms and affords a mixture of products — compounds **99** and **100**. The formation of substituted benzophenone **100** is a result of cycloaddition of methyl acrylate to chromone **99** followed by decarboxylation of the adduct, opening of the pyrone ring and dehydrogenation induced by palladium.¹²⁰

R = CO₂Me.

Chromone **9** proved to be a poor dienophile in the Diels–Alder reaction. Only with 1,3-cyclohexadiene and under rigorous conditions (300 °C, 120 h), does it form adduct **101** with a low stereoselectivity (the isomer ratio is equal to 2:1, yield < 16%). Chromone-3-carbonitrile and especially its 6-chloro- and 6-bromo-substituted derivatives proved to be more reactive. Compounds **102** were synthesised in 44%–50% yield and with 93% stereoselectivity.¹²¹

Homo-coupling of 3-iodochromones in the $\text{NiCl}_2(\text{PPh}_3)_2$ – PPh_3 – Zn – NaH – PhMe system occurs almost quantitatively giving rise to bischromones **103**, which are of interest for the synthesis of natural biflavonoids.^{122, 123}

R = H, Me, MeO.

In order to develop a method for the synthesis of natural biflavonoids, homo-coupling of 3-iodo derivatives of flavones, thioflavones and thiochromones **104** under the Ullmann reaction conditions has been studied.¹²⁴ It was shown that heating of these compounds with copper powder at 200–210 °C under argon leads to products **105**, the yields of biflavones and bithioflavones being 71%–86% and the yields of bithiochromones being 31%–33%.

X = O: R¹ = Ph, 4-MeOC₆H₄; R² = H, 7-MeO;
X = S: R¹ = Ph, Me; R² = H, 6-Me.

Isoflavone (**1d**) and its derivatives **106**^{125, 126} have been prepared in high yields by cross-coupling of 3-bromo- and 3-iodochromones with arylboronic acids catalysed by tetrakis-(triphenylphosphine)palladium(0) in the presence of Na₂CO₃ (Suzuki reaction).

R¹ = H, MeO, Cl; R² = H, Me, MeO, F, NO₂; X = Br, I.

Annulation of 3-iodoflavone **40** by internal alkynes catalysed by Pd(OAc)₂ in the presence of NaOAc and LiCl yields a mixture of compounds **107** and **108**. In this mixture, the expected benzoxanthenes **107** are the minor products,¹²⁷ while tetrasubstituted furans **108**, resulting from the electrophilic attack on the carbonyl

oxygen atom by the vinylpalladium intermediate followed by pyrone ring opening, are the major products.

R¹ = R² = Ph; R¹ = Me, R² = Bu^t.

IV. Methods for the synthesis of 2-polyhaloalkyl- and halomethylchromones

1. Synthesis of 2-polyfluoroalkylchromones

The first representatives of 2-trifluoromethylchromones were obtained in 1951 by condensation of substituted 2-hydroxyacetophenones with ethyl trifluoroacetate in the presence of sodium followed by dehydration of the initially formed β-diketones in an acid medium.¹²⁸ It has long been considered¹²⁹ that these diketones have a linear keto-enol structure **109**; however, subsequently, it has been found on the basis of ¹H NMR data^{130, 131} that they exist as cyclic semiketals **110** both in solutions and in crystals. Cyclisation is facilitated by the presence of the electron-withdrawing trifluoromethyl group in the side chain and the hydroxy group in the *ortho*-position of the benzene ring. It was found that open tautomers start to appear in CDCl₃ solutions with an increase in the number of fluorine atoms in the polyfluoroalkyl group.^{132, 133} Indeed, the condensation products of 2-hydroxy- and 2-hydroxy-5-methylacetophenones with H(CF₂)₂CO₂Et in CDCl₃ represent a tautomeric mixture containing the keto-enol and semiketal forms in ~1 : 10 ratio.¹³³ Short-term refluxing of 2-hydroxychromanones **110** in ethanol¹²⁸ or acetic acid¹³⁴ in the presence of concentrated HCl results in 2-polyfluoroalkylchromones **111**.

R = H, Me, MeO, Cl, Br;

R^F = CF₂H, CF₃, (CF₂)₂H, C₂F₅, C₃F₇, C₄F₉.

Modification of natural products by replacing an alkyl group by a polyhaloalkyl group has long attracted the attention of researchers, because the electron-withdrawing effect of the halogenated substituent entails electron density redistribution in the molecule and thus changes its reactivity with respect to nucleophilic reagents.¹³⁵ In this connection, of obvious interest is the synthesis of 7-polyfluoroalkylnorkhellins **112**,^{136, 137} which are fluorinated analogues of khellin **2a**, because it opens up the way for the synthesis of a broad range of fluorine-containing heterocyclic derivatives that incorporate the natural benzofuran fragment and are potentially biologically active.

Fluorokhellins **112** were prepared by the reaction of khellinone **113** with $R^F\text{CO}_2\text{Et}$ in the presence of LiH followed by dehydration of the condensation products, which exist as furochromanones **A** in crystals and in $\text{DMSO}-d_6$ solutions. In CDCl_3 , these compounds (except for $R^F = \text{CF}_3$) are mixtures of tautomers **A**–**C**. Irrespective of length of the fluoroalkyl group, cyclic form **A** predominates (50%–78%), while the content of the diketone form **C** usually does not exceed 8%.¹³⁷

$R^F = \text{CF}_2\text{H}, \text{CF}_3, (\text{CF}_2)_2\text{H}, \text{C}_2\text{F}_5, \text{C}_3\text{F}_7, \text{C}_4\text{F}_9$.

The Claisen condensation is the most convenient and efficient method for the synthesis of 2- R^F -chromones as it is based on simple and readily available initial compounds. This reaction can proceed in the presence of sodium¹²⁸ or other condensing reagents such as sodium hydride¹³¹ or lithium hydride.¹³⁴ Ether¹³¹ and THF¹³⁴ are commonly used as solvents. Due to the low solubility of phenolates, derivatives hydroxylated at the benzene ring are synthesised using hexamethylphosphorotriamide¹³⁸ or the Kostanecki–Robinson method. For example, 7-hydroxy-2-trifluoromethylchromone was prepared in 68% yield by heating 2,4-dihydroxyacetophenone with trifluoroacetic anhydride and sodium trifluoroacetate.¹⁴

If a heterocyclic or another 2-hydroxyacetophenone derivative such as dehydroacetic acid, 2-acetyldimedone, 3-acetyl-4,6-dimethyl-2-pyridone and 2-aminoacetophenone is used as the methylene component in the condensation with $R^F\text{CO}_2\text{Et}$, the reaction gives chromone, 7-methyl-2-polyfluoroalkylpyrano[4,3-*b*]pyran-4,5-diones,¹³⁹ 7,7-dimethyl-2-polyfluoroalkyl-7,8-dihydro-6*H*-chromene-4,5-diones,¹⁴⁰ 8-aza-2-polyfluoroalkylchromones¹⁴¹ and 2-polyfluoroalkyl-4-pyridones.¹⁴²

$R^F = \text{CF}_2\text{H}, \text{CF}_3, (\text{CF}_2)_2\text{H}$.

In addition to the Claisen condensation, other methods for the synthesis of 2- R^F -chromones have also been developed. For example, the reaction of 2-hydroxyacetophenones with $R^F\text{CN}$ in the presence of *N*-methylanilinomagnesium bromide affords aminovinyl ketones **114** with geminal arrangement of the amino group and the fluorinated substituent (yields 35%–60%). Unlike diketones **109**, these compounds usually exist in the open form as

Z-isomers having a coplanar *S*-*cis*-conformation stabilised by an intramolecular hydrogen bond.¹⁴³

$R = \text{H}, \text{Me}, \text{MeO}, \text{Cl}; R^F = \text{CF}_2\text{H}, \text{CF}_3, (\text{CF}_2)_2\text{H}$.

However, the products of condensation of CF_3CN with sterically hindered 2-hydroxy-4,6-dimethylacetophenone and 1-acetyl-2-naphthol exist predominantly as 2-aminochroman-4-ones **115** and **116**. In these compounds, the aminoenone form is destabilised due to unfavourable interactions between the vinylic hydrogen atom and the *ortho*-substituent in the benzene ring.^{144, 145}

A similar ring–chain isomerism occurs also in the series of aliphatic hydroxyoxoenamines with a *gem*-dialkyl group in the α -position to the carbonyl group.^{146–148} In an acid medium, compounds **114**–**116** are converted almost quantitatively into 2- R^F -chromones **111**.

The condensation of ketimines prepared from 2-hydroxyacetophenones and primary amines with $R^F\text{CO}_2\text{Et}$ in the presence of LiH yields aminovinyl ketones **117** with γ -arrangement of the NHR and R^F groups, which exist only in the open form.^{149, 150} In an ethanol solution of HCl ($\sim 20^\circ\text{C}$, 2 h), these compounds cyclise to 2-polyfluoroalkyl-4*H*-chromene-4-iminium salts **118**, which can be neutralised with ammonia to form 2-polyfluoroalkyl-4*H*-chromene-4-imines **119**.

$R^1 = \text{H}, \text{Me}; R^2 = \text{CH}_2\text{Ph}, \text{Pr}^i, (\text{CH}_2)_2\text{OH}; R^F = \text{CF}_3, (\text{CF}_2)_2\text{H}$.

On treatment with aqueous acetic acid ($\sim 20^\circ\text{C}$, 12 h or 80°C , 1 h), compounds **117** and **119** are hydrolysed to chromanones **110**, which can be easily converted into chromones **111**. Chromeneimines **119** are of interest for synthesis by themselves, because they exist in an acid medium as highly reactive iminium cations **118**, which are more reactive than 2- R^F -chromones **111**.¹⁵¹

The reactions of polyfluoroalk-2-ynoic acids with a fivefold excess of ArOH and KOH in an aqueous solution are stereospecific and result in (*Z*)- β -polyfluoroalkyl- β -aryloxyacrylic acids **120a**. On treatment with concentrated H_2SO_4 at $\sim 20^\circ\text{C}$, compounds **120a** are converted into 2- R^F -chromones **121a** (yields 51%–76%).¹⁵² Due to the higher nucleophilicity of arenethiols, a similar reaction involving arenethiols can be carried out in aqueous ethanol at a reactant molar ratio of 1 : 1. The resulting arylthioacrylic acids **120b** also have the *Z*-configuration of the

double bond; on successive treatment with PCl_5 and AlCl_3 in benzene at $\sim 20^\circ\text{C}$, they produce 2- R^{F} -thiochromones **121b** (yields 68%–87%).¹⁵²

$\text{R}^{\text{F}} = \text{CF}_2\text{H}, \text{CF}_3, (\text{CF}_2)_3\text{H}$; $\text{R} = \text{H}, \text{Me}, \text{MeO}, \text{Cl}$; $\text{X} = \text{O}$ (a), S (b).

A similar approach to the synthesis of 2- R^{F} -chromones has been described in a study¹⁵³ in which ethyl 2,2-dihydropolyfluorocarboxylates were used as the starting substrates. They were made to react with phenols in the presence of Et_3N in MeCN at 60°C , which gave ethers **122**, most often, as mixtures of *Z*- and *E*-isomers. When heated with polyphosphoric acid (PPA) at 170°C , they were converted into chromones **111** in high yields.

$\text{R}^{\text{F}} = \text{CF}_2\text{Cl}, (\text{CF}_2)_3\text{Cl}, (\text{CF}_2)_5\text{Cl}$; $\text{R} = \text{H}, \text{Me}, \text{Ph}, \text{Cl}, \text{Br}$.

The reaction of *o*-fluorobenzoyl chloride with β -ketoesters in the presence of NaH has been proposed as a method for the synthesis of 2-methylchromone-3-carboxylic acids and their esters;¹⁵⁴ in particular, this reaction proved to be suitable for the preparation of ethyl 2-trifluoromethylchromone-3-carboxylate (**123**).

Heating compound **124**, containing an easily replaceable fluorine atom in the *ortho*-position to the carbonyl group, with urea results in 2-trifluoromethyl-5,6,7,8-tetrafluorochromone (**125**), instead of the expected pyrimidin-2(1*H*)-one derivative.¹⁵⁵

2. Synthesis of 2-trichloromethylchromones and halomethylchromones

Esters of trichloroacetic acid undergo haloform cleavage under the Claisen condensation conditions in the presence of sodium alkoxides giving rise to chloroform¹⁵⁶ and dichlorocarbene.¹⁵⁷ Apparently, this is the reason why the first 2-trichloromethylchromones **126** were obtained only in 1972 by the reaction of 2-methylchromone or 7-hydroxy-2-methylchromone with thionyl chloride proceeding as chlorination of the side methyl group.¹⁵⁸ Later, this method has found no use.

$\text{R}^1 = \text{H}, \text{OH}$; $\text{R}^2 = \text{H}, \text{Cl}$.

A simple and more general method for the synthesis of chromones **126** consists of condensation of 2-hydroxyacetophenones with CCl_3CN in the presence of *N*-methylanilinomagnesium bromide. This reaction affords aminovinyl ketones **127**, which are converted into chromones **126** on treatment with concentrated HCl at $\sim 20^\circ\text{C}$ (yields 77%–96%).^{143, 159}

$\text{R} = \text{H}, \text{Me}, \text{MeO}, \text{Cl}$.

When sterically hindered ketones are used, the aminovinyl ketones formed initially cyclise spontaneously to yield 2-aminochromanones **128** and **129**.^{144, 145}

It is of interest that compound **130** exists only as the open form, despite the presence of the methoxy group in the *ortho*-position with respect to the carbonyl group. Acid hydrolysis of aminovinyl ketone **130**, prepared in 37% yield from 5-acetyl-6-hydroxy-4,7-dimethoxybenzo[*b*]furan (khellinone) and trichloroacetonitrile, gives 7-trichloromethylnorkhellin **131** in a yield of 87% (the overall yield over two steps was 32%).¹³⁶

Recently,¹⁶⁰ we proposed a new method for the synthesis of chromones **126**, underlain by the Baker–Venkataraman rearrangement. When trichloroacetates **132** (prepared *in situ* by acylation of 2-hydroxyacetophenones with trichloroacetyl chloride) is treated with potassium *tert*-butoxide in THF at -30°C , 2-hydroxy-2-trichloromethylchroman-4-ones **133** are formed; they represent the cyclic form of the corresponding β -diketones. Refluxing of these compounds in AcOH in the presence of concentrated HCl results in the corresponding chromones. In the synthesis of trichlorokhellin **131** by this procedure, an overall yield of 64% was attained.¹⁶⁰

$\text{R}^1 = \text{R}^2 = \text{H}$; $\text{R}^1 = \text{MeO}, \text{R}^2 = \text{H}$; $\text{R}^1 = \text{R}^2 = \text{Me}$.

The Claisen condensation, which proceeds successfully with esters of polyfluorocarboxylic acids that contain ≥ 2 fluorine atoms, proves to be inapplicable to alkyl trichloroacetates or monohaloacetates. In the latter case, this is due to the easy replacement of the halogen atom under the action of nucleophilic species. Therefore, 2-halomethyl chromone derivatives are more difficult to prepare than 2-polyhaloalkylchromones. Only a few examples of synthesis of these compounds have been reported. For example, treatment of 2-ethoxymethyl-7-methoxychromone (obtained by condensation of 2-hydroxy-4-methoxyacetophenone with ethyl ethoxyacetate) with a mixture of HBr and AcOH yields 2-bromomethyl-7-methoxychromone.¹⁶¹ The bromination of 3-benzoyl-2-methylchromone with *N*-bromosuccinimide furnishes 3-benzoyl-2-bromomethylchromone.¹⁶²

A natural furochromone — khellol **134** — was used to prepare 7-iodomethyl-¹⁶³ and 7-chloromethylnorvisnagins **135**.¹⁶⁴ 7-Methylthiomethylnorkhellin (**136**), obtained by condensation of khellinone **113** with ethyl methylthioacetate in the presence of NaH or NaOMe, reacts with methyl iodide to give 7-iodomethyl-norkhellin **137**.¹⁶⁵

3-Halomethylchromones are prepared by the reaction of 3-hydroxymethylchromones with SOCl_2 , chloromethylation of chromones, or bromination of 3-methylchromones with *N*-bromosuccinimide.² When 2,3-dimethylthiochromone is treated according to Ziegler [NBS , $(\text{PhCOO})_2$, CCl_4], only the hydrogen atom of the 3-methyl group is substituted, which gives 3-bromo-2-(methyl)thiochromone (yield 74%).⁴⁹ The chloromethylation of 2-(methyl)thiochromone and thioflavones is carried out by treating these compounds with chloromethyl methyl ether in sulfuric acid. The reaction results in the formation of 3-(chloromethyl)thiochromones **138**; the only exception is 6-methoxythioflavone, which is converted into 5-chloromethyl derivative **139**.¹⁶⁶

$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$; $\text{R}^1 = \text{Ph}$, $\text{R}^2 = 6\text{-Me}$, 6-MeO , 8-Me , $8\text{-CO}_2\text{Me}$.

V. Chemical properties of 2-polyhaloalkyl- and halomethylchromones

1. Reactions of 2-polyfluoroalkylchromones

Unlike halochromones considered in Sections II and III, haloalkylchromones containing halogen atoms in the side chain have not received adequate attention. Transformations involving the active halogen atom in the halomethyl or haloacetyl substituent have been mainly considered. In recent years, a number of features of 2-polyfluoroalkyl- and 2-trichloromethylchromones important from the synthetic standpoint have been found; this allowed these compounds to be recommended as readily accessible highly reactive substrates for the synthesis of various heterocyclic derivatives including CF_3 -containing compounds with a potential biological activity.^{167, 168}

a. Nitration and halogenation

On heating with a mixture of nitric and sulfuric acids, 6- and 7-substituted 2-trifluoromethylchromones are nitrated into the 5- and 8-positions, which is in line with the directing effect of substituents, giving rise to compounds **140** and **141**.^{134, 169} The reaction of 5,7-dimethyl-2-polyfluoroalkylchromones with a nitric-sulfuric acid mixture gives 6-nitro derivatives **142** as intermediates, which can be isolated at $0-3^\circ\text{C}$ and converted into 6,8-dinitrochromones **143** at 75°C .^{169, 170} 6,8-Dibromo-2-trifluoromethylchromone is nitrated at 75°C at the 5-position to give chromone **144**. Under more rigorous conditions ($100-160^\circ\text{C}$), 6,8-dibromo-2-trifluoromethylchromone is unexpectedly converted into tribromochromone **145**, i.e., the nitration is accompanied by oxidative destruction giving molecular bromine, which brominates derivative **144** to give **145**.¹⁷¹

2- R^{F} -Chromones **111** unsubstituted in the benzene ring, like their non-fluorinated analogues,³² are smoothly nitrated at the 6-position yielding chromones **146**. When treated with chlorine in the light (CCl_4 , $\sim 60^\circ\text{C}$, 1 h), compounds **111** add a chlorine molecule at the double bond of the pyrone ring and, after elimination of HCl, they are converted into 3-chlorochromones **147**, which are readily nitrated at a high rate to give compounds **148**.^{150, 169, 172} Chloronitrochromones **148** are also formed upon chlorination of compounds **146** but this takes a longer time (8 h).^{150, 169, 172}

$R^F = \text{CF}_2\text{H}, \text{CF}_3, (\text{CF}_2)_2\text{H}$.

The bromination of 6-methyl-2-trifluoromethylchromone **149** with *N*-bromosuccinimide on refluxing in CCl_4 in the presence of azobis(isobutyronitrile) for 1.5 h is directed at the methyl group and results in 6-bromomethyl-2-trifluoromethylchromone (yield 49%).¹⁷³

b. Reactions with mono-, di- and triamines

In 1981, an attempt at using chromone **149** as a protective group in the peptide synthesis was made, which showed for the first time¹⁷³ that secondary amines (dimethylamine and piperidine) add reversibly to the C(2) atom without opening of the pyrone ring to give unstable compounds **150** (in the case of sterically hindered diethylamine, the reaction does not proceed). However, even mere mixing of chromone **149** with primary amines (ethyl- and propylamines) induces opening of the pyrone ring, characteristic of the chromone system, to give aminovinyl ketones **151**.^{174, 175}

$R^3 = \text{Me}, \text{Et}, \text{CO}_2\text{Et}$.

A similar transformation takes place (although at a lower rate) when the chromone **149** is treated with ethyl glycinate in MeCN and DMF but the methyl ester of alanine does not react with this chromone for steric reasons.

Subsequently, the significance of the steric factor in the reactions of 2- CF_3 -chromones **111** ($R^F = \text{CF}_3$) with ammonia and primary amines was also demonstrated for other examples. The nature of the substituent at the 5-position of the chromone system influences the form of existence of the products of this reaction, which can be either ring or open. The attack by the amine on the C(2) atom of 2- CF_3 -chromones **111** for $R^1 = \text{H}$ is accompanied by opening of the pyrone ring and yields aminovinyl

ketones **152**; when $R^1 \neq \text{H}$, the process stops after the nucleophilic addition of the amine, which gives 2-aminochromanones **153** stable on storage. This is due to destabilisation of the open form with $R^1 \neq \text{H}$ by the repulsion between the R^1 substituent located in the *ortho*-position to the oxo group and the vinylic hydrogen atom of the aminoenone system.¹⁷⁶

$R^1 = R^3 = \text{Me}, R^2 = R^4 = \text{H}; R^1 - R^2 = 5,6\text{-benzo}, R^3 = R^4 = \text{H};$
 $R^1 = R^2 = R^3 = R^4 = \text{H}; R^1 = R^2 = \text{H}, R^3 - R^4 = 7,8\text{-benzo};$
 $R^5 = \text{H}, \text{Me}, \text{Bn}$.

In spite of the presence of the methoxy group in the *peri*-position, fluorokhellins **112** also react with ammonia and primary amines mainly along the pathway of pyrone ring opening.^{177, 178}

A change in the direction of nucleophilic attack has been found in a study of the reaction between chromones **111a–g** unsubstituted in the benzene ring and 2-aminoethanol at $\sim 20^\circ\text{C}$. This amine easily reacts with compounds **111a–d** yielding aminovinyl ketones **154a–d**, which precipitate from the reaction mixture over a period of 10–15 min; on long storage, they are hydrolysed to give the starting chromones. Completion of the reaction between 2-aminoethanol and chromones **111e–g** requires more than 24 h. In this case, chromeneimines **119e–g** are formed as products of transformation of 2-aminoethanol involving the carbonyl group.¹⁷⁹ This behaviour of compounds **111e–g**, difficult to explain and unusual for a chromone system, may be related to a specific combination of steric and electronic effects of the R^F groups in these molecules.

$R^F = \text{CF}_3$ (a), CF_2H (b), $(\text{CF}_2)_2\text{OCF}_3$ (c), C_4F_9 (d),
 $(\text{CF}_2)_2\text{H}$ (e), C_2F_5 (f), C_3F_7 (g).

The reactivity of the C(2) and C(4) atoms in chromones **111** towards 2-aminoethanol depends on not only the length of the polyfluoroalkyl chain but also on the nature of the substituent at the 6-position. For example, aminoethanol reacts with 6-methyl-substituted chromone **111** at the C(4) atom (*i.e.*, at the carbonyl group) giving imine **119**, whereas its reaction with 6-nitro-substituted chromone **111** involves the C(2) atom and gives the corresponding aminovinyl ketone **154**, as the electron-withdrawing nitro group facilitates opening of the pyrone ring due to stabilisation of the leaving phenoxide anion.¹⁸⁰

R = NO₂, Me; R^F = (CF₂)₂H, C₂F₅.

6-Nitro-2-trifluoromethylchromone, unlike 2-methyl- and 2-trifluoromethylchromones, reacts with aniline to give aminovinyl ketone. The bulky *tert*-butylamine does not react with 2-CF₃-chromones, and morpholine adds to the C(2) atoms to form 2-morpholino-2-trifluoromethylchroman-4-ones stable during storage. The formation of these products is facilitated by the nitro group present in the benzene ring of 2-CF₃-chromones.^{134, 181}

Unlike non-fluorinated chromones, whose reactions with ethylenediamine give complex mixtures of products,¹⁸² the reactions of 2-R^F-chromones **111** with excess ethylenediamine (EDA) in an ethanol solution (~20 °C, 3 h) are more unambiguous and give rise to 5-(2-hydroxyaryl)-7-polyfluoroalkyl-2,3-dihydro-1*H*-1,4-diazepines **155** (75%–91%).¹⁸³ The reaction is accompanied by opening of the pyrone ring with the formation of aminovinyl ketones **156**, which occur in equilibrium with imidazolidines **157**[‡] and cyclise into the final dihydrodiazepines **155**.

R = H, Me, MeO, Cl; R^F = CF₂H, CF₃, (CF₂)₂H.

Compounds **155** exist in CDCl₃ as the 1*H*-7-R^F-tautomers due to the formation of an intramolecular bond between the phenolic proton and the imine nitrogen atom of the heterocycle. This conclusion was based on the values of the ³J_{H,F} spin–spin coupling constants, which are 2.8–4.5 Hz for molecules with the HCF₂CF₂–C(X)=C fragments, where X = O, N.¹⁸⁴ The values ³J_{H,F} = 3.2–3.4 Hz have been found for dihydrodiazepines **155**; thus, they contain this type of fragment.^{183, 185}

With diethylenetriamine (DETA), chromones **111** are converted into 5-(2-hydroxyaryl)-7-polyfluoroalkyl-1,4,8-triazabicyclo[5.3.0]dec-4-enes **158** (35%–91%), which represent the cyclic form of dihydrodiazepines containing a 2-aminoethyl group at the nitrogen atom located most closely to the fluorinated group. This reaction has virtually no limitations as regards the nature of the polyfluoroalkyl group or the nature and position of the substituent in the benzene ring. It is facilitated by the formation of a strong intramolecular hydrogen bond between the phenolic hydroxyl and the imine nitrogen atom (¹H NMR and X-ray diffraction data).^{186, 187} The first step is nucleophilic addition of the primary amino group to the C(2) atom accompanied by opening of the pyrone ring yielding *N*-substituted aminovinyl ketones, which further cyclise to triazabicyclic products **158** with participation of both electrophilic centres.

[‡] The cyclic products **157** formed in the reaction of ethylenediamine with 8-aza-5,7-dimethyl- and benzo[*h*]-2-trifluoromethylchromones have been isolated.

R = H, Me, MeO, Cl; R^F = CF₂H, CF₃, (CF₂)₂H, (CF₂)₂OCF₃, C₄F₉.

Note that similar products have been obtained from compounds **159** and diethylenetriamine. This reaction can be used to prepare bicyclic compounds **158** having no *o*-OH group in the aromatic ring. In the presence of CD₃CO₂D, the five-membered ring opens and compound **158** is transformed into dication **160**.^{188, 189}

Ar = Ph, 4-MeC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄, 4-BrC₆H₄, 4-NO₂C₆H₄, 2-HOC₆H₄, 2-C₄H₃S, 2-C₄H₃O; R^F = CF₃, (CF₂)₂H.

It should be emphasised that the formation of bicyclic products **158** is typical only of 2-R^F-chromones and R^F-aminovinyl ketones, where the polyfluoroalkyl group substantially increases the reactivity of the carbon atom that carries this group. This reaction does not proceed for non-fluorinated analogues. For example, 2-methylchromone reacts with diethylenetriamine under conditions used to prepare compounds **158** to give bisaminoenone **161**.¹⁸⁷

On keeping in ethanol for a week, compound **158a** [Ar = 2-HO-5-MeOC₆H₃, R^F = (CF₂)₂H] isomerises into dihydrodiazepine **162**; its structure was established by X-ray diffraction.^{187, 190} This unusual rearrangement may start with cleavage of the C(7)–N(1) bond, while the triazacyclodecadiene thus formed may be converted into **162** by intramolecular transamination.

Thus, the reaction of 2- R^F -chromones with amines usually starts with the attack by the amino group on the C(2) atom. In the case of secondary amines or in the presence of a substituent at the 5-position, the reaction can stop after 1,4-nucleophilic addition; however, in most cases, it is accompanied by pyrone ring opening giving the corresponding aminovinyl ketones, whose structural features and subsequent transformations provide a variety of products. An exception is the reaction of 2- R^F -chromones with 2-aminoethanol; with $R^F = (CF_2)_2H$, C_2F_5 and C_3F_7 , it gives chromeneimines **119**, pointing to the possibility of an attack by the amine on the carbonyl group.

c. Reactions with hydrazines, hydroxylamine and sodium azide

The reactions of chromanones **110** and chromones **111** with hydrazine hydrate resulted in the synthesis of 3(5)-(2-hydroxy-aryl)-5(3)-polyfluoroalkylpyrazoles that have a planar conformation and mainly exist as 1*H*-5- R^F -tautomers **163a** in $CDCl_3$ and as 1*H*-3- R^F -tautomers **164a** in DMSO. The reaction with phenylhydrazine allows one to synthesise regioisomeric 5- R^F -pyrazole **163b** from compounds **110** and 3- R^F -pyrazoles **164b** from compounds **111**. With methylhydrazine, only the 3- R^F -regioisomers **164c** are formed. Under mild conditions, the reaction of chromanones **110** with hydrazines can be arrested after the formation of dihydropyrazoles **165**.¹⁹¹

$R^1 = H, Me, MeO, Cl$; $R^2 = H$ (a), Ph (b), Me (c).

The products formed from chromanones **110** and hydroxylamine hydrochloride in the presence of AcONa are oximes existing in the ring isoxazoline form **166** owing to the high electrophilicity of the carbonyl carbon atom.¹³³ Under similar conditions, chromones **111** react at the C(2) atom rather than at the oxo group and give isomeric oximes **167**, which do not tend to cyclise, unlike the aliphatic analogues,¹⁹² and exist in the linear oxime form. The change in the direction of the nucleophilic attack on passing from compounds **110** to **111** makes it possible to synthesise regioisomeric 5- R^F -isoxazoles **168** (refluxing of isoxazolines **166** in toluene with $SOCl_2$) and 3- R^F -isoxazoles **169** (refluxing of oximes **167** in AcOH with HCl). By investigating isoxazoles **168** and **169** by ^1H , ^{19}F and ^{13}C NMR spectroscopy, a number of specific features were revealed, which make it possible to distinguish between these regioisomers.¹³³

Fluorokhellins **112** react with hydrazine and hydroxylamine in a similar way; they were used to prepare R^F -containing pyrazoles and regioisomeric isoxazoles of the benzofuran series.^{177, 178}

$R = H, Me$; $R^F = CF_2H, CF_3, (CF_2)_2H$.

3-Chlorochromones **147** and **148** are resinified even at $\sim 20^\circ C$ on treatment with hydrazine hydrate, while refluxing of these compounds in ethanol with hydrazine dihydrochloride for 4–48 h gives 4-chloropyrazoles **170** in good yields.¹⁷² In view of the chemical reactivity of the 3-halochromones considered above (see Section III.2), this transformation does not appear evident, because it is the first example of a reaction of 3-halochromone with a nucleophile with retention of the halogen atom in the reaction product. When chromones **147** and **148** are refluxed with hydroxylamine hydrochloride in ethanol in the presence of AcONa, contraction of the pyrone ring to the furan ring, typical of 2-unsubstituted 3-halochromones, takes place to give derivatives **171** (58%–91%). These products are of interest as regards subsequent transformations into various R^F -containing heterocycles.¹⁹³

$R = H$ (**147**), NO_2 (**148**); $R^F = CF_2H, CF_3, (CF_2)_2H$.

It has been suggested¹⁹³ that the reactions of chromones **147** and **148** with hydrazine and hydroxylamine involve intermediate **A** resulting from the attack of the NH_2 group on the C(2) atom with opening of the pyrone ring. This is followed by either an intramolecular A_N-E reaction between the $C=O$ and NH_2 groups (for $X = NH_2$) or nucleophilic substitution of the phenolic hydroxyl for the chlorine atom ($X = OH$). According to the IR, ^1H NMR and ^{19}F NMR data, the isomer and tautomer composition of oximes **171** depends on the number of fluorine atoms in the R^F -substituent, the nature of substituents in the benzene ring and the solvent nature. The nitro derivatives exist almost entirely, both in the solid state and in solution in $CDCl_3$ or

DMSO- d_6 , as the enol form represented by the *Z*-isomer when $R^F = CF_3$, $(CF_2)_2H$ and by a *Z*- and *E*-isomer mixture when $R^F = CF_2H$. When the nitro group is missing, a mixture of two stable keto-enol tautomers of oximes **171** is formed.¹⁹³

By the reaction of 2- CF_3 -chromones **111** with sodium azide (AcOH, EtOH, 80 °C, 4–10 h), salicyloyltriazoles **172** were prepared (50%–86%); hence, the 2- CF_3 -chromones **111** can be considered as synthetic equivalents of trifluoropropynyl ketones **173**, which are difficult to prepare.¹⁵¹ This reaction is a novel transformation involving the chromone system. It should be noted that on replacement of the CF_3 group by H, CF_2H , $(CF_2)_2H$ or CCl_3 , the reaction does not take place and without an electron-withdrawing group at the 6-position, the reaction slows down to such an extent that 2-trifluoromethylchromone is recovered unchanged after a 10-hour contact with NaN_3 under the conditions described above.¹⁵¹

The reactivity of the pyrone ring with respect to NaN_3 can be increased by replacement of the $C=O$ group by the $C=NR$ group. It was shown¹⁵¹ that the presence of an electron-withdrawing group in the benzene ring is not obligatory for chromoneimines **119**, and they easily react with NaN_3 in the presence of AcOH to give aryltriazolylketone imines **174**. This is due to the fact that, being rather strong bases, compounds **119** are protonated at the imine nitrogen atom even in the presence of AcOH,¹⁷⁹ thus generating iminium cations, which participate in the reaction. Hydrolysis of imines **174** affords triazoles **172**, which could not be synthesised from the corresponding 2- CF_3 -chromones. Since the transformations **117** $\rightarrow$ **119** and **119** $\rightarrow$ **172** proceed *via* common iminium intermediate **118**, it comes as no surprise that aminovinyl ketones **117** are converted under these conditions into triazoles **172** as easily as chromoneimines **119**.

d. Reactions with alkyl sulfanylacetaes

One of the most unexpected and interesting reactions of 2- CF_3 -chromones **111** is the reaction with ethyl sulfanylacetaes in the presence of Et_3N , which results in 1,2-dihydro-2-trifluoromethyl-4*H*-thieno[2,3-*c*]chromen-4-ones **175** (66%–93%) and diethyl 3,4-dithiaadipate.¹⁹⁴

The formation of these products is indicative of the redox pattern of the given transformation. The nature and the positions of substituents in the benzene ring do not affect significantly the course of the reaction; however, as in the case of sodium azide, this reaction can be accomplished only with 2- CF_3 -chromones. The reaction mechanism is not entirely clear but, most likely, as in the case of 3,3-dialkyl-6-trifluoromethyl-2,3-dihydro-4-pyrones,¹⁹⁵ the reaction starts with the formation of the benzo derivative of 2-oxa-7-thiabicyclo[3.2.1]octane **176**. The subsequent reductive opening of the pyrone ring in **176** induced by ethyl sulfanylacetaes leads to ether **177**, which cyclises yielding dihydrothienocoumarin **175**.

Interestingly, the reaction of alkyl sulfanylacetaes with fluoro-khellins **112**, although they are closely related to chromones, stops after the formation of products **178** (66%–85%), represented by a single diastereomer with *cis*-arrangement of substituents in the thiolane fragment (X-ray diffraction data).^{150, 196} Only under rigorous conditions (sealed tube, 150 °C), were 7- CF_3 - and 7- CF_2H -norkhellins **112** converted into dihydrothienopsoralens **179**, which can also be synthesised from compounds **178**. This proves that compounds **178** are intermediates.¹⁹⁶

Selective oxidation of dihydrothienocoumarins **175** gives rise to highly reactive substrates, namely, sulfoxides **180** (NO_2 , CHCl_3) and sulfones **181** (H_2O_2 , AcOH). Under Pummerer rearrangement conditions, sulfoxides **180** produce thienocoumarins **182**,¹⁵⁰ and sulfones **181** are transformed into 3-hydrazino-6-(2-hydroxyaryl)pyridazines **183** under the action of hydrazine.¹⁹⁷ Previously, these pharmaceutically valuable products providing the basis for a series of 3-hydrazinopyridazine drugs,¹⁹⁸ were synthesised in seven steps starting from phenols and succinic anhydride.¹⁹⁹

R = H, Me, Cl.

R = H, Me, MeO, NO_2 , NH_2 .

The reaction of 8-nitosulfone with hydrazine has been used to elucidate the mechanism of the unusual transformation of sulfones **181** into pyridazines **183**. The reaction was arrested after an intermediate step that gave intermediate **A**. On the basis of spectroscopic data, the isolated intermediate **A** was identified as having a benzocyclononene structure, which allowed the researchers to propose a possible reaction pathway. It was suggested¹⁹⁷ that this reaction starts with the attack of the keto group of sulfone **181** by the hydrazine molecule, resulting in the replacement of the carbonyl oxygen atom by a hydrazone group. The subsequent hydrazinolysis and hydrolysis of the CF_3 -group to CONHNH_2 , the addition of a hydrazine molecule to the activated double bond and cleavage of the shared bond in the bicyclic structure furnish intermediate **A**. Further transformation of this intermediate

involves elimination of SO_2 yielding the hydrazine derivative of β -aroylacrylic acid, which is then converted into pyridazine **183** upon an intramolecular cyclisation.

This reaction can find wide application, as it represents a new approach to the synthesis of 3-hydrazinopyridazines from readily available compounds, namely, 2-hydroxyacetophenones and ethyl trifluoroacetate.

e. Reactions with C-nucleophiles

Nucleophilic trifluoromethylation of organic compounds is complicated by appreciable instability of the free trifluoromethyl anion, which tends to decompose giving the fluoride anion and difluorocarbene. By using trimethyl(trifluoromethyl)silane (Ruppert's reagent) in the presence of fluoride anions, one can avoid decomposition and accomplish direct insertion of the CF_3 group into the organic substrate. Ruppert's reagent easily reacts with both saturated and α,β -unsaturated carbonyl compounds according to the 1,2-nucleophilic addition pattern yielding the corresponding trifluoromethylated alcohols.^{200–202} The reaction of $\text{R}^{\text{F}}\text{SiMe}_3$ with 2- R^{F} -chromones is the first example of preparative 1,4-trifluoromethylation of the α,β -enone system.^{203,204} ^{19}F NMR monitoring of this system showed that in the presence of the nucleophilic initiator Me_4NF (THF, 0°C , 4 h), chromones **111** react almost quantitatively and with high regioselectivity with CF_3SiMe_3 along the 1,4-addition route to give trimethylsilyl ethers **184** (the contents of 1,2-addition products **185** in the reaction mixture does not exceed 10%–12%). When the reaction mixture is treated with dilute HCl, only 1,4-addition products **184** are hydrolysed giving 2,2-bis(trifluoromethyl)chroman-4-ones.

R = H, Me.

This reaction has been used²⁰⁴ to prepare fluorinated analogues of naturally abundant chromanones with the *gem*-dimethyl group at the 2-position. Oxidation of the 6-Me group of chromanone **186** with a mixture of $\text{K}_2\text{S}_2\text{O}_8$ and CuSO_4 in aqueous acetonitrile provided the synthesis of aldehyde **187a** — an analogue of natural lactarochromal (a metabolite of the fungi *Lactarius deliciosus*²⁰⁵) in which both methyl groups have been replaced by trifluoromethyl groups. Apart from hexafluorolactarochromal **187a**, the corresponding acid **187b** was obtained, which is also a fluorinated analogue of the natural acid isolated from the plant *Chrysothamnus viscidiflorus*.

R = H (a), OH (b).

A fairly unexpected reaction has been reported.²⁰⁶ By refluxing equimolar amounts of *N*-benzyl-2-trifluoromethylchromene-4-imines **119** and malonic acid in dioxane, 2-methyl-2-trifluoromethylchroman-4-ones **188** were obtained in ~60% yields. In this transformation, malonic acid functions as a methylating agent. Presumably,²⁰⁶ the first step of the reaction is mutual activation of the starting compounds; in particular, malonic acid protonates the chromeneimine to give the iminium

cation, which results in a higher electrophilicity of the C(2) atom, while chromeneimine, which is a rather strong base, deprotonates the activated CH₂ group of the acid, thus increasing its nucleophilicity. This mutual activation is crowned with the addition of malonic acid at the C(2) atom to form intermediate **A**, whose decarboxylation gives acid **B**. The ease of decarboxylation of the second CO₂H group is attributed to opening of the pyrone ring in intermediate **B**. As a result, intermediate **C** is produced. The subsequent cyclisation and hydrolysis of intermediate **C** in the presence of HCl afford chromanones **188**.

R = H, Me.

Methylmalonic and phenylacetic acids do not react with chromeneimines under similar conditions. Malonic acid does not methylate 2-CF₃ chromones in the presence of pyridine.

Oxidation of the 6-Me group in chromanone **188** by K₂S₂O₈ has yielded aldehyde **189a**, an analogue of lactarochromal in which, unlike aldehyde **187a**, only one of the methyl groups is replaced by the trifluoromethyl group. In addition to trifluoro-lactarochromal **189a**, the corresponding carboxylic acid **189b** was also isolated.²⁰⁶

R = H (a), OH (b).

The reaction of 6-nitro-2-R^F-chromones **111** with 1,3,3-trimethyl-3,4-dihydroisoquinolines (THF, 20 °C, 4 days) affords coloured (from orange to dark red) chiral zwitter-ions **190** in 50%–80% yields; the structure of these products was confirmed by X-ray diffraction analysis.^{150, 207} This reaction is typical only of 6-nitro derivatives, it involves an attack of the C(2) atom of chromone by the enamine tautomer of dihydroisoquinoline followed by cyclisation involving the carbonyl group with elimination of a water molecule. According to the ¹H NMR spectra of these compounds, the protons of the CH₂ group attached to the heterocyclic fragment are diastereotopic and account for an AB system with J_{AB} = 16.5 Hz. This attests to hindered rotation around the bond that connects the phenolate residue and the heterocycle and to the existence of the zwitterions **190** as atropoisomers. On heating or in the presence of sulfuric acid, the steric strain in the molecule is removed due to cleavage of the Me₂C–N bond, resulting in the formation of isomers **191**, differing in the position of the double bond in the alkenyl substituent.

R^F = CF₃, CF₂H, (CF₂)₂H; R = H, Me, OMe.

Thus, as distinct from highly reactive 5,5,5-trifluoropent-3-en-2-one studied previously, which easily adds a variety of nucleophilic species to the C=C bond,²⁰⁸ 2-R^F-chromones considered in this Section incorporate, apart from a similar fragment, a good leaving group at C(2), which increases appreciably the synthetic value of these compounds. Modification of 2-R^F-chromones by introducing electron-withdrawing substituents and/or a halogen atom into the 3-position of the benzene ring not only increases the reactivity of these compounds with respect to nucleophiles but also alters the route of some reactions. The replacement of the C=O group by a C=NR group further extends the synthetic potential of the chromone system. It is also noteworthy that the trifluoromethyl group occupies a special place among polyfluorinated substituents, because the most interesting and peculiar transformations with N-, S- and C-nucleophiles, such as addition of morpholine and reactions with sodium azide, ethyl sulfanylacetate and malonic acid can be carried out only for 2-CF₃-chromones and their derivatives.

2. The properties of 2-trichloromethylchromones and halomethylchromones

The trichloromethyl group is known to be a synthetic equivalent of the carboxy group to which it is transformed upon hydrolysis. For example, refluxing of 5-trichloromethylisoxazole with water or alcohols in the presence of sulfuric acid affords isoxazole-5-carboxylic acid and its esters in high yields.²⁰⁹ However, the 2-trichloromethyl group in chromones cannot be hydrolysed in an acid medium, while on treatment with a methanol solution of KOH, this group is replaced by a hydroxy group, which results in the formation of 4-hydroxycoumarins **192**. On treatment with an alcohol solution of ammonia, the pyrone ring in 2-CCl₃-chromones **126** is opened, giving rise to aminoenones **127**, which are hydrolysed in hydrochloric acid giving again chromones **126**.¹⁵⁹

$\text{R} = \text{H, Me, MeO, Cl; } n = 1 \text{ (193a), } 2 \text{ (193b)}.$

The 2- CCl_3 -chromones **126** react with ethylene- and trimethylenediamines differently from 2- R^{F} -chromones. This reaction is a new convenient method for the synthesis of 2-phenacylideneimidazolidines **193a** and -hexahydropyrimidines **193b** ($\sim 20^\circ\text{C}$, 3–5 h, yield 50%–95%),^{210, 211} which have been prepared formerly by cyclocondensation of diamines with α -oxoketene dithioacetals.²¹² The reaction involves the intermediate formation of aminoenones with a 2-aminoethyl or 3-aminopropyl group at the nitrogen atom. Cyclisation of these aminoenones is accompanied by elimination of the CCl_3 group, which leads to products **193a,b**, existing in DMSO- d_6 and CDCl_3 solutions as keto-amine tautomers.^{210–212} The conjugation of the lone electron pairs of the nitrogen atoms with the carbonyl group markedly increases the electron density on the *exo*-methylene carbon atom of enediamines **193a,b**; as a consequence, this atom is the first to be attacked by electrophiles and 1,3-dipoles. The subsequent involvement of nitrogen or the carbonyl group in the reaction makes these substances valuable substrates for the synthesis of new heterocyclic systems that are difficult to obtain by other methods.^{213, 214}

7-Trichloromethylnorkhellin **131** reacts with ethylene- and trimethylene-diamines in a similar way, giving rise to enediamines of the benzofuran series. The reaction of compound **131** with a methanol solution of KOH gives a new khellin derivative, 7-methoxynorkhellin,¹⁷⁷ instead of the expected 4-hydroxyisopimpinellin.²¹⁵

Thus, the high reactivity of 2-trichloromethylchromones, which is manifested as easy opening of the pyrone ring with simultaneous replacement of the CCl_3 group under the action of aliphatic diamines, makes these compounds useful substrates for the preparation of partially hydrogenated heterocycles, which are of synthetic interest by themselves.

The reactivity of halomethyl derivatives of chromones is similar to that of benzyl halides, which was reflected in a series of publications. For example, 6-bromomethyl-2-trifluoromethylchromone reacts with caesium salts of α -amino acids (DMF,

25°C , 4 h) to give esters **194**, which have been proposed as protective groups for the carboxy function in the peptide synthesis.¹⁷³ The easy replacement of the carboxylate group in **194** on treatment with propylamine during the synthesis of aminovinyl ketones **195** was attributed¹⁷³ to the formation of the quinone-methide intermediate.

The bromine atom in ethyl 3-bromomethylchromone-2-carboxylate is readily replaced by an amino-, cyano- or acetate group, or can be involved in intramolecular cyclisation giving 1*H*-furo[3,4-*b*]chromene-3,9-dione.⁵³

The reduction of 7-iodo- and 7-chloromethylnorvisnagins **135** by zinc dust in AcOH smoothly leads to visnagin.^{163, 164} Ammiol **196** — the natural furochromone least abundant of the furochromones isolated from the plant *Ammi visnaga* L., — has been prepared from 7-iodomethylnorkhellin **137** via intermediate acetate **197** in a high final yield. Upon oxidation by potassium peroxide, 7-iodomethylnorkhellin **137** is directly converted into ammiol **196**, but the yield is low (27%). On treatment with dimethylamine, **137** is transformed into the amino-substituted khellin **198**.¹⁶⁵

The reaction of iodokhellin **137** with 4,4'-trimethylenedipiperidine in MeCN in the presence of K_2CO_3 affords bisaminofurochromone **199**, which is a potential antiatherosclerotic agent.²¹⁶

Bromoacetyl derivatives of chromones have found use in the synthesis of biologically active compounds. The condensation of 3-bromoacetyl-2-methylchromones **200** with thioamides and thiourea results in 3-(thiazol-4-yl)-2-methylchromone hydrobromides, which were converted into free bases **201** (69%–85%) by treatment with an aqueous solution of NH_3 .^{217, 218} The reaction of chromone **200** with potassium thiocyanate allows one to obtain 3-thiazolylchromones **202**, which contain a residue of a cyclic secondary amine in the thiazole ring and exhibit a high anti-inflammatory activity.²¹⁹ The last-mentioned reaction involves the intermediate formation of compounds **203** and 3-(2-chloro-4-thiazolyl)-2-methylchromones **204**.

$R^1 = \text{H, Me}; R^2 = \text{Ar, NH}_2, \text{NHAr, Het}; Z = \text{O, NH}.$

VI. Conclusion

Analysis of the published data demonstrates that of the diverse halogen-containing chromones, 3-halo- and 2-polyhaloalkylchromones, as well as chromones with the perfluorinated benzene ring have now been studied most comprehensively.¹⁸ Data on 2-halo-chromones are quite scarce and data on 3-polyhaloalkylchromones are totally missing. The introduction of a halogen atom into the 3-position of the chromone system changes crucially the reactivity of the pyrone ring with respect to nucleophiles and stipulates the broad synthetic potential of 2-unsubstituted 3-halochromones. The diversity of properties of these compounds is due to the fact that, being actually highly reactive geminally activated haloalkenes¹⁰¹ with a good leaving group at the β -carbon atom, they acquire the ability to undergo additional reactions related to opening and transformation of the γ -pyrone ring. In addition, 3-halochromones are valuable substrates in homo- and cross-coupling reactions catalysed by transition metal complexes. These reactions have been used to prepare various 3-substituted chromones, 3,3'-bischromones and isoflavones.

Strangely enough, but, despite the ready accessibility of 2-polyfluoroalkylchromones, these compounds have long remained out of sight of chemists engaged in synthesis, and their systematic study has started only in recent years. Nevertheless, it is already clear that 2- R^F -chromones and, in particular, fluorinated analogues of a natural furochromone, khellin **2a**, are valuable substrates for the synthesis of diverse fluorine-containing heterocycles with a potential biological activity. Indeed, a polyfluoroalkyl group present at the C(2) atom entails dramatic changes in the reactivity of the pyrone ring, which is manifested as a bunch of new transformations (this is especially pronounced for the CF_3 group) absolutely uncharacteristic of 2-alkylchromones. It is of interest that 2- R^F -chromones substantially differ in reactivity from 2- CCl_3 -chromones, which tend to give off the trichloro-

methyl group on treatment with nucleophiles. In view of the fact that 20% to 30% of modern pharmaceuticals and 30% to 40% of agrochemical preparations contain at least one fluorine atom in the molecule,²²⁰ the research dealing with modification and study of the reactivity of 2- R^F -chromones and their derivatives aimed at extending the synthetic scope of the chromone system appear to be a topical and promising line for the future research into fluorine-containing heterocyclic compounds and search for new biologically active substances.

The review was written with support from the Russian Foundation for Basic Research (Project No. 02-03-32706). The author is grateful to D V Sevenard and M A Shafeev for assistance in selection of publications.

Sulfide hydrodesulfurisation catalysts: structure of the active component and mechanism of the catalytic action

A N Startsev, I I Zakharov

Contents

I. Introduction	517
II. The structure of the active component of sulfide catalysts of hydrodesulfurisation	518
III. The concerted mechanism of thiophene hydrogenolysis on sulfide catalysts	525
IV. The concept of the determining role of the metal–sulfur bond energy in heterogeneous catalysis by metal sulfides	528
V. Conclusion	533

Abstract. A new phenomenon in heterogeneous catalysis, namely, oxidative addition of hydrogen to active metal atoms (Ni, Co) within sulfide hydrodesulfurisation catalysts, is considered. The possibility of hydrogen occlusion into the MoS₂ matrix of the active components of these catalysts is demonstrated. The electronic structure of Ni(IV) and Co(III) active sites with d⁶ electronic configuration is analysed. The concerted mechanism of thiophene hydrogenolysis on a bimetallic active site is considered and substantiated. The concept of the governing role of the metal–sulfur bond energy in catalysis by metal sulfides is analysed critically. The bibliography includes 198 references.

I. Introduction

Hydrotreating of oil fractions is the largest-scale process in the petroleum refining industry. Over 80 million barrels of oil (about 12.7 million m³) are processed in the world daily; the average sulfur content in this oil being 1.0 mass %–1.3 mass %.¹ In the last decade, the requirements for the quality of motor and jet fuels have increased considerably due to deterioration of the environmental conditions. According to the EC Directive of 11.05.2001, the total content of sulfur in diesel fuel should not exceed 50 ppm by 2005, whereas the content of aromatic compounds should not exceed 10 vol.%. The existing industrial hydrotreating catalysts only ensure a decrease in the sulfur content to ~ 500 ppm in diesel fuel; the required level can be achieved by either increasing the process temperature by 38 °C,² or decreasing considerably the liquid hourly space velocity of the feed stock, or, finally, enhancing considerably the activities of catalysts. The latter variant is the most cost-effective because the contribution of the catalyst cost to the production cost of the hydrotreating product is less than 0.5%. Therefore, world leading laboratories pay much attention to the development of new-generation catalysts for the deep hydrotreating of oil fractions. This can be illustrated by the fact that the range of hydrotreating catalysts includes more than 200 trade names.³

In this review, we will not dwell on the methods for catalysts' preparation, their chemical compositions, porous structures, kinetic studies of the hydrotreating process, *etc.* The issues of catalytic hydrotreatment of oil fractions are probably considered in most detail in the monograph by Topsøe *et al.*;⁴ the problems of deep hydrotreating, in the review by Vasudevan and Fierro;⁵ specific features of hydrogenolysis of polyaromatic sulfur-containing compounds, in the paper by Whitehurst *et al.*;⁶ and certain technological problems are analysed in the paper by Furimsky.⁷

The main purpose of this review is to analyse the fundamental aspects of hydrogenolysis of the C–S bond on sulfide hydrotreating catalysts. A decade has passed since the publication of the previous review on this subject.⁸ Considerable progress in understanding the mechanism of action of sulfide catalysts at the molecular level has been made during this period. Generally speaking, establishing the mechanism of heterogeneous catalysis and the nature of chemical interaction of reactants with solid catalyst surfaces is a very difficult task. This originates from the following reasons:

- as a rule, several types of compounds differing in composition and structure are present on a catalyst surface; as a result, chemical transformations occur in various directions and pathways to give diverse intermediates and side products in the gas phase;

- the degree of surface coverage by adsorbed molecules can vary over a very broad range, which complicates kinetic studies;

- in the overwhelming majority of cases, the structures of active sites on solid catalysts are unknown; therefore, certain theoretical models of the active component have to be used, based on analogies with the known structures [in this sense, sulfide hydrotreating catalysts present a rare exception: the geometric structures of their active components have been studied rather thoroughly (see below)];

- until now, there has been a lack of sufficiently sensitive physical methods (similar to multinuclear NMR in homogeneous catalysis) that would enable *in situ* studies of adsorption and chemical transformations of molecules on a surface;

- as a rule, heterogeneous catalytic reactions occur under drastic conditions (at high temperatures and pressures) where the reaction medium can affect the structure of the active component.

It is only the chemical and phase compositions of a catalyst that are usually known, and the structure of the active component is determined using a number of physical, chemical and kinetic methods in order to obtain responses of the catalytic system to various external impacts. Subsequently, correlations between the catalyst's activity and selectivity, on the one hand, and some

specific parameter, on the other, are plotted and general features of a given chemical reaction are revealed.

There are two independent and mutually exclusive concepts of the mechanism of hydrodesulfurisation which are being developed simultaneously. In one of them it is assumed that the decisive role in the mechanism of catalysis by metal sulfides belongs to the bond energy of surface sulfur atoms with the solid catalyst. The other one, which is being developed at the G K Boreskov Institute of Catalysis, is based on the concept of the common nature of heterogeneous, homogeneous and enzyme catalysis as a natural phenomenon. The present review is devoted to the consideration of these concepts.

II. The structure of the active component of sulfide catalysts of hydrodesulfurisation

1. The geometric structure of the active component

Industrial catalytic hydrotreating of oil fractions began in the middle of the 1950s because of the necessity of preparation of gasoline fractions for the reforming process. In turn, reforming served as a source of inexpensive hydrogen required for hydrotreating. Hydrotreating was initially performed on a composition of sulfide compounds of two metal pairs, *viz.*, Mo(W)–Ni(Co). These catalysts were used in coal liquefaction which was developed in Germany in the middle of the 1930s. Until now, they remain unsurpassed and possess the best combination of operational properties,⁹ *viz.*, activity, stability, resistance against poisons, cost, *etc.*, though intense searches for new catalytic systems were carried out throughout all these years.

The accumulation of experimental data on the general regularities of hydrogenolysis of the C–S bond on these catalysts favoured the appearance in the 1950s–1960s of the first model of the structure of the active component;¹⁰ it was called the ‘monolayer’ model.¹¹ Later, this model was improved^{12,13} taking into account the inevitable sulfidation of the catalyst under the working conditions.

In parallel with the monolayer model, other models based on concepts of the sulfide forms of the MoS₂ and WS₂ catalysts appeared and were developed; these include intercalation models^{14–16} and models with spatially separated MoS₂ and Co₉S₈ clusters.¹⁷ A special place is occupied by models of surface complexes and boundary grains proposed by Phillips and Fote.¹⁸

The appearance in the 1960s of new methods for the study of highly dispersed species in supported catalysts opened prospects for more detailed studies of the active component of hydrodesulfurisation catalysts. This led to new models suggesting that bimetallic sulfides are the active components.^{19,20} The model known as ‘synergism upon contact’ was transformed into the ‘long-range control’ model.²¹ We believe that the most attractive model is that proposed by Ratnasamy and Sivasanker.²² It assumes that ‘promoter’ atoms, *viz.*, Co or Ni, are added to free valence bonds of the S atoms at the MoS₂ edge plane. However, this viewpoint did not receive convincing experimental confirmation; therefore, other models were created later (in the 1980s) based on the concept of a single MoS₂ slab[†] with Co ions incorporated at the edge plane.

Probably, the model of ‘Co–Mo–S phase’ developed by Topsøe *et al.*⁴ was recognised as the best; it assumed the localisation of Co ions at the edge plane of a single MoS₂ slab. This model was based on results of a Mössbauer emission spectroscopic study of catalysts, which was later confirmed by EXAFS data. Subsequently, this model was developed by other authors.^{23–27} The similarity of the structures of MoS₂ and the

Co–Mo–S phase is undoubted, but there are at least three viewpoints on the localisation of the Co(Ni) ions. For example, Nieman *et al.*²⁸ assume that Co or Ni atoms have a square-planar coordination of sulfur atoms located at the (10 $\bar{1}$ 0) edge of a single MoS₂ slab. Bouwens *et al.*²⁹ believe that a square-pyramidal surrounding of five sulfur atoms at the edges of a single MoS₂ slab is characteristic of Co, whereas Ledoux *et al.*³⁰ proposed distorted tetrahedral and octahedral coordinations for them (which followed from data obtained by ⁵⁹Co NMR).

An essentially similar model called ‘SBMS’ (sulfide bimetallic species) has been developed at the G K Boreskov Institute of Catalysis.^{8,31–35} Using modern physicochemical methods for studies of solid catalyst surfaces, it was shown that an SBMS consists of a single MoS₂(WS₂) slab with Ni(Co) atoms at its (10 $\bar{1}$ 0) edge plane. Figure 1 shows the structure of an SBMS active complex with an occluded hydrogen atom. The Ni(Co) atoms are coordinated to four sulfur atoms of the MoS₂ matrix, while the fifth coordination site is occupied by an adsorbed H₂S molecule. In such a case, the Ni(Co) atom is located in the centre of a square pyramid of sulfur atoms (the distance from the base plane to the Ni(Co) atom is 0.5 Å). The occluded hydrogen atom is located in the centre of an ‘empty’ trigonal prism of the MoS₂ sulfide matrix at a distance of 1.5 Å under the Ni(Co) atom.

Figure 1. Structure of the active component of sulfide hydrodesulfurisation catalysts with an occluded hydrogen atom.

The bases of the trigonal prisms made of sulfur atoms, in the centres of which molybdenum atoms are located, are cross-hatched.

The SBMS model differs from other similar models in a number of points which we believe to be fundamental; they are listed below.

1. The necessary and sufficient structural element in SBMS consists of a single slab of MoS₂ (or some other disulfide that crystallises according to the molybdenite structural type) with ions of a transition metal (nickel, cobalt or any other metal that can interact with the sulfide matrix) situated at its edge plane. These ions are the catalyst active sites. This structure is also found in bimetallic sulfides ‘Ni–W–S’, ‘Cu–W–S’, ‘Ni–Nb–S’, ‘Ni–Re–S’, *etc.*, whose matrices crystallise according to the molybdenite (MoS₂) structural type.³¹

2. Hydrogen occluded during the catalyst sulfidation step is the second essential element of SBMS. It is hydrogen that defines the electronic structure of the active metal atom. The SBMS model does not make distinction between the square-planar and square-pyramidal coordination of active metal ions; these two states are transformed into each other once occluded hydrogen and adsorbed hydrogen sulfide have been eliminated.

3. The bimetallic sulfide species is an electrically neutral macromolecule.

4. The SBMS sizes on the surfaces of various supports in the most active catalysts do not exceed 10–20 Å, which means that no separate phase of this compound exists (in the crystallographic sense). Only the MoS₂ or WS₂ phase is detected by diffraction methods.

[†] A single MoS₂ slab is a sandwich in which a layer of molybdenum atoms is arranged between two layers of sulfur atoms, so that a molybdenum atom is located in the centre of a trigonal prism of sulfur atoms and every second prism remains ‘empty’.

The SBMS model was developed using highly active sulfide catalysts obtained by the synthesis of the corresponding metal-complex precursors on supports of differing nature (Al_2O_3 , SiO_2 , a new carbon material Sibunit) followed by their conversion to the sulfide form.^{36,37} The catalysts prepared by this method had uniform chemical compositions. This made it possible to obtain more reliable information about the structure of the active component and about the electronic state of the constituent metal ions. The following methods were used to study the structure of the active component: high-resolution transmission electron microscopy (HRTEM),³⁸ X-ray photoelectron spectroscopy (XPS),³⁹ X-ray radial atomic distribution,⁴⁰ EXAFS.⁴¹ In all the cases (except XPS, as explained below), the results obtained are in good agreement with the available literature data; therefore, we have the right to state that synthesis of catalysts from metal-complex precursors provides the same structure of the active component as that in catalysts prepared by traditional methods. On the other hand, the higher activity of the catalysts obtained from metal-complex precursors in comparison with those prepared by traditional methods demonstrates the superiority of systems with uniform composition of surface compounds. It can be expected that in this case all the supported metal is involved in the active component and participates in the catalytic reaction.

2. The electronic structure of the active component

The electronic structure of the transition metal atom (or ion) is a key factor determining the catalytic activity of sulfide catalysts. It is the metal electronic structure and the ligands surrounding it that determine its ability to adsorb a substrate molecule. However, the electronic structure of metal atoms in the active component of sulfide catalysts has not been considered in the literature. This stems from the complexity of the system in question and the absence of adequate models describing the state of active metal atoms.

X-Ray photoelectron spectroscopy is a main method for the study of the electronic state of metals in supported catalysts. Numerous XPS studies of complex compounds of metals with organic and inorganic ligands showed⁴² that the binding energy (E_b) of electrons on the central atom levels is a complex function of the metal oxidation state, coordination state and the nature of atoms involved in the first coordination sphere. The metal-metal chemical bond can also contribute significantly to this dependence. Nevertheless, E_b can characterise the metal oxidation state or its formal charge provided that the first coordination sphere of the metal is the same. However, studies of solid catalysts inevitably involve a number of experimental difficulties in the determination of this magnitude, as described in sufficient detail in reviews.^{43,44}

XPS was also used to study the electronic state of metals in sulfide catalysts.^{45–49} Different types of catalytic systems were studied, including bulk catalysts and catalysts on oxide (Al_2O_3 , SiO_2) and carbon (Sibunit) supports, at different steps of genesis. While the results regarding the state of Mo (or W) ions are in most cases consistent with data on bulk MoS_2 and WS_2 samples, the state of Co (or Ni) ions is a matter of discussion.⁴ This is primarily due to the non-uniform composition of surface compounds which results in broadening of XPS spectral lines.

Shortly after we started studies on sulfide catalysts prepared from organometallic precursors, we obtained quite an unexpected result:³⁹ the $\text{Ni}2p_{3/2}$ line turned out to be shifted by 1 eV towards higher binding energies in comparison with the similar line of highly dispersed nickel sulfide, which suggested an increase in the oxidation state of the Ni atom. Later, this result was reproduced with remarkable permanency for many systems, including both bulk systems⁵⁰ and those supported on alumina.⁵¹ Opponents asked a reasonable question: considering that nickel (or cobalt) should be reduced to lower oxidation states at high temperatures in a hydrogen environment, how is it possible that you observe the opposite phenomenon?

Figure 2. Electronic states of $\text{Ni}2p_{3/2}$ (a) and $\text{Mo}3d$ (b) atoms within the active component of sulfide catalysts $(\text{Ni},\text{Mo})\text{S}_x/\text{Al}_2\text{O}_3$ according to XPS data.^{52,53}

(1) Highly dispersed $\text{NiS}/\text{Al}_2\text{O}_3$ catalyst (a) and $\text{MoS}_2 + \text{Al}_2\text{O}_3$ mechanical mixture (b); (2) $(\text{Ni},\text{Mo})\text{S}_x/\text{Al}_2\text{O}_3$ catalyst sulfided *ex situ* in a stream of H_2S at 400 °C; (3) sample 2 preheated *in vacuo* at 300 °C to a residual pressure of 5×10^{-9} Torr; (4) sample 3 sulfided *in situ* in an $\text{H}_2 + \text{H}_2\text{S}$ mixture at 300 °C.

Figure 3. Electronic states of $\text{Ni}2p_{3/2}$ (a) and $\text{Mo}3d$ (b) atoms within the active component of sulfide catalysts $(\text{Ni},\text{Mo})\text{S}_x/\text{Sibunit}$ according to XPS data.^{52,53}

(1) Highly dispersed $\text{NiS}/\text{Sibunit}$ catalyst (a) and mechanical mixture $\text{MoS}_2 + \text{Sibunit}$ (b); (2) $(\text{Ni},\text{Mo})\text{S}_x/\text{Sibunit}$ catalyst sulfided *ex situ* in a stream of H_2S at 400 °C; (3) sample 2 preheated *in vacuo* at 300 °C to a residual pressure of 5×10^{-9} Torr; (4) sample 3 treated with hydrogen at 300 °C; (5) sample 4 sulfided *in situ* in an $\text{H}_2 + \text{H}_2\text{S}$ mixture at 300 °C; (6) sample 5 preheated *in vacuo* at 400 °C to a residual pressure of 5×10^{-9} Torr; (7) sample 6 sulfided *in situ* in an $\text{H}_2 + \text{H}_2\text{S}$ mixture at 300 °C.

We undertook a special study to answer this question using *in situ* XPS for sulfide (Ni,Mo) -catalysts[‡] supported on alumina and Sibunit.^{52,53} Catalysts sulfided *ex situ* were placed in the chamber of an XPS spectrometer without contact with air. The $\text{Mo}3d$ line in the spectra of $(\text{Ni},\text{Mo})\text{S}_x/\text{Al}_2\text{O}_3$ sulfide catalysts is a narrow, poorly resolved doublet. The E_b ($\text{Mo}3d_{5/2}$) value matches similar values for bulk and highly dispersed MoS_2 (Fig. 2). In the spectra of bimetallic sulfide catalysts supported on Sibunit, this line is represented by a narrow, well-resolved doublet (Fig. 3) shifted

[‡] The catalysts were obtained using metal complex precursors.

towards higher E_b values (in comparison with similar values for the bulk and highly dispersed MoS_2) due to epitaxial interaction of the active component with the surface of the conducting carbon material. It should be noted that the position of this line in the spectra of both catalysts did not change upon their thermal treatment in the spectrometer chamber (see Figs 2 and 3).

The situation with the Ni2p line is quite different. In the spectra of catalysts supported on alumina (see Fig. 2), the Ni2p_{3/2} line is rather narrow and is shifted by 1 eV towards higher E_b values in comparison with the spectrum of highly dispersed NiS. This shift is even more significant in the spectra of catalysts supported on Sibunit (see Fig. 3). After thermal treatment of sulfide catalysts in high vacuum at 300–400 °C, the Ni2p_{3/2} line shifts back towards lower binding energies so that its new position corresponds to a formal charge of 2+ on the nickel atom in highly dispersed NiS. If the sample is sulfided again in the spectrometer chamber, this line is shifted back to higher E_b values (see Figs 2 and 3). The reversible shift of the Ni2p line (see Fig. 3) implies that reduction reverts the catalyst to its original state.

When studying solid catalysts by XPS, the changes in the binding energies of electrons on inner levels of the atom of interest are often related to the impossibility of relaxation of the energy accumulated in dispersed species upon their photoionisation (see e.g., Refs 54 and 55). However, at least four counterarguments can be offered against this interpretation of results for the given catalytic system.

1. The NiS species in catalysts supported on Al_2O_3 are no larger than 10 Å (see Ref. 56). Thermal treatment of such catalysts in the chamber of an XPS spectrometer first in high vacuum and then in hydrogen actually reduces the sulfide species to the metal. It is very important that heating of reduced catalysts in an $\text{H}_2 + \text{H}_2\text{S}$ mixture does not result in the re-formation of sulfide species.⁵³

2. Thermal treatment of sulfide catalysts in the spectrometer chamber under various conditions does not change the position of the Mo3d line, whereas the position of the Ni2p line changes significantly and reversibly. Had the relaxation effect existed, similar changes in E_b would be expected for both metals.

3. An increase in E_b is also observed for bulk catalysts Ni– MoS_2 (Ni– WS_2),⁵⁰ in which the nickel atoms are situated at the edge planes of the bulk disulfide.

4. The carbon support Sibunit is a conducting material, which excludes ‘charging’ of a sample under ionising irradiation.

These arguments allow us to state that the reversible change in the E_b of electrons on the inner levels of nickel cannot be explained by any physical effect of irradiation on the object being studied. It should be interpreted as a chemical phenomenon, namely, the increase in the binding energy of electrons on the inner levels of nickel (or cobalt) should be ascribed to an unusually high oxidation state of nickel within the active component of sulfide hydrosulfurisation catalysts.

Let us try to explain why our data disagree with those obtained by other authors who studied similar systems. First, as noted above, sulfide catalysts synthesised from metal-complex precursors are characterised by high uniformity of the composition of surface species; as a result, the XPS lines become rather narrow. Second, these effects are not observed if sulfide catalysts have been exposed to air for a long time, as it is quite obvious that oxidation processes can occur in this case. It should be noted that results obtained by other researchers in experiments that took all the possible unfavourable effects into account (see, e.g., Ref. 57) are in good agreement with our data.

The possibility of existence of Ni(IV) ions with the d^6 electronic configuration was confirmed by *ab initio* theoretical studies of the $\text{Ni}(\text{S}_2\text{C}_2\text{H}_2)_2$ and $\text{Ni}(\text{S}_2\text{C}_2\text{H}_2)_2(\text{H}_2\text{S})$ complexes.^{58–60} The results obtained show that the square planar complex $\text{Ni}^{\text{II}}(\text{S}_2\text{C}_2\text{H}_2)_2$ with the d^8 electronic configuration⁶¹ is converted to a square-pyramidal Ni(IV) complex with the d^6 configuration upon adsorption of an H_2S molecule on the fifth coordination position. This is accompanied by the displacement of the nickel

atom by 0.35 Å from the plane of the four sulfur atoms. Similar conversion occurs upon adsorption of H_2S on active Ni sites within the active component. In this case, the electron density is transferred from nickel atoms to the neighbouring sulfur atoms bound to nickel, rather than to the molybdenum atom. It should be noted that this conclusion agrees with the XPS data (see Figs 2 and 3).

To explain the unusually high oxidation state of Ni, we assumed the possibility of the oxidative addition of hydrogen to a nickel ion within the active component.^{52, 62, 63} *Ab initio* calculations confirmed that the oxidative addition of hydrogen accompanied by the formation of Ni(IV) with the d^6 electronic configuration is thermodynamically favourable. It is assumed that a hydrogen molecule adds to a Ni(II) ion in a dissociative way to give a ‘surface’ hydrogen atom (H_s) and an ‘occluded’ hydrogen atom (H_o). The latter is localised in the matrix of the active component under the nickel atom, in the centre of an ‘empty’ trigonal prism formed by six sulfur atoms (see Fig. 1).

The concept of the oxidative addition of hydrogen to the nickel atom within the active component allows us to explain the XPS data presented above. In fact, *ex situ* evacuation of a sulfided sample at elevated temperature should remove occluded hydrogen due to reductive elimination to give Ni(II). Treatment with an $\text{H}_2 + \text{H}_2\text{S}$ mixture results in the oxidative addition of hydrogen; as a result, the Ni2p line is displaced towards higher binding energies. Prolonged exposure of samples to air can result in the oxidation of occluded hydrogen.

The first compound containing Ni(IV) ions was obtained more than 90 years ago.⁶⁴ It was the heteropolymolybdate anion $[\text{NiMo}_9\text{O}_{32}]^{6-}$. It is important for the existence of nickel in the high oxidation state that the number and electronegativity of the ligands surrounding the nickel atom be sufficiently high. The Ni(IV) cation in the complex mentioned above is located in a pseudo-octahedral coordination of oxygen atoms and has a d^6 electronic configuration. All the known Ni(IV) complexes are diamagnetic and tend to have an octahedral coordination.^{65, 66} Of other Ni(IV) compounds, the following inorganic compounds deserve mentioning: K_2NiF_6 , BaNiO_3 , NiO_2 , NaNiO_6 , NiAs_2 , etc. (see Ref. 67).

3. Substantiation of the possibility of oxidative addition of hydrogen in heterogeneous catalysis

Since at present there are no direct experimental methods for studying the nature of transient species formed upon adsorption of the starting reagents on the sites of heterogeneous catalysts, we will refer to analogies in the structures and mechanisms of action of homogeneous catalysts in order to explain the possibility of oxidative addition of hydrogen to these sites, although the conditions of the corresponding processes (temperature, pressure, presence of a solvent) differ considerably. Our approach is based on the concept of the common nature of the homogeneous, heterogeneous and enzyme catalysis.^{68–71}

The oxidative addition of hydrogen to square-planar Ir(I) complexes was discovered over 40 years ago⁷² and is now one of the key reactions in homogeneous catalysis.⁷³ In particular, it is well known that this reaction is the first step in the formation of active sites on catalysts for alkene hydrogenation.⁷⁴ In such a case, hydrogen acts as a unique molecule that simultaneously displays both reducing and oxidising properties under the same catalytic reaction conditions.

The oxidative addition of hydrogen is a particular case of the addition of neutral molecules XY to transition metal compounds with free coordination centres. The molecule XY is reduced in this reaction to give two anionic ligands X^- and Y^- , whereas the metal is oxidised. One of the examples best known is the oxidative addition of hydrocarbons $\text{R}-\text{H}$ to complexes of M(0) metals discovered by Shilov;^{75, 76} this reaction is accompanied by an increase in the formal oxidation state of the metal by two units and formation of alkyl hydride complexes. Since alkyl and hydride

ligands are very strong reducing agents, stable reaction products contain metals in low oxidation states only.

Numerous examples of the oxidative addition of hydrogen to various transition metals are currently known.⁷³ Two types of oxidative addition of hydrogen, *viz.*, two- and single-electron addition, are distinguished. In the study mentioned above,⁷² the oxidative addition of hydrogen resulted in the formal transformation of Ir(I) (d^8 electronic configuration) into Ir(III) (d^6 configuration):

The addition of hydrogen to metals in higher oxidation states, *e.g.*, to Os(II), is also known:⁷⁷

The oxidative addition of hydrogen can also involve Group VI metals, *e.g.*, Mo(II):⁷⁸

A typical example of the two-electron hydrogen addition to square-planar complexes is the synthesis of the Wilkinson catalysts:⁷⁹

It is important to note that the oxidative addition occurs readily if the coordination sphere of the metal comprises donor molecules such as PPh_3 , PBu_3 and the like. In the reactions considered above, the formal oxidation state of the metal and its coordination number increase by two units. Examples of the single-electron oxidative addition of hydrogen, *e.g.*, to Co(II) [$\text{Co}^{\text{II}}(d^7) \longrightarrow \text{Co}^{\text{III}}(d^6)$], are also known.^{80, 81}

dmg is dimethylglyoxime.

The latter reaction is typical of square-planar complexes that have a pronounced tendency towards oxidative addition.

Because the possibility of oxidative addition of hydrogen to an active metal atom within the active component of sulfide catalysts was only shown by non-empirical quantum-chemical methods, it was desirable to confirm the validity of this conclusion for known structures. The square-planar complex $\text{NiCl}_2(\text{PH}_3)_2$ with the d^8 electronic configuration of the central atom was selected for this purpose.⁶² The calculation details are described in our publications.^{58–60, 62, 63}

In this kind of theoretical calculations, the change in the system free energy upon formation of a new chemical compound is the main validity criterion. For example, a theoretical study⁸² showed that the oxidative addition of hydrogen to the structural analogues $\text{PtCl}_2(\text{PH}_3)_2$ and $\text{PdCl}_2(\text{PH}_3)_2$ results in an energy decrease (ΔE) by -32.2 and -67.8 kJ mol⁻¹, respectively. In the reaction

the ΔE value was found to be -52.4 kJ mol⁻¹ (see Refs 61 and 62). The geometric structure of the complex obtained was optimised totally; the interatomic distances and bond angles are shown in Fig. 4.

The electronic state of nickel on transition from a square-planar $\text{Ni}^{\text{II}}(d^8)$ complex to an octahedral $\text{Ni}^{\text{IV}}(d^6)$ complex is shown in a correlation diagram (Fig. 5). As follows from the calculations, the oxidative addition of hydrogen results in a considerable destabilisation of the nickel d_{z^2} orbital, whereas the

Figure 4. Geometric structure of the d^6 complex $\text{Ni}^{\text{IV}}\text{H}_2\text{Cl}_2(\text{PH}_3)_2$ totally optimised at the MP2 level (C_{2v} symmetry).⁶³ The bond lengths and angles are specified in angstroms and degrees, respectively.

Figure 5. Correlation diagram of oxidative addition of hydrogen to the square-planar complex $\text{Ni}^{\text{II}}\text{Cl}_2(\text{PH}_3)_2$ in the d^8 electronic configuration.⁶⁵ The coordinate of the $\text{H}_2 + \text{M}(d^8)\text{L}_2\text{Cl}_2 \rightarrow \text{M}(d^6)\text{L}_2\text{Cl}_2\text{H}_2$ reaction maintains the C_{2v} symmetry.

$4p$ orbital stabilises due to the formation of a Ni–H bond. Thus, the d_{xy} and d_{z^2} orbitals become formally vacant, whereas the electron density on the Ni4s and Ni4p orbitals increases. The binding energy of electrons on the Ni2p level was calculated using this correlation diagram.⁶³ It was found to be 1.5 eV lower for Ni(II) than for Ni(IV). This result agrees very well with experimental results for nickel metal complexes⁸³ and with X-ray photoelectron spectra of sulfide catalysts.^{39, 50–53, 57}

Such a good agreement allowed us to use the same quantum-chemical methods for the analysis of the electronic states of nickel and cobalt within the active component of sulfide catalysts.

Calculations were carried out for the $\text{Ni}(\text{Co})\text{Mo}_2\text{S}_{10}\text{H}_{10}$ cluster, which has the following characteristic features:^{63, 84}

(1) this cluster is a fragment of the active component's structure, the interatomic distances in which were found experimentally by EXAFS;^{85–87}

(2) the Ni(Co) atom is located at the vertex of a square pyramid formed by four sulfur atoms; the pyramid height is 0.5 Å^{85–87} (Figs 6 and 7);

Figure 6. Quantum-chemical model of the $\text{NiMo}_2\text{S}_{10}\text{H}_{10}$ cluster after oxidative addition of a hydrogen molecule to a nickel atom (the bond lengths are indicated in Å).⁶³

Figure 7. Quantum-chemical model of an $(\text{H})\text{CoMo}_2\text{S}_{10}\text{H}_{10}$ cluster [the active site is Co(III) in the d^6 electronic configuration] in Co/MoS₂ catalyst with occluded (a) and adsorbed (b) hydrogen.

□ — vacant coordination site.

(3) the stoichiometry of this cluster differs from MoS₂, but the calculated charges on Mo and S are ‘stoichiometric’ due to the compensation of the free valence bonds of sulfur atoms by terminal hydrogen atoms.⁸⁸

Non-empirical calculations were carried out using the Gaussian 92 quantum-chemical computational complex⁸⁹ at the Hartree–Fock method (HF), the Müller–Plesset perturbation theory (MP2) and the density functional theory (DFT) levels.

Dissociative adsorption of a hydrogen molecule on nickel atoms within the active component results in the formation of a complex containing an adsorbed (H_s) and an occluded (H_o) hydrogen atom (see Fig. 6) and in a considerable decrease in the calculated energy of the system ($\Delta E = -192.9 \text{ kJ mol}^{-1}$). The optimised interatomic distances $\text{Ni}-\text{H}_s$ and $\text{Ni}-\text{H}_o$ are 1.43 and 1.48 Å, respectively. The calculated formal charges on these atoms suggest that surface hydrogen H_s is more ‘acidic’ ($q = +0.16$) than occluded hydrogen H_o ($q = -0.42$). The oxidative addition of a hydrogen molecule results in a considerable increase in the formal charge on nickel (from +0.45 to +0.79) due to the covalent binding of nickel ions to the sulfur ions in the pyramid base. Two important circumstances should be emphasised in this connection:

(1) the electron density is partially transferred from the nickel atoms to the sulfur atoms bound to them rather than to the molybdenum atoms as one could expect; this result is in good agreement with XPS data (see the previous section);

(2) the d_{z^2} and d_{xy} orbitals of nickel (in the coordinate system used in Fig. 6) become formally ‘vacant’, and, as shown below, it is these orbitals that participate in the adsorption of donor molecules.

A similar situation is observed in the oxidative addition of hydrogen to Co(II) ions within the active component (see Fig. 7). Zakharov and Startsev⁸⁴ calculated the thermodynamic probability of the formation of surface and occluded hydrogen. *Ab initio* calculations showed that the total decrease in the free energy is

approximately the same in both cases shown in Fig. 7; therefore, it can be stated with a high degree of certainty that if hydrogen adsorption is possible, then its occlusion into the active component matrix should occur with the same probability. The optimised interatomic distances $\text{Co}-\text{H}_o$ and $\text{Co}-\text{H}_s$ are 1.52 and 1.42 Å, respectively.

It follows from *ab initio* calculations that an important role in the stabilisation of the electronic state of Ni(IV) and Co(III) within the active component belongs to the hydrogen sulfide molecule adsorbed on the active metal atom. The interaction scheme of the orbitals of a donor H_2S molecule with vacant orbitals of Co(III) is presented in Fig. 8 [this scheme also applies to Ni(IV)]. The calculated heats of adsorption of hydrogen sulfide on Ni and Co sites are 82.6 and 69.6 kJ mol^{-1} , respectively,^{67,84} whereas the heat of adsorption of hydrogen sulfide on Ni(II) is as small as 36.0 kJ mol^{-1} (see Ref. 67). Due to the difference in the heats of adsorption of the H_2S molecule on Ni(II) and Ni(IV) sites, the equilibrium bond lengths $\text{Ni}^{\text{II}}-\text{S}$ and $\text{Ni}^{\text{IV}}-\text{S}$ are different (2.77 and 2.60 Å, respectively).⁶⁷

Figure 8. Scheme of interaction of n_σ and n_π orbitals of a hydrogen sulfide molecule with $3d_{z^2}$ and $3d_{xy}$ orbitals of the Co(III) atom in the d^6 electronic configuration.

4. Experimental proof of the existence of occluded hydrogen

Since direct experimental proof of the existence of occluded hydrogen is absent in the literature, let us try to analyse numerous data available on the $\text{MoS}_2 + \text{H}_2$ system in order to obtain information about the state of hydrogen in this system. We will pay attention to whether or not particular experimental data are consistent with the concept of the existence of occluded hydrogen.

The considerable adsorption of hydrogen by bulk molybdenum disulfide was probably first noted by Badger *et al.*⁹⁰ At 140 °C and 1 atm, the quantity of hydrogen retained by the sample is 0.37 mol of H_2 per mol of MoS_2 , which is much higher than that corresponding to the monolayer coverage. It was shown^{91–94} that the quantity of hydrogen adsorbed by bulk MoS_2 and WS_2 at 300–400 °C is at least three times higher than that in the case of monolayer coverage (the latter was measured using the adsorption of N_2 and CO_2). If MoS_2 is supported on alumina, the quantity of adsorbed hydrogen increases considerably.^{95–98} Since the layered packing of molybdenum disulfide is irregular in this case, Jalowiecki *et al.*^{96,97} assumed that spillover of hydrogen from MoS_2 to the surface of the support occurs. The latter serves as a ‘reservoir for hydrogen storage’.⁹⁷ Some other aspects of hydrogen sorption by bulk and supported molybdenum sulfide were described in a review by Moyes.⁹⁹

However, the existence of 'excessive' hydrogen in sulfide catalysts can also be explained from a different standpoint. Let us consider the strength of hydrogen binding to catalysts, which can easily be evaluated from the temperature at which hydrogen appears in the gas phase during the temperature-programmed heating (TPH) of catalysts. Erofeev and Kaletchits^{100, 101} were the first to discover strongly bound hydrogen which was desorbed from Co–Mo sulfide catalysts at temperatures above 400 °C. Hoodless *et al.*¹⁰² showed the presence of both weakly and strongly bound hydrogen in bulk MoS₂ (the total hydrogen content corresponded to the formula H_{0.027}MoS₂). If cobalt was introduced in a MoS₂ sample, the peak of hydrogen evolution shifted towards higher temperatures; at the optimum catalyst composition, the maximum hydrogen desorption was observed at 600 °C (the hydrogen content in the catalysts corresponded to the formula H_{0.015}Co_{0.8}MoS₂). Similar results were later obtained by other authors.^{103–107}

We undertook a study of the forms of hydrogen desorption from sulfide catalysts in the TPH mode (Fig. 9).¹⁰⁸ The catalysts were prepared by supporting metal-complex precursors on alumina followed by sulfidation of the samples in a stream of H₂S at

400 °C. There are two regions in which hydrogen is removed from all the catalysts studied: a low-temperature region (desorption temperatures up to 500 °C) and a high-temperature region. Weakly bound hydrogen is removed in the low-temperature region, whereas strongly bound hydrogen is removed in the high-temperature region. After removal of hydrogen from the catalysts in the TPH mode at temperatures up to 750 °C, the samples were again sulfided portionwise with H₂S at 400 °C and re-desorption was carried out in the TPH mode (see Fig. 9, curves 2). It was found that re-sulfided samples did not contain strongly bound hydrogen.

We believe that the strongly bound hydrogen is the hydrogen occluded in the sulfide matrix. In fact, every second trigonal prism built of sulfur atoms in the structure of molybdenum disulfide (see Figs 1 and 10) is 'empty'. If we subtract the ionic radius of S^{2–} (1.58 Å) from the interatomic distance Mo–S (2.41 Å), we obtain the radius of the 'empty' space (0.83 Å), which is slightly longer than the H–H distance in the hydrogen molecule (0.74 Å). Thus, the introduction of a hydrogen atom or even a hydrogen molecule into this space will not distort the structure of molybdenum disulfide. *Ab initio* calculations of the active component structure with an occluded hydrogen atom showed^{62, 84} that the optimised interatomic distances Ni–H_o (1.48 Å) and Co–H_o (1.52 Å) correspond to covalent binding. It is easy to show that these 'optimised' distances coincide with those calculated from the geometric structure of molybdenum disulfide.

Figure 9. Desorption of hydrogen from sulfide catalysts.¹⁰⁸ (1) Catalysts sulfided *in situ* in a stream of H₂S at 400 °C; (2) the same samples sulfided after TPH with portions of H₂S at 400 °C. Catalysts: (a) 3.0 Co/Al₂O₃, (b) 3.0 Ni/Al₂O₃, (c) 7.1 Mo/Al₂O₃, (d) 1.6 Co + 7.5 Mo/Al₂O₃, (e) 1.6 Ni + 7.1 Mo/Al₂O₃.

Figure 10. An electrically neutral (MoS₂)_x macromolecule.

The term 'occluded hydrogen'[§] in relation to sulfide catalysts was introduced because of the necessity to emphasise its specific role in the formation and functioning of the active component. Let us note the most important properties of occluded hydrogen:

- (1) strong bonding to the active component matrix (occluded hydrogen is removed only at temperatures much higher than those of typical catalytic reactions);
- (2) localisation only on specific sites of the active component matrix [unlike dissolved (absorbed) hydrogen];
- (3) interaction with surface metal atoms, owing to which occluded hydrogen favours the creation of an 'active' electronic configuration of these atoms (it is this configuration that determines the catalytic and adsorption properties of the active component);
- (4) oxidative properties (occluded hydrogen appears due to the oxidative addition of hydrogen to an active metal atom at the step of formation of the active component and therefore plays the role of an oxidant).

Hexagonal layered disulfide H_{0.76}NbS₂, which crystallises in the molybdenite structural type (Table 1), is one of the few

[§] Occlusio (Latin) means locking, hiding; occlude (English) — to close, seal. In metallurgy, the term 'occlusion' means dissolution of gases in solid or molten metals. In chemistry, there are synonyms for this word: absorption and dissolution.

Table 1. Crystallographic data on the structure of hexagonal NbS₂ with and without occluded hydrogen. The corresponding parameters of hexagonal single-crystal MoS₂ are shown for comparison.

systems where the presence of occluded hydrogen has been proved experimentally.^{109–111} The neutron diffraction method was used to study the structure of a single crystal of this disulfide and to determine the hydrogen atom coordinates.¹¹⁰ The latter indicate that this atom is situated in the centre of an ‘empty’ trigonal prism formed by six sulfur atoms. It was found that the hydrogen atom is located in the centre of the triangle formed by niobium atoms (the Nb–H distances are ~1.93 Å). One can see from Table 1 that the structure of niobium disulfide¹⁰⁹ undergoes minor changes upon hydrogen occlusion: the unit cell volume and the interatomic distances Nb–S and Nb–Nb increase slightly. This proves that atomic hydrogen introduced in the centre of an ‘empty’ trigonal prism does not distort the structure of the disulfide. Similar results, albeit with less unambiguous conclusions, were previously obtained by the same research group¹¹² for the H_xTaS₂ system.

Let us compare the vibration frequencies of occluded hydrogen calculated by non-empirical methods with literature data

obtained by different spectroscopic methods (Table 2). The stretching vibrations of the S–H bonds in H_xMoS₂ lie in the region 2450–2650 cm^{−1} (see Ref. 113), which corresponds to the similar parameters for pure compounds containing thiol groups.¹¹⁴ Inelastic neutron scattering (INS) spectra of a H_{0.5}TaS₂ sample contained¹¹² a band at 744 cm^{−1}, which was assigned to the deformation vibrations of the Ta–S–H group. It was concluded that this compound was non-stoichiometric covalent tantalum hydrosulfide. However, the absence of bands of the stretching vibrations of the S–H bonds casts doubt on the validity of this assignment. A similar band was found by Wright and co-workers¹¹⁰ in the spectra of an H_{0.76}NbS₂ sample. Of the three possible variants of assigning this band, deformation vibrations of the Nb–H bond in the direction parallel to axis *c* were preferred. The INS method was later used to study the H_xMoS₂ and H_xWS₂ systems.^{91–94} The absence of structural data for these systems made Wright and co-workers be very careful when

^a INS is inelastic neutron scattering, CNS is Compton neutron scattering. ^b The vibration frequencies of the S–H bond in gaseous H₂S, thiophene and thiols are 2668, 2550 and 2550–2650 cm^{−1}, respectively (see Ref. 114). ^c The stretching vibration bands of the S–H bonds are absent. ^d The results obtained were interpreted as evidence of activated adsorption and formation of intercalated hydrogen.

assigning the observed absorption bands. However, they noted the following facts: (1) treatment of sulfide catalysts with hydrogen at 300–400 °C resulted in the appearance of bands corresponding to the stretching vibrations of the S–H bonds, whereas these bonds were not observed at low temperatures; (2) the bands at ~ 870 and ~ 660 cm^{-1} were observed in the spectra of samples which did not contain bands corresponding to the stretching vibrations of the S–H bonds, hence they should be assigned to other types of vibration [e.g., the former band may be assigned to the deformation vibrations of the M–H bond, whereas the latter, to the deformation vibrations of the H–S₃ bond (vibrations of the hydrogen atom located in the centre of the triangle of S atoms) within the molybdenum disulfide matrix].

Anderson *et al.*¹¹⁷ employed the semiempirical molecular orbital method ASED-MO[¶] to calculate the vibration frequencies of hydrogen in the H_xMoS₂ matrix (Table 3). A comparison of data in Tables 2 and 3 shows that the band around ~ 870 cm^{-1} can be assigned to the deformation vibrations of occluded hydrogen located in the centre of the triangle of molybdenum atoms, and hence in the centre of the ‘empty’ trigonal prism of sulfur atoms. The calculated bond length Mo–H (1.82 Å) totally agrees with the structural characteristics of molybdenum disulfide, hence the results obtained may be considered rather reliable.

Table 3. Vibration frequencies of hydrogen in a MoS₂ matrix calculated by the ASED-MO method.¹¹⁷

Very few spectroscopic studies of hydrogen adsorption by bimetallic sulfide catalysts are known. In their meticulous study, Sandberg *et al.*¹¹⁵ carried out hydrogen adsorption at high pressure; subsequently, the samples were evacuated at 200–400 °C and studied using the INS method (see Table 2). Thus, the study was aimed at the ‘residual’, strongly bound hydrogen which is not removed at temperatures above the catalytic reaction temperature. The band at 650 cm^{-1} was assigned to the deformation vibrations of the S–H groups, although the spectra did not contain bands corresponding to the stretching vibrations of these groups and the preparation conditions of the samples favoured, most likely, the elimination of the SH groups from the surface. The broad band with a maximum at 795 cm^{-1} overlaps the band of stretching vibrations of the S–H bonds and the band of vibrations of hydrogen atoms in Raney nickel (950 cm^{-1}). The second broad band at 1895 cm^{-1} was assigned to the stretching vibrations of the Ni–H bond, although vibrations of hydride bonds in metal complexes have frequencies above 1970 cm^{-1} , and those in Raney nickel are equal to 2070 cm^{-1} .

In order to reveal the nature of hydrogen bonding in Ni–Mo sulfide catalysts, we calculated⁶² the frequencies of the stretching and deformation vibrations for adsorbed and occluded hydrogen atoms in the NiMo₂S₁₀H₁₀ structure (see Fig. 6). As one can see from Table 4, the band at 1895 cm^{-1} in the INS spectra

Table 4. Vibration frequencies and intensities of adsorbed and occluded hydrogen atoms in the active component of Ni–Mo sulfide catalysts calculated by non-empirical methods.⁶²

Vibration	Vibration frequency / cm^{-1}		Intensity (arb. units)
	calculated	found	
ν_z^s	1890.0	1895.0	174.0
ν_z^{as}	2010.0		124.5
$\delta_x(\text{H}_s)$	704.0		28.4
$\delta_y(\text{H}_s)$	834.0	795.0	45.8
$\delta_x(\text{H}_o)$	2062.0		339.2
$\delta_y(\text{H}_o)$	926.0		12.9

(see Ref. 115) is in good agreement with the deformation vibrations of the H_o–Ni–H_s fragment, whereas the band at 795 cm^{-1} can be assigned to the deformation vibrations of hydrogen adsorbed on nickel. Thus, the vibration frequencies of adsorbed and occluded hydrogen atoms that we have calculated are in better agreement with experimental data than the assignments made by Sandberg *et al.*¹¹⁵

Based on measurements of the mean kinetic energy of hydrogen in Co–Mo sulfide catalysts by Compton neutron scattering,¹¹⁶ the mean vibration frequency of hydrogen in these catalysts was calculated to be 1392 cm^{-1} (see Table 2). The arithmetic mean frequency of the stretching and deformation vibrations of the S–H bond was found to be 1270–1310 cm^{-1} . Based on this, Mitchell *et al.*¹¹⁶ concluded that hydrogen in these catalysts is bound to sulfur atoms because the M–H_s bond frequencies are much lower (~ 1100 cm^{-1}).

We calculated the vibration frequencies for adsorbed and occluded hydrogen on Co–Mo sulfide catalysts⁸⁴ in the coordinate system shown in Fig. 7. The following results were obtained: for Co–H_s, $\nu = 1972$ cm^{-1} and $\delta_x \approx \delta_y = 652$ cm^{-1} ; for Co–H_o, $\nu = 1696$ cm^{-1} , $\delta_x = 1764$ cm^{-1} and $\delta_y = 880$ cm^{-1} .

The calculated mean vibration frequency of adsorbed hydrogen in Co–H_s is 1092 cm^{-1} and that of occluded hydrogen in Co–H_o is 1447 cm^{-1} , which also agrees satisfactorily with the reported data.¹¹⁶

Thus, the spectral characteristics, considered in this section, of hydrogen in sulfide catalysts do not contradict the hypothesis of the existence of occluded hydrogen in these systems but even confirm it. To prove explicitly the existence of occluded hydrogen, it was necessary to perform directed experimental studies of sulfide catalysts with the same chemical composition and structure, either containing or not containing such hydrogen. The first steps in this direction have already been taken. For example, Shalagina *et al.*¹⁰⁸ were the first to obtain this type of sulfide catalysts.

III. The concerted mechanism of thiophene hydrogenolysis on sulfide catalysts

Synchronous (concerted) mechanisms play a key role in enzyme catalysis. Publications on homogeneous and heterogeneous catalysis in which the concerted mechanism of catalytic transformations is also assumed appear currently with increasing frequency.^{68–71} Numerous examples of concerted mechanisms in acid-base reactions were considered in a number of papers.^{68, 69, 71} Such catalytic transformations are possible if the acidic and basic sites of the catalyst act in a concerted way, provided that they are sufficiently close to each other and are oriented strictly in such a

[¶] Atom Superposition and Electron Delocalisation Molecular Orbital.

manner that the substrate coordination becomes favourable for catalysis. In such a case, the high rate of catalytic transformation is ensured by synchronous proton transfer along a system of chemical and hydrogen bonds in cyclic intermediate structures. There are also examples of concerted mechanisms in heterogeneous catalysis involving molecular oxygen.^{118–121} Concerted mechanisms are characterised by low activation energies (E_a) and high process selectivity.

Hydrogenolysis of thiophene on sulfide catalysts is the best-studied reaction involving a concerted mechanism.

The main regularities of thiophene hydrogenolysis on bimetallic sulfide catalysts have been considered in detail in a number of reviews;^{8,31–35} let us note just the most important specific features of this reaction.

1. Hydrogenolysis of thiophene on bimetallic sulfide catalysts is characterised by low activation energies, *viz.*, 42–63 kJ mol^{−1} in the temperature range 300–400 °C. Modification of catalysts with phosphorus or fluorine decreases the E_a value to 30 kJ mol^{−1}. Even for sulfide catalysts with non-optimum chemical composition (Ni–Nb, Ni–Re, Cu–W) where the reaction rates are low, the E_a values for different metal pairs also range within 38–63 kJ mol^{−1}.

2. The thiophene hydrogenolysis on bimetallic sulfide catalysts with any chemical composition is characterised by high selectivity: four hydrogen molecules are added at once to one thiophene molecule, so, no products of partial hydrogenation of the thiophene ring (in particular, butadiene) appear in the gas phase. Butenes are the only real intermediates; the fraction of butenes in the resulting mixture with butane is the lower the higher the catalyst activity.

These two features serve as a weighty argument that the thiophene hydrogenolysis mechanism should be concerted. Below we describe the mechanism that we suggested for the activation of hydrogen and thiophene molecules and for the transfer of activated hydrogen to an adsorbed thiophene molecule.

1. The mechanism of activation of molecular hydrogen on sulfide catalysts

Hydrogen is the main ‘character’ in all processes of hydrotreatment of oil fractions; however, there are very few studies on the mechanism of its activation on sulfide catalysts. As a rule, the authors confine themselves to general guesswork without a theoretical substantiation of the interaction of hydrogen with sulfide catalyst surfaces. This happens because few appropriate physicochemical methods are available for *in situ* studies of the adsorption and activation of hydrogen on real catalysts and under real process conditions. On the other hand, the hydrogen activation mechanism has been studied rather thoroughly in homogeneous catalysis. Our subsequent consideration will be based on the concept that the nature of heterogeneous catalysis is the same as that of homogeneous catalysis.

The activation of molecular hydrogen can occur either as a result of its oxidative addition or homolytic and heterolytic cleavage.¹²² However, the homolytic activation of a hydrogen molecule on the surfaces of metallic catalysts can be regarded as a particular case of the hydrogen oxidative addition.⁷³ Each metal atom in the catalyst bulk is surrounded by neighbours on all sides, whereas surface atoms possess free coordination places; therefore, the adsorption of molecular hydrogen on the surface is accompanied by its dissociation (Fig. 11). The liberation of energy upon formation of two metal–hydrogen bonds serves as the driving force of the hydrogen addition to the metal. From the chemical viewpoint, this process can formally be represented as

The thermodynamic parameters of hydrogen activation on metals are listed in Table 5. The change in the free energy upon the homolytic (dissociative) adsorption of a hydrogen molecule on metals at room temperature is $-(25–109)$ kJ mol^{−1}. To estimate

Figure 11. The scheme of interaction between molecular orbitals in the homolytic activation of hydrogen at a metal catalyst surface: (a) HOMO, (b) LUMO.

whether heterolytic dissociation of molecular hydrogen on sulfide catalysts is thermodynamically possible, we used the available thermochemical data.¹²³ As follows from Table 5, the change in free energy is $-(34–117)$ kJ mol^{−1} at temperatures within 300–400 °C typical of catalytic reactions. Thus, there is a reason to believe that the heterolytic activation of a hydrogen molecule on sulfide catalysts is as efficient as the homolytic activation on metals.

Table 5. Some thermodynamic parameters of the activation of a hydrogen molecule on metals and sulfides (a thermochemical estimate).

Parameter	Homolytic activation on metals ¹²²	Heterolytic activation on sulfide catalysts ¹²³
Bond energy, H–H /kJ mol ^{−1}	436	—
Bond energy, M–H /kJ mol ^{−1}	251–293	335–377
Bond energy, S–H /kJ mol ^{−1}	—	210–251
Enthalpy, ΔH° (experimental value) /kJ mol ^{−1}	−(67–151)	−(109–456)
Entropy, ΔS° (estimate) /J mol ^{−1} deg ^{−1}	−147	−126
$-T\Delta S^\circ$ /kJ mol ^{−1}	42 (at 300 K)	75 (at 600 K)
Free energy change, ΔG° /kJ mol ^{−1}	−(25–109)	−(34–117)

However, one should not reject the mechanism of homolytic activation of molecular hydrogen on sulfide catalysts involving terminal sulfur atoms. In fact, it is evident from Fig. 10 that the edges of a single slab of an electrically neutral MoS₂ macro-molecule are restricted by either (10 $\bar{1}$ 0) or (30 $\bar{3}$ 0) planes. In the former case, the edge is represented by coordinatively unsaturated sulfur atoms; in the latter case, by molybdenum atoms. Taking the principle of electric neutrality into account, it can be stated that free valence bonds of peripheral sulfur atoms can participate in the formation of pairwise S–S bonds, whereas the excess electron density will be delocalised on peripheral molybdenum atoms; these effects can result in the formal ‘reduction’ of Mo⁴⁺ into Mo²⁺. The presence of disulfide groups (S–S)^{2−} in bulk MoS₂ is indicated by the presence of a characteristic band at 529 cm^{−1} in the Raman spectra.¹²¹ The possibility of dissociative (homolytic) activation of hydrogen on terminal disulfide groups was also confirmed by quantum-chemical calculations (see below).

Binuclear molybdenum clusters (C₅H₅)Mo(μ-S)₂(μ-S₂) with bridging disulfide groups described by Rakowski DuBois^{124,125} can serve as good model compounds for studying the dissociative adsorption of the hydrogen molecule on terminal sulfur atoms.

Molecular hydrogen reacts with disulfide ligands of these complexes under very mild conditions.^{124, 125}

The possibility of dissociative adsorption of hydrogen on disulfide ligands was noted in other studies as well.^{121, 126} It should be emphasised that a specific role in the interaction with molecular hydrogen belongs to the S–S chemical bond in the disulfide group, since molecular hydrogen does not react with, *e.g.*, sulfur atoms sputtered onto the (110) plane of a molybdenum single crystal.^{123, 127}

Thus, molecular hydrogen can be activated on sulfide catalysts according to different mechanisms depending on the catalyst composition and the process conditions. The ease of its activation on sulfide catalysts is indicated by the fact that the isotope exchange $\text{H}_2\text{--D}_2$ occurs at 80–150 °C, *i.e.*, at much lower temperatures than the thiophene hydrogenolysis.^{128–131} Hence, hydrogen activation cannot limit the overall reaction rate under real hydrotreating conditions.

2. The concerted mechanism of thiophene hydrogenolysis

As noted above, the active component of sulfide hydrodesulfurisation catalysts is an electrically neutral macromolecule (MoS_2)_x with Ni(IV) or Co(III) ions in the d^6 electronic configuration situated at its edge. A fragment of this macromolecule in real scale with allowance for all interatomic distances and ionic radii is represented in Fig. 12. There is occluded hydrogen inside the macromolecule; the former reacts with nickel or cobalt surface atoms, creating the electronic configuration of the active metal atom required for adsorption and catalysis. Under catalysis conditions, the active site always contains an adsorbed hydrogen sulfide molecule; this favours stabilisation of the ‘active state’ of nickel or cobalt. Adsorption occurs due to efficient interaction between the vacant d_{z^2} and d_{xy} orbitals of the metal atom and the n_σ and n_π orbitals of hydrogen sulfide (see Fig. 8).

The catalytic cycle starts with the displacement of the hydrogen sulfide molecule from the coordination sphere of the active metal atom by a thiophene molecule; this occurs because the heat of adsorption of the latter is higher. The heats of adsorption of

Table 6. Heats of adsorption of hydrogen sulfide, thiophene and tetrahydrothiophene (THT) on active sites with different compositions.

Calculation method	Composition of the active component	Heat of adsorption /kJ mol ^{−1}			Ref.
		H ₂ S	thiophene	THT	
Method of interacting bonds (MIB)	Co–MoS ₂	48	89	147	132
	Ni–MoS ₂	51	92	151	
	Co–WS ₂	50	91	150	
	Ni–WS ₂	53	95	154	
Hartree–Fock method	Co–MoS ₂	69	77	112	84

sulfur-containing molecules on active sites with different compositions calculated by semiempirical and nonempirical methods are listed in Table 6.¹³² It has been shown¹³³ that electron density flows from a sulfur atom to a MoS₂ macromolecule if a thiophene molecule is η^1 -coordinated with a coordinatively unsaturated molybdenum atom at an edge plane of MoS₂. Obviously, this process can also occur if the thiophene molecule is coordinated with an active metal atom (Co, Ni). In such a case, an additional negative charge appears on the electrically neutral molecule of the active component. Since all valence bonds inside a macromolecule are saturated, the excess negative charge will be localised on the terminal sulfur atoms. In turn, this can become an additional driving force for the dissociative adsorption of the hydrogen molecule by the homolytic activation mechanism according to which electron density is transferred from sulfur atoms to the antibonding orbital of the hydrogen molecule (see the previous section).

The activated hydrogen is transferred through the system of chemical bonds created by bridging sulfur atoms to the adsorbed thiophene molecule, thus providing hydrogenation of the thiophene ring (see Fig. 12). This process results in the removal of π -conjugation from the aromatic thiophene ring and the buildup of additional electron density on the sulfur atom. The tetrahydrothiophene (THT) molecule, which is more basic than the thiophene molecule, remains strongly bound to the active site,¹³² whereas the excess electron density is transferred back to the macromolecule of the active component and concentrated on the terminal sulfur atoms. This excess negative charge becomes the driving force of dissociative hydrogen adsorption. The activated hydrogen formed due to dissociation is transferred back to the adsorbed THT molecule through the system of valence bonds. This results in the cleavage of C–S bonds, liberation of butane (butenes) to the gas phase and formation of adsorbed hydrogen sulfide. An adsorbed H₂S molecule, which is a weak ligand, can again be replaced by a thiophene molecule. The catalytic cycle is thus closed.

In order to understand why thiophene is adsorbed and THT is not desorbed during a catalytic cycle, Bulgakov and Startsev¹³² used the method of interacting bonds to calculate the heats of adsorption of these molecules on bimetallic sulfide catalysts with different chemical compositions (see Table 6). The low heats of H₂S adsorption imply the considerable reversibility of its adsorption under the catalysis conditions and confirm that adsorbed hydrogen sulfide can be replaced by thiophene. The high heat of THT adsorption completely agrees with the virtual irreversibility of adsorption of this molecule. This also means that the cleavage of C–S bonds and desorption of H₂S and hydrocarbons to the gas phase is the only way to complete the catalytic cycle. The only reason for the strong adsorption of THT on active sites is that the basicity of the sulfur atom in this molecule is higher than that in the thiophene molecule due to the removal of π -conjugation upon hydrogenation of the thiophene ring.

Direct experimental evidence of this mechanism was obtained by EXAFS in an *in situ* study of the adsorption of selenophene (a

Figure 12. The catalytic cycle of thiophene hydrogenolysis on a bimetallic sulfide compound, *viz.*, the active component of hydrodesulfurisation catalysts [the ratios of interatomic distances and ionic (covalent) radii correspond to actual values].

structural analogue of thiophene) on (Ni,Mo)/Al₂O₃ sulfide catalysts of metal-complex origin.¹³⁴ It was shown that the adsorption of selenophene occurs on Ni atoms (the Ni–Se distance is 2.50 Å) but not on Mo atoms.

Thus, adoption of the hypothesis that the electric neutrality of such catalysts is violated and consideration of anionic vacancies as participants in the catalytic process are not required to describe the thiophene hydrogenolysis mechanism on bimetallic sulfide catalysts. The low activation energy, *i.e.*, high degree of compensation of the energy consumed for the cleavage of ‘old’ valence bonds in the thiophene molecule, results from the redistribution of the excess energy which is evolved upon the adsorption of thiophene and hydrogenation of its ring inside the macromolecule of the active component. The high rate of the catalytic process (synergism) is ensured by the fast transfer of electrons and protons along the closed system of valence bonds in a macromolecule of the active component with an optimum chemical composition.

Synergism is found in the catalytic systems Cr–WS₂ and Ni–NbS₂, whereas pronounced antagonism is found in the systems V–WS₂, Mn–WS₂, Cu–WS₂, Zn–WS₂ and Ni–ReS₂ (see Ref. 135). In order to explain this effect within the framework of the method of interacting bonds, the heats of thiophene adsorption on bimetallic sulfide catalysts with different compositions were calculated.¹³⁶ Good correlation between the heat of thiophene adsorption and the catalytic activity of bimetallic sulfides was observed (Fig. 13). The non-additive decrease in the activity may be due to the formation of either very strong (Ti, V, Mn, Zn) or very weak (Cu) M–S bonds. In the framework of the concerted mechanism considered here, this can mean (provided that the source of activated hydrogen is the same and the metal ion of the first transition row has the same environment) that high strength of M–S bonds prevents the displacement of H₂S adsorbed on an active site by thiophene, whereas the weakness of the M–S bond does not allow thiophene to remain on the active site for a period of time sufficient for completing the catalytic cycle. Certainly, the electronic factor should now be considered for understanding the deeper reasons for this phenomenon. In order to reveal the nature of the thiophene–metal bonding, it is necessary to study the electronic structure of the transition metal ion in the active component using quantum-chemical methods and taking into account the possibility of hydrogen occlusion into the matrix; revealing the deep reasons for synergism (or antagonism) requires that ‘cooperative’ electronic properties of the active component with a given chemical composition be established.

Figure 13. Dependences of activity (A) of catalysts in the hydrogenolysis of thiophene (curve 1) and deviations of the enthalpy of thiophene adsorption δ (assuming the heats of adsorption on nickel and cobalt as the optimum values) on the nature of the metal contained in the active component of bimetallic sulfide catalysts (curve 2).¹³⁶

It was noted at the beginning of this section that concerted mechanisms are mainly known for acid–base reactions. In fact, it is hard to expect that the concerted mechanism would be realised in redox catalytic reactions where the catalyst surface undergoes successive reductions–reoxidations on exposure to the reaction medium as is the case in, *e.g.*, the ‘classical’ version of the hydrogenolysis mechanism of the C–S bond, according to which the MoS₂ surface first undergoes reduction to give an anionic vacancy and then undergoes reoxidation by a thiophene molecule (see the next section).

The concerted mechanism of thiophene hydrogenolysis considered here cannot be attributed to redox reactions, as it does not explicitly assume reduction and reoxidation of the sulfide catalyst surface. It should formally be considered as an acid–base mechanism. In fact, Ni(IV) or Co(III) ions in the d^6 electronic configuration located at the edge plane of the MoS₂ matrix are Lewis acid sites; the unshared electron pair of the adsorbing molecule (a base, *e.g.*, thiophene) is transferred to the vacant d_{z^2} and d_{xy} molecular orbitals of these sites. On the other hand, the coordinatively unsaturated sulfur atoms located at the (0110) plane of the active component have an uncompensated valence bond and, as shown above, obtain an additional negative charge in the catalytic process. In other words, they act as a Lewis basic site that transfers electron density to the antibonding orbital of the hydrogen molecule which is being adsorbed, resulting in its dissociation. Thus, the electrically neutral macromolecule of the active component contains acid–base pairs; this is a prerequisite of the concerted mechanism. The electron density redistribution and the transfer of activated hydrogen to the thiophene molecule during the catalysis are not accompanied by changes in the formal oxidation states of the metals contained in the active component.

The concerted hydrogenolysis mechanism of the C–S bond on bimetallic sulfide catalysts, which has been proposed as an alternative to the generally accepted redox mechanism of this reaction, agrees completely with the concept of the common nature of heterogeneous, homogeneous and enzyme catalysis. The active component of sulfide catalysts is considered as an electrically neutral macromolecule containing acid–base pairs which serve as adsorption and activation sites for the reacting molecules. The high rate and selectivity of the catalytic process and the low activation energy are ensured by the synchronous activation of reacting molecules in the coordination sphere of the active component due to the fast transfer of electrons and protons along the closed system of valence bonds. This also ensures a high degree of compensation of the energy which has been spent for the cleavage of old bonds by the energy liberated in the exothermic steps of adsorption, hydrogenation and formation of new bonds.

IV. The concept of the determining role of the metal–sulfur bond energy in heterogeneous catalysis by metal sulfides

In the middle of the 1950s, G K Borekov proposed a hypothesis about the determining role of the bond energy of oxygen with the surface of oxide catalysts in oxidation reactions.¹³⁷ This concept was developed most consistently in the studies by V V Popovskii (see Ref. 138 and references cited therein). However, it was found already at that time that, in many cases, partial oxidation and deep oxidation obey different rules. Therefore, a concept appeared simultaneously about a conjoint mechanism of interaction of reactants with each other and with the solid catalyst.⁷⁰

Probably, the hypothesis on the participation of anionic vacancies of sulfide catalysts in the catalytic reaction was first put forward by Lipsch and Schuit,¹³⁹ although they did not give any experimental evidence for this mechanism.† Anionic vacancies

† It is this publication that was subsequently referred to most often to substantiate the role of anionic vacancies.

are formed on the surfaces of sulfide catalysts due to the reaction of the surface sulfur atoms with hydrogen at elevated temperatures, followed by removal of the sulfur atoms as hydrogen sulfide.

The following studies have been carried out in order to substantiate the concept of the determining role of the energy of bonding of sulfur atoms to surfaces of sulfide catalysts in their catalytic activity:

- (1) estimation of the strength of bonding of sulfur to sulfide catalyst surfaces under conditions of their temperature-programmed reduction in hydrogen;
- (2) determination of the mobility of surface sulfur atoms by measuring the isotope exchange rate between hydrogen sulfide from the gas phase and solid catalyst surfaces;
- (3) quantum-chemical calculations of the electronic structure of the active site.

1. The strength of bonding of sulfur to sulfide catalyst surfaces

The temperature-programmed heating of solid catalysts in different gases (or gas mixtures) is a relatively popular and informative method for the study of the nature of surface compounds and possible intermediates of catalytic reactions.¹⁴⁰ Correlations between the strength of bonding of surface sulfur atoms to the catalyst, on the one hand, and its catalytic activity, on the other hand, for sulfide catalysts are most commonly determined using temperature-programmed reduction (TPR) in hydrogen. Hydrogen reacts with surface sulfur atoms to remove them as hydrogen sulfide and to form anionic vacancies:

where $\square$ is an anionic vacancy. It is assumed *a priori* that the amount of removed hydrogen sulfide can serve as a quantitative measure of the number of vacancies formed on sulfide catalyst surfaces.

It has been shown in one of the first studies¹⁴¹ on the TPR of sulfide catalysts that the first maximum of the evolution of hydrogen sulfide from Ni–Mo and Co–Mo catalysts corresponds to 320 and 380 °C, respectively. A subsequent increase in the temperature is accompanied by the continuous evolution of H₂S. The continuous evolution of hydrogen sulfide from both mono- and bimetallic sulfide catalysts at temperatures above 300 °C found by Burch and Collins¹⁴² was used as the basis for drawing the conclusion that nickel does not affect the nature of surface sulfur compounds.

On the other hand, the temperature-programmed reduction of bulk molybdenum disulfide starts at higher temperatures, *viz.*, above 700 °C.¹⁴³ Non-stoichiometric sulfur (S_x) is found in catalysts supported on Al₂O₃; it can be adsorbed both on mono- and bimetallic sulfide catalyst surfaces. An analogy with the adsorption of oxygen on oxide catalysts is evident here. It is this non-stoichiometric sulfur that is readily hydrogenated with hydrogen at low temperatures, whereas the reduction of stoichiometric sulfides starts only at temperatures > 500 °C, which is much higher than typical temperatures of catalytic reactions. Similar results were obtained in a study of sulfide Ni–W catalysts.¹⁴⁴ A mechanism of the formation of non-stoichiometric sulfur was proposed by Mangnus *et al.*¹⁴⁵

No considerable difference between the TPR spectra of sulfide Co–Mo catalysts at low and high hydrogen pressures (1 and 31 atm, respectively) was found.¹⁴⁶ In both cases, low-temperature evolution of hydrogen sulfide was observed, which ceased at 200 °C. A further increase in temperature resulted in the evolution of an insignificant amount of H₂S; this amount increased at temperatures above 500 °C. Labruyere *et al.*¹⁴⁶ do not reject the possible formation of non-stoichiometric sulfur on catalyst surfaces due to the decomposition of hydrogen sulfide during their sulfidation; however, they do not rule out that other H₂S sources, *e.g.*, SH groups, can exist.

We will not analyse other works that deal with the TPR of sulfide catalysts, since poorly characterised samples and samples thermally treated under non-comparable conditions were studied in most of them. The corresponding references can be found in the monograph by Topsøe *et al.*⁴ and in studies cited above. Let us note just one short communication¹⁴⁷ describing an attempt to obtain direct experimental correlations between the M–S bond strength and the number of anionic vacancies, on the one hand, and the catalytic activity, on the other hand. However, the lack of sufficient information about the experimental conditions does not allow us to be sure that the conclusions are reliable.

2. The mobility of surface sulfur

Isotope exchange between molecular oxygen and oxygen in the solid oxide lattice (heteroexchange) was widely used for determining the mobility of surface oxygen in oxide catalysts.^{70, 137, 138} Sulfide catalysts were also studied using the heteroexchange between ³⁵S-labelled hydrogen sulfide and the sulfur atoms in MS₂ crystal lattices. Lukens *et al.*¹⁴⁸ were probably the first to show that the heteroexchange between H₂³⁵S and the surfaces of bulk or supported WS₂ occurs in toluene even at room temperature. These data were used to determine the specific surfaces of sulfide catalysts. In the gas phase, exchange occurs at 70 °C.¹⁴⁹

Radioactive hydrogen sulfide was detected^{150, 151} in thiophene hydrogenolysis products on sulfide catalysts containing radioactive sulfur. Analysis of pulse-mode kinetic curves allowed the conclusions to be drawn that catalyst sulfur atoms are involved in the reaction and that two types of sulfur atoms exist, *viz.*, those capable of fast and slow exchange.

Systematic studies on the conversion of radioactive dibenzothiophene ([³⁵S]DBT) on different catalysts^{152–154} made it possible to substantiate the hydrogenolysis mechanism of the C–S bond with involvement of anionic vacancies. The conclusions drawn were based on data on the appearance or disappearance of radioactive hydrogen sulfide in the hydrogenolysis products of [³⁵S]DBT upon periodic changes in the process conditions.

A study of the heteroexchange between H₂³⁵S and surfaces of sulfide catalysts at high hydrogen pressures (10–50 atm) showed^{155, 156} that the amount of ‘mobile’ sulfur does not depend on pressure but does depend on temperature. The ratio of the amount of ‘mobile’ sulfur to its total amount varied from 10% at 200 °C to 44% at 400 °C. A decrease in the hydrogen sulfide concentration in the gas phase decreased the exchange rate, but the amount of ‘mobile’ sulfur remained unchanged. It should be

Figure 14. Temperature dependences of the rates of thiophene hydrogenolysis (1) and isotope heteroexchange of H₂³⁵S (2) on sulfide Ni–Mo catalysts.¹⁵⁷

The hydrogenolysis activation energy within segment *a* is 14 kcal mol^{–1} and that within segment *b* is 28 kcal mol^{–1}; the activation energy of heteroexchange is 10 kcal mol^{–1}.

stressed that exchange occurs with a measurable rate even at 200 °C, where the hydrogenolysis of the C–S bond is certainly impossible.

The heteroexchange of H_2^{35}S in highly dispersed sulfide catalysts of ‘organometallic origin’ occurs at temperatures ≤ 150 °C.¹⁵⁷ A comparison of the temperature dependences of heteroexchange and hydrogenolysis of thiophene (Fig. 14) shows that at moderate temperatures (250–300 °C), the heteroexchange rate is 2–5 orders of magnitude higher than that of the catalytic reaction. At lower temperatures, the hydrogenolysis of thiophene that requires high activation energy does not occur at all, whereas heteroexchange, which is characterised by low activation energy, occurs readily. It was concluded on this basis^{35,157} that the heteroexchange and hydrogenolysis on sulfide catalysts under conditions of the catalytic reaction occur simultaneously and independently following different unrelated mechanisms.

3. Quantum-chemical calculations

The hypothesis about the decisive role of the energy of bonding of sulfur to the catalyst surface dominates in the concept of the hydrogenolysis mechanism of the C–S bond on sulfide catalysts. Numerous attempts were made to substantiate this hypothesis from the standpoint that vacancies can be formed and involved in the coordination of sulfur-containing molecules, and also to explain the origin of the synergism discovered.

Duben¹⁵⁸ was probably the first to consider the electronic interaction of a thiophene molecule with a molybdenum ion. Although the active site model used (molybdenum in an oxygen environment) was inadequate, the expanded Hückel method made it possible to demonstrate the possibility of donor–acceptor interaction of a thiophene molecule and the vacant d_{z^2} orbital of a Mo^{4+} ion in the d^2 electronic configuration. Based on an estimate of the Mo–S bond strength, it was concluded that the Mo^{3+} active site in the d^3 electronic configuration is the most preferable for adsorption, as it ensures an energetically favourable possibility for the elimination of sulfur and regeneration of the active site.

A study of thiophene adsorption on a molybdenum cluster and on cobalt atoms in a hypothetical active site within the framework of the same expanded Hückel method showed,^{159,160} albeit indirectly, that two ways of thiophene adsorption are possible, *viz.*, either single-point adsorption on an anionic vacancy, or two- or four-point adsorption on cobalt atoms.

However, no studies on the electronic configuration of an active metal atom and its interaction with the substrate were carried out subsequently; instead, research mainly focused on the search for general regularities of catalytic properties as a function of the electronic structure of transition metal sulfides. It was found¹⁶¹ that the reactivities of sulfides of metals belonging to the second and third transition rows in the dibenzothiophene hydrogenolysis differed by 2–3 orders of magnitude. On the other hand, this difference is small for metals of the first transition row. The attraction of this kind of studies was that the regularities obtained could provide a universal key for unravelling the catalysis by metal sulfides as a general phenomenon, since similar dependences of activity on the nature of the catalyst have also been found for other systems, including metals and oxides.¹⁶² Binary transition metal sulfides have been well studied by physical and structural methods (see, *e.g.*, Refs 163 and 164 and references cited therein). The covalency of the metal–sulfur bond, which makes the dominant contribution to the electronic structure of the disulfide, is an important property of binary sulfides used as the basis in theoretical studies.^{165,166}

Calculations aimed at the determination of how the electronic structure of a transition metal depends on its position in the Periodic system and which electronic factor determines the catalytic activity have been performed in a series of studies.^{166–168} The energy levels and charge distribution in octahedral clusters MS_6^{n-} were analysed in a calculation by the scattered wave method (SCF- $X\alpha$). Metals of the first and second transition rows were

used as central atoms in these clusters; the formal oxidation state of sulfur was taken to be 2–, whereas the formal oxidation state of the metal corresponded to that found experimentally. It was found that the calculated covalency of the M–S bond did not correlate explicitly with the sulfide activity. On the other hand, a correlation was found between the number of d-electrons in the HOMO of the transition metal and the activity of its sulfide. Based on the analysis of the HOMO symmetry, it was concluded that not only the presence of a certain number of electrons in the HOMO but also its $2t_{2g}$ -symmetry are prerequisites for high activity. In view of this, a new parameter B was introduced, which specifies the strength of the given bond:

$$B = n_{\sigma}D_{\sigma} + n_{\pi}D_{\pi},$$

where the D_{σ} and D_{π} values determine the contribution of the metal d orbitals to the σ - and π -bonding orbitals of the molecule, whereas n_{σ} and n_{π} are the numbers of the σ - and π -bonding electrons, respectively. Thus the products $n_{\sigma}D_{\sigma}$ and $n_{\pi}D_{\pi}$ are measures of the relative contributions of the σ - and π -components to the M–S bond strength. However, the correlation still remained unsatisfactory; therefore, yet another parameter was introduced, *viz.*, the bond activity parameter A_2 :

$$A_2 = nB,$$

where n is the total number of electrons.

Although this resulted in a relatively good correlation between A_2 and catalytic activity,¹⁶⁶ the physical meaning of this parameter is vague.

This approach was used to explain the nature of synergism in bimetallic sulfide catalysts of hydrotreating. The $[\text{M}'\text{MoS}_9]^{n-}$ cluster, where M' is a metal of the first transition row, was used as the model. This cluster consists of two MoS_6 octahedra sharing three sulfur atoms at their base. The calculations show^{166,167} that if $\text{M}' = \text{Co}$ or Ni , the electrons from the $3d(e_g)$ orbital of the ‘promoter’ atom are transferred to a lower orbital of molybdenum, *viz.*, $4d(t_{2g})$, resulting in the formal reduction of molybdenum. If $\text{M}' = \text{Cu}$, the electron transfer occurs in the reverse direction. No electron transfer occurs in the case of Fe and Zn; for other metals of the first transition row, the situation is uncertain. Thus, the promoting effect is explained by the electron transfer from a promoter’s orbital to the antibonding orbital of molybdenum. Since these electrons are located on an antibonding orbital, the Mo–S bond strength decreases, which results in a decrease in parameter B and an increase in the catalytic activity. Thus, the role of a promoter is to increase or decrease the number of electrons on the antibonding orbital of molybdenum: the higher the electron density on the metal the higher the catalyst activity. Anionic vacancies play the role of active sites; their formation is facilitated when the Mo–S bond weakens.

However, the correlations found do not explain why a linear combination of calculated electronic parameters determines the catalytic properties of binary sulfides of transition metals. Therefore, Topsøe *et al.*^{4,169,170} carried out *ab initio* calculations of the energy-band structures of these catalysts. All calculations were based on the idea of the determining role of the M–S bond strength in the catalyst activity; therefore, the hypothesis was called the bond energy model (BEM). This model considers the hybridisation of the valence states of sulfur with the d-states of the transition metal and hybridisation of the states of sulfur with the s-states of the metal. Different terms were combined to calculate the total bond energy of sulfur in binary sulfides of transition metals. The M–S bond strength was in good correlation with the observed catalyst activity; it was therefore concluded that the activity of transition metal sulfides originates from the difference between the energy gain due to the hybridisation of the metal states with sulfur valence states and the energy loss due to the weakening of the metal–metal bond when sulfur atoms are located on the surface. This viewpoint differs fundamentally from that considered above as, according to it, the maximum catalyst activity is reached at some optimum M–S bond strength.

Thus, the hydrogenolysis rate of the C—S bond should be proportional to the concentration of anionic vacancies on the surface of sulfide catalysts, which depends on the composition of the reaction mixture and the M—S bond strength.

At the next stage of the BEM development, the possibility of the formation of vacancies on an edge plane of a single molybdenum disulfide slab was considered.¹⁷¹ It was shown within the framework of the density functional theory (DFT) that the elimination of a sulfur atom from the (30 $\bar{3}$ 0) MoS₂ edge plane (see Fig. 10) requires no less than 326 kJ mol⁻¹. Considerably less energy (46 kJ mol⁻¹) is required to eliminate sulfur from the (10 $\bar{1}$ 0) edge. It is noteworthy that the interatomic distances in a single molybdenum disulfide slab without anionic vacancies, calculated within the DFT method, differ noticeably from the corresponding distances in a single crystal. Byskov *et al.*¹⁷¹ explain this by the fact that only a relatively small part of the surface was considered in the calculations.

If part of the molybdenum atoms is replaced by cobalt atoms, the elimination of a sulfur atom bonded both to molybdenum and cobalt becomes thermodynamically favourable and gives an energy gain of 34 kJ mol⁻¹. On the other hand, the 'remaining' sulfur atom is very strongly bound to the matrix (222 kJ mol⁻¹). This fact agrees with the calculated Co—S bond lengths (2.34 Å in the former case and 2.24 Å in the latter).

Byskov *et al.*¹⁷² undertook an attempt to determine the geometric form of an active component with the maximum possible number of anionic vacancies, which they believe to be necessary to acquire the maximum catalyst activity. Since the possible number of anionic vacancies at the edge plane of a regular hexagon is quite limited (see Fig. 10), it was assumed that the geometric shape of the active component can be a dynamic function of the reaction conditions. It was found that the maximum concentration of active sites (anionic vacancies) per unit volume is provided by the triangular configuration of the active component. DFT calculations confirmed that the higher the structure defectiveness of the active component the lower the M—S bond strength and the higher the catalyst activity.

The study by Byskov *et al.*¹⁷¹ was based on studies of molybdenum sulfide nanoclusters by scanning tunnelling electron microscopy (STM).^{173,174} The nanoclusters were obtained by sputtering molybdenum atoms on the surface of an Au(111) single crystal in hydrogen sulfide at 127 °C followed by annealing at 400 °C (also in hydrogen sulfide). It was shown by STM that the sample contained islets, mainly triangular, with a mean side length of 30 Å; these are molybdenum sulfide nanoclusters whose basal plane (0001) is oriented parallel to the Au(111) plane. Analysis of nanocluster images obtained at atomic resolution made it possible to establish that the interatomic distances in it are 3.15 ± 0.05 Å, *i.e.*, they are the same as those in molybdenum disulfide. This served as the basis for the conclusion that this method gave a triangular MoS₂ nanocluster, whose edge planes are limited by single sulfur atoms located in irregular lattice positions. After treatment of the cluster with atomic hydrogen, pictures obtained at atomic resolution revealed point defects, *i.e.*, anionic vacancies. The authors claim that they were the first to observe the active site of a catalytic reaction.

Without doubt, these studies^{173,174} have been carried out on the highest experimental level and can be regarded as classical studies of solid surfaces. The results obtained in these studies had a certain resonance in scientific circles (see, *e.g.*, Ref. 175). However, let us try to consider the results described above from the viewpoint of the consistency of the picture obtained with real catalytic systems.

First, the unusual triangular shape of the species is doubtful: the most thermodynamically stable shape of any isolated system is a sphere¹⁷⁶ (or a circle for two-dimensional systems). It was confirmed experimentally that a regular hexagon is the most thermodynamically stable shape of a single molybdenum disulfide slab. The triangular shape of the species indicates that molybdenum disulfide nanoclusters possess an excess of internal energy.

The invariability of this shape after annealing at 400 °C in a hydrogen sulfide atmosphere is only possible in the case of strong epitaxial interaction of the nanocluster with the surface.

In fact, the Au(111) plane is a hexagonal closely packed structure with the Au—Au distance of 2.884 Å. It is well known¹⁷⁷ that epitaxial interaction of solids is only possible if the symmetry groups of the interacting bodies are the same and the interatomic distances are equal to within 10%. In this case, such a coincidence is in fact observed: molybdenum disulfide has a hexagonal densely packed structure with a lattice parameter of 3.16 Å, which differs from the lattice parameter of gold by less than 9%. If the symmetry of the crystal lattice differs from that of the nanocluster, single slabs of molybdenum disulfide are oriented orthogonally to the substrate surface on which they have been deposited by some method (see Ref. 111). This is explained by the absence of strong chemical interaction between the basal surface of molybdenum disulfide and the substrate surface. Therefore, stabilisation occurs due to the formation of chemical bonds between the atoms of the MoS₂ edge plane and the support atoms. For example, parallel orientation of slabs was observed in the MoS₂/Mo(111) system.¹⁷⁸

The second important criticism also corresponds to the shape of the nanocluster species. It is easy to show (see, *e.g.*, Ref. 179) that MoS₂ species of any shape that differs from the regular hexagon are non-stoichiometric; as a result, the macromolecule is no longer electrically neutral. If the species are triangular, sulfur atoms are present in a considerable excess, which inevitably results in a charged cluster [MoS_x]ⁿ⁻. Since epitaxial growth implies the electronic interaction of the substrate with the support, one should expect the electron density transfer from the surface atoms of the support to the triangular nanoclusters of MoS₂. Thus, a considerable excess of sulfur atoms is inconsistent with the conclusion drawn by the same authors^{173,174} regarding the 'inherent' defects of the molybdenum disulfide structure.

The third important issue is related to the discovery of defects (anionic vacancies) after treatment of a nanocluster with atomic hydrogen. As the authors state,^{173,174} a side of the triangle consists of sulfur atoms located in irregular positions of the nanocluster crystal lattice. It is these sulfur atoms that are eliminated upon the reaction of a cluster with atomic hydrogen. On the other hand, according to their calculations,¹⁷¹ elimination of these atoms requires an energy of 326 kJ mol⁻¹. This means that elimination of these atoms is impossible under catalysis conditions, and this defect can exist only in ultra-high vacuum.

Finally, there is the fourth important issue. The model suggested by Byskov *et al.*¹⁷¹ assumes the existence of 'inherent' defects, *viz.*, anionic vacancies.[‡] It is known (see, *e.g.*, Ref. 180) that the linear size of the active component in the most active catalysts is no higher than 10–15 Å. An electrically neutral (MoS₂)_x macromolecule of this size is shown in Fig. 10. On an alumina surface, the active component can have the form of filiform structures up to 50 Å long and several atomic layers high. This is the type of structure considered within the BEM approach. The number of 'inherent' defects in such a structure should be one per cobalt atom or one per two molybdenum atoms. It is easy to see that in this case a single filiform MoS₂ slab should be represented as Mo₂S₃, as the number of anionic vacancies should match the number of defects. Table 7 lists the interatomic distances in a Mo₂S₃ single crystal published by Jonge *et al.*¹⁸¹ and the interatomic distances calculated for a defective molybdenum disulfide structure.¹⁷¹ One can see that these interatomic distances agree well, which is not surprising: the elimination of a sulfur atom

‡ It should be noted that a strong deformation of the MoS₂ slab structure results in new interatomic distances, which favours weakening of the Mo—S bonds. The introduction of cobalt deforms the structure of a MoS₂ slab further. In the most active catalysts, the defectiveness reaches a maximum value, so that a vacancy appears at each cobalt atom.¹⁷²

Table 7. Interatomic distances in the structure of a Mo₂S₃ single crystal and in the defective structure of molybdenum disulfide.

Bond	Interatomic distances (Å) in	
	single crystal Mo ₂ S ₃ ¹⁸¹	defective structure ¹⁷¹
Mo–Mo	2.86	2.85
	3.208	3.12
	3.22	—
Mo–S	2.31–2.72	2.34–2.43

from the MoS₂ structure must inevitably be accompanied by the reduction of Mo(IV) into Mo(III). However, reduced forms of molybdenum disulfide have not been found in any XPS studies of sulfide catalysts. Furthermore, it was reported¹⁸¹ that Mo₂S₃ is crystallised in monoclinic system with space group *P*2₁/*m* (*C*_{2h}), which differs from the MoS₂ symmetry group (see Table 1). It is MoS₂ species that are always detected by high-resolution electron microscopy.

Thus, studies by Topsøe *et al.*^{169–174} contain an internal logical contradiction between the experimental results and theoretical calculations, which they invariably interpret in favour of the bond energy model they are developing, without consideration of the laws of thermodynamics and structural chemistry.

The bond energy concept was also used as the basis of a series of studies carried out by Raybaud *et al.*^{182–186} They used the *ab initio* DFT method to study the crystal structure and the electronic and energetic properties of over 30 transition metal sulfides.^{182, 184} The calculations took into account the actual crystal structure of each sulfide and the possibility of rearrangement (relaxation) of surface atoms in comparison with bulk atoms. The cohesion energy, *i.e.*, intermolecular bonding, was calculated in these studies, unlike in other works.^{169–174} As opposed to the standard heat of formation of sulfides, the cohesion energy is the atomisation energy of a compound. Thus, the energy of each particular bond is a fraction of the total intermolecular interaction energy. In the simplest case, the strength of the M–S bond can be determined as the intermolecular cohesion force divided by the number of valence bonds in a unit cell. The M–S bond strength calculated this way correlates very well with the activity of catalysts measured by Pecoraro and Chianelli.¹⁶¹ However, it should be noted that the bond energies found reflect the actual strength of the M–S bond in the sulfide and are totally unsuitable for kinetic equations for a catalytic reaction. In fact, the M–S bond strength is 210 kJ mol^{−1} in the most reactive sulfide, *viz.*, RuS₂, and 251 and 272 kJ mol^{−1}, respectively, in the less reactive sulfides MoS₂ and WS₂. On the other hand, it is well known that the activation energy of the catalytic hydrogenolysis of the C–S bond is 42–63 kJ mol^{−1} (see, *e.g.*, Ref. 8). If we assume that the elimination of a sulfur atom from the active site is the limiting step, the bond energy of sulfur with this site should not exceed the activation energy.

The DFT method was used to calculate the geometric structure of the surface of a single MoS₂ slab and the electronic structure of molybdenum at the edge plane of this slab.¹⁸³ According to the data obtained, the (3030) edge plane undergoes a noticeable rearrangement: the surface molybdenum atoms are shifted by 0.04 Å into the macromolecule, whereas the surface sulfur atoms are shifted by 0.6 Å in the opposite direction. In our opinion, this agrees very well with the structure of a real macromolecule affected by surface tension forces. Yet another important conclusion drawn by Raybaud *et al.*¹⁸³ is that a rearranged side of a macromolecule is stable at least up to 400 °C.

Finally, the localisation sites of cobalt in the MoS₂ structure were considered.¹⁸⁶ It was found that the replacement of molybdenum atoms by cobalt atoms inside a macromolecule and the coordination of cobalt to sulfur atoms at the (1010) edge plane are less energetically favourable than the replacement of molybdenum atoms at the (3030) edge plane of a single MoS₂ slab. The

optimised interatomic distances Co–S and Co–Mo, which are 2.21 and 2.84 Å, respectively, are in good agreement with the values found experimentally using EXAFS. Based on the concept of the determining role of the M–S bond strength in the catalyst activity, the enthalpy of adsorption of sulfur atoms on metal atoms at the edge plane of a MoS₂ slab was calculated. It should be emphasised that it was the adsorption on coordinatively unsaturated metal atoms that was considered, not the formation of anionic vacancies which was postulated in the previous works. It is believed that the adsorption of sulfur (probably H₂S, as indirectly follows from Ref. 186) involves two adjacent metal atoms simultaneously. The adsorption of sulfur on two cobalt atoms is a weakly isothermic process (the heat of adsorption is 3.8 kJ mol^{−1}). The heat of adsorption of sulfur on the Co–Mo pair increases to 9.6–28.9 kJ mol^{−1} and reaches a maximum value on the Mo–Mo pair (122 kJ mol^{−1}). On the other hand, the adsorption of sulfur on the Ni–Ni and Cu–Cu pairs is endothermic (−38 and −113 kJ mol^{−1}, respectively). The heats of adsorption of sulfur on single metal atoms were not reported in this work, which, as we believe, may be due to their negative values. We calculated the heats of adsorption of sulfur-containing molecules and found⁸⁴ that Ni(II) and Co(II) ions cannot adsorb donor molecules. Such adsorption becomes possible only if these atoms are bound to occluded hydrogen and the active metal is in the d⁶ state.

We are not going to analyse other theoretical studies in detail as this would require a separate review on this subject. Let us just note some remarkable results directly related to the subject of our paper. For example, it was shown¹⁸⁷ that no less than 5 eV is required to create an anionic vacancy in an end face of a molybdenum disulfide molecule. Smit and Johnson,¹⁸⁸ who considered the bond strength of the 3p orbitals of sulfur with the d orbitals of metals, attributed the greatest importance to the metal oxidation state: as a result of the electron density transfer from nickel or cobalt atoms to molybdenum, their oxidation states became higher than those in the binary sulfides. A similar electron density transfer from the Ni atom to MoS₂ was observed by Collman *et al.*¹²² They considered the adsorption of thiophene on coordinatively unsaturated atoms rather than on anionic vacancies (the adsorption of pyridine occurs similarly¹⁸⁹). The totally optimised hexagonal structure of an electrically neutral cluster Mo₂₇S₅₄ was calculated.^{190, 191} According to the calculations, the adsorption of thiophene occurs on the molybdenum atoms located in the vertices and edge planes of this cluster; anionic vacancies were not considered.

Thus, although many authors initially postulate that the M–S bond strength has a determining role in the activity of sulfide catalysts (*i.e.*, that anionic vacancies are involved in catalytic transformations), the majority of them eventually consider the interaction of sulfur-containing molecules with coordinatively unsaturated surface metal atoms. We believe that this is quite an objective reflection of the real situation that the active sites of heterogeneous catalysts participate in the catalytic process.

In conclusion, let us offer several additional arguments against the involvement of anionic vacancies in the catalytic cycle. A thermodynamic estimate of the possibility of formation of anionic vacancies in the MoS₂ and WS₂ structures by the interacting bonds method showed¹⁹² that the appearance of such bonds in a hydrogen atmosphere is unfavourable since the adsorption of hydrogen sulfide on a vacancy gives a much larger energy gain. Therefore, the equilibrium

is always shifted to the left under catalytic reaction conditions.

Direct experimental proof of the absence of correlation between the MoS₂ activity and the concentration of anionic vacancies was obtained in an *in situ* study of the electric conductivity of a MoS₂ single crystal under conditions of pulse-mode hydrogenolysis of butanethiol.^{193–195} A MoS₂ single crystal reduced in a stream of H₂ at 257 °C contained over 10¹⁸ electrons

per cm^3 , which corresponded to the concentration of anionic vacancies. After a portion of butanethiol was injected, the conductivity decreased abruptly and then increased without reaching its original value. The degree of butanethiol conversion did not exceed a few percent. Periodic injection of new portions of butanethiol decreased the conductivity (decreased the concentration of anionic vacancies) and increased the conversion. The conversion in the absence of n-type conductivity was $\sim 100\%$. Thus, an increase in the concentration of anionic vacancies during the reduction of MoS_2 results in a decrease in its reactivity in the hydrogenolysis of the C–S bond, whereas, on the contrary, a decrease in their concentration due to the surface upbuilding by sulfur from the gas phase is accompanied by an increase in the catalytic activity.

Doping of a MoS_2 single crystal with Co^{2+} ions results in p-type conductivity,^{193–195} the concentration of current carriers is almost independent of the thermal treatment conditions in an H_2 or He atmosphere and does not change during the catalytic reaction. The conversion of butanethiol under these conditions is close to 100%. On the one hand, it means that Co stabilises the MoS_2 structure and hinders its reduction. On the other hand, these data confirm again that the involvement of anionic vacancies in a catalytic reaction is not mandatory.

As noted above, sulfide catalysts are highly dispersed systems that operate steadily under real conditions at high temperatures (350–380 °C) and hydrogen pressures of 20–150 atm for long periods (months and years). The following calculations may be shown as an example. The hydrogenolysis rate of dibenzothiophene (the main contaminant in diesel fuel) at 400 °C is $\sim 3 \text{ (g S) (g Co)}^{-1} \text{ h}^{-1}$ (see, e.g., Ref. 165). Let us assume that the liquid hourly space velocity of diesel fuel containing 0.5% sulfur is $5 \text{ g (g Cat)}^{-1} \text{ h}^{-1}$ (where Cat stands for the catalyst). If the catalyst contains 3% of cobalt, it turns out that $0.8 \text{ (g S) (g Co)}^{-1} \text{ h}^{-1}$ passes through it. Thus, at 100% conversion of dibenzothiophene and under the condition that each cobalt atom has an anionic vacancy and can accelerate the reaction, three-fourths of the vacancies are not involved in the catalytic cycle at each time instant but are necessarily present on the surfaces of highly dispersed species. Hence, the active component is a highly defective structure which, nevertheless, works in a stable mode for a period of one year; each active site undergoes a reduction–reoxidation cycle more than 50 000 times during this period.

On the contrary, we believe that the site centre of sulfide catalysts is a thermodynamically stable system[§] with a minimum amount of structural defects.

A brief analysis of studies that dealt with the bond energy model shows that there is a trend to reconsider its fundamental postulate, namely, it is admitted more and more often that it is a coordinatively unsaturated metal atom rather than a point defect in the active component crystal structure that serves as an active site. This concept is consistent with that of the concerted mechanism of action of sulfide catalysts which is being developed at the Institute of Catalysis. Indeed, many experimental facts interpreted within the bond energy model can be explained in terms of the synchronous interaction of reacting molecules in the coordination sphere of a bimetallic active site. For example, the M–S bond strength is identical to the heat of adsorption of a sulfur-containing molecule on the active metal atom. Thus, the necessity of an ‘optimum bond strength’ becomes clear.¹³⁶ The fast heteroexchange of ^{35}S at low temperature^{148–157} should be considered as the intermolecular exchange of an adsorbed hydrogen sulfide molecule with the structure-building sulfur atoms of the active component. It is quite obvious that such exchange does not

require a considerable consumption of energy. The temperature-programmed heating of a sulfide catalyst in hydrogen or in an inert gas atmosphere results in the elimination of adsorbed hydrogen. This follows decisively from a study of the benzene hydrogenation on sulfide catalysts under non-steady-state conditions.^{196–198}

We hope that further progress in the study of the mechanism of action of sulfide catalysts will result in merging of the two alternative concepts into a unified theory of catalysis by metal sulfides.

V. Conclusion

Sulfide catalysts of hydrotreating of oil fractions constitute one of the best-studied and thoroughly characterised systems in heterogeneous catalysis. The success in the studies of these catalysts was considerably favoured by the specific structure of their active component, which is easily recognised among various supports and catalytically inactive surface compounds. However, we are still far from the understanding of the fundamentals of the nature of the catalytic action of sulfide catalysts. The generally accepted views that have been elaborated as a result of studies in areas bordering heterogeneous catalysis turned out to be unsuitable for describing many regularities of catalytic reactions on sulfide catalysts. However, the knowledge of the structure of the active component of these catalysts offers wide opportunities for the understanding of the fundamental bases of heterogeneous catalysis.

The concerted mechanism of action of sulfide catalysts described above is based on the principle of the common nature of heterogeneous, homogeneous and enzyme catalysis as a natural phenomenon. We believe that the active component of a solid catalyst is an electrically neutral macromolecule containing sites of adsorption and activation of substrate molecules. The chemical transformation of the substrate occurs in the coordination sphere of the active component without involvement of structure-forming atoms. Any point defects, including anionic vacancies, should be considered as a result of deviation of this system from the equilibrium state, which should have irreversible consequences, *viz.*, catalyst deactivation, poisoning of active sites, side processes, *etc.*

Below we formulate the main specific features of the concerted mechanism of thiophene hydrogenolysis on sulfide hydrodesulfurisation catalysts.

1. The chemical reaction occurs in the coordination sphere of the bimetallic sulfide active component without involvement of structure-forming atoms in the catalytic cycle.

2. The active sites of thiophene adsorption consist of Ni(IV) or Co(III) atoms in the d^6 electronic configuration. Adsorption occurs due to the interaction of the unshared electron pairs (n_σ and n_π) of sulfur atoms of a donor molecule with vacant d_{z^2} and d_{xy} orbitals of the active metal atom.

3. An indispensable part of the active site consists of an occluded hydrogen atom that appears in the active component due to oxidative addition of a hydrogen molecule to Ni(II) and Co(II) ions during the catalyst sulfidation. The occluded hydrogen is located in the matrix of a single MoS_2 slab in the centre of an ‘empty’ trigonal prism formed by sulfur atoms, under a nickel (cobalt) atom at a distance of 1.5 Å from it.

4. The activation of hydrogen occurs on paired sulfur atoms at the edge planes of a single $\text{MoS}_2(\text{WS}_2)$ slab. The driving force of this process is the presence of the S–S chemical bond at terminal sulfur atoms that border an electrically neutral macromolecule of the active component and act as the Lewis basic site. The excess electron density is transferred from these atoms to the antibonding orbital of a hydrogen molecule, which results in its homolytic dissociation.

5. The high rate of catalytic transformation is ensured by the fast transfer of electrons and protons along the system of chemical

§ Molybdenite, a natural mineral consisting of MoS_2 , is one such stable structure; furthermore, molybdenum disulfide is formed upon thermal decomposition of many molybdenum compounds with sulfur-containing ligands.¹¹¹

bonds within an electrically neutral macromolecule of the active component.

6. The low hydrogenolysis activation energy is explained by the high degree of compensation of the energy required for the cleavage of 'old' bonds in a thiophene molecule by the energy liberated in exothermic processes of adsorption and hydrogenation of the thiophene ring.

7. The concerted mechanism of thiophene hydrogenolysis on sulfide hydrosulfurisation catalysts corresponds to the class of acid–base heterogeneous catalytic reactions.

8. The concerted mechanism is also applicable to other sulfide catalysts that are crystallised in the molybdenite structural type.

Probably, concerted (synchronous) mechanisms of catalytic processes apply to a wider range of heterogeneous catalysts than was believed until recently. The main difficulties in finding such mechanisms are created by the non-uniform composition of the surface compounds and the possibility of their transformation on exposure to the reaction medium. This complicates considerably the analysis of kinetic regularities and makes it necessary to build complex kinetic models. Obviously, the solution to this problem should be searched for on the route to creating heterogeneous catalysts with homogeneous composition and with a known structure of the active component.

Ferrocene-containing nucleic acids. Synthesis and electrochemical properties

T S Zatsepin, S Yu Andreev, T Hianik, T S Oretskaya

Contents

I. Introduction	537
II. Synthesis of ferrocene-containing nucleic acid fragments	538
III. Electrochemical detection of nucleic acids	546
IV. Conclusion	552

Abstract. The published data on the synthesis of ferrocene-containing nucleic acid fragments are generalised. The known methods are systematised and their advantages and disadvantages are discussed. The use of nucleoside, nucleotide and oligonucleotide conjugates with ferrocene in the design of systems for electrochemical detection of nucleic acids is considered. The bibliography includes 121 references.

I. Introduction

Studies of nucleic acids (NA) and their complexes with proteins require the development of highly sensitive procedures for their identification and quantitation in analysed samples. The use of spectrophotometric, autoradiographic and electrochemical techniques for the analysis of nucleic acids envisages usually incorporation of appropriate reporter groups. Incorporation of reporter groups favours higher selectivity of analysis and allows detection of low concentrations of NA with a minimum effect on their structures and functions.

Labelling of NA with radioactive isotopes, ^{32}P in particular (see Ref. 1), has become a very popular procedure. Phosphorus isotopes are incorporated by enzymatic methods using labelled nucleoside 5'-triphosphates or nucleoside 3',5'-diphosphates. The efficiency of this reaction is very high for both short-chain and extended NA. However, manipulations with radioactive isotopes demand certain precautions. Other limitations of the method include short half-lives of ^{32}P , ^{35}S and ^{125}I and radiolysis of labelled NA.

The use of fluorescent labels has received the widest acceptance for the detection of nucleic acids.^{2,3} 5'-Triphosphates of nucleosides, 2'-deoxynucleosides and 2',3'-dideoxynucleosides containing various fluorescent labels are commercially available at present. The use of nucleoside triphosphate conjugates with biotin in enzymatic synthesis of NA enables detection and

selective isolation of target oligonucleotides due to the formation of stable biotin–avidin or biotin–streptavidin complexes immobilised on a polymeric substrate.⁴ Detection of nucleic acids by mass spectrometry [MALDI-MS (see Ref. 5) and ESI-MS (see Ref. 6)] is also being developed at a racing pace.

Electrochemical detection holds a tremendous potential in the analysis of nucleic acids. High sensitivity, low cost, the possibility of performing express analysis and, especially, simplicity of miniaturisation make electrochemical detection a promising tool in the design of DNA chips,⁷ in HPLC and capillary electrophoresis of NA.⁸

Synthesis of modified nucleosides, nucleotides and oligonucleotides containing various metal complexes is an approach to the design of electrochemical NA sensors.⁹ Conjugates of modified oligonucleotides with metal ions can also be used as chemical nucleases^{10,11} and in the studies of electron transfer in DNA.^{12–14} There are several methods for the synthesis of such compounds: (1) conjugation of a metal complex and an oligonucleotide containing a reactive group at the 5'- or 3'-end;^{15,16} (2) addition of metal ions to an oligonucleotide bonded to a chelating group;^{17,18} (3) synthesis of a nucleoside phosphoramidite derivative containing a metal complex^{19,20} and its subsequent incorporation into the oligonucleotide chain by automatic solid-phase synthesis. A recently published review²¹ is devoted to the synthesis of oligonucleotide complexes with platinum-group metals.

The present review deals with the methods of the synthesis and applications of ferrocene-containing nucleosides, nucleoside-5'-triphosphates and oligonucleotides. Nucleosides can be incorporated into NA *via* automated oligonucleotide synthesis and nucleoside-5'-triphosphates enzymatically respectively. Owing to their small size, high stability of oxidised and reduced forms, reversibility and high rates of redox reactions and accessibility, ferrocene derivatives represent promising starting compounds for the synthesis of metal-containing oligonucleotides.²²

Immobilisation of ferrocene-containing oligonucleotides on electrodes permits determination of the primary structure of NA[†] by hybridisation. An alternative approach to the study of nucleotide sequences entails the synthesis of ferrocene conjugates with various molecules capable of selective and effective binding to NA.²⁴ In some cases, ferrocene conjugates with intercalators are used for this purpose.^{25–27} However, the use of ferrocene-containing oligonucleotides ensures the highest specificity of binding

Received 20 December 2002

Uspekhi Khimii 72 (6) 602–621 (2003); translated by R L Birnova

[†] It is known²³ that peptides containing a ferrocene moiety at the *N*-end are used for the studies of spatial structures by electrochemical methods and X-ray diffraction analysis. Unfortunately, no such studies of ferrocene-containing NA have been carried out so far.

to NA targets in comparison with other ferrocene derivatives suggested.

Electrochemical detection of NA on the electrode surface is a promising approach to the study of single nucleotide polymorphism (SNP), the most common type of genome mutations affecting one out of one thousand nucleotide units. It has been shown²⁸ that these mutations are responsible for certain genetic diseases. Direct sequencing studies have demonstrated²⁹ that the human genome contains about 1 420 000 SNP. Other popular procedures for recognition of SNP include the polymerase chain reaction (PCR) with nucleoside triphosphates bearing fluorescent labels³⁰ and the use of DNA chips.³¹

In addition, studies of SNP may include an analysis of single-³² and double-stranded³³ conformational polymorphism and hybridisation in solution followed by gel electrophoresis with denaturing gradient³⁴ or temperature gradient.[‡]

Thus, the methods for the synthesis of ferrocene-containing oligonucleotides and their applications described in this review present interest for specialists in the chemistry of nucleic acids and those engaged in the diagnostics of genetic diseases.

II. Synthesis of ferrocene-containing nucleic acid fragments

1. Synthesis of nucleic acid fragments containing ferrocene in a heterocyclic base

The first paper devoted to the synthesis of ferrocene-containing heterocyclic bases and nucleosides was published in 1991.³⁵ It described several synthetic strategies.

The first of them is based on the reaction of protected 5-iodo-2'-deoxyuridine (**1a**) or 5-iodouridine (**1b**) with ethynylferrocene **2** under conditions of the Sonogashira reaction,^{36,37} viz., stirring of the reactants in triethylamine in the presence of catalytic amounts of bis(triphenylphosphine)palladium dichloride and copper(I) iodide at 40 °C. The yields of the pyrimidine derivatives **3a,b** after removal of trimethylsilyl protective groups were as low as 10%–15%, since under the conditions used these compounds are partly converted into ferrocenylfuro-pyrimidones **4a,b**. The analogous reaction of 8-bromo-adenosine **5** yielded 70% of the ferrocenyl derivative **6**.³⁵

‡ R M Wartell, S Hosseini, S Powell, J Zhu *J. Chromatogr. A* **806** 169 (1998).

It has been shown³⁸ that the 5-(ferrocenylethynyl)uridine derivatives **3a,b** being incorporated into NA were converted into ferrocenylfuro-pyrimidones **4a,b** upon standard postsynthetic treatment of oligonucleotides with aqueous ammonia. The presence of furo-pyrimidone in the oligonucleotide chain reduces thermal stability of a DNA duplex.

Later, Houlton *et al.*³⁹ used another palladium catalyst, viz., tetrakis(triphenylphosphine)palladium, and reduced the reaction temperature to room temperature. Such a change in the experimental conditions and the presence of a 5'-dimethoxytrityl protective group, which enhances the solubility of the starting nucleoside **7**, increase the yield of the substitution product **8** to 75%.

DMTr = $(4\text{-MeOC}_6\text{H}_4)_2\text{PhC}$.

Prior to the incorporation of the nucleoside **8** into the oligonucleotide chain, this was converted into a phosphoramidite derivative. The use of acetyl or phenoxyacetyl groups for the protection of exocyclic amino groups of heterocyclic bases in the oligonucleotide synthesis allowed postsynthetic deprotection of the target oligomers under milder conditions, viz., with 50 mM potassium carbonate in methanol instead of concentrated ammonia, which reduced the risk of cyclisation reactions. However, subsequent hydrolysis of the modified oligonucleotides with snake venom phosphodiesterase and alkaline phosphatase revealed that about 50% of ferrocene-containing nucleosides existed as ferrocenylfuro-pyrimidones. Storage of oligonucleotides in solution causes gradual oxidation of ferrocene with atmospheric oxygen and results in the formation of a ferrocenium cation as demonstrated by reversed-phase HPLC. Therefore, dithiothreitol was added to the solution to stabilise modified uridine residues.³⁹

At present, the Sonogashira reaction is still the most popular procedure for the introduction of a ferrocenyl unit into a heterocyclic base.^{38–43} Thus compounds **11a,b** were prepared starting from 5-iodo-2'-deoxyuridine **9** or its 5'-dimethoxytrityl derivative **7** and alkynyl derivatives of ferrocene **10a,b**. The reaction of compound **10a** with protected 8-bromo-2'-deoxyadenosine **12** yielded a modified nucleoside **13**.

Modified 2'-deoxyuridine **11b** bearing a ferrocene derivative at C(5) was converted into 2',3'-dideoxy-5'-triphosphate **14** and attached to the 3'-end of an oligonucleotide using terminal deoxynucleotidyl transferase.⁴² Compound **14** and its analogues can be used for DNA sequencing according to Sanger⁴⁴ with electrochemical detection.

Grinstaff *et al.*^{40, 41, 45} have developed an original procedure for the incorporation of ferrocenyl derivatives into a growing oligonucleotide chain. This involved coupling of the propynyl ferrocene derivative **10a** with a modified oligomer **15** obtained by attachment of protected 5-iodo-2'-deoxyuridine **7** to the 5'-end of the protected immobilised oligonucleotide in the presence of a palladium catalyst and copper(I) iodide after which the oligonucleotide synthesis was continued. In the last step, the modified oligomer **16** was deprotected with concentrated aqueous ammonia (Scheme 1). Oligonucleotides **17** containing a modified deoxyadenosine residue were prepared in a similar way. The Sonogashira reaction is extremely sensitive to numerous factors, particularly to the presence of trace amounts of primary amines and water; therefore, the yields of the oligonucleotides were 20%–50%. It is of note that the yield of the target product **16** decreased to 8% when coupling of the ferrocene derivative **10a** was carried out after termination of the oligonucleotide synthesis. This can be attributed to steric hindrances created by the 5'-terminal fragment of the immobilised oligonucleotide. The yields of

Scheme 1

R^1, R^2 are fragments of a protected oligonucleotide chain; R^3, R^4 are fragments of an oligonucleotide chain; CPG, controlled pore glass.

the modified oligomers after incorporation of the ferrocene-containing nucleosides **11a** and **13** into the oligonucleotide chain were 10%–15%. The presence of a ferrocenyl-2'-deoxyadenosine derivative in the oligonucleotide chain induces greater destabilisation of a DNA duplex in comparison with its 2'-deoxyuridine analogue.

The second approach³⁵ to the synthesis of NA fragments containing a ferrocene residue in the heterocyclic base includes condensation of the halogenonucleosides **1a,b** and **5** with the organometallic vinylferrocene derivative **18**. The yields of the products **19a,b** and **20** were 15%–20%, which is significantly lower in comparison with the Sonogashira synthesis.

R = H (a), OSiMe₃ (b).

The third variant of the synthesis of NA fragments modified with ferrocene at the heterocyclic base³⁵ consists of cross-coupling of 5-chloromercurioorganic derivatives of uridine **21a,b** and cytosine **22a–c** with vinylferrocene in the presence of lithium tetrachloropalladate and subsequent treatment with sodium borohydride in methanol. This represents a modification of the Heck reaction.^{46,47} Methanol present in the reaction mixture interacts with the exocyclic double bond of the modified nucleoside, whereas sodium borohydride partly reduces it. Thus, the reaction of the uridine derivatives **21a,b** affords, along with the cross-coupling products **23a,b**, compounds **24a,b** and **25a,b** as well. Reaction of the cytosine derivatives **22a,b** with vinylferrocene gave the corresponding ferrocene-containing nucleosides **26–28**. In both cases, the total yields of the modified nucleosides were

15%–30%. The conditions favouring the predominant formation of one of the reaction products were selected.³⁵

21: R = H (a), OSiMe₃ (b); **23–25**: R = H (a), OH (b).

22: R = H (a), OSiMe₃ (b); **26–28**: R = H (a), OH (b).

The cytotoxic activities of deprotected 5-ferrocenylvinyl-2'-deoxyuridine **23a** and 5-ferrocenylvinyluridine **23b** were studied in L1210 cells *in vitro*.³⁵ The lethal dose causing death of 50% of cells (LD₅₀) was by several orders of magnitude lower than that of the traditional antibiotic adriamycin and commensurable with that of ferrocenylmethanol.

The Heck alkenylation of protected 5-iodo-2'-deoxyuridine **7** with vinylferrocene resulted in the formation of two products, (*E*)-**29** and **30** (3 : 1), in a total yield of 60%.^{39,43} An attempt to separate these compounds by TLC and HPLC failed; however, after deprotection of the 5'-hydroxy group (*E*)-5-ferrocenyl vinyl-2'-deoxyuridine was isolated by recrystallisation.

The *Z*-isomer of protected 5-ferrocenylvinyl-2'-deoxyuridine **29** was obtained by Houlton *et al.*^{39,43} by reduction of protected 5-ferrocenylethynyl-2'-deoxyuridine **8** with sodium borohydride in the presence of nickel chloride (yield 30%). Further reduction of compound (*Z*)-**29** under the same conditions afforded 5'-dimethoxytrityl-5-ferrocenylethyl-2'-deoxyuridine **31** in 25% yield.

A method⁴⁸ for the introduction of a ferrocenyl group at the N(3) atom of protected thymidine **32** by Mitsunobu reaction⁴⁹ of ferrocenylmethanol in the presence of tributylphosphine and diethyl azodicarboxylate (DEAD) in THF at room temperature has been proposed. The modified nucleoside **33** was further converted into the phosphoramidite derivative **34** employed for the preparation of ferrocene-containing oligonucleotides. Stacking interactions in such oligonucleotides are strongly violated as can be judged from CD spectroscopic data. As a consequence, duplexes of these oligonucleotides with DNA and RNA are less stable in comparison with natural ones, which makes this modification unacceptable for the design of NA detectors. Incorporation of a phosphoramidite derivative of the modified nucleoside **34** into the oligonucleotides increased the thermal stability of triplexes with double-helical DNA by 1–6 °C; however, their structures differed from the classical one (CD spectroscopic data). An attempt to explain the stabilisation phenomenon failed.⁴⁸

A method for the synthesis of a modified ferrocene-containing nucleoside triphosphate has been proposed.⁵⁰ 5-(3-Aminoprop-1-enyl)-2'-deoxyuridine triphosphate **35** was acylated with ferrocenecarboxylic and ferrocenylacetic acids in the presence of a condensation reagent, *O*-(benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU). The yields of compounds **36a,b** were only 30 and 8%, respectively. Nevertheless, this approach seems to be promising by virtue of its simplicity. Interestingly, the ferrocenecarboxylic acid derivative **36a** is a substrate of DNA polymerase, whereas its structural analogue, the ferrocenylacetic acid derivative **36b**, terminates the enzymatic reaction of elongation of the oligonucleotide chain.

$n = 0$ (**a**), 1 (**b**).

It was recommended⁵¹ to attach ferrocenecarbohydrazide to the aldehyde group of a nonnative heterocyclic base of the oligonucleotide **37** immobilised on a polymeric support. However, the stabilities of the free aldehyde group in compound **37** with respect to oxidation with iodine under conditions of a standard phosphoramidite oligonucleotide synthesis and of the hydrazone formed in the standard postsynthetic treatment with aqueous ammonia are doubtful.

X = NC(CH₂)₂; R¹, R² are fragments of a protected oligonucleotide chain; R³, R⁴ are fragments of an oligonucleotide chain.

A multistep synthesis of an adenine analogue **38** from a ferrocene derivative **39** has been described.⁵² The aldehyde group in the latter was converted into a cyano group in two steps, *viz.*, by reaction with hydroxylamine to give an oxime and dehydration with dicyclohexylcarbodiimide in boiling benzene. The ester group in nitrile **40** was hydrolysed to a carboxy group using NaOH in THF. The reaction of the acid formed with diphenyl phosphoryl azide in the presence of triethylamine and benzyl alcohol was accompanied by Curtius rearrangement and gave compound **41** as the intermediate product; catalytic hydrogenolysis of the latter yielded aminonitrile **42**. Its one-pot reaction with triethyl orthoformate in the presence of *p*-toluenesulfonic acid and treatment of the imidate **43** with methanolic ammonia resulted in compound **38**. The structure of the latter was confirmed by ¹H, ¹³C NMR and IR spectroscopy and mass spectrometry. Further attempts will be aimed at the synthesis of the corresponding adenosine analogue which can be introduced into the oligonucleotide chain and used for the study of electron transfer in DNA duplexes. Most probably, the presence of such a modification within the oligonucleotide chain will strongly impede stacking interactions between 'stacked' heterocyclic bases.

DCC = cyclo-C₆H₁₁–N=C=N–C₆H₁₁–cyclo.

The synthesis of purine and pyrimidine heterocyclic bases containing a ferrocene moiety has been described.^{53, 54} 9-Ferrocenylmethyladenine (**44**) was prepared by alkylation of adenine (Ade) with (ferrocenylmethyl) trimethylammonium iodide.⁵³

The use of this alkylating reagent enables preparation of N(1) thymine (Thy) and cytosine (Cyt) derivatives **45** and **46** as the main products, whereas uracil (Ura) is preferentially alkylated at N(3) to yield compound **47**.⁵⁴

R = H (Ura), Me (Thy).

N(2)-mono- and N(2),N(9)-dialkyl derivatives **49** and **50** were isolated from 2-amino-6-chloropurine **48** as the guanine precursor, whereas the alkylation of 2-acetylguanine **51** occurred at N(7) and N(9) and afforded the products **52** and **53**. The structures of the synthesised compounds were established by X-ray diffraction analysis.

1-[3-(*N,N*-Dimethyl-*N*-ferrocenylmethyl)ammoniopropyl]thymine **54** was prepared by a reaction of 1-(3-bromopropyl)thymine **55** with (ferrocenylmethyl)dimethylamine and isolated in the form of a tetrafluoroborate.⁵³

A method for the introduction of ferrocene residues into oligonucleotides based on a photochemical reaction of a ferrocenyl derivative of psoralene with thymine residues within double-stranded DNA has been developed.⁵⁵ To this end, *N,N*-dimethylaminomethylferrocene was alkylated with chloromethyl psoralene and the resulting compound **56** reacted with DNA in a buffer solution upon irradiation with the light of a mercury lamp ($\lambda = 365$ nm) for 10 min. This resulted in an efficient formation of ferrocene-containing conjugates of double-stranded DNA. The presence of a ferrocene residue was confirmed by cyclic voltammetry. This method enables electrochemical identification of double-stranded DNA, since the ferrocenyl–psoralene derivative reacts exclusively with the DNA duplex.

R^1 , R^2 are fragments of an oligonucleotide chain.

2. Synthesis of nucleosides and oligonucleotides containing ferrocene in the 2'-position of the carbohydrate moiety

There are several methods for the synthesis of 2'-*O*-alkylnucleosides⁵⁶ among which alkylation of free nucleosides with alkyl halides in the presence of sodium hydride is one of the most widespread and efficient procedures. In this case, the selectivity of the reaction involving the 2'-hydroxy group is explained by its higher acidity in comparison with 3'- and, especially, 5'-hydroxy groups. This method was used^{57, 58} for the synthesis of nucleosides containing ferrocenyl units in the 2'-position of the carbohydrate moiety.⁸ The yields of the alkylation products of adenosine **57a** and cytidine **57b** were 40 (isomer ratio 2' : 3' = 2.7 : 1) and 76% (isomer ratio 2' : 3' = 1.8 : 1), respectively.

B = Ade (a), Cyt (b).

Compound **58** containing a dimethylcarbamoylferrocene residue in the 2'-position was synthesised in a similar way; it possessed a redox potential different from that of ferrocene.

Nucleosides **57a,b** and **58** were converted into phosphoramidite derivatives that were employed in the automatic oligonucleotide synthesis. Incorporation of the modified nucleosides into the oligonucleotide chain did not change the thermal stability of the DNA duplexes, which is typical for 2'-*O*-alkyl nucleosides.⁶⁰

The data on the thermal stabilities of ferrocene-containing DNA duplexes are listed in Table 1.

Acylation of 5'-protected 2'-amino-2'-deoxyuridine **59** with *N*-hydroxysuccinimide ester of ferrocenecarboxylic acid is patented.^{61–63} Subsequent phosphorylation of nucleoside **60** occurred at a low rate and resulted in compound **61** in a low yield (30%), which is due to the presence of a bulky substituent in the 2'-position of the carbohydrate fragment.

§ The first report on the use of oligonucleotides containing ferrocene in the 2'-position of the carbohydrate fragment was published three years earlier. However, no detailed description of this synthesis was given.⁵⁹

R is an oligonucleotide.

3. Synthesis of oligonucleotides containing ferrocene at the 5'- or 3'-termini

For the first time, the ferrocene-containing oligonucleotide **62** was prepared by acylation of the 5'-terminal amino group of compound **63** by *N*-hydroxysuccinimide ester of ferrocenecarboxylic acid ^{64–66} containing a ⁵⁷Fe isotope. Later, this approach was used many times, ^{67–71} e.g., for the synthesis of an analogous derivative of ferrocenylacetic acid.⁷² Incorporation of the modified compound into the oligonucleotide structure significantly increased the stability of the triplex with double-helical DNA ($\Delta T_m = 2.5–2.6$ $^\circ\text{C}$).

Recently, it has been proposed ⁷³ to use iodoacetamidoferrocene, which interacts selectively with thiols, for modification of biomolecules. The specificity of incorporation of this reagent was demonstrated using the 5'-thiol-containing oligonucleotide **64** as an example.

R is an oligonucleotide.

The introduction of a ferrocenyl residue at the 3'-end of the oligonucleotide was carried out using postsynthetic acylation of the 3'-terminal amino group of the oligonucleotide **66** with ferrocenecarboxylic acid in the presence of 1-(3-dimethylamino-propyl)-3-ethylcarbodiimide (DEC)⁷⁴ or the addition of 1-aminoethylferrocene to the activated 3'-phosphate group.⁷⁵

ImH is imidazole.

Letsinger *et al.*⁷⁶ recommended the use of the phosphoramidite derivative **69** for the synthesis of ferrocene-containing oligonucleotides. This approach is widely used for incorporation of such markers as biotin, acridine, fluorescein, *etc.* into oligonucleotides. 6-Bromohexylferrocene **70** was synthesised by the Friedel–Crafts acylation of ferrocene with 6-bromohexanoyl chloride with subsequent reduction of the carbonyl group with zinc amalgam. The bromo derivative **70** was converted into alcohol **71** and then into the phosphoramidite **69**.

Synthesis of an analogous phosphoramidite **72** and its application for the synthesis of modified oligonucleotides have been described.⁵⁷

The synthesis of a series of phosphoramidite derivatives including nucleosides entails attachment of a ferrocene residue to the 5'-end of the oligonucleotide.⁷⁷ This is achieved by acylation of amino groups of compounds **73a,b** with ferrocenecarboxylic acid in the presence of a condensation reagent, *viz.*, dicyclohexylcar-

bodiimide. After removal of a *tert*-butyldiisopropylsilyl protective group by treatment with tetrabutylammonium fluoride, the phosphoramidite derivatives **74a,b** were synthesised.

TBDPS = Bu^tPr₂ⁱSi; HOBT = ; TBAF = Bu₄N⁺ F⁻; $n = 2$ (a), 4 (b).

The phosphoramidite derivative of 5'-ferrocenecarboxamido-5'-deoxythymidine **75** was synthesised in a similar way.

Synthesis of 5'-ferrocenecarboxamido-5'-deoxyadenosine **76** from *N*-hydroxybenzotriazole ester of ferrocenecarboxylic acid has been developed recently by Kraatz and co-workers.⁷⁸

Synthesis of compound **77**, which can be used for incorporation of the ferrocene residue inside or at the end of the oligonucleotide chain, has been described.⁷⁹ Condensation of 1,1'-ferrocenedicarboxylic acid **78** with *O*-protected aminoethanol in the presence of dicyclohexylcarbodiimide and subsequent deprotection of the hydroxy groups afforded compound **79**; treatment of the latter with dimethoxytrityl chloride in pyridine affords the monoprotected derivative **77**. Compound **77** was converted into a standard building block for oligonucleotide synthesis (**80**) by phosphitylation. The reaction of the derivative **77** with succinic anhydride and subsequent immobilisation on a solid phase support containing aminoalkyl groups afford compound **81** (Scheme 2). It is known⁸⁰ that non-nucleoside inserts strongly destabilise DNA duplexes; therefore, compound **80** was attached to the 5'-end of the oligonucleotide in the last step of the synthesis (yield 50%). The ferrocene-containing fragment was attached to the 3'-end using compound **81**. The yield of the target oligonucleotide was 12% (possibly due to degradation of the ferrocene residue in the course of an automatic oligonucleotide synthesis, particularly during oxidation of phosphites into phosphates).

The same work⁷⁹ describes the use of a modified polymeric support **82** for the synthesis of oligonucleotide conjugates containing ferrocene at the 3'-end and of 5'-conjugates for inverted automatic oligonucleotide synthesis. Reaction of ferrocene with paraformaldehyde in the presence of butyllithium gave 1,1'-ferrocenedimethanol **83** in which one hydroxy group was protected by dimethoxytrityl chloride and the other one was acylated with succinic anhydride and immobilised on a solid phase support to obtain compound **82**. A phosphoramidite for incorporation inside the oligonucleotide chain can also be synthesised from the ferrocene derivative **83**.

Scheme 2

Synthesis of ferrocene conjugates with peptide nucleic acids has recently been described.^{81, 82} It is known⁸³ that peptide nucleic acids form stable specific duplexes with DNA. These duplexes when they contain mismatches in base pairs are strongly destabilised.^{81, 82} This property was used in the design of a DNA sensor.^{61, 84}

III. Electrochemical detection of nucleic acids

The need for identification and quantitative determination of NA has stimulated the development of numerous analytical methods. Certain known procedures were adapted to the detection of these biomolecules. Electrochemical methods occupy an important place among other techniques for quantitative and qualitative detection of DNA.

Electrochemical activity of NA was discovered about 40 years ago;⁸⁵ the first evidence for the polymorphism of the double helix of DNA was confirmed some time later using electrochemical methods.⁸⁶

Interaction of NA with a charged electrode surface is usually accompanied by strong absorption and concomitant charge transfer reactions. The electrochemical signals thus generated provide evidence about the type of adsorbed molecules, their concentrations, structural changes and an ability to interact with various compounds. Thus NA fragments immobilised on an electrode surface can be used in the design of NA detectors.⁸⁷ Native DNA

is usually analysed using mercury or carbon (less frequently gold, platinum, copper or silver) electrodes. Solid metal electrodes are more suitable for the study of DNA oxidation; the oxidation of guanine and adenine is also carried out on carbon electrodes, whereas reduction is most conveniently studied on the surface of mercury electrodes. Heterocyclic bases are the main NA fragments involved in the redox reactions on electrodes.

Hydrogen bonds formed by complementary base pairs in electrochemically active DNA molecules influence strongly signals elicited during adenine and cytosine reduction on mercury electrodes and provide information about the presence or absence of complementary interactions on the electrode surface, structural transitions and local conformational changes in DNA molecules.^{88, 89}

Redox reactions of native DNA are irreversible and require the application of high positive or negative potentials, which may cause unwanted destruction of DNA chains. The sensitivity of analytical methods can be increased through incorporation of electroactive reporter groups covalently or noncovalently linked to a single-stranded DNA or a DNA duplex. Such markers are capable of reversible redox conversions at low electric potentials on electrodes. Non-covalent binding of reporter molecules to natural DNA can involve: (1) electrostatic and, as a consequence, nonspecific binding to charged phosphate groups of DNA; (2) minor or major groove binding; and (3) intercalation of aromatic molecules between heterocyclic bases of a DNA duplex. Chelate complexes of transition metals and ferrocene derivatives are often used as markers.^{90, 91}

There are two approaches different in principle to detect DNA. In one of them, complexes of stable isotopes of iron or other metals are used as labels. Incorporation of chemically identical labels carrying different isotopes of the same element into the DNA primers has virtually no effect on their physicochemical properties, *e.g.*, electrophoretic mobilities. This allows sequencing of extended NA fragments with high precision. Labelled DNA fragments are identified using resonance ionisation spectroscopy or mass spectrometry. The efficiency of this method for NA detection in the Sanger sequencing and amplification of DNA in the polymerase chain reaction (PCR) was demonstrated by Jacobson *et al.*^{64, 65} However, despite the significant progress in this field in the early 1990's, this method has not received wide recognition, because many reagents and materials used in molecular biological studies, *e.g.*, nylon membranes, contain iron which decreases drastically its sensitivity.⁹²

An alternative approach consists of the use of amperometric techniques for detecting Fe(II)/Fe(III) redox signals. It should be noted that the use of ferrocene and its derivatives as markers permits directed changes in the halfwave potential ($E_{1/2}$) of the redox pair due to inductive effects of substituents in cyclopentadiene rings. This allows variations of electrochemical properties of reporter groups without any significant changes in their size or reactivity.⁶⁶

1. Redox characteristics of ferrocene-containing nucleic acids

The value of the halfwave redox potential $E_{1/2}$ determined experimentally by amperometric methods is an important characteristic feature of molecules involved in redox processes.

Introduction of electron-donor groups into the cyclopentadiene ring of ferrocene decreases the $E_{1/2}$ value, whereas electron-withdrawing groups increase it as was demonstrated by Morris in 1974.⁹³ There are several groups of nucleoside and oligonucleotide ferrocenyl derivatives with similar redox potentials (Table 2). The simultaneous use of several ferrocenyl derivatives enables parallel detection of different NA fragments, *e.g.*, in a flow.

The change in the redox potential upon absorption of ferrocene-containing derivatives on the electrode surface is due to the increase in the dielectric component of the potential of the adsorbed molecule. A comparison of $E_{1/2}$ values for ferrocene oxidation in oligonucleotides (*e.g.*, at the end of an alkyl linker in the 2'-position of the carbohydrate fragment) and in a water-soluble ferrocenyl ethyl phosphate devoid of nucleotide units has been carried out.⁵⁷ It was found that electrochemical characteristics of ferrocene-containing oligonucleotides in solution differ only slightly from those of other ferrocene derivatives.

Studies by cyclic voltammetry have shown that the electrochemical characteristics of the ferrocene unit have virtually no dependence on either the structures of the complexes of ferrocene-containing oligonucleotides with DNA (a duplex or a triplex) or their nucleotide compositions.⁶⁸ A small (10–30 mV) decrease in the halfwave oxidation potential of the ferrocene unit at the 5'-end of a short oligonucleotide upon its incorporation into a triplex may be attributed to the interaction of the ferrocenyl cation with the phosphate groups as a result of which the former is less exposed to the solution. Thus, it was concluded⁶⁸ that ferrocene

can be used as a versatile electrochemical marker for detection and quantitation of DNA.

2. Electrochemical detection of ferrocene-containing DNA fragments and their complexes using HPLC analysis and capillary electrophoresis

High-performance liquid chromatography with UV detection is a popular conventional procedure for purification and analysis of NA^{95,96} owing to its high efficiency and a relatively low cost. Wlassoff and King⁵⁰ have carried out a comparison of various

UV and electrochemical techniques for detecting ferrocene-containing oligonucleotides to demonstrate that the latter enable quantitative determination of DNA in femtomolar concentrations, while the sensitivity of the optical methods does not exceed picomolar concentrations (Table 3), *i.e.*, it is by about three orders of magnitude lower.

Takenaka *et al.*⁶⁷ have developed a highly sensitive method for detecting polynucleotides in solution by hybridisation with complementary oligonucleotides containing ferrocene residues at the 5'-end followed by HPLC analysis and electrochemical detection.

Table 3. Detection limits of ferrocene-containing oligonucleotides established by different analytical methods.

Method	Detection limit /mol (sample concentration /mol litre ⁻¹)	Ref.
HPLC with electrochemical detection	1×10^{-15} (1×10^{-9})	50
HPLC with electrochemical detection (hybridisation of a ferrocene-containing oligonucleotide with a target)	1×10^{-15}	67
HPLC with electrochemical detection, preliminary PCR	1×10^{-19}	69
Capillary gel electrophoresis with sinusoidal voltammetric detection	3×10^{-14} (3×10^{-9}) 1.8×10^{-15} (9×10^{-10})	72 97
Hybridisation of a ferrocene-containing oligonucleotide with a target bound to an oligonucleotide immobilised on an electrode; differential pulse voltammetry	1×10^{-15}	71
Hybridisation of a ferrocene-containing oligonucleotide with a target immobilised on a chitosan-coated glass electrode; differential pulse voltammetry	2×10^{-11} (2×10^{-9})	75
Hybridisation of a ferrocene-containing oligonucleotide with a target immobilised on a carbon electrode; differential pulse voltammetry	5×10^{-11} (5×10^{-9})	74

The sensitivity of this method is comparable with the detection limit of radioactive labels (10^{-15} mol, see Table 3). It is noteworthy that fluorescent and luminescent methods, which demand preliminary enzymatic amplification of DNA with modified nucleoside triphosphates, appeared to be more sensitive, but were more time-consuming in comparison with electrochemical methods (2–3 days vs. 2–3 hours). HPLC with electrochemical detection was successfully used⁶⁷ for quantitation of a series of natural polynucleotides (transport gene of yeast choline, oncogen *v-myc*, eukaryotic mRNA). The analysis of mRNA is facilitated by the presence of a 3'-terminal poly-A sequence, which enables the use of homothymidine sequence as a signal oligonucleotide.

An improved procedure for the detection of DNA in solution developed in 1997⁶⁹ is based on the combination of HPLC⁶⁷ and PCR, which makes it possible to increase the number of DNA copies using ferrocene-containing oligonucleotides as primers.⁹⁸ The amplification products were analysed by HPLC with electrochemical detection, which significantly lowered the detection limits (see Table 3). Yet another advantage of this method is that the analysis does not require the use of control DNA samples, whereas in routine quantitative analyses using PCR, DNA amplification is performed in the same tube with DNA under analysis. This method was used for quantitation of the oncogen *v-myc* and the human muscular dystrophin gene.

Capillary gel electrophoresis has been extensively used over the past decade for the analysis of DNA. It represents a standard and the most efficient procedure for DNA sequencing.⁹⁹ This method combined with the use of fluorescently labelled NA has received wide acceptance. Detection by mass spectrometry is also becoming very popular.¹⁰⁰ In recently published papers,^{8,101} capillary electrophoresis of PCR products (ferrocenyl derivatives of NA) was carried out with electrochemical detection.^{72,97}

The authors of a device for electrochemical detection of biomolecules in capillary gel electrophoresis by an amperometric method suggested that electrochemical labels were directly incorporated into the molecules to be analysed.⁸ Such an approach

allows simultaneous detection of different molecules and is analogous to fluorescence detection at several wavelengths.

Capillary gel electrophoresis with sinusoidal voltammetric detection¹⁰² was used for selective identification of DNA amplification products.⁹⁷ This method is characterised by high signal/noise ratios and maximum selectivity in detecting electrochemically active molecules based on their unique frequency spectra. Oligonucleotides **62**, **86**, **90** and **92** containing ferrocene residues in their 5'-terminal units were used as PCR primers. The electrochemical originality of each of the four oligonucleotide primers was achieved owing to the presence of substituents in the ferrocenyl fragments able to influence the redox potential of ferrocene. This, in turn, enables detection and analysis of distribution patterns of ferrocene-containing oligonucleotides in electrophoretic fractions. In addition, cyclic voltammetric studies have shown that static voltammograms of ferrocene-containing primers virtually do not differ from those recorded under electric field in the electrophoresis. This allows one to extend the scope of the method, since it does not require the use of additional corrections for an electric field.

It was recommended⁷² to use sinusoidal voltammetry for the analysis of single base extension products of an oligonucleotide chain by capillary gel electrophoresis. This was carried out by hybridisation of a DNA probe with a ferrocene-containing primer followed by addition of 2',3'-dideoxynucleoside triphosphate (ddNTP) complementary to the nucleotide under study and thermostable Ampli Taq polymerase from *Thermus aquaticus* (Fig. 1). The extension reaction stopped in the case of a point mutation in the DNA sample. The unreacted primer was separated from the reaction product by capillary gel electrophoresis.[†] The fractions were analysed by sinusoidal voltammetry. This method allows easy miniaturisation, which makes it a convenient tool for the development of an automatic portable system for detecting mononucleotide polymorphism in the genome.

**Figure 1.** A scheme of a one-unit elongation reaction of an oligonucleotide chain.⁷²

3. Electrochemical detection of ferrocene-containing DNA fragments and their complexes on the electrode surface

A biosensor (or a biodetector) consists of an element that selectively recognises biologically active molecules and is connected to a sensor which converts molecular recognition into a physically measurable quantity.¹⁰³ A standard electrochemical detector for DNA hybridisation represents an electrode with short (as a rule, 15–20-mer) oligonucleotides immobilised on its surface (Fig. 2). When such an electrode is placed into a solution containing DNA to be sequenced, a duplex is formed on the electrode surface. The changes in the surface layer are detected by electrochemical or gravimetric methods. The choice of the elec-

[†] It should be noted that this method allows separation of oligonucleotides differing in one unit and containing up to 250 bases.

Figure 2. The formation of a duplex on the electrode surface.

trode material and the immobilisation procedure are crucial steps in the design of DNA sensors.

Immobilisation of oligonucleotides is performed by various methods which include covalent and noncovalent binding to the electrode surface. Thus immobilisation on carbon and mercury electrodes is carried out by the electrostatic adsorption method. Adsorption on positively charged electrodes is achieved owing to electrostatic attraction of negatively charged phosphate groups, which leaves heterocyclic bases accessible for the interaction with specific DNA sequences.

Covalent immobilisation of oligonucleotides on the electrode surface, which involves reactive groups of heterocyclic bases, is hardly recommendable because of a decrease in sensitivity of DNA sensors. The attachment of one end of an oligonucleotide molecule to the electrode surface is the most efficient approach. In the general case, covalent immobilisation of oligonucleotides is more convenient for the design of biosensors, since it permits one to avoid nonspecific binding of electrochemically active molecules.⁸⁷

At present, chemisorption of oligonucleotides on an electrode surface makes use of both modified oligonucleotides and electrodes with a modified surface.¹⁰⁴

In 1996, Letsinger *et al.*⁷⁶ developed a procedure for electrochemical characterisation of a monolayer formed by molecules of an immobilised nucleotide **99** on the surface of a gold electrode. This approach entails incorporation, into the nucleotide, of both a 3'-terminal linker with a thiol group essential for immobilisation and a 5'-terminal ferrocene residue. The monolayer formed after chemisorption of such molecules on the electrode surface was studied by cyclic voltammetry. The data obtained suggest that the surface density of nucleotide molecules on gold is 3.0×10^{-10} mol cm⁻². The applicability of such systems for detection of DNA hybridisation has been demonstrated.⁷⁶

An original gene diagnostics procedure has been developed.⁷⁰ In this method, several phosphothioate groups were introduced into the 5'-terminal region of an oligonucleotide complementary to a specific site of the DNA target and the oligonucleotide was immobilised on a gold electrode. After hybridisation with DNA, the electrode was treated with a solution of a ferrocene-containing oligonucleotide **62** complementary to the free region of the DNA molecule (Fig. 3). The detection was performed using differential pulse voltammetry. If a solution contained a DNA target complementary to both fragments, a sandwich-like system was formed on the surface of a gold electrode, which resulted in the appearance of a peak of anodic oxidation of the ferrocene unit of the oligonucleotide **62**. The concentration of the DNA fragment to be assayed was ~ 50 μ mol litre⁻¹. In control experiments with a nucleotide sequence different from that of the DNA target and an oligonucleotide containing only one mismatch within the recognising seven-nucleotide site, the anodic oxidation peak of ferrocene was virtually absent.

Figure 3. The formation of a three-component sandwich-like system immobilised on a gold electrode.⁷⁰

Later, immobilisation of the phosphothioate-containing oligonucleotide followed by hybridisation with a DNA probe and the signal oligomer **62** were studied in more detail⁷¹ using quartz crystal microgravimetry. The density of the molecules on the electrode surface calculated from the results obtained was equal to 77 pmol cm⁻². Taking into account the magnitude of the square per ferrocene molecule within the complex with DNA (~ 200 – 700 Å²), a conclusion was drawn that the density of the molecules inside the layer was rather high. Since the roughness of the electrode surface was neglected in this study, the theoretically calculated density of the layer package could be significantly overestimated. This, in turn, can be the reason for excessive charge density and a significant (by 215 mV) increase in the redox potential of the ferrocene-containing oligonucleotide **62** in comparison with its oxidation potential in solution (see Table 2). An increase in its potential can be attributed to the destabilisation of the oxidised form of ferrocene in the conjugate, since the DNA chain prevents the approach of counterions to the ferrocenyl cation because of increased density of anionic phosphate groups. This finding is consistent with the results of Letsinger *et al.*⁷⁶ which suggest that the difference in the redox potential values of ferrocene in the immobilised oligonucleotide and in solution amounts to 110 mV. This approach appeared to be extremely sensitive to one-letter substitutions.⁷¹

This method was modified further (Fig. 4).^{58, 59, 61, 62, 105} A gold electrode, following immobilisation of an oligonucleotide, was treated with 16-mercaptohexadecanol in order to protect the

Figure 4. A modified version of an electrochemical analysis of DNA.^{58, 59}

electrode surface from the molecules that can nonspecifically be absorbed and thus violate the results of measurements. This improves the efficiency of measurement.

Immobilisation of oligonucleotides on the surface of a gold electrode was performed using three types of linkers,^{58, 59, 61, 62} viz., a standard linker A and linkers B and C which improve the electron transfer.¹⁰⁶

Immobilisation of sulfur-containing oligonucleotides on the surface of a gold electrode was used in the design of a DNA chip for detecting mutant fragments of DNA in solution at a concentration of $\sim 50 \text{ nmol litre}^{-1}$.⁵⁸ Two ferrocene-containing oligonucleotides differing in their oxidation potentials and complementary to DNA regions of natural and mutant types were used (the probe was taken in a 5–10-fold excess with respect to the DNA under study). Hybridisation of these oligonucleotides with DNA was carried out at an elevated temperature which was optimum for the formation of perfect duplexes. Ferrocene-containing DNA duplexes were detected by alternating current voltammetry. It was found⁵⁸ that such a system enables reliable identification of mononucleotide polymorphism.

The same group of investigators^{105, 107} have developed a new procedure for electrochemical detection of DNA using DNA chips.⁵⁸ This method is based on a comparison of temperature dependences of signal intensities on voltammograms for the formation of perfect and imperfect duplexes with a ferrocene-containing oligonucleotide. With an increase in temperature, imperfect duplexes become unstable, which ensures reliable identification of mononucleotide polymorphism of extended (up to 100 bases) DNA fragments. The advantage of this method includes long-term operation of biosensors without any loss in electrochemical signal intensity.^{105, 107} Such DNA chips were recommended for detection of mononucleotide substitutions in human DNA samples.^{108, 109} The use of DNA chips based on ferrocene-containing oligonucleotides in clinical diagnostic procedures has been surveyed in detail.^{110, 111}

An alternative approach to immobilisation of oligonucleotides has been recently proposed by Houlton and co-workers^{112, 113} who performed direct synthesis of NA on a surface further used as a support.

It is known^{114, 115} that unfolding of hairpin structures of NA can be favoured by interactions with completely complementary oligonucleotides. Detection and analysis of hairpin structures are usually performed with the help of a fluorophore and a fluorescence quencher attached to the opposite ends of the oligonucleotide hairpin (Fig. 5). The formation of a duplex, which competitively interacts with the hairpin, increases the distance between the fluorophore and the fluorescence quencher which results in the enhancement of fluorescence. Such a scheme was

Figure 5. Unfolding of an NA hairpin structure in the presence of a complementary oligonucleotide.^{114, 115} X is fluorophore; Y is fluorescence quencher.

implemented in the case of an oligonucleotide immobilised on gold nanoparticles¹¹⁶ used as fluorescence quenchers.

The same approach was used in the design of a DNA sensor (Fig. 6).^{45, 79} The hairpin immobilised on a gold electrode retains its structure in the presence of mismatching oligonucleotide fragments, while a duplex is formed in the presence of a matching DNA sequence. As a result, the distance between the ferrocene and the electrode increases which reflects on the efficiency of the electron transfer and, as a consequence, on the current.

Figure 6. Electrochemical detection of DNA using a hairpin oligonucleotide.^{45, 79}

A method for detecting DNA on the electrode surface⁷⁴ consists of the following. Single-stranded extended DNA fragments that are analysed are immobilised on a carbon electrode by applying an electric potential of +0.5 V as described by Wang *et al.*¹¹⁷ This is followed by hybridisation with electrochemically active DNA fragments containing a residue of ferrocenecarboxylic acid. The resulting conjugates are analysed by differential pulse voltammetry.

Later, this method was optimised.⁷⁵ For the first time, the carbon electrode was replaced by a glass electrode coated with chitosan, a polysaccharide containing amino groups able to electrostatically interact with negatively charged phosphate residues of DNA. This ensures the strongest binding of DNA under study to the electrode surface. A complementary DNA containing a 3'-terminal ferrocenyl residue is used as a probe. After hybridisation, the signal of ferrocene oxidation was recorded by differential pulse voltammetry. In this case, the detection limit could be lowered to $2 \times 10^{-11} \text{ mol}$ (see Table 3) and the selectivity remained high. However, the ability of DNA immobilised on chitosan due to electrostatic interactions to undergo hybridisation with the probe to form a double helix without disturbing these interactions is questionable.

An interesting application of ferrocene-containing oligonucleotides immobilised on a gold electrode as a model in studies of DNA flexibility has been described.⁹⁴ A 20-mer homothymidine oligonucleotide containing a thiol group at the 5'-end and a ferrocene unit at the 3'-end was used as a model DNA. This

oligomer manifests minimum rigidity in comparison with other sequences. After hybridisation of the immobilised oligonucleotide with a complementary template, the mobility of the 3'-terminal fragment containing a ferrocene residue decreased as could be evidenced from cyclic voltammetry data. At high sweep rates, the peak of ferrocene oxidation disappeared from the voltammograms.

A procedure for detecting ferrocene-containing molecules by a flow injection method has been developed.¹¹⁸ Here, quantitative analysis of electroactive molecules is performed in a buffer solution containing potassium hexacyanoferrate(II), the so-called 'sacrificial reagent' which yields hexacyanoferrate(III) upon oxidation. Direct oxidation of the 'sacrificial reagent' on the surface of a gold electrode is excluded due to preliminary immobilisation of an alkanethiol monolayer (Fig. 7). The hydrophobic ferrocene moieties attached to the analyte can be incorporated into the alkanethiol monolayer. If a potential is applied, the ferrocene immobilised on the electrode surface begins to act as a catalytic mediator of hexacyanoferrate(II) oxidation which is recorded by voltammetry. This method has sufficiently low detection limits for ferrocene detection (an amplification factor of about 300 in comparison with direct measurement of ferrocene-containing molecules in solution).

Figure 7. Detection of ferrocene-containing molecules by a flow injection method.¹¹⁸ R is a molecule to be quantified.

In the general case, HPLC and capillary electrophoresis coupled with electrochemical detection (see Table 3) allow attainment of lower limits for DNA detection in solutions than immobilisation of oligonucleotides on electrodes. Nevertheless, the latter approach seems to hold much promise for the detection of one-letter substitutions.

IV. Conclusion

A variety of methods for attachment of the ferrocene residue at the 5'- and 3'-ends and inside the oligonucleotide chain are presently available. Some of them enable incorporation of ferrocenyl derivatives during automatic oligonucleotide synthesis, while others are used for postsynthetic modification. The choice of an optimum procedure is determined by the experimental task; preference is given to postsynthetic attachment of ferrocene. In the first place, this is due to the commercial availability of nucleosides and oligonucleotides containing reactive groups, since ferrocene-containing nucleosides and their phosphoramidite derivatives are commercially unavailable. Moreover, under standard conditions of an oligonucleotide synthesis ferrocene undergoes partial destruction in the oxidation stage of phosphite groups and during postsynthetic workup in alkaline media. The problem of ferrocene degradation in the oxidation step can be solved by replacing iodine by milder commercially available oxidants, such

as *tert*-butyl hydroperoxide or (1*S*)-(+)-(10-camphorsulfonyl)oxaziridine. It is also recommended to use phosphoramidite nucleoside derivatives with labile acetyl or phenoxyacetyl protective groups which can be removed under very mild conditions. This allows one to increase the yields of modified ferrocene-containing oligonucleotides.

Preparation of modified nucleoside triphosphates is yet another trend in the synthesis of ferrocene-containing NA fragments. It has been shown¹¹⁹ that nucleoside triphosphates with substituents at C(5) of pyrimidine or at C(7) of purine bases are ideal modified substrates for DNA polymerase and RNA polymerase. Earlier, it was found¹²⁰ that 2'-deoxyuridine triphosphate derivatives modified at C(5) with propynyl or (*E*)-propenyl groups are substrates for Taq polymerase unlike (*Z*)-propenyl and propyl derivatives. Based on these data, two synthetic strategies can be distinguished: (1) synthesis of a ferrocene conjugate with a modified nucleoside triphosphate residue containing a chemically reactive group and (2) alkynylation or alkenylation of a nucleoside by a ferrocene-containing derivative and its subsequent conversion into a triphosphate. However, account must be taken of the fact that many nucleoside triphosphate (*E*)-propenyl⁵⁰ and propynyl¹²¹ derivatives are not substrates for DNA polymerases and individual testing of each triphosphate of the modified nucleoside may be required.

The possibility of incorporating a ferrocene residue into a predetermined position of an oligonucleotide chain opens up broad opportunities for the development of diverse systems for electrochemical detection of nucleic acid fragments. There are two approaches to the analysis of DNA. One of them consists of enzymatic synthesis of NA by PCR and makes use of triphosphates of ferrocene-containing nucleosides or 5'-ferrocene-containing primers. The product is further analysed by HPLC or capillary electrophoresis with electrochemical detection. This may also include hybridisation of a ferrocene-containing oligonucleotide with an NA target and detection of the duplex formed. This approach enables detection (including quantitation) of very small concentrations (down to attomoles) of polynucleotides.

The second approach includes detection of DNA on the surface of electrodes containing immobilised oligonucleotides bearing covalently linked ferrocene residues. The use of various detection schemes holds great promise for the analysis of SNP in extended DNA fragments. To obvious advantages of this method one can relate its high sensitivity and selectivity; however, in this case larger amounts of NA are required.

Electrochemical detection is far less efficient than the fluorescent method where parallel capillary electrophoresis is used. However, it is a promising tool in the design of DNA chips. DNA chips, eSensorTM (Motorola Clinical Micro Sensors, Pasadena, CA, USA) and an eSensorTM 4800 Reader allowing DNA analysis simultaneously on 48 chips, have been developed based on original publications.^{57–59, 105}

The authors are grateful to O Yu Smirnova (DKFZ Heidelberg, Germany) for her valuable assistance in preparing this review.

Abstract. Data on the chemistry of the key types of large homo- and heteronuclear polyoxomolybdate clusters published over the last 10 years are generalised. The bibliography includes 95 references.

I. Introduction

Polyoxometallate compounds formed by d elements of Groups V and VI of the Periodic Table have been attracting the rapt attention of researchers for many years.¹ The interest in these substances is related first of all to the possibility of using them as efficient catalysts, biologically active compounds or new analytical reagents.^{1,2} Polyoxometallate complexes often form unique supramolecular ensembles which possess unusual magnetic or spectral properties. For the preparation and practical application of such systems, reliable and efficient methods for the synthesis of polyoxometallates are needed first of all. It is very important to find approaches to the chemical design of clusters containing open shell metal centres,^{3–7} because these systems are expected to form structures possessing unusual electronic characteristics.⁸ It has been suggested that these polyoxometallates can be regarded as representing a new class of inorganic compounds whose chemical activity can be deliberately controlled. This is due to the exceptionally high reactivity of their molecules with respect to various reagents due to the presence of metal centres of different electronic nature.^{1,9}

Some (giant) polyoxomolybdate clusters can be used to perform the design and deliberate engineering of materials with desired properties.¹⁰ For instance, some polyoxometallates can be employed to model n-type semiconductor oxides.¹ Meanwhile, the capability of binding to one another discovered for giant polyoxomolybdate ring-shaped clusters containing nano-sized cavities opens up prospects for the design of unusual polymeric

materials.¹¹ The possibility of introducing magnetically active centres into polyoxometallates makes these compounds promising for the preparation of molecular magnets — magnetic materials of a new generation. All these facts stimulate studies along these lines; nevertheless, development of target-directed synthesis of polynuclear compounds with a specified structure and elucidation of structure – properties relationships still remain among the most important problems.

II. Key principles of the formation of polyoxometallate clusters

Modern inorganic chemistry often deals with large structured systems. The routes for their formation are usually analysed by means of a fairly versatile strategy that has proved to be efficient. According to this strategy, an object is split (at least, hypothetically) into elementary fragments called building blocks (polygons, polyhedra, aggregates composed of such blocks, *etc.*) and then the rules of interaction and mutual binding of these blocks are studied.¹² Such a strategy is used in this review to consider large polyoxometallate clusters.

The ability of elementary building blocks and their derivatives to be linked to one another in different modes is important in many fields of synthetic chemistry, especially in polyoxometallate chemistry. This permits the synthesis of a variety of compounds including those with nano-size properties. Of interest from this standpoint are anionic species composed of building blocks of the {MO_x} type where M are d elements in high oxidation states.^{1,2,9}

In Nature, complex molecules are often formed stepwise, either under conditions of genetic control or in self-assembly processes under dissipative conditions far from equilibrium. Such complex compounds are normally synthesised using a sequence of several reactions, which often proceed over very long periods of time. During these reactions, functional groups are manipulated to form covalent bonds one after another. Modern knowledge in the field of polyoxometallate chemistry allows the use of self-assembly processes in which fragments formed from simple starting compounds can be linked to each other to form various mesoscopic structures (with linear dimensions of several tens

[†] Dedicated to Professor Achim Müller, who has greatly contributed to the development of inorganic chemistry, on the occasion of his 65th birthday.

angstrom or more) and can further form macroscopic substances with network structures.^{13, 14}

The structural principle of the assembly of polyoxovanadates, -molybdates and -tungstates is the same, in particular, in all structures, each metal atom forms a $\{\text{MO}_x\}$ coordination polyhedron mainly due to the $\text{M}-\text{O}$ π -bonding, and these polyhedra, in turn, form the vertices of structural surfaces.¹² Nevertheless, more detailed examination of these unique objects reveals substantial differences depending on the metal atom incorporated in the structure.

The structure of almost any of the very large polyoxotungstate anions, unlike those of vanadates and molybdates, can be represented as being composed of subunits based on defect (lacunary) fragments of the Keggin ion [containing groups of the $\{\text{W}_3^{\text{VI}}\text{O}_{13}\}$ type] or its isomers. This can be explained, in principle, by high stability of such fragments, which is apparently due to the presence of very weak (but not negligible) $\text{W}-\text{W}$ interactions in the $\{\text{W}_3\}$ triangles.¹ A significant feature of polyoxovanadates is the existence of different base types of polyhedra: $\{\text{VO}_4\}$, $\{\text{VO}_5\}$, $\{\text{VO}_6\}$. The pyramidal $\{\text{O}=\text{VO}_4\}$ fragments tend to form cluster shells topologically similar to fullerenes or V_2O_5 layers.^{13, 14}

Most of the very large mixed-valence molybdates can be represented as structures consisting of the same or similar fragments — the $\{\text{Mo}_8\}$ or $\{\text{Mo}_{17}\}$ building blocks, which can be linked in different modes directly to one another or *via* some coordinating centres. Numerous growth processes that conform to these rules have been discovered; they result in the formation of giant ring-shaped, spherical or other systems containing 102, 132, 154, 176 and even 368 molybdenum atoms.¹⁵ The classical $\{\text{Mo}_3\text{O}_{13}\}$ fragment is much less significant and exhibits a much lower tendency for participation in the subsequent assembly of the cluster (at least, in the case of reduced systems) compared to analogous tungstate systems.

Since the chemical behaviours of polyoxometallates derived from different elements are fairly different, the minimum number of metal atoms that allows the cluster to be regarded as large is not the same for vanadates, molybdates and tungstates ($n \geq 19$ for V_n ; $n \geq 24$ for Mo_n ; and $n \geq 20$ for W_n).¹²

This brings about an important question: whether it is possible to assemble even larger molecular structures, for example, clusters of a mesoscopic size. It should be borne in mind that real processes involve binding of a very large number of base fragments. The self-assembly of the tobacco mosaic virus consisting of a large number of pre-organised fragments can serve as an impressive example (see Section VI.1).¹⁶

Undoubtedly, a useful strategy for the formation of giant systems is to create rather large intermediates that could be easily connected in self-assembly processes; in particular, this can involve various cationic metal centres.^{1, 12, 17} Indeed, quasi-pre-organised building blocks present in the solution can be linked to each other either directly or *via* some cations to give giant compounds.¹⁸ At this stage, it is very important to have comprehensive information about the system. The key factor is to preserve high solubility of the intermediates (for example, due to a substantial negative charge), which is necessary to avoid uncontrolled binding and/or too early precipitation. This approach can be illustrated in relation to the replacement of metal centres with a high positive charge by formally less positive centres, in particular, replacement of Mo^{VI} atoms by V^{IV} atoms in the α -Keggin anions $[\text{Mo}_{12}\text{XO}_{40}]^{3-}$ ($\text{X} = \text{P}, \text{As}$). This process gives rise to anionic intermediates with a high negative charge (nucleophiles), which can be either merely stabilised by electrophilic centres or linked by means of these centres to form markedly bigger systems.^{19–21} For instance, during the substitution of vanadium for molybdenum in the $[\text{Mo}_{12}\text{AsO}_{40}]^{3-}$ cluster, the arising intermediates $\{\text{Mo}_8^{\text{VI}}\text{V}_4^{\text{IV}}\text{AsVO}_{40}\}^{11-}$ can be stabilised, for example, by As^{III} centres to give the $[\text{As}_2^{\text{III}}\text{Mo}_8^{\text{VI}}\text{V}_4^{\text{IV}}\text{AsVO}_{40}]^{5-}$ cluster. In the absence of As^{III} and in the presence of NH_2OH as a reducing agent, further condensation takes place.^{19, 21} Finally, the $\{\text{Mo}_{17}\}$ fragments formed as reactive intermediates can be linked in

different ways by cations or cationic groups (VO^{2+} , Fe^{III} , MoO_2^{2+}) to form bigger molecular structures.

According to an empirical rule,¹² if the size of the polyoxometallate anion increases, this anion can participate in further growth processes as a soluble and non-hydrolysable particle only provided that its electron density remains virtually constant (which implies an increase in the overall charge). However, in some cases, the solubility is determined by other factors, for example, the presence of a very large number of coordinated water molecules. The isolation of several giant ring-shaped polyoxomolybdate clusters containing more than 150 molybdenum atoms and anions with low or very low charges can be considered as evidence supporting this statement.²²

To summarise the foregoing, we will list the conditions favourable for the formation of large molecular complex systems from polyoxometallate building blocks in the course of a single reaction (without complicated multistage processes).²³

1. The presence of linkable fragments, *i.e.*, building blocks.
2. The possibility of generating fragments with high values of free enthalpy to initiate polymerisation or growth processes accompanied, for example, by evolution of H_2O molecules.
3. The ready possibility of changing the structure of the building blocks.
4. The possibility of introducing heteroatoms into the fragment blocks.
5. The possibility of forming larger fragment blocks suitable for linking in different ways.
6. Neither too weak nor too strong binding between the fragments.
7. The possibility of controlling structuration processes by templates.
8. The possibility of forming structural defects, for example, lacunary structures, in reaction intermediates.
9. The presence of low-lying unoccupied molecular orbitals in the fragments.
10. The possibility of electron density localisation and delocalisation.
11. The opportunity to control and change the charge, for example, by protonation, electron transfer reactions or by replacement of some fragments.

In principle, by selecting and creating particular conditions, one can synthesise molecular systems comparable in size even with proteins.

III. Formation of cluster anions containing $\{\text{Mo}_{17}\}$ fragments

The fragment containing 17 molybdenum atoms ($\{\text{Mo}_{17}\}$) is one of the most frequently encountered building blocks incorporated in polyoxomolybdate clusters. This fragment can be found in the $[\text{Mo}_{36}\text{O}_{112}(\text{H}_2\text{O})_{16}]^{8-}$ cluster anion (**1a**) (produced upon acidification of an aqueous solution of sodium molybdate with hydrochloric or nitric acid at a 36:64 molar ratio) and the $[\text{Mo}_{36}(\text{NO})_4\text{O}_{108}(\text{H}_2\text{O})_{16}]^{12-}$ cluster anion (**1b**) [formed upon the reduction of aqueous solutions of molybdates(VI) with hydroxylamine].^{21, 24–30}

It is noteworthy that the structures of both cluster anions formally include a large number of diverse coordination polyhedra (Fig. 1, see p. 559), namely, two $\{\text{MoO}_6\}$, four $\{(=\text{O})\text{MoO}_4(\text{H}_2\text{O})\}$, eight $\{(=\text{O})_2\text{MoO}_3(\text{H}_2\text{O})\}$, eight $\{(=\text{O})\text{MoO}_5\}$ and two $\{(=\text{O})_2\text{MoO}_4\}$ octahedra; four $\{\text{Mo}(\text{X})\text{O}_6\}$ pentagonal bipyramids [$\text{X} = \text{O}$ (**1a**), NO (**1b**)] and four $\{\text{Mo}_2\text{O}_8(\mu\text{-O})(\mu\text{-H}_2\text{O})\}$ fragments consisting of two octahedra sharing an edge. Anion **1b** contains two fairly large fragments, $\{\text{Mo}_{15}^{\text{VI}}(\text{MoNO})_2^+ \text{O}_{58} \cdot (\text{H}_2\text{O})_2\}^{20-} \equiv \{\text{Mo}_{17}\}$, connected by two $\{\text{MoO}_2\}^{2+}$ groups in which two terminal oxygen atoms occupy *cis*-positions.

The $\{\text{Mo}_{17}\}$ fragments are composed, in turn, of two $\{\text{Mo}_8\}$ fragments linked through eight oxygen atoms and one molybdenum atom. The centres of these fragments are formed by

{MoXO₆} pentagonal bipyramids, each of them being linked to five {MoO₆} octahedra *via* edges; two of these octahedra are bound additionally to two more peripheral octahedra. The hypothetical replacement of the {MoNO}³⁺ groups by {MoO}⁴⁺ groups results in non-reduced anion **1a**. Similar {Mo₈} fragments can also be found in the structures of molybdenum oxides, Mo₅O₁₄ and Mo₁₇O₄₇ (see Ref. 31).

In anions **1a** and **1b**, the {Mo₁₇} fragments are linked by two {MoO₂}²⁺ centres to *cis*-arranged oxygen atoms. Cluster **1b** is stabilised due to double protonation of two bridging and four terminal oxygen atoms contained in two bridging and four terminal H₂O ligands, respectively. The presence of altogether four bridging H₂O ligands is an interesting structural feature of anion **1b** in which each of the four bridging water molecules belongs to one of four {Mo₂O₈(μ-O)(μ-H₂O)} fragments and participates in the binding of two corresponding octahedra by sharing an edge.

By further reduction of the cluster anion [Mo₃₆(NO)₄·O₁₀₈(H₂O)₁₆]¹²⁻ (**1b**) with excess hydroxylamine, it is possible to isolate a compound containing one-dimensional chains consisting of 38-nuclear cluster anions [(H₂O)Mo_{2.5}{Mo₃₆·(NO)₄O₁₀₈(H₂O)₁₆}O_{2.5}Mo(H₂O)]¹²⁻ (**2a**) (here and below, letter 'a' denotes the cluster anion derived from the corresponding compound).³² Compound **2** can be represented as consisting of initial cluster anions **1b** attached to each other by neutral binuclear fragments, {(H₂O)₂Mo^{VO}Mo^{VO}O₂(H₂O)}, which are shaped like two tetrahedra sharing a vertex. It is considered that not only some molybdenum(VI) ions (arising probably upon the destruction of some cluster anions **1b**) are reduced during the reaction to give binuclear {(H₂O)₂Mo^{VO}Mo^{VO}O₂(H₂O)} fragments but some molybdenum atoms in anions **1b** are also reduced with generation of active sites. These are the active sites that participate in the binding to the {(H₂O)₂Mo^{VO}Mo^{VO}O₂(H₂O)} fragments during further self-assembly and are finally oxidised by air oxygen.³²

The presence of large {Mo₁₇} fragments in type **1b** systems is a very important feature of these clusters. This opens up the possibility of generating larger systems by binding {Mo₁₇} fragments as ligands with a high negative charge by various electrophilic groups. In the case of cluster **1b**, this function is performed by the {MoO₂}²⁺ cations.

When other electrophiles such as Fe^{III} or V^{IV} are used in the preparation of cluster **1b**, this yields giant cluster anions with the {Mo₅₇M₆} metal core. The synthesis can be carried out in two ways by using either compounds of heterometal M in higher oxidation states (Fe^{III}, V^V) in the presence of a reducing agent (NH₂OH·HCl) or a reducing agent alone containing atoms of the heterometal in a lower oxidation state (Fe^{II}, V^{IV}).

The resulting highly symmetrical (*D*_{3h}) cluster anions [{V^{IV}(H₂O)O}₆{Mo^V(μ-H₂O)₂(μ-OH)Mo^V}₃{Mo₁₅^{VI}(MoNO)₂O₅₈·(H₂O)₂}₃]²¹⁻ ≡ {Mo₅₇V₆} (**3a**)²¹ and [{Fe^{III}(H₂O)₂}₆{Mo^V·(μ-H₂O)₂(μ-OH)Mo^V}₃{Mo₁₅^{VI}(MoNO)₂O₅₈(H₂O)₂}₃]¹⁵⁻ ≡ {Mo₅₇Fe₆} (**4a**)¹⁹ each contain 276 non-hydrogen atoms. They tend to form a variety of different coordination polyhedra. Each of these anions (Fig. 2, see p. 559) includes three MoO₆, six (O=)MoO₄(H₂O), twenty four (O=)MoO₅, twelve (O=)₂MoO₄ and six (O=)V(H₂O)O₄ or FeO₄(H₂O)₂ octahedra, six Mo(NO)O₆ pentagonal bipyramids, as well as O₃{Mo^V(μ-H₂O)₂(μ-OH)Mo^V}O₃ fragments, which can be described as two octahedra sharing a face. These structures are formally composed of three above-noted large {Mo₁₅^{VI}(MoNO)₂O₅₈(H₂O)₂}²⁰⁻ ≡ {Mo₁₇} fragments functioning as bridging ligands connecting six cationic centres [(O=)VO₄]²⁺ in anion **3a** and {FeO₄(H₂O)₂} in anion **4a**] and three {Mo^V(μ-H₂O)₂(μ-OH)Mo^V}⁹⁺ binuclear groups. Yet another important feature of structures **1b**, **3a** and **4a** is the presence of bridging H₂O ligands, six in anions **3a** and **4a** and four in anion **1b**. In clusters **3a** and **4a**, these ligands occupy bridging positions between neighbouring Mo^V centres, giving rise to three {Mo^V(μ-H₂O)₂(μ-OH)Mo^V} fragments, which can

be described as two octahedra sharing a face. In anion **1b**, each of four bridging H₂O molecules belongs to one of four {Mo₂O₈(μ-O)(μ-H₂O)} fragments, the corresponding octahedra sharing an edge.

The fairly large cavities inside these cluster anions are formally accessible, for example, to solvent molecules, owing to two 'holes' situated on the S₃ axis. These cavities whose diameter (without taking into account the hydrogen atoms) equals ~0.9 nm in the direction normal to the S₃ axis and ~0.5 nm in the direction parallel to the S₃ axis are formed by the central {O₃₃} polyhedron. Two 'holes' are confined by two nearly planar 12-membered rings with the Mo—O—M—O fragments [M is V (**3a**) or Fe (**4a**)] in which metal atoms alternate.

One more important structural feature of these systems is the presence of three, rather large cavities between the {Mo₁₇} fragments. These cavities are accessible for further coordination of highly electrophilic oxometallate fragments, for example, {MoO}⁴⁺ (see Ref. 8) or {VO}³⁺ (see Ref. 33), which results in discrete growth of such structures to give anions such as {Mo_{57+x}V₆} and {Mo₅₇V_{6+x}} (x = 0–6). Each {MoO}⁴⁺ or {VO}³⁺ group is bound to three oxygen atoms belonging to the {Mo₅₇V₆} core; hence, the metal atoms in these groups exist in a tetrahedral environment. The degree of occupancy of the cavities can be brought in correlation with the degree of reduction of the initial cluster **3a**. The reduction of anion **3a** (Fig. 3, see p. 559) results in an increase in its nucleophilicity, thus initiating the growth, which may involve the insertion of up to six electrophilic centres, {MoO}⁴⁺ or {VO}³⁺, to give [H₃Mo₅₇V₆(NO)₆·O₁₈₉(H₂O)₁₂(MoO)₆]²¹⁻ and [H₃Mo₅₇V₆(NO)₆O₁₈₉(H₂O)₁₂·(VO)₆]¹⁵⁻ clusters, respectively.

Despite the fact that compounds **3** and **4** lose some water of crystallisation when stored in air, this does not influence their stability. According to IR spectroscopy data, they do not decompose up to a temperature of 225 °C. These compounds are also stable in aqueous solutions at pH 2.5–3.5 for several days. At lower or higher pH values, anions **3a** and **4a** decompose instantaneously, apparently, due to the electrophilic character of the NO group.

Note that by addition of various amounts of FeCl₂·4H₂O or FeCl₃·6H₂O to the reaction solution (crystallisation of which gives compound **3**), one can prepare a series of clusters with the same cluster core but with different statistical distribution of oxovanadium(IV), iron(II) and iron(III) centres among octahedral 'heterometallic' positions. Examples of compounds synthesised in this way are compounds with {Mo₅₇V₄Fe₂}, {Mo₅₇V₃Fe₃}, {Mo₅₇V₂Fe₄} and {Mo₅₇VFe₅} cluster anions containing iron(II) and iron(III) and the {Mo₅₇VFe^{III}₅} cluster anion incorporating only iron(III) atoms. It should be noted that both the overall number of inserted iron atoms and the Fe^{II}/Fe^{III} ratio depend on the reaction conditions, in particular, on whether it was carried out in air or under an inert atmosphere.³⁴ This circumstance allows one to change the ratio of the number of vanadium centres to the number of iron centres (*n_V*/*n_{Fe}*) distributed over six positions, which form a trigonal prism inside the cluster, by varying experimental conditions. During the formation of a heterometallic cluster, only a small amount of FeCl₃·6H₂O is required for the insertion of iron into the giant cluster anion. However, when FeCl₂·4H₂O is used as the iron-containing component, a large excess of iron(II) chloride is needed to reach the same *n_V*/*n_{Fe}* ratio. Apparently, this outcome is related, according to the Pearson principle, to the higher reactivity of 'hard' iron(III) centres with respect to 'hard' acids (oxygen atoms), which are present in the coordination environment provided by the shell of the initial homomolybdenum cluster. Upon the addition of excess FeCl₃·6H₂O, compound **4** can be isolated.

Magnetic properties of compounds of this type depend on both the overall content of iron and the Fe^{II}/Fe^{III} ratio. As expected, an increase in the iron content results in an increase in the magnetic susceptibility χ.³⁴ In the case of compounds containing both iron(II) and iron(III), the χ*T*(*T*) curve passes through a

maximum in the field of low temperatures, this maximum being more pronounced for clusters with high contents of iron. Although full analysis of the magnetic parameters for such systems is as yet rather difficult, this type of $\chi T(T)$ dependence is usually observed for ferrimagnetic systems. As the iron content decreases, the χT decreases and the ferrimagnetic properties become less pronounced. In the limiting case, where no iron is involved (e.g., in $\{\text{Mo}_{57}\text{V}_6\}$), as for the intermediate compound (in $\{\text{Mo}_{57}\text{V}_4\text{Fe}_2\}$), the system follows an antiferromagnetic type of behaviour. It is noteworthy that the insertion of iron(II) enhances the ferrimagnetic properties, while the $\chi T(T)$ curve for $\{\text{Mo}_{57}\text{VFe}_5^{\text{III}}\}$, unlike that for $\{\text{Mo}_{57}\text{VFe}_5\}$, does not exhibit a maximum typical of ferrimagnetics. Müller *et al.*³⁴ believe that the pattern of the $\chi T(T)$ curves, especially in the case of ferrimagnetic systems, can be interpreted only by assuming the presence of different paramagnetic centres in the same cluster anion (rather than in different anions with the same average ratio of the numbers of such centres over all anions).

These data may suggest that deliberate variation of the electronic state of heterometallic centres would allow one to control the magnetic properties of the synthesised clusters.

The compound $(\text{NH}_4)_{21}[\text{Mo}_{45}^{\text{VI}}\text{Mo}_6^{\text{V}}(\text{MoNO})_6\text{Cu}_2^{\text{II}}\text{V}_4^{\text{IV}}\text{O}_{178} \cdot (\text{OH})_3(\text{H}_2\text{O})_{16}] \cdot 60\text{H}_2\text{O}$ (**5**), containing three sorts of metal atoms — molybdenum, copper and vanadium,³⁵ is produced in the reaction of the $(\text{NH}_4)_{12}[\text{Mo}_{36}(\text{NO})_4\text{O}_{108}(\text{H}_2\text{O})_{16}] \cdot 33\text{H}_2\text{O}$ cluster (**A**) with excess $\text{Cu}^{\text{I}}\text{Cl}$ on heating in water at 60 °C with subsequent addition of VOSO_4 . The geometry of the corresponding cluster anion **5a** is similar to that observed for structures **3a**, **4a** except that in this anion, about two $\{\text{Cu}(\text{H}_2\text{O})_{1.2}\}^{2+}$ centres (the corrected occupancy of positions is close to unity) and about four $\{\text{V}=\text{O}\}^{2+}$ centres are distributed statistically over six heterometallic positions. Since these centres are disordered, they cannot be distinguished by X-ray diffraction; however, according to elemental analysis, the V/Cu ratio is equal to 4:2. The binuclear linkers in anion **5a** are fully reduced, and their structure can be described as $\{\text{Mo}^{\text{V}}(\mu\text{-H}_2\text{O})_2(\mu\text{-OH})\text{Mo}^{\text{V}}\}^{9+}$.

Thus, the synthetic strategy chosen can be used to prepare giant cluster anions $\{\text{Mo}_{57}\text{M}_x^{\text{I}}\text{M}_{6-x}^{\text{II}}\}$ with metal atoms of different sorts, which is especially important as regards the development of multifunctional catalysts.

As noted above, the $\{\text{Mo}_{57}\text{M}_6\}$ type anions are formally assembled from different blocks and linkers. However, due to the presence of reactive fragments, they can themselves function as building ‘superblocks’ for the formation of supramolecular structures. For instance, the reaction of cluster **A** with excess $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ on heating in water (65 °C) gave the compound $^{36} \{(\text{NH}_4)_{12}[\text{Mo}_{45}^{\text{VI}}\text{Mo}_6^{\text{V}}(\text{MoNO})_6\text{Fe}_6^{\text{III}}\text{Fe}_{1.5}^{\text{II}}(\text{OH})_3(\text{H}_2\text{O})_{30}] \cdot 64\text{H}_2\text{O}\}_n$ (**6**), containing a $\{\text{Mo}_{57}\text{Fe}_{6.5}^{\text{III}}\}^{12-}$ type cluster anion (**6a**), which is similar in structure to other clusters of this family considered above. Three large $\{\text{Mo}_{17}\}$ building blocks are linked to each other by three binuclear $\{\text{Mo}^{\text{V}}(\mu\text{-H}_2\text{O})_2(\mu\text{-OH})\text{Mo}^{\text{V}}\}^{9+}$ fragments and six octahedral $\{\text{Fe}(\text{H}_2\text{O})_2\}^{3+}$ centres. However, the structure of **6** has a significant distinction from the structures of **3–5** (Fig. 4), namely, the crystal contains additional $\{\text{Fe}(\text{H}_2\text{O})_4\}^{2+}$ centres in 12 symmetrically equivalent positions, the degree of occupancy of each of them being 25% (which corresponds to 1.5 Fe^{II} centres per one cluster anion). The ^{57}Fe Mössbauer spectrum of compound **6** recorded at 150 K contains two doublets, $\delta_1 = 0.48/\Delta E_1 = 1.10$ (typical values for $\text{Fe}^{\text{III}}\text{O}_6$) equal to 80%; $\delta_2 = 1.29/\Delta E_2 = 3.13$ (typical values for $\text{Fe}^{\text{II}}\text{O}_6$) equal to 20% (δ_i is the position of the line centre, ΔE is splitting). The $\text{Fe}^{\text{III}}/\text{Fe}^{\text{II}}$ ratio according to Mössbauer spectroscopy is also equal to $6/1.5 = 4$. These additional metal centres play a role of linking fragments between the clusters; they form a planar network structure in which any two neighbouring cluster anions are bound according to the $\text{Mo}-\text{O}-\text{Fe}^{\text{II}}-\text{O}-\text{Mo}$ pattern (see Fig. 4).

Compound **6** is the first example of polymeric anionic networks formed by the $\{\text{Mo}_{57}\text{M}_6\}$ cluster blocks. The principle of formation of this structure can be clearly followed: first, the $\{\text{Mo}_{17}\}$ fragments are connected by $\{\text{Fe}(\text{H}_2\text{O})_2\}^{3+}$ linkers to

form cluster anions of the $\{\text{Mo}_{57}\text{Fe}_6^{\text{III}}\}$ type, while the resulting fragments are connected by the $\{\text{Fe}(\text{H}_2\text{O})_4\}^{2+}$ linkers to form a cross-linked network. Finally, the chemical and physical properties of this compound are determined by a diversity of metal centres in different oxidation states (Mo^{VI} , Mo^{V} , Fe^{III} , Fe^{II}). Its electronic structure may be favourable for the temperature-dependent transfer of electrons in anion **6a**.^{37,38}

IV. Interconversions of some polyoxomolybdates in organic solvents

Whereas studies dealing with the chemistry of water-soluble polyoxomolybdates carried out in recent years revealed a great number of diverse structures containing giant cluster anions including mixed-valence and heterometallic ones (see, for example, Refs 12, 23), the chemistry of polyoxomolybdates in solutions in organic solvents has been much less studied. The studies mainly dealt with modification of the known polyoxometallate systems such as the $[\text{Mo}_6^{\text{VI}}\text{O}_{19}]^{2-}$ anion (Lindqvist's structure)³⁹ by various functional groups, resulting in nitrosyl, diazenide, hydrazide, cyclopentadienyl and diazoalkane derivatives.^{40–47} The conditions and ways of generation, and, what is most important, the interconversions of unsubstituted polyoxomolybdates in organic solvents have been little studied. The relevant data are described systematically in a publication.⁴⁸

The exchange reaction of ammonium heptamolybdate $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24} \cdot 4\text{H}_2\text{O}$ with tetrabutylammonium halides gives, after recrystallisation of the precipitated white solid from acetonitrile, colourless crystals of $(\text{NBu}_4)_4[\text{Mo}_8\text{O}_{26}] \cdot 4\text{MeCN}$ (**7**). According to X-ray diffraction data (Fig. 5), the octanuclear cluster anion $[\text{Mo}_8(\mu_3\text{-O})_6(\mu_2\text{-O})_6\text{O}_{14}]^{4-} \equiv [\text{Mo}_8\text{O}_{26}]^{4-}$ (**7a**) present in this compound contains six Mo^{VI} atoms in an octahedral environment and two Mo^{V} atoms in a tetrahedral environment. Each molybdenum atom in the octahedral environment is connected to two terminal, two μ_2 -bridging and two μ_3 -bridging oxygen atoms, while each molybdenum atom in the tetrahedral environment is linked to one terminal and three μ_3 -bridging oxygen atoms. In the polyhedral representation, anion **7a** can be regarded as an assembly formed by a ring composed of six MoO_6 octahedra, any of which shares two edges with two neighbouring octahedra. This gives rise to a ring closed on two sides by two MoO_4 tetrahedra, which are rotated through 60 ° relative to each other. The solvation acetonitrile molecules occupy the voids between the tetrabutylammonium cations and the cluster anions.

The reaction of cluster **A** with NBu_4^+X^- ($\text{X} = \text{Cl}, \text{Br}, \text{I}, \text{ClO}_4$) in an aqueous solution in air at room temperature followed by recrystallisation of the resulting beige-coloured precipitate from acetonitrile afforded yellow-coloured compound $(\text{NBu}_4)_2[\text{Mo}_6\text{O}_{19}]$ (**8**). The corresponding hexanuclear cluster anion $[\text{Mo}_6\text{O}_{19}]^{2-}$ (**8a**)³⁹ contains six Mo^{VI} atoms in a distorted octahedral environment.⁴⁸ Note that during this reaction, four $\{\text{Mo}^{\text{II}}(\text{NO})\}^{3+}$ groups of cluster **1b** are oxidised, probably, by air oxygen to yield four $\{\text{Mo}^{\text{VIO}}\}^{4+}$ groups. Correspondingly, each 36-nuclear cluster anion **1b** decomposes to give six anions **8a** with the loss of 16 electrons. In cluster **8a**, each of the six molybdenum atoms (Fig. 6) is connected to one terminal, four μ_2 -bridging and one μ_6 -bridging oxygen atoms. In terms of the polyhedral representation, anion **8a** can be regarded as a structure consisting of six MoO_6 octahedra, each of them sharing four edges with four neighbouring octahedra and all six octahedra having one common vertex.

The composition of the products of decomposition of cluster **1b** on treatment with tetrabutylammonium salts depends appreciably on the reaction conditions.⁴⁸ When an aqueous solution of cluster **A** is refluxed in air for 40 min, its colour changes from red-brown to blue-green, while the addition of tetrabutylammonium halides gives rise to a blue-green precipitate. Recrystallisation of this product from acetonitrile in air affords the crystals of octanuclear cluster **7**.

Figure 1. Structure of anions **1a** and **1b**. One $\{\text{Mo}_{17}\}$ fragment is shown in the polyhedral representation and the other is in the atomic representation.

The turquoise-coloured pentagonal bipyramids are the $\{\text{Mo}(\text{X})\text{O}_6\}$ fragments, the yellow octahedron is the $\{\text{MoO}_6\}$ fragment, and blue octahedra are the other fragments; yellow spheres are the molybdenum atoms in the $\{\text{MoO}_6\}$ and $\{(\text{O}=\text{O})_2\text{MoO}_4\}$ fragments and blue spheres are the other molybdenum atoms.

Figure 2. Structure of cluster anions **3a** and **4a**.

In the polyhedral representation, heterometallic centres (turquoise-coloured polyhedra) and binuclear linking groups (blue polyhedra) are shown.

Figure 3. Molecular growth of clusters of the $\{\text{Mo}_{57}\text{M}_6\}$ family with filling of outer cavities.⁸

The turquoise-coloured polyhedra are heterometallic fragments; blue polyhedra are fragments formed by molybdenum atoms; yellow polyhedra are $\{\text{MoO}\}^{4+}/\{\text{VO}\}^{3+}$ fragments.

Figure 4. Network structure of cluster **6** and hierarchy of building blocks during its formation.

Figure 5. Structure of anion **7a** in the atomic (*a*) and polyhedral (*b*) representations.

Figure 6. Structure of anion **8a** in the atomic (*a*) and polyhedral (*b*) representations.

Figure 7. Fragment of the linear supramolecular structure of compound **9**.

Figure 8. Structure of cluster anion **10a** in the polyhedral representation. Yellow octahedra are $\{\text{Mo}_1\}$ fragments, blue pentagonal bipyramids are the central $\{(\text{O}=\text{O})\text{MoO}_6\}$ parts of the $\{\text{Mo}_8\}$ fragments, red octahedra (in pairs) are $\{\text{Mo}_2\}$ fragments.

Figure 9. Structure of $\{\text{Mo}_{176}\}$ and $\{\text{Mo}_{248}\}$ cluster anions in the polyhedral representation and scheme of the molecular growth $\{\text{Mo}_{176}\} \rightarrow \{\text{Mo}_{248}\}$.⁵⁸ For designations of the polyhedra, see Fig. 8. The green colour marks fragments that cannot be represented in terms of fragments that constitute ring-shaped anions.

However, refluxing of compound **7** for several hours in a polar solvent such as acetone, acetonitrile or dimethyl sulfoxide induces cleavage of the octamer yielding hexanuclear cluster **8**.

Upon the heterogeneous reaction between cluster **A** in MeCN and Ph_4PCl (refluxing for 3 h), the cluster is completely converted into yellow-coloured compound $(\text{Ph}_4\text{P})_2[\text{Mo}_6\text{O}_{19}] \cdot 2 \text{ MeCN}$ (**9**),⁴⁸ which also contains the hexanuclear cluster anion **8a**. The solva-

tion acetonitrile molecules occupy in the cell the voids between the cluster anions and form shortened contacts between the terminal oxygen atoms of the anions and the hydrogen atoms of the methyl groups. In addition, the presence of shortened contacts between the hydrogen atoms of the benzene rings of the cations and the μ_2 oxygen atoms of the anions is favourable for the formation of a complex supramolecular structure (Fig. 7).

The ways of controlling the structure of the resulting polyoxomolybdate anion by variation of the solvent and the reaction conditions during decomposition of cluster **A** have been summarised in a publication.⁴⁶ This procedure allows deliberate synthesis of octa- or hexanuclear polyoxometallate anions soluble in organic solvents in accordance with the following scheme:

(a) (1) $\text{Bu}_4\text{N}^+\text{X}^-$, H_2O , 20 °C, (2) MeCN; (b) (1) $\text{Bu}_4\text{N}^+\text{X}^-$, H_2O , 100 °C, (2) MeCN; (c) $\text{Ph}_4\text{P}^+\text{Cl}^-$, MeCN, 82 °C; (d) refluxing in polar solvents.

V. Molybdenum blues

Solutions of molybdenum blues are formed almost instantaneously in the reduction of molybdenum(VI) compounds in acid media ($\text{pH} \leq 3$). The suitable reducing agents include metals (Al, Pb, Mo, Cu, Zn, Cd, Hg), B_2H_6 , NaBH_4 , N_2H_4 , NH_2OH , H_2S , SO_2 , SO_3^{2-} , $\text{S}_2\text{O}_3^{2-}$, $\text{S}_2\text{O}_8^{2-}$, SnCl_2 , MoCl_5 , MoOCl_3 , formic acid, ethanol, ascorbic acid, thiourea, hydroquinone, D-glucose, saccharose, hydrogen or CO gas (under pressure). The blues can also be prepared by electroreduction, photochemical reduction or reduction induced by γ -radiation.^{2, 49}

The history of soluble molybdenum blues goes back to 1783 when a study by C W Scheele was published,⁵⁰ although blue waters from the springs of the Valley of Ten Thousand Smokes (Idaho) had been known much earlier. Berzelius was the first to propose the general formula for these compounds, namely, $\text{Mo}_5\text{O}_{14} \cdot n \text{H}_2\text{O}$.⁵¹ Subsequently, researchers have used the formula MoO_x ($2.5 < x < 3$), as they have already believed that several types of molybdenum blues exist. Generations of chemists have attempted without success to crystallise these compounds in order to determine reliably their composition. The problem was in their very high solubility in water, which is now known to be due to the presence of numerous H_2O ligands. In recent years, this problem has been solved by A Müller and co-workers who used high concentrations of electrolytes to destroy the hydration shells. This allowed them to prepare single crystals of a large number of compounds containing giant ring-shaped anions of the $\{\text{Mo}_{154}\}$ (with and without defects) and $\{\text{Mo}_{176}\}$ types.^{10, 11, 18, 52–57} The formulae of some of them are given below:

(1) $(\text{NH}_4)_{28}[\text{Mo}_{154}(\text{NO})_{14}\text{O}_{448}\text{H}_{14}(\text{H}_2\text{O})_{70}] \cdot \text{ca. } 350 \text{ H}_2\text{O}$ (discrete rings);

(2) $\text{Na}_{14}[\text{Mo}_{154}\text{O}_{462}\text{H}_{14}(\text{MeOH})_8(\text{H}_2\text{O})_{62}] \cdot \text{ca. } 400 \text{ H}_2\text{O}$ (discrete rings);

(3) $\text{Na}_{26}[\text{Mo}_{142}\text{O}_{432}\text{H}_{14}(\text{H}_2\text{O})_{58}] \cdot \text{ca. } 300 \text{ H}_2\text{O}$ (discrete rings with defects);

(4) $\{\text{Na}_{24}[\text{Mo}_{144}\text{O}_{437}\text{H}_{14}(\text{H}_2\text{O})_{56}] \cdot \text{ca. } 250 \text{ H}_2\text{O}\}_n$ (chains of rings with defects);

(5) $\{\text{Na}_{16}[\text{Mo}_{152}\text{O}_{457}\text{H}_{14}(\text{H}_2\text{O})_{66.5}] \cdot \text{ca. } 300 \text{ H}_2\text{O}\}_m$ (layers of rings with defects).

It is worth mentioning that the first of these compounds, which contains the $[\text{Mo}_{154}(\text{NO})_{14}\text{O}_{448}\text{H}_{14}(\text{H}_2\text{O})_{70}]^{28-} \equiv \{\text{Mo}_{154}(\text{NO})_{14}\}$ cluster anions (**10a**), can be prepared by acidification and reduction of solutions containing anions **1b**.¹⁸ The

giant ring-shaped anion **10a** (Fig. 8) consists of 140 $\{\text{MoO}_6\}$ octahedra and 14 $\{\text{Mo}(\text{NO})\text{O}_6\}$ pentagonal bipyramids. The diameter of the central cavity in the equator is $\sim 20 \text{ \AA}$. The anion **10a** (approximate D_{7d} symmetry) can be described as an assembly consisting of 14 subunits. Each subunit is an octanuclear fragment with the $\{\text{Mo}_8\}$ core whose centre is the $\{\text{Mo}(\text{NO})\text{O}_6\}$ pentagonal bipyramid connected to seven $\{\text{MoO}_6\}$ octahedra through common vertices and edges. These $\{\text{Mo}_8\}$ fragments are situated above and below the equatorial plane of the cluster. Equivalent $\{\text{Mo}_8\}$ building blocks are also present in anions **1b**, **3a** and **4a** (see Section III). The key difference between two above-mentioned structural types (**1b**, **3a** and **4a**, on the one hand, and **10a** on the other hand) is that the $\{\text{Mo}_8\}$ fragments in clusters **1b**, **3a** and **4a** are arranged exactly one above another being separated by a reflection plane, whereas these fragments in anion **10a** are rotated relative to each other about a C_7 axis through an angle of $360^\circ/14$. Since in anions **3a** and **4a**, the pentagonal bipyramids of each fragment are connected to each other *via* one $\{\text{Mo}_1\}$ fragment located in the equatorial plane, the $\{\text{Mo}_{17}\}$ fragments can formally be regarded as 'pseudo-discrete'. Thus, they can be considered to be isolated transferable ligands linked through the $\{\text{Fe}^{\text{III}}(\text{H}_2\text{O})_2\}^{3+}$ or $\{\text{V}^{\text{IV}}\text{O}(\text{H}_2\text{O})\}^{2+}$ cationic groups or the $\{\text{Mo}^{\text{V}}(\mu\text{-H}_2\text{O})_2(\mu\text{-OH})\text{Mo}^{\text{V}}\}^{9+}$ groups. In contrast to this, the shift of the $\{\text{Mo}_8\}$ fragments with respect to one another in cluster **10a** means that linking of every two of these structural elements requires two equatorial $\{\text{Mo}_1\}$ fragments. Every two neighbouring $\{\text{Mo}_8\}$ fragments situated above and below the equatorial plane are linked additionally through the $\mu_3\text{-O}$ atom. In addition, every two neighbouring $\{\text{Mo}_8\}$ fragments located in one plane are linked by a $\{\text{Mo}^{\text{VI}}\text{O}_2(\text{H}_2\text{O})(\mu\text{-O})\text{Mo}^{\text{VI}}\text{O}_2(\text{H}_2\text{O})\} \equiv \{\text{Mo}_2\}$ group. This gives rise to a ring-shaped structure; in terms of the building block concept, its formula can be written as $[\{\text{Mo}_2^{\text{VI}}\text{O}_5(\text{H}_2\text{O})_2\}\{\text{Mo}_7\text{Mo}(\text{NO})\text{O}_{25}(\text{OH})_2(\text{H}_2\text{O})_3\text{Mo}\}]_{14} \equiv [\{\text{Mo}_2\}\{\text{Mo}_8\}\{\text{Mo}_1\}]_{14}$.

As noted above, a series of similar ring-shaped anions containing no NO groups have been prepared in recent years. Among these, noteworthy is the ring-shaped $\{\text{Mo}_{176}\}$ cluster (**11a**),⁵⁴ which can be represented as consisting of sixteen $[\{\text{Mo}_2\}\{\text{Mo}_8\}\{\text{Mo}_1\}]$ sets instead of fourteen sets (as is observed for anion **10a** and its analogues). In another unusual cluster (which can be prepared by reduction of anion **10a** with ascorbic acid) containing 248 Mo atoms (**12a**),⁵⁸ the $\{\text{Mo}_{176}\}$ ring is capped from two sides by two neutral polyoxomolybdate fragments $\{\text{Mo}_{36}\text{O}_{96}(\text{H}_2\text{O})_{24}\}$ (Fig. 9). Their structure is almost identical to the structure of the crystalline Mo_5O_{14} oxide.⁵⁹ On the one hand, this similarity opens up the way for simulating the crystal growth and especially nucleation processes that take place during the formation of metal oxides and, on the other hand, it allows one to mimic the pattern of organisation of metal centres in biological systems, in particular, for some types of biomineralisation.

Detailed investigation of a large number of diverse structures of molybdenum blues demonstrated that they all contain 14 (or 16 in the case of hexadecamers) $\{\text{Mo}_5\text{O}_6\}$ fragments and each of the fragments has two 4d electrons.⁶⁰

By linking ring-shaped cluster anions including those containing defects (*i.e.*, missing $\{\text{Mo}_2\}$ groups), one can obtain a multitude of solid-state chain or layer structures.⁵⁶ The structures of some of these compounds incorporate nano-sized channels. In addition, it was demonstrated that $\{\text{Mo}_{154}\}$ type ring-shaped anions can form colloid particles with a hydrodynamic radius of $\sim 80 \text{ nm}$ in organic solvents.

The ring-shaped clusters connected in chains can also act as hosts with respect to smaller polyoxometallate clusters, for example, $\{\text{Mo}_{36}\}$ type clusters (**1a,b**). In such supramolecular systems $\{\text{Mo}_{36} \subset \text{Mo}_{148}\}$,²³ the host and the guest (located exactly in the host cavity) are connected *via* 16 hydrogen bonds and four Na^+ cations arranged in the gap between the host and the guest (Fig. 10, see p. 563).

Thus, one can list the following most typical properties and potential applications of the polyoxomolybdate clusters belonging to the ‘molybdenum blue’ class.²²

1. The presence of nano-sized cavities, which opens up broad opportunities for the formation of supramolecular architectures according to the host–guest principle.

2. High hydrophilicity of the surfaces due to the presence of a large number of H₂O ligands, which entails the formation of an unusually extended hydration shell (this accounts for the high solubility of these clusters).

3. The presence of surfaces with large areas, which is the reason for the high affinity of these clusters for adsorbents such as activated carbon or silk.

4. The possibility of formation of discrete structural defects on the outer surface of the cluster rings.

5. Linking of the ring-shaped blocks both during ageing of their solutions and during oriented crystallisation processes.

6. The possibility of introducing molecules onto various sections of the cluster surface by means of replacement of H₂O ligands (this is accompanied by successive changes in the properties of the cluster and especially of its surface) and study of the reactions between molecules placed into the cluster cavities.

7. Structural analogy between the fragments and the catalytically active metal oxides; this allows these clusters to be regarded as molecular models of some heterogeneous catalysts.

VI. Spherical systems (keplerates)

Although molecular systems, even fairly large ones, can, in principle, be obtained by a multistage synthesis, the construction of exceedingly big, giant molecular systems, including those with unusual structures having very high symmetry (similar to the structures of simple spherical viruses) and unusual properties requires different approaches.

For example, in order to construct giant spheres that resemble in size and structure spherical viruses having an icosahedral symmetry (*C*₅, *C*₃, *C*₂), it is necessary to select a reaction system in which pentagonal fragments capable of producing 12 icosahedron vertices upon linking should first be generated.

1. Spherical giant clusters with binuclear Mo^V–Mo^V linkers

In the case of polyoxomolybdates, the {(Mo)Mo₅} pentagonal fragments mentioned above consist of the central MoO₇ bipyramid connected to five MoO₆ octahedra through shared edges. When the solution contains classical binuclear {Mo₂O₄}²⁺ linkers (which are often formed in reduced molybdate solutions in the presence of bidentate ligands)⁶¹ capable of connecting pentagonal fragments, an icosahedral molecular system is formed consisting of 12 pentagons and 30 binuclear linkers mentioned above. If acetate anions function as bridging ligands for the [Mo₂O₄]²⁺ groups, this gives a spherical cluster with the composition [Mo₇₂Mo₆₀O₃₇₂(AcO)₃₀(H₂O)₇₂]^{42–} ≡ {Mo₁₃₂} (13a),⁶² in which the positions of the central Mo atoms in the {(Mo)Mo₅} fragments form 12 vertices, while the [Mo₂O₄]²⁺ groups (with the metal–metal bond and with a Mo–Mo distance of ~2.6 Å) form 30 edges of the icosahedron (Fig. 11). Thus, the formula of anion 13a can be written as follows: [(Mo)Mo₅O₂₁·(H₂O)₆]₁₂·{Mo₂O₄}(AcO)₃₀]^{42–}. The salt (NH₄)₄₂[Mo₇₂Mo₆₀O₃₇₂·(AcO)₃₀(H₂O)₇₂]·300 H₂O·10 AcONH₄ (13) crystallises in the space group *Fm*3 with a close cubic packing of the spherical anions. In the cluster molecule, all the 132 oxygen atoms of the terminal Mo=O groups are directed outside the giant spherical anion 13a, while the *trans*-arranged H₂O ligands of all the 72 Mo^{VI} centres are directed toward the centre of this anion.

This molecular system with sixty MoO₆ subfragments belonging to twelve {(Mo)Mo₅} pentagons is a topological model of spherical viruses, namely, the tobacco mosaic virus. This virus contains 60 identical protein subfragments (coded by only one gene) or, in other words, 12 pentagonal capsomers (morphological fragments). Each capsomer is composed of 5 protomers.⁶³

When the acetate bridging ligands are replaced by formate ones, a guest system represented by a water cluster consisting of ~60 H₂O molecules connected by hydrogen bonds is formed in the cluster anion cavity due to the decrease in the steric restrictions.⁶⁴

The acetate bridging ligands can also be replaced either completely by phosphate or hypophosphite anions or partially by hydrosulfate anions. These groups enter the [(Mo)Mo₅O₂₁·(H₂O)₆]₁₂{Mo₂O₄(H₂PO₂)₃₀]^{42–} (14a) and [(Mo)Mo₅·O₂₁(H₂O)₆]₁₂{Mo₂O₄(HSO₄)₁₈{Mo₂O₄(AcO)}₁₂]^{42–} (15a) cluster anions, formed upon the addition of excess bidentate anions derived from the corresponding acids to freshly prepared solutions of salt 13.⁶⁵

The compound Na₄₆[Mo₆₆Mo₅₀O₃₃₁(AcO)₃₀(H₂O)₅₆]·ca. 300 H₂O (16) (space group *Pmn*2₁) isolated as a salt,⁶⁵ which contains giant basket-like cluster anions (Fig. 12), crystallises from solutions of anions 13a containing Na⁺ cations on keeping in air for a long period. The structure of the [Mo₆₆Mo₅₀O₃₃₁(AcO)₃₀(H₂O)₅₆]^{46–} anion (16a) can formally be obtained from structure 13a by removing the [(Mo)Mo₅](Mo₂O₄)₅ ≡ {Mo₁₆} fragment. The relative content of Mo^V centres in anion 16a is lower than that in anion 13a; therefore, the formation of cluster 16a from 13a can be regarded as partial oxidation.

Salt 16 is much more soluble in water than compound 13, whose anion (13a) contains mainly terminal oxygen atoms as ligands on the surface of a closed sphere. This difference in solubility is due to the easy ingress of solvent (water) molecules inside the cluster anion 16a, whose internal surface is hydrophilic due to the presence of a large number of H₂O ligands. Therefore, salt 16 crystallises only in the case where the equilibrium is appreciably shifted toward the formation of basket-like particles. The solution should always remain dilute in order to avoid crystallisation of compound 13. If the reaction is carried out at high concentrations of sodium acetate (which induces salting-out due to destruction of the hydration shell) or even in the presence of NH₄⁺ ions whose salts are less soluble (than sodium salts), salt 13 crystallises.

The knowledge of the structure of anion 16a is important for understanding the processes of ligand replacement in cluster 13a, resulting in the formation of anions 14a and 15a. In addition, the following facts should be taken into account.

1. Ligand exchange cannot occur through the ‘molecular windows’ present in anion 13a on *C*₃ axes because these windows (formed by {Mo₉O₉} rings) are too small for the anionic ligands.

2. Compounds 14 and 15 can be isolated if a substantial amount of spherical cluster anions remains in the reaction medium.

3. The exclusion of ligand exchange through the ‘windows’ suggests that either the ligands that approach the spherical anion 13a induce its opening or that the closed spherical cluster anions exist in equilibrium with the corresponding basket-like cluster anions.

In terms of the latter assumption, one can explain the easy crystallisation (after the ligand exchange) of compounds 14 and 15 containing spherical cluster anions 14a and 15a. The reason is a lower hydrophilicity of their surfaces compared to that of the surface of cluster 16a. They are much less soluble than the basket-like anions equilibrated with them. Yet another argument supporting the existence of such an equilibrium is the fact that compound 13 can be isolated from solutions of compound 16 and *vice versa*. This does not provide any grounds for suggesting that the {Mo₁₆} fragment is stable in solutions.⁶⁵

2. Spherical giant clusters with mononuclear linking fragments

Binding of pentagonal {(Mo)Mo₅} fragments by fragments other than binuclear {Mo₂O₄L} makes it possible to vary the dimensions and properties of the giant spherical clusters formed. For example, oxidation of the spherical anion 13a with air oxygen at

Figure 10. Structure of the $\{\text{Mo}_{36}\}\text{C}\{\text{Mo}_{148}\}$ supramolecular system. The $\{\text{Mo}_{148}\}$ cluster is given in the polyhedral representation and the $\{\text{Mo}_{36}\}$ cluster is in the atomic representation.²³ For designations of the polyhedra, see Fig. 8.

Figure 11. Structure of cluster anion **13a** in the polyhedral representation. Blue pentagonal bipyramids are the central parts MoO_7 of the $\{(\text{Mo})\text{Mo}_5\}$ fragments; red octahedra (in pairs) are the $[\text{Mo}_2^{\text{V}}\text{O}_4]^2+$ fragments.

pH ~ 2.5 and at high NaCl concentrations gives rise to a dark-blue crystalline compound, $[\{(\text{Mo})\text{Mo}_5\text{O}_{21}(\text{H}_2\text{O})_6\}]_{12} \cdot \{[\text{Mo}^{\text{VO}}(\text{H}_2\text{O})]_{30}\} \cdot \text{ca. } 150 \text{ H}_2\text{O}$ (**17**), containing neutral spherical cluster **17a** (Fig. 13). This product crystallises in the $C2/c$ space group and, unlike cluster anion **13a** (the space group of salt **13** is $Fm3$), it does not form a close cubic packing. Like cluster anion **13a**, neutral cluster **17a** comprises 12 pentagonal fragments,

$\{(\text{Mo})\text{Mo}_5\}$, which are partially reduced (unlike those in anion **13a**). The pentagonal fragments in cluster **17a** are linked to one another by thirty $\text{O}=\text{Mo}^{\text{V}}(\text{H}_2\text{O})$ fragments [the $\text{Mo}=\text{O}$ bond length is $\sim 1.67 \text{ \AA}$; the $\text{Mo}-\text{O}(\text{trans-H}_2\text{O})$ distance is $\sim 2.30 \text{ \AA}$] to form an Archimedean solid, namely, icosidodecahedron. The $\text{Mo}=\text{O}$ groups of the linkers are directed inside the sphere.⁶⁶

In conformity with the Robin–Day classification, cluster **17a** can be defined as a mixed-valence compound of type II,⁶⁷ as indicated by its intensive dark blue colour. Of the 36 4d electrons belonging to molybdenum atoms (which are formally Mo^{V} centres determined by cerium redox titration), 30 electrons are mainly concentrated on the 30 molybdenum atoms that act as linkers, whereas the other six electrons are mainly delocalised among the molybdenum atoms of the pentagonal groups.

It is of interest that the EPR spectra of compound **17** measured at room temperature do not exhibit resonance signals in spite of the presence of a large number of unpaired electrons. Apparently, the absence of signals can be attributed to strong exchange interactions of the antiferromagnetic type.⁶⁶

It should be noted that a structure with $\text{Mo}^{\text{V}}-\text{Mo}^{\text{V}}$ fragments (*i.e.*, with localised $\text{Mo}-\text{Mo}$ bonds) does not exist in cluster **17a**, despite the fairly large number of Mo^{V} centres (formal). Local (partially) single-electron oxidative degradation of the $[\text{Mo}_2^{\text{V}}\text{O}_4]^2+$ linkers under mild conditions corresponds formally to the reaction $\{\text{Mo}_2^{\text{V}}\} \rightarrow \{\text{Mo}^{\text{V}}\} + \text{Mo}^{\text{VI}}$ followed by the formation of soluble polyoxomolybdates(VI). As this takes place, thirty Mo^{V} centers are trapped by a spherical matrix [twelve $\{(\text{Mo})\text{Mo}_5\}$ pentagonal blocks], and their structure does not change. It is significant that this reaction involves the binding functional groups located on the surface of the giant sphere. This inevitably changes the dimensions of the molecule. Further

Figure 12. Structure of cluster anion **16a** in two projections in the polyhedral representation (*a*) and its formal difference from anion **13a** (*b*) (the {Mo₁₆} fragment is shown separately). Binuclear fragment {Mo₂O₄L} (*c*) in which the $L \rightleftharpoons L'$ ligand exchange takes place.⁶⁵

oxidation does not take place, as neutral cluster **17** has a low solubility and crystallises immediately after formation.

When a solution of salt **13** reacts with $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ (pH ~ 3) in the presence of ammonium acetate, the replacement of the {Mo₂^V} linkers in cluster **13a** by Fe^{III} centres gives rise to a yellow-coloured crystalline compound, $[\{(\text{Mo})\text{Mo}_5\text{O}_{21}\text{L}_6\}_{12}\{\text{Fe}^{\text{III}}(\text{H}_2\text{O})\text{L}\}_{30}] \cdot \text{ca. } 150\text{H}_2\text{O}$ (**18**),⁶⁸ where L is H₂O, AcO[−] or Mo₂^{VI}O_{8/9}[−]. Compound **18** contains 12 acetate ligands and three ‘additional’ Mo₂O_{8/9} fragments (their total charge is -6). The structures of these fragments are given by $\{(\mu\text{-O})_2\text{O}=\text{Mo}^{\text{VI}}(\text{OH})_2(\text{H}_2\text{O})\text{Mo}^{\text{VI}}=\text{O} \cdot (\mu\text{-O})_2\}^{2-}$ and $\{(\mu\text{-O})_2\text{O}=\text{Mo}^{\text{VI}}(\text{H}_2\text{O})\text{Mo}^{\text{VI}}=\text{O}(\mu\text{-O})_2\}^{2-}$ with octahedral and square-bipyramidal coordination environments of the Mo atoms, respectively. These fragments are markedly disordered and function as tetradentate ligands inside the cluster shell. The twelve acetate ligands are also disordered, and their positions cannot be determined exactly, first of all, due to the large number (≥ 120) of possible positions. It is evident that the hypothetical positively charged cluster formed upon substitution of the Fe^{III} centres for all linkers in anion **13a**, namely, $[\{(\text{Mo})\text{Mo}_5\text{O}_{21} \cdot (\text{H}_2\text{O})_6\}_{12}\{\text{Fe}^{\text{III}}(\text{H}_2\text{O})_2\}_{30}]^{18+}$, would be exceptionally unstable under the reaction conditions. Thus, the formula of this compound can be written as $[\text{Mo}_{72}\text{Fe}_{30}\text{O}_{252}(\text{AcO})_{12}\{\text{Mo}_2\text{O}_7(\text{H}_2\text{O})\}_2 \cdot \{\text{H}_2\text{Mo}_2\text{O}_8(\text{H}_2\text{O})\}(\text{H}_2\text{O})_{91}] \cdot \text{ca. } 150\text{H}_2\text{O}$.

Compound **18** crystallises in the space group *R*3 and contains discrete neutral spherical clusters **18a**. Each spherical cluster (see Fig. 13) consists of 12 pentagonal fragments of the {Mo}Mo₅ type connected by 30 Fe^{III} centres; thus, the structure of **18a** has an approximate icosahedral symmetry and contains 102 metal atoms, and, in addition, their terminal ligands (O or H₂O) that belong to two concentric spheres. Each octahedron formed by a

Figure 13. Structure of clusters $[\{(\text{Mo})\text{Mo}_5\text{O}_{21}(\text{H}_2\text{O})_6\}_{12} \cdot \{\text{MoVO}(\text{H}_2\text{O})\}_{30}]$ (**17a**) and $[\{(\text{Mo})\text{Mo}_5\text{O}_{21}\text{L}_6\}_{12}\{\text{Fe}^{\text{III}}(\text{H}_2\text{O})\text{L}\}_{30}]$ (**18a**) in the polyhedral representation. The yellow octahedra are the {Mo^VO(H₂O)}³⁺ centres (in **17a**) or {Fe^{III}(H₂O)L}³⁺ centres (in **18a**).

Fe^{III} centre is connected to two neighbouring pentagonal fragments. The midpoints of 12 pentagonal fragments, namely the Mo atoms in the MoO₇ pentagonal bipyramids, form an icosahedron, while thirty Fe^{III} centres form an icosidodecahedron.⁶⁹

The Raman spectrum of compound **18** in a concentrated aqueous solution is virtually identical to the spectrum recorded for the solid. It should be noted that these solutions are acidic due to partial deprotonation of the H₂O ligands belonging to the Fe^{III} centres. The slight yellow colouring of the compound corresponds to the presence of polyoxomolybdate(VI) fragments and Fe^{III} centres. Magnetochemical measurements^{70, 71} indicate that cluster **18** contains high-spin Fe^{III} centres (the Fe^{III}–Fe^{III} distance is $\sim 6.4\text{Å}$), which are involved in rather weak antiferromagnetic exchange interactions described by the classical Heisenberg model.^{70, 71} The ⁵⁷Fe Mössbauer spectrum confirms the presence of only Fe^{III} centres in a slightly distorted octahedral oxygen environment.

The reaction of vanadyl sulfate with an acidified solution of sodium molybdate in the presence of high concentrations of an electrolyte (NaCl) gives the compound $\text{Na}_{20} \cdot [\{(\text{Mo}^{\text{VI}}\text{O}_3 \cdot (\text{H}_2\text{O}))_{10}\{\text{V}^{\text{IV}}\text{O}(\text{H}_2\text{O})\}_{20}\{(\text{Mo}^{\text{VI}})\text{Mo}_5^{\text{VI}}\text{O}_{21}(\text{H}_2\text{O})_3\}_{10} \cdot \{(\text{Mo}^{\text{VI}}\text{O}_2 \cdot (\text{H}_2\text{O})_2\}_{5/2}\}_2\{\text{NaSO}_4\}_5\}_2] \cdot 170\text{H}_2\text{O}$ (**19**).⁷² The cluster anion $[\{(\text{Mo}^{\text{VI}}\text{O}_3(\text{H}_2\text{O}))_{10}\{\text{V}^{\text{IV}}\text{O}(\text{H}_2\text{O})\}_{20}\{(\text{Mo}^{\text{VI}})\text{Mo}_5^{\text{VI}}\text{O}_{21} \cdot (\text{H}_2\text{O})_3\}_{10}\{(\text{Mo}^{\text{VI}}\text{O}_2(\text{H}_2\text{O})_2\}_{5/2}\}(\text{NaSO}_4)_5\}_2]^{20-}$ (**19a**) present as a part of this structure is nearly spherical (its greatest and smallest outer diameters are equal to 25 and 23 Å, respectively) and has a *C*₅ symmetry axis (Figs 14, 15). The structure of this anion is best described as a distorted icosidodecahedron containing 20 triangular and 20 pentagonal faces, which are formed by 10 Mo^{VI} centres and 20 V^{IV} centres. Ten triangular faces composed of 20 V^{IV} centres form an unusual equatorial ‘ring-shaped magnetic ribbon.’ The other 10 triangular faces, each being formed by one V^{IV} centre and two Mo^{VI} centres, complete the distorted icosidodecahedron (see Fig. 14).

The cavity of cluster anion **19a** accommodates ten sulfate groups in a previously unknown mode [each group is connected to three neighbouring Mo^{VI} centres of each {Mo^{VI}}Mo₅^{VI} group *via* three oxygen atoms] and ten Na⁺ cations. The Na⁺ cations are located between the neighbouring sulfate groups, which gives rise to two unusual {NaSO₄}₅ rings [the Na–O(SO₃) distance is 2.48–2.60 Å] lying above and below the equatorial ring composed of ten V^{IV} centres. Note that in this case, the Na ions possess a unique pentagonal-bipyramidal coordination environment. Five

For designations of the polyhedra, see Fig. 14.

of the seven corresponding oxygen centres belong to the cluster shell.

The measurements of the magnetic susceptibility of compound **19** showed a sharp decrease in the χT value in the range from 200 to 100 K ($3.4\text{--}2.3\text{ cm}^3\text{ K mol}^{-1}$), indicating the presence of strong antiferromagnetic exchange interactions despite rather long distances between the V^{IV} atoms ($6.27\text{--}6.46\text{ Å}$).

VII. Spherical giant clusters as building blocks in chemical design

The deliberate design of cross-linked structures having pre-specified properties from reliably characterised building blocks is among the most promising lines of research in modern inorganic chemistry.^{73,74} Thus linking of giant ring-shaped polyoxomolybdate clusters (see Section V) having open nano-sized cavities gives rise to two-dimensional networks.¹¹

By varying the size of cluster anions (and, hence, their inner cavities) and by changing the nature of linkers on passing from

anion **13a** to anion **18a**, one can create unusual chemical structures resulting from absolutely new reactions including insertion of a guest into the host cavity and/or cross-coupling of spherical clusters to form cross-linked polymeric structures. When a freshly prepared solution of salt **18** is acidified by hydrochloric acid to pH 2, the compound $[\text{Mo}_{72}\text{Fe}_{30}\text{O}_{252}(\text{AcO})_{10}\{\text{Mo}_2\text{O}_7(\text{H}_2\text{O})\}\cdot\{\text{H}_2\text{Mo}_2\text{O}_8(\text{H}_2\text{O})\}_3(\text{H}_2\text{O})_{91}]\cdot 140\text{ H}_2\text{O}$ (**20**) is formed; this product contains neutral spherical clusters $[\text{Mo}_{72}\text{Fe}_{30}\text{O}_{252}(\text{AcO})_{10}\cdot\{\text{Mo}_2\text{O}_7(\text{H}_2\text{O})\}\{\text{H}_2\text{Mo}_2\text{O}_8(\text{H}_2\text{O})\}_3(\text{H}_2\text{O})_{91}]$ (**20a**), very similar to the cluster **18a**. The major difference between compounds **20a** and **18a** is the fact that the former has fewer acetate ligands and more binuclear oxomolybdate ligands. This can be sketched as follows:

However, even such minor changes in the structure of these clusters result in substantial changes in their reactivity: when dried in air at room temperature, compound **20a** undergoes solid-state condensation to give a cross-linked structure, $\{[\text{H}_4\text{Mo}_{72}\text{Fe}_{30}\text{O}_{254}(\text{AcO})_{10}\{\text{Mo}_2\text{O}_7(\text{H}_2\text{O})\}\{\text{H}_2\text{Mo}_2\text{O}_8(\text{H}_2\text{O})\}_3\cdot(\text{H}_2\text{O})_{87}]\cdot 80\text{ H}_2\text{O}\}_n$ (**21**) (Fig. 16).⁷⁵ It is noteworthy that this process does not take place during drying of the crystals of **18a** with a different packing of cluster units. The clusters **20a** form the structure $[\text{H}_4\text{Mo}_{72}\text{Fe}_{30}\text{O}_{254}(\text{AcO})_{10}\{\text{Mo}_2\text{O}_7(\text{H}_2\text{O})\}\{\text{H}_2\text{Mo}_2\text{O}_8(\text{H}_2\text{O})\}_3(\text{H}_2\text{O})_{87}]$ (**21a**) via closure of Fe–O–Fe bridges between the neighbouring cluster units, which implies deprotonation of the H_2O ligands belonging to the iron atoms with subsequent condensation:

In addition, the intermediate of this process $\{[\text{Mo}_{72}\cdot\text{Fe}_{30}\text{O}_{252}(\text{AcO})_{10}\{\text{Mo}_2\text{O}_7(\text{H}_2\text{O})\}\{\text{H}_2\text{Mo}_2\text{O}_8(\text{H}_2\text{O})\}_3(\text{H}_2\text{O})_{91}]\cdot 100\text{ H}_2\text{O}\}_n$ (**22**) was isolated as a single crystal and structurally characterised (so were both compounds described above). In compound **22**, close contacts occur between the $[\text{Mo}_{72}\text{Fe}_{30}\text{O}_{252}\cdot(\text{AcO})_{10}\{\text{Mo}_2\text{O}_7(\text{H}_2\text{O})\}\{\text{H}_2\text{Mo}_2\text{O}_8(\text{H}_2\text{O})\}_3(\text{H}_2\text{O})_{91}]$ cluster units (**22a**); however, chemical bonds between them have not yet been formed.⁷⁵

Since the reaction $\mathbf{20} \rightarrow \mathbf{22} \rightarrow \mathbf{21}$ takes place in the crystal at room temperature and mainly involves the transformation of giant spherical fragments, the crystal unit cells of the three compounds are fairly similar. Compounds **20** and **22** crystallise with a monoclinic space group $P2_1/n$ and have similar unit cell

Figure 16. Structure of the metal core of the network structure of cluster **21a**.⁷⁵

Blue spheres are molybdenum atoms; red and yellow spheres are iron atoms involved and not involved in the intersphere binding, respectively.

parameters and similar patterns of packing of the spherical clusters. During the condensation resulting in structure **21**, the clusters are re-oriented; consequently, the structure passes to a more symmetrical orthorhombic system (space group *Cmca*). The cluster re-orientation accompanied by the loss of crystal water mainly involves the translational shift of clusters towards one another with a very slight rotation. The shortest distance between the Fe^{III} centres of neighbouring spheres in structure **20** is 6.74 Å,

Figure 17. Structure of the cluster composite $[H_2PMo_{12}O_{40} \cdot H_4Mo_{72} \cdot Fe_{30}(AcO)_{12}O_{254}(H_2O)_{98}]$ (**23a**), a fragment of the layered structure **23**.⁷⁷

For designations, see Figs 8, 13. The dashed polyhedra are encapsulated Keggin anions.

Figure 18. Interatomic distances in the $\{Mo_6O_6\}$ metal rings of the spherical polyoxomolybdate cluster with integrated K^+ cations.⁸⁴

while this distance in cluster **22** amounts to 5.39 Å, and, finally, in structure **21**, the Fe—O—Fe distance is 3.79 Å. Magnetic measurements indicate that cluster **22** contains thirty Fe^{III} atoms, four of which are involved in strong exchange interactions of the antiferromagnetic type.

This process is analogous to classical inorganic condensation reactions, resulting in the formation of polycations;⁷⁶ however, unlike, for example, the hydrolysis of $[Fe(H_2O)_6]^{3+}$, this process is not chaotic.

Even more complex systems based on spherical clusters of the $\{Mo_{72}^{VI}Fe_{30}^{III}\}$ type can be synthesised in one step from simple reactants. Thus the addition of $FeCl_2 \cdot 4H_2O$ in air to an acidic (pH 2) aqueous solution of polyoxomolybdate(VI) containing acetic acid and slight amounts of phosphate induces a complex self-assembling process giving rise to the neutral compound $\{[H_xPMo_{12}O_{40} \cdot H_4Mo_{72}^{VI}Fe_{30}^{III}(AcO)_{12}O_{254}(H_2O)_{98}] \cdot 60H_2O\}_n$ (**23**), which is a novel type layered material (Fig. 17).^{77,78} The building blocks that constitute this system are nano-sized oxometallate composites consisting of paramagnetic icosahedral

Figure 19. Structural details of cluster anion **24a**.⁸⁴

Three pentagonal $\{(Mo)Mo_5\}$ fragments and three $\{Mo_2\}$ linkers, which form the $\{Mo_9O_9\}$ metal ring encapsulating the $[(NH_2)_3C]^+$ cation are given in the polyhedral representation and the other (similar) parts of the cluster are in the atomic representation.

cluster capsules (the diameter of the inner cavity is ~ 16 Å) of the $\{\text{Mo}_7^{\text{VI}}\text{Fe}_3^{\text{III}}\}$ type as hosts and reduced Keggin ions $[\text{H}_x\text{PMo}_{12}\text{O}_{40}]^{3-x-}$ ($x = 1, 2$; the diameter of the Keggin anion is ~ 14 Å)⁷⁹ as guests. The reduced Keggin ion tightly fits in the cluster cavity, the shortest $\text{O}_{\text{guest}} \cdots \text{O}_{\text{host}}$ distances being ~ 2.6 Å, which is typical of hydrogen bonding. Each of these cluster–cluster composites is linked to four neighbouring ones by Fe–O–Fe fragments, giving rise to a layered structure. The cluster capsule contains twelve pentagonal fragments of the $\{(\text{Mo})\text{Mo}_5\}$ type connected by thirty $\{\text{Fe}(\text{H}_2\text{O})_2\}^{3+}$ linkers. The acetate ligands in them are disordered and are arranged within a sphere, mainly functioning as bidentate bridging ligands between the Mo and Fe atoms.

The binding in cluster–cluster composites is based on the well studied process called inorganic condensation in which the guest molecule acts as the template in the formation of the host (capsule). It is worth noting that composite **23a** can also be prepared by adding a salt of the usual Keggin anion $[\text{PMo}_{12}\text{O}_{40}]^{3-}$ to the reaction mixture described above devoid of phosphate. The method for the synthesis of composite **23a** is a ‘cascade’ procedure, which gives the Keggin ion at an initial stage. However, in the presence of greater amounts of phosphate, the reaction follows a different route and composite **23a** cannot be prepared. One more important point is worth mentioning, namely, only iron(II) chloride $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ is appropriate as the starting reagent, because the use of $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ results in an amorphous precipitate of a variable composition and structure.

The physicochemical investigations of the structure of **23** (see Ref. 77) not only proved the presence of separate, not bonded by covalent bonds parts (the capsule and the guest) in each spherical unit of cluster **23a** but also revealed interesting topological, spectroscopic, electronic and magnetic properties. For example, nanocapsules of the $\{\text{Mo}_7^{\text{VI}}\text{Fe}_3^{\text{III}}\}$ type form a system of magnetic dots (each of them is the strongest known molecular paramagnet with the spin $S = 150/2$ at room temperature) and, simultaneously, they encapsulate the reduced Keggin ions (quantum dots) as guests. This system can be considered as a potential electron reservoir. It should be emphasised that the free Keggin ion can be reduced in several stages, its charge remaining constant due to the concomitant protonation.⁸⁰

Evidently, knowledge of the chemistry of nanocapsules with a variable size^{66,68} which can be linked together to form polymeric structures^{76,79} is exceptionally important for the synthesis of new polymeric materials with unique properties. In addition, the possibility of introducing guest molecules (a cluster in a cluster) opens up prospects for target-directed variation of the properties of such materials by varying the properties of guests.

VIII. Polyoxomolybdate clusters as nanoreceptors

As has been noted in Section VI, variation of the nature of linkers allows one to change the overall dimensions of spherical objects constructed as $\{(\text{pentagonal fragment})_{12}(\text{linker})_{30}\}$ and the dimensions of 20 corresponding pores (Mo_nO_n metal rings); the same structural principle is met for spherical viruses.⁸¹ If the linker is represented by the binuclear $\{\text{Mo}_2^{\text{V}}\}$ fragment, the pores on the surface of such spherical system are formed by the $\{\text{Mo}_9\text{O}_9\}$ rings with a diameter of 0.6–0.8 nm.⁶² In the case of mononuclear linkers such as M^{n+} where $\text{M} = \text{Fe}^{3+}$ (see Ref. 68), MoO^{3+} (see Ref. 66) or $\text{VO}^{2+}/\text{MoO}^{3+}$ (see Ref. 72), smaller rings are formed, namely, $\{\text{Mo}_6\text{O}_6\}$, whose size is just appropriate for ‘trapping’ potassium cations.⁸² Note that every one of these 20 pores (rings) has, in principle, the properties of a receptor comparable with those of crown ethers, which are classical objects of supramolecular chemistry.⁸³ It has been shown⁸⁴ that spherical clusters like $\{\text{Mo}_{132}\}$ with different types of ligands stabilising the $\{\text{Mo}_2^{\text{V}}\text{O}_4\}^{2+} \equiv \{\text{Mo}_2^{\text{V}}\}$ groups have pores the sizes (Fig. 18) of which allow encapsulation of rather big complementary substrates present in solution, for example, guanidinium cations. This is especially important, as guanidine, acting as a ligand^{85,86}

Figure 20. Interatomic distances in the $\{\text{Mo}_9\text{O}_9\}$ metal rings reflecting the interaction between receptors and substrates.⁸⁴

or a receptor of anions⁸⁷ and functioning as a sterically flexible molecule, plays a noticeable role in coordination chemistry, supramolecular chemistry and solid state chemistry and is often used in the chemical design for the formation of cross-linked structures.⁸⁸ For example, the $\{[(\text{Mo})\text{Mo}_5\text{O}_{21}(\text{H}_2\text{O})_6]_{12}\{\text{Mo}_2^{\text{V}}\text{O}_4 \cdot (\text{H}_2\text{PO}_2)\}_{30}\}^{42-}$ (**14a**) cluster reacts with guanidinium sulfate to give the compound $\{[(\text{NH}_2)_3\text{C}^+]_{20} \subset \{(\text{Mo})\text{Mo}_5\text{O}_{21}(\text{H}_2\text{O})_6\}_{12} \cdot \{\text{Mo}_2\text{O}_4(\text{SO}_4)\}_{10}\{\text{Mo}_2\text{O}_4(\text{H}_2\text{PO}_2)\}_{20}\}^{32-}$ (**24a**) as a crystalline salt (Fig. 19).

In the structure $\{[(\text{NH}_2)_3\text{C}^+]_{32} \subset \{[(\text{NH}_2)_3\text{C}^+]_{20} \subset \{(\text{Mo})\text{Mo}_5\text{O}_{21}(\text{H}_2\text{O})_6\}_{12}\{\text{Mo}_2\text{O}_4(\text{SO}_4)\}_{10}\{\text{Mo}_2\text{O}_4(\text{H}_2\text{PO}_2)\}_{20}\}^{32-} \cdot 200\text{H}_2\text{O}\}$ (**24**), the guanidinium cations fit exactly into the pores, *i.e.*, the $\{\text{Mo}_9\text{O}_9\}$ rings, owing to their size and symmetry, and are bound by hydrogen bonds formed between the bridging oxygen atoms of the binuclear $\{\text{Mo}_2^{\text{V}}\}$ groups of the metal rings and the NH_2 groups of the cations. The same type of binding of guanidinium cations has been observed for monotopic receptors⁸⁹ (Fig. 20).

It should be emphasised that in this case, highly important is the possibility of ‘plugging’ 20 pores of the giant spherical cluster where the pore sizes are large enough for relatively small substrates to enter the central cavity. This provides the possibility of complete removal of these substrates from a solution — which would be a phenomenon comparable with substrate recognition by nanosponges.⁸⁹ The plugging of pores substantially decreases the negative charge of the cluster, stabilises the cluster and affects the structure of the unique water cluster $\{\text{H}_2\text{O}\}_n$ (see Ref. 90), which is disordered in the case of polyoxometallate clusters with open pores.⁹¹ This process can formally be compared with the process in which a cell converts the extracellular response.⁹² In the absence of encapsulated cations, the structure of the water cluster is determined by interactions with water of crystallisation through open pores.⁸⁴ In the case of anion **24a**, the central cavity contains only highly symmetrical $\{\text{H}_2\text{O}\}_n$ polyhedra — clusters with endohedral hierarchy — an $\{\text{H}_2\text{O}\}_{20}$ dodecahedron is embedded into an $\{\text{H}_2\text{O}\}_{60}$ rhomboicosidodecahedron, which is in turn embedded into another $\{\text{H}_2\text{O}\}_{60}$ rhomboicosidodecahedron.

Thus, various spherical clusters of the keplerate type possess a large number of receptor centres and can act as receptors for both cations and neutral substrates. The variation of linkers (*i.e.*, mono- and binuclear metal centres) makes it possible to change the pore size in metal rings and, hence, such clusters can act as effective and specific nanosponges with respect to complementary substrates. In addition, the reactivity of such nanosponges should differ from the reactivity of monotopic receptors and should change with a change in the electronic properties of the cluster shell.⁹³ This can be compared with the situation where the substrates have been applied onto ‘classical’ surfaces, for example,

onto industrial metal oxide catalysts,⁹⁴ and the reactivity of these substrates can also change upon the variation of the surface properties.⁹⁵

* * *

The data presented in this review demonstrate the scope and prospects of the inorganic synthesis of compounds of a new type — large polyoxometallate clusters of various structures. These objects, the properties of which are being currently studied, are of interest not only from the standpoint of fundamental chemistry but, apparently, can also find application in processes of chemical industry as catalysts and bioactive substances. However, the most important point is that in relation to these compounds, one can follow the development of a new field of chemistry — the chemistry of molecular materials, which are materials of the future.

Abstract. The results of recent investigations on the reactions proceeding at low and ultra-low temperatures are considered. Trends in development of new avenues of cryochemical research, related to reactions of metal atoms, clusters and nanoparticles and to processes occurring in quantum nanocrystals and superfluid helium nanodroplets are analysed. Specific features of the formation of films and metal-containing nanosystems at low temperatures are discussed. The bibliography includes 265 references.

I. Introduction

Most chemical compounds at low (10–100 K) and ultralow (0.2–10 K) temperatures are in the solid state. Under such conditions, the diffusional mobility is restricted. According to the Arrhenius equation, the rates of chemical processes decrease as temperature decreases, so the reactions become nearly ‘frozen’ at temperatures close to 100 K. These general considerations underlie the development of efficient methods for cryoconservation of various chemical, food and biological products. Nevertheless, the midtwentieth century was marked by the discovery of unusual fast (nearly explosive) reactions proceeding at low and ultralow temperatures. These are reactions of free radicals, halogens and halocarbons with unsaturated compounds, polymerisation of reactive monomers and some other processes.^{1–4}

Advances made in cryochemistry during the last decade include the development of methods for generation and stabilisation of metal atoms and small clusters, metastable complexes and nanoparticles, the number of metal atoms in which varies from several to hundreds and thousands.^{5–8} These high-energy and highly reactive species can participate in various low-temperature chemical reactions resulting in novel hybrid materials possessing unusual optical and electronic properties and in highly active sensor and catalytic systems. Cryocondensates with encapsulated

metal nanoparticles can be considered as novel chemical energy sources and storage systems.

Of particular interest are low-temperature size effects due to dependence of the reactivity of metal clusters and nanoparticles on the number of constituent atoms. Indeed, such systems provide examples of development of a new research avenue, *viz.*, cryonanochemistry. The dependences of diffusion parameters, mechanical stabilities and reactivities of samples of organic and organometallic condensates and co-condensates on the thickness of the growing films can also be considered as the effects specific to cryochemistry. Thus, in cryochemical studies it is possible to draw a line between the microscopic and macroscopic properties of systems comprising atoms, clusters and nanoscale particles.

In this review we analyse experimental data on unusual low-temperature reactions and new phenomena accompanying these processes. We present some examples of chemical reactions in supersonic jets, quantum crystals and liquid helium droplets and on the surfaces of ice crystallites and cosmic dust particles in the interstellar medium. Considerable attention is given to self-assembly of inorganic clusters and nanoparticles in structured polymer matrices and ordered mesogenic systems, resulting in the formation of anisotropic metal–polymer and metal–mesogenic nanosystems. We also illustrate the possibility of targeted preparation of nanostructured materials with prescribed properties.

II. General peculiarities of low-temperature chemical reactions

Radicals, molecules and metal atoms and clusters are usually stabilised using different variants of the low-temperature matrix isolation technique and preparative cryochemistry, which are also employed to study chemical reactions of these species. Usually, low-temperature chemical reactions proceed under conditions of layer-by-layer or co-condensation of reactant vapours or an inert matrix on continuously cooling surfaces of various cryostats *in vacuo*. It should be noted that reactions at the gas–solid, gas–liquid and solid–solid interfaces are also possible. Often, carrying out a chemical reaction between two substances in a co-condensate film requires preliminary formation of labile complexes of the reactants to provide an optimum orientation of the species in the course of mutual diffusion. Evolution of the surface structure and energetics of chemical reactions are studied by structural methods, microscopy, thin-film calorimetry and spectroscopy.

1. Sample preparation on cold surfaces: specific features

Sample preparation techniques are critical to cryochemical research. Currently, two methods are most widely used. The first of them, the matrix isolation method, involves co-condensation of the compound under study with a large excess (from a hundred to a thousand times) of inert component (usually, an inert gas or hydrocarbon).^{9, 10}

This technique allowed the discovery and investigation of a new class of compounds, *viz.*, metastable complexes of photochemically generated Rg_n-HX and $H-Rg-X$ ($Rg = He, Xe, Ar$; X is electron-acceptor group, *e.g.*, OH, SH or F, Cl, I) molecules. These species are stabilised in low-temperature matrices of inert gases.^{11, 12} Quantum-chemical calculations of their electronic structures were reported.^{13, 14} Chaban *et al.*¹⁴ studied xenon insertion into some organic molecules (*e.g.*, $HXeC_2H$, $HXeC_6H_5$, $HXeOC_6H_5$) and predicted the existence of stable inclusion compounds and linear oligomers $H(XeC_2)_nXeH$ ($n \geq 1$). The matrix isolation technique has been successfully used for stabilisation and spectroscopic studies of radical and molecular intermediates in pyrolysis and photolysis reactions.¹⁵ It permits identification of labile complexes, various isomers and conformers and investigations of their interconversions.¹⁶ A method for stabilisation and spectroscopic investigation of radicals and short-lived intermediates on an activated silica gel surface has been proposed.^{17, 18}

The second approach is based on co-condensation of reactant vapours on cooled surfaces at rates that exclude collisions between the reactant molecules in the gas phase (molecular beam condensation).¹⁹ Possible modifications of this technique include, *e.g.*, condensation of particles of the same type; layer-by-layer condensation of particles of different types; co-condensation of particles of different types; co-condensation of reactive species with a large excess of inert component; co-condensation of reactive species with a third component (an activator or initiator). In all cases the system can be additionally activated by irradiating samples,^{20, 21} exposing them to high-frequency, ultrasonic and heat fields^{22, 23} and by mechanochemically treating them.^{24, 25} For instance, reactions of photogenerated mobile fluorine atoms with the O_3 , NH_3 , C_2H_4 and HCN molecules in argon matrices at 10–40 K have been studied in detail by EPR, IR and optical spectroscopies.²⁶

A general scheme of physicochemical processes occurring during condensation of atoms and molecules on cooling surfaces is presented in Fig. 1. Condensation-driven growth of a film sample can be accompanied by accommodation effects, surface diffusion, tunnelling interaction, clustering and nucleation. These processes are determined by such parameters as the condensation rate (particle flux through a unit of surface area per unit time) and the surface temperature. Raising the temperature causes diffusion of small particles, which were produced and stabilised in the first stage, in the matrix followed by formation of larger particles and clusters. Clearly, processes occurring (i) in the course of inter-

Figure 1. A scheme of physicochemical processes occurring during condensation of atoms and molecules on a cold surface.

action between atom and molecular beams and the surface and (ii) on subsequent heating of the samples are of crucial importance. They determine specific features of low-temperature chemical reactions and control the morphology of newly formed surface nanostructures.

The most stubborn problem is to predict and describe those properties of low-temperature film co-condensates that are due to their inhomogeneity and nonequilibrium nature. There are two important consequences. First, reactive species in low-temperature co-condensates are kinetically and thermodynamically non-equivalent. Second, particles stabilised at low temperatures possess an excess energy (as compared to the mean energy of particles at a given temperature) and, as a rule, high reactivity upon addition of a third reactive component. Therefore, low-temperature co-condensates can be considered as chemical energy storage systems. The excess energy stored in the growing film of a low-temperature co-condensate can be estimated taking into account the following data: the excess energies of metastable crystalline and amorphous phases range from 5 to 20 kJ mol⁻¹, the energies of donor–acceptor interactions and complexation lie between 10 and 40 kJ mol⁻¹, the enthalpies of exothermic chemical reactions are 100 to 200 kJ mol⁻¹, the excess energies of stabilised reactive species (atoms and small clusters) or the recombination energies of radicals vary from 100 to 400 kJ mol⁻¹ and the energy of mechanical stress is nearly 10 kJ mol⁻¹ (see Ref. 7).

2. Size effects

The size effects manifest themselves as dependences of the physical and chemical properties of particles under study on the number of constituent atoms. Usually, they are divided into two main groups. These are internal size effects associated with nonmonotonic change in the bulk-to-surface atom ratio and external size effects due to the interaction of particles of different sizes and shapes with external electric and magnetic fields. The former group of effects is due to changes in the structural and electronic characteristics of particles including their reactivity, binding energy, ionisation potential, melting point, crystal structure parameters, *etc.*^{27–36} External size effects manifest themselves as co-operative electron or lattice excitations, which in the case of, *e.g.*, metal nanoparticles are responsible for the appearance of electron–plasmon resonance bands in the optical spectra.^{37–39}

Two types of size effect can be distinguished in cryochemistry. One of them is the effect of the size of the reacting species (number of structural units, *i.e.*, atoms or molecules) on the mechanism and kinetics of their chemical transformations.⁴⁰ The other effect is the influence of the thickness of the growing low-temperature co-condensate film on its reactivity.^{41, 42} In both cases small variations of the size parameters cause changes in the chemical properties of the system. Studies of interrelations between the reactivity and size of the reacting species (thickness of condensate films) are a topical avenue of cryochemical research.

High reactivity of metal nanoparticles is due to the presence of uncompensated chemical bonds of the surface atoms. According to calculations, almost all of the 10 to 15 atoms constituting a 1-nm particle can be considered as the surface atoms, while 10-nm particles ($\sim 10^4$ – 10^6 atoms) have only 15% of the atoms on the surface. The size effect is illustrated in Fig. 2 in which we present data on the reactivities of niobium clusters of different sizes, prepared using supersonic jet and mass selection techniques, in reactions with alkyl bromides.⁴³

The particle size can be considered as a thermodynamic property determining the state and reactivity of the system at low temperatures. In Fig. 3, the relative reactivities of metal particles are schematically shown as functions of their sizes. According to this scheme, the reactivity reduces as follows: free atoms > oligomeric clusters > nanoparticles > aggregates > bulk metal. Thus, metal atoms and small clusters are the most reactive species. Usually, their properties are investigated using the matrix isolation technique at liquid helium temperatures. An

Figure 2. Cluster-size dependences of reactivities of niobium clusters Nb_x in reactions with EtBr (1) and Pr^iBr (2);⁴³ x is the number of atoms in the cluster.

Figure 3. A scheme illustrating changes in the relative reactivities of metal particles as functions of their sizes and temperature of the reaction system.

increase in the particle size reduces the reactivity. It should be noted that this dependence is nonmonotonic because more stable particles, *e.g.*, the so-called magic clusters, are periodically formed. The reactivity is reduced to the greatest extent upon aggregation of small clusters, *i.e.*, as the properties of the aggregates become more and more similar to those of bulk material.

The particle size and reactivity can be preset using some experimentally controllable parameters, *e.g.*, the substrate temperature, metal-to-ligand (inert component) ratio, reactant condensation rate, heat treatment regime of samples and the presence of activators or stabilisers. As the condensation temperature decreases and the proportion of the inert component increases, diffusion-controlled processes in the system become less intense. Using this correlation, it is possible to stabilise high-energy and

highly reactive particles in low-temperature matrices. The ratio of the reactant condensation rates usually has a strong effect on the size of the particles formed at a given temperature. As the metal-to-ligand ratio and temperature increase, the proportion of metal clusters and aggregated particles increases. The reactant condensation rates affect the properties of the growing condensate film in a complex manner. When highly reactive particles (atoms, dimers, trimers) are deposited on a cold surface, their lifetimes are inversely proportional to the condensation rate, being also dependent on the nature of relaxation processes in the system. The collision numbers of the reactant molecules with the surface and with one another are functions of the flux intensity of the particles being deposited. The above-mentioned factors and the chemical nature of the reactants govern the pathways and kinetics of low-temperature chemical reactions.

3. Defects and mechanical stress in the growing surface films

Various defects and mechanical stress produced during the growth of condensate films affect low-temperature chemical processes.^{40,41} Analysis of elastic deformations responsible for initiation of chemical reactions in a film sample⁴⁰ showed that the formation of a co-condensate film begins with growth of islands. The growing islands can merge together, thus forming close-packed columnar aggregates. Interfacial interactions produce mechanical stress. As the growing film thickens, the columnar aggregates increase in size. After reaching a critical film thickness, cracking occurs, being accompanied by structural phase transitions that initiate fast chemical reactions and crystallisation. The initial amorphous system has an excess free energy. An increase in internal mechanical stress during condensation of reactants causes deformation and cracking of the film upon reaching a critical film thickness. Plastic deformations are responsible for enhancement of molecular mobility in the system and subsequent acceleration of chemical processes. Elastic deformations and cracks 'initiate' fast crystallisation of amorphous films.

Development of elastic deformation and occurrence of chemical reactions are interconnected by a feedback. This is a possible reason for autowave chemical transformations in the system during the growth of co-condensate film. The system's behaviour is determined by the particle size, the extent of deviation from the equilibrium state and by the rates of relaxation processes. This approach provides a qualitative explanation for the dependence of the reactivity of the film co-condensate on the growth conditions. Raising the temperature causes enhancement of the molecular mobility, thus favouring the growth of the existing nuclei rather than nucleation. The process is accompanied by relaxation of internal stress due to a decrease in the interface area. This causes weakening of mechanical stress and thickening of the sample.

Mechanical stress and critical thickness of a growing film were measured in a study of condensation of a water film using a low-temperature tensometer and calorimeter.⁴² The results obtained confirmed the existence of an interrelation between spontaneous crystallisation of the film and chemical transformations in the sample. Thus, low-temperature co-condensation is accompanied by generation and storage of the mechanical energy, development of elastic and plastic deformations in the sample, enhancement of the molecular mobility in the system and by cracking. These processes can initiate chemical reactions in the system.

Release of excess energy stored in the mechanically non-equilibrium matrix component of a frozen bulk sample *via* brittle fracture of the sample has been studied.⁴⁴ Initiation of autowave chemical transformations in irradiated, cryochemically stabilised samples subjected to local fracture was observed during chlorination of saturated hydrocarbons, hydrobromination of olefins and polymerisation of 2-methylbuta-1,3-diene. γ -Radiation energy storage in the course of low-temperature radiolysis of solid HCN results in accumulation of stabilised radicals in the matrix.⁴⁵

III. Reactions of metal atoms and small clusters in low-temperature matrices

Metal atoms and small clusters are highly reactive species. Because of this, investigations on their spectral and chemical properties require the use of special equipment and the matrix isolation technique. In particular, the Al_3 , Cu_3 , Ag_3 , Ga_3 and Au_2Ag clusters were studied by EPR spectroscopy⁴⁶ using isolation in matrices of inert gases and hydrocarbons. Dimers and higher clusters of various metals (Na_n , Ag_n , Au_n , Cr_n , Mn_n , Sc_n , Y_n , Ln_n ; $n = 2-9$) were investigated by UV and photoelectron spectroscopies, a fluorescence technique and using quantum-chemical calculations.⁴⁷⁻⁵¹ Currently, matrix isolation of mass-selected clusters is employed to obtain and perform spectroscopic studies of clusters and fragment ions of prescribed size.⁵²⁻⁵⁶ The matrix isolation method allowed one to synthesise, stabilise and spectroscopically investigate a large number of coordinatively saturated and unsaturated metal complexes with N_2 , O_2 , CO , CO_2 , C_2H_4 and C_2H_2 .⁵⁷⁻⁶¹

Both UV and electron (ion) beam initiated elementary reactions in low-temperature matrices are accompanied by electronic and structural relaxation of the cryomatrixes containing various 'host' atoms, molecules and ions.^{62,63} Interactions between reactive species including recombination of atoms, radicals and ions are often accompanied by luminescence and exoelectron emission.⁶⁴ Using data on thermally and photo-assisted exoelectron emission and luminescence, one can obtain information on the mobility mechanisms of neutral and charged reactive species and on the electronic relaxation in metastable matrices containing various additives.^{65,66} The mechanisms of diffusion and electron transport in atomic and molecular cryomatrixes (N_2 , CH_4 , CD_4 , Ar and Kr) have been discussed.⁶⁷⁻⁶⁹

As mentioned above, unusual chemical reactions occurring at low temperatures cannot be performed under normal conditions. A general problem of cryochemistry is the impossibility of predicting the chemical behaviour of low-temperature systems containing metal atoms, clusters and nanoparticles based on the properties of bulk samples. Detailed investigations on the conditions for and mechanisms of low-temperature reactions involving metal atoms and clusters have been reported.⁵⁻⁸ When studying reactions of atoms and small clusters, a third reactive component is often introduced in the low-temperature matrix doped with the metal atoms or clusters to provide an additional thermal or photochemical activation of the system. The most impressive examples of such studies are given below.

Reactions of the first-row transition metals with CO_2 and its isoelectronic analogues (CS_2 and OCS) in argon matrices were studied by UV and Fourier IR spectroscopies and by density functional quantum-chemical calculations.⁷⁰⁻⁷⁴ These reactions are of interest from the standpoint of activation of the CO_2 molecule to involve it in low-temperature catalytic transformations. The results obtained show that these transition metals (Fe, Co, Ni and Cu) form 1:1 complexes with CO_2 , whereas atoms of the early elements (Sc, Ti, V, Cr) insert into C–O bonds to give oxocarbonyls. Two isomeric Ni– CO_2 complexes differing in stability were found in the carbon dioxide matrix at 10 K.⁷² The yields of the complexes dramatically decrease upon dilution of the system with argon. When using a nitrogen matrix, complexation enhances, resulting in more stable complexes $\text{Ni}(\text{CO}_2)(\text{N}_2)$ and $\text{Ni}(\text{CO}_2)(\text{N}_2)_2$. A co-operative effect of two ligands was pointed out. Namely, coordination of the nitrogen molecule causes hybridisation of the 4s and 3d orbitals of the nickel atom, which increases the degree of Ni → CO_2 charge transfer in the structure of the biligand complex compared to the monoligand complex $\text{Ni}(\text{CO}_2)$. An analogous effect was observed in a study of the reaction of copper vapours with dinitrogen.⁷⁴ Co-condensation of copper with dinitrogen taken in excess results in $\text{Cu}_2(\text{N}_2)$ and $\text{Cu}_2(\text{N}_2)_2$ complexes with ease. Dilution of the system with argon causes a dramatic decrease in the yields of the complexes, while

introduction of CO enhances complexation and favours the formation of mixed biligand complexes.

Reactions of magnesium atoms and clusters with CO_2 and ethylene were studied in argon matrix at 10–80 K (the metal species were stabilised) and in low-temperature co-condensates at 77–100 K by IR and UV spectroscopies and by chromatography.⁷⁵⁻⁷⁷ Both the experimental data and the results of quantum-chemical calculations of the reaction system indicate formation of four- and five-membered cyclic complexes in the first stage.⁷⁸ *Ab initio* MP2/6-31G(d) and QCISD/6-31G(d) calculations⁷⁹ showed that conversion of CO_2 into CO occurs much more easily in the presence of Mg atoms:

The reaction is spin allowed and the potential barrier to the $\text{CO}_2 \rightarrow \text{CO}$ conversion becomes nearly halved; however, the reaction is still highly endothermic. The reverse reaction

is an exothermic process with a potential barrier of 2.8 kcal mol⁻¹.

Reactions of samarium atoms and clusters with ethylene in the temperature range 12–30 K result in π -complexes $\text{Sm}(\text{C}_2\text{H}_4)$ and $\text{Sm}(\text{C}_2\text{H}_4)_2$.^{80,81} An unexpected effect was observed in studies of reactions of metals (Mg and Sm) with a mixture of C_2H_4 and CO_2 . Under identical conditions samarium reacts only with CO_2 , whereas magnesium forms complexes with both ligands.⁸⁰ The results obtained demonstrate different reactivity of metal atoms and clusters.

Unusual behaviour of magnesium atoms and clusters in reactions with halocarbons has been reported.⁸²⁻⁸⁵ In particular, carbon tetrachloride does not react with bulk magnesium at ambient temperatures. The situation changes in the case of co-condensation of magnesium vapour and CCl_4 at 77–80 K. Magnesium atoms and clusters efficiently react with CCl_4 to give a variety of intermediates and stable products.⁷⁵

The spectra of $\text{Mg}/\text{CCl}_4/\text{Ar}$ ($\text{Mg}:\text{Ar} = 1:1000$) co-condensates at 12 K first of all exhibited a decrease in the intensity of absorption of small magnesium clusters followed by consumption of magnesium atoms (Fig. 4).⁸³ The results of IR spectroscopic study showed that the major reaction products are C_2Cl_6 and C_2Cl_4 .

Magnesium atoms and clusters possess different reactivities in reactions with alkyl(aryl) halides (RX , $\text{X} = \text{F}$, Cl , Br , I).⁸⁴ Magnesium atoms initiate radical recombination and disproportionation reactions with the formation of various products. Reactions in Mg/RX co-condensates ($\text{Mg}:\text{RX} = 1:1$ to $1:100$) resulted in aggregation of magnesium atoms and preferred formation of CCl_3MgCl (a Grignard reagent). Magnesium and calcium clusters were shown to be more reactive species than the corresponding atoms.⁸⁶ The relative reactivity of metal particles in reactions with alkyl halides reduces as follows: $\text{Ca}_2 > \text{Mg}_4 > \text{Mg}_3 > \text{Mg}_2 > \text{Ca} > \text{Mg}$. The reactivity of methyl halides reduces in the order $\text{CH}_3\text{I} > \text{CH}_3\text{F} > \text{CH}_3\text{Br} > \text{CH}_3\text{Cl}$.

Co-condensation of sodium, magnesium and samarium vapours with alcohols causes a competition between two processes, e.g.,⁷⁵

Figure 4. Absorption spectra of 1:100:1000 Mg/CCl₄/Ar co-condensate (temperature increases from the top down in the range 12 to 34 K) (a) and temperature dependence of the normalised integrated intensity of absorption of magnesium atoms and clusters in this co-condensate (b).⁸³ Mg (1), Mg₄ (2), Mg₃ (3), Mg₃ (4) and Mg₂ (5).

At 77 K, metal atoms stabilised at low metal concentrations (metal:ligand $\approx$ 1:500) reduce alcohols to hydrocarbons. Metal clusters formed in co-condensates at metal-to-ligand ratios of about 1:5 form alcoholates.⁸⁷

The dependence of the reactivity of metal particles on the co-condensation conditions was confirmed by the results of studies on the synthesis and catalytic properties of samarium–hydrocarbon co-condensates⁸⁸ with hexane, cyclohexane, hex-1-ene and cyclohexene chosen as the model compounds. Comparison of the catalytic systems obtained by low-temperature co-condensation of (i) samarium and hexane and (ii) samarium and cyclohexene revealed higher activity of the former system in the hydrogenation of hex-1-ene. Similar results were obtained in studies of cyclohexene hydrogenation using a catalytic system prepared by low-temperature co-condensation of samarium and cyclohexane. Thus, there is a ‘matrix memory’ effect, *i.e.*, the system prepared by low-temperature co-condensation governs the reactivity and selectivity of subsequent catalytic transformations. It is possible to draw an analogy to enzymatic reactions, where the enzyme–substrate interactions are accompanied by rearrangement of the active site to match the substrate structure.

A systematic study of co-condensates of some transition metals with CH₄/Ar mixtures at 10 K was carried out by Klambunde *et al.*⁸⁹ Oxidative insertion of electronically excited metal atoms into C–H bonds has been reported.⁹⁰ The reactions of laser ablated iron atoms with methane and ethylene were studied by Mössbauer and IR spectroscopies in doped argon matrices at 17 K; quantum-chemical calculations of newly formed species and stable products were also performed.^{89,90} The excited iron atoms are inserted into the C–H bond of methane to give

CH₃FeH.⁹¹ The first reaction stage involves decomposition of methane molecule to give a methyl radical CH₃ and a hydrogen atom. The reaction in a methane matrix results in products of the interaction between primary radicals CH₃ and H atoms with one another (C₂H₆, C₂H₄, C₂H₂) and with iron atoms, *viz.*, compounds CH₃FeH and Fe₂H₂(CH₃)₄ with Fe–H–Fe bridging bonds. Reactions of iron atoms with dilute ethylene in argon matrix give a Fe(C₂H₄) complex. As the concentration of ethylene increases, complex Fe(C₂H₄)₂ becomes the major product. A study by Mössbauer spectroscopy revealed the formation of monomeric and dimeric halides FeF₃ and Fe₂F₆ and FeI₂ and Fe₂I₄ in the reactions of iron with halogen donors SF₆ and CH₃I.^{92,93}

Co-condensation of transition metal atoms with aromatic hydrocarbons at 77–80 K often results in bisarene complexes of (formally) zero-valent metals.⁹⁴ For instance, co-condensation of lanthanide atoms and 1,3,5-tris-*tert*-butylbenzene produces thermally stable ‘sandwich’ complexes of Nd, Tb, Dy, Ho, Er and Lu, as well as thermally unstable complexes of La, Pr, Sm, Eu, Tm and Yb.⁹⁴ Metal complexes with phosphorus and nitrogen derivatives of aromatic hydrocarbons have been synthesised.⁹⁴ Reactions of titanium and vanadium vapours with 1,4-di-*tert*-butylbuta-1,3-diene resulted in novel compounds of general formula [M(η^2 -Bu₂C₄H₂)₂] (M = Ti, V).⁹⁵ The complexes obtained can be modified by introducing various ligands, *e.g.*, phosphines, diazadienes and isonitriles, which replace the diene ligand, thus forming novel ‘half-sandwich’ complexes.

Low-temperature co-condensates of lanthanides (Sm, Eu) with mesogenic ligands 4-pentyl-4'-cyanobiphenyl (5CB) and 4-octyl-4'-cyanobiphenyl (8CB) were studied by IR and UV spectroscopies in the temperature range 90–300 K. Formation of two labile complexes with 1:2 and 1:1 metal-to-ligand ratios was established.^{96,97} Complex Sm(CB)₂ undergoes a solid-phase transformation into Sm₂(CB)₂ (CB is 4-alkyl-4'-cyanobiphenyl) in the temperature range 170–210 K. The process exhibits a polychronous kinetics,⁹⁷ which can be due to the presence of some solid-phase reactivity distribution of the complexes.⁹⁸ The IR spectra of Sm/5CB co-condensates with various metal-to-ligand ratios were studied at 95–273 K and at 95 K. Two new (compared to the IR spectrum of a neat 5CB film) bands with maxima at 2135 and 2085 cm⁻¹ were observed in the region of stretching vibrations of the CN group. Based on a nearly 100 cm⁻¹ shift towards the low-frequency region, these bands were assigned to the absorption bands of π -complexes. At 90–95 K, the spectrum of co-condensate exhibits a single absorption band at 2135 cm⁻¹. The absorption at 2085 cm⁻¹ increases, while the absorption at 2135 cm⁻¹ decreases on heating of the sample from 95 to 213 K. Thus, here we deal with conversion of one complex into the other. In addition, changes in the band intensity ratio upon variation of the metal-to-ligand ratio suggest the presence of two complexes of different compositions.⁹⁷ The UV and visible spectra of Sm/5CB film co-condensates revealed two new overlapped absorption bands with maxima at 390 and 420 nm.⁹⁷ Absorption in this spectral region is characteristic of charge-transfer complexes of transition metals with molecules of unsaturated organic compounds. The band intensities are also temperature dependent. This trend serves as an additional argument in favour of the existence of two complexes.

Labile 1:1 complexes of difluorostannylene (a hetero-element carbene analogue) with some aromatic molecules (benzene, chlorobenzene and toluene) were obtained and characterised by matrix IR spectroscopy.⁹⁹ Co-condensation of vanadium and chromium vapours with tetraphenylsilane ligands results in stable ‘sandwich’ complexes. Low-temperature co-condensation of vapours was employed to prepare novel di- and trinuclear clusters of molybdenum, rhenium and palladium.¹⁰⁰ Iron complexes containing η^6 -arenes and trichlorosilyl ligands (Fig. 5) were also synthesised by co-condensation of vapours of the corresponding reactants.¹⁰¹

Figure 5. Structure of iron complexes containing η^6 -arenes and trichlorosilyl ligands.¹⁰¹

Reaction products of iron atoms with polycyclic aromatic hydrocarbons (PAH) pyrene and coronene were studied by UV and Fourier IR spectroscopies in argon and nitrogen matrices.¹⁰² The spectra of the co-condensates revealed the presence of mononuclear π -complexes of iron atom with pyrene, $\text{Fe}(\text{C}_{16}\text{H}_{10})_n$ ($n = 1, 2$), which are stable at temperatures of up to 24 K. In the structure of the π -complex, the iron atom is above the centre of one of the two outer aromatic rings. Formation of unstable Fe–H complexes with one or two hydrogen atoms of one aromatic ring of the ligand molecule or with two hydrogen atoms of different rings was also detected. The coronene molecule, which contains a large number of fused aromatic rings, preferentially reacts with iron dimer to give π -complexes $\text{Fe}_2(\text{C}_{24}\text{H}_{12})_n$ ($n = 1, 2$). These species are thermally stable up to the sublimation temperature of the argon matrix (40 K) and exhibit stability to 200–700 nm radiation. Two iron atoms can be arranged above two adjacent aromatic rings of the same ligand molecule or perpendicular to the ring plane, thus bonding two ligand molecules. The latter type of bonding can result in ‘multi-sandwich’ complexes. Relatively stable iron–PAH compounds comprising several iron atoms, small (nanoscale) iron aggregates formed under the action of external factors and thin films on carbon surfaces can be responsible for characteristic 3.3, 7.8, 8.6 and 11.3 μm IR radiation, which is often observed in space.^{103–105}

IV. Reactions in quantum crystals and superfluid helium nanodroplets at ultralow temperatures

The use of quantum crystals (solid ^3He , ^4He , ortho- and para-hydrogen, HD)^{106–109} and nanodroplets of quantum liquids (superfluid liquid helium) as matrices is of particular interest for investigations of chemical reactions at ultralow temperatures.^{110–113}

Here, one deals with weak intermolecular interactions (absence of matrix effects), absence of ‘cage effects’ for photo-induced processes and quantisation of rotational motion of guest molecules. As a consequence, IR spectra exhibit narrow spectral lines with fully resolved rotational structure.^{114–116} The effects observed are of great importance for astrophysics and astrochemistry^{117,118} because the most abundant substances in space are hydrogen, helium and products of their ionisation by cosmic rays (H_2^+ , H_3^+ and He^+).

The use of superfluid helium nanodroplets (He_N , $N \approx 10^2$ – 10^5) as matrices opens up new prospects for investigations of atoms, clusters, metastable molecules and complexes.¹¹⁹ Nanodroplets are prepared by supersonic expansion of helium gas jets under high pressure at low temperatures. Surface evaporation causes cooling of a nanodroplet, so a temperature of 0.2 to 0.4 K is maintained inside it. Atoms and molecules can be included into helium nanodroplets by trapping the dopant in the gas phase

Figure 6. A scheme of formation of helium nanodroplets containing encapsulated impurity atoms (molecules).¹²⁰

(Fig. 6).^{120–123} Molecules, clusters and loosely bound complexes can be synthesised immediately during trapping of dopant atoms (molecules) into helium nanodroplets. Currently, this method is employed to obtain and perform spectral characterisation of alkali metal,^{124,125} magnesium¹²⁰ and silver^{126,127} clusters and rubidium–helium exciplexes.¹²⁸ Alkali metal atoms form loosely bound surface states due to Coulombic repulsion between the helium electrons and the valence electrons of the metal. The van der Waals metal clusters formed on the surface of nanodroplets are in the high-spin state. This phenomenon was studied by femtosecond multiphonon ionisation spectroscopy.¹²¹ The mass distribution of spin-polarised clusters is shown in Fig. 7. Thus, even large clusters ($N > 10$) are completely spin-polarised. The observed alternation of the intensities of the peaks corresponding to clusters of different sizes is due to specific features of the mechanism of laser-induced spin relaxation.

Figure 7. Mass distribution of Na_N clusters (N is the number of atoms in clusters). Laser excitation at 850 (1) and 425 nm (2).¹²¹

The vibronic spectra of mixed clusters M^4He_N and M^3He_N comprising aromatic molecules (M) and helium atoms have been studied at 0.4 K.¹²⁹ Taking these systems as examples, the intramolecular fine vibronic structure of $S_0 \rightarrow S_1$ electronic transitions in the spectra of various molecules was experimentally studied. Peculiar features of formation of atomic and molecular clusters during free gas expansion in vacuum have been considered.¹³⁰

The structures of impurity systems prepared by trapping D_2 , Ne, N_2 and Kr into the bulk of superfluid ^4He were studied by X-ray diffraction and ultrasonically.¹³¹ The van de Waals interactions between the components result in the formation of a nanoscale system similar to aerogel, which comprises clusters of impurity molecules and atoms of size 50 ± 20 Å and density of up

to 10^{20} atom cm^{-3} . The possibility of stabilisation of high concentrations of atoms in such systems makes them promising energy sources. Water nanoclusters surrounded by layers of solid and liquid helium have been reported. They form a specific 'watergel', which acts as a matrix stabiliser and a dispersion medium.^{131, 132}

Unusual tunnelling chemical reactions of light impurity atoms and molecules

were investigated in solid helium at ~ 1.35 K.^{133, 134} Deuterium atoms efficiently replace hydrogen atoms in the H_2 and HD molecules, thus favouring accumulation of rather high steady-state concentrations of hydrogen atoms (up to 10^{18} cm^{-3}).

An EPR study of tunnelling reactions of hydrogen atoms produced by γ -radiolysis of a mixture of ortho- and parahydrogen at 4.2 K^{135, 136} showed that diffusion of atoms in solid hydrogen occurs by repeating tunnelling reactions

and is completed with a highly exothermic reaction

where M is a third particle acting as an energy drain.

Radiolysis of solid parahydrogen containing small amounts of deuterium impurity at 4.2 K causes formation of electron 'bubbles' that dissociate *via* tunnelling recombination with cations stabilised in the system.¹³⁷ In both cases the efficiency of tunnelling reactions is determined by weak interactions with orthohydrogen impurity and by energy dissipation in the matrix.¹³⁵ The contributions of two main mechanisms (sequential two-body process involving quasi-bound resonant states and tunnelling and a direct three-body recombination involving matrix atoms or molecules) to atom–atom recombination in matrices of inert gases have been analysed.^{138, 139}

Studies on photoinduced reactions of dopant molecules (CH_4 , CO_2 , NO) in solid parahydrogen matrices have been reported.^{140, 141} The absence of cage effects for the primary radicals and efficient reactions of 'hot' photofragments

are due to weak intermolecular interactions with the matrix molecules.

The possibility of using tunnelling reactions of hydrogen atoms for hydrogenation of various organic and inorganic compounds under conditions of cryochemical synthesis has been considered.^{142, 143} Experiments carried out at 10 K showed that cyclic olefins (cyclopentene and cyclohexene) nearly instantaneously (in a few seconds) react with hydrogen atoms to give the corresponding cyclic alkanes.^{142, 143} The reaction of hydrogen atoms with solid CO results in quantitative yields of formaldehyde and methanol.¹⁴⁴ The last-mentioned compound is efficiently formed upon additional UV irradiation of the system. These laboratory studies have first demonstrated the possibility of synthesis of these compounds in interstellar ice as a result of tunnelling reactions of hydrogen atoms with CO molecules. It was also shown that matrix-stabilised C, O and N atoms can be involved in reactions occurring on spraying H atoms over solid samples at 10 K. The reactions result in CH_4 , H_2O and NH_3 . The authors of this study¹⁴⁴ considered the possibility of tunnelling

Figure 8. Yields of products of tunnelling reactions of H atoms with C_2H_4 (1), CO (2), C_3H_6 (3) and C_2H_2 (4) as functions of temperature in the range 10–60 K.¹⁴⁴

interaction of H atoms with acetylene, ethylene, propylene and carbon monoxide in the temperature range 10–60 K. In all the cases the reaction rates increase as the temperature decreases from 50 down to 10 K and reach maximum values at 10 K (Fig. 8). Negative temperature dependence of the rate constant for tunnelling reaction of hydrogen atoms with acetylene in highly dilute samples in xenon or carbon dioxide matrices was unambiguously proved. The effect observed was explained by the possibility of increasing the steady-state concentration of hydrogen atoms in the solid film and by an increase in the rate constant for tunnelling reaction on lowering the temperature. Negative temperature dependences of the rate constants for tunnelling reactions were theoretically predicted by Hiraoka and Sato.¹⁴⁴ The influence of various factors (mutual arrangement of atoms, structural rearrangement of reactants and medium, orientational intermolecular vibrations) on the rates of tunnelling reactions and on the temperature dependence of the rate constants for tunnelling reactions involving hydrogen atoms has also been analysed.^{139, 145–149}

V. Reactions in low-temperature film co-condensates

Vacuum co-condensation of reactant vapours on cooled surfaces of spectral and preparative cryostats provides conditions that exclude collisions between the reactant molecules in the gas phase. As a rule, in this case the reaction occurs within a thin surface layer. On heating, chemical reactions proceed in the bulk of the sample due to enhancement of the molecular mobilities of the reactants. In Fig. 9 we present a general scheme of successive and concerted reactions occurring in the course of low-temperature co-condensation of vaporous metals (M) and various organic or inorganic ligands (L). At low temperatures and high dilutions, reactions of metal atoms mainly occur. In more concentrated systems, aggregation is possible, resulting in the formation of clusters, nanoparticles, organometallic compounds and ligand-stabilised mono- and polynuclear complexes of metals and nanoparticles.

Fast spontaneous reactions occurring in the absence of external factors are of greatest interest for cryochemistry of film co-condensates. Such reactions involve consumption of internal energy stored in the film co-condensate; some of them are considered in this review. They proceed by different mechanisms but exhibit an identical kinetics pattern, namely, these are fast (almost explosive) solid-phase low-temperature reactions.

Examples can be found in such reactions as olefin halogenation and hydrohalogenation involving formation of unstable donor–acceptor complexes that prescribe a certain organisation of the reactant molecules, which is necessary to perform the solid-

Figure 9. Scheme of successive and concerted reactions proceeding in the course of low-temperature co-condensation of metal (M) and ligand (L) vapours.

phase chemical transformations.^{150, 151} No reactions occur in the absence of complexation. This is confirmed by the results of hydrohalogenation of 2-methylbut-2-ene. The reaction rate depends on the extent of complexation in the system 2-methylbut-2-ene–HCl (HCl : olefin = 6 : 1) at 80 K as follows:

Degree of complexation (%)	100	50	0
Conversion (%)			
on co-condensation	39	22	0
on annealing	25	13	0

An explosive reaction was observed in the growing films of magnesium – 1,2-dichloroethane co-condensate⁴¹

The reaction products were obtained in nearly 100% yields as the film thickness reaches a critical value (L_c). There is a clear-cut distinction between the reacted and unreacted film regions. Explosive reaction can be accompanied by mechanical fracture of the film. The critical thickness depends on the reactant ratio and on the temperature of the sample. The L_c value is minimum at 1 : 1 Mg : CH₂Cl–CH₂Cl ratio. As the temperature of the sample increases, the region of the explosive reaction becomes more narrow. The reaction is accompanied by fast heat release and crystallisation of the initially amorphous co-condensate film. The process acquires a wave character and the internal energy stored in the co-condensate film initiates explosive reaction. A decrease in the reactant condensation rates and an increase in the temperature of the co-condensate improve the efficiency of relaxation processes in the film, thus making explosive processes less probable. Similar effects were also observed in a study on the reactions of acetyl chloride with diethylamine and cyclopentadiene with titanium tetrachloride.¹⁵² Growth of co-condensate film is accompanied by generation and accumulation of internal strain (excess internal energy) in the sample, which initiates a vigorous reaction and fast crystallisation of the co-condensate after reaching a critical value. Explosive polymerisation reactions initiated by magnesium vapours were observed.¹⁵³

The HCN molecule was found in various space objects, namely, giant clouds of interstellar dust, comets and other galactic objects.^{154, 155} It is commonly accepted that the formation of this molecule is a result of one of the main stages of pre-biological chemical evolution, because processes involving HCN can result in amino acids, purines, pyrimidines and other bioactive compounds.¹⁵⁴ Chemical reactions of HCN and its derivatives, *viz.*, cryopolymerisation of HCN and its copolymerisation with acetaldehyde and ethylene oxide as well as polymerisation of cyanogen bromide under conditions similar to those in the interstellar medium (low temperature and initiation by γ -radiation and local brittle fracture) have been studied in detail.^{156–158}

VI. Cryochemical synthesis and reactions involving metal nanoparticles

Metal nanoparticles of size 1 to 10 nm are of crucial interest for cryochemical research, because in this case small variations of the particle size cause significant changes in their physical and chemical properties. Such objects can be considered as surface structures, because most of the constituent atoms are surface or near-surface ones. An increase in the concentration of uncompensated valence bonds enhances the particles' reactivities.

Main methods for preparation of metal clusters and nanoparticles have been well documented.^{159–162} Going to low and ultralow temperatures opens up new prospects for production of small metal particles.

Interesting results were obtained using metal evaporation under static pressure of inert gas in the reaction vessel or the inert gas stream technique. A metal can be evaporated by resistive heating and by exposing it to electron or laser beams. Metal clusters and nanoparticles are deposited on internal walls of a reactor or on various substrates.¹⁶⁰ In particular, copper, silver and gold particles of size nearly 10 nm were produced by gas-phase evaporation followed by trapping the freshly obtained particles in frozen liquids (ethanol, methanol and some alkanes).^{6, 163} Magnesium particles of size 2 nm were obtained by condensation in liquid helium nanodroplets; larger magnesium particles of size ~100 nm were prepared by condensation in solid argon.¹⁹ Laser evaporation has been employed in studies of almost all metals. For instance, low-energy neutral clusters of iron, cobalt, nickel and nanostructured films of thickness up to 100 nm were produced by deposition on various cooled substrates.¹⁹ Laser and electron beam evaporation of metals are convenient for preparation of bimetallic nanoparticles. A mass spectrometric study of particles formed by co-vapourisation of zinc, cadmium, mercury and sodium revealed the possibility of formation of bimetallic particles comprising one heavy atom surrounded by several (up to 18) sodium atoms.¹⁹ Experiments with sources of ionised cluster beams allowed control of the kinetic energy of the clusters deposited by applying an accelerating potential difference.^{164, 165} Gas-phase cluster beams can be size selected and deposited on appropriate substrates. For instance, Pt_n and Pd_n ($n = 1–15$) particles were produced on the (100) surface of Ag single crystals.¹⁶⁶

Novel organometallic clusters and solvated metal nanoparticles are also obtained by condensation of metal vapours.^{5, 19} Usually, vapours of metals and organic components are co-deposited on the surfaces of reaction vessels cooled down to 77–100 K and lower temperatures. At such temperatures, metal atoms and clusters insert into solid organic matrices. During warm-up of the samples the atoms and small clusters aggregate into large metal clusters and particles of size 10–30 nm, which form stable colloidal solutions at room temperature. Further growth of the particles is restricted by solvation and electrostatic effects.

Co-condensation of silver and methyl acrylate vapours on the surface cooled to 77 K followed by heating of the system to room temperature causes partial polymerisation of methyl acrylate and formation of organic colloids comprising silver nanoparticles stabilised by the polymer layer. At room temperature, the optical absorption spectrum of molten co-condensate exhibits a maximum at 400 nm, which is characteristic of spherical silver particles of diameter less than 20 nm.¹⁶⁷ Transmission electron microscopy data indicate formation of silver particles of size less than 15 nm. Co-condensation of silver, lead and methyl acrylate vapours results in colloids of polymer-stabilised bimetallic nanoparticles.¹⁶⁸ The size of lead particles and bimetallic Pb/Ag particles thus obtained is at most 5 nm, which is much smaller than the size of individual silver particles formed under analogous conditions.

Formation of metal nanoparticles during low-temperature co-condensation of silver and 2-(dimethylamino)ethyl methacrylate vapours was studied by optical spectroscopy and dynamic light

scattering.¹⁶⁹ Experimental data as well as the results of electron microscopy investigation of the co-condensates heated up to room temperature indicate initial formation of silver nanoparticles 5 to 12 nm in diameter stabilised in the polymer layer. Low-temperature synthesis of colloidal silver nanoparticles in water, acetone and toluene has also been reported.¹⁷⁰

Co-condensation of two metals allows preparation of bimetallic core-shell particles. For instance, analysis of Fe/Li co-condensates revealed the presence of particles comprising an iron metal core coated with a $\text{Li}_2\text{O}/\text{Li}_2\text{CO}_3/\text{Fe}_2\text{O}_3$ protective layer.¹⁷¹ The same approach was employed for the synthesis of bimetallic core-shell nanoparticles in Fe/Mg co-condensates (Fig. 10).¹⁷² These results have first demonstrated the possibility of using cryochemistry for preparation of bimetallic metastable clusters of metals that are immiscible under normal conditions.

Figure 10. Scheme for preparation of bimetallic core-shell nanoparticles in Fe/Mg co-condensates.¹⁷²

Surface-immobilised metal particles of size 3–8 nm were obtained by impregnating oxide (Al_2O_3 , SiO_2 , MgO) matrices with molten organometallic co-condensate.¹⁷³ Bimetallic particles stabilised on an oxide surface were also prepared by co-condensation of reactant vapours.¹⁷⁴ Colloidal solutions of metal nanoparticles provide an efficient tool for fabrication of nanostructured metallic coatings by solvent evaporation. Such films possess unique properties, *viz.*, a higher resistance compared to metal films produced by other methods and the ability to redissolve in appropriate solvents.

Redox reactions on the surface of gold nanoelectrodes, resulting in deposition of the second metal (Pb, Cd, Tl), have been studied.¹⁷⁵ The reactions are initiated by electron transfer from radiolytically generated organic free radicals to the gold nanoparticles rather than application of an external electric field. Because of the large surface area of nanoparticles the reaction can be monitored with a spectrophotometer. Deposition of the second metal causes changes in the size, chemical nature and redox properties of the gold nanoparticles. The physicochemical behaviour of the bimetallic particles thus produced depends on the electronic properties of the adatom layer and on electron exchange at the interface between two metals with different electron work function.

Bukhtiyarov and Slin'ko reported a comprehensive review on the properties of metal nanoparticles stabilised on solid surfaces.¹⁷⁶ They analysed the reactivities and selectivities of metal particles in relation to particle size and to the atomic and electronic structure of bulk metals. This allowed consideration of the properties of metal clusters and nanoparticles and of the active sites of heterogeneous catalysts in the framework of a unified approach.

Studies on the reactivity of metal nanoparticles over a wide temperature range revealed novel unusual chemical reactions. Namely, silver nanoparticles encapsulated into poly(*p*-xylylene) films possess catalytic activity in the reaction of methanol oxida-

tion into formaldehyde, silver nanoparticles stabilised on an alumina surface catalyse epoxidation of ethylene⁷ while the reaction of zinc nanoparticles with CCl_4 in water causes an increase in the rate of dechlorination and results in methane.¹⁷⁷

VII. Assembly of hybrid nanostructures at low temperatures

Novel technologies widely use nanoscale hybrid materials (organic compound-metal; metal-semiconductor; metal-dielectric) that are stable at room temperature.¹⁷⁸ These materials are characterised by large interface areas and extended boundaries between different structural elements. Interactions of such nanoscale structures with photons and electrons cause manifestation of unusual optical, magnetic and electrophysical properties.^{179, 180} The properties of individual nanoparticles and nanostructured films, methods for their preparation, self-organisation of nanoparticles, growth of oriented nanoscale films and template synthesis of nanoparticles have been reviewed.^{27–33} In the text below we present some examples of preparation of these materials using cryochemical techniques.

1. Low-temperature condensation and surface reactions

Various hybrid nanostructures were fabricated by condensation of atom-molecular beams on cooled dielectric, semiconductor and metal surfaces. For instance, multilayer dinitrogen films adsorbed on a graphite surface were studied at 12–20 K.¹⁸¹ This allowed determination of the tilt angles of the molecular axes with respect to the graphite surface and establishment of two main types of molecular packing within the layer with an increase in the surface coverage from submonolayer to formation of a bilayer structure. Detailed neutron diffraction studies on the growth mode of methyl chloride (CH_3Cl), dichloromethane (CH_2Cl_2) and chloroform (CHCl_3) condensate films on a graphite surface have been reported.^{182, 183}

Monolayers of long-chain saturated hydrocarbons were adsorbed on the Cu(111) surface cooled down to 80–160 K.¹⁸⁴ At low temperatures, octane forms a commensurate crystal lattice and undergoes a first-order phase transition on heating. Nonane forms a domain surface structure with parallel arrangement of molecules and experiences an unusual, strongly broadened phase transition on heating. This is consistent with the known odd-even effect observed in the structures of solid alkanes. Whereas alkanes $\text{C}_n\text{H}_{2n+2}$ with even n values have structures with monoclinic or triclinic unit cells, odd-numbered alkanes have an orthorhombic unit cell. These organic layers adsorbed on metal surfaces can be used in molecular electronics and optoelectronics.^{185–187} Electron transfer in structured layers of hexafluorobenzene and phenylthiol on the Cu(111) surface has been studied.¹⁸⁸ The interaction between organic molecules and the surface layer of the metal crystal affects charge transfer across the interface.

Ultrathin gold films were prepared by low-temperature condensation on a silicon surface at 173–300 K.¹⁸⁹ It was found that the surface of the silicon crystal and the pure metal layer are separated by a layer of amorphous gold silicide 13–28 Å thick.¹⁹⁰ A study of 0.3 nm silver films deposited on the Si(111), Si(100) and Ge(001) surfaces at 100–300 K revealed formation of ordered 2D structures,¹⁹¹ which are assigned to the most promising objects for creation of a novel class of 2D superconductors with $T_c = 2–8$ K.¹⁹¹ As the thickness of the silver layer increases, island 3D structures are mainly formed. Cold-deposited silver thin films exhibited second harmonic generation.¹⁹² Analysis of the results obtained confirmed a homogeneous structure of the deposited 3D silver films of thickness 15–20 nm. Lead films prepared by depositing Pb on the Si(111) surface provide the most convenient system for analysing various effects in the absence of interdiffusion and chemical reactions.¹⁹³ The Schottky barrier to a Pb/Si diode depends on the structure of the near-surface layer at the interface. Using surface X-ray diffraction, it was shown that growth of initially amorphous film is followed by

its crystallisation to well-ordered Pb(111) structures after reaching a critical thickness of 5 atomic Pb layers. Layer-by-layer deposition at 100 K allows suppression of the growth of 3D island structures.

Interfacial bimetallic systems formed by deposition of adatoms of the second metal on the crystal surface of the major metal component are of considerable interest.^{194–196} Catalytic activity of such systems has long been known; however, reliable investigation techniques were developed only in the last decade. Condensation of adatoms on metal surfaces at 100–200 K eliminates all types of mobility, except for surface diffusion during the film growth. Specific features of nucleation and the kinetics of formation of layer-by-layer deposited surface monolayers and island films as well as the growth of bulk 3D phases are first of all determined by close values of the lattice parameters of the two metals, by the ability to form bimetallic compounds and alloys, by strain in the growing film and by the relaxation mechanism of excess elastic energy. The lifetime of the adatom in the excited state and the electron states of the metal surface at low temperatures can be studied by time-resolved two-photon photoemission spectroscopy.¹⁹⁷ It was established that ternary hybrid metal nanostructures Cu/Co/Cu(001), Pd/Co/Pd(001) and Fe/Cu/Fe(001) possess unusual magnetic properties including magnetic anisotropy and tunnelling magnetoresistance. Substances exhibiting these properties can be used as magnetic sensors and magnetic recording systems.¹⁹⁸ Deposition of metal atoms and clusters on an oxide surface is of particular interest because this technique allows preparation of size-selected metal particles and modelling of the efficiency and selectivity of catalysts.^{199,200}

The vapour deposition technique allows controlled condensation of atoms and clusters on various surfaces by thermal or photochemical decomposition of precursor vapours.²⁰¹ Controlled adsorption and decomposition of iron pentacarbonyl, chromium hexacarbonyl and cyclopentadienylrhodium dicarbonyl on the single-crystal surfaces of Ag, Pt, Au and Cu at 80–300 K were studied by reflection absorption IR spectroscopy.^{202,203} Photodissociation of neutral molecules on cold surfaces of various metals was studied; some examples are provided by the CH₃I/Cu(110),²⁰⁴ Bu^tNO₂/Ag(111)²⁰⁵ and NH₃/Pt(111), Ge(100), Si(100) pairs.^{206,207}

Yet another promising method of cryochemical research, which allows preparation of hybrid nanostructures, involves the action of aggressive gases on the surface of metal crystals at low temperatures. Chlorination of different crystallographic planes of silver and copper single crystals has been studied.²⁰⁸ A 2-nm thick metal chloride layer is formed upon exposure of the Ag(111) surface to chlorine gas at 150–250 K. Thin layers of silver and copper chlorides can be used for fabrication of nanocrystalline materials (metal clusters dispersed in the bulk of the chloride phase: Ag_x/AgCl and Cu_x/CuCl). Local oxidation of titanium, aluminium and copper surfaces was performed by exposing them to an oxygen stream accompanied by scanning the corresponding local area with the probe tip of a scanning tunnelling microscope. By applying an appropriate potential difference between the surface and the probe tip and moving the probe tip across the specified surface area it is possible to 'draw' metal oxide lines 10–20 nm thick (Fig. 11).²⁰⁹ A local nanoscale etching technique was also used for modification of the surface of a silicon crystal.²¹⁰ Nanoscale silicon rods on the surface treated were prepared by nitration and subsequent oxidation of the surface monolayer. Efficient etching of the Si(111) surface by thermalised hydrogen atoms was performed at 105 K.^{207,211} The products obtained, silanes and disilanes, were removed from the surface by heating the samples to 480 K.

Silver, copper and platinum crystals are good catalysts of oxidation processes. However, organic molecules are poorly adsorbed on their surfaces at temperatures above 150 K. The situation changes in the presence of adsorbed oxygen.²¹² Efficient low-temperature oxidation of cyanogen (CN)₂, carbon monoxide, ethyl iodide, methanol, nitrobenzene and styrene molecules on the

Figure 11. AFM image of crystalline titanium surface after nanoscale local oxidation by simultaneous action of oxygen and the probe tip of a tunnelling atomic force microscope (a) and the current-vs.-voltage curves for the system at different temperatures (b).²⁰⁹ T/K: 250 (1), 190 (2), 130 (3), 90 (4) and 77 (5).

Ag(110), Pt(113) and Cu(110) surfaces was carried out in the presence of adsorbed oxygen.^{213–215}

The most important oxidation processes in the environment and in living organisms involve dioxygen. They can also retain selectivity at low temperatures as, e.g., industrial catalytic processes involving C₁-molecules on gold-containing catalysts. A complete catalytic cycle for the transformation

on gold cluster anions Au_N[−] is illustrated by Fig. 12. The reaction exhibits nonmonotonic cluster-size dependences of the amount of adsorbed carbon oxide and of the conversion efficiency (Fig. 13). This reflects improved stabilities of nanoclusters with closed outer electron shells (N = 8, 14, 18 and 20).^{216–218}

Dissociative adsorption of methane on the surface of Ni single crystals was considered as a model for reforming on small nickel crystallites dispersed in a highly porous Al₂O₃/MgO matrix.²¹⁹ Reactions of hydrogen atoms with acetone on graphite monolayers coated on the Pt(111) surface were studied by high-resolution electron energy loss spectroscopy and thermal desorption spectroscopy at 90 K.²¹⁹

2. Polymer films containing metal nanoparticles

Low-temperature vacuum codeposition of metal (Ag, Mg, Cd, Zn, Pb, Sm, Sn, Mn) vapours with *p*-xylylene, which polymerises at low temperatures (100–120 K), was employed to prepare metal nanoparticles (d = 5–10 nm) encapsulated into polymer films.^{220–227} Polymerisation at cryogenic temperatures and formation of the polymer network preclude subsequent aggregation

Figure 12. Scheme of complete catalytic cycle for conversion $\text{CO} + 1/2 \text{O}_2 \rightarrow \text{CO}_2$ on gold clusters Au_N^- (see Ref. 216). N is the number of atoms in the cluster.

Figure 13. Dependences of the reactivity (a), free energy (b) and amount of adsorbed carbon oxide (c) on the size of Au_N^- clusters at different exposure times in CO (1–3).²¹⁶

of the metal particles. Poly-*p*-xylylene films containing encapsulated metal nanoparticles can be separated at room temperature and investigated by various spectral and physicochemical methods. The following scheme of cryochemical synthesis of poly(*p*-xylylene) films containing nanoscale metal particles (M) was proposed:

The films obtained were studied by transmission electron microscopy and X-ray diffraction. The content of metal in the samples was determined by X-ray fluorescence analysis. It was found that globular lead particles are homogeneously dispersed in the film (Fig. 14). The average particle size was 5.5 nm, being independent of the metal content in the film from 0.1 to 6.5 mass %. The particles were treated as crystals.²²⁴ The lattice parameters of the zinc and cadmium particles encapsulated into poly(*p*-xylylene) films were in good agreement with the lattice parameters of bulk metals. Exposure of the films to oxygen over a period of several days led to formation of new metal-oxide crystalline phases ZnO and CdO.²²⁴

Poly(*p*-xylylene) is a typical insulator. Encapsulation of lead nanoparticles into the film (up to 10% by mass) has no effect on the material's characteristics, the resistivity of the films is $10^{16} \Omega \text{ cm}^{-2}$ (see Ref. 225). Changes in the conductivities of the

Figure 14. Electron micrograph (a) and size distributions (b) of lead particles stabilised in poly(*p*-xylylene) films ([Pb] = 6.5 mass %);²²⁴ n is the number of nanoparticles of a given size and N is the total number of nanoparticles.

samples were studied during low-temperature co-condensation of vaporous components and on heating of the samples in the temperature range 80–300 K.²²⁵ Polymer films containing nanoscale lead particles exhibit activity as gas and vapour sensors towards various organic and inorganic substances.^{226–230} The conductivity of the film samples varies by four to six orders of magnitude.

3. Hybrid metal–mesogen nanosystems

Ordered nanoscale structures are of considerable interest because of unusual physical and chemical properties. The use of liquid crystals as self-organising organic matrices opens up new prospects for the synthesis of anisotropic metal nanoparticles and their compounds and for fabrication of organised ensembles of nanorods and nanowires based on them.

Silver-containing cyanobiphenyl films were prepared by vacuum co-condensation of vaporous components on cooled CaF_2 , quartz and copper surfaces.^{231–233} Silver/4-alkyl-4'-cyanobiphenyl co-condensate samples were studied by EPR, IR and UV-visible spectroscopies in the temperature range 80–350 K and by transmission electron microscopy at room temperature. The spectral features observed were analysed using the results of model quantum-chemical calculations of the equilibrium structures and vibrational analysis.²³⁴

Spectroscopic studies of binary Ag/CB co-condensate films with the component ratio varied from 1:1 to 1:100, as well as investigation of ternary Ag/CB/decane co-condensate films at 90 K revealed the presence of metastable complexes formed as a result of interaction between silver atoms and cyanobiphenyl molecules. In particular, the IR spectra of the Ag/5CB co-condensates exhibited two new bands at 2080 and 2030 cm^{-1} in the region of CN stretching vibrations (see Ref. 231). These bands are shifted by -150 and -200 cm^{-1} , respectively, with respect to the corresponding band of 5CB (2230 cm^{-1}). The observed decrease in the stretching vibration frequencies indicates the formation of a silver–cyanobiphenyl π -complex. Indeed, partial donation of electron density from the bonding orbital of silver to the ligand antibonding orbital should cause elongation of the multiple bond in the complex and, hence, a decrease in its vibrational frequency. The frequency shifts by 100–200 cm^{-1} towards the low-frequency region were observed in a study on π -complexation of some transition metals with unsaturated compounds.²³⁵ The spectra of the Ag/5CB and Ag/5CB/ $\text{C}_{10}\text{H}_{22}$ co-condensates also exhibited a new band in the region 650–660 cm^{-1} , which was assigned to the vibrations of the metal–ligand bond in the π -complex Ag(5CB). Similar results were obtained for co-condensates of silver with 8CB and 4-octyloxy-4'-cyanobiphenyl (8OCB). In both cases the intensities of the IR bands of π -complexes changed with the co-condensate temperature following an identical pattern. Because of this, the bands were assigned to the same complex. Complexes Ag(CB) are stable at low temperatures and decompose on heating of the co-condensates to 200–300 K into starting CB and silver clusters. At room temperature, the IR spectrum of Ag/CB co-condensate is similar to that of the CB condensate film. The results obtained are consistent with the low thermal stabilities of the complexes of zero-valence metals with unsaturated compounds.

The formation of π -complexes in the system under study was confirmed by the results of quantum-chemical calculations of 5CB and of the central cyanophenyl fragment of the complex.²³⁴ The calculations were carried out by the multiconfiguration self-consistent field method and by the restricted Hartree–Fock method for open-shell systems. The Stevens–Basch–Krauss effective core pseudopotential was employed for all heavy atoms. Both geometry optimization and of vibrational analysis for the $(\text{PhCN})\text{Ag}$, $(\text{PhCN})\text{Ag}^+$ and $(\text{PhCN})\text{Ag}_2$ particles have demonstrated that global energy minima for these systems correspond to σ -complexes with linear arrangement of the $\text{C}–\text{N}\cdots\text{Ag}$ fragment. The shifts of the $\text{C}–\text{N}$ stretching vibration frequencies in the complexes relative to the corresponding value for the ligand

molecule were $+9$, -7 and $+20 \text{ cm}^{-1}$ for the equilibrium $\text{N}\cdots\text{Ag}$ distances of 2.81, 2.24, and 2.46 Å, respectively. Therefore, the calculated configurations do not correspond to real structures in the Ag/5CB films since the experimentally observed shifts of the CN stretching vibration frequency are -150 and -200 cm^{-1} .

At the same time liquid-crystalline cyanobiphenyls are known to form dimeric structures in the solid and liquid-crystalline phases. Structural studies^{236,237} showed that cyanobiphenyl molecules in the solid phases are arranged in the ‘head-to-tail’ manner. Based on this, the following structure of the silver–cyanobiphenyl complex was proposed (shown is the central part of the complex):

The cyano groups in this structure are nonequivalent and give two bands in the IR spectrum of the complex.

Multiconfiguration self-consistent field calculations revealed the possibility of two ground-state electronic configurations of the complex, $(\text{PhCN})_2\text{Ag}$ and $(\text{PhCN})_2\text{Ag}^+$.²³⁴ At long interligand distances R ($R \geq 4.7 \text{ Å}$), neutral silver atoms fill the interligand cavities. At $R < 4.7 \text{ Å}$, the charge-transfer configuration $(\text{PhCN})_2\text{Ag}^+$ dominates. If $R = 4.4 \text{ Å}$ (a charge-transfer complex), the calculated shifts of the $\text{C}–\text{N}$ vibrational frequencies in the $(\text{PhCN})_2\text{Ag}$ complex relative to the corresponding value for the PhCN molecule (2501 cm^{-1}) were found to be -150 and -175 cm^{-1} , which is in agreement with the experimentally observed shifts for the Ag/5CB films at 90 K.

Thermal behaviour of the metal-containing atom–molecular systems based on co-condensates of silver and mesogenic cyanobiphenyl 5CB was investigated in the temperature range 80–300 K.²³³ At 80 K, the EPR spectra of the co-condensates exhibited well-resolved signals of hyperfine coupling (HFC) with the metal atoms. This indicates formation of complexes between silver atoms and mesogenic ligands under conditions of low-temperature co-condensation. The parameters of the doublets, obtained by simulating the spectra of the Ag/5CB and Ag/5Py co-condensates are characteristic of π -complexes of the ^{107}Ag ($J = 1/2$) and ^{109}Ag ($J = 1/2$) atoms. By comparing the HFC constants of the complexes with those of free atoms [$A(^{107}\text{Ag}) = 611$ and $A(^{109}\text{Ag}) = 705.4 \text{ G}$]⁴⁶ it is possible to estimate the unpaired s-electron density on the metal atom: $\rho_s = 0.89$ (Ag/5CB). The central signal in the region characteristic of the g-factor of a free electron is due to absorption of the silver clusters stabilised in the 5CB matrix. Similar signals were observed for concentrated samples of co-condensates of silver with inert gases and hydrocarbons. They were treated as the spin resonance signals of conduction electrons in the metal nanoclusters. The average size of silver clusters in the Ag/5CB co-condensate (Ag:5CB = 1:10) estimated from the experimental spectrum recorded at 90 K is 1–2 nm (several tens of atoms). Raising the temperature from 80 to 150 K causes a decrease in the relative intensities of the doublets in the spectrum and an increase in the relative intensity of the central component, which indicates thermal degradation of the complex and the growth of silver nanoclusters. The possibility of formation of silver nanoclusters by UV irradiation of samples at 80–90 K was demonstrated.²³⁸ Heating of such samples above 200 K also causes a rapid decrease in the intensity of the central line in the EPR spectra and the appearance of a broad background absorption, which can be explained by the formation of larger silver nanoparticles and their aggregates.

At 90 K, the optical absorption spectra of Ag/5CB co-condensates exhibited²³³ a structured band at 360 nm. Quantum-chemical calculations of excited states of the complex revealed a number of intense transitions corresponding to

metal–ligand and ligand–ligand charge transfer in this region.²³⁹ It should be noted that small clusters of silver can also absorb in the region 390–420 nm.³⁷ The structured band at 360 nm disappears on heating of the co-condensate film to 200–300 K.²³⁴ Thus, heating of the sample to room temperature causes thermal degradation of the complex and aggregation of the silver atoms thus released. The broad band with a maximum at 440 nm which appeared in this case is due to absorption of surface plasmons of nanoscale silver particles²⁴⁰ that are formed as a result of aggregation of silver atoms upon decomposition of the complex. Fast heating of the co-condensate to 300 K causes a transition of the sample to the nematic mesophase. This is followed by an increase in the absorption of the plasmon resonance in the long-wavelength region of the UV spectrum, which can be due to both the growth of silver particles due to further aggregation and the formation of non-spherical anisotropic metal particles in the orientationally ordered matrix.

Thus, the sample prepared by low-temperature co-condensation of the metal (silver) and mesogenic component vapours and heated to room temperature is a material containing silver nanoparticles stabilised in the cyanobiphenyl matrix.²⁴⁰ The material retains nematic properties. The samples obtained and the pure 5CB are characterised by an identical thermogram pattern and by textures typical of the nematic phase.

Low-temperature layer-by-layer co-condensation of silver, 5CB and *p*-xylylene vapours followed by heating of the film sample results in encapsulation of the metal–mesogen system into the polymer film.²⁴⁰ An electron microscopy study of the films prepared by encapsulating silver-containing 4-pentyl-4'-cyanobiphenyl into poly(*p*-xylylene) under conditions of vacuum co-condensation of reactants revealed the presence of two types of

metal particles stabilised in the mesogenic matrix at room temperature.²⁴⁰ These are globular silver particles of diameters 15 to 30 nm and anisotropic rod-like particles more than 200 nm long (Fig. 15). The UV spectrum of the Ag/5CB films in poly(*p*-xylylene) exhibits a broad absorption band at 440–600 nm at room temperature. An increase in the metal-to-ligand ratio in the sample causes a preferred growth of rod-like silver particles.

Thus, silver-containing mesogenic cyanobiphenyl films prepared by low-temperature co-condensation of component vapours (molecular beam regime) incorporate metastable π -complexes of the metal with dimeric cyanobiphenyl molecules. The formation of metastable π -complexes in the temperature range 90–200 K was confirmed by EPR, IR and UV spectroscopies and by the results of quantum-chemical calculations of a model silver–cyanophenyl system. Raising the temperature causes degradation of thermally unstable complexes and aggregation of silver atoms in the anisotropic liquid-crystalline matrix, resulting in silver nanoclusters and nanoparticles. Thermal and photo-induced decomposition of the complexes in the temperature range 90–200 K is accompanied by the formation of nanoscale silver clusters and further aggregation of these species in the anisotropic matrix. The formation of globular metal particles (15–30 nm) and anisotropic metal–mesogen nanostructures including rod-like aggregates more than 200 nm long stabilised in the cyanobiphenyl matrix was established.

4. Nanoparticle ensembles and superlattices

Recently, intensive research on preparation and self-assembly of nanoparticles on various surfaces has been carried out.^{241,242} These investigations are aimed at finding possible applications of surface nanostructures and nanostructured films in various nanoelectronic data recording and processing devices, optical and magnetic filters, displays, switches, etc.

Silver and gold nanoparticles are convenient for studying self-assembly effects. Periodic structures are formed immediately in colloidal solutions of gold and silver nanoparticles stabilised by a variety of thiol- and nitrogen-containing ligands^{125,243} and on various surfaces modified with amines and thiols.²⁴⁴ Formation of alternating positively and negatively charged gold and silver nanoparticles and their organisation into ordered structures on glass surfaces in the presence of 4-aminothiophene and 4-carboxythiophene was observed.²⁴⁵ Detailed analysis of the stabilisation of the metal nanoparticles by ligands and of their organisation into periodic 1D, 2D and 3D structures has been reported.²⁴⁶

Self-assembly of spherical gold nanoparticles 2–5 nm in diameter into rod-like aggregates has been studied.²⁴⁷ It was shown that the size, shape and morphology of aggregates can be controlled by varying the substrate temperature. For instance, the species prepared were spherical aggregates of particles of diameter 97 ± 17 nm (23 °C), spherical particles of size 0.5–1 μ m (–23 °C) and nearly 50-nm long chain-like 1D aggregates comprised of spherical units (intermediate temperature, 10 °C). It was assumed that the formation of large globular aggregates from small spherical particles involves an intermediate stage in which linear aggregates are formed and that this stage is controlled by the enthalpy-to-entropy contribution ratio. Orientationally ordered gold nanorods were prepared.²⁴⁷ Using femto- and nano-second lasers, nanorods were reversibly transformed into spherical nanoparticles.

Self-assembly of Sb₄ clusters on the surface of highly ordered pyrolytic graphite or molybdenum disulfide was studied.²⁴⁸ The evolution of the structure and morphology pattern of the particles with an increase in the surface coverage was studied by electron microscopy and electron diffraction (Fig. 16). It was found that amorphous spherical nanoparticles are formed at low surface coverages. After reaching a critical size of 120 nm (at room temperature), finger-like island and planar 2D structures were formed. Well-shaped, orientationally ordered 3D nanocrystals

Figure 15. Optical absorption spectra of a Ag/5CB (Ag : 5CB = 1 : 10) co-condensate film at 90 (1), 200 (2) and 300 K (3) (a) and an electron micrograph of the film at 300 K (b) (1 cm = 100 nm).²⁴⁰

Figure 16. Evolution of the morphology pattern of antimony nanoclusters Sb_4 on the surface of highly ordered pyrolytic graphite with an increase in the surface coverage (from left to right) according to electron microscopy data.²⁴⁸

with narrow size distribution grew with increasing surface coverage. Thus, the authors of this study observed a size-dependent structural phase transition from the amorphous to the crystalline state. An analogous transition was earlier observed in the formation of gold nanocrystals by deposition on a graphite surface²⁴⁹ and ice crystals from amorphous supercooled water vapour.²⁵⁰ The phase transition observed depends on the condensation rate, surface coverage and the temperature of the sample.

The influence of the nature and surface morphology of the substrate (pyrolytic graphite or molybdenum disulfide) on the formation of ordered 2D and 3D superlattices was observed taking dodecanethiol-stabilised silver nanoparticles of diameter 5.8 nm as examples.²⁵¹ Control of substrate morphology is of great importance for pharmaceutical and food-industry applications.²⁵² For instance, self-assembled organothiol monolayers on the Au(111) surface were used as templates for the growth of glycine crystals.²⁵² Highly ordered styrene structures on the Si(100) surface were produced by scanning the corresponding local areas with the probe tip of a scanning tunnelling microscope. By modifying the silicon surface it is possible to change the orientation and length of molecular arrays on the surface, control their direction and vary the angle of chain propagation.

Self-ordering of alkanethiol monolayers on the surface of gold nanoparticles has been reported.²⁵³ Introduction of fluorocarbon substituents improves the stability of the ordered layers. Their thermal stability increases with an increase in the number, n , of methylene groups in the organic stabiliser molecule. At $n = 33$, the ordered films do not experience thermal degradation at 150 °C for 1 h in air. Gold nanoparticles stabilised by fluoroalkyl ligands can form hexagonal close-packed and cell structures.²⁵⁴ The type of ordering is primarily determined by the nanoparticle size ratio and by steric hindrance produced by the stabilising ligands. Stable nanosystems comprising gold particles ($d = 4$ nm) incorporated into polyethyleneimine and poly(L-lysine) films and additionally stabilised by carboxylic acids were obtained.²⁵⁵

Monolayers of ordered 2D structures comprised of ligand-stabilised nanoparticles can be used as selective chemoresistive sensors for volatile organic compounds. In particular, ordered 2D structures formed in monolayers of gold nanoparticles stabilised by alkanethiol ligands (Fig. 17) are highly sensitive to toluene, tetrachloroethylene, propan-1-ol and water vapour.²⁵⁶ Ordered thin-film surface structures built of functionalised organic molecules specifically bound to the surfaces of metallic and polymeric substrates also exhibit the properties of selective sensors. As an example, Fig. 18 presents a scheme of organisation of resorcin-[4]-arene monolayers that are covalently bound to the Au(111) surface and can selectively bind various organic molecules ($\text{CCl}_2 = \text{CCl}_2$, $\text{CCl}_2 = \text{CHCl}$, CCl_4 and toluene).²⁵⁷

Highly ordered organic monolayers adsorbed on the surface of inorganic nanoparticles can be used for selective binding of various functional blocks to organise hybrid nanostructures. This can be done using, *e.g.*, biomacromolecules. In particular, the ability of peptides and DNA molecules to show molecular 'recognition' can be modelled using relevant synthetic analogues.

Recent advances in molecular biology allowed one to obtain natural and synthetic biomolecules, which can selectively bind metal and metal oxide particles. There are two approaches to exploiting biomolecules as the 'glue' for different inorganic blocks.²⁵⁷ The first involves mutual organisation due to 'programmed' interaction between biomolecules with the known 'recognition' mechanism. In this case, the hybrid material is generated from two different inorganic blocks modified with molecules of peptides, antibodies, oligonucleotides or other bioligands complementary to one another. The second strategy involves specific interactions between inorganic blocks bearing particular functional groups and the bifunctional biomolecule. Recently, this approach was implemented practically.²⁵⁸

Nanostructured surfaces prepared by deposition of size-selected metal clusters and nanoparticles can be used for selective binding and immobilisation of particular biomolecules. Such systems are promising for fabrication of sensitive biochips. For instance, by depositing size-selected gold clusters onto graphite surfaces it is possible to create stable organised structures for selective binding of such practically important biomolecules as peroxidase and DNA.^{259–260} This method also permits optical detection of individual biomolecules bound to the nanoparticle surface.²⁶¹

Figure 17. Ordered 2D structures formed in monolayers of gold nanoparticles stabilised by alkanethiol ligands (a) and their sensitivity to toluene (1), tetrachloroethylene (2), water (3) and propan-1-ol (4) vapours (b).²⁵⁶

$\Delta\sigma/\sigma_0$ is the relative change in the layer conductivities; P/P_0 is the ratio of the partial vapour pressure of the organic compound to the total pressure in the system.

Figure 18. A scheme of organisation of resorcin-[4]-arene monolayers covalently bound to the (111) surface of gold single crystals and capable of selective binding of various organic molecules (a) and binding selectivity diagram for these molecules (b);²⁵⁷ K is the binding constant.

VIII. Conclusion

Cryochemistry allows one to investigate highly reactive particles, atoms, clusters, metal nanoparticles and their organised ensembles. At cryogenic temperatures, chemical interactions begin at the atomic level. Co-condensation and subsequent warm-up of samples are characterised by competition between aggregation and stabilisation of atoms and small clusters in matrices. Introduction of complexing ligands and reactive species into the system causes additional chemical and physicochemical processes resulting in unusual chemical compounds and complexes. Aggregation of atoms and their interaction with ligands occur almost barrierlessly. High reactivities of metal atoms, clusters and nanoparticles preclude establishment of correlations between the particle sizes (number of atoms in the particle) and their reactivities. This problem, as well as the problems of synthesis and stabilisation of atoms, clusters and nanoparticles can be solved only by carrying out spectroscopic studies at cryogenic temperatures.²⁶² Based on the results obtained thus far, the size of the reacting particle can be considered as a parameter which determines the state and chemical properties of a reaction system along with the temperature.²⁶³

At cryogenic temperatures, processes occur under strongly nonequilibrium conditions in metastable systems characterised by a broad reactivity distribution of the reacting species. This

manifests itself as peculiar features of the kinetics of low-temperature processes.

Operation at cryogenic temperatures allows preparation of small particles of size less than 1 nm. Potential applications of such species are related to the search for highly efficient stabilisers of nanoparticles. Novel catalysts and sorbents, optical and anti-corrosive coatings, pharmaceuticals and dyes, degassing agents and bioactive components can be prepared at cryogenic temperatures. High reactivities of small stabilised particles make it possible for them to be considered as chemical systems for energy accumulation and storage and as specific nanoscale chemical reactors. Such systems allow the carrying out of novel chemical reactions and unusual chemical transformations, which cannot proceed under normal conditions.

Currently, efficient cryochemical methods for stabilisation of nanoparticles in matrices and on various surfaces and procedures for fabrication of nanostructured film materials with prescribed optical, magnetic, electrophysical and mechanical characteristics are being developed. The future of these approaches is closely related to extension of the field of possible practical applications of nanosystems in nanotechnologies.^{264, 265} These are primarily creation of toxic gas sensors, highly selective and reactive catalytic systems, membranes and highly porous sorbents with large surface areas and prescribed pore sizes, novel ultrahard and superplastic materials, coating-protective nanoalloys, absorbing and reflecting ceramics, pharmaceuticals with improved bioavailability and controlled delivery, novel hybrid organometallic materials and bio-metallo-ceramic composites.

Abstract. Various theoretical and experimental methods for studying nucleation are considered. Since theoretical methods have fundamental limitations, information is gained from experimental research. It is demonstrated that the nucleation theory is entering a new phase of development, which is going to be, in essence, semiempirical. A semiempirical method for constructing nucleation rate surfaces is described. The topology of these surfaces in the limit of the zero nucleation rate can be determined using phase equilibrium diagrams. This opens up possibilities for revising certain approximations employed in experiments and particular axiomatic statements of the classical nucleation theory. Examples of the practical use of nucleation essential for the development of modern technologies are given. The bibliography includes 396 references.

I. Introduction

In the last two decades, the problems of nucleation have attracted considerable interest. These problems are related to many disciplines and the vast majority of systems in which first-order phase transitions can occur. The available nucleation theories are arbitrarily divided into the so-called 'theories of original potential' and phenomenological theories. With the aim of simplifying the problem of determination of the nucleation rate, the authors who uphold the former line of investigation consider average fluctuations of a nucleating medium to find conditions under which the 'averaged' cluster evolves into a droplet.¹ The principle of detailed equilibrium is invoked to solve the kinetic problem of cluster growth. In doing so, one should specify the equilibrium distribution in such a way that the averaged clusters could, to a certain degree, simulate non-equilibrium clusters.¹

Generally, a method for describing nucleation follows, with some delay, after the development of approximate methods in the many-body theory (see, for example, Ref. 2). The non-equilibrium state of a macroscopic system can be indirectly taken into

account, using, in particular, the linear reaction theory. In this theory, the effects caused, for example, by thermal perturbations are expressed in terms of mechanical perturbations. Alternative methods employ the theory of stochastic processes and the Fokker–Planck equation or Onsager's hypothesis according to which the fluctuation damping follows the same law as the change in the corresponding macroscopic variables. There are also methods based on the use of a local-equilibrium distribution (*i.e.*, on the assumption that a near-equilibrium distribution occurs in small volumes in the case of moderate deviations from equilibrium) as the initial condition for the fulfilment of the Liouville equation. The methods of statistical Gibbs ensembles for non-equilibrium systems (for example, Zubarev's method of a non-equilibrium statistical operator based on the construction of local integrals of motion) as well as the method accounting for the effect of thermostatting by considering non-potential forces find wide application.

In recent years, certain advances have been made in the study of non-equilibrium processes in dense multiparticle systems. Thus, the Vlasov equation was derived for a multiparticle system involving the field $U(r)$, which depends on the nature of particles

$$\frac{\partial f}{\partial t} + \mathbf{v} \text{grad}_r f + \mathbf{a} \text{grad}_r f = 0.$$

Here f is the distribution function of single-particle states in the phase space of coordinates (r) and rates ($\mathbf{v}$), $\mathbf{a} = -\text{grad}_r U(r)/m$ (m is the particle mass). In the monograph,³ this equation was considered as a special case of the more general Vlasov–Uehling–Uhlenbeck equation allowing for the formation of coupled states. The Vlasov equation results from the averaging of the generalised equation in the lowest approximation, where the energy of quasiparticles is calculated in the self-consistent Hartree–Fock approximation and collisions can be ignored. Vlasov deduced this equation by assuming that particles are not localised and their properties are responsible for the state of the system. This eliminates the problem of field averaging.

Vlasov reasoned that this equation does not follow from the Hartree–Fock or Liouville equations because of the presence of the property of branching of solutions, whereas neither processes of crystal formation nor crystal structures can be described using equations of classical statistics and quantum mechanics. Hence, the problem of allowing for collective interactions in a multiparticle system is replaced by the problem of finding an interaction potential of non-localised particles, including its functional dependence on the characteristics of the macroscopic state of the

system (for example, on the temperature in the consideration of a crystallisation process). In other words, simplified relations were proposed for the description of physical systems, which allow one to obtain results consistent with experimental data. This is achieved due to the fact that many systems can be described in an approximation of noninteracting particles in a potential field.² Of methods employing this approximation, let us note first of all the effective (self-consistent) field methods. The idea is that a certain simplification is introduced, whereby the motion of a given particle can be considered as a motion in a potential field, which depends only on the coordinate of this particle and is independent of the coordinates of all other particles. If the properties of all particles in this effective field are known, the assumed potential can be calculated. If no consistency with the expected result is achieved, the effective field can be 'corrected' until the desired result is obtained.

In the approximation used in the classical nucleation theory, the cluster is considered as a liquid droplet of uniform density equal to the density of the macroscopic liquid; the droplet has a sharp boundary with the surrounding metastable phase. Using this model, one can calculate the free energies of real systems taking into account the translational degrees of freedom of the cluster.⁴ The droplet model describes only some of the possible configurations of the cluster consisting of a particular number of molecules, and there is no assurance that it is one of these configurations that plays a decisive role in the dynamic process.¹

The clusters under consideration can be divided into two types, *viz.*, stable clusters whose configurations are determined by their own structures and clusters whose structures depend on the results obtained in the context of a particular theory (for example, the density functional theory). The former type of clusters corresponds to the approximation of noninteracting particles, whereas the latter type corresponds to the approximation of interacting particles, which is similar to the self-consistent field approximation. It should be noted that by specifying *a priori* the type of the cluster (rather than determining it by analysing intermolecular interactions), we actually go from analytical theories to phenomenological approaches.¹

The best results, which are in quantitative or semiquantitative agreement with experimental data, were obtained using models based on the classical nucleation theory. In essence, such models are phenomenological rather than molecular.¹ The foundations of the classical nucleation theory were laid by Gibbs. In the 1940–1950s, this theory acquired its modern meaning after publications by Zeldovich⁵ and Frenkel.⁶

In recent years, many studies have been devoted to the development of molecular theories of nucleation. However, the applications of certain relations of statistical mechanics to nucleation were not always justified.^{2,3} The thermodynamic approach to the description of nucleation leads essentially to more than noting the introduction of additional terms to equations for the work of formation of critical nuclei of a new phase. For instance, Abraham⁷ took into account characteristic features of dipole–dipole interactions. Dillmann and Meier^{8,9} proposed various phenomenological coefficients. Overlapping of clusters was accounted for in the study.¹⁰

The correlation between the modern theoretical and experimental data can be judged from the curves shown in Fig. 1.¹¹ It should be noted that the agreement between the results can be substantially improved by varying a certain parameter of the theory, *e.g.*, the surface tension, within its experimental error. At the same time, out of numerous theories one can always choose a theory, which is best suited for the description of a particular series of experimental results. Therefore, a good agreement between theoretical and experimental data does not evidence the predictive force of the theory.

In the last five decades, the accuracy of experimental methods was substantially improved. It was expected that the classical nucleation theory would be experimentally confirmed. Actually, abundant experimental data, which have been accumulated, are

Figure 1. Experimental (1) plots of the nucleation rate J vs. supersaturation S of an octanol vapour in an octanol–sulfur hexafluoride system and analogous dependences calculated according to the classical theory (2) and the Dillmann–Meier theory (3).¹¹

Nucleation temperatures for each series of experiments /°C (from right to left): 261.8, 266.3, 271.2, 276.4, 281.5, 286.6, 291.7.

not contradictory with this theory. However, taking into account the ever-increasing accuracy of experimental results, it becomes more and more evident that the classical nucleation theory has limits of applicability. Presently, there is a pressing need to reveal these limits and develop new nucleation models, which can predict nucleation rates in various systems.

Approximately 10 years ago, semiempirical methods were proposed for constructing nucleation rate surfaces based on phase equilibrium diagrams.^{12,13} Based on this idea, nucleation rate surfaces were constructed for a series of simplest systems.¹⁴ Assuming this rather evident concept, it is apparent that the multitude of nucleation rate surfaces can be constructed from the multitude of phase equilibrium lines. In other words, 'multiple' nucleation rate surfaces are a rule rather than an exception. Hence, scarce experimental data on nucleation rates need analysis for 'singularity'. A direct experiment on the detection of two rate surfaces upon glycerol nucleation in the vicinity of its triple point was described in study.¹⁵ Each surface corresponds to its own nucleation channel. By contrast, the classical nucleation theory generally considers a singular nucleation rate surface. Of course, the multiplicity is implicitly embedded in the classical theory; however, no attention has been given to this fact until recently. Evidently, in the presence of many surfaces, attempts to describe the overall nucleation rate in the singular approximation of the classical theory are unjustified.

In the present review, attention is primarily given to studies published in the last 10–15 years. Earlier publications are considered, when the retrospective analysis of the problem is necessary. It may seem that the number of references relating to some problems, which have been covered in detail in scientific publications, is insufficient, whereas references relating to other problems, which are no less important but have not been adequately explored, are excessive. Some reviews devoted to rather narrow subject matters are mentioned with the aim of demonstrating the generality of approaches to the description of nucleation in different systems. The present review does not include particular details, for example, the preparation of sols for chemical syntheses in homogeneous solutions, micelles, vesicles, Langmuir–Blodgett films, polymers, glasses, zeolites, *etc.* Undoubtedly, the main conclusions are applicable to all systems in which nucleation takes place. The lines of investigation, which, in my opinion, show promise for the development of the

nucleation theory, are considered in most detail. Presently, it seems reasonable to focus efforts on developing individual parametric semiempirical theories for particular systems characterised by topologically similar (brought to a single topological form) phase equilibrium diagrams. Apparently, a combination of these theories based on the similarity criteria will be the next step in the development of concepts of nucleation. Progress in experimental methods gives promise that new unique results will be obtained in the nearest future, which will give impetus to further theoretical investigations of nucleation.

II. Nucleation theory

Nucleation accompanies first-order phase transitions. They occur in the initial metastable phase due to the fluctuation formation and nucleation (cluster formation) of a new phase.¹⁶ The formation of a macroscopic nucleus requires energy for the formation of an interface between the old and newly formed phases. A need for an excess energy gives rise to hysteresis phenomena, such as supercooling (or superheating) of melts and solutions relative to the equilibrium melting point, supercooling of gases, overvoltage upon electrodeposition of films, *etc.*

In 1878, Gibbs was the first to describe theoretically the formation of a new phase.¹⁷ He has provided a rigorous thermodynamic definition for critical nuclei of a new phase and laid foundations for the formalised description of nucleation rates. Almost five decades later, Volmer and Weber¹⁸ elaborated the Gibbs model in a study devoted to nucleation kinetics. Volmer considered the nucleation work as the activation energy and described qualitatively the nucleation of a new phase in the course of crystallisation.¹⁹ He also introduced the concept of three- and two-dimensional nuclei of a new phase and related their fluctuation appearance to the nucleation and crystallisation rates.

However, the proposed model has drawbacks. For example, the pre-exponential factor in the corresponding kinetic equations remains undetermined due to which the theory is only semi-quantitative. Further efforts by researchers were directed at searching for more rigorous theoretical foundations of the kinetics of the process. Farkas²⁰ solved a system of Szilard kinetic equations describing the formation of droplets from a vapour. The nucleation theory as applied to the stationary kinetics of the droplet formation from a supersaturated vapour was elaborated in studies by Kaischew and Stranski.²¹ Becker and Döring²² completed the study aimed at determining the constants in equations considered by Farkas. They created a general picture of various molecular events proceeding upon the formation of a new phase.

Becker and Döring's statistical theory considers a simplified stationary model according to which the average number of nuclei consisting of 2, 3, 4, ..., n molecules remains constant with time, although depends on external conditions. Clusters whose sizes are larger than the critical value are withdrawn from the system, and the vapour pressure is maintained constant due to the introduction of monomers (molecules, atoms). For nuclei of each size, the evaporation and condensation rates are in balance. By going from a discrete to continual problem and using integration, the authors estimated the nucleation rate (J). The latter is equal to the number of clusters, which are capable of growing and are formed in a unit volume (generally, in cubic centimeter) in a unit time (1 s). It was assumed that clusters containing n molecules are formed from nuclei containing $(n - 1)$ molecules.²² This theory was completed in the above-mentioned studies by Zeldovich⁵ and Frenkel.⁶ The specificity of formation of crystalline nuclei from liquid and gas phases and the problem of heterogeneous nucleation were discussed in Refs 6, 23 and 24. The theory, as it formulated by Zeldovich and Frenkel, is called the 'classical nucleation theory'.

Up to the early 1960s, it was believed that this theory adequately described homogeneous condensation of a supersaturated vapour. The predictions based on this theory were in good agreement with results of experimental measurements of critical

supersaturations using a Wilson chamber and studies of isentropic expansion of a gas in a nozzle or a turbulent vapour flow evaporated into a cold gas. However, in succeeding years, the determination of the dependence of the nucleation rate on supersaturation became possible and the principal foundations of the classical theory and its applicability to interpretation of experimental data were doubted. This gave rise to several tens of equations for the nucleation rate of a new phase.

1. Free energy of nucleation in the classical nucleation theory

For a metastable (according to the Gibbs definition¹⁷) system to become stable, energy sufficient for the creation of a phase interface is required. The free energy of cluster formation involved in a number of thermodynamic equations is one of the main parameters in the nucleation theory. The macroscopic approach, which employs concepts of thermodynamics and statistical physics developed for systems consisting of a large number of molecules, provides a quantitative description of nucleation. Below is given a brief derivation of the equation for the free energy of nucleation in approximations of the classical nucleation theory, which was described in detail in many publications (in particular, the latest versions were published in the book of collective works²⁵).

In the droplet approximation, a change in the Gibbs free energy (ΔG) upon the formation of a cluster consisting of n molecules in a closed system, which contains a vapour at the temperature T and pressure p , can be written as follows

$$\Delta G = n(\mu_l - \mu_v) + 4\pi r^2 \sigma, \quad (1)$$

where μ_l and μ_v are the chemical potentials of molecules in the liquid and vapour phases, respectively, r is the radius of the cluster and σ is the surface tension. Under isothermal conditions, the first component in the right-hand side of Eqn (1) can be estimated from the equation

$$d(\mu_l - \mu_v) = (v_l - v_v)dp_v, \quad (2)$$

where v_l and v_v are the specific volumes of molecules in the liquid and vapour phases, respectively, and p_v is the vapour pressure. If the vapour is considered as an ideal gas and the volume of the molecule in the condensed phase is ignored, the integration of Eqn (2) gives

$$\mu_l - \mu_v = -k_B T \ln S, \quad (3)$$

where k_B is the Boltzmann constant, $S = p_v/p_0$ is supersaturation (p_0 is an equilibrium vapour pressure over the planar interface at the temperature T). Assuming that nuclei of a new phase (clusters) retain the macroscopic physicochemical properties, the overall work of formation of rather large clusters in the droplet approximation can be expressed as a sum of surface ($4\pi r^2 \sigma$) and volume ($nk_B T \ln S$) changes in the Gibbs free energy.[†] Then, the change in the free energy upon cluster formation is

$$\Delta G = 4\pi r^2 \sigma - nk_B T \ln S, \quad (4)$$

where $n = (4/3)\pi r^3/v_l$. A liquid nucleus can grow to a droplet only when its size becomes larger than the critical radius r^* . The terms in Eqn (4) depend differently on r and have opposite signs at $S > 1$. Hence, the plot of ΔG vs. r passes through a maximum. The free energy of formation of a cluster with a critical size is

$$\Delta G^* = -\frac{4}{3}\pi(r^*)^3 \frac{k_B T \ln S}{v_l} + 4\pi(r^*)^2 \sigma. \quad (5)$$

[†] In the present review, the problem is considered in no more detail than follows from the early droplet model and determination of the surface and volume contributions. According to this model, a cluster is represented as an isotropic sphere covered with an infinitely thin film with a surface tension σ .

At a maximum, $r = r^*$ and $d(\Delta G)/dr = 0$. Hence, the radius of a critical nucleus can be easily determined as follows

$$r^* = \frac{2\sigma v_l}{k_B T \ln S}. \quad (6)$$

Equation (6) enables one to determine the equilibrium pressure of a saturated vapour over a droplet of radius r^* as a function of initial vapour supersaturation and cluster size. From Eqns (5) and (6), we have the following known equation

$$\Delta G^* = \frac{4}{3} \pi (r^*)^2 \sigma. \quad (7)$$

In the droplet approximation, ΔG^* is equal to one-third of the surface energy of the cluster. By excluding r^* , we obtain another form of the same equation

$$\Delta G^* = \frac{16}{3} \frac{\pi \sigma^3 v_l^2}{(k_B T \ln S)^2}. \quad (8)$$

The dynamics of droplet formation at pressures close to the equilibrium vapour pressure over the planar surface can be represented as follows. At $p < p_0$, the free energy of cluster formation rapidly increases as the cluster size increases. In the system occurring under these conditions, clusters of any sizes can, in principle, exist; however, the smallest clusters generally prevail in such systems. At $p > p_0$, the number of nuclei with a radius smaller than r^* undergoes random fluctuations. When the nucleus reaches a critical size, any favourable fluctuation leads to its infinite growth. Then the problem lies in estimating the rate (frequency) of formation of nuclei of the critical size.

The nucleation rate J is determined by the number of viable nuclei formed in a unit volume in a unit time. According to the classical theory,

$$J = \beta Z s^* c_{n^*} = 2v_l \zeta_c \sqrt{\sigma} \frac{N^2}{\sqrt{2\pi m}} \exp\left(-\frac{\Delta G^*}{k_B T}\right), \quad (9)$$

where β is a flow of condensing monomers, Z is the Zeldovich non-equilibrium factor; s^* is the surface area of the critical nucleus, c_{n^*} is the concentration of the critical nuclei, ζ_c is the condensation coefficient determined by the ratio of the number of molecules condensed on the nucleus surface to the total number of collisions between the molecules, m is the mass of the monomer and N is the concentration of the monomers. The Zeldovich non-equilibrium factor is determined as follows

$$Z = \sqrt{\frac{1}{2\pi k_B T} \left(\frac{\partial^2 \Delta G}{\partial n^2} \right)_{n^*}}. \quad (10)$$

The flow of condensing monomers can be expressed by the equation

$$\beta = \zeta_c \frac{p}{\sqrt{2\pi m k_B T}}, \quad (11)$$

where p is the partial pressure of the monomer.

As a result, the stationary growth rates are identical for clusters of any sizes.^{22, 25}

One of the most important problems of non-stationary nucleation kinetics is to determine the period (time) of non-stationarity. Zeldovich was the first to demonstrate that upon a sudden change in vapour supersaturation, a new stationary distribution of clusters follows the exponential law with a characteristic time constant τ called the time delay or relaxation time.⁵

According to the concepts proposed by Zeldovich, under conditions of a non-stationary process, the condensation rate is a function of time t (see Ref. 26)

$$J = J_s \left[1 - \exp\left(-\frac{t}{\tau}\right) \right],$$

where J_s is the stationary nucleation rate. Based on the results of the experimental investigation of the water vapour condensation in supersonic nozzles, Kantrowitz²⁷ found an empirical relationship between τ and vapour supercooling ΔT

$$\tau(\Delta T)^4 = 9.36 \times 10^3 \text{ (s K}^4\text{)}.$$

The simplest approximation, which allows one to estimate the time required for the achievement of constant amount of nuclei, was proposed in the study²⁸

$$\tau_s = \frac{25(n^*)^2 (2\pi m_1 k_B T)^{1/2}}{4\pi p (r^*)^2},$$

where m_1 is the mass of the monomer. According to this approximation, the time τ under standard experimental conditions of vapour nucleation (at $\zeta_c = 1$) is $10^{-5} - 10^{-7}$ s.

In the studies,²⁷⁻²⁹ it was assumed that clusters whose sizes are similar to the size of the critical nucleus are of kinetic importance. The time required for the achievement of 95%–99% of the stationary nucleation rate is often taken as the period of non-stationarity.^{30, 31} In principle, this level should be chosen depending on the accuracy of experimental measurements of the function $J(t)$ within the limits, where the change in the nucleation rate can be estimated. Knowing the dependence $J(t)$, the period of non-stationarity can be calculated.

In the investigation,³² it was demonstrated that the period of non-stationarity depends on the value and shape of the energy barrier to nucleation. The formation of a cluster consisting of two atoms is the slowest step of nucleation. Kantrowitz²⁷ quantitatively estimated the influence of cluster heating through the latent condensation heat on the nucleation rate. In a typical case of nucleation of a 2% water vapour in air, this effect leads to a fivefold decrease in J_s . In the study,³³ it was hypothesised that corrections for a non-equilibrium state are generally of little importance in the classical nucleation theory. Hence, such corrections are introduced only in extreme cases.

The condition of consistency of supersaturation in the system is a substantial limitation, which hinders the application of theoretical conclusions to the solution of practical problems, because nucleation most often occurs at variable temperature and supersaturation. It was demonstrated³⁴ that the rate of nucleation, which proceeds under conditions of a slow increase in supersaturation of the system, is lower than the rate calculated provided that the process is stationary. A decrease in the nucleation rate is proportional to a change in supersaturation, the time of non-stationarity and the size of the critical nucleus. The macroscopic nucleation theory includes certain unjustified assumptions and mathematical approximations. For example, it is assumed that small clusters can be considered as small portions of a macroscopic phase.

In principle, nucleus formation and growth should occur at any vapour supersaturation. The critical supersaturation is arbitrarily determined as a condition for rather fast nucleation. The nucleation rate changes with a change in the degree of supersaturation so rapidly that no significance has been attached to an error of even several orders of magnitude in the estimation of the pre-exponential factor in Eqn (9) (see, for example, Ref. 35).

Lothe and Pound^{36, 37} revised the classical nucleation theory and suggested an alternative scheme of condensation involving the following three steps:

- (1) nN_n molecules of a vapour are condensed into a liquid through isothermal compression;
- (2) this liquid is mechanically disintegrated giving rise to N_n droplets of equal size;
- (3) translational and rotational motion is imparted to all the droplets formed.

The authors of the cited studies introduced two additional multipliers, which were found based on the concepts of quantum statistics. Taking into account these multipliers, the nucleation rate increases by a factor of $10^{17} - 10^{20}$ (!). It should be noted that

the authors simply assumed that Eqn (8) is incomplete and should include a change in the translational and rotational entropy of the cluster. This question has been discussed in detail, for example, in Ref. 38. This problem was solved using statistical thermodynamic analysis. Finally, it was concluded that the correction for the translational and rotational motion of nuclei lacked experimental support (this problem was analysed in the review³⁹). It should be noted that the concept of formation of a stationary droplet in a vapour is a principal drawback of the classical theory because clusters execute, for example, Brownian motion.

Critics of the foundations of the classical nucleation theory primarily note that the properties characteristic of a macroscopic droplet (density, surface tension, saturated vapour pressure) cannot be extended to clusters consisting of only several tens of molecules. Since the properties of small clusters cannot be divided into volume and surface characteristics, the concept of surface tension seems to be artificial as applied to these clusters. To eliminate this problem, the excess free energy of the cluster can be, for example, determined as the difference between its free energy and the free energy of the same number of molecules present in a macroscopic volume of the condensate.

In the studies,^{40,41} the following dependence of the surface tension on the radius of the droplet was deduced:

$$\sigma(r) = \sigma_0 \left(1 - \frac{2}{kr} + \frac{2}{k^2 r^2} \right), \quad (12)$$

where σ_0 is the surface tension of the planar surface of the liquid, $1/k \approx (0.2-0.5) \times 10^{-7}$ cm.

When considering rather small clusters, not only the equation for σ but also the Kelvin equation [Eqn (6)] should be changed.⁴² However, the authors of the studies^{43,44} believed that the Kelvin equation is applicable to droplets of sizes ≥ 20 Å. This is contradictory to the Tolman equation. The latter equation relates the surface tension to the droplet size. According to the Tolman thermodynamic theory,⁴⁵ in the case of high surface curvature, a change in the surface tension should be described by the equation

$$\frac{\sigma}{\sigma_0} = \frac{1}{1 + 2\delta/r}, \quad (13)$$

where δ is 0.25–0.6 of the diameter of the molecule.

Until recently, the efforts of many researchers were directed primarily towards the improvement of the classical model by making it consistent with thermodynamics by introducing additional correction coefficients, which take into account individual factors. However, the theory did not become universal.

2. Modifications of the classical nucleation theory

In recent years, one of the versions of the classical theory, the so-called self-consistent theory (SCT) of nucleation, has gained acceptance.^{46–48}

From Eqn (1) describing the change in the free energy of a cluster in the classical nucleation theory, it follows that the work of formation of cluster consisting of one monomer is not equal to zero. By contrast, the change in the free energy of monomers in SCT is equal to zero due to the introduction of the corresponding corrections. According to this theory,

$$\Delta G = (4\pi r^2 - s)\sigma - (n - 1)k_B T \ln S, \quad (14)$$

where s is the area of monomer surface.

Using Eqn (14) written for the droplet approximation, we have a new equation for the nucleation rate

$$J_{\text{SCT}} = \frac{\exp(\sigma s/k_B T)}{S} J, \quad (15)$$

where J is the rate calculated in the context of the classical nucleation theory according to Eqn (9). It can be seen that this equation differs from the classical one by the presence of the

coefficient e^{Θ}/S (here $\Theta = \sigma s/k_B T$ is the surface energy of the monomer). The remaining physical assumptions in SCT are identical to those used in the classical nucleation theory.

The basis for the Dillmann–Meier theory is the semiphenomenological droplet model of the cluster formation.⁸ In this case, the expression for the free energy includes such vapour parameters as virial coefficients, pressure and density at the critical point. The Dillmann–Meier theory takes into account all significant (in the author's opinion) contributions to the energy of cluster formation. The agreement between experimental results and data obtained in the context of the Dillmann–Meier theory was discussed in the studies.^{8,49}

Dillmann and Meier modified Fisher's expression⁵⁰ for the free energy of cluster formation by adding the coefficient k_n , which reflects the difference between the surface energies of the cluster and macroscopic liquid droplet

$$\Delta G = k_n \sigma s n^{2/3} + \tau k_B T \ln n - k_B T \ln q_0 V - n k_B T \ln S, \quad (16)$$

where k_n , τ and q_0 are parameters of the model and V is the volume of the system. The first term corresponds to the surface energy of the cluster and the last term takes into account relaxation of the metastable state. It should be noted that the authors did not discuss the question as to how the surface tension should be specified. The remaining two terms take into account the contributions of the translational, vibrational and rotational degrees of freedom to the free energy of the droplet. Unlike Lothe and Pound,^{36,37} who calculated these contributions from the Boltzmann distribution, the authors of the cited study introduced the parameters τ and q_0 normalised to the experimental values. The configurational contribution to the overall sum is small and, hence, it is ignored.

The expression for the coefficient k_n was proposed by Tolman⁴⁵

$$k_n = f\left(\frac{\delta}{r}\right),$$

where δ is the submolecular length, which is smaller than the radius of the monomer. Using the approximation of a spherical cluster, Dillmann and Meier⁸ expressed the dependence of k_n on the cluster radius as the first terms of the power series

$$k_n = 1 + \alpha_1 n^{-1/3} + \alpha_2 n^{-2/3}, \quad (17)$$

where

$$\alpha_1 = \frac{(k_2 - 1) - (k_1 - 1)2^{-2/3}}{2^{-1/3} - 2^{-2/3}}, \quad (18)$$

$$\alpha_2 = -\frac{(k_2 - 1) - (k_1 - 1)2^{-1/3}}{2^{-1/3} - 2^{-2/3}}. \quad (19)$$

These authors obtained the expressions for k_1 and k_2
first two derivatives of the density with respect to pressure

$$k_1 = -\frac{1}{\Theta} \ln \left(\frac{p_s}{q_0 k_B T} \right), \quad (20)$$

$$k_2 = -\frac{1}{2^{2/3} \Theta} \ln \left[-\left(\frac{p_s}{q_0 k_B T} \right)^2 2^{\tau-1} q_0 B \right], \quad (21)$$

where B is the second virial coefficient. The parameters τ and q_0

the state of the liquid
 ρ

$$c = q_0 \xi(\tau - 1), \quad (22)$$

$$p_c = q_0 k_B T_c \xi(\tau).$$

Here, ρ_c , p_c and T_c are the critical density, pressure, respectively, and ξ is the Riemann function.

The nucleation rate in the Dillmann–Meier theory is calculated by the equation:

$$J_{\text{DM}} = \frac{1}{3} \sqrt{\frac{\Theta}{\pi} \left[1 + \alpha_1 (n^*)^{-1/3} + \frac{9\tau}{2\Theta} (n^*) \right]^{-2/3} \frac{s_1 p_v}{\sqrt{2\pi m k_B T}}} \times \quad (23)$$

$$\times q_0 \exp[-k_n \Theta (n^*)^{-2/3} - \tau \ln n^* + n^* \ln S],$$

where p_v is the vapour partial pressure and m is the molecular mass.

The size of the critical nucleus (the number of atoms or molecules in this nucleus) n^* is determined by finding the real root of the cubic equation

$$\tau x^3 + \frac{1}{3} \alpha_1 \Theta x^2 + \frac{2}{3} \Theta x - \ln S = 0.$$

Here

$$x = (n^*)^{-1/3}, \quad \Theta = \frac{\sigma s_1}{k_B T}.$$

The Dillmann–Meier theory is consistent with the classical nucleation theory at $\tau = 0$, $q_0 = p/k_B T$ and $k_n = 1$. The contradictions in the Dillmann–Meier theory were discussed in the study,⁴⁹ where corrections for the imperfectness of a vapour were introduced. However, the calculations performed with consideration for these corrections resulted in even poorer agreement with experimental observations.

Frenkel⁶ introduced the concept of heterophase fluctuations in a vapour, which are small density fluctuations and do not disturb a particular aggregate state of the system. According to this concept, Frenkel assumed that the system is not quite homogeneous, *i.e.*, it contains prenuclei of a new phase already before the onset of the phase transformation.

The fluctuation mechanism of nucleation of a supersaturated vapour was developed in the publications.^{51–53} It was suggested that in small subsystems isolated from a large system, fluctuations could occur such that their density reaches the value corresponding to conditions of spinodal decomposition, *i.e.*, of activationless nucleation of the condensate. The conditions of spinodal decomposition were considered using nonane as an example. For this purpose, the Peng–Robinson equation of state (see references in the study⁵¹) was rearranged to give

$$P = \frac{RT}{v-b} - \frac{a_T}{v(v+b) + b(v-b)} - \frac{d(\sigma s/n)}{dv}, \quad (24)$$

where P is the pressure in the subsystem, v is the molar volume of the cluster consisting of n molecules, a_T is a temperature-dependent constant, b is a constant, s is the surface area of the fluctuating volume. In this case, the Gibbs potential takes the form

$$G = A + PV = A - v \left(\frac{dA}{dv} \right),$$

where A is the Helmholtz potential. The latter term in Eqn (24) describes the contribution of the bubble pressure within the microvolume.

A change in the Helmholtz potential due to a fluctuation of a small subsystem is described by the equation

$$\Delta A_s = v_s(P_s - P_p),$$

where the index s signifies the spinodal conditions and P_p is the pressure in the starting phase. Following the well-known Landau–Lifshits approximation, the frequency of cluster formation (J) was determined^{51–53} as the density fluctuation

$$J = \Omega \exp\left(-\frac{\delta n_0 \Delta A_s}{k_B T}\right) \exp\left(-\frac{t}{\tau}\right),$$

where Ω is the coefficient corresponding to the number of fluctuations in the starting phase in a unit volume in a unit time; $\Omega = \Omega_0(1 - T_r)^{3.57}$ ($\Omega_0 \approx 10^{23}$, $T_r = T/T_c$, T_c is the critical temperature); δn_0 is the fluctuation of the number of molecules in the cluster. The second exponent describes relaxation of fluctuation

$$\frac{t}{\tau} = \beta^{-1}(1 - T_r)^3,$$

where β^{-1} is the constant associated with the diffusion coefficient within the fluctuating bulk. As a result, the expression for the nucleation rate takes the form

$$J = \Omega_0(1 - T_r)^{3.57} \exp\left[-\alpha \frac{(1 - T_r)^5}{T^4} (\ln S)^{-3}\right] \times \quad (25)$$

$$\times \exp[-\beta(1 - T_r)^{-2}],$$

where α is a constant. It was assumed⁵¹ that the nucleation begins when the size of the cluster reaches a size larger than the size of the classical critical nucleus. For such clusters, the condition of equality of the surface and volume contributions to the Gibbs free energy is fulfilled. The pre-critical nucleus has a lower density. At the pre-critical nucleus–vapour interface, the pressure jump is absent. Finally, as applied to the Peng–Robinson equation of state, nucleation is considered as local spinodal decomposition to give the Ostwald nucleus and supersaturated mother phase. In this case, the nucleation rate (like in the classical nucleation theory) is described by the exponential equation but with a different pre-exponential factor at the logarithm of supersaturation. According to the classical nucleation theory [see Eqn (8)], the logarithm of the nucleation rate should be a linear function of the value reciprocal to the square of the logarithm of supersaturation. By contrast, according to Eqn (25), this value is inverse to the cube of the logarithm of supersaturation. However, the linear regressions of the experimental nucleation rates both as the functions $(\ln S)^{-3}$ and $(\ln S)^{-2}$ give equally good approximations.

It was noted⁵² that within the framework of the fluctuation model, the effect of the total pressure in the system on the nucleation rate, which is not predicted by the classical theory, can be attributed to compression of a nucleus under the action of a carrier gas. The limitation of the fluctuation model is that it assumes the independence of the density (or supersaturation) fluctuations. The fluctuation lifetime should be sufficient for spinodal decomposition giving rise to a pre-critical nucleus. At high temperatures and large supersaturations, the independence of fluctuations can be disrupted due to an increase in the coherence length. The above-considered approach has not been further developed, but can be mentioned as one of examples of possible theoretical models.

The theory of heteromolecular (binary) nucleation, as noted by Volmer,⁵⁴ began to be developed after the publication by Flood, who used the thermodynamic method, calculated the critical vapour supersaturation for aqueous-alcoholic mixtures and studied experimentally this supersaturation in a Wilson chamber. The experimental data were in qualitative agreement with the theoretical results. This theory was further elaborated in the investigation,⁵⁵ where the work of formation of two-component critical nuclei with different compositions and of different sizes was examined.

The solution of a differential equation describing the nucleation kinetics⁵⁶ made it possible to reveal the characteristic features of the free-energy surface of clusters as a function of the cluster composition, *viz.*, n_1 and n_2 , where n is the number of molecules of the corresponding component (1 or 2) in the cluster. The equation for the homogeneous nucleation rate in a binary system is analogous to Eqn (9) for one-component nucleation

$$J = C \exp\left(-\frac{\Delta G}{k_B T}\right), \quad (26)$$

where the pre-exponential coefficient C depends only slightly on the external conditions and ΔG is the energy of formation of a critical nucleus. For binary nucleation, the coefficient C was first determined by Reiss.⁵⁶ Stauffer⁵⁷ studied nucleation in an analogous system without considering the direction of nucleation in the bulk (like in the studies^{56,58,59}) and obtained a self-consistent expression for the growth angle.

A quantitative simulation of vapour nucleation in a binary water–ethanol system,⁶⁰ which was carried out as a continuation of the study,⁵⁶ made it possible to calculate the critical supersaturations and achieve good qualitative agreement with experimental data.¹⁸

The correct determination of a saddle point on the free-energy surface of clusters is of great importance for an adequate prediction of the binary nucleation rate. This point can be determined by solving two equations:

$$\left(\frac{\partial \Delta G}{\partial n_1}\right)_{n_2} = 0,$$

$$\left(\frac{\partial \Delta G}{\partial n_2}\right)_{n_1} = 0.$$

Generally, it is assumed that the cluster retains a homogeneous composition throughout the bulk. The equations include the derivatives of the surface tension

$$\left(\frac{\partial \Delta G}{\partial n_1}\right)_{n_2} = \mu_{1l} - \mu_{1v} + \frac{2\sigma v_1}{r^*} - \frac{3X^* v}{r^*} \frac{\partial \sigma}{\partial X} \Big|_{X=X^*} = 0, \quad (27)$$

$$\left(\frac{\partial \Delta G}{\partial n_2}\right)_{n_1} = \mu_{2l} - \mu_{2v} + \frac{2\sigma v_2}{r^*} - \frac{3v(1-X^*)}{r^*} \frac{\partial \sigma}{\partial X} \Big|_{X=X^*} = 0, \quad (28)$$

where μ_l and μ_v are the chemical potentials of the liquid and vapour phases, respectively; v_1 and v_2 are the partial molar volumes of components 1 and 2, respectively; $v = (1-x)v_1 + xv_2$ is the molar volume of the solution; $X = n_2/(n_1 + n_2)$.

However, it was demonstrated^{60–63} that the coordinates of the saddle point cannot precisely be determined using Eqns (27) and (28) because of the insufficiently correct description of the clusters. Various numerical methods have been proposed for calculating saddle points. In particular, it was postulated⁶⁴ that σ is constant at a particular composition of the nucleus. However, this assumption excludes, for example, the dependence of the excess energy on the cluster size and, hence, the coordinates of the saddle point cannot be accurately determined. An example of the practical use of these calculations is the study,⁶⁵ where the nucleation rate of a mixture of water and sulfuric-acid vapours was determined. More recently, analogous calculations were carried out at different supersaturations.⁶⁶

A two-channel mechanism of nucleation in a binary system was considered in the study.⁶⁷ Two-channel nucleation occurs, when two saddle points appear on the surface of the Gibbs free energy. The relative contributions of individual channels to the nucleation process were estimated by thermodynamic methods.⁶⁸ Binuclear nucleation of vapours as liquids with limited mutual solubility was investigated.^{69–71} Besides, binuclear nucleation of miscible liquids was also studied.⁷²

A mixture of a vapour and a carrier gas is a special case of a binary system. Nucleation of propane-1,2- and -1,3-diols in carbon dioxide and sulfur hexafluoride was studied.⁷³ A phase transition in the condensate was observed for each propane-diol–gas pair. An increase in the concentration (pressure) of the carrier gas was accompanied by a shift in the phase transition temperature toward the critical temperature of this gas. By changing the carrier gas (for example, from CO₂ to SF₆), the temperature of the phase transition in nuclei of the condensate can be changed by 15–20 °C. It should be noted that phase transitions

in equilibrium propane-1,2- and -1,3-diols do not occur in the temperature range in which the nucleation rates were measured. The appearance of phase transitions in the condensate upon the addition of a carrier gas is indicative of the involvement of its molecules in the formation of critical nuclei of the condensate. The composition of the nuclei was determined from the slopes of isotherms of the nucleation rate and it was found that they contained up to 20% of carrier-gas molecules.

Experimental and theoretical studies often do not take into account the fact that a carrier gas can act as a nucleating component (see, for example, Refs 74 and 75), and vapour nucleation in a gas atmosphere is considered in the approximation of a one-component vapour. In this case, the gas is considered as a medium providing thermostatic control of nucleation. This assumption, which has been accepted in early experimental studies of vapour nucleation, should be revised.

It was demonstrated⁷⁶ that two different methods of calculations of nucleation rates in heteromolecular systems in a stationary state, which have been proposed in the studies,^{57,77} are virtually equivalent. One method⁵⁷ is based on the classical theory of binary nucleation, whereas an alternative method⁷⁷ is based on the solution of the Fokker–Planck equation. Although calculation by these two methods gave the same binary nucleation rates, the latter are inconsistent with the experimental data.⁷⁵ Analysis⁷⁷ of different conclusions⁴³ of the classical theory of binary nucleation^{62,78,79} demonstrated that the methods under consideration give different estimates of the size and composition of critical nuclei. It should be noted that the solution of the Fokker–Planck equation requires the introduction of coefficients accounting for evaporation and accommodation of molecules in the cluster, and their uncertainty leads to a substantial decrease in the reliability of the results of calculations. The use of different values of these coefficients enables one to find numerical and sometimes even analytical solutions, which are nevertheless only of qualitative importance.

The parametric model considered in the study⁸⁰ was based on the equation reduced as applied to the nucleation rate of a one-component vapour (26) and the following assumptions were made: (1) the cluster grows (decreases) through condensation (evaporation) of monomers; (2) the probability of fixation of the molecule on the cluster surface upon collision is equal to unity; (3) clusters have a spherical shape; (4) interactions between clusters are absent. The authors of the cited study believed that incorrect results were obtained primarily because of the use of surface tensions measured for a planar interface. Hence, following Tolman,⁴⁵ the excess energy of clusters was calculated using expansion in a series

$$\sigma_{\text{micro}} = \sigma_0(1 + \alpha_\sigma n^{-1/3} + \alpha_\sigma^2 n^{-2/3} + \dots),$$

where σ_0 is the surface tension coefficient for the planar interface; $\alpha_\sigma = 2\delta/r_1$ is the so-called Tolman length (δ is the length of the order of the molecular size; r_1 is determined from the equation $r_n = r_1 n^{1/3}$, r_n is the radius of the cluster consisting of n monomers). The work of formation of the cluster was determined using Eqn (16) converted to the parametric form

$$\beta\Omega_n = \beta\sigma_{\text{micro}}sn^{2/3} + \tau \ln n - \ln q_0 V_c.$$

The parameters of this equation are as follows: $\beta = (k_B T)^{-1}$, $2.1 < \tau < 2.2$, $q_0 \sim \rho_c/5$, where ρ_c is the density at the critical point.

The equilibrium density (ρ_n) of clusters is calculated assuming the Boltzmann distribution

$$\rho_n = \frac{1}{V_c} \exp(-\beta\Omega_n),$$

where V_c is the volume of integration for the determination of the configuration integral for the cluster. The parameters are normalised by extrapolation to the critical point.

A comparison of the nucleation rates calculated within the framework of the classical and parametric theories demonstrated

that the difference is very small in the case of water. In the study,⁸⁰ the nucleation rate predicted by different theories was compared with the published experimental data for vapours of different compounds. It appeared that the use of the parametric model gave the best results.

In the study,⁸¹ the influence of an increase in the pressure of a carrier gas as a perturbing parameter was taken into account. The properties of the nucleating vapour vary depending on this parameter. The authors believed that this fact leads to reduction of binary nucleation to nucleation of a one-component vapour. The criterion characterising the perturbing action of the pressure of a carrier gas should meet the condition $x_g \ll (S - 1)/S$, where x_g is the solubility of the carrier gas in the liquid phase at supersaturation S . Another parameter was introduced to compensate the effects of a decrease in the surface tension and an increase in the saturating vapour density. This modification of the nucleation theory is consistent with the model proposed in the study⁸⁰ as well as with the density functional theory.⁸² Evidently, the introduction of additional parameters can lead to agreement between the theory and experiment. In the study,⁸³ multicomponent nucleation was described for a ternary system using a one-component model and introducing the effective parameters of the process.

Apparently, such approaches can be applied to the parametric description of practically important systems. However, these approaches seem to hold little promise from the viewpoint of the development of the theory because they have poor predictive ability even with respect to the model system under consideration. It is more correct to refer to this type of parametrisation as interpolation of experimental data. This parametrisation has no predictive potential outside the range of experimental characteristics parametrised and there is little likelihood that it will be correct even if only one family of nucleating systems is treated.

Below are considered models in which the intermolecular interaction potential is introduced in an explicit form, *i.e.*, through parameters determining the force interaction and geometric arrangement of molecules in the system. A simplified consideration of collective interactions can be, in particular, performed by introducing the dependence of the distribution function on a particular macroscopic parameter, for example, on the distribution density of molecules (density functional theory), which, in turn, includes the effect of collective interactions. The classical theory takes into consideration the fluctuation character of the exchange of substance between a nucleus and its environment. The number of molecules in the nucleus is a variable characterising the state of the system, all other parameters being equal to their average values.

In a number of studies (for example, in the study⁸⁴), the influence of the pressure of a carrier gas on vapour nucleation was considered. It was demonstrated that the gas can either accelerate or decelerate the nucleation frequency. This depends on the sign of the second virial coefficient. If a carrier gas is absent, the different degrees of freedom of the cluster and particles forming the cluster can correspond to different temperatures.^{85,86} This effect is observed in experiments with molecular beams expanding into vacuum. In experiments with a monosilane–argon mixture, nucleation was observed in a pulse supersonic jet.⁸⁷ In addition to clusters, mixed argon–silane complexes were detected for the first time and conditions for their formation in a flow were determined. The existence of mixed clusters is direct evidence for the involvement of the carrier gas in the nucleation of a new phase. The dependences of the concentrations of monomers and cluster ions on the stagnation pressure indicate that condensation in a flow at low stagnation pressure gives rise only to individual monosilane clusters, whereas condensation at high pressure affords monosilane–argon clusters. It is advantageous to analyse the nature of this phenomenon using phase diagrams of the system.

The determination of the nucleation rate by solving the one-dimensional Fokker–Planck equation for the probability density

of the size distribution of nuclei is justified if rather rapid relaxation of all degrees of freedom takes place in the cluster. The necessity of taking into account relaxations and, correspondingly, using the multidimensional Fokker–Planck equation appears only when the above-mentioned condition is violated. Admittedly, the classical theory, which has made it possible to solve the fundamental problem of the formation of a new phase in the first approximation, is characterised by a high degree of completeness and can serve as an example of a reasonable combination of the approximations and the minimum necessary complexity of the mathematical apparatus used. At the same time, it is evident that the classical nucleation theory should give way to a theory possessing an essentially different axiomatic basis, whose foundations are already being developed.

The density functional theory holds considerable promise.[‡] In this theory, only a part of collective interactions responsible for the attraction energy of molecules is taken into account in an explicit form. Short-range interactions are determined in the approximation of rigid spheres. This approach enables one to consider interactions between molecules in the pair-additive terms for which good approximations based on experimental data are available.

Oxtoby and co-workers^{88–91} considered the nucleation process using the density functional theory. Unlike Vlasov,³ who introduced the concept of a collective interaction from the very beginning (*i.e.*, he assumed that weak collective interactions between molecules lead to the existence of the system as an organic whole and cause a phase transition at particular parameters), Oxtoby believed that the presence of a gas–liquid interface is a manifestation of weak density inhomogeneity of the system. The profile of the equilibrium average density is determined from the condition of equality of the thermodynamic potential to zero. In this case, the expression for the free energy functional takes the form

$$\Omega_V(\rho) = \int \{f[\rho(r)] - \mu\rho(r)\}dr + \frac{1}{2} \iint \phi(|r - r_1|)\rho(r)\rho(r_1)drdr_1,$$

where f is the free energy of the unit volume of a liquid in the approximation of rigid spheres,⁸⁸ which was assumed to be known. Here, it is assumed that the potential of interactions can be represented as the sum of repulsion forces (in the approximation of rigid spheres) and attraction forces. This sum is denoted as ϕ . The functional derivative of this equation is an integral equation for the critical density profile.

In the study,⁸² the pre-exponential factor used in the equation for the nucleation rate is identical to that in the classical nucleation theory. At the same time, it was noted that it is improper to use the classical pre-exponential factors in other theories. The description of the dynamics of the first-order phase transition presented in the study⁹² is still of great interest.

The density functional theory was applied^{93,94} to the investigation of gas–liquid nucleation in binary mixtures consisting of Lennard-Jones atoms in the approximation of one-point (monomers), two-point (dimers) and three-point (trimers) rigid spheres. The temperature dependence of the nucleation rate calculated within the framework of this theory is similar to the corresponding experimental dependence. At the same time, the results of calculations are not always consistent with the data obtained by other methods, for example, by numerical simulation. Numerical simulation (based on the Lennard-Jones potentials) was carried out for homogeneous gas–liquid nucleation in a binary mixture⁹⁵ and the dependences of the size and composition of critical nuclei on the composition and supersaturation of a vapour were studied. Growing nuclei are characterised by bifurcation of the composition. In the case of non-ideal systems, components cease to be soluble and droplets enriched with a particular component

[‡] In 1998, W Kohn (Austria) was awarded the Nobel Prize in Chemistry for his development of the density functional theory.

appear. However, in studies using the density functional theory, the researchers did not reveal fractionation of phases within the critical nucleus.^{96–98}

The theory of molecular homogeneous nucleation in a vapour phase¹ includes a minimum number of assumptions and parameters. Preliminary calculations carried out for argon by the Monte Carlo method⁹⁸ demonstrated that the free energy varies within two orders of magnitude. The authors of the cited study believe that areas of application of this method to the description of real processes of homogeneous nucleation in a vapour will be extended as the method is improved. One can partially agree with this statement, because it seems plausible that a reasonable simplification of the model of a nucleating system will allow one to obtain results, which can be verified experimentally.

The average values of the main parameters of an equilibrium system are determined by the conditions of its contact with the environment. To describe the non-equilibrium state, it is necessary to introduce additional parameters characterising the deviation of this system from equilibrium. The number and character of additional parameters required for the determination of the non-equilibrium state depend on a particular model.

The irreversibility can be described by equations for random processes, for example, by the Fokker–Planck kinetic equation or the Langevin equation. It should be noted that the area of application of such equations can be narrowed under certain conditions. As an example, let us consider the kinetic equation, which, on the one hand, serves for the description of transitions between the states of the system and, on the other hand, was derived using methods of non-equilibrium statistical mechanics in the approximation of noninteracting particles.^{2,3} In the absence of memory effects, the time dependence of the probability $[p_n(t)]$ of the system occurring in the state n is determined by the frequency of its transitions (w_{nm}) from the state m

$$\frac{dp_n(t)}{dt} = \sum_m w_{nm} [p_m(t) - p_n(t)].$$

According to the principle of detailed equilibrium, the frequencies of direct transitions are equal to those of reverse transitions, *i.e.*, $w_{nm} = w_{mn}$. Taking into account the identical relation $\sum_n p_n(t) = 1$, we find the time derivative of entropy

$$\frac{dS(t)}{dt} = \frac{1}{2} k_B \sum_n \sum_m w_{nm} [p_m(t) - p_n(t)] [\ln p_m(t) - \ln p_n(t)] \geq 0.$$

Therefore, if the states, between which transitions are allowable, are equiprobable, *i.e.*, $p_n(t) = p_m(t)$, the process under consideration is an equilibrium. The deviation from the identity of the conditions of stationarity and equilibrium of the process (which follows from the above-given equations) can take place only if the principle of detailed equilibrium breaks down. Consequently, if this principle is fulfilled, the kinetic equation in stationary conditions is inapplicable to the description of irreversible processes, in particular, of nucleation. It should be noted that the description of processes of the appearance and growth of clusters in a non-equilibrium system presents problems related to the non-equilibrium thermodynamics and the kinetic theory of rarefied gases (see, for example, the review⁹⁹).

Roldugin¹⁶ described the nucleation process in the context of concepts of non-equilibrium thermodynamics and analysed the symmetry of the diffusion tensor in the generalised parameter space of the process. He hypothesised that in the case of, for example, a one-dimensional system, the nucleation rate should be several orders of magnitude lower than that predicted by the classical theory. It should be noted that these conclusions may be influenced by a popular error in overestimating the reliability of experimental data. The above-discussed inconsistency between experimental data obtained by different researchers could be explained quite prosaically taking into account that many important problems associated with experimental procedures for per-

forming nucleation remain to be solved. For example, there is a pressing need for the determination of an absolute error of experimental measurements.

In the classical kinetic theory of gases, collisions are taken into account only in short-range interactions. The question of whether it is possible to improve the description of long-range interactions in an ensemble of particles by successive inclusion of double, triple, quaternary, *etc.* collisions remains to be answered. Moreover, the kinetic equations include terms related to both the flow and collisions, which cannot be separated from each other.^{99–101} An approach was developed as applied to non-equilibrium processes in non-ideal gases. This approach allows one, in principle, to derive closed kinetic equations provided that the initial correlations between two, three, *etc.* particles are weakened. However, it appeared that collision integrals, which determine dissipative processes in kinetic equations, become divergent when interactions of four and larger numbers of particles are taken into account¹⁰² and only summation of the infinite number of multi-particle processes eliminates the divergence.

3. Use of the formal apparatus of quantum mechanics for the description of nucleation

First studies of nucleation at temperatures close to absolute zero using the formal apparatus of quantum mechanics were carried out as early as 1972.^{103,104} In these investigations, relaxation of a metastable state was associated with tunnelling of a nucleus of a new phase through a potential barrier in the configuration space. The nucleus passes through a series of local inhomogeneous states. In the phenomenological description of nucleation accepted in early studies, the problem of growth of a new phase was separated from the quasiclassical problem of the determination of a spectrum of cluster sizes. Later on, the quantum-mechanical description was proposed.¹⁰⁵ This approach includes quantum fluctuations, which lead to the tunnel transition of virtual clusters.

As an example, let us consider a brief scheme of quantum calculations of the nucleation rate.¹⁶ A change in the nucleus radius r in the potential

$$V(r) = 4\pi r^2 \sigma - \frac{2}{3} \frac{4\pi \sigma}{r}$$

can be described by the Schrödinger equation

$$\left[-\frac{\hbar^2}{2m} \nabla^2 + V(r) \right] \psi(r) = E \psi(r),$$

where $\psi(r)$ is the wavefunction and E is the set of energies of quantum states.

Assuming spherical symmetry, the variables of the wavefunction $\psi(r) = [Z_n(r)/r] Y(\theta, \varphi)$, where $Y(\theta, \varphi)$ is a spherical function, can be separated. Hence it follows that the motion equation can be deduced for $Z_n(r)$ in the potential

$$U(r) = V(r) + \frac{l(l+1)\hbar^2}{2mr^2},$$

where l is the quantum number of the angular moment. At $l \neq 0$, there is an additional barrier, which noticeably decreases the probability of nucleation. Hence, the main contribution to nucleation is provided at $l = 0$. The probability of tunnelling P_t is determined by the equation

$$P_t \propto \exp \left\{ -\frac{2}{\hbar} \int_0^{r^+} [2m(r) V(r)]^{1/2} dr \right\},$$

where $r^+ = (3/2)r^*$ (r^* is the radius of the critical nucleus) and $m(r)$ is the effective mass determined by the relation

$$m(r) = \frac{4\pi}{\rho_v} (\rho_l - \rho_v)^2 r^3,$$

where ρ_l and ρ_v are the liquid and vapour densities, respectively.

A somewhat different approach was used in the studies.^{106, 107} According to the corrections^{108, 109} to the Lifshits–Kagan theory,^{103, 105} clusters are considered to be spherical and consist of an incompressible liquid whose energy depends on the cluster size. It is assumed that the centre of gravity of the clusters is at rest, whereas the surface layer and vapour environment move. The authors of the cited studies^{106, 107} examined the possibility of tunnelling from all energy levels, except for the ground level.

To summarise, it should be noted that the quantum theory of nucleation is still being developed. However, this is the only theory, which may be useful for the interpretation of the results of experiments, for example, on binary nucleation in the ^3He – ^4He system at temperatures close to 10^{-3} K,¹¹⁰ from the quantum standpoint. The quantum-mechanical approach to the description of ion-induced nucleation was employed in the investigation,¹¹¹ where the nucleation rate of a water vapour on Na^+ ions was estimated. The results of this investigation are comparable with the results following from the classical nucleation theory. In particular, the free energy minima and the sizes of the corresponding clusters are identical to within experimental error. The free energy maxima are also virtually identical, but the size of the critical cluster evaluated by the classical theory is 20% larger.

A system of noninteracting particles can be considered with the use of conventional methods of statistical mechanics, where the Hamiltonian of the system is represented as a sum of the Hamiltonians of individual particles. The applicability of these methods is limited by the region, where the Boltzmann statistics is fulfilled. Systems consisting of many particles obey the Boltzmann statistics.⁸

In the classical nucleation theory, molecules of a metastable phase and the nuclei formed in this phase are also treated as a mixture of noninteracting particles. In the thermodynamic consideration, the frequency of collisions of molecules with the cluster consisting of n molecules is calculated in the ideal gas approximation, *i.e.*, without regard for their interactions. In the kinetic consideration, an analogous approach was used for determining the frequencies of transitions of nuclei from one size to another, *i.e.*, the dependence of these frequencies on interactions of a nucleus with other molecules and clusters of the mother phase are ignored.

Phenomenological theories describing states of solutions (for example, the theory of regular solutions), which employ equations for a particular average state of the system consisting of many particles, can be assigned to the same type of theories. Since these equations are, generally, empirical, it is more correct to refer to these theories as empirical theories. One of the simplest phenomenological theories of equilibrium phase transitions taking into account the co-operative effect is the van der Waals theory of condensation.¹⁰⁰ It should be noted that the Kac potential (as an effective potential) used in the study¹⁰⁰ is not a realistic value and the extension of the results thus obtained to real (in a physical sense) potentials is still an open problem. Certain progress in the use of the models under consideration is attributable not to the validity of their main concepts but to an appropriate choice of additional factors, which, in turn, allows one to consider these models as phenomenological.

III. Experimental methods for studying nucleation

Experimental studies of nucleation were carried out for various objects, *viz.*, from a mixture of the ^3He – ^4He isotopes at temperatures of several thousandths of Kelvin up to a plasma. Complex processes, such as the formation of solid-phase nuclei from cooled molten metal and metal boiling upon superheating, formation of exciton drops and cavitation, for example, in a screw propeller or

in the case of nuclear reactor accidents, *etc.*, were also investigated.

Experimental investigation of bulk nucleation is a complicated problem, because the parameters of the formation of a new phase rapidly vary with time and space, which substantially complicates their measurements. Hence, experimental publications on nucleation are scarcer than theoretical studies. Experiments on nucleation are hindered due to the lack of well-developed algorithms for the determination of parameters for many nucleating systems. Procedures for studying bubble frequencies in liquids and nucleation in a supersaturated vapour have been best elaborated. These methods can be extended to other systems.

1. Thermal effects of condensation

The non-isothermality of a real nucleation process is the subject of considerable attention. However, the classical theory assumes that nucleation is an isothermal process. In other words, a mixture of clusters and monomers is treated as if it were in a thermostat. In real systems, an inert gas, which is not condensed under the experimental conditions, plays a role of such a thermostat. The energy transfer occurs due to collisions of molecules of an inert gas with a vapour and clusters, and the final number of gas molecules as well as the final rate of this process are such that the system is transformed into the state in which the average temperature of clusters is higher than that of the vapour–gas mixture. This leads to a decrease in the efficiency of elementary events of the addition of vapour molecules to small clusters. According to an estimate made in the study,³⁹ the effect of non-isothermality should be manifested at nucleation rates higher than $10^2 \text{ cm}^{-3} \text{ s}^{-1}$. More recent data obtained by methods of non-equilibrium thermodynamics¹¹² demonstrated that the influence of non-isothermality should decrease as the vapour supersaturation is increased, *i.e.*, at high nucleation rates.

The thermal effects of condensation were considered in a series of studies by Kuni and co-workers.^{113–124} The data on a stationary flow and stationary distribution of near-critical droplets, their temperatures and characteristic sizes, rates of free-molecular and diffusion growth of overcritical droplets, the spectrum of their sizes and time of formation as well as information on the conditions of applicability of a macroscopic approach to the kinetics of condensation were surveyed in the study.¹¹³ The final step of non-isothermal condensation was discussed in the publication.¹¹⁴ Non-isothermal condensation at moderate concentrations of an inert gas was considered in the investigation.¹¹⁵ A two-dimensional description of the material and heat balance of particles of a nucleating liquid phase in a vapour–gas medium was published and the effect of the quasi-isolated state of a nucleus of a liquid phase under non-isothermal conditions was examined in the studies.^{116, 117} The two-dimensional Zeldovich–Frenkel equation in the kinetics of non-isothermal nucleation of a liquid phase was considered.¹¹⁸ Problems of thermal relaxation of particles of a nucleating liquid phase were discussed in the study.¹¹⁹ The effect of the temperature of particles of a liquid phase on the rate of non-isothermal nucleation and other effects associated with heat exchange were investigated in a series of studies.^{120–124}

The theoretical problem of thermal effects of condensation seems to be solved, but the predictions of the theory remain to be experimentally confirmed.

2. Nucleation in electrochemical processes

Let us consider an electrochemical process as an example of practical application of the nucleation theory.[¶]

A substrate plays a very important role in such processes. The effect of the substrate state on the nucleation kinetics was

§In this case, the motion of each particle in the field of surrounding particles is considered as a motion in the averaged field, which is independent of the local arrangement of the particles.

¶Problems of nucleation in electrochemical processes were surveyed in detail in the review.¹²⁵

studied.^{126–129} In particular, chemical interactions upon adsorption and the role of the real surface in crystallisation of a new phase were discussed in detail.¹²⁷ The concept of nucleation on active centres of the substrate surface, which have a high free energy, was developed.^{128,129} If the effect of shielding zones occurring around growing nuclei is ignored,¹³⁰ the activity distribution function of the centres can be determined based on experimental dependences of the number of nuclei on supersaturation.¹³¹

When describing the nucleation in electrochemical systems, it is generally assumed that

— in the presence of a double electric layer and electric charges on particles that arrive at the electrode surface, it is necessary to take into account the kinetics of charge transfer at the electrode;

— adsorption of water molecules, cations, anions and organic compounds on the electrode leads to a change in the work of nucleation and influences the discharge kinetics of ions;

— diffusion is of importance: the lower is the activation energy of surface diffusion and the stronger are the interactions of the adsorbed atoms with the substrate, the higher is the nucleation rate on the electrode surface.

The heterogeneous nucleation theory assumes that a liquid nucleus on the surface of a solid substrate has a shape of a spherical segment. A change in the energy of the system upon the formation of a liquid nucleus is proportional to the work of homogeneous nucleation

$$\Delta G_{\text{het}} = \Phi \Delta G_{\text{hom}},$$

where Φ is the shape factor, which depends on the wetting angle and is equal to the ratio between the volume of the spherical segment of the liquid phase on the substrate surface and the volume of the sphere of the same radius.

In this case, the supersaturation can be characterised by the overvoltage at the cathode η . The dependence of the stationary nucleation rate J_0 on the work of nucleation has the form

$$J_0 = D_c Z(1) \exp\left(-\frac{\Delta G}{RT}\right) = K_1 \exp\left(-\frac{K_2}{\eta^2}\right), \quad (29)$$

where D_c is the flow of atoms that add to the critical nucleus; $Z(1)$ is the concentration of individual atoms; K_1 and K_2 are constants. Equation (29) adequately describes experimental data within a narrow range of the overvoltage at the cathode.¹²⁵ This is not surprising because the use of the classical theory is most efficient for describing simple nucleation processes in electrochemical systems, *viz.*, vapour nucleation or cavitation.

The experimental results obtained within narrow ranges of supersaturation were discussed in the publications.^{126,132–137} Analysis of the data obtained within the framework of thermodynamic and atomistic models led to virtually the same conclusions. In the model representations used in the cited studies, interactions between the nuclei formed are ignored.

In broad overvoltage ranges, the step of charge transfer assumes great importance. Hence, it is necessary to take into account the kinetics of ion discharge.^{138–143} In this case, the $\ln J_0 - (1/\eta^2)$ or $\ln J_0 - \eta$ dependences are linear and the constant K_2 in Eqn (29) can be determined from their slopes. Experimental investigations of the nucleation kinetics within broad ranges of supersaturation present considerable problems. At high supersaturations, coalescence of nuclei giving rise to aggregates is highly probable. The surface curvature of nuclei influences the activation energies of both the cathodic and anodic processes.^{142–144} The expressions for the stationary nucleation rate are deduced based on the Becker and Döring kinetic method.²²

Nucleation requires an expenditure of work proportional to the electrochemical potential difference.^{126,132,135,140,145,146} This work characterises the deviation of the system from equilibrium (values with the subscript 0 belong to a stable state and the

corresponding values without the subscript belong to a metastable state)

$$\Delta \bar{\mu} = \bar{\mu} - \bar{\mu}_0 = zF(\psi - \psi_0) = zF(E - E_0) = zF\eta,$$

where $\bar{\mu}$ is the thermodynamic potential, z is the ion charge, F is the Faraday number and E is the electrode potential. The potential of a metal nucleus is equal to the electrode potential E . The nucleus formation requires an expenditure of work

$$\Delta G = \Phi \frac{16\pi\sigma^3 V^2}{3(zF\eta)^2} = \frac{1}{2} n_c zF\eta.$$

In this case, Eqn (6) takes the form

$$r_c = \frac{2\sigma V}{zF\eta}.$$

It is assumed that the nucleation energy is determined by the amount of metal atoms deposited on the electrode surface rather than by the electrochemical potential difference.^{138,139,147–150} This approach corresponds to the assumption that the ion discharge giving rise to adsorbed atoms is independent of nucleation in a medium of neutral atoms on the substrate surface.

In electrochemical nucleation processes, the nucleus formation proceeds most probably by the direct insertion mechanism.^{151,152} In the gas phase, heterogeneous nucleation through the direct insertion of atoms or molecules into a nucleus is highly improbable.¹⁵³ The concentration of surface atoms has an effect only on the pre-exponential coefficient in the equation for the rate of the process. The work of nucleation is determined by the cathode overvoltage.¹⁵⁴

It should be noted that the work of nucleation is generally treated¹⁴¹ as a continuous function of the number of atoms in the cluster n , although this function is actually discrete. It is assumed that the nucleus is in metastable equilibrium with the mother phase and has a size at which the probability of further growth is equal to the probability of dissolution. In the case of fluctuation formation, the maximum work corresponds to the critical nucleus. The nucleus size depends on the structure of the cluster and the interaction forces between the atom and substrate.

It was believed¹²⁵ that the changes in the surface energy and the kinetic factor can be ignored in the consideration of nucleation processes within narrow ranges of supersaturation. Hence, the number of molecules (atoms) in the critical nucleus can be determined from the slope of the experimental dependence of the nucleation rate on supersaturation according to the equation

$$n_c = RT \frac{d \ln J}{d \Delta \mu}.$$

This equation was first proposed in the study devoted to nucleation of supersaturated vapours. Below the deduction of this equation is considered in detail. It should be noted that this equation enables one to determine the critical nucleus size regardless of the nucleation model used as well as to find the dependence of this size on supersaturation $\Delta \mu$.

In the review,¹²⁵ it was stated that a decrease in the nucleation rate in an electrochemical process following the stationary region in a voltammogram is attributed to an exhaustive consumption of the active centres of the substrate, overlapping of shielding zones or coalescence of growing crystals. In the nucleation theory, it was assumed that in the case of electrodeposition, active centres of the substrate can appear during the action of a nucleation pulse, the rate of their formation being dependent on the degree of supersaturation. The nucleation kinetics in various systems can be studied experimentally, in particular, by determining the time of formation of the first nucleus. Methods for calculations of the space and time distributions of nucleation events upon electrodeposition, which have been developed in the studies,^{126,132,151,154} allow one to perform more detailed analysis of the mechanism of nucleation. The magnetic properties of electrodeposited amor-

phous Fe–Cr melts were investigated, for example, in the study.¹⁵⁵

Adsorption of surfactants has an effect on the work of nucleation and the critical size of nuclei due to changes in the surface energy at nucleus–electrolyte and nucleus–substrate interfaces accompanied by changes in the wetting angle and shape factor.^{156, 157} The effect of surfactants on the initial steps of electrocrystallisation is manifested in the redistribution of the rates of formation and growth of nuclei of a new phase due to blocking of active centres of the substrate and inhibition of ion discharge on the surface of growing crystallites. On the whole, the effect of surfactants on nucleation is poorly known. Experimental studies are generally aimed at solving applied problems. In these studies, the frequencies of nucleation of a new phase are, as a rule, not measured. Scarce data on the measured nucleation rates in the presence of surfactants cannot as yet be systematised. A more detailed discussion of this problem is beyond the scope of the present review.

The phase formation upon electrodeposition was studied by analysing the time dependences of the current under potentiostatic conditions. The theory of growth of two-dimensional layers and formation of three-dimensional crystals was developed in the investigations.^{151, 158} In the last decade, the structures of various electrode materials, primarily, of atomic- and molecular-modified single-crystalline electrodes and electrodes including isolated nanoparticles have been established with very high accuracy by high-precision X-ray diffraction methods. These data enable one to reveal the characteristic features of a nucleation process giving rise to a particular structure. Evidently, coalescence and agglomeration, which accompany nucleus growth in the solid phase, hinder calculations of the number of nuclei of a newly formed phase.

Much less progress has been made in studying the structures of electrodes acting as catalysts, which are characterised by a large specific surface and a broad size distribution of particles (or blocks). Examples of such systems are electrolytic deposits of platinum metals on polycrystalline substrates. The dependence of the activity of platinum and palladium electrolytic deposits on the deposition potential is one of the prominent manifestations of the so-called 'structural effects' in electrocatalysis.^{159, 160} Multilayer deposits, for example, of platinum metals on polycrystalline foils, are very complex systems characterised by a multi-level structural hierarchy. It is hardly probable that their structures could be established at the nanostructural level. However, it is of great interest to reveal factors responsible for the reproducible formation of nanostructural fragments and find reliable correlations between the macroscopic properties of materials and structural characteristics as the first step of such investigations.

Measurements of copper *K* X-ray radiation made it possible to observe co-deposition of copper and chloride ions from an electrolyte solution on the Au(111) surface. These results are indicative of a high degree of statistical disorder of molecules in the deposit, the Cu–Cl, Cu–Au and Cu–Cu bond lengths and the corresponding bond angles varying within narrow ranges. These data are very useful in simulating nucleation and subsequent film growth by molecular dynamics methods. Chronocoulometric measurements provided information on the film composition and the number of electrons crossing the interface per copper ion. Electrocrystallisation on dislocation-free faces of silver single crystals was studied experimentally.¹⁵¹ The formation of anodic films was investigated.¹⁶¹ The results of studies using mathematical simulation (see, for example, Refs 162 and 163) are consistent with the classical nucleation theory. A model of two-dimensional nucleation and subsequent three-dimensional crystal growth was proposed in the study.¹⁶⁴

However, the seemingly good situation, which is manifested in the agreement between the results of theoretical studies of electrochemical nucleation and experimental data, resembles a situation, which has been observed in the field of investigation of vapour nucleation, when high-precision data have been lacking. Begin-

ning in the 1980s, the necessity of developing a universal theory of vapour nucleation and a need for searching new ideas for the elaboration of this theory became evident because a rather large number of systems were studied and experimental data were obtained with a sufficiently high accuracy.

3. Nucleation in dense ion plasma

Atomic and molecular systems are traditionally studied by approximate methods based on expansion of a small parameter in a series (for example, virial expansions in statistical physics, the non-linear perturbation theory in non-equilibrium statistical mechanics, the perturbation theory in quantum mechanics, *etc.*). In the review,¹⁶⁵ it was emphasised that a small system follows the Gibbs distribution law provided that interactions with the environment are weak. Hence, the choice of such a system from a statistical ensemble should be the subject of the special consideration. There are different ways of isolating a small system from a macroscopic one.

It should be noted that the time it takes for the equilibrium to be established within a cluster is much shorter than the time interval between collisions of the cluster with gas particles. Hence, the cluster can be considered as an isolated system during a certain (short) period of time. The properties of the cluster as a small system influence the behaviour of the macrosystem as a whole. The thermodynamic properties of critical nuclei are responsible for the nucleation rate. A nonideal gas is considered as a mixture of clusters of different sizes, *viz.*, dimers, trimers, *etc.*

The description of clusters of charged particles in the region of a substantial deviation from the ideal state is hampered by the necessity of taking into account long-range Coulombic interactions. The collective effects are not weakened as the plasma density decreases. By contrast, this effect increases because the radius of the Debye shielding sphere increases. For ionic systems, the main results are obtained with the use of integral equations. A macrosystem is divided into clusters and the phase space of the system is divided into the corresponding regions. When estimating the equilibrium properties, the statistical integral reduces to the configuration integral over the coordinates of the molecules.

Nucleation in an ion plasma is associated with shielding of Coulombic interactions of ions in a liquid phase due to which the long-range Coulombic potential becomes an efficiently short-range potential. Investigations of the equilibrium properties of a model of charged spheres by the Monte Carlo method demonstrated that the shielding typical of a macrosystem is also observed in systems consisting of several tens of ions at the same temperatures as those in the macrosystem.

The fact that supersaturation cannot be attained in a cooled ionic system, *i.e.*, the fact that metastable thermodynamic states cannot occur, is associated with the absence of an energy barrier to the formation of microdroplets. The charge symmetry breaking in plasma causes a change in the nucleation mechanism. Of all possible orientations of triplets, only one type of orientation at which the symmetry axes of the triplets are mutually orthogonal leads to their mutual attraction. This result was obtained only by computer simulation.

The thermodynamic stability of a dense phase in ion plasma is determined by short-range attractions and medium-range repulsions between the molecules. Repulsions are changed to attractions as the temperature decreases. The formation of a stable dense phase is attributed to the appearance of a short-range orientational order. In a macroscopically homogeneous system, a short-range orientational order occurs at higher temperatures compared to those in a small system because surface particles in the former system are absent and the average number of the nearest neighbours in the former system is larger than that in the latter system. Mutual repulsions between ionic triplets can be interpreted as an additional internal pressure equilibrating the external pressure of the macrosystem. Hence, in the approximation of charged spheres microdroplets of a particular radius are formed at higher pressures and lower temperatures compared to

those in a neutral system. Due to a competition between Coulombic attraction and repulsion forces, emission of charged particles from the cluster can take place. The inhibition effect of microcondensation due to repulsions between ionic triplets is most pronounced in the case of microdroplets consisting of 10^2 – 10^3 ions. The mechanism of nucleation inhibition was studied by different methods, including numerical simulation by the Monte Carlo method, the lattice approximation and the approximation of physical groups.

4. Growth of critical nuclei in solid solutions

Coalescence in solid solutions is described using the Lifshits–Slezov theory,^{166,167} which considers a change in the size of a spherical nucleus with time. It is assumed that there are weak interactions between nuclei and the nucleus size is a small fraction of the average distance between these nuclei. Based on this theory, spinodal decomposition of a binary system upon coalescence in solid solutions was studied.¹⁶⁸

In the course of spinodal decomposition, it can happen that upon rapid removal of a system outside the spinodal, interactions between nuclei cannot be considered as weak. Using a nonlinear equation for the free energy of a two-component solution,¹⁶⁹ all steps of spinodal decomposition can be described. Nonlinear members of this equation take into account interactions between nuclei. The nonlinearity restricts the exponential growth of fluctuations in the region of thermodynamic instability and gives rise to the coalescence effect.

In the study,¹⁶⁸ a truncated equation for spinodal decomposition was used for estimating a change in the nucleus size in the ordered structure formed. The equation describing a change in the wavenumber as a characteristic of the structure was deduced using asymptotic methods. In the long-time limit, rather simple relationships were obtained, whose form depends on the size of the decomposition region d ($d = 1$ corresponds to coherent platelet-like structures, $d = 2$ corresponds to cylindrical structures and $d = 3$ corresponds to nearly spherical three-dimensional structures).

Upon nucleation and nucleus evolution of a new phase on solid substrate surfaces in closed multicomponent and multiphase systems, film formation proceeds through several steps.¹⁷⁰ First, dispersed particles appear on the substrate surface (generally, on its defects). Then the substance is redistributed between these particles. Evolution of ensembles of dispersed particles is accompanied by latent heat release and an increase in the temperature of the system. One mode of redistribution of the substance between dispersed particles involves coalescence.¹⁷¹ Due to a decrease in the free energy upon interface reduction, the average particle size increases as a result of mass transfer from smaller to larger particles.

Interactions between dispersed particles upon crystallisation of one-component melts associated with the occurrence of a heat field is called ‘heat coalescence’.^{172,173} A consideration of the evolution processes occurring in multicomponent closed dispersed systems in the general form demonstrated that in the asymptotic limit, the concentrations of components and the equilibrium temperature on the particle surface are independent of the nature of the particles. The distribution functions of phases depend only on the heat and mass transfer. The types of phases formed are determined by the ratios between the amounts of compounds dissolved, temperature and rate constants of chemical reactions. The time dependence of the size distribution function of new phases was found.

Investigations of evolution processes in ensembles of multicomponent and multiphase dispersed particles were continued in the study.¹⁷⁴ The phase formation in closed systems has also been examined.¹⁷⁵ Real systems are open, and the heat and mass transfer can take place in such systems. Dispersed particles on a substrate, the generalised field of adsorbed atoms and mass and heat flows interact with each other.

The effect of heat, which is evolved in chemical reactions proceeding under adiabatic conditions, on the dynamics of decomposition and crystallisation of multicomponent multiphase solid solutions and melts was examined.¹⁷⁶ The final step of decomposition and crystallisation of solutions involves coalescence accompanied by heat evolution. Under adiabatic conditions, the temperature of the system increases and the equilibrium concentrations of the components change. As a result, some phases decompose. It should be noted that the phase co-existence regions differ from analogous regions occurring upon isothermal decomposition. The condensed phase grows as a result of two concerted processes, *viz.*, diffusion and heat exchange. The system of equations proposed in the study¹⁷⁶ describes evolution of phase isolation in the step of coalescence in an N -component solid solution, where both the temperature and composition fluctuations can be ignored. This system consists of K continuity equations, N equations of the law of conservation of matter, $(N - K)$ stoichiometric relations for flows, K equations of the law of mass action, the heat balance equations and an equation relating the characteristic size of the phase deposited to the matter flow. The dependence of the equilibrium constants of chemical reactions on the temperature and sizes of the phases being deposited was taken into account and an additional equation for the rate of their growth was introduced. The asymptotic solution of the above-mentioned system of equations allows one to determine the boundaries of the co-existence regions of all possible K phases in the space of the initial amounts of components and temperature. The authors of the publications^{174–176} believed that their results can be considered as laws, which can enable one to control evolution of ensembles of multicomponent dispersed particles in the course of the growing of films with desired structures and compositions.

5. Boiling of stretched liquids

An adequate theoretical description of the boiling process of the so-called stretched (superheated) liquids based on high-precision experimental studies was published in the studies.^{177–179} Phase transitions in systems occurring in the vicinity of the boundary of thermodynamic stability (the so-called spinodal) were analysed in the review.¹⁸⁰ These transitions of the critical type are characterised by a strong space–time correlation of perturbations and a high degree of fluctuations. In the case of rapid liquid–vapour phase transitions, one or both co-existing phases are outside the region of stable states.

Spinodal decomposition is a special case of the initial step of a phase transition whose occurrence requires that the system be initially transformed into a labile state. The system relaxation is accompanied by an increase in the number of random inhomogeneities, which may give rise to modulated relaxation structures. Propagation of small perturbations is characteristic of a system occurring in an unstable state, whereas perturbations dissipate in the case of stable states.

At high supersaturations, metastable states occur at the boundary of the region of absolute instability. In rapid processes, a labile state can occur along with a metastable stable; the compound rapidly loses the spatial homogeneity and acquires a cellular granular structure. Unlike the phase transition from a metastable state, spinodal decomposition does not require activation. Nuclei of a new phase appear if a stable surface layer is formed. In this case, certain portions of the system can be located in a metastable region. If the stability condition is violated, a stable layer between two phases cannot occur. As the spinodal is approached, the mechanism of phase transition changes. Spinodal decomposition and nucleation are the initial and final steps of a continuous process of instability propagation.

In a one-component system, the rate of spinodal decomposition is limited by heat exchange between the contracting and expanding volume units.¹⁸¹ The time of formation of an unstable state should be shorter than the characteristic time of spinodal decomposition.

In multicomponent systems, the region of unstable homogeneous states is limited by the critical liquid–vapour conditions. The diffusion instability is characterised by the negative diffusion coefficient (ascending diffusion). In the case of two-component systems, diffusion instability is preceded by mechanical instability.¹⁸² The diffusion mass transfer is determined by the chemical potential gradient. In the case of stable states, the approach to the stability boundary is characterised by deceleration of the diffusion transfer (the diffusion coefficient D tends to zero). For unstable states, $D < 0$.

The phenomenological theory of spinodal decomposition was first presented in the study.¹⁶⁹ The use of the Fourier representation for analysis of the stability of a two-component isotropic solution made it possible to determine the critical wavenumber k_c and the critical wavelength $\lambda_c = 2\pi/k_c$. Within a spinodal, the solution is unstable with respect to relatively small fluctuations in composition with the wavelengths $\lambda > \lambda_c$. The plot of the amplification coefficient R , which characterises a change in the amplitude of the concentration wave, vs. the wavenumber k has a sharp maximum at

$$k = k_m = \frac{k_c}{\sqrt{2}}.$$

This indicates that all concentration waves, except for those characterised by the wavenumber k_m , can be ignored within a time interval after the onset of decomposition. At $k < k_c$ [$R(k) > 0$], the concentration waves are exponentially amplified. At $k > k_c$, these waves are exponentially attenuated [$R(k) < 0$]. The Cahn theory¹⁶⁹ is based on the self-consistent field theory. In the vicinity of a spinodal, there are strong interactions between fluctuations due to which the concept of the free energy may appear to be inapplicable. The usual linearised equation for diffusion is valid only in the initial steps of decomposition, when deviations of the composition from the average value are small.

The Cahn theory was further elaborated by Cook,¹⁸³ who considered thermal fluctuations in composition. This made it possible to explain the fact that the experimental critical wavevector k'_c is larger than the theoretically predicted wavevector k_c .

The work of formation of a near-critical bubble plays an important role in phase transitions to which decomposition of a gas-supersaturated solution belongs.¹⁸⁴ Under isothermal conditions, which occur at high thermal conductivity of a solution, two variables are required for the description of a nucleus of a stable phase. The work of formation of a near-critical bubble was approximated by the equation

$$F = F^* - x^2 + y^2,$$

where F^* is the work of formation of a critical bubble; $x = (V - V^*)/\Delta V^*$; $y = (P - P^*)/\Delta P^*$; V^* and P^* are the volume of the critical bubble and the pressure in this bubble, respectively.

The work of bubble formation includes the squares of variables with opposite signs. Hence, the activation barrier F has a saddle. The variable x is unstable (therefore, the bubble volume can increase infinitely), whereas the variable y is stable. On going from the variables x and y to variables characterising the bubble state, which are specified by the number of molecules in the bubble v and a series of critical parameters, the bilinear approximation is retained.

The intensity of the phase transfer is proportional to the normalising coefficient C corresponding to the equilibrium distribution of the clusters. After integration of a two-dimensional equilibrium distribution with respect to the stable variable v , we obtain a one-dimensional distribution of bubbles over this variable

$$g_c(v) = \frac{C\pi^{1/3}}{\Delta v_c} \exp[-F(v)],$$

where $F(v) = F_c - (v - v_c)^2/(\Delta v_c)^2$. The correction ΔF for the work of accommodation of a gas molecule was found thermody-

namically, which made it possible to refine the normalising coefficient

$$C = \frac{P_c[2v_c(1 - \varepsilon^2)]^{1/2}}{\pi^{1/2}\varepsilon k_B T},$$

where $\varepsilon = [2\sigma/(3r^*p^*)]^{1/2}$ (r^* is the radius of the critical bubble).

The normalising coefficient in the thermodynamic equation was refined in the study.¹⁸⁵

The above-considered theory can be applied to solutions supersaturated by an increase in their concentration by gas pumping or a decrease in the concentration upon a change in the temperature or pressure. The rate of formation of a metastable state in a gas-supersaturated solution influences all variables describing solution decomposition.¹⁸⁶ Conditions were found for attaining the maximum intensity of the formation of overcritical gas bubbles and supersaturation of a solution, and all characteristics of solution decomposition at this instant were studied. The size spectrum of overcritical bubbles in the stage of their formation was determined.

The work of formation of a critical bubble is a function of solution supersaturation. The metastability of a solution is described by the law of increase in ideal supersaturation with time, the time being measured from the instant when the ideal supersaturation is equal to zero. The coordinate z of the maximum of the overcritical bubble distribution over the excess free energy increases with time at a rate dependent on the supersaturation, temperature and some other parameters of the solution. The variable x , which is the deviation of the coordinate z from the size of the overcritical bubble, is introduced to characterise the size spectrum of overcritical bubbles $f(x)$. Throughout the growth process, each overcritical bubble is characterised by its own value of x . At $x = 0$, the spectrum $f(x)$ has a maximum. The material balance equation for a solution includes the function g corresponding to the difference between the ideal and real supersaturations. The dependence $g(x)$ and the related spectrum $f(x)$ are found by an iteration method.

Most researchers reasoned that the classical nucleation theory adequately describes experimental data on the frequency of formation of gas nuclei upon liquid boiling. Presumably, this is associated with rather large sizes of critical nuclei, although this assumption is evidently unjustified in the case of spinodal decomposition.

Skiprov and co-workers^{177–179} have achieved much success in experimental investigations on boiling of stretched (superheated) liquids. Since the elementary event of bubble formation can be observed experimentally, it is possible to demonstrate that the nucleation process is accidental. Thus, the expectation time cannot be predicted, and only the time of the elementary event of formation of the first bubble can be estimated at the probability level. Experimental studies showed that the expectation time is determined by the distribution of random values.

It should be noted that nucleation rates in any system are only certain average values. To determine these rates, it is necessary to carry out a statistically sufficient number of individual tests, like in studies of stretched liquids and investigations of the boiling of superheated metallic wires. Another way is to observe the appearance of numerous nuclei of a new phase. Apparently, the latter approach allows one to reduce the experimental time. Generally, researchers, who use this approach, do not measure elementary nucleation events and observe only average values. In the case of an insufficient number of parallel nucleation events, fluctuations of nucleation events can be observed. To obtain reliable average values, it is generally necessary to increase the time of observation. In the case of a statistically sufficient number of measurements (with the variance in average values of $\sim 1\%$) and a rather high relaxation rate, the experiment can be quasistationary, *i.e.*, one of the parameters of the system can slowly (compared to the relaxation rate of the system) change. In this case, one can obtain

more experimental data than in the case of accumulation of the results of individual tests.

One of the main schemes used in experimental investigations of boiling of stretched liquids (in particular, of the cavitation phenomenon) involves stretching of a column of a temperature-controlled liquid by relieving pressure. Several tens of experiments are already sufficient for the determination of the average expectation time for the breaking (boiling) of a liquid (the value inverse to the expectation time normalised to the volume unit is the nucleation rate). Hence, it is necessary to carry out several hundreds of tests of the system to obtain 10–20 points for the construction of one isotherm.

In an alternative scheme, a metastable state is achieved by superheating, which is provided by passing an electric current through a conductor. This scheme allows one to attain high degrees of superheating when heterogeneous boiling centres no longer play an essential role. This way of performing experiments allows the use of electronic means of automation and control. If relaxation of a system is achieved in a short period of time, a statistically reliable data set can be collected in an automatic mode rather rapidly. For example, the bubble formation in liquid nitrogen on a conducting film surface was studied,¹⁸⁷ and the kinetics of bubble formation in glassy methyl methacrylate and polycarbonate containing dissolved carbon dioxide was investigated.¹⁸⁸ In the latter case, the bubbling was monitored using a light beam. The light-transmission factor served as a quantitative measure of the concentration of pores formed in the polymers. Pressure jumps and surface tension at the boundary of critical bubbles at different temperatures and concentrations of dissolved CO₂ were determined. In some cases, these values corresponded to parameters typical of homogeneous nucleation, otherwise they corresponded to those of heterogeneous nucleation. It should be noted that it is possible to carry out a more detailed interpretation of results. For this purpose, one should use phase diagrams of a polymer–gas system, because some characteristic features of nucleation rate surfaces may be associated with the characteristic features of phase equilibrium diagrams of the systems under study. Nevertheless, the conclusion that the nucleation properties of a polymer–gas solid solution vary with saturation with gas is beyond question. This result confirms the generality of the concept (which was considered using vapours as an example) that the nucleation rate depends on the total pressure in a medium.

The bubble nucleation can also be studied using a two-piston chamber.¹⁸⁹ A constant negative pressure pulse is applied to a liquid sample during several milliseconds after which stretching is decreased by 10%–20%. As a result, the formation of new nuclei ceases and the bubbles grow to sizes, which can be observed by an optical method. The advantage of this scheme is that several bubbles can be formed simultaneously, which allows one to obtain abundant data in a single experiment, thus accelerating measurements of elementary events of bubble formation a hundred times.

In a study of the boiling of polymers,¹⁹⁰ the thermal stability of a polymeric liquid was estimated using a controlled pulse heating technique. The average lifetime of the polymeric liquid before its boiling was determined from a temperature plateau in a thermogram of the process. A correlation was found between the thermal stability and the slope of the plot of the average lifetime of superheated liquids *vs.* the temperature. A distinct relationship between the average time of bubble nucleation and the total pressure was revealed.

Cavitation in binary systems has long attracted the attention of researchers. The kinetics of phase transitions in binary solutions of several systems based on hydrocarbons and water was examined¹⁹¹ in the vicinity of critical stratification points. The stratification was detected by photomicrography. Corrections for the equations describing the growth of a new phase volume were found. It was demonstrated that at the late step of the process, the dependence of the reduced average radii of the droplets of a new phase on the reduced time is described by an exponential equation with the exponent of 0.81.

Achievements in the field of research of liquid boiling under the action of a current pulse have not gained wide acceptance. Some researchers concerned, for example, with the boiling of metallic wires, did not employ the concepts of the nucleation theory at all. For instance, in the study¹⁹² devoted to the dynamics of microplasticity of whisker single crystals under the action of a current pulse, the nucleation of dislocations in single crystals and their propagation were investigated. However, the experimentally observed incubation period determined by the plasticity delay time of the initially dislocation-free silicon whisker crystal¹⁹² is nothing else as the expectation time for nucleation of dislocations. The nucleation of dislocations is a nucleation process involving all inherent metastable states and accident events. The delay time should be a random value and be characterised by the distribution, which was not discussed in the cited study. The evident drawback of this study is that the authors did not use the formal apparatus of the nucleation theory, which could substantially change the direction of investigation and interpretation of the results.

To summarise, it should be noted that the methods for studying nucleation in vapours and cavitation in liquids have gained most acceptance. However, these methods are not rigorously justified and need a thorough validation of the assumptions used for the interpretation of experimental data. Thus, in spite of a rather reliable verification of the dependence of the vapour nucleation rates on the total pressure in a nucleating system (see, for example, Refs 73 and 81), some researchers traditionally, like a quarter of a century ago, reject the effect of gas pressure as such.¹⁹³ These researchers use a variable pressure in a two-piston chamber to maintain both the nucleation temperature and initial composition of the vapour–gas mixture constant. Undoubtedly, this makes experimental studies with adiabatic cooling easier, but leads to an error associated with the dependence of the nucleation rate on the total pressure in the nucleating system. In other words, experiments are carried out under isothermal conditions but at a variable total pressure. For the results to be interpreted correctly, the experimental data are necessary to recalculate as applied to the constancy of the total pressure. For example, such a procedure should be carried out in calculations of the compositions of critical nuclei from the slopes of nucleation isotherms. In the investigation,¹⁹³ one variable in the parameter space was ignored and, in actuality, a particular section from different subspaces was measured without an adequate description of the trajectory in this space.

The nucleation, for example, of a binary vapour can be described in a five-dimensional space including the nucleation rate, the composition of the initial vapour, the composition of the nuclei of the condensate, the total pressure in the system and the nucleation temperature. It should be noted that the level of description of the experimental processes is not sufficiently high to give an estimate of the changes in the state of a nucleating system in the above-mentioned space. Different trajectories in this space give different projections onto subspaces, which is one of the factors responsible for the disagreement in the results obtained by different methods. The common aim of researchers is to develop experimental techniques for obtaining more precise and reliable data in the well-determined conditions of nucleation.

6. Nucleation in condensed phases

Nucleation in condensed phases assumes the existence of transformations from one condensed phase to another. Experiments on crystallisation of supercooled liquids were surveyed in the review.¹⁹⁴ The rate of crystalline phase formation was estimated using the maximum supercooling with respect to the temperature of the equilibrium melting–crystallisation process. The nucleation begins to proceed at a substantial rate once a sufficiently high supersaturation is attained. Generally, the supercooling limit is determined by the rate of heterogeneous nucleation on the walls, the presence of a liquid surface and heterogeneous nuclei in this surface, *etc.*, rather than by a homogeneous process. In emulsions and on substrates, the liquid breaks into droplets. To weaken

interactions, droplets are coated with surfactants or salt melts. When droplets are rather large, many of them do not contain heterogeneous nuclei. The supercooling maximum is generally taken as a homogeneous limit. Container-free methods of investigations are of considerable interest. In the falling drop method, a molten drop falls in a tube, which is filled with an inert gas (or evacuated) and whose walls are cooled. By hanging a drop in an electromagnetic field, one can more easily control the phase state of a sample. In this case, observations can be more prolonged and measurements are more accurate. In the case of metals, the maximum supercooling is $\sim 20\%$ of the melting point.

In the study,¹⁸⁵ homogeneous nucleation was treated as a heterogeneous process in which individual molecules serve as nuclei. This approach enables one to introduce a correction in the equation for the work of nucleation under different conditions.^{195–197} The type of the correction is determined by the presence or absence of a thermal equilibrium between the nucleus and the medium. The work of nucleation depends on the external conditions of the nucleation process. The equation was derived for the work of nucleation upon homogeneous nucleation in the absence of an equilibrium between the nucleus and the medium in the case of an isentropic isochoric process. Under other conditions, this work can be evaluated by removing the corresponding terms from the equation for the potential of a critical nucleus. In the case of a complete equilibrium between the nucleus and the medium, the results correspond to the classical theory. The Gibbs equation describing the work of nucleation in the case of a heterogeneous process includes the work of wetting. To determine the work of wetting, one should consider an ensemble of macroscopic nuclei, which are in equilibrium between the mother and new phases. Each nucleus is considered as a dispersed particle and its chemical potential is taken into account.¹⁹⁸

Studies of glass relaxation are of great technological and scientific interest. Here the question arises as to the existence of the limit of liquid supercooling.¹⁴ Liquid supercooling gives rise to an increase in viscosity, the possible spinodal transformation of the liquid to a crystalline state being 'diffused'. At the same time, it is common practice to treat a glass as a liquid occurring in a metastable state, which is reasonable to regard as one of the states of the supercooled liquid. In any case, investigations of glass relaxation rates provide a unique possibility to answer the above question. The maximum glass relaxation rate is observed at low temperatures. Samples are kept at a low temperature until nucleation of crystals starts and then the samples are annealed at higher temperatures. In this process, the rate of formation of new nuclei is low, whereas the rate of cluster growth is much higher compared to those under the conditions of nucleation. The clusters grow to sizes such that their amount can be measured by simple methods. In metallic glasses, nucleation and nucleus growth are often not separated. Investigations of metallic glasses did not provide new information compared to that obtained in studies of well-known silicate glasses. In studies of a series of metallic glasses, including Zr–Ti–transition metal, Al–Fe, Ni–rare-earth metal and Fe–Si–B systems, anomalously high nucleation rates (which sometimes approach $10^{17} \text{ cm}^{-3} \text{ s}^{-1}$) were observed.^{199–202}

Investigations of nucleation in condensed phases are of importance for both fundamental knowledge and the solution of applied problems. Tauer and Padtberg²⁰³ devised a system for computer collection of data on conductivity and haziness (transmission of light) of aqueous solutions. The authors of the cited study believed that this system is a universal tool for investigating nucleation in such systems. The onset of nucleation in solutions is determined from the discontinuity of the first derivative of the conductivity and the appearance of a bend in the curve of the transmitted light intensity vs. the composition. These experiments closely resemble the initial stage of investigation of aerosol nucleation, in which aerosol was observed, whereas the nucleation rate has not been measured. Emulsion polymerisation was studied in a similar way.²⁰³

Nucleation in chemically reacting systems is of great interest. The theory of this process was developed within the framework of classical notions of nucleation as early as the 1980s. The effect of surfactants on nucleation was simulated in the study.²⁰⁴ It was demonstrated that due to the presence of surfactants, clusters can occur before the onset of phase transition. The addition of surfactants is equivalent to an increase in the deviation from the equilibrium state because the term proportional to the concentrations of the introduced compounds is added to the equation for the thermodynamic potential. The energy of cluster formation passes through a minimum, which provides the occurrence of metastable states. Due to anisotropy of the surface energy, the adsorption pressure is different on different crystal faces and the latter grow at different rates. This fact can account for the formation of dendrites in the presence of surfactants.

Recently, a general model was proposed for nucleation in chemically reacting systems.²⁰⁵ This model is based on the Becker–Döring kinetic scheme²² according to which clusters grow and decompose due to one-step aggregation and fragmentation processes. The model takes into account the catalytic effect of the already formed clusters on the rate of appearance of other clusters. The role of precursors (or specific reagents), which spontaneously decompose to form relaxing metastable states, and inhibitors, which hinder the cluster growth to sizes larger than a particular value, was discussed. The model includes several key equations describing the experimentally observed macroscopic behaviour of a system. Based on these equations, the most important components of the reacting system can be revealed and the steps of the process dependent on the rate can be determined. One of the versions of this model was used for the description of cement hydration. The problem was solved in the asymptotic mode. The results of calculations were consistent with the experimental data.

In the scientific literature, the problem of spontaneous formation and the existence of dimers in a nucleating system is actively discussed. In the theoretical investigation of the drop growth in a medium of an inert gas containing monomers and dimers of the agent condensed,²⁰⁶ analytical equations were proposed for estimating the effect of dimerisation of vapour molecules on the rate of growth in an isothermal approximation. The growth of cesium drops in a helium atmosphere was calculated as an example. At high supersaturations, the rate of drop growth increases substantially due to formation of dimers.

The kinetic molecular mechanism of the onset of snowballing condensation from a supersaturated vapour with a high concentration of dimers was described in the general form.²⁰⁷ The possibility of cluster growth due to the presence of dimers was taken into account. The enthalpy effects were taken into consideration by fitting the parameters of the model to the experimental values. This model can be used for calculating the total entropy of the clusters. At high pressures, the rate constants of condensation are corrected for the restriction of diffusion of monomers and dimers involved in the growth process. The description of the nucleation process in the density functional approximation was extended to condensation in an associated liquid. The theory of associated liquids in a system of spherical molecules with one associated bond was used for this purpose. Calculations demonstrated that the use of the classical nucleation theory led to a substantial overestimation of the activation barrier to nucleation in these systems. This deviation can be to a large degree compensated using the model proposed in the study.²⁰⁸

The investigation of nucleation in a benzene vapour giving rise to dimers in the temperature range of 15–123 K is of obvious interest.²⁰⁹ For the range of 15–88 K, the coefficient of the rate of dimer formation was calculated. The formation of benzene dimers was proved by studying the reactions of hydrocarbons with C_6H_6 and analysing the optical spectra of the products. Model calculations showed that the systematic error of measurements is low. The coefficients of the dimerisation rate calculated on the assumption of free rotation of dimers are in good agreement

with the experimental values for the temperatures above 30 K at which decomposition effects should be small.

Agglomeration of nanosols can be considered as a model of a phase transition without long-range interactions. The activation energy of restructurisation of agglomerates from nanoaerosols was determined *in situ*.²¹⁰ In experiments with agglomerates of silver and copper nanoparticles, the height of the activation barrier to the rearrangement of particles in the agglomerate was determined. Agglomerates are formed due to collisions of several tens of the initial nanoparticles. The structures of the agglomerates can be described by the exponential law relating the number of the initial nanoparticles to the radius of the agglomerate. The exponent including the radius is generally referred to as the fractal dimensionality. This exponent is determined from electron microscopic images.

Interactions between nanoparticles can be of a different nature from van der Waals forces to ionic or covalent bonds. Agglomeration in which strong bonds are formed gives rise to rigid (generally, porous) structures. Agglomeration characterised by weak bonds affords clusters with more compact structures, the number of nanoparticles involved in the clusters being increased. The temperature dependence of the restructuring rate is described by the Arrhenius equation whose exponent includes the activation energy of the process. The pre-exponential factor has the dimensionality of frequency. To estimate the bond energy of nanoparticles in an agglomerate, it is necessary to know how the coordination number of the nanoparticles changes with time and to determine the fractal dimensionality at a particular instant of time. The initial particles interact only with the adjacent closely located particles. The activation energy of this process is an order of magnitude lower than the bond energy calculated with the use of the Hamaker constant,²¹⁰ for example, for silver and copper. In the range of the nanosol sizes under study, the energy of activation for silver is similar to that for copper. The maximum activation energy corresponds to the particles with a diameter of ~ 18 nm. This energy decreases as agglomerates grow. The addition of oxygen before the onset of agglomeration of the initial nanoparticles leads to a twofold increase in the activation energy, the maximum energy corresponding to the particles with a diameter of 15 nm.

In the review,²¹¹ it was mentioned that the development of theories of solid-state nucleation allowing for the thermodynamic aspects of nucleation and cluster growth is presently underway. To detect nuclei and determine their phase states, Rayleigh scattering of Mössbauer radiation and Mössbauer spectroscopy are used. Diffusion of clusters in pores is investigated using the microprobe method. Generally, studies are accompanied by investigations of the catalytic activity of clusters.

7. Photonucleation

Based on the results of the investigation of photonucleation,[†] a new procedure was developed for the determination of ultralow concentrations of molecules.^{212,213} The high level of analytical sensitivity is attained by exciting molecules with UV radiation. Upon vapour supersaturation, particles of photonucleation products (radicals, ions, *etc.*) grow to sizes, which can be easily detected by simple methods. Due to high spectral sensitivity of photo-detection, the desired compound can be selectively excited and detected. For example, resonant excitation made it possible to detect nitrotoluene vapours at such a low concentration that their pressure is 50 000 times lower than the saturated vapour pressure.^{212,213} As a result, the sensitivity with respect to the concentration of ~ 10 particles per billion was achieved.

The explanation for the photoactivation effect was put forward, for example, in the publications,^{214,215} where the distribution of vibrational energy in a binary reacting gas mixture after

optical excitation was theoretically analysed. Stationary optical pumping gives rise to a distortion of the equilibrium distribution function of molecules with resonant levels, the distribution of vibrational degrees of freedom of other molecules remaining unchanged. In a two-component system, the vibrational temperature of both components differs substantially from the translational one. These effects open up the possibility of performing experiments on nucleation upon relaxation of the levels pre-excited with resonant electromagnetic radiation.

Advances in the studies of photographic processes were made largely due to intuition and practical skills of researchers and are to a lesser extent associated with theoretical studies. In studies of the mechanisms of spectral sensitisation of silver halides with dyes, it was concluded²¹⁶ that the primary event of electron transfer from the photoexcited dye and the secondary dark reactions involving an oxidiser (silver) play a decisive role. In these processes, numerous various nucleation phenomena take place. Unfortunately, these phenomena have not been considered in the context of the nucleation theory. For example, AgBr crystals are formed in an emulsion, and the sizes of these crystals influence the quality of photographs. The formation of aggregated cyanine dyes on the surface of silver halide crystals is also associated with nucleation. Such dyes are used for spectral sensitisation of photomaterials.

Knowing the mechanism of photoprocesses at the molecular and atomic levels, one can follow the dynamics of changes in the electron density and the course of chemical reactions associated with photoactivated electron jumps. In studies of the formation, for example, of photoaerosols, researchers often restrict themselves to the detection of the photoeffect with no investigation of its kinetics and mechanism. Among a few exceptions are the investigations,^{217,218} where the mechanism of atmospheric nucleation upon photoactivation of the simplest aldehydes was proposed. When studying the mechanism of formation and growth of an aerosol upon photolysis of tungsten hexacarbonyl, the authors gave particular attention to the time range during which vapours leave the irradiation zone. The generation of the condensed product was discontinued to measure the concentration and evaluate the size distribution of the aerosol formed. The kinetics of aerosol formation was simulated by numerical methods using the Smoluchowski equation. The rates of monomer formation were calculated at different photolysis rates, which were varied by changing the irradiation time. These calculated values were in good agreement with the measured photolysis rates. It should be noted that some methodological problems remain unresolved, which hinders the quantitative determination of the frequency of aerosol formation upon photoactivation.

The translational energy release upon multiphoton dissociation of organometallic compounds was studied.²¹⁹ The results were discussed from the viewpoint of expenditure of energy in aerosol formation from photolysis products of $W(CO)_6$. The processes of the preparation of aerosols and thin films were controlled by a laser. The properties of semiconducting CdSe nanoparticles with a diameter of 2–15 nm were examined.²²⁰ It was assumed that the addition of butylamine to a colloidal solution of nanoparticles excludes the radiation path for their luminescence. An observation of interactions between nanoparticles and a hole acceptor (to which butylamine belongs) allows one to detect electron transitions in surface atoms of nanoparticles.

8. Search for similarity criteria

Many researchers are concerned with a search for similarity criteria allowing one to carry out rescaling of the results of studies of nucleation (see, for example, Ref. 221). The asymptotic limit of the activation energy on going from heterogeneous to homogeneous nucleation was determined depending on the contact angle.²²² This value is consistent with the results of numerical simulation. The possibilities of scaling as applied to the properties of molecules in the critical cluster and then to nucleation were

[†] Atmospheric nucleation giving rise to morning fog, which appears with the first sunbeam, is an example of photonucleation.

analysed.²²³ The scaling properties of nuclei were treated based on the Kelvin equation. Analysis was carried out using the formal apparatus of the density functional theory and the molecular dynamics method. The concept of the reduced height of the barrier to nucleation was introduced. It was demonstrated that both modes of scaling are related to each other by the nucleation theorem and, hence, can be combined.

The model of scaling invariance for binary nucleation in ideal systems³⁵ was used for analysing experimental data on nucleation rates in a hexanol–ethanol system.²²⁴ Nucleation in a water vapour was simulated by the Monte Carlo method²²⁵ and the results were presented in a criteria form. The results of simulation are in agreement with the data from the experimental study.²²⁶ Based on scaling, corrections applicable to the results obtained by other researchers were proposed.

9. Adiabatic expansion method

Homogeneous vapour nucleation can occur upon rapid adiabatic expansion of a vapour–gas mixture. First data on this type of nucleation were obtained already in the late 19th century. In early experiments (see, for example, Ref. 227), the critical supersaturation S_c , to which the nucleation rate $J = 1 \text{ cm}^{-3} \text{ s}^{-1}$ corresponds, was determined. The construction of a Wilson chamber used for studying homogeneous nucleation has gradually been improved.^{71, 228–231} Apparatus was devised to maintain a constant nucleation temperature over a long period of time, which made it possible to control the changes in the concentrations of the particles formed and their size distribution with time.^{228, 232} The nucleation rates were measured with high accuracy in different systems using an adiabatic two-piston expansion chamber.^{224, 233–235} Presently, a Wilson chamber is used most generally for studying different processes associated with volume nucleation.

In a number of studies (see, for example, Refs 236–238), condensation was examined in a shock tube. A shock tube is a device, where a vapour is heated and rapidly cooled due to generation of shock waves in a vapour–gas mixture. Generally, a tube consists of two cells separated by a diaphragm containing a vapour (gas) at high (driving chamber) and low (driven chamber) pressures. Once the diaphragm is broken, the shock wave propagates to the section containing the low-pressure vapour and rapidly heats the latter. The high-pressure gas is simultaneously cooled under the action of a rarefaction wave. Heating can cause decomposition of a chemical compound into non-volatile components,²³⁶ while cooling leads to vapour supersaturation.²³⁷

The construction of a tube with two diaphragms made it possible to extend substantially the range of compounds under study.²³⁹ In this tube, the vapour is compressed by a shock wave after breaking of the first diaphragm and then the vapour is expanded into vacuum after breaking of the second diaphragm. This tube can be used for studying compounds characterised by a high vapour pressure at room temperature (for this purpose, these compounds are mixed with an inert gas). Compounds occurring in the solid state at room temperature are introduced as aerosols. The shock wave causes evaporation of aerosols and the vapour formed is condensed in the expansion cycle.

The studies of nucleation of different systems at high pressures using a shock tube are of great interest.^{240–242} The authors of the cited studies were among the first who concluded that nucleation under an atmosphere of a carrier gas should be considered as a binary process.²⁴²

A shock tube is extensively used in studies of nucleation at pressures of 70 atm.^{243–245} The kinetics of formation of methane hydrates was the main subject of investigation. For example, nucleation of water in methane was studied at pressures up to 40 bar²⁴³ and an *n*-nonane–methane system was investigated in the pressure range from 10 to 40 bar.²⁴⁴ In the latter case, the dispersion in experimental measurements was much smaller than that achieved, for example, in the study.²⁴⁵ The scheme was proposed for the use of a shock tube in studies at high temper-

atures.²⁴⁶ The geometry of a shock tube was devised so that the reflected wave again increases the pressure after the expansion cycle, thus preventing the appearance of new nuclei and providing conditions for the growth of the already formed nuclei.

The processes occurring in the systems under consideration are non-stationary, which hinders interpretation of experimental results. A spontaneously formed aerosol can be prepared in experiments using a supersonic flow of a vapour or a vapour–gas mixture through Laval nozzles. The state of the gas throughout the length of the nozzle can be precisely determined with the use of the gas dynamics equations.^{247–249}

Interesting results were obtained in the studies of nucleation of light and heavy water in nozzles.^{250, 251} It appeared that the compositions of the aerosols thus prepared correspond to the initial compositions of the samples. These experiments were carried out with the use of computer simulation. The experimental results were more similar to the values calculated on the assumption of isothermal conditions of the process rather than non-isothermal conditions. Analogous results were obtained in parallel measurements in a two-piston chamber.²⁵²

Nucleation in Laval nozzles cannot be described on the basis of the isothermal theory because the process under consideration is non-isothermal. The nucleation theory at high supersaturations³⁹ (including the theory of processes occurring in nozzles) has not been developed in sufficient detail. The difference in the temperatures corresponding to different degrees of freedom was observed in experiments using high-intensity molecular beams.^{253, 254} However, a theoretical description of these results is lacking. The developed methods for diagnostics of molecular beams enable one to study directly critical nuclei and distributions of clusters in a vapour expanded into a vacuum. These methods are very useful for quantitative studies of non-stationary non-isothermal nucleation.

10. Method for turbulent mixing

Studies of homogeneous condensation of a vapour by turbulent mixing of a hot vapour–gas mixture with a cold gas are of considerable interest.^{255, 256} Up to the 1960s, qualitative studies were primarily carried out. The main results were systematised by Amelin in the monograph.²⁵⁷ First data obtained by Friedlander were presented in the publications.^{258, 259} The method under consideration was widely used in the investigations.^{260–262} In spite of the simplicity, this method enables one to investigate nucleation processes in broad ranges of temperature, supersaturation and nucleation rate under stationary conditions due to which it has advantages over methods in which an adiabatic expansion chamber is used in a cyclic mode.

Similar apparatus were used in the studies^{257–259} devoted to the determination of the critical vapour supersaturation at which the aerosol formation began. A gas flow heated to a particular temperature is ejected at high velocity through a nozzle into a surrounding atmosphere moving at a certain velocity²⁵⁷ or into a resting gas.²⁵⁸ The flow was initially saturated with a vapour of the compound under study and its cooling with the surrounding flow leads to vapour supersaturation to give an aerosol. To detect the aerosol, the flow is illuminated with a collimated light beam and photographed. A common drawback of the cited studies is that the presence of an aerosol is determined in an arbitrary way and the beginning of the particle detection depends on the point in time at which the critical vapour supersaturation is attained. However, these studies provided qualitative insight into the transformations that occur in this process.

In subsequent studies, the parameters of an aerosol formed in a turbulent flow were measured quantitatively. The aim of the study²⁶³ was to validate the homogeneous nucleation theory proposed by Becker and Döring.²² In the investigation,²⁶³ the concentrations of particles formed in a generator were determined (unlike the above-considered studies) using a photoelectric counter.²⁶⁴ A comparison of the calculated and measured concentrations of the particles demonstrated that the best agreement

between these values was achieved for dibutyl phthalate. There was a substantial discrepancy between the experimental and calculated concentrations of the particles of ethylene glycol, octadecane and sulfur.

A similar problem was solved in the studies.^{265, 266} Octadecane and heneicosane were used as working compounds. At that time, the discrepancy between the calculated and experimental data of four orders of magnitude was considered to be satisfactory.

Procedures were developed for determining the concentrations and disperse compositions of aerosols formed by turbulent mixing of a vapour–gas mixture. The aerosol concentrations up to 10^7 cm^{-3} can be measured using a flow-through ultramicroscope constructed by Deryagin and Vlasenko.²⁶⁷ Besides, the concentration can be determined with lower accuracy but then rapidly from light scattering. After enlargement in a vapour of an organic compound, an aerosol can be considered as monodispersed and its concentration can be easily determined using a nephelometer.²⁶⁰

Time scales of nucleation under turbulent conditions were simulated by Barrett.²⁶⁸ He studied the temperature and concentration distributions with no account for condensation. An increase in the rate as the nucleation peak is approached and a decrease in the rate after passing the peak were evaluated. The value inverse to time corresponds to the pulse rate. The number of the particles formed was estimated from the nucleation rate multiplied by the peak duration. The results of calculations were verified by comparing the results of more precise calculations performed on a computer and with the data obtained in a real turbulent flow containing water vapour. Under laboratory conditions at a temperature below 90°C , condensation has only a slight effect on the number of droplets along the flow axis. However, condensation noticeably suppresses nucleation at temperatures above 95°C . Barrett believed that the proposed model can be useful for the construction of systems in which nucleation and particle growth occur simultaneously.

In investigations of condensation under turbulent conditions, it is very important to estimate the amount of particles which are deposited on walls limiting the flow. Simulation of the particle motion in a near-wall turbulent layer²⁶⁹ is based on analysis of the flow stability in a channel. The equation of motion includes the Stokes, gravitational and lifting forces. In the cited study,²⁶⁹ the efficiency of particle deposition from a flow was analysed by considering trajectories ending in particle deposition. The precipitation rates predicted by the model were in good agreement with the available experimental data. Particle deposition on a small-disc target was studied.²⁷⁰ The deposition effects associated with convection, diffusion, sedimentation, electrification and thermophoresis were investigated. It was found that thermophoretic purification from particles can be reduced to zero because of very weak attractions between charges.

The turbulence effect on the rate of particle formation in a vapour flow was studied experimentally.²⁷¹ The authors of the cited study investigated nucleation in a flow with the temperature of 400 K , which was injected into air at 298 K and 1 atm . To simplify calculations, the Levi number was taken equal to unity. The temperature fluctuations in an axis-symmetric flow were estimated and local rates of particle formation averaged over fluctuations were calculated. Turbulent pulsations substantially decrease the nucleation rates at local maxima and increase the nucleation volume. In the cited study, particle distribution fields were reported.

In the last two decades, the scheme using a turbulent flow was virtually not used for studying the rate of vapour nucleation because there was no assurance that homogenisation of a system occurs before nucleation. The data on nucleation at large temperature and concentration gradients remain to be adequately interpreted. However, it can be expected that this ‘drawback’ will soon become an advantage because this approach can be used for the quantitative determination of the delay times of nucleation

under gradient conditions. This field of investigation is of importance because such processes often take place in practice.

11. Methods based on molecular diffusion

Of all the apparatus used for studying nucleation, a thermodiffusion chamber is of most interest from the viewpoint of accuracy of measurements, because only in this chamber (unlike a Wilson chamber, Laval nozzles and shock tubes), condensation proceeds in a stationary mode. This provides the possibility of measuring the parameters of the process with high accuracy. A thermodiffusion chamber was first proposed by Langsdorf.²⁷² The action of this chamber is based on the use of vertical diffusion of the vapour under study through a light carrier gas. A compound evaporates from a hot plate and diffuses through an inert carrier gas to a cold plate. The temperature and pressure of the vapour between the plates change approximately linearly, whereas the saturation pressure depends exponentially on the temperature which gives rise to supersaturation. At a supersaturation higher than the critical value, homogeneous condensation with the formation of droplets is observed.

There are two types of thermodiffusion chambers, which differ by the direction of vapour diffusion. Langsdorf evaporated the compound under study from an upper (hot) plate. However, this construction was rejected at a later time, and researchers used chambers in which the hot plate was located under the cold one.²⁷³ The convenience of such chambers is that the condensate from the upper plate drains down and compensates the volume of the liquid that evaporates from the lower plate due to which the cycle becomes closed and the stationary mode is maintained during many hours. Due to the stationarity of the process, self-purification of the chamber from heterogeneous nucleation centres becomes possible. Relatively rare nucleation events caused by solar beams can be excluded from the statistics. A diffusion chamber was used for studying the dependence of the nucleation rate on supersaturation in different systems,^{273–279} including those occurring at high pressures (up to $40–100 \text{ bar}$).^{273–275}

In detailed studies of homogeneous nucleation of higher alkanes, critical supersaturations and nucleation rates were measured,²⁸⁰ the relations between the corresponding states were found and the dependences of the critical supersaturation of hydrocarbons on the number of carbon atoms and the number of molecules in the critical nuclei were revealed.²⁸¹ In the investigation,²⁸² ion-induced nucleation of vapours of six compounds was examined in a thermodiffusion chamber. Ions were generated using an α emitter. Either positive or negative ions were generated by varying the electric field. Experiments were carried out both in the presence and absence of an electric field in the nucleation zone. In the presence of the field, nucleation on positive and negative ions proceeded differently.

Interesting experiments on nucleation were carried out using photoactivated ions.^{212, 213, 283} Dose amounts of ions were produced with the use of small additives of 4-fluoroaniline or hexamethyldisilazane, which can be ionised upon resonance excitation. A resonance excitation pulse from a tunable UV laser initiated the generation of ions in the region below the point of maximum vapour supersaturation. Ions with the required sign were shifted to the nucleation zone by applying an electric field.

Diffusion chambers enable one to measure the frequencies of nucleus formation within $10^{-2}–10^2 \text{ cm}^{-3} \text{ s}^{-1}$. The lower limit is determined by the long expectation time for the appearance of a viable nucleus, whereas an upper limit is determined by the fact that at nucleation rates higher than $10^2 \text{ cm}^{-3} \text{ s}^{-1}$ the droplets that appear substantially disturb the diffusion and heat flows. The dependences of the distribution of vapour and temperature in a thermodiffusion chamber as well as of the nucleation rates on both the stationary homogeneous vapour condensation on droplets and the release of the phase transition heat were examined, for example, in the study.²⁸⁴ Moderate changes in supersaturation and temperature in a chamber caused by the release of phase transition heat and a decrease in the concentration of a vapour

upon its condensation on droplets lead to a substantial decrease in the nucleation rate as compared to the rate which should be observed (according to the nucleation theory) provided that the vapour is not consumed and the condensation heat is not released.

Distortions of the results obtained in flow diffusion chambers may be a consequence of particle deposition on walls. With the aim of estimating this effect experimentally, thermodiffusiophoresis of growing droplets of dioctyl phthalate formed in a supersaturated vapour upon homogeneous nucleation was studied.²⁸⁵ It appeared that the thermodiffusiophoresis theory, which was developed as early as the 1970s, gives an adequate prediction of results obtained in real conditions. This theory allows one to estimate the effect of thermodiffusiophoresis on the overall nucleation rate in a flow diffusion chamber. The first experiments with the use of this chamber have already demonstrated²⁸⁶ that an aerosol column formed along the flow axis does not virtually spread out during the period (several tenths of a second) of the presence of particles in the chamber. A noticeable (at the error threshold) effect can be observed if the number of particles decreases by a factor of 2–3 due to thermodiffusiophoresis. Such a decrease has not yet been observed in flow diffusion chambers. In investigations of nucleation of chemical compounds under conditions of a high vapour pressure (> 30 Torr), it is necessary to estimate additionally the effects under consideration.

In experiments on nucleation, there is a probability that aerosol particles undergo aggregation due to which their number and size distribution can change. This problem is most pressing in experiments with the use of adiabatic expansion methods, where high concentrations of aerosols are produced in the nucleation volume. This problem is rather easily solved based on the assumption that substantial coagulation cannot be observed in a fraction of a millisecond required for the particle detection. In studies with the use of a flow chamber, tenths of a second are required for the detection, the maximum concentrations of particles being four orders of magnitude lower than those in the case of adiabatic expansion methods, which also eliminates the problem of aggregation. In experiments with the use of a static diffusion chamber, this problem does not occur at all because the maximum concentrations of particles are too low to influence coagulation. A certain insight into the effect of aerosol aggregation on the nucleation rate was offered in the study.²⁸⁷ A model of coagulation of a two-component aerosol was described in the investigation.²⁸⁸ Coagulation occurring at different compositions and sizes of particles was examined in the publication.²⁸⁹

In experimental studies, the question as to the effect of vapour depletion on the nucleation rate is of importance. In a real system, only a limited amount of a vapour can be used and, hence, nucleation occurs inevitably on the background of a varying supersaturation. This fact is often ignored and the results of studies are related to average parameters of the system or conditions at which the maximum nucleation rate is achieved. In the study,²⁹⁰ the nucleation rates and nucleus growth were examined under conditions of a limited amount of a vapour. The equations were derived for the particle growth and changes in the concentration of a vapour due to its condensation under conditions corresponding to a combination of continuous and free-molecular modes. The characteristic times for these modes were found depending on the particle sizes and these times were compared with the characteristic times of nucleation, coagulation and chemical reactions. The vapour concentration decreases as the number of particles in the system increases. The authors of the study²⁹⁰ believed that an estimate of characteristic times is an efficient method for the determination of the relative importance of condensation compared to other competitive processes.

The idea of a thermodiffusion chamber was used in the study²⁸⁶ of spontaneous vapour nucleation in a flow. A flow diffusion chamber was constructed such that two coaxial flows with different temperatures, *viz.*, a heated gas saturated with the vapour of the compound under study and a cold blowing gas flow free from the vapour, move in a laminar mode. Supersaturation of

the vapour of the condensed compound is achieved as a result of equalisation of the temperature and concentration through thermal conductivity and molecular diffusion. Under conditions of a laminar flow, the temperature and concentration distributions of a vapour in the bulk of a tube can be calculated using the standard heat-conduction and diffusion equations. Simplified examples of such calculations in vapour–gas laminar flows were given, for example, in the monograph.²⁵⁷ The influence of perturbations occurring at the interface of hot and cold flows was studied in detail²⁸⁶ and conditions at which these perturbations have virtually no effect on the nucleation rate were found experimentally.

In the study,²⁹¹ the nucleation and growth of aerosols in a laminar axis-symmetric flow were analysed theoretically, problems of heat and mass transfer were considered and the dynamics of the establishment of the size distribution of particles was investigated. Nucleation of one- and multicomponent condensation aerosols was studied using an experimental apparatus with a laminar axis-symmetric flow.²⁹² The measured aerosol concentrations were compared with those calculated within the framework of the classical nucleation theory. Nucleation of a dibutyl phthalate vapour as a function of temperature and supersaturation was studied in a flow diffusion chamber.^{293, 294} An algorithm was proposed for solving the two-dimensional problem of heat and mass transfer.²⁹⁵ It was demonstrated²⁹⁶ that a carrier gas affects the nucleation rate of alcohols at atmospheric pressure. This result is of great importance because it provides independent evidence in support of the thesis about the influence of a carrier gas on nucleation, which I proposed earlier.²⁹⁷

In a modified version of a flow diffusion chamber,²⁹⁷ a gas together with a vapour first go from a saturating reactor to a heated tube, where the flow becomes stationary and laminar, and then it passes to a condenser. Laminarisation of the starting vapour–gas flow facilitates substantially the specification of the boundary conditions for the flow rate distribution and vapour concentration distribution, which simplifies the solution of the stationary problem of heat and mass transfer in a chamber. Experience of the use of a flow diffusion chamber is being gradually accumulated. For example, reproduction²⁹⁸ of earlier experiments²⁹⁹ on nucleation of a dibutyl phthalate vapour gave results, which differ from the earlier data by a factor of 2–3. This is quite satisfactory for the initial stage of investigation.

Experimental methods for studying vapour nucleation are being extensively developed. Information on nucleation rates under precisely fixed conditions of nucleation can be gained in different ways. However, the method of a laminar axis-symmetric flow or a flow diffusion chamber holds, apparently, most promise. The simplicity of this method and the possibility of measuring a large number of experimental points in a rather short period of time enable one to observe, for example, a change in the phase state of critical nuclei.⁷³ Undoubtedly, this approach will be further elaborated and will find wide application in studies of processes of aerosol formation. It should be noted that different experimental methods complement each other. These methods can be arranged in the following order of increasing measured nucleation rates: a static diffusion chamber ($10^{-2} \div 10^{-3} \text{ cm}^{-3} \text{ s}^{-1}$), a flow diffusion chamber ($10^{0 \div 1} \div 10^{6 \div 7} \text{ cm}^{-3} \text{ s}^{-1}$) and adiabatic expansion methods ($10^1 \div 10^5 \text{ cm}^{-3} \text{ s}^{-1}$). The employment of a flow diffusion chamber can be supplemented by the method for turbulent mixing ($10^{5 \div 7} \div 10^{9 \div 12} \text{ cm}^{-3} \text{ s}^{-1}$). The adiabatic expansion methods assume the use of apparatus such as a Wilson chamber, shock tubes and nozzles.

IV. Excess energy of clusters. Experiment

It is known that the behaviour of a thin layer of a compound at the interface, in particular, at the vapour–condensate interface differs substantially from the behaviour of each of the homogeneous phases in the bulk. The theoretical representation of a surface layer as an inhomogeneous film, which separates homoge-

neous or virtually homogeneous substances, has been proposed already by Gibbs. The surface energy and, as a consequence, the surface tension are among the main thermodynamic characteristics of the surface layer. The available surface tension theories are far from being perfect and are, generally, applicable to only a narrow range of compounds (see, for example, Refs 8 and 80).

The excess (surface) energy of clusters plays a key role in the nucleation theory because it determines the activation energy of the nucleation process. Since our knowledge about complex systems are scarce, it is advantageous to use a simplified approach involving similarity methods and analysis of dimensionalities. The fundamental similarity criteria characterising microdisperse systems were found.²²¹ Calculations based on reference data for 38 liquids (condensed inert gases, alkanes, alkenes, dienes, aromatic hydrocarbons, alcohols, liquid metals) indicated that these criteria are temperature-dependent. The authors of the cited study believed that two systems are thermodynamically similar if their similarity numbers have (their pairs) close values. Presently, it is difficult to evaluate the importance of this approach for the nucleation theory because the proposed criteria need further verification with the use of a greater body of data for various chemical compounds. However, a search for similarity criteria undoubtedly belongs to classical problems of thermodynamics. It seems likely that the application of this or an analogous approach will pave the way to considerable progress in the development of the nucleation theory. It should be noted that a search for scale invariance requires that as much data should be used as possible and has need for intuition or research. Successive theoretical approaches are more unlikely to give a reasonable set of axiomatic statements favourable for the development of the parametric theory as compared to an essentially semiempirical search for scale invariants.

The importance of the determination of the excess energy of critical clusters was illustrated in the investigation,³⁰⁰ where the size distribution of clusters was estimated in a broad range (from dimers to macroscopic drops). In the cited study, the ratios between the equilibrium constants of dimers and the surface tension coefficients were determined and the correction for the surface tension coefficient in the Frenkel equation was found. The chemical potential of a cluster is written as a linear function of the number of 'inner' and surface molecules. The author of the cited study believed that his semi-phenomenological model and data on the size distribution of clusters can explain, for example, the experimentally observed abnormally high nucleation rate of a mercury vapour.

In the study,³⁰⁰ a vapour was treated as an ideal mixture of clusters with different sizes. The state of the atom in the cluster is characterised by the coordination number, which is similar to its value N for the corresponding condensed phase. The coordination number of the surface atoms is smaller than N . The surface tension of clusters can be described by the equation

$$\frac{\sigma}{\sigma_0} = 0.414(n-1)n^{-2/3},$$

where n is the number of molecules in an arbitrary cluster.

If the size of the critical nucleus $n^* < 30$, the surface tension of the cluster σ is much smaller than σ_0 . Consequently, the Frenkel model substantially underestimates the nucleation rate as if nucleation had occurred at high supersaturation S . Nucleation of a mercury vapour proceeds, for example, at $S \approx 10^5$ at an abnormally high rate.³⁰¹

The study³⁰² is yet another example of a search for an adequate description of the excess energy of critical nuclei. The authors introduced a correction to the equation for the surface tension and intermolecular interaction, which takes into account the second virial coefficient thus modifying the Fischer droplet model.⁵⁰ This leads to changes in the average area of the cluster surfaces and the number of molecules in the clusters. The authors of the cited study believed that their approach is applicable to any temperatures below the critical point, which was supported by the

fact that the calculated values were consistent with experimental data.

The study³⁰³ was concerned with nucleation in gases. The surface tension was described by modified McLeod's equation

$$\sigma(w_g, w_l, \theta) \simeq \Theta(\theta)(w_l^{-1} - w_g^{-1})^\delta,$$

where $w_{g,l} = v_{g,l}/v_c$ is the ratio of the specific volume of gas (or liquid) molecules to the specific critical volume; $\Theta(\theta) = (A/v_c)^4(w_{l,eq}^{-1} - w_{g,eq}^{-1})^{4-\delta}$, where A is a constant, $w_{l,eq}$ and $w_{g,eq}$ are normalised specific volumes corresponding to bimodal conditions; $2 \leq \delta \leq 4$; in most calculations, it was taken that $\delta = 2.5$.

It is assumed that as the system approaches the conditions for spinodal decomposition, the work of formation of a critical cluster decreases more rapidly than is expected from the classical nucleation theory. The authors of the cited study reasoned that their approximation combines the simplicity of the classical theory and the ease of its use. In the region of small supersaturations (like in the limiting case), the results of the classical theory are reproduced. This is attributed to the fact that the surface tension of clusters in the case of slow nucleation is close to the equilibrium value corresponding to the planar surface and high supersaturation; the surface tension deviates from the reference data and approaches the dynamic values corresponding to the appearance of new interfaces. Therefore, the surface tension is inconsistent with its macroscopic value. Hence, the application of the classical theory to systems with high supersaturations leads to substantial errors. It can be readily seen that this approach includes a useful but rather trivial parametrisation, which is present in an indirect form as the consideration of the notion of dynamic surface tension. Hence, the calculation possibilities of this approach are no higher than those of other theories. The parametrisation enables one to describe correctly the behaviour of a series of nucleating systems. However, this parametrisation does not solve the problem of the development of a universal theory.

The drawbacks in the procedures for the determination of the excess energy of critical clusters were discussed in the study.³⁰⁴ Concepts of statistical mechanics were employed for the development of the nucleation theory based on the determination of the potential energy of clusters, which is independent of the space distribution of molecules. It is assumed that the excess energy of the cluster consisting of one molecule should be equal to zero. Using the potential constants from models of macroscopic samples, one can calculate the latent heat and surface tension of clusters.

It was proposed to use a fractal model and the corresponding kinetic equations for the description of cluster formation.³⁰⁵ Clusters formed due to coalescence can be characterised by a lognormal size distribution. The results obtained with the use of the Smoluchowski equation and different theories describing a cluster size spectrum are similar to those obtained in experiments with the use of molecular beam expansion into a vacuum and in the laser chemistry of organometallic compounds. The authors of the cited study believed that the model provides a statistically perfect basis for the interpretation of data on the distribution of clusters synthesised by different methods.

In the study,³⁰⁶ a semi-phenomenological correction was proposed, which made it possible to refine the surface energy taking into account the curvature of a spherical drop known as the 'Tolman length'.⁸⁰ The following equation of state was derived with the use of Fischer's droplet model:⁵⁰

$$\frac{P_{\text{sat}}}{q_0 k_B T} = \sum_{n=1}^{\infty} n^{-\tau} \exp[-\theta_0(1 + \alpha_\sigma n^{-1/3})n^{2/3}],$$

where P_{sat} is the saturated vapour pressure, $\theta_0 \equiv \sigma_0 s_1 / k_B T$ is the dimensionless surface tension at the planar interface and $\alpha_\sigma \equiv -2\delta_T / r_1$. At low temperatures, the surface tension is high and the Tolman length is, as expected, small ($|\alpha_\sigma| \ll 1$). In this case, the solution of the equation of state takes the form

$$\alpha_\sigma = -\frac{1}{\theta_0} \ln \left(\frac{P_{\text{sat}}}{q_0 k_B T} \right) - 1.$$

In the general case, the equation of state for different nonpolar compounds is solved by numerical methods. Away from the critical temperature, the Tolman length is positive and, according to the Dillmann–Meier model, is equal to $\sim 20\%$ of the surface tension of the droplet. The Tolman length becomes negative as the critical temperature is approached and its change is consistent with that predicted by the density functional theory.

The problem of the excess energy of clusters is closely related to the question about the limits of applicability of the droplet model to small clusters. A model, which is alternative to the droplet model used for small clusters, was suggested for the description of atomic chains spontaneously formed at rather high temperatures.³⁰⁷ Analytical estimates were made on the assumption that the atom interacts only with the nearest neighbours. The interaction potential is additive and short-range. A model with a minimum number of bonds and a statistical model of a macroscopic droplet represented as many linked chains are two limiting models of the cluster. In the study,³⁰⁷ the authors used both an analytical equation for the statistical sum of a gas-like cluster, which was derived within the framework of simplified model representations of the interaction potential of particles and the cluster structure, and numerical simulation of the cluster evolution in a supersaturated vapour by molecular dynamics.³⁰⁸ The equilibrium size distribution of clusters was found by discrete methods. This distribution made it possible to calculate the homogeneous nucleation rate in a supersaturated vapour.

Studies by molecular dynamics and the Monte Carlo method demonstrated that in the first steps of cluster formation, the generation of branched chains (fractals) is energetically favourable. The latter are folded into a sphere as the size becomes rather large. A computer simulation showed³⁰⁹ that the formation of chain clusters is typical of a polar Lennard-Jones liquid. The chain length increases with increasing number of dipoles in the cluster. As a particular size is reached, the fractal is broken to form a compact spherical cluster. At the boundary of spherical clusters, chain fragments still persist. The authors of the cited study stated that the interface of spherical clusters differs substantially from a planar boundary. Collapse of fractals occurs when the number of dipoles is as much as ~ 200 .

The fact that atoms tend to be combined into clusters as energetically favourable structural units is evidenced by the results of mass spectrometric measurements. Dark-blue crystals of clusters with composition $\text{Na}_{48}[\text{H}_x\text{Mo}_{368}\text{O}_{1032}(\text{H}_2\text{O})_{240}(\text{SO}_4)_{48}] \cdot (\sim 1000 \text{H}_2\text{O})$ were prepared.³¹⁰ In these clusters, 368 molybdenum atoms form a virtually spherical shell with two open mouths on the opposite sides and the inner cavity of size $\sim 2.5 \times 4 \text{ nm}$. This structure was called a ‘nanohedgehog’ because of the presence of numerous protruding (like hedgehog hair) $\text{Mo}=\text{O}$ bonds. The ‘nanohedgehog’ has a diameter of $\sim 6 \text{ nm}$. Regions with both positive and negative curvatures are present on the cluster surface thus breaking the ‘monotonicity’ of symmetry within this nanoobject comparable in size to proteins. It is assumed that the nanocluster possesses catalytic properties. In addition to this surprising cluster, families of fullerenes and carbon nanotubes, huge nanoclusters, supramolecular compounds, *etc.* are known.

The idea that diamonds can be prepared by impact loading or rapid deposition of carbon onto a substrate followed by cooling was put forward rather long ago. Investigations of deposition on substrates have been successfully performed by Russian researchers. The results of these studies were generalised in papers and monographs.^{311,312} It was demonstrated³¹³ that meteorite diamonds are key objects, which can help in elucidating the nature of impact-wave cosmic phenomena. Studies of meteorite diamonds provided a reliable interpretation of impact recrystallisation of silicate minerals in meteorites.

Calculations by the Monte Carlo method³¹⁴ demonstrated that spheroidal silicon clusters consisting of more than 36 atoms are stable and showed that the bond energy rapidly increases as the cluster size increases. Such an increase in the bond energy is not observed if clusters are described in the droplet approximation. Calculations using the Hartree–Fock approximation for the icosahedral Si_{60} cluster gave similar results.^{315–317} In the review³¹⁸ devoted to the computer simulation of nanotubes, it was noted that the synthesis of the first carbon nanomaterials was carried out virtually simultaneously with a series of studies on simulation of their electronic structures and almost all nanotube compounds and many of their properties were predicted based on the results of calculations. Due to the unique properties of nanomaterials, the latter attract great interest, which, in turn, causes an increase in the number of investigations.

Theoretical problems of nucleation as applied to nanotube materials remain to be solved. The practical realisation of the process has not yet sufficiently developed. Hence, the quantitative determination of the nucleation rate is not a problem to be solved. Nanostructures are prepared predominantly in an arc discharge using graphite electrodes. This method was used for the synthesis of structurally different clusters.

The results of the above-considered studies provide arguments in favour of the fractal model of critical nuclei. The formation of a nucleus of a new phase can be represented as a series of successive fluctuation transformations from one relatively stable configuration of the cluster to another one. Obviously, the problem of calculating the excess energy of clusters for the description of the nucleation kinetics without resorting to the droplet model becomes more complex. However, as will be demonstrated below, this problem can be resolved.

Presently, in spite of the complexity of the experimental determination of the size (and all the more, the shape) and the excess energy of critical nuclei, such attempts are made. The surface tension at the crystal–melt interface at atmospheric pressure was calculated based on experimental data on the kinetics of spontaneous crystallisation of a supercooled liquid.³¹⁹ The region where the surface tension was determined was extended beyond the triple point. Calculations were carried out with the use of a dimensionless parameter relating the surface tension, entropy of melting and specific volume of the crystal.

In the study,³²⁰ the excess energy of the cluster formed upon crystallisation was determined using a computer experiment with the Lennard-Jones approximation, whereas other calculations were carried out using the density functional theory in the rigid-sphere approximation. In a parallel direct experiment, the nucleation and growth of crystalline nuclei was observed using a laser confocal microscope. The results of the study were compared with the results of computer simulation. Apparently, a combination of experimental investigations with theoretical methods has the most chance of making progress in studies of the nature of nucleation.

Based on generalisation of the results of experiments on nucleation, algorithms were developed for the determination of the numbers of molecules (atoms) in critical nuclei^{228,321–324} and evaluation of the surface tension.^{323,325–328}

It is known that the nucleation rate is expressed by an exponential relation analogous to Eqn (26). In the classical nucleation theory and its different modifications, the pre-exponential coefficient C is a weak function of supersaturation. In the general form, this factor can be written as

$$C = \frac{1}{\rho} \sqrt{\frac{2\sigma m}{\pi}} \left(\frac{p_0}{k_B T} \right)^2 S^{n_0}, \quad (30)$$

where ρ and σ are the density and surface tension of the condensed phase, respectively, m is the molecular mass, p_0 is the equilibrium vapour pressure under given conditions, n_0 is the exponent equal to 1 or 2. The size of the critical nucleus n^* can be calculated from the dependence of the nucleation rate on the supersaturation at constant temperature

$$\left(\frac{d \ln J}{d \ln S_i}\right)_T = \frac{d \ln C}{d \ln S_i} + n_i^* - \frac{\partial f(n, p)}{k_B T \partial \ln S_i}, \quad (31)$$

where the subscript i is the ordering number of the component. In the study,³²⁴ it was demonstrated that this equation is applicable to multicomponent nucleation. In the study,³²⁰ the possibility of determining the size of a critical nucleus upon non-isothermal nucleation under conditions of crystallisation was substantiated. The assumption that there is a relationship between the nucleation rate J , supersaturation S_i and the nucleus size n^* was made, for example, in the publication.²²⁸

It should be noted that Eqn (31), which has gained wide acceptance, has one term less than the thermodynamically exact equation derived for one-component nucleation,^{326, 327}

$$\left(\frac{d \ln J}{d \ln p}\right)_T = \frac{d \ln C}{d \ln p} + \frac{n_i^*}{k_B T} (v_v - v_l) - \frac{\partial f(n, p)}{k_B T \partial \ln p} \bigg|_{n^*}, \quad (32)$$

where v_v and v_l are the molar volumes of the vapour and liquid, respectively. In the general case, v_v and v_l should be considered as the molar volumes of the initial and equilibrium phases, respectively. In the case of nucleation in a vapour, the vapour serves as the initial phase and the volume of the liquid away from conditions for spinodal decomposition and critical conditions can be ignored. In the case of cavitation, the volume of the initial liquid phase is ignored for the same reason, and the volume of the equilibrium phase, *viz.*, the vapour, is considered.

Equation (31) for a one-component system was independently derived in the study,³²³ where it was called the nucleation theorem. The difference between the chemical potentials of phases $\Delta\mu$ was used instead of the variable $\ln S_i$; however, judging from the estimate of the summands, this difference is described in the ideal gas approximation, *i.e.*, $\Delta\mu \equiv k_B T \log S$. This immediately excludes the term associated with the specific volume v_v with the result that Eqn (31) becomes inapplicable in the region of critical and spinodal conditions, where these volumes are virtually identical. Oxtoby and Kashchiev⁷⁹ discussed the possibility of determining the number of molecules in a nucleus from the slopes of experimental isotherms of nucleation rates on the assumption that the first and third terms in Eqn (32) make only small corrections. In normal conditions, the situation is saved because the first and third terms have opposite signs, which provides their virtually complete compensation, and the specific volume of the vapour in the second term is three orders of magnitude larger than the specific volume of the condensate. However, in the case of transitions in condensed phases or in the vicinities of the critical or spinodal points, the difference between the specific volumes virtually vanishes and, hence, it is necessary to take into account all terms.

It should be noted that the exact solution of the problem of the determination of the critical nucleus size, *viz.*, Eqn (32), exists only for a one-component system. Such a problem for multicomponent systems remains to be solved. As mentioned above, the use of the ideal gas approximation leads to a loss of significant terms. Hence, it is hardly probable that Eqn (31) can be considered as the nucleation theorem. The term 'nucleation theorem' has already gained acceptance. However, it should be remembered that this term is arbitrary. Presumably, this idea will be developed to the level of the theorem in the future.

Undoubtedly, the above-considered equations extend the possibilities of studying nucleation. However, the problem of the description of multicomponent nucleation calls for further analysis. This problem is being debated in scientific literature (see, for example, Ref. 79), which, undoubtedly, will help in gaining more precise insight into the fields of application of Eqns (31) and (32). These equations can be used for considering all first-order phase transitions. The specificity of the transition can be refined by calculating a change in the Gibbs thermodynamic potential corresponding to the formation of a critical nucleus of a new phase. The study of electrocrystallisation¹²⁵ provides an example.

The usual error is to use these equations for the description of two-channel nucleation without separation of the channels. An example is the study,¹⁹³ where the estimation of the composition of critical nuclei from the slope of the nucleation rate surface in the case of two-channel nucleation was not substantiated.

Let us attempt to justify the possibility of determining the excess energy of clusters upon nucleation in a one-component system.

The necessity of taking into account such factors as the ambient pressure and, particularly, the radius of surface curvature in the deduction of an equation for the surface energy (or surface tension) requires a careful thermodynamic analysis. In the studies,^{326–328} the method for the determination of the excess energy of critical nuclei in the case of homogeneous nucleation was theoretically validated. Let us consider the deduction of the corresponding equation.

The derivative of the change in the thermodynamic potential of nucleation ΔG takes the form³²⁸

$$\frac{d\Delta G(n, T)}{dT} = \left(\frac{\partial \Delta G}{\partial T}\right)_n + \left(\frac{\partial \Delta G}{\partial n}\right)_T \frac{dn}{dT}.$$

The condition for the formation of a critical nucleus is met when the second term in the right-hand side of the equation is equal to zero. At constant pressure,

$$\frac{d\Delta\mu}{dT} = -\Delta s,$$

where Δs is the difference between the entropies of the old and new phases per molecule. Without any assumptions about the shape of the cluster, the work of its formation ΔG can be written as follows

$$\Delta G(n, \Delta\mu, p, T) = n\Delta\mu + \Theta(n, \Delta\mu, p, T), \quad (33)$$

where $\Delta\mu$ is the difference between the chemical potentials in the macroscopic volume of the liquid and in the gas phase; p is the total pressure; T is the temperature; Θ is the energy of the cluster determined by the presence of the phase interface. Then the final equation for the surface (excess) energy of the critical nucleus Θ^* with consideration for Eqn (26) takes the following form:^{70, 325, 326}

$$\frac{d}{dT} \left(k_B T \ln \frac{J}{C} \right) = n^* \Delta s - \left(\frac{\partial \Theta^*}{\partial T} \right)_n. \quad (34)$$

The solution of this equation includes the known values determined by the boundary conditions. An additional theoretical study is required to determine the multipliers in the expression for the pre-exponential coefficient C (which depends on the temperature).

Another way of estimating the surface (excess) energy of a critical nucleus was developed by Ford.^{325, 329} The excess energy can be determined using critical supersaturation; however, another equation was also derived³²⁵

$$\left(\frac{\partial \ln J}{\partial T}\right)_S = \frac{\Delta H - k_B T + \Theta^*}{k_B T^2},$$

where ΔH is the heat of vapour formation per molecule. Ford did not report data sufficient for reproducing his results [in particular, it is necessary to know how the derivative of Θ in Eqn (34) was determined] and comparing these results with the data published in the literature. It should be noted that the monotonicity and continuity conditions of $J = J(S, T)$ as a function of independent variables, *viz.*, the temperature T and supersaturation S , are not fulfilled in the vicinity of the phase transition temperature in the condensate

$$\left(\frac{\partial \ln J}{\partial \ln S}\right)_T \left(\frac{\partial \ln S}{\partial T}\right)_J \left(\frac{\partial T}{\partial \ln J}\right)_S = -1.$$

This can be attributed to the fact that the temperature dependence of the critical nucleus size in the nucleation isorate curve has a bend in the vicinities of the phase transition points.^{330, 331} Evidently, the surface energy should also undergo certain changes. These changes can be found using the criteria for singularity of nucleation surfaces.

Let us consider the experimental method for the determination of the surface energy of a critical nucleus³³² with the constraint $p = \text{const}$. Assuming that the behaviour of a vapour is described by the equation of state of an ideal gas, *i.e.*,

$$\Delta\mu = -k_B T \ln S,$$

let us go to new independent variables in Eqn (33)

$$\Delta G(n, \ln S, T) = -n k_B T \ln S + \Theta(n, \ln S, T). \quad (35)$$

For a critical nucleus, the following equation is valid

$$\left(\frac{\partial \Delta G}{\partial n} \right)_{n=n^*, S, T} = 0.$$

The number of independent variables in Eqn (35) for the work of formation of a critical nucleus decreases by unity because the nucleus size is unambiguously determined at fixed temperature and supersaturation. Let us choose S and T as independent variables. Then

$$\Delta G^*(\ln S, T) = -n^*(\ln S, T) k_B T \ln S + \Theta(\ln S, T). \quad (36)$$

After differentiation of Eqn (36) with respect to T at a constant supersaturation, we obtain

$$\left(\frac{\partial \Delta G^*}{\partial T} \right)_S = -n^* k_B \ln S - k_B T \ln S \left(\frac{\partial n^*}{\partial T} \right)_S + \left(\frac{\partial \Theta^*}{\partial T} \right)_S.$$

Let us consider this equation as applied to nucleation. The exponential dependence of the rate of formation of a new phase J on the work of nucleus formation of this phase ΔG^* described by Eqn (26) is beyond question. However, the pre-exponential coefficient C was not unambiguously determined. According to the classical nucleation theory, the factor C is proportional to the square of supersaturation. However, in more recent studies (self-consistent theory),^{46–48} this coefficient was reduced. While staying within the framework of the classical nucleation theory, the pre-exponential coefficient can, in the general case, be represented by Eqn (30).

By differentiating Eqn (26) with respect to T at a constant supersaturation, we have

$$\left(\frac{\partial \ln J}{\partial T} \right)_S = \left(\frac{\partial \ln C}{\partial T} \right)_S + \frac{\Delta G^*}{k_B T^2} - \frac{1}{k_B T} \left(\frac{\partial \Delta G^*}{\partial T} \right)_S. \quad (37)$$

Taking into account Eqn (30),

$$\left(\frac{\partial \ln C}{\partial T} \right)_S = \frac{1}{2} \frac{\partial \ln \sigma}{\partial T} - \frac{\partial \ln \rho}{\partial T} + 2 \frac{\partial \ln p_0}{\partial T} - \frac{2}{T}. \quad (38)$$

In the analysis of the temperature dependences of the surface tension and density for a series of compounds (water, glycerol, pentanol, *etc.*), the first two terms in Eqn (38) are two orders of magnitude smaller than the third term and, hence, they can be ignored. Equation (37) can be rearranged to Eqn (39) using the Clausius–Clapeyron equation

$$\begin{aligned} \left(\frac{\partial \ln J}{\partial T} \right)_S &= \frac{2(\Delta H - k_B T) + \Theta^*}{k_B T^2} + \ln S \left(\frac{\partial n^*}{\partial T} \right)_S - \\ &- \frac{1}{k_B T} \left(\frac{\partial \Theta^*}{\partial T} \right)_S. \end{aligned} \quad (39)$$

The latter equation reduces to the first-order linear differential equation

$$y' + f(x)y = g(x), \quad (40)$$

where $y = \Theta^*$, $x = T$. If the functions $f(x)$ and $g(x)$ are continuous, the integral curve passing through the point $(x, y) = (\xi, \eta)$, provided that $y(x) = \eta(\xi)$ is known, is described by the following equation

$$y = e^{-F} \left(\eta + \int_{\xi}^x g(x) e^F dx \right), \quad (41)$$

$$F(x) = \int_{\xi}^x f(x) dx.$$

Therefore, to solve Eqn (40), it is necessary to know at least one point at which the required parameters of the system are determined. The dependence of $\ln p_0$ on the inverse temperature specified by the Clausius–Clapeyron equation can be considered to be linear at a vapour pressure corresponding to a constant supersaturation up to the conditions for spinodal decomposition.³³³ At fixed supersaturations, an increase in the temperature of a system leads to the state at which the vapour pressure is equal to the pressure of spinodal decomposition. According to Eqn (36), the following equation should be fulfilled at the spinodal decomposition point

$$\Theta_{sp}^* = k_B T_{sp} n^* \ln S.$$

The use of this equation for solving Eqn (41) with consideration for Eqn (39) leads to the following expression for the surface energy of a critical nucleus:

$$\frac{\Theta^*}{k_B T} = n^* \ln S + 2 \frac{\Delta H}{k_B T} \left(\frac{T}{T_{sp}} - 1 \right) - 2 \ln \frac{T}{T_{sp}} - \ln \frac{J}{J_{sp}}. \quad (42)$$

It can be seen that it is necessary to know the number of molecules in a critical nucleus n^* and the temperature T_{sp} at the spinodal decomposition point to determine the surface energy. The critical nucleus size is calculated from the slope of the curve of the isothermal nucleation rate in double logarithmic coordinates. The temperature of spinodal decomposition T_{sp} at a constant supersaturation is found from the equation of state for a one-component mixture on the condition that $(\partial P / \partial V)_T = 0$. The corresponding nucleation rate J_{sp} is determined by linearisation of experimental data followed by the linear extrapolation of the temperature dependence of the nucleation rate to the point T_{sp} .

The applicability of the method proposed for the determination of the surface energy of critical nuclei was tested using supersaturated vapours of polyhydric alcohols (propanediols and glycerol) under an atmosphere of carbon dioxide and sulfur hexafluoride.³³² These experiments were preceded by detailed investigations of the effect of the parameters of systems on the characteristics of critical nuclei.⁷³ For example, the phase transition was observed in critical nuclei in the investigation of nucleation of a supersaturated propane-1,3-diol vapour under an atmosphere of sulfur hexafluoride at different temperatures and pressures. The isotherms of nucleation rates at a total system pressure of 0.30 MPa are shown in Fig. 2. The isotherm measured at a nucleation temperature of 334 K corresponds to the transformation from one nucleation rate surface to another. At the temperature corresponding to a change in the phase state in critical nuclei, the isotherm of the nucleation rate becomes non-monotonic. The temperature dependence of the surface energy of nuclei should also have some characteristic features indicative of the discontinuity of the first derivative of the thermodynamic potential, which is a direct condition for the first-order phase transition.

The experimental investigation of nucleation of glycerol under an atmosphere of CO₂ in the temperature range of 310–320 K demonstrated that the parameters of critical nuclei undergo a jump caused by a first-order phase transition in the vicinity of the critical line of a binary glycerol–carbon dioxide system.⁷³ In the

T/K : (1) 320.92, (2) 323.17, (3) 325.29, (4) 327.63, (5) 329.88, (6) 332.31, (7) 334.25, (8) 336.45, (9) 338.62, (10) 340.84, (11) 343.16, (12) 345.48, (13) 347.54, (14) 349.75, (15) 351.90.

melting-temperature range of glycerol (295 K), the cluster surface energy shows anomalous behaviour.

The temperature dependences of the size and surface energy of critical nuclei of propane-1,2-diol, propane-1,3-diol and glycerol under an atmosphere of carbon dioxide and sulfur hexafluoride were found.³³² The surface energy was calculated using Eqn (42) at a constant nucleation rate ($10^3 \text{ cm}^{-3} \text{ s}^{-1}$).

Figure 3 shows the experimental dependence of the excess energy on the nucleus size and presents the results of calculations of the surface energy of critical nuclei that appear (using the droplet model in a one-component approximation) in an octa-

Figure 3. Surface energy vs. the critical nucleus size of octanol under an atmosphere of sulfur hexafluoride. Points correspond to the experimental data; the solid line indicates the data calculated using the droplet model. The total pressure in a vapour–gas system /MPa: (1) 0.10, (2) 0.15, (3) 0.20, (4) 0.25, (5) 0.30.

nol–sulfur hexafluoride system.³³² It can be seen that a decrease in the excess energy depending on the number of molecules in the nucleus is more rapid than that predicted according to the droplet model. Extrapolation to larger numbers allows one to estimate the critical nucleus size at the energies found according to the proposed algorithm which are identical with those determined using the droplet model. Beginning with this size, the droplet model of a nucleus becomes applicable. In the case under consideration, a nucleus should contain ~ 100 –140 molecules.

To extrapolate the dependence under consideration to the size of the nucleus consisting of one molecule (atom), it is necessary to define such a notion as the surface (excess) energy of the molecule. Langmuir proposed (using some simple compounds as examples) that the heat of evaporation of one molecule could be considered as an analogue of the surface energy.³³⁴ This assumption is rather arbitrary in spite of the fact that the evaporation energy and surface energy depend on the same factors, *viz.*, intermolecular interactions. The inconsistency is attributed to the differences in the distribution of intermolecular bonds in the bulk of a macroscopic object and in the cluster.

The order of the dependence of the surface energy of critical nuclei on the cluster radius is higher than two.³³⁵ This fact confirms the conclusion, which was made based on the results of computer simulation, that clusters have a fractal structure in the initial step of condensed phase growth. By extrapolating the logarithmic dependences of the energy on the nucleus size, the ‘surface’ energy of one molecule can be determined. A comparison of the surface energies of critical nuclei of polyhydric alcohols with the reference data³³⁶ on the heats of evaporation of individual compounds demonstrated that, for instance, the heat of evaporation of the glycerol molecule is two times larger than its surface energy. Apparently, this difference can serve as the characteristic (in energy units) of the excess energy accumulated in the cluster. Another reason for this discrepancy is the presence of the dissolved gas in the cluster.

The method proposed for the determination of the surface energy of critical nuclei based on experimental results can, undoubtedly, be a convenient tool for the quantitative estimate of this very important physicochemical parameter. However, the incorrect interpretation can be made, for example, based on the results of measurements of the overall rates in the presence of two nucleation surfaces. A lack of reliable methods for the measurement of the nucleation rates corresponding to each individual surface hinders a comparison of theoretical and experimental data. The application of the theory developed for single-channel nucleation to the interpretation of the results of measurements of the overall rates in the presence of two (or more) nucleation surfaces leads to a deadlock situation. It becomes apparent that there is a need to elaborate on the experimental methods for separate measurements of nucleation rates for each surface.

The development of procedures for examining experimental methods is of great importance. An *n*-pentanol–helium mixture can be used as a testing system.³³⁷ Evidently, the approximate dependence of the nucleation rate on the total pressure in this system has some errors, but the parameters of the approximation can be refined with more reliable data.

To test large sets of experimental data, it is advised to use differential values,³³¹ which formally characterise the conditions for monotonicity and continuity of the function. Therefore, one can achieve higher accuracy in the analysis of data and reveal inflections in the corresponding experimental curves.

The available analytical methods do not meet modern requirements. When performing theoretical analysis, one has to make initial assumptions about phase transitions and their kinetics rather than obtain the corresponding parameters based in more general laws. Experimental results often serve as a source of new theoretical ideas. For example, the possibility of using phase equilibrium diagrams for the development of the nucleation theory was not considered until recently. Taking into account that these diagrams (or their cross-sections) given in various

handbooks are lines of zero nucleation rates, the topology of the nucleation surface can be represented in the limit of its zero rates. By performing a few experimental measurements, one can determine the slope of the linearised nucleation rate surface thus estimating the rate with an accuracy, which is obviously higher than the accuracy of any theoretical calculations. This simple idea provided the basis for semiempirical methods for the construction of nucleation rate surfaces^{14, 338} considered below.

V. Semiempirical methods for constructing nucleation rate surfaces

It is not always possible to determine nucleation rates in practically important systems using theoretical models. A method for the semiempirical construction of nucleation rate surfaces was described.¹⁴

It is known that the chemical potential surface of one phase as a function of temperature and pressure in a system can intersect the chemical potential surface of another phase. The intersection of these surfaces is a phase equilibrium line. If the first derivatives exhibit discontinuities along this line, the first-order phase transition occurs. In the case of the vapour–liquid equilibrium, the equilibrium line consists of numerous points of first-order phase transitions with the phase transition temperature T_p (Fig. 4). The critical point corresponding to the second-order phase transition with the temperature T_c is at the end of this line. At the critical point, the chemical potential and its first derivative for the liquid phase are identical with those for the vapour phase. An individual phase is ‘insensitive’ to the equilibrium line. The phase can cross this line and reach the region, where the chemical potential of this phase is higher than that of another phase. These metastable states are denoted by V_m and L_m for the vapour and liquid, respectively. The lines of spinodal decomposition serve as metastable state boundaries. Figure 4 gives the lines of spinodal decomposition having projections cs_1 and cs_2 onto the PT plane. The projection of the equilibrium line of chemical potentials forms a vapour–liquid equilibrium line $T_p c$. This pattern can be readily generalised to multicomponent systems.

Figure 4. Chemical potential surface μ for the vapour–liquid equilibrium as a function of the pressure P and temperature T .^{12, 14}

Metastable states appear upon first-order phase transitions due to the necessity of expending energy for the creation of the interface of critical nuclei. The lifetime of a metastable phase depends on the depth of penetration of one phase into the region of another co-existing stable phase, *i.e.*, on the degree of supersaturation of the initial phase. The diagrams of metastable states in processes of melting and cavitation have been discussed many times (see, for example, Refs 339–342). A diagram of a metasta-

ble state of a vapour and a nucleation rate surface were proposed and analysed in the study.³³⁸

1. Phase PT diagram of unstable equilibria

The basic knowledge about the topology of the nucleation rate surface can be gained by analysing a simplified PT diagram of a one-component system with a critical point.¹⁴ Regions of metastable states, which exist for each phase, are shown in Fig. 5.

Figure 5. Simplified PT diagram of metastable states.¹⁴ The zero temperature limit is indicated by an arrow; the liquid, solid and gas states are denoted by L , S and V , respectively; the subscript m signifies the metastable state.

It is known that the phase equilibrium lines never end in a triple point. For this reason, the S – L equilibrium line intersects with the line of spinodal decomposition (kbd) of a superheated (stretched) crystal and with the line of spinodal decomposition (cbl) of a stretched (supercooled) liquid. The point b is the point of critical instability¹⁴ at which the S – L equilibrium line intersects with the spinodal for cavitation cbl . At the point b , the line of labile states of a liquid cbl intersects with both the line of labile states of a crystal kbd and the line of liquid–crystal unstable equilibrium $ftpb$.

The viscosity of a supercooled liquid increases as the temperature decreases and this liquid can exist at as low temperatures as is wished,¹⁴ the liquid being able to occur in the liquid or glassy state. The glassy state is not an independent phase because it has no equilibrium lines with other phases. In the degree of order, the glassy state is closer to the liquid in which the long-range order is absent. It seems reasonable to consider glassy states as metastable states of a liquid. However, glasses are sometimes (see, for example, Ref. 341) treated as individual phases and lines of spinodal decomposition of a liquid are passed to the region of existence of crystalline states. In this connection, it should be noted that the transformation of a liquid into the glassy state does not mean the glass–supercooled liquid equilibrium and it cannot be characterised by the equilibrium transition temperature. Hence, a glass cannot be considered as an individual phase. Nevertheless, the region of existence of a glass was approximated³⁴¹ by a line and it was assigned to conditions for spinodal decomposition of the liquid, the end of this line being called the critical point. In my opinion, the concept of the absence of a

temperature limit for spinodal decomposition of a liquid (see the line *cbl* in Fig. 5) up to the limiting temperature, *viz.*, absolute zero, is preferable.

The *S*–*V* equilibrium line passes from the point *a* to the point 0. It is essential that this line begins at the point *a*, where the spinodal line for crystals *kb* intersects with the spinodal line for a vapour *ca0*. This indicates that the vapour–crystal equilibrium line extends upward to higher temperatures. The point *a* corresponds to the highest temperatures and pressure at which the solid–liquid–vapour metastable state can occur over a short period of time. The crystalline state is spontaneously transformed into the liquid state. It was stated that¹⁴ the point *a* is not the crystal–vapour critical point, like the point *c*, because both phases at the point *a* occur at the same temperature and pressure, although they differ in density, structure and other properties and cannot be transformed into each other without activation. It should be noted that the difference in the density can be insignificant because the vapour supersaturation in an experiment can reach several hundred units. In the case of spinodal decomposition, it is reasonable to expect the vapour supersaturation to be as great as several thousand units, which is similar to the ratio between the densities of the condensed and vapour phases, *i.e.*, the difference in the densities of the crystal and vapour can appear to be vanishingly small. The possibility of a continuous change in the order parameter when going round the point *a* remains an open question.

In experiments on the generation of aerosols, it is possible to produce crystalline particles at moderate supersaturations. At high supersaturations, particles with a non-crystalline structure, *i.e.*, a supercooled liquid or an amorphous solid, are predominantly formed. Under the conditions for spinodal decomposition, the nucleation rate of a metastable liquid should be higher than the rate of crystal formation due to kinetic limitations. The above-mentioned limitations result from the fact that the formation of a nucleus with a crystalline structure requires that molecules (atoms) be able to migrate to sites of the crystal lattice formed. Evidently, in the case of a large flux of molecules that appears under conditions for spinodal decomposition, there can be not enough time for jumps of the molecules, which occupy crystal lattice sites and form a crystalline nucleus. Correspondingly, the probability (and the rate) of formation of droplets (or glasses) should be higher than the probability (and the rate) of formation of crystalline nuclei.

2. Examples of construction of nucleation rate surfaces

A nucleation rate surface can be constructed¹⁴ above a simplified *PT* diagram with a triple point (see Fig. 5). Nucleation rates are considered to be steady. Transient phenomena upon the establishment of a stationary nucleation rate or effects of vapour depletion are ignored. Nucleation rate surfaces are constructed using the following assumptions.

1. An individual phase can exist behind the line of interphase equilibrium in a metastable state. The equilibrium line can be extended to the region of an equilibrium state of another phase as a line of unstable equilibrium.
2. Equilibrium lines in the phase diagram are lines of zero nucleation rate.
3. Under conditions for spinodal decomposition, the highest nucleation rate is achieved at a constant pressure or constant temperature.
4. Under conditions for spinodal decomposition, the nucleation rate giving rise to less stable states is higher than the rate of nucleus formation of a more ordered stable phase.
5. The nucleation rate at the critical point is equal to zero.

The first three assumptions correspond to known empirical results of studies of first-order phase transitions. The fourth assumption seems to be reasonable taking into account data on the kinetics of phase formation. Thus, under conditions for spinodal decomposition, molecules do not have time to be incorporated into crystal lattice sites and, hence, form amorphous

particles with high probability. The fifth assumption is a consequence of the fact that the critical point corresponds to the second-order phase transition, where separation into phases is absent and, consequently, nucleation at the critical point cannot occur. It was noted¹⁴ that the fifth assumption can follow from the second one.

Let us consider a fragment of the phase equilibrium diagram in the vicinity of the triple point *t* (Fig. 6). The vapour–crystal (*kt*) and vapour–liquid (*tm*) equilibrium lines are extended to the region of existence of the third equilibrium phases. The nucleation rate surface of liquid-droplet nuclei is pale-grey. The dark-grey surface corresponds to the nucleation rate of crystalline nuclei. The surfaces intersect in the line *et*. The intersection of the surfaces forms an ascending branch *ke* (and the dashed line is its extension to conditions for spinodal decomposition) corresponding to the nucleation rate of crystals. The nucleation rate of liquid-droplet nuclei is represented by the line *eh* (and its extension to zero rates). If a saturated vapour at the point *m* begins to be cooled at a constant pressure, a liquid-droplet aerosol can be prepared. At the temperature corresponding to the point *l* and below, the formation of crystalline nuclei starts. The nucleation rates of both phases increase as the temperature is decreased, but the nucleation rate of crystals increases faster. At the point *e*, the rates of formation of liquid-droplet and crystalline nuclei are equalised. It is easy to understand that if the phase state of nuclei is retained in the course of subsequent condensation growth, the sizes of aerosol particles are different due to the known nonequality of the accommodation coefficients of molecules on surfaces with different phase states. This conclusion was experimentally confirmed in the study.¹⁵

Figure 6. Nucleation rate surfaces for a one-component vapour.¹⁵

Surfaces of nucleation rates in superheated (or stretched) crystals, nucleation in a supercooled liquid and cavitation were constructed.¹⁴ It should be noted that the assumption of a non-zero nucleation rate in the zero temperature limit¹⁴ is, most likely, erroneous. Actually, the pressure vapour at absolute zero is also equal to zero and there is no question about nucleation in a vapour. Hence it follows that the nucleation rate in a vapour above the line of spinodal decomposition first increases as the temperature decreases from the critical one, then reaches a maximum and falls to zero in the zero temperature limit. Under conditions for spinodal decomposition, the nucleation rate is equal to the pre-exponential coefficient in the equation for the nucleation rate. In the case of a vapour, this coefficient increases from zero to a maximum and then again decreases to zero as the temperature decreases from the critical value to absolute zero. By contrast, in the case of nucleation in condensed phases, the pre-exponential coefficient, apparently, only increases with decreasing

temperature. However, this assumption needs further verification. Such a verification can be performed in the case of simultaneous homogeneous and heterogeneous nucleation, as was demonstrated using ion-induced nucleation as an example.³³³

Nucleation rate surfaces of binary vapours can be represented in the four-dimensional surface JTa_1a_2 , where J is the nucleation rate, T is the temperature and a_1 and a_2 are the activities of the vapours of the components. Let us consider the simplified PX diagram of a binary solution at the fixed temperature T , total pressure in the system P and composition x . In this case, the phase diagram is cigar-like in shape (lines mfn and $nrgm$ in Fig. 7).

Figure 7. Nucleation rate surface (J) for ideal solutions (P is the total pressure, x is the composition of a binary solution).¹⁴

The nucleation rates of individual components are represented by the curves nd and mh . At the point of vapour equilibrium (n, m), the nucleation rates of the vapour are equal to zero. The nucleation rates of the components have maximum values above the spinodal decomposition points a and b . These maximum rates in a simplified form can be related by the line deh corresponding to maxima of the binary nucleation rate. The nucleation of a binary vapour with composition x_0 starts at the point f .

A condensed phase has the composition x_1 at the point r . Each point on the line nfm corresponds to a point on the line $nrgm$. The latter line, which is an equilibrium line between a liquid and two-phase states, is the trajectory of points of the zero nucleation rate and forms a surface boundary of the nucleation rates. The nucleation rate surface is contoured by $hednrgm$. Above the spinodal, the composition of a vapour is identical with those of condensed phases due to the absence of the barrier to transformation into the condensed phase. The line re describes the nucleation rate of a vapour (with the known composition of critical nuclei) in the course of an increase in the pressure from the point r to the point e at the constant nucleation temperature T and the initial composition of the vapour x_1 . The curve fe is a projection of the curve re onto the plane corresponding to the composition x_0 . No information on the composition of critical nuclei can be extracted from the curve fe .

In the case of an unknown composition of critical nuclei, a nucleation rate surface can be constructed if all experimental nucleation rates (analogous to the curve re) correspond to the initial composition of the vapour in the phase diagram (for example, the line fe for the composition x_0). In this case, the points of the zero rate of vapour nucleation are located on the lower line of the cigar-like diagram. The rate surface under consideration is presented in the JxP coordinates. Apparently, the mode of representation of binary nucleation rates of a vapour depends on whether or not the composition of critical nuclei is known. If the composition of critical nuclei is unknown, a nucleation rate surface for an ideal binary solution is contoured by $hednfm$ (see Fig. 7). In experiments, the composition of nuclei is usually unknown and the measured nucleation rate in a binary

system is assigned to its initial composition. Thereafter, the composition of nuclei of the condensate can be determined from the slopes of nucleation rate isotherms.^{324, 343}

The nucleation in a binary system with partial mutual solubility of the components was discussed in the study.³⁴⁴ Earlier, it was demonstrated⁶⁹ that in this case, two-channel nucleation takes place. In the publication,³⁴⁴ a new assumption was made according to which each channel is characterised by its own nucleation rate surface for ideal solutions. The authors of the cited study used the rule of summation of nucleation rates for both channels in the linear approximation analogous to the lever rule for solutions. The validity of assuming linear summation of nucleation rates calls for experimental verification. However, an essential advantage of this approach is that it substantiates the possibility of the presence of local maxima in a nucleation rate isotherm, which does not follow from the classical theory. This result can be illustrated by the experimental dependence of the nucleation rates on the activity of an alcohol vapour in n-pentanol–argon (Fig. 8) and n-pentanol–sulfur hexafluoride systems.³⁴⁴

Figure 8. Nucleation rate in an n-pentanol–argon system vs. the activity of an n-pentanol vapour.³³⁸

The pressure in the system influences the course of nucleation. However, this fact has not been noted in early experiments performed by Wilson and other researchers. Examples of the pronounced effect of the pressure in the course of boiling water, ethanol, acetone and their solutions were given in the studies.^{345, 346} Noteworthy is the idea of bond percolation used by the authors of these studies. However, this idea was not confirmed experimentally and, hence, the assumption about the continuity threshold of unbroken intermolecular bonds in a liquid in the metastable region was made. The authors of the study³⁴⁷ and their colleagues^{233, 348–350} still attributed the pronounced effect of the total pressure on the nucleation rate in vapours of a number of chemical compounds to other factors by referring to corrections for non-ideality of a vapour, compressibility of a critical cluster and the Poynting effect. Undoubtedly, all these factors should be taken into account, but there is one more important factor as well. Thus, direct experiments demonstrated (see, for example, Ref. 73) that a gas and a vapour form a binary system in which phase transitions take place in critical nuclei due to the presence of a carrier gas.

VI. Nucleation in binary systems

The nucleation in a binary solution in which a chemical reaction proceeds (see, for example, Ref. 351) has distinguishing features. In this case, the phase diagram consists of the phase diagrams of two individual binary systems and a newly formed compound is considered as a limiting compound in each of these diagrams.

None of the available nucleation theories can predict nucleation rate surfaces resulting from interactions. Many problems remain to be solved among which is the problem of the rates of non-stoichiometric chemical reactions, which are determined by extension of the nucleation rate surface to the non-stoichiometric region. It is not inconceivable that in further studies, approaches of chemical kinetics will be combined with nucleation kinetics.

1. Phenomenological consideration of intermolecular interactions

A semiempirical approach to the construction of nucleation surfaces^{12–14} is based on the relationship between nucleation rates and phase diagrams. This relationship is evident in the case of stationary dynamic systems, which occur close to the equilibrium. However, a more careful examination should be carried out for systems existing far from equilibrium. For example, large flows of matter occur upon the formation of a cloud layer in the atmosphere or upon atmospheric precipitation. It is known that a strong dynamic response is characteristic of flow systems.¹⁸² This dynamic response is manifested in the transformation of the system to another dynamic mode (hydrodynamic or thermodynamic crisis, autowave mode). The effect of this type, which was studied first, is called the Benard (convective) instability. This effect is manifested in the appearance and rearrangement of convective cells in a liquid layer heated from below. Under conditions far from equilibrium, instabilities are responsible for the long-range order and, as a result, the system acts as an organic whole.¹⁸² Besides, in the case of a non-equilibrium first-order phase transition, a compound goes through a metastable state (supersaturated vapour, superheated or supercooled liquid). As a result, the metastable phase by itself becomes a flow system, which can produce a stationary flow of nuclei of a new phase at a given temperature, pressure and composition. The study³⁵² examined the evolution of dynamic phase diagrams of a binary system as the flow J (nucleation rate) increases on the assumption that the latter plays a dominant role compared to other types of flows (for example, a hydrodynamic flow). The deviations of the nucleating system from equilibrium are characterised by the flow of nuclei of a new phase. Hence, nucleation isorates ($J = \text{const}$) can be treated in the corresponding coordinates as dynamic phase diagrams.

Experimental data on nucleation rates were compared with empirical phase diagrams of binary systems using a water–propan-1-ol system with an azeotropic point as an example.³⁵³ Figure 9 shows static ($J = 0$ at $T = 298$ K) and dynamic ($J = 1 \text{ cm}^{-3} \text{ s}^{-1}$ at $T = 298$ K and $J = 10^7 \text{ cm}^{-3} \text{ s}^{-1}$ at $T = 260$ K) phase diagrams of a water–propan-1-ol system in the coordinates of the mole fraction of alcohol vs. the reduced pressure (the total pressure related to the pressure of the saturated

Figure 9. Phase diagrams of a water–propan-1-ol system at nucleation rates $J = 0$ [(1) vapour, (2) liquid]; $J = 1$ [(3) vapour] and $J = 10^7 \text{ cm}^{-3} \text{ s}^{-1}$ [(4) vapour, (5) liquid].³⁵³

propan-1-ol vapour in an ideal solution $P_{298} = 2700 \text{ Pa}$ at $T = 298 \text{ K}$ and $P_{260} = 125 \text{ Pa}$ at $T = 260 \text{ K}$). The line 5 for a liquid in the dynamic phase diagram is constructed based on the data on the molar composition of critical nuclei (see references cited in the study³⁵³).

In the case of large deviations from an ideal solution, dynamic phase diagrams are transformed as the nucleation rate increases. As can be seen from Fig. 9, this transformation is accompanied by a shift of the azeotropic point of a water–propan-1-ol system along the axis of composition. An analogous change from a convex diagram to a concave one was observed for a water–ethanol system.³³⁵ In Fig. 10, the spinodal is schematically represented by the line be . It was taken into account that the convexity of the diagrams changes for concavity as the nucleation rate increases and it was also considered that the lines for a vapour and a liquid should coincide under conditions of spinodal decomposition. The dynamic diagrams corresponding to $\log J = 0, 4, 7$ and $10 \text{ (cm}^{-3} \text{ s}^{-1})$ are schematically represented by the corresponding contours (the nucleation rate surface shown in grey colour passes through the vapour lines). The spinodal be has a concave shape, i.e., the vapour pressure of the mixture at the end of the line of azeotropic solutions is lower than the vapour pressures of the pure components. By contrast, the equilibrium diagram (ad) is convex (the pressure reaches the maximum values at the azeotropic point in the phase equilibrium diagram). Deviation of dynamic diagrams from the equilibrium diagram should primarily be observed upon enrichment of the mixture with water, which takes place in the experiment (see Fig. 9). A change in the shape of the spinodal curve can lead to another transformation of dynamic diagrams.

Figure 10. Schematic representation of the nucleation rate surface in a binary system constructed on the basis of experimental data for a water–ethanol system.

As a binary system moves away from the equilibrium, small contributions of binary interactions between the molecules can, on the contrary, appear to be prevailing. In such nonlinear systems, components lose their individuality (typical of an equilibrium state) and the mixture behaves as a whole, i.e., in the case of substantial deviations from equilibrium, intermolecular interactions are collective in character. A strengthening of intermolecular interactions, as applied to static phase diagrams of binary systems, is manifested in an increase in the negative deviation of the system from an ideal solution (the total vapour pressure is lower than the additive value). The evolution of the phase diagrams presented in Figs 9 and 10 is also accompanied by a decrease in the total

pressure as the system moves away from the equilibrium (as J increases). In other words, the changes in dynamic phase diagrams are analogous to the changes in usual phase diagrams as intermolecular interactions are strengthened.

In calculations of phase diagrams of a binary system within the framework of a single-liquid model (homogeneous liquid), the correction parameter k , which takes into account binary interactions and determines mutual attractions between molecules of different components, was entered into the equation of state (for example, into the van der Waals equation).³⁵³ Therefore, the nucleation isorates of a vapour can be interpreted as phase diagrams corresponding to the parameters of the binary interactions k . For a metastable state, the boundary of a stable homogeneity of a phase is determined by the condition of vanishing vapour tension ($\partial P/\partial V$) in an isotherm of state, *i.e.*, by a spinodal.

A choice of an algorithm for calculating a spinodal is governed by the condition for stability of a binary solution. As the system moves deep inside the metastable region, it retains the fixed entropy S , volume V and amount of matter at a constant internal energy $dU = 0$. Instability of relatively continuous changes in the parameters of state is initially manifested in the vanishing of the diffusion coefficient of stability

$$\left(\frac{\partial \Delta \mu}{\partial x}\right)_{P,T} = 0, \quad (43)$$

where x is the composition of the binary system. Then the necessary and sufficient conditions for stability of a binary solution are expressed by the inequality

$$\left(\frac{\partial \Delta \mu}{\partial x}\right)_{P,T} > 0 \quad (44)$$

or a system of inequalities

$$-\left(\frac{\partial P}{\partial V}\right)_{T,x} > 0, \quad (45)$$

$$\left(\frac{\partial T}{\partial S}\right)_{V,x} > 0. \quad (46)$$

In the van der Waals single-liquid model, a binary solution at fixed x is considered as an efficient one-component fluid obeying the equation of state in the above-mentioned variables

$$\pi = \frac{8\tau}{\varphi - b(x)/b_{11}} - \frac{27a(x)/a_{11}}{\varphi^2}, \quad (47)$$

where $\pi = P/P_{c1}$, $\tau = T/T_{c1}$ (P_{c1} and T_{c1} are the pressure and temperature, respectively, at the critical point of the low-temperature component 1); $\varphi = V/b_{11}$; the coefficients $a(x)$ and $b(x)$ depend on the concentration of the second component and are calculated by the equations

$$a(x) = (1-x)^2 a_{11} + 2(1-x)x a_{12} + x^2 a_{22}, \quad (48)$$

$$b(x) = (1-x)b_{11} + xb_{22}, \quad (49)$$

the constants a_{11} and a_{22} characterise the intensity of intermolecular attractions in the components 1 and 2, respectively; the constant a_{12} characterises the intensity of attractions between the molecules of different components; the parameters b_{11} and b_{22} are determined by the sizes of the molecules of the solution. According to the combination rule, the constant a_{12} can be written through the binary interaction parameter k^*

$$a_{12} = k^*(a_{11}a_{22})^{1/2}. \quad (50)$$

Taking into account Eqn (47), Eqn (46) is fulfilled. The condition (45) goes to zero at the spinodal line. Considering Eqn (47), we obtain the equation for the diffusion spinodal

$$\varphi^3 - \left[\varphi - \frac{b(x)}{b_{11}}\right]^2 \frac{a(x)}{a_{11}} \frac{27}{4\tau} = 0. \quad (51)$$

The constants in the equation of state can be determined using the critical parameters

$$a_{11} = \frac{27}{64} \frac{(RT_{c1})^2}{P_{c1}}; \quad a_{22} = \frac{27}{64} \frac{(RT_{c2})^2}{P_{c2}};$$

$$b_{11} = \frac{RT_{c1}}{8P_{c1}}; \quad b_{22} = \frac{RT_{c2}}{8P_{c2}}.$$

Figure 11 shows the calculated spinodal curves for a water – propan-1-ol system at 260 K and different values of the parameter k^* in the coordinates of the mole fraction of propan-1-ol *vs.* the reduced pressure (the total pressure related to the critical pressure of the alcohol). It can be seen^{352,353} that the asymmetry associated with the difference in the individual properties of the components decreases as the binary interaction is strengthened. At high k^* , the spinodal curve becomes symmetric with respect to an equimolar composition. This fact can be attributed to a loss of individuality of the components of the system as the latter moves away from equilibrium. Apparently, this situation is something common to the phenomenon mentioned in the review:³⁵⁴ ‘...a loss of individuality of a substance appears as the system approaches the critical conditions. The character of the properties is determined by the degree of approach to the critical conditions rather than by the individuality of substances and even rather than by the type of phase equilibrium’. As the system approaches the conditions for spinodal decomposition, the free energy of formation of critical nuclei decreases. The vanishing of this energy is the condition for spinodal decomposition. This superficially resembles a continuum of liquid – vapour phase transitions ending in the critical point. It should be noted that under normal conditions of vapour nucleation, vapour supersaturation is as great as a thousand units. This indicates that the density of a supersaturated vapour approaches the density of a condensate thus providing conditions for a phase change with a low enthalpy of transition. Here one can speak about a first-order phase transition similar to a second-order phase transition. Hence, there are certain grounds to assume that a substance can lose individuality as it approaches the spinodal curve.

Dynamic phase diagrams become similar to a spinodal curve as J increases. It is assumed that the parameter k^* in the equation of state for a metastable phase can be substantially larger than that allowable in the equation of state for an equilibrium phase. In other words, the equations of states for equilibrium and metastable phases can differ in the parameters determining intermolecular interactions in a binary system. For example, according to the above-considered calculations [see Eqns (43)–(51)], the pres-

Figure 11. Spinodals of a water – propan-1-ol system at 260 K for various parameters of binary interactions. k^* : (1) 1, (2) 2, (3) 4, (4) 8.

sure in the spinodal corresponds to the binary interaction parameter $k^* = 5.65$.

Based on a spinodal curve for which the binary interaction parameter k^* is close to unity, the transformation of phase diagrams shown in Fig. 9 becomes impossible. Therefore, the behaviour of a binary system as it moves away from equilibrium is determined by the spinodal. It was assumed³⁵³ that the deviation of the system from linearity characterises a change in intermolecular interactions as the system moves away from equilibrium. Knowing the parameter k^* in a metastable state, one can determine the limiting values J thus finding the stability boundary of the state under consideration. As the system moves further away from equilibrium, it should go to another mode, which is, as a rule, accompanied by an organisation of a new structure.¹⁸²

2. Bimodal distribution of aerosols

The well-known effect of the bimodal distribution of an atmospheric aerosol remains to be adequately explained. Attempts to attribute this effect to fluctuations of the parameters of atmosphere with time and space seem to be artificial, because the time interval of averaging is generally equal to a few minutes. As a result, the conditions of growth of all heterogeneous nuclei are statistically equalised giving rise to a broad unimodal distribution. Actually, the use of time-averaged values cannot lead to a bimodal distribution because the nucleation time is several orders of magnitude smaller than a hundredth of a second, *i.e.*, the nucleation has time to proceed and nuclei have time to grow within one fluctuation cycle.

The bimodal distribution of aerosols can be reasonably explained assuming the existence of two independent surfaces (channels) of nucleation for the separate formation of crystals and liquid nuclei. Evidently, the accommodation coefficients of molecules on nuclei occurring in different phase states differ from each other. The difference in the growth rates of liquid and crystalline aerosol particles can lead to a bimodal distribution of particles in the atmosphere, where nucleation of a water vapour generally occurs in the vicinity of the triple point. A direct experiment on nucleation of glycerol in the vicinity of the triple point¹⁵ demonstrated that the presence of condensation nuclei is not required for the occurrence of the bimodal distribution of particles. It should be noted that in a real atmosphere, condensation nuclei undoubtedly make an additional contribution to the size distribution of particles.

The above-mentioned experiment¹⁵ is of fundamental importance for testing the semiempirical procedure for the construction of nucleation rate surfaces above phase equilibrium diagrams. The problem of the order of phase formation upon vapour nucleation below the triple point was easily solved. Crystalline and liquid-droplet nuclei appear simultaneously in ratios determined by the arrangement of the rate surfaces of formation of each phase relative to one another. Evidently, supercooled droplets can adopt a crystal or amorphous structure with certain probability. Apparently, the initial phase states of nuclei were retained in the study¹⁵ due to the use of a high-viscosity sample. Undoubtedly, such experiments give a clue to the separation of nucleation channels, which is of fundamental importance for the estimation of the agreement between theory and experiment. Actually, researchers had no possibilities to test the validity of a particular theory because theoretical results obtained in the one-channel approximation were generally compared with the characteristics corresponding in reality to two-channel nucleation.

3. Ion-induced nucleation

In the present review, the problem of heterogeneous nucleation is not discussed in detail. The detailed description of this process under conditions of a slowly changing supersaturation was given in the study.¹²⁰

Under conditions of ion-induced nucleation, the following rules are fulfilled.³⁵²

1. The energy of ion-induced vapour nucleation is always lower than the energy of homogeneous nucleation. Compared to homogeneous nucleation, lines (or in the case of a multicomponent system, a subspace) of ion-induced nucleation rates correspond to lower supersaturations (activities) of a vapour or, in the case of isobaric nucleation, to higher nucleation temperatures.

Let us note the well-known fact^{326, 327} that the lines of ion-induced nucleation rates coincide with the line of homogeneous nucleation rate when all ions pass into a condensed phase. The properties of a nucleating substance (for example, polarisability) can influence the relative intensity of heterogeneous nucleation of various vapours. This parameter depends on the differences in the vapour activity and temperature in the case of isothermal and isobaric nucleation, respectively.³³³

2. At a constant vapour supersaturation, the rate of heterogeneous isothermal (or isobaric) vapour nucleation is proportional to the concentration of ions. If the concentration of ions is nearly equal to or higher than the concentration of nucleating molecules, the heterogeneous nucleation rate reaches its upper limit. This limit determines the envelope curve (or a multidimensional surface), which corresponds to the limiting rate of ion-induced nucleation as a function of vapour activity. The lines of the highest and zero rates of heterogeneous nucleation are located on the surface of homogeneous nucleation rates.

3. Surfaces of homogeneous and heterogeneous vapour nucleation intersect at high temperatures in the line of spinodal decomposition.

Examples of the qualitative construction of nucleation rate surfaces describing phase transformations of various initial phases were given in the study.¹⁴

4. Experimental determination of conditions for spinodal decomposition

The experimental method for the determination of conditions for spinodal decomposition was developed in the study.³³³ The lines ct_p and mt_p in Fig. 12 correspond to vapour–liquid and vapour–solid equilibria. For simplicity, the spinodal line sc is considered to be common to the liquid and solid states. The isorates of homogeneous and heterogeneous nucleation of a liquid can be measured at moderate supersaturations. The extrapolation of both lines gives an intersection w belonging to the spinodal line for a liquid as follows from the third rule for ion-induced nucleation. An analogous extrapolation can be carried out also in the case of the crystalline state (point r in Fig. 12). The results of measurements of the supersaturation as a function of the nucleation temperature of *n*-butanol³⁵² are presented in Fig. 13. For homogeneous nucleation, the linear regression of the logarithm of the vapour pressure on the inverse temperature is described by the equation

Figure 12. Schematic representation of vapour–liquid and vapour–solid equilibria for $\log P$ vs. $1/T$.³³³

Figure 13. Experimental data on critical supersaturations of n-butanol for $\log P$ vs. $1/T$.³³³

(1) Homogeneous nucleation, (2) ion-induced nucleation.

$$\log P_{\text{hom}} = 7.4076 - \frac{1582}{T}.$$

For ion-induced nucleation, this regression is described by the equation

$$\log P_{\text{het}} = 8.0728 - \frac{1791}{T}.$$

The extrapolation allows one to determine the pressure (230 mmHg) and temperature (310 K) of spinodal decomposition. This pressure corresponds to a reasonable estimate of the vapour supersaturation in the spinodal ($\log S = 2.6$). In other words, studies of heterogeneous and homogeneous nucleation enable one to estimate experimentally the conditions for spinodal decomposition, which makes it possible to find the temperature dependence of the pre-exponential coefficient in the equation for the nucleation rate in the classical theory. Evidently, in the case of spinodal, the exponential multiplier becomes equal to unity and, hence, the only remaining multiplier is pre-exponential. Generally, this multiplier is considered to be constant. Taking into account that the nucleation rate at the critical point of a liquid–vapour system is equal to zero, it is easily understood that the pre-exponential coefficient increases from zero at the critical point to a maximum value and then again decreases and goes to zero at absolute zero of temperature.

The studies by Fuks[‡] and Sutugin³⁵⁵ have made an impact on the development of concepts of aerosol mechanics and the application of these concepts to the description of cluster growth.

VII. Use of nucleation in scientific studies and some technological processes

Nucleation is used in one way or another in many scientific studies and in a number of technological processes. This phenomenon is so widespread that researchers are often not aware that they deal with nucleation.

Aerosols are used for visualisation of particle motions, which occur upon nuclear decay, in a Wilson chamber. The latter is extensively employed for studying nucleation of supersaturated vapours. More than a half-century ago, Sinclair and La Mer designed a generator of monodispersed particles, which was

described, for example, in Ref. 356. In different laboratories throughout the world, researchers extensively used a particle condensation counter, which is based on the Sinclair–La Mer scheme. A lack of theoretical support for the principles of its action stimulated experimental and theoretical investigations. In the study,³⁵⁷ a theoretical model of the counter was proposed and the results of its tests at different pressures, nucleation temperatures and amounts of the gas to be analysed were reported. A condensation counter was used as a detector for capillary chromatography.³⁵⁸ Initially, the sensitivity has been 100 ng ml^{-1} , but then this limit was improved by two orders of magnitude.^{347, 359} Being an instrument for research, a condensation counter by itself was also the object of an individual study.³⁶⁰ The construction of a counter of aerosol particles is gradually improved. Thus, the schemes have already been developed,^{361, 362} which enable one to detect particles with sizes of 3 nm with an efficiency of almost 100%.

Nanoparticles are used for creating quantum points, luminescent materials, gas sensors, resistors, conducting and capacitive films, high-temperature superconductors, thermoelectric, optical, magnetic, laser materials, etc. Methods for the synthesis of such particles were surveyed in the study.³⁶³

The generation of nanoparticles in plasma holds promise. Powders formed by evaporation and condensation of various materials in a plasma were studied experimentally and their numerical simulation was carried out.³⁶⁴ The theoretical consideration of the processes occurring in an inductively coupled plasma made it possible to give recommendations on the construction of apparatus for the production of nanoparticles.³⁶⁵ In the investigation on simulation of nucleation and growth of iron particles in a plasma reactor, a parametric equation was derived for the description of a spectrum of sizes and number of the particles formed.³⁶⁶ These parameters depend substantially on the rate of cooling and the initial concentration of monomers. A mathematical model was proposed for the formation of metal powders and ceramics of high purity.^{367, 368} Experimental methods for the preparation and simple models of generation of metal clusters were surveyed in the review.³⁶⁹ An experimental apparatus for the generation of ultradispersed titanium oxide, which is used as a pigment, catalyst, for the construction of electronic devices, etc., was described in the study.³⁷⁰ It was noted that the nanoparticles thus formed have a high mechanical strength and low sintering temperatures.

High-temperature chemical reactors, in which materials are oxidised under an oxygen atmosphere and conditions are provided for the generation of ultradispersed particles, are characterised by high performance and relative simplicity. The scheme was elaborated for the production of ultradispersed powders (with particle sizes of $< 100 \text{ nm}$) of titanium oxide.³⁷¹ Experimental investigations of metal evaporation under the action of electrical pulses followed by the formation of ultradispersed metallic powders in a medium of various gases at different temperatures and pressures were carried out in Russia as early as the 1960s. The results of these studies were analysed in the review.³⁷² It was noted that the nucleation processes depend on the nature of the gas and the total pressure.

Advances in the new line of research, viz., nanochemistry, demonstrated that the classical equations of chemical kinetics are inapplicable to nanosized particles. The excess energy of surface atoms whose percentage with respect to internal atoms is high has a substantial effect on the temperature of phase transitions in nanoparticles. If their sizes are comparable, for example, to the radius of delocalisation of charge carriers, nonlinear optical and electrical phenomena take place. This fact gives rise to the development of new original methods for the preparation of nanoparticles.

It was proposed to prepare nanoparticles by metal evaporation in a static diffusion chamber under the action of pulse laser radiation.^{373–375} The desired compound is formed by the chemical reaction of heated metal atoms with a gas reagent (for example,

[‡] The monograph by N A Fuks 'The Mechanics of Aerosols' (Moscow: Academy of Sciences of the USSR, 1955), which the author wrote in Stalin's camps, is still extensively cited. The contribution of N A Fuks to the development of the science of aerosols was recognised by establishing the prize in his memory. This prize is awarded at International Conferences on Problems of Aerosols.

O₂, N₂, NH₃, *etc.*) in a medium of an inert gas (Ne or Ar) at a pressure of 1–0.01 Torr. The molecules thus formed and the unconsumed metal atoms deposit on the cold upper surface of a diffusion chamber. By varying the gas composition, temperature gradient and laser pulse power, one can control the chemical composition and size of nanoclusters.

The size of a nanocluster influences, for example, the gap width in semiconductors,³⁷⁶ which, in turn, has a strong effect on the rate of luminescence quenching. It was noted³⁷⁷ that the rate of luminescence quenching by oxygen molecules depends on the size of light-irradiated MoS₂ nanoparticles. Therefore, nanoparticles can influence redox processes, which is of importance for solving a number of practical problems. Examples of such a 'size' influence on the gap width, in particular, upon photoreduction of methyl viologen on nanoparticle surfaces of metal chalcogenides can be cited.^{378, 379} The use of nanoparticles in photocatalysis opens up considerable possibilities. Metals deposited onto nanoparticle surfaces can serve as catalysts. For instance, platinum deposited onto TiO₂ nanoparticles catalyses the liberation of hydrogen from water.³⁸⁰

The kinetics of formation of a metal-polymer material was studied.³⁸¹ Metal polymers are composite materials whose properties depend on the composition and size of dispersed particles distributed in a polymer matrix. The widely used methods for their preparation were surveyed in the publications.^{382, 383} The simplified scheme of the thermal synthesis involves three steps, *viz.*, decomposition of a metal-containing compound, the nucleus growth of a metal phase and the formation of a volatile compound, which is then removed from the reaction zone. Real processes occurring in the course of formation of a composite are much more complicated.

Industrial technologies are devised using numerical simulation of the kinetics of growth of metal clusters. The reaction space is divided into cubic cells in which only one nucleus can form. It is assumed that the appearance of a new phase results from homogeneous nucleation. The probability of nucleus formation is calculated within the framework of the classical theory.³⁸⁴ Nuclei grow due to diffusion of the substance from the bulk of the solution to the phase formed. It is believed that nuclei do not decompose and do not migrate due to high viscosity of polymer melts. Two models of the substance exchange between the adjacent cells were considered. In a model with stirring, a change in the concentration in one cell leads to instantaneous changes in the concentrations in other cells. In a model without stirring, the substance exchange between the adjacent cells takes place. In the latter case, the average particle size first increases with time and then remains virtually constant. The number of particles also sharply increases until the nucleation rate reaches a maximum after which it ceases to change. In a system with stirring, larger particles are formed, but their number is smaller than that observed in a system without stirring. The calculated size distributions of particles are in agreement with experimental values.³⁸⁵ If a reagent is added dropwise, a model with stirring is characterised by a polymodal distribution. In the absence of stirring, the modes overlap.

Nucleation processes are used for the preparation of metallic ultradispersed powders serving as catalysts. Studies of such catalysts contribute to the development of scientific fundamentals of catalysis and corresponding technologies. For example, the use of ultradispersed powders, which are prepared using an electrical explosion of conductors, instead of usual silver powders made it possible to extend substantially the temperature range of selective oxidation of ethanol to acetaldehyde.³⁸⁶ It appeared that ultradispersed metals are essentially non-equilibrium systems whose relaxation gives rise to particles of the same type exhibiting high catalytic activity.

Van der Waals interactions play a decisive role in the formation of such compounds.³⁸⁷ In the mid-1930s, Nikitin formulated the analogy rule: 'If two substances have similar van der Waals forces and their molecules are similar in size and shape, they

should form analogous compounds with a third substance, and the resulting compounds should exhibit similar stability and can form mixed crystals with each other'. Nikitin has forestalled one of the main concepts of supramolecular chemistry, *viz.*, spatial complementarity, and its decisive role in the formation of supramolecular compounds.

A radically new organisation of a chemical material at a higher level has been discovered and described.³⁸⁸ In this case, the compatibility of sizes and shapes of one type of molecule, the so-called guests, with the cavities of the framework consisting of molecules of another type, the so-called hosts (or a cavity of another larger host molecule), rather than their reactivities plays a decisive role in the formation of particular compounds from components. This principle of organisation of compounds allows one to combine coordinatively saturated molecules, which are not involved in chemical interactions with each other, into supramolecules or supramolecular crystalline phases, which are thermodynamically more stable than mixtures of the starting components. From the viewpoint of traditional chemistry, it is difficult to imagine that compounds of different chemical nature, such as Xe, SO₂, H₂S, HBr, CH₄, CO, HCOOH, *etc.*, can react in a similar way, for instance, with hydroquinone to form isostructural clathrate compounds. However, these compounds are analogous from the viewpoint of clathrate chemistry. At the same time, of two chemical analogues, *viz.*, CH₃OH and C₂H₅OH, only methanol forms a clathrate with hydroquinone because the ethanol molecule is too large to be located in the cavity of the hydroquinone framework.

The main concepts of clathrate chemistry stated by Powell³⁸⁸ stimulated studies in this field and gave impetus to a target search for supramolecular substances. A number of discoveries were made. Statistical thermodynamic studies of clathrates^{389, 390} provided an explanation why the initial components can be combined to form a thermodynamically stable phase in the case of the absence of chemical valence bonds between the molecules.

The French chemist Lehn has emphasised an important role of nonbonded interactions in the formation of such compounds.[§] He introduced a new concept 'supramolecular chemistry', which he defined as the 'chemistry beyond the molecule', the 'chemistry of molecular ensembles and intermolecular bonds'.^{391, 392}

The discovery of clathrate-forming metal complexes gave rise to the preparation of numerous new compounds and offered inexhaustible possibilities for the rapid and target construction or modification of host molecules. The discovery of supramolecular compounds made it possible to reveal yet another mechanism of nucleus formation of a new phase. This mechanism is thermodynamically favourable to an extent that it enables one to solve a complex problem of preparing high-purity gases (gaseous hydrates were recognised as a new class of impurities in high-purity gases and gas mixtures).³⁹³

In 1970, deposits of methane hydrates were discovered in Yakutiya,³⁹⁴ after which it was found that huge deposits of fossil methane are available in the world. Presumably, methane will be the main fuel in the future. However, safe conditions of its recovery is a limiting factor. This problem is directly associated with nucleation. Actually, the equilibrium of methane hydrate can be easily disturbed after drilling operations. Upon decompression, methane hydrate becomes unstable and decomposes to eliminate methane, which can give rise to a substantial volume of metastable water ice. Since the thermodynamic potential of the metastable state is higher than the corresponding potential of the stable state, relaxation can assume a character of explosion in the case of a large volume of ice, and the energy of such an explosion can be higher than the energy of a powerful hydrogen bomb.³⁹⁵ The frequencies of the 'boiling' of methane hydrates remain to be studied. The seemingly special problem of estimating the rates of

§ In 1987, J-M Lehn (France), C J Pedersen and D J Cram (USA) were awarded the Nobel Prize in Chemistry.

formation of gas bubbles in gas-hydrate systems becomes one of the key current problems. The possible schemes of experimental investigations of the frequencies of gas nucleation in metastable gas hydrates were analysed in the publication.³⁹⁵

Intercalation compounds of graphite and fullerene belong to an important class of clathrates.³⁹⁶ The specific chemical and physical properties of intercalation compounds offer considerable possibilities for their use in different fields among which heterogeneous catalysis and electrochemistry are of the most importance. These compounds are also used in analytical chemistry and pharmacology.

* * *

Theoretical methods for studying nucleation have some fundamental limitations. Hence, experimental investigations are of great importance, because they provide information, which cannot be obtained by theoretical methods. By analogy with classical mechanics, it can be stated that the classical stage of nucleation theory has come to an end. However, in the nucleation theory there are no analogues equivalent to quantum mechanics.

The present-day situation can be characterised as 'pre-revolutionary' when the stage was set for the development of a semi-empirical nucleation theory because all drawbacks of the theory become increasingly evident, nucleation models become increasingly complicated and theorists have high skills. However, a new key idea is required, whose appearance can be facilitated by an original experiment in combination with a critical review of the axiomatic concepts of the theory. One of the steps involves a semiempirical method for the construction of nucleation rate surfaces. Actually, this seemingly simple approach based on the use of phase equilibrium diagrams enables one to determine the topology of the nucleation rate surfaces in the zero limit. This is already sufficient for revision of certain approximations employed in experiments and particular axioms of the nucleation theory.

I acknowledge Academicians I I Moiseev and V N Parmon for helpful discussion, encouragement and valuable advice.

IV. The use of neural network algorithms for elucidating structure – property relationships	647

Abstract. The published data devoted to the use of the neural network approach in the simulation of structure – property relationships for organic compounds are reviewed. The basic principles of the neural network simulation are discussed along with the characteristic features of the neural network approach typical of the representation and classification of structural chemical data. Brief information on neural network models of spectral characteristics, reactivities, physicochemical properties and biological activities of organic compounds is presented. The bibliography includes 159 references.

I. Introduction

The use of computer technologies in virtually all branches of science has really acquired a mass character in the past decade. The wealth of experimental data accumulated by now makes it possible to focus specific attention on the methods for generalisation and mathematical processing of diverse parameters of known compounds aimed at the computer simulation and forecasting of properties of novel compounds that have not been synthesised nor investigated hitherto. This, in turn, opens up broad opportunities for the solution of one of the central tasks of chemical science, *viz.*, a purposeful search for novel compounds and materials with predetermined properties.

Artificial neural networks have become one of the most popular methods for the construction of various quantitative relationships. The methodology of artificial neural networks, which enables the construction of nonlinear models of any degree of complexity, has found wide application in a search for quantitative relationships between structures of organic compounds and their physicochemical properties (QSPR) or biological activities (QSAR).

Among the known architectures of neural networks used for elucidating structure – property relationships (hereinafter, the term ‘property’ relates to both physicochemical properties and biological activities of organic compounds), multilayered feedforward backpropagation neural networks come first in popularity. Their attractiveness is mostly due to the ability of such neural networks to generalise and approximate data with high accuracy and to the possibility of processing large arrays of disembodied data.

A search for neural network structure – property relationships may be reduced to sequential execution of the following operations: (1) description of structures of compounds under study by special numerical parameters (descriptors); (2) choice of an optimum set of descriptors; (3) classification of the whole set of experimental data into training and control samples; (4) selection of the most adequate type, architecture and the method for training of the neural network; (5) choice of statistic parameters for estimating the quality of training; (6) training of neural networks and estimation of training results; (7) the use of neural network models for forecasting the properties and activities of hitherto unknown compounds.

The first publications devoted to the application of neural networks (perceptrons) to the solution of various chemical problems appeared in the late 1980's.¹ The interest of chemists in the new method has begun to increase sweepingly since that time.

Neural networks, commonly referred to as artificial neural networks or computing neural networks, represent a simplified mathematical model for information processing by the human brain. However, the majority of existing architectures of neural networks cannot reproduce brain functions exactly and should be considered as a modification of parallel algorithms.^{2,3}

Owing to their ability for being trained, combining and generalising information, neural networks have been successfully used in chemistry, especially in those cases where the analytical types of relationships between the structures and properties of chemical compounds are unknown.⁴

II. Basic principles of neural network simulation

1. Description of architectures and methods for training of neural networks used for elucidating structure – property relationships

Neural networks consist, as a rule, of a set of relatively simple computing elements termed neurons; the latter are arranged in several layers and are linked to one another by numerous connections. The layers are usually subdivided into three groups, *viz.*, input, hidden and output (Fig. 1). Each connection between two neurons is defined by a real number termed connection

Figure 1. The structure of a feedforward neural network. The enlarged fragment depicts the main computational operations performed by the neuron with a sigmoidal transfer function. Desc is descriptor.

weight. The sum of connection weighting coefficients of interneuronal bonds determines the computational capabilities of neural networks; therefore, training of neural networks is reduced to the adjustment of their connection weighting coefficients.

The computations within each i th neuron of the n th layer are performed in two steps (see Fig. 1), *viz.*, computation of the net input signal Net_j by summation of all weighted input signals and computation of the output signal Out_j of this neuron on the basis of the transfer function:

$$Net_j = \sum_i w_{ij} Out_i + \theta_j,$$

$$Out_j = f(Net_j),$$

where Net_j is the net input signal of the neuron j pertaining to the layer n ; Out_i is the output signal of the neuron i pertaining to the layer $n-1$; w_{ij} is the weighting coefficient of the connection between the neurons i and j ; θ_j is the threshold value for the neuron j ; and Out_j is the output signal of the neuron j in the layer n .

The sigmoidal functions (1) are used most commonly as transfer functions, but threshold (2), linear (3), hyperbolic tangential (4) and some other functions can also be used.^{5,6}

$$Out_j = \frac{1}{1 + e^{-Net_j}}, \quad (1)$$

$$Out_j = \begin{cases} 0, & Net_j < 0 \\ 1, & Net_j \geq 0, \end{cases} \quad (2)$$

$$Out_j = k Net_j \quad (k = \text{const}), \quad (3)$$

$$Out_j = \frac{e^{Net_j} - e^{-Net_j}}{e^{Net_j} + e^{-Net_j}}. \quad (4)$$

The so-called bias pseudoneurons² with a constant output signal equal to 1 are usually added to each (except for the output layer) layer of a neural network instead of the threshold values θ .

Prior to training, all connection weights are initialised by random numbers. A correct choice of initialisation boundaries enables reduction of the training time and improvement of the quality of the neural network models derived.^{7,8} In some cases, where the training procedures (*i.e.*, the adjustment of connection weights) do not converge, the training is repeated using another set of parameters or a different mode of initialisation of connection weights.

The architecture of a neural network is determined by the connection topology between the neurons. Simulation of structure–property relationships usually employs multilayered neural networks the number of layers in which is determined by a specific architecture of the neural network.^{2,9} Each neuron pertaining to one layer has the same number of input connections with the preceding layer. The output signals of the last computing layer of the network represent computed output values of the whole network. When neural networks are used for forecasting the properties of chemical compounds, the values of output signals of the input neurons are set up with regard for the values of computed descriptors after normalisation (see below); the signals identified with the values of predicted properties (also, taking normalisation into account) are read from the output neurons.

a. Multilayered feedforward neural networks

The majority of publications devoted to the elucidation of structure–property relationships deal with multilayered feedforward neural networks. The main advantages of such networks include their ability to establish multiparametric nonlinear relationships with a high interpolation accuracy even in those cases where experimental data are not representative enough or contain noises.¹⁰

A characteristic feature of feedforward neural networks is a layer-by-layer transfer of signals from the input of the network to its output. Classical feedforward neural networks usually possess several hidden layers (Fig. 2a) or contain exclusively an input and an output layer (Fig. 2b).

The adjustment of weighting coefficients of the connections during training of multilayered feedforward neural networks is carried out sequentially starting from the output layer connections; therefore, the methodology of training of such networks has got the name of back propagation of errors.^{11,12} A brief description of the most popular procedures is given below.

Figure 2. The classical feedforward neural networks with one hidden layer (a) and without any hidden layers (b).

b. A generalised delta rule

Training of each layer n out of N layers of a neural network is carried out in accordance with the Widrow–Hoff rule or the delta rule:^{13, 14}

$$\Delta w_{ij} = \eta \delta_j o_i,$$

where Δw_{ij} is the change in the weighting coefficient of the connection between the neurons i and j ; η is the empirical constant for the training rate; δ_j is the computational error for the neuron j pertaining to the layer n and o_i is the output signal of the neuron i pertaining to the layer $n - 1$.

In the case of a generalised delta rule, an additional parameter termed a ‘training momentum’ and calculated with consideration of changes in the weighting coefficients in the previous iteration is introduced in order to avoid oscillations which often take place where error surface is characterised by a very narrow valley region:^{13–15}

$$\Delta w_{ij}^{(k+1)} = \eta \delta_j o_i + \alpha \Delta w_{ij}^{(k)},$$

$$\delta_j = \begin{cases} f'(\text{Net}_j)(t_j - o_j), & n = N \\ f'(\text{Net}_j) \sum_m \delta_m w_{jm}, & n \neq N, \end{cases}$$

where t_j and o_j are the experimental and the calculated values of the property under investigation for the neuron j , respectively; α is the constant reflecting the influence of the training momentum and k is the iteration number.

c. The resilient propagation method (RPROP)

If the training is performed with the use of RPROP, the adjustment of connection weighting coefficients is performed exclusively on the basis of the data about the signs of partial derivatives of error functions of the neural network E usually defined as a sum of squared errors on the output neurons.^{16, 17} The changes in the connection weighting coefficients are calculated in the following way:

$$\Delta w_{ij}^{(t)} = \begin{cases} -\Delta_{ij}^{(t)}, & \text{if } \frac{\partial E^{(t)}}{\partial w_{ij}} > 0 \\ +\Delta_{ij}^{(t)}, & \text{if } \frac{\partial E^{(t)}}{\partial w_{ij}} < 0 \\ \frac{\partial E^{(t)}}{\partial w_{ij}} = 0, \end{cases}$$

$$\Delta_{ij}^{(t)} = \begin{cases} \eta^+ \cdot \Delta_{ij}^{(t-1)}, & \text{if } \frac{\partial E^{(t-1)}}{\partial w_{ij}} \cdot \frac{\partial E^{(t)}}{\partial w_{ij}} > 0 \\ \eta^- \cdot \Delta_{ij}^{(t-1)}, & \text{if } \frac{\partial E^{(t-1)}}{\partial w_{ij}} \cdot \frac{\partial E^{(t)}}{\partial w_{ij}} < 0 \\ \frac{\partial E^{(t-1)}}{\partial w_{ij}} \cdot \frac{\partial E^{(t)}}{\partial w_{ij}} = 0. \end{cases}$$

Here, $\frac{\partial E^{(t)}}{\partial w_{ij}}$ is the value of the partial derivative of the error

function of the neural network with respect to the connection weight w_{ij} in the i th iteration, η^+ and η^- are the empirical constants for the increase or decrease in the training rate and t is the iteration number.

d. Quasi-Newtonian training methods

This group of methods is based on the Newtonian principle of function fitting. A vector all the components of which are taken equal to the partial derivatives of the error function of the network with respect to all weighting coefficients is calculated for each iteration. The Broyden–Fletcher–Goldfarb–Shanno (BFGS) method is the most efficient in this group.^{14, 18}

2. Other neural network architectures

Neural networks having different architectures are successfully used for the simulation of structure–property relationships. A brief description of some of these architectures is given below.

Feedforward neural networks containing at least one hidden layer may possess additional direct connections linking the neurons of the input and output layers^{19–21} as well as recursive bonds between the output and the input of a neuron.^{21, 22}

Kvasnicka *et al.*^{23, 24} have proposed the use of a tree-shaped neural network for the solution of problems related to classification of compounds; the topology of such a network was the most close to the molecular structures under investigation. The values 0 or 1 were ascribed to the input neurons so as to obtain subgraphs isomorphous to the structures of the molecules. Later, a similar approach was realised in the computer programme ‘ChemNet’.²⁵

An interesting neural network procedure for the description of chemical compounds has been proposed, which allows elucidation of structure–property relationships without computation of descriptors for molecules as a whole using only atom and bond descriptors.^{26, 27} In this method, the presentation of structures is effected through the use of an additional neural network which consists of two principal elements, *viz.*, a sensorial area to which the basic structural information is fed and an ‘eye’ which transforms the data from the sensorial area into a signal invariant to the renumbering of the atoms in compounds under study. The structural information thus processed is fed to the input of ordinary feedforward neural networks in order to obtain structure–property relationships.

The Kohonen neural networks (see Refs 28–32) (Fig. 3a) widely employed in cluster analysis allow data mapping in such a way that similar vectors of input values are mapped onto neighbouring output neurons on the lattice.

Counterpropagation neural networks^{33, 34} utilise two different types of layers, *viz.*, a hidden Kohonen layer and an output Grossberg layer (Fig. 3b). The salient advantages of networks trained by counterpropagation include a relatively small (of the order of several hundreds) number of interactions required for the training of networks^{35, 36} and the possibility of finding a global minimum of the error function for any starting setup of the weighting coefficients.^{37, 38} One disadvantage is a weaker approximating capacity of such networks in comparison with other architectures.

A neural network with a linear transfer function for the output-layer neurons and hidden neurons which accomplish radial-basis nonlinear approximation is usually referred to as a radial-basis neural network. This is also used for elucidating structure–property relationships.^{39–41}

The functioning of Fuzzy ARTMAP (Fuzzy Adaptive Resonance Theory for Mapping) neural networks is based on clusterisation (categorisation) of training set vectors in accordance with the adaptive resonance theory (see Ref. 42 and References cited therein). In this method, categorisation of vectors is performed by comparing each successive vector to reference vectors describing previously established categories (clusters). If a successive vector ‘resembles’ a reference vector in terms of a definite proximity criterion, it is used for its adjustment. In the opposite case, a vector becomes a representative of a new data category and is memorised as a new reference vector. This procedure is implemented in a neural network consisting of a reference layer, which estimates the ‘similarity’ of the vectors, a recognising layer where each neuron describes its own data category (cluster) and several accessory elements. Such architectures have been termed ART-1 (categorisation of binary vectors) and ART-2 (categorisation of real number vectors). ARTMAP represents a modular neural network made up of two networks for categorisation of vectors of the ART type (in QSAR/QSPR studies, these vectors are linked to the vectors corresponding to descriptors and properties of organic compounds) and a comparison module responsible for memorisation of ‘associations’ between different categories of descriptors and properties.

Figure 3. A schematic representation of architectures of some neural networks used for the simulation of structure–property relationships. (a) The Kohonen neural network, (b) back propagation neural network, (c) cascade-type neural network.

A neural network of functional links⁴³ is made up of two layers. The outputs of the neurons forming the input layer result from nonlinear transformations (e.g., squaring, taking a square root, a sinus, *etc.*) of the values of a descriptor; each neuron in the output layer corresponds to a predicted property. It is of note that this category represents a neural network simulation of a linear regression analysis based on the use of nonlinearly transformed descriptors and properties.

Sometimes, in the simulation of structure–property relationships several neural networks having different architectures are combined into a hierarchical system.^{21, 44}

Alongside neural networks with static architectures (which have to be selected prior to training) there are the so-called cascade networks (Fig. 3 c); their topology is formed during training.^{45–47} The training is begun with a neural network containing exclusively input and output neurons. If the error of the neural network exceeds the threshold value, one hidden neuron which accumulates signals from all input and previously added hidden neurons is added after each training cycle. It may therefore be assumed that each hidden neuron forms a separate layer. After addition of a successive hidden neuron, the weights of its connections are determined only once to enable maximisation of covariation of values of output signals with the error and do not change any further in the course of training. As far as the output neurons are concerned, the weights of their connections have to be adjusted every time in order to diminish the error function of the network.

III. Approaches to structural description of compounds

The first question arising in connection with the application of neural networks, especially in the solution of various chemical problems, is related to the choice of a method for the description of source data.

The combination of parameters fed to the input of a neural network is usually presented in the form of a vector. Therefore, a topological or a three-dimensional molecular structure has to be described as a unidimensional array without considerable losses of significant information. The following conditions should be met:³⁶

- (1) the quantity and the type of descriptors are the same for all the structures to be described;
- (2) there is a correspondence between each descriptor and a particular component in a parameter vector;
- (3) different parameter vectors correspond to different molecules.

As a rule, neural network simulation of structure–property relationships utilises a set of numeric values (descriptors)⁴⁸ for the description of structures of chemical compounds containing all relevant information. According to the type of information, all descriptors are subdivided into fragmental,⁴⁹ topological,^{50, 51} quantum-chemical⁵² and physicochemical. All of them demand additional computation prior to construction of neural network models. Moreover, one should have a clear idea about the nature of a relationship in order to select an appropriate group and a type of descriptors for each concrete case.

In the majority of studies devoted to neural network simulation of structure–property relationships, descriptors are computed with the aid of various software packages, e.g., ADAPT.^{53–55} This usually results in an excessive set of descriptors; the most significant ones are selected for further analysis using various procedures. Sometimes, it is rather difficult to explain the physical sense of the descriptors selected and to establish their relationship to the property under investigation.

The first attempts to use a well-known procedure for the presentation of chemical structures as modified connectivity matrices with charges on nuclei of the corresponding atoms on their diagonals and formal bond orders as non-diagonal elements were undertaken by Elrod *et al.*⁵⁶ It was proposed to form input vectors for neural networks by combining the diagonals of the connectivity matrices with subdiagonal elements taken row-by-row. These authors recommended using two connectivity matrices (one for reactants and one for reaction products) for the description of chemical reactions.⁵⁷ Evidently, the use of this approach is confined to compounds containing a small number of atoms due to a great number of elements in the connectivity matrix. In addition, such a presentation of structures is not invariant with respect to the renumbering of atoms.

The classical approach to the construction of quantitative structure–property relationships is used for the description of a series of structural analogues using substituent constants, *e.g.*, Hammett σ constants, Taft's E_s constants, lipophilic constants π , parameters L , B_1 , B_2 (STERIMOL), *etc.* However, if structures contain topologically equivalent substitution positions, the use of these parameters is not quite correct. For example, the pyridine molecule contains two pairs of topologically equivalent positions of substituents, *viz.*, the α -position for R^2 and R^6 and the β -position for R^3 and R^5 . As a consequence, the same compound will be represented by different sets of descriptors based on the use of different parameters of substituents, which may result in ambiguous prognosis.

This problem may be overcome through the introduction into the source set of copies of compounds with different arrangements of substituents in topologically equivalent positions,⁵⁸ possessing the same activities as the starting compound. Such an enlargement of the source sample makes prognosis independent in cases of ambiguous assignment of substituents to topologically equivalent positions.

An interesting method has been proposed which enables one to reduce the number of input parameters of neural networks without any loss of significant information.⁵⁹ This approach is based on the computation of the principal components⁶⁰ which represent linear combinations of original descriptors. The values thus obtained are further used as the input parameters of neural networks.

1. Normalisation of input parameters of neural networks

Almost all publications devoted to the use of neural networks for the solution of various chemical problems describe normalisation of input data. As a rule, input parameters are normalised in such a way that their values lie in the range between 0 and 1 or are characterised by unit variance.

2. Selection of the most significant descriptors

Of no less importance is the selection, among all computed parameters, of only those parameters which make a significant contribution to the property under study. Such a selection can be made in advance or in the course of training of neural networks.

Preliminary selection of parameters is performed using independent methods, *e.g.*, stepwise multiple regression analysis,^{61, 62} or neural network algorithms.⁶³ In the latter case, the type of neural network used for the selection of descriptors does not usually coincide with the type of main neural network used for the construction of the model.

A neural network utilising a 'genetic' training algorithm can serve as an example.^{64–66} The 'genetic' algorithm represents a stochastic optimisation procedure based on evolutionary principles. Its operation ensures the selection of a description with the most significant parameters from the whole set of object descriptions over the course of several generations. The significance of parameters, *i.e.*, the success of genetic combinations, is defined by a criterion function computed by a neural network as a residual error for the property under investigation. Diverse methods for the production of a new generation within the framework of a 'genetic' algorithm have been described. Approximation of the genetic function⁶⁷ and evolutionary programming⁶⁸ are the most popular.

Brinn *et al.*⁶⁹ have recommended using the so-called evolutionary approximation for the rejection of insignificant descriptors. Some descriptors randomly selected from a multitude of computed descriptors are fed to the input of a neural network after which the root-mean-square error is computed at the output of the

network. Then, one of the input neurons is excluded from the neural network and the new root-mean-square error is recalculated. This procedure is repeated for all neurons. The descriptors are scored according to the magnitude of the change in the error at the output of the neural network. The neurons are then removed from the neural network starting from the least significant descriptors until the change in the error at the output of the network becomes significant. After replacement of discarded descriptors by new ones taken from the set of computed descriptors, the calculations are repeated.

In the course of training of neural networks, less significant descriptors can be discarded using the so-called pruning algorithms. Their main function consists of simplification of neural network architectures by discarding the connections with less significant weighting coefficients. If all the connections of input neurons are insignificant, these neurons are discarded.^{70, 71} Pruning procedures can be classified into two groups,⁷² *viz.*, sensitivity methods based on computation of significance or sensitivity of all connections followed by elimination of the connections with the least sensitivity, and 'penalty component methods' based on the introduction of the so-called penalty functions which reduce weighting coefficients to zero values in the course of training.

Tetko *et al.*⁷³ have provided a detailed description of five methods designed for the computation of connection sensitivities. A method for the selection of the most significant descriptors based on the calculation of sensitivities of connections and the contribution of each descriptor to the total error of the neural network has been developed.^{74, 75}

A reconstructive method based on the forgetting principle, *i.e.*, a sequential decrease in the absolute values of all weighting coefficients, has been developed.⁷⁶ Reiteration of training–forgetting cycles enables enhancement of significant or weakening of less significant connections.

The degeneration algorithm of weighting coefficients is yet another example of a procedure based on penalty functions.^{13, 20} In each training step, the values of calculated weighting coefficients of the connections diminish by a fraction of their previous values as a result of which insignificant weighting coefficients decrease to 0 in the course of training.

3. Choice of an optimum training set

The design of training samples is yet another problem related to the application of neural networks in chemistry. Chemical compounds constituting a training set should be evenly distributed along the whole range of possible values of input parameters.

The majority of published data deal with random division of the whole array of compounds under investigation into training and control sets, but only some of them provide a description of special procedures for the selection of an optimum training set. The use of Kohonen neural networks has been described in Refs 35, 77, 78; a neural network based on the theory of adaptive resonance (ART 2-A, see above) and intended for preliminary classification of the whole set of experimental data has been described.⁷⁹ The choice of a correct size of training set is yet another critical factor.

4. Optimisation of the number of hidden neurons

The number of adjustable parameters (weighting coefficients) of neural networks is determined by the number of hidden neurons. If the number of hidden neurons is too large and the number of adjustable parameters is comparable with the number of structures in the training set, the neural networks will try to 'memorise' the training set (the over-determination effect). Neural networks with an insignificant number of hidden neurons are unable to utilise the whole array of input information for generalisation and classification.^{80, 81}

The expediency of the introduction of a special parameter r for the estimation of an optimum number of hidden neurons has been demonstrated.^{82–84}

$$r = \frac{N}{P},$$

where N is the number of molecules in the training set and P is the total number of connections in the neural network.

The optimum values of this parameter lie in the range $1.8 < r < 2.2$. The number of hidden neurons thus calculated enables the construction of neural networks manifesting the best forecasting ability.⁸⁰

5. Effect of 'overtraining' of neural networks

The overdetermination of a model (see above) leads to the so-called 'overtraining' of neural networks.^{85–87}

The training of neural networks includes two phases, *viz.*, generalisation and memorisation of information. The first phase is characterised by a decrease in the mean computational error of the property under study for compounds in both training and control sets. However, in the next phase, memorisation, the error calculated for the control set increases in parallel with a constantly decreasing error of the training set. As a consequence, completely trained neural networks can reliably forecast the properties of only those compounds which are included in the training set; for other compounds, the quality of forecasting is much worse. This effect is especially pronounced when the first phase of neural network training is either short-lasting or absent. 'Overtraining' can be avoided by reducing the number of adjustable parameters of a neural network model either actual (by decreasing the number of input parameters of the neural network) or effective⁸⁶ (by 'regularisation', *e.g.*, Bayesian regularisation^{88,89}).

Early termination of training of neural networks at the moment of phase changes is yet another popular procedure. In the majority of publications, the forecasting ability of neural networks was estimated using the same control set as that used in previous studies for establishing the starting point for 'overtraining'. However, in this case the error can be underestimated (see Ref. 90).

6. Analysis of activities of hidden neurons

An analysis of results obtained with a three-layered neural network used for the simulation of structure–property relationships has shown that hidden neurons can be used for cluster analysis of starting compounds.

Kvasnicka *et al.*⁹¹ have carried out a recurrent cluster analysis aimed at classification of functional groups. Each functional group was represented as an output vector of hidden neurons which was normalised for all compounds under investigation using standard statistical methods.

An analysis of activities of hidden neurons of a three-layered associative neural network aimed at classification of data from the training set was used for the determination of the content of eight fatty acids in samples of olive oil produced in nine different regions of Italy.³¹ The use of this approach has made it possible to obtain a more precise, in comparison with the Kohonen neural network, classification of samples with respect to oil-producing regions.

7. Analysis of derived neural network relationships

The need for reliable interpretation of derived models consistent with the data available from the corresponding branches of chemistry, physics or biology is an extremely important aspect which determines the application of virtually all statistical methods including neural networks to the construction of structure–property models in chemistry (particularly those based on the use of physicochemical and quantum-chemical descriptors). Very often, it is this interpretation that represents the most weighty argument in favour of the validity of the constructed model. The impossibility of establishing clear-cut relationships between the properties under study and the input parameters of neural networks, *viz.*, the presentation of a neural network as a 'black box',

is still the main argument against the application of neural networks to the solution of various chemical problems.

The majority of papers do not provide any interpretation of neural network models; however, the possibility of analysis of neural network relationships has been demonstrated^{92,93} as well as that of estimation of contributions of input parameters to neural network models in neural networks with one output neuron based on analytical formulas for the calculation of partial derivatives of neural network functions.^{94–96} It was recommended to supplement a standard sigmoidal transfer function with a parameter b which reflects the degree of mixing of linear and nonlinear functions.

$$\text{Out}_j = \frac{\beta}{(1 + e^{-\alpha \text{Net}_j})} + (1 - b)\text{Net}_j,$$

where Out_j is the output signal of the neuron j ; Net_j is the net input signal of the neuron j ; α and β are the coefficients.

The use of specially computed statistical parameters which characterise the function of a trained neural network has been proposed.⁹⁷ These parameters allow interpretation of neural network models by conventional methods similar to those used for the interpretation of linear regression models. Indeed, the significance of one or another parameter of a linear regression equation is determined by the value and sign of the corresponding numerical coefficient which, in turn, is equal to the value of a partial derivative of the regression function with respect to this particular parameter. The coefficients are calculated on the whole set of experimental data in the course of regression analysis. A similar interpretation of neural network models demands computation of partial derivatives of properties under study on all examples in succession from the training set for all descriptors. This approach enables computation of a set of statistical functions which allows estimation of the contribution of all original descriptors to the derived neural network models.

8. Choice of a function for estimating computational errors

The derived neural network models are usually estimated on the basis of standard statistical functions by calculation of, *e.g.*, root-mean-square errors,^{61,98} correlation coefficients,^{36,99} recognition coefficients,^{43,100} *etc.*

The forecasting ability of neural network models is often estimated using a cross-validation procedure (see, *e.g.*, Refs 35, 82, 101).

9. Comparison of a neural network algorithm with standard statistical methods used for information processing

In many cases, conclusions on the adequacy of the use of neural network simulation are drawn by comparing models obtained using neural network algorithms with the models obtained by other methods.

Thus the results of neural network classification of compounds are compared with the results of the hierarchical cluster analysis, analysis of the main components,³² the results of PLS (Partial Least Squares) in the framework of CoMFA (Comparative Molecular Field Analysis),⁹ chemical expert systems,⁵⁶ *etc.*

Neural network models of structure–property relationships are most frequently compared with equations obtained by the multiple linear regression method.^{77,102,103} Most authors conclude that the use of neural network methods ensures the best results in both the description of structure–property relationships and forecasting properties of novel compounds. However, a conclusion¹⁰⁴ about a poor forecasting ability of neural networks in comparison with multiple linear regression can be explained by an incorrect choice of parameters for a neural network model.

Some papers^{95,105} point to a relationship between neural network simulation and multiple regression analysis. It was shown that the results obtained with neural networks containing one hidden layer and utilising a linear transfer function for all

^a Designations as in Table 1; ^b RBA is the affinity for the receptor; ^c IC_{50} is the concentration causing 50% inhibition; ^d AZT is azidothymidine; ^e TIBO is 4,5,6,7-tetrahydroimidazo[4,5,1-*j,k*][1,4]benzodiazepin-2(1*H*)-one; ^f C is the concentration of a compound causing a certain biological response; ^g K is the inhibition constant; ^h MW is the molecular weight; ⁱ ID_{50} is the dose causing 50% inhibition; ^j TA_{98} is the number of revertants in the Ames test TA_{98} ; ^k N_{his^+} is the number of revertants in the Ames test TA_{1538} ; ^l MU are the muscarine units; ^m the initial set of compounds was supplemented with topologically equivalent structures; ⁿ without multiplication of the initial set of compounds; ^o EC_{50} is the effective concentration; ^p MIC is the minimum inhibiting concentration /mg ml^{−1}.

neurons are identical with the results obtained by multiple linear regression analysis.

If the neurons of the hidden layer of a three-layered neural network are described by a nonlinear (most commonly, sigmoidal) transfer function and the neuron of the output layer is described by a linear function, the resulting neural network (termed MR neural network) will function similarly to a nonlinear multiple regression.^{96, 106, 107}

IV. The use of neural network algorithms for elucidating structure–property relationships

The neural network approach can successfully be employed for elucidating both qualitative and quantitative structure–property relationships. Some brief information about the use of neural network models for the simulation of spectral characteristics, reactivities, physicochemical properties and biological activities of organic compounds is given in Tables 1–4.

The information contained in the IR^{99, 108} and NMR spectra^{22, 24, 44, 109–112} as well as chromatographic retention indices^{37, 102, 103, 113} is closely related to the structures of organic molecules. In the studies cited in Table 1, the neural network algorithm for processing of such information was successfully used for the solution of miscellaneous practical problems related to the search for relationships between molecular structures and spectral properties, classification and forecasting of structural data and refinement of molecular structures on the basis of spectral information.

In one pioneering study, neural network methods were used for the classification of reactions of organic compounds, viz., according to the cleaved bond type,^{2, 28} regiochemistry of the addition reaction,⁵⁷ isomer ratios,^{2, 23, 56} main reaction products,⁵⁷ etc. (Table 2). In these studies, connectivity matrices of organic compounds were used as input information for neural network models, since they do not require additional calculations at the preceding steps. Neural network methods can be used for quantitative estimation of reactivities of organic compounds and simulation of complex kinetic processes in the course of chemical transformations.

The publications devoted to the analysis of various physicochemical properties of chemical compounds using neural networks are rather numerous; the most popular characteristics of organic compounds include boiling temperature^{19, 39, 40, 42, 82, 101, 118–123} (predominantly with the use of topological indices), density,^{101, 121, 122} solubility in water,^{128–131} lipophilicity^{134–137}, etc. (Table 3).

Today, simulation of biological activities of organic compounds presents considerable practical interest: the overwhelming majority of publications devoted to the use of artificial neural networks for elucidating structure–property relationships are related to this particular area (Table 4).³¹ Some publications describe the results of successful quantitative neural network simulation of affinities of organic compounds to various receptors^{20, 145, 146} and transport proteins,^{29, 30, 99} simulation of inhibition constants of enzymes,^{20, 35, 55, 74, 75, 80, 83, 145, 147} antitumour,^{20, 38, 43, 105, 150} carcinogenic,^{36, 76, 152, 153} mutagenic^{69, 145, 154–156} and antibacterial activities,¹⁵⁹ etc.

* * *

Artificial neural networks represent a potent comprehensive computational tool for the solution of miscellaneous problems related to processing of chemical information, particularly classification and simulation of disembodied experimental data. The number of publications on the subject is increasing annually, which testifies to the unrelenting interest of chemists in the simulation of structure–property relationships using artificial neural networks.

Erratum

to the article by M V Basilevsky, M V Vener

‘Theoretical investigations of proton and hydrogen atom transfer in the condensed phase’

published in *Russian Chemical Reviews* **72** 1 – 33 (2003)

The following text should be inserted at the end of Section III.1.b, page 17.

The HAT reactions in the H + H system and its isotope analogues make an exception. There are no high curvature regions on the canonical reaction path (RP) curves for these reactions and it is just this condition that is required in order to construct a curvilinear coordinate system using a RP curve as a frame. The variational TS theory in its conventional formulation is applicable to for such systems. Their computations proved to be successful even at low temperature.^{1–4} On the other hand, special effort is needed for extending the variational approach to the HAT between heavy atomic or molecular fragments (the systems considered in Section II.3.b with a large curvature of the RP in the vicinity of the TS region). Here a significant modification of the theory is required that includes a search of tunneling trajectories avoiding the RP.^{5–7}

Abstract. The review concerns conservative and dissipative self-organisation phenomena in those physicochemical systems, whose evolution involves formation of diverse chemically complex products, including functional ceramics, supramolecular compounds, and nanocomposites as well as fractal, template and epitaxial structures. It is demonstrated that the use of nonlinear dynamics approaches facilitates organisation of the reaction zone during the synthesis of materials under nonequilibrium conditions in an optimum manner and that biomimetism and biomineralisation processes open up new prospects for materials design. The bibliography includes 308 references.

I. Introduction

Design of advanced functional and structural materials is a critically important research field.¹ Attempts at employing basic research methods in materials design have long been undertaken. It is sufficient to remind readers of an approach proposed by the author of this review nearly two decades ago; this strategy was then successfully applied to the chemistry of magnetic dielectrics and semiconductors as well as materials with ionic and electronic conduction.^{2,3} However, modern chemistry of materials is still characterised by the predominance of intuitive approaches and experimental screening techniques that underlie the combinatorial chemistry (the development of this research field is associated with the development of fast screening techniques).^{4–6}

Methods for the design of advanced materials can be conventionally divided into two groups:

— techniques involving variation of the composition of the precursor system and

— methods involving variation of processes (including synthesis) and conditions for subsequent treatment (*e.g.*, heat treatment).

Often, the role of the temporal evolution of a system during the preparation of a certain material becomes so important that one should use the *TTT* (Temperature–Time–Transition) diagrams.^{7,8} In particular, this approach has proved itself in determining the nature of changes in the critical temperature (T_c) of the neodymium/barium cuprates that are characterised by very low rate of cation ordering.

While on the subject of a material's structure, one should keep in mind different levels of structural organisation of matter, from the structure of a unit cell to the polycrystalline structure exhibiting specific defects including domain boundaries, pores and cracks (Fig. 1). At the same time, interrelations between different levels of structural organisation of a material should also not be overlooked, though this does not imply the possibility of controlling the situation. The diversity of manifestations of synergism as an effect of co-operative behaviour of certain elements (such elements exhibit a chaotic behaviour at the microlevel) of a complex system is often analysed in the framework of the nonlinear dynamics paradigm.^{9–12}

II. Nonlinear behaviour of physicochemical systems during the preparation of materials

Considering the chemical complexity of a precursor system, one should take into account the nonlinear character of the physical response. The nature of this nonlinearity is not known with certainty; it is determined by both thermodynamic and kinetic factors.^{2,3,13,14} Methods for improving the properties of a material by successively complicating its chemical composition and structure are not necessarily efficient. This can be exemplified by the dependence of the superconducting transition temperature (critical temperature) of cuprates belonging to the $\text{HgBa}_2\text{Ca}_{n-1}.\text{Cu}_n\text{O}_{2n+2+x}$ homologous series on the number of CuO_2 layers (Fig. 2).¹⁵

When preparing homogenous chemically complex products, the best precursor systems are either true or colloidal solutions, melts or gaseous mixtures with the highest possible (ideally, atomic or molecular) degree of mixing of the material-

Figure 1. Structural levels of a material (bulk ceramics).

Macroscopic level (10^{-3} – 10^{-2} m): pores, cracks, domains, ceramics; mesoscopic level (10^{-6} – 10^{-3} m): inclusions, dislocations, twins, lamellae; microscopic level (10^{-10} – 10^{-6} m): the unit cell, atomic rows, nanoscale compositional fluctuations. Ceramics is the visual appearance of a sample of the high-temperature superconductor $\text{R}\text{Ba}_2\text{Cu}_3\text{O}_x$; domains are macroscopic pseudo-single-crystal regions of the superconductor; cracks are macroscopic cracks developed as a result of thermal shock; pores are channels formed as a result of exchange of the superconductor matrix with oxygen from the gaseous atmosphere during the melting–crystallisation process; lamellae are intergrown plate-like crystallites; twins are defects formed as a result of oxidation of the superconductor; dislocations are a network of dislocations; inclusions are associated with boundaries between the particle of the normal phase (Y_2BaCuO_5) and the superconducting matrix; nanoscale compositional fluctuations are microscopic inhomogeneities of the chemical composition of the superconductor; atomic rows are the rows of atoms constituting the unit cell of the crystal along a specified direction; and the unit cell is a fragment of the crystal structure.

forming components. However, even in these cases there are basic obstacles associated with the incongruence of virtually all multi-component systems (different compositions of the coexisting phases).^{16,17} Hence one should carry out thorough studies of phase equilibria and use equilibrium or quasi-equilibrium processes. The field of application of such processes is of crucial importance but limited to the growth of perfect single crystals from solutions and melts¹⁸ and the preparation of thin films by the chemical vapour deposition technique.¹⁹

Another approach, which seems to be the simplest one, involves the use of individual oxides or salts of oxygen-containing acids as precursors. Mixtures of these compounds are transformed into the target product as a result of solid-phase reactions.¹³ For

Figure 2. Superconducting transition temperatures (critical temperatures) of cuprates $\text{HgBa}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+2+x}$ plotted vs. the number of CuO_2 layers.¹⁵

instance, magnetic ceramics based on yttrium orthoferrite are synthesised by the reaction

The small driving force of this and similar reactions ($-\Delta G_{1273\text{K}}^\circ \approx 20$ – 30 kJ mol^{−1}) and low solid-phase diffusion coefficients ($D < 10^{-12}$ cm² s^{−1}) preclude preparation of single-phase chemically complex oxides and the more so highly homogeneous products. Diffusion limitations are usually eliminated by using intermediate grinding levels (degrees of mixing) or by increasing the reaction temperature; however, both methods give rise to some additional difficulties. These are uncontrollable contamination of the product with particles of the abraded container in the former case and evaporation of the most readily volatile oxide components (*e.g.*, ZnO and alkali metal hydroxides), dissociation of readily reducible oxides (CuO , Fe_2O_3) and formation of non-stoichiometric (first of all, with respect to oxygen) complex phases of uncontrollable composition in the latter case.²⁰

The driving forces of solid-phase processes can be not only the chemical potential gradient, as in the case of the reaction of yttrium orthoferrite formation

$$\Delta G^\circ = \Delta \mu^\circ = \frac{1}{2} \Delta \mu_{\text{Y}_2\text{O}_3} + \frac{1}{2} \Delta \mu_{\text{Fe}_2\text{O}_3}$$

but also the temperature and pressure gradients (for oxides, the gradient of the partial pressure of oxygen is most often used), as well as the mechanical strain (in compaction and sintering of ceramic powders) or electrochemical potential gradients (in solid-phase galvanic cells). Often, these forces exhibit synergistic effects. For instance, intense sonication of heterophase systems gives rise to cavitation due to the simultaneous appearance of very large temperature and pressure gradients and mechanical strain.²¹

Nonequilibrium processes can occur in both isolated (or closed) and open systems, which differ from one another in character of response to external conditions and in evolution pattern. For any system, the total change in entropy can be written as the sum

$$dS = d_e S + d_i S,$$

where $d_e S$ is the entropy change due to exchange with the environment and $d_i S$ is the entropy change within the system under study (for the nonequilibrium state, this term is always positive).

For an isolated system (no exchange of matter and energy with the environment), one has $d_e S = 0$ and $dS = d_i S > 0$. Hence, the spontaneity of a process in the isolated system is governed by the trend towards an increase in the system's entropy, which reaches

its maximum value in the equilibrium state. In other words, the evolution of an isolated system causes the disappearance of the reasons that gave rise to the evolution.

Irreversible processes in isolated systems include mixing, interdiffusion (in the case of, *e.g.*, diffusion welding) and poisoning of ultrapure substances. Strictly speaking, perfectly isolated systems are a kind of idealisation, so we can deal with a certain extent of approximation in such systems.

If isolated systems can exchange energy with the environment (no mass transfer), the spontaneity of processes in such systems is governed by the trend towards a decrease in the Gibbs free energy

$$\Delta G = \Delta H - T\Delta S < 0.$$

For this relationship to hold, the entropy contribution, $T\Delta S$, must be larger than the enthalpy term ΔH . This means that raising the temperature of any isolated system from 0 K causes thermodynamically unavoidable defect formation processes involving different types of disordering^{22,23} and the appearance of non-stoichiometry in binary and more complex crystals with mainly ionic bonding.²⁴ Here, the source of the increase in entropy is of no concern: it can be the free surface, dislocations or point defects. Depending on particular experimental conditions, the growing crystal acquires those defects that provide a maximum increase in entropy at the lowest energy expenditure.

For instance, hematite $\alpha\text{-Fe}_2\text{O}_3$ dissociates to give a black substance, magnetite ($\text{Fe}_3\text{O}_{4+x}$), on heating to 1300 °C in air. This transformation is due to a substantial increase in entropy owing to structural (cation vacancies) and electronic disorder intrinsic in magnetite. However, the undesired dissociation can be inhibited by adding titania to hematite. The lattice of the iron titanate (or titanium ferrite) thus obtained can be so easily disordered on heating (in this case, ΔG decreases) that dissociation becomes thermodynamically unfavourable.

Being guided by their intuition, materials scientists have long employed the method of chemical and structural complication of materials in order to improve their chemical stability and mechanical strength. Based on the aforesaid, it becomes understandable why sintering of highly pure polycrystalline alumina does not result in transparent ceramics irrespective of the duration of heating. The reason is that internal pores, intercrystallite boundaries and dislocations are a source of the disorder, which provides a minimum value of the Gibbs free energy. However, transparent yttria-based ceramics were prepared by doping Y_2O_3 with zirconia and thus producing heterovalent defects (the sources of increased entropy). Doping causes formation of a structure with high concentration of point defects (the source of additional disordering).¹⁴

Taking into account the systems' trend towards a minimum Gibbs free energy and using the equivalence principle of entropy sources, it is an easy matter to understand why a perfect single crystal is thermodynamically unstable and spontaneously tends to acquire defects (formation of dislocations, adsorption of impurity atoms from the environment) on heating provided that no defect structure relevant to the operating characteristics of the material was designed artificially. Clearly, the higher the quality of a single crystal, the more pronounced its ability to spontaneously develop dislocations, form domain structures and adsorb impurity atoms.

Based on the above-mentioned considerations, one can explain such seemingly paradoxical phenomena as an increase in the rates of solid-phase reactions in the presence of a chemically inert component or a decrease in the very small thermal expansion coefficient of quartz upon doping with titania.

An abnormally large jumpwise increase in entropy is observed in some salts and salt-like systems due to a polymorphous transformation giving rise to high ionic conductivity. Noteworthy is that the entropy jump accompanying the solid-phase transformation is comparable with and sometimes greater than the change in entropy upon melting of the crystal. For instance, the transformation of Li_2SO_4 into the highly conducting α -modification at 850 K is accompanied by a jumpwise increase in entropy

$\Delta S = 31.9 \text{ J (mol K)}^{-1}$ [*cf.* $\Delta S = 6.7 \text{ J (mol K)}^{-1}$ for melting of Li_2SO_4 at 1130 K]. The substantial increase in entropy is associated with disordering of one sublattice in the crystal structure, which goes to the 'quasi-liquid' state.²⁵

Table 1 lists the changes in entropy upon polymorphous transformations and melting of some binary crystals that are used as solid electrolytes or electronic-ionic conductors.

Table 1. Change in entropy upon polymorphous transformations and melting of some crystals.

Crystal	T_{tr}/K	$\Delta S_{\text{tr}}/\text{J (mol K)}^{-1}$	T_{m}/K	$\Delta S_{\text{m}}/\text{J (mol K)}^{-1}$
AgI	419	14.5	830	11.3
Ag_2S	452	9.3	1115	12.6
BaCl_2	1193	14.4	1233	13.3
LuF_3	1230	20.4	1457	20.8
YF_3	1350	24.0	1428	19.6

Chemically complex crystals (*e.g.*, ferrites, aluminates, manganites and cuprates) having two or more cation sublattices often exhibit the so-called antistructural disorder on heating. In binary crystals this is possible if the atoms of the constituent elements have similar characteristics (Cu-Sn bronzes). The existence of antistructural disorder in superconducting cuprates was proved taking $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_7$ ('123' phase) as an example. In this compound, mutual substitution in the Nd and Ba positions can occur despite different stable oxidation states of these elements.^{26,27}

III. Conservative and dissipative self-organisation

As the temperature of an equilibrium or near equilibrium isolated system decreases, some ordering processes called conservative self-organisation²⁸ occur spontaneously. Though the term 'conservative self-organisation' was introduced in connection with the development of supramolecular inorganic chemistry, it has a much broader sense and covers many physical phenomena, such as melt or solution crystallisation, re-crystallisation upon sintering in polycrystalline systems, martensite transformations, spinodal decomposition and formation of magnetic or ferroelectric domains on cooling of the corresponding materials. Conservative self-organisation can also occur during the solid-phase interaction between, *e.g.*, wüstite and corundum in the reaction

which is accompanied by a large decrease in entropy, $\Delta S = -17 \text{ J (mol K)}^{-1}$. However, this reaction is irreversible, since iron aluminate dissociates at high temperatures by the reaction

Supramolecular chemistry has two terms, static self-assembly²⁸ and strict self-assembly,²⁹ for the ordering processes in isolated systems, which proceed towards minimisation of the Gibbs free energy. Such processes undoubtedly include ion hydration, complexation, clustering and formation of molecular crystals through the van der Waals forces.^{28–32}

A classical example of static self-assembly in biology is provided by the self-assembly of a DNA double helix. The change in the Gibbs free energy for this process is illustrated in Fig. 3. Other examples of static self-assembly of supramolecular structures can be found in the literature.^{33–42}

The open systems can exchange matter and energy with the environment. In essence, they provide a case for persistently nonequilibrium systems. The evolution of open systems can be characterised in terms of entropy production (dS_i/dt) and entropy

Figure 3. Change in the Gibbs free energy during self-assembly of a DNA double helix.

flow (dS_e/dt). If the negative entropy flow (entropy release) towards the environment exceeds the entropy production in the system, the total change in the entropy of the open system is negative

$$\frac{dS}{dt} = \frac{dS_e}{dt} + \frac{dS_i}{dt} < 0$$

or, which is the same, the negative entropy (negentropy) of the system increases. As the negentropy exceeds a certain critical value, the formation of new structures (dissipative structures after Nikolis and Prigogine⁴³) in the system becomes possible. Dissipative structures are formed due to co-operative interactions between microscopic building blocks in a strongly nonequilibrium macrosystem. The ability of the macrosystem to form various structures is sometimes characterised by exergy (the maximum work, which can be produced by the system on the pathway towards the equilibrium state).⁴⁴

Spontaneous formation and evolution of complex ordered structures in the open systems is called self-organisation while the theory of self-organisation is called synergetics. Having its origin in cybernetics, nonlinear optics and nonequilibrium thermodynamics, synergetics has a strong impact upon the development of modern physics, chemistry, biology, earth sciences, economics, as well as social and political sciences. Synergetics has its own specific lexicon, which includes such concepts as bifurcation, critical state, dissipative structures, feedback, autocatalysis, hysteresis, attractors, scaling, topochemical memory and stochastic and deterministic chaos. Of course, our interest in both synergetics and self-organisation phenomena is limited to their utility in designing advanced materials and technologies.[†]

Currently, several thousands of communications concerning the use of self-organisation models in solving materials science and technological problems are available. Most of them have been reported during the last five or six years. But admittedly, the equilibrium thermodynamics methodology is still at the frontiers of materials science, especially when one deals with problems concerning high-temperature processes, though most of them occur in strongly nonequilibrium open systems rather than isolated ones. Of course, linear, or additive, thinking is more customary; however, the future may undoubtedly lie with nonlinear models and systems including those used in the field of materials science.⁴⁵

The evolution of an open system can be illustrated by the dependence of the generalised flux I (mass, heat, *etc.*) on the

Figure 4. Generalised flux, I , as function of the driving force, ξ , of a process (for details, see text).

driving force of the process ξ (Fig. 4). The excess Gibbs free energy can act as the driving force in a chemical system. At $\xi = 0$, the system is in the equilibrium state. At small deviations from the equilibrium state (region I), the flux is a linear function of the driving force and the system behaves deterministically, which can be described by the Onsager reciprocal relation. In region II, the $I = f(\xi)$ dependence becomes nonlinear, while transition to region III at a certain critical value $\xi = \xi_2$ is associated with a bifurcation (appearance of several possible pathways of the system's evolution instead of one stable evolution pattern of the process). Here, the system chooses the evolution route by itself but the choice is fluctuation driven.⁴⁶ Going to region IV means the appearance of the so-called deterministic or turbulent chaos, which is characterised by an extremely complex structure and is fundamentally different from the stochastic chaos characterising the system in the equilibrium state.

It is possible to formulate at least three necessary (but not always sufficient) conditions for self-organisation in the open systems, resulting in dissipative structures:

- a deviation from the equilibrium state must exceed a certain critical value (*i.e.*, the system must be in the bifurcation region);
- the system's volume must be large enough and, in particular, be larger than a certain critical volume in which a necessary number of undamped fluctuations occur; the interaction between these fluctuations creates ordering in the system; and
- the presence of a positive feedback.

At small deviations from the equilibrium state, the system is on the so-called thermodynamic branch of its evolution pathway and its behaviour is a combination of many independent random events. Assuming that such behaviour can be characterised by a certain 'statistically averaged' parameter $\bar{X}_0$ (Fig. 5a), one gets that, in accord with the law of large numbers, for a sufficiently large system the deviations from the average value $\bar{X}_0$ are small and normally distributed with the probability distribution $P(X)$. In this sense the behaviour of the system can be treated as deterministic.

As the driving force increases due to the nonlinear behaviour of the system, any possible fluctuations are not damped and, hence, become equiprobable. Therefore, the $P(X)$ distribution near the bifurcation point becomes flattened (Fig. 5b). A feature of this state of the system is that any fluctuation can manifest itself on the macroscopic scale, *i.e.*, extend to a rather large volume and be undamped for an infinitely long time. At a critical point corresponding to sudden predominance of a certain fluctuation, a minor increase in the driving force of the process is sufficient for the system to make the ultimate choice of a new thermodynamic branch between several alternative branches. Thus, after passing the bifurcation point the distribution $P(X)$ becomes multimodal (Fig. 5c), while the choice of the new average value X (new

[†] To this end, the author of this review initiated the foundation of the Laboratory of Chemical Synergetics at the N S Kurnakov Institute of General and Inorganic Chemistry, Russian Academy of Sciences, in 1994.

Figure 5. Probability distribution, $P(X)$, at different deviations of the system from the equilibrium state (for details, see text).

thermodynamic branch) from several possible values ($\bar{X}_{01}, \bar{X}_{02}, \dots, \bar{X}_{0n}$) occurs stochastically.

In real systems, such a behaviour can be due to the fact that local nonlinear processes (e.g., an autocatalytic reaction in a small volume or formation of a new solid phase with an ordered crystal lattice) in these systems coexist with the transport (diffusion) processes responsible for different types of exchange between adjacent local volume elements. Were chemical processes to occur in the adjacent local volume elements, they will tend to make the system less spatially homogeneous, while the diffusion processes act in the opposite direction, towards a maximum spatial homogeneity of the system. Clearly, uncorrelated behaviour of the local volume elements (hindered diffusion or no diffusion) results in a random set of combinations of local states. In the case of infinitely fast diffusion (zero response time of the cells) fluctuations are instantaneously damped and disappear. Both limiting cases do not give rise to spatial ordering.

At the same time, both diffusion and local chemical interactions are those essentially nonlinear processes, which are responsible for nonlinear behaviour of the entire system. At a large deviation from the equilibrium state, it can happen that these processes (different in their nature) will have similar characteristic times τ_d and τ_r . In this case both the frequency of chemical fluctuations, $\sim 1/\tau_r$, and the probability of their extension to the adjacent volume elements (relaxation within a given volume element), $\sim 1/\tau_d$, are high.

Thus, under particular conditions the complex systems can go to a certain 'critical state' in which the entire system behaves in a concerted way and chooses a new evolution pathway stochastically.

There is a variety of dissipative structures, e.g.,

- spatially nonuniform structures;
- temporal periodic structures (self-sustained oscillations);
- spatio-temporal periodic structures (waves);
- coexistence of several stationary states (bi- and tristability);
- structures with scaling properties (spatial self-similarity — fractals); and
- chaotic dynamic structures.

Figure 6. Formation of Benard cells on increasing the temperature gradient.

Dissipative self-organisation can be exemplified by the formation of Benard cells (Fig. 6). As the temperature gradient ($\Delta T = T_2 - T_1$) between horizontal walls of a vessel containing a liquid increases and reaches a critical value corresponding to the bifurcation point, ΔT_c , the type of heat transfer process is changed from convection (chaotic molecular motion similar to Brownian motion) to correlated molecular motion in microscopic fluid cells. The molecular motion occurs in a concerted way by clockwise (R) or counterclockwise (L) rotation. Formation of one of the two dissipative structures shown in the right part of Fig. 6 occurs as a random event as a result of the system's choice. A further increase in ΔT causes destruction of the cell structure and the appearance of turbulent chaos.

This example shows that diffusion, viscous flow and heat transfer, which disorder simple linear systems, can be 'architects of ordering' in nonlinear systems. Numerous examples of dissipative self-organisation in various open systems have been considered in monographs.^{47–49} Pioneering observations of self-organisation in physicochemical systems date back to 1828. At that time, Fechner discovered spontaneous oscillations of the electrochemical potential of iron in nitric acid as a result of alternating passivation and depassivation processes (Lillie wires).⁵⁰ The best example of self-organisation in homogeneous chemical systems is undoubtedly provided by the Belousov–Zhabotinsky redox reaction, i.e., oxidation of citric (or malonic) acid by potassium bromate in the presence of cerium(III) sulfate.^{51,52} This is a very complicated reaction, though visually it appears as a simple oscillating process involving a change in the colour of a solution. According to calculations, changes in the rate constants for the reaction stages by infinitesimal fractions of per cent can cause radical changes in the character of the process at the microlevel. However, under any conditions the most important is the self-oscillation stage, which can be tentatively described by the following equation:

Interestingly, pure temporal structures (self-sustained oscillations) can undergo transformation into spatio-temporal ones after some time.

It was Ostwald who contributed largely to the understanding of the energetics of oscillating chemical reactions.^{53–55} He generalised extensive experimental information accumulated by the early 20th century, including the data on famous Liesegang rings, dissolution of chromium in acids with oscillating character of H_2 liberation and on periodic decomposition of H_2O_2 on a mercury surface. Some monographs^{56–58} provide a rich source of information on recent studies of oscillating reactions. Returning to the problems of materials science, it should be noted that such important properties as the plasticity and yield of materials cannot be adequately described in the framework of the equilibrium methodology. Fracture of a mechanically loaded material is always preceded by ordering of planar defects and formation of dislocations in the region to be fractured. For instance, applying a periodic load to a metal rod causes formation of dislocation packets, which are ordered in some way.⁵⁹

Mechanical fracture of a material can be treated as a consequence of a critical transition (bifurcation) from the elastic

Figure 7. Strain (1), stress (2), temperature (3) and acoustic radiating capacity (4) of a mechanically loaded sample as functions of time.

deformation to the plastic deformation regime under the action of a rather heavy external load acting as the driving force of the process. Figure 7 presents the plots of the strain, stress, temperature and acoustic radiating capacity of a mechanically loaded sample constructed vs. time. Extrema or singularities in all the plots correspond to the critical point σ_0 . It should be noted that the maximum value of the acoustic radiating capacity at the critical point corresponds to ordering of defects in the sample. Moving the bifurcation point towards the heavy load region favours improvement of a material's strength. For instance, it was found that the doping of metals with zirconia causes a shift of the point corresponding to transition from elastic to plastic deformation due to the fact that ZrO_2 experiences a structural phase transition accompanied by heat release under load.⁶⁰

Of considerable interest are chemical vapour deposition (CVD) processes under strongly nonequilibrium conditions. Figure 8 presents micrographs of ordered structures formed using the CVD technique at high gas flow rates.⁶¹

Figure 8. Micrographs of ordered structures formed using the CVD technique at high gas flow rates. Crystals: Cr_3Si (a) and CrB_2 (b).

Self-organisation processes also include a class of phenomena accompanying shock-compression induced crystallisation of metastable solid phases. Researchers at the I M Frantsevich Institute of Materials Science (National Academy of Sciences of Ukraine, Kiev) elaborated some methods for creation of strongly nonequilibrium conditions during the formation and quenching of metastable phases.⁶² Crystallisation in the presence of strong temperature and pressure gradients allowed the obtention of crystalline modifications with lower entropy compared to the samples synthesised under nearly equilibrium conditions.

Solid-phase crystallisation of graphite-like boron nitride $(\text{BN})_g$ under supercritical regime of energy supply causes formation of a new modification, wurtzite-like boron nitride $(\text{BN})_{w-II}$.^{63, 64} The entropy of the newly prepared compound is lower than that of $(\text{BN})_{w-I}$,⁶⁵ which is formed at lower energy supply rates.

Nonequilibrium crystallisation of diamond from the concentrated vapour phase and plasma is accompanied by unusual phenomena. Synthesis at 4500 °C gives a fine-crystalline cubic modification of diamond (X-ray phase analysis data), which is nearly free from microscopic distortions. Carrying out crystallisation at 4300 °C (this temperature corresponds to the triple point in the phase diagram) leads to a crystalline diamond-like phase containing a large number of microdistortions.⁶⁶ Hence, synthesis under strongly nonequilibrium conditions permits a structure with less defects to be obtained.

Most likely, formation of 'whiskers' (needle-shaped single-crystals of superconducting bismuth-containing cuprates with $T_c = 100$ K), which grow on slow cooling of the starting amorphous phase $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$ in an air stream (Fig. 9)⁶⁷ is also governed by self-organisation.

Figure 9. Whiskers of bismuth-containing superconducting cuprates formed on slow cooling of the starting amorphous phase $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$.

IV. Optimum organisation of reaction zone during synthesis of materials

In all stages of its evolution from precursor to the end product, any system exists under thermodynamically nonequilibrium conditions and can be described by some bifurcation pattern with one

or several bifurcation points corresponding to the intermediate phase transformations. It is convenient to consider the evolution of such a system using a model of deterministic chaos.^{68,69} This model implies that

- the evolution of a system makes its behaviour increasingly less predictable (*i.e.*, irreproducible);
- the higher the chemical or structural complexity of the system, the shorter the time necessary for transition to the region of indeterministic behaviour; and
- the longer the duration of the process, the more severe the requirements on the initial state of the system (*i.e.*, precursor).

To organise the reaction zone in an optimum manner, one should take into account the following.

1. The higher the complexity of the system, the more indeterministic its behaviour and less reproducible the initial state of the precursor. In this case 'complexity' means not only the chemical and phase compositions but also precursor's reactivity, which is determined by the chemical and heat treatment aspects of its prehistory ('topochemical memory' effect⁷⁰). In this connection the best precursors are provided by compounds with a molecular type of bonding,⁷¹ coordination compounds,⁷² solid solutions of double salts (shoenites or alms which are used in, *e.g.*, the synthesis of ferrites⁷³) and salt-like products of cryochemical synthesis.⁷⁴

2. The extent to which transformations from precursors to target products deviate from the equilibrium state is in essence the driving force of solid-phase interactions. It affects not only the reaction rates but also their mechanisms and can have both positive and negative effects on the formation of the target product. In particular, the highest homologue in the Bi–Pb–Sr–Ca–Cu–O system, $(\text{Bi,Pb})_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10+\delta}$, is usually prepared from Bi_2O_3 , CuO , PbCO_3 , SrCO_3 and CaCO_3 (a mechanical mixture of these precursors is used). If such a mixture is heated in a gaseous atmosphere at a reduced total pressure, the lead, strontium and calcium oxides are formed under strongly non-equilibrium conditions. Being highly reactive, these oxides readily react with bismuth and copper oxides, thus forming a number of intermediate products simultaneously. Transformation of the products into the highest homologue, $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10+\delta}$ ('2223' phase) is a very complicated task and is usually completed only after heating over a period of several days.⁷⁵ Decomposition of carbonates at a standard pressure (1 atm) occurs much more slowly, and it is possible to inhibit formation of some intermediates, though in this case low diffusion mobility of cations hampers the formation of the end product ('2223' phase) during reasonably short time intervals. A possible way out is to use efficient methods of activation of the reaction mixture including ultrafine grinding,⁷⁶ sonication^{77,78} or microwave irradiation.^{79–81}

3. Duration of the evolution from precursors to end product. The shorter the evolution, the more easily the deterministic behaviour of the system can be provided and a product with reproducible properties can be obtained. The question arises as to how to shorten the duration of the process taking into account that operation at elevated temperatures leads to bifurcation and to formation of such intermediate products whose crystallisation precludes shortening of the duration of the synthesis. In this case, the use of other methods for activation of the reaction mixture (and, especially, their combination) seems to be more efficient than heating. However, only an empirical approach, *e.g.*, combinatorial chemistry,⁸² provides the best way to optimise conditions for treatment of the system.

The efficiency of ultrafast synergistic effects can be clearly exemplified by sintering of ultradispersed ceramic powders of oxide–oxide composites $\text{Al}_2\text{O}_3\text{--Y}_3\text{Al}_5\text{O}_{12}$ using a press that furnished an increase in pressure on passing pulsed electric current (up to 2000 A) with millisecond-range pulse durations. Sintering was completed after several minutes, resulting in ceramics with rather high density and very narrow crystallite size distribution centred at the size typical of the precursor powder.⁸³

4. Bifurcation transformations, which occur during the evolution of a system and manifest themselves as formation of intermediate decomposition products in the reaction zone, should be eliminated, whenever possible. This is all the more important in those cases where such products are formed as readily crystallisable phases characterised by low diffusion mobility of components. This is possible if the phase diagram allows decomposition of the system into some components, which then interact to give the target product. 'Linear' synthesis of superconducting cuprates from copper-free precursors and copper oxide provides a good example of the efficiency of this technique. It was found that the phases $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ and $\text{Bi}_{1.7}\text{Pb}_{0.4}\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10+x}$ can be efficiently prepared using mechanical mixtures of CuO with $\text{Bi}_2\text{Sr}_2\text{CaO}_6$ (Fig. 10) and $\text{Bi}_{1.7}\text{Pb}_{0.4}\text{Sr}_2\text{Ca}_2\text{O}_{7.35}$, respectively.^{75,84}

Figure 10. Decomposition of quasi-ternary system $\text{CuO--BiO}_{1.5}\text{--Sr}_{0.66}\text{Ca}_{0.33}\text{O}$ along the $\text{CuO--Sr}_2\text{CaBi}_2\text{O}_6$ direction.⁷⁵

In principle, the reaction zone can be organised in such a way that both the precursor and intermediate reaction products lying on the pathway of the figurative point of the system during its evolution are X-ray amorphous and, hence, the formation of a crystalline end product is the first bifurcation. Particular methods for practical implementation of such a process depend on the target oxide products or materials (both of them are chemically complex systems) and, in particular, on the differences between the thermodynamic parameters of the constituent oxides. If these differences are rather large (the most often case), amorphisation of the precursor and intermediate decomposition products is achieved by quenching oxide melts (*e.g.*, preparation of whiskers⁸⁵) or by freezing of aqueous salt solutions of the material-forming elements (sulfates, nitrates, acetates) followed by thermal decomposition under optimum conditions.⁷⁴

5. Deterministic evolution of a system can be organised using templates (including seeds) in the form of perfect crystals of the oxide product (bulk ceramics) or under conditions that provide epitaxial film growth (substrate with optimally matched structural parameters). An example of a perfect substrate for the growth of perfect high-temperature superconducting films is provided by NdGdO_3 single crystals whose parameters are close to those of films, including the thermal expansion coefficients.

An original method for preparation of homogeneous microporous SiO_2 , TiO_2 and ZrO_2 ceramics has been reported.⁸⁶ The technique involves an oil-in-water emulsion and is based on the use of the interface between monodispersed oil droplets and the water phase as a template (Fig. 11).

6. Intense suppression of chaos by interaction based on a feedback requires thorough knowledge of chaotic behaviour of

Figure 11. Scheme of formation of homogeneous microporous SiO_2 , TiO_2 or ZrO_2 ceramics involving an oil-in-water emulsion and based on the use of the interface between monodispersed oil droplets and the water phase as a template.

the system. This method for control of chaos involves both computer simulation and experimental studies of topochemical reactions proceeding in the kinetic, diffusion or mixed regimes.

Controlled suppression of chaos can be achieved using different methods including directed chemical complication of the system. This can be exemplified by the effect of rare-earth element (REE) ions, which partially replace yttrium in the superconducting cuprate $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$, upon melt crystallisation of this compound.⁸⁷ For instance, doping with Yb^{3+} ions results in the formation of giant ribbed crystals of the BaCuO_2 phase, which cover nearly the whole surface of the sample. Doping with Eu^{3+} ions causes the formation of rather large square-shaped surface crystallites, while Nd^{3+} -doped samples are comprised of small plate-like crystallites of the $(\text{R},\text{Y})\text{Ba}_2\text{Cu}_3\text{O}_{7-x}$ phase, which form a fine-grained ceramic structure. Finally, studies of both blank samples and samples doped with Ho^{3+} ions revealed the presence of two types of crystallite, viz., 'cubic' crystallites of the superconducting phase and 'pyramidal' barium cuprate crystallites.

As can be seen in Fig. 12, doping with Nd^{3+} , Eu^{3+} and Gd^{3+} should favour retention of homogeneity of the system and formation of high-temperature superconducting material with strongly coupled grains. This is due to the fact that the crystallisation centres of the superconducting phase are formed in the 'stable' crystallisation branch of $(\text{R},\text{Y})\text{Ba}_2\text{Cu}_3\text{O}_{7-x}$ solid solutions (line 2), which is characterised by higher temperatures than the crystallisation temperature of $\text{R}_x\text{Ba}_{1-x}\text{CuO}_{2+x}$ (line 4).

No crystallisation centres of the '123' phase occur upon doping of the system with Yb^{3+} ions. As a result, barium cuprate is formed in the 'unstable' crystallisation branch of solid solutions (line 3) in the melt region of the system, which precedes crystallisation of the superconducting phase.

In the case of intermediate 'unstable' crystallisation of $(\text{Y},\text{Ho})\text{Ba}_2\text{Cu}_3\text{O}_{7-x}$ the process becomes very sensitive to particular experimental conditions.

Figure 12. Crystallisation model of REE-doped yttrium-containing cuprates.

(a) Crystallisation temperatures of the ' $\text{R}_x\text{Ba}_{1-x}\text{CuO}_{2+x}$ ' and $(\text{R},\text{Y})\text{Ba}_2\text{Cu}_3\text{O}_2$ phases doped with different REE at constant dopant concentrations ($V_{\text{REE}}/V_{\text{Y}} = 0.1$): stable crystallisation branch of barium cuprate [$T_{\text{cr}(011)} \approx \text{const}$] (1), stable crystallisation branch of yttrium-barium cuprate [$T_{\text{cr}(123)} \neq \text{const}$] (2), unstable crystallisation branch of yttrium-barium cuprate [$T_{\text{cr}(011)} > T_{\text{cr}(123)}$] (3) and unstable crystallisation branch of barium cuprate [$T_{\text{cr}(011)} < T_{\text{cr}(123)}$] (4); (b) results of computer simulation of crystal morphology corresponding to real experiments.

This model was substantiated by the results of computer simulation of crystallisation. It was established that

- under certain critical conditions, local interactions in the complex system are responsible for the appearance of new interrelations determining transformation of the evolution pattern of the entire system into a self-organisation regime;

- depending on the initial state of a peritectic melt, its solidification can occur in different manners, thus causing the appearance of different crystallisation regions. Each of them corresponds to a specific morphology of polycrystalline finished material (target product). The most important condition for preparation of high-temperature superconducting materials with high current densities is to provide stable crystallisation of the superconducting phase by stabilising the nucleation process;

- preparation of high-temperature superconducting materials in the region of stable crystallisation of the superconducting phase requires the formation of a rather large number of seeds; if the seed lifetimes are longer than the mutual seed 'adjustment' time, the one and only process in the system is 'front-side' crystallisation followed by the formation of a material comprised of strongly coupled crystallites.

Based on the aforesaid, we can state that the nonlinear character of the evolution of processes in the open physicochemical systems complicates preparation of many chemically complex products and materials with reproducible compositions, structure and properties. This problem can be to some extent solved⁸⁸ by organising the reaction zone in an optimum manner. This includes:

- the use of highly homogeneous (better, molecularly bonded) precursors (alkoxides) or complex compounds in the form of solutions, melts, or vapours;

- treatment of precursors to provide preparation of X-ray amorphous intermediate states and formation of target crystalline products at lowest possible temperatures due to synergistic effects

of different forces (low pressure, intense grinding, sonication and microwave irradiation); and

— template synthesis or directed chemical complication of the system to ensure the preferred formation of the product with a prescribed structure.

V. Onset and suppression of chaos in metal corrosion processes

A number of communications concerning the conditions for onset and suppression of chaos in metal corrosion processes have been reported.^{89–91} Figure 13 presents a scheme of corrosion of metal M in an aqueous solution. The process is accompanied by the formation of two products, a metal hydroxide and a metal oxide. Let S_{OH} and S_O be the fractions of the metal surface covered by the hydroxide film and oxide film, respectively, and c_M be the concentration of metal ions in the solution. Then, the state of the system at any instant of time can be characterised by the position of the point in a three-dimensional phase space, *i.e.*, in the $S_{OH}-S_O-c_M$ coordinate system.

Figure 13. Corrosion scheme of metal M in aqueous solutions. Oxide film (MO), hydroxide film (MOH), dissolved hydroxide (MOH_{aq}), metal ions (M^+) and salt (MA).

The rate of change in each parameter can be calculated by solving the corresponding kinetic equations and plotting the trajectory of the motion of the figurative point based on the results obtained. Figure 14 presents a projection of this trajectory on the S_O-S_{OH} plane. As can be seen, after some time the trajectory represents an attractor of a rather complex shape. The question arises as to how to distinguish between the deterministic chaos and the pure stochastic process (the so-called stochastic chaos) based on experimental results. For instance, corrosion studies allow one to measure the corrosion current I at different time instants. The $I(t)$ plot (Fig. 15) is typical of random processes. Construction of the phase trajectory using these data requires the use of the return map method. The essence of the method is as follows: an appropriate time interval, τ , is chosen, corresponding to repetition of the height of corrosion current peaks, and then the phase trajectory is constructed in the $I(t)-I(t+\tau)$ coordinates. The shape of this trajectory (Fig. 16) indicates that the corrosion process is in some way deterministic. Though at first glance the corrosion current changes randomly during the process, the trajectory of the system in the correctly chosen phase space is a strange attractor. To inhibit corrosion, one should find certain conditions corresponding to degeneration of the system's attractor into a point. The results of suppression of the corrosion process using the return map technique are demonstrated in Fig. 17. The initial $S_O(t)$ dependence is shown in the left part, while the $S_O(t)$ plot after applying the suppressing signal

Figure 14. Phase trajectory of corrosion process (projection of the trajectory on the S_O-S_{OH} plane).

Figure 15. Experimental dependence of corrosion current, I , on time t .

(specially chosen voltage pulse) is presented in the central part; switching off the suppressing signal causes re-appearance of chaotic oscillations in the system (right part of Fig. 17), indicating that corrosion continues. By regularly applying such voltage pulses it is possible to achieve complete inhibition of corrosion.

Figure 17. Suppression of chaotic oscillations during metal corrosion using special voltage pulses (for details, see text).

VI. Application of deterministic chaos models to poorly reproducible physicochemical processes

Chemistry of materials often deals with poorly reproducible solid-phase or heterophase processes. For instance, a yield of 25% is considered good in large-scale production of single crystals of many functional materials (ferrites, piezoelectrics). In the case of single crystals the (potentially) changeable (variable) parameters are the size, shape, composition, dislocation structure and some other, despite a high accuracy of control of the synthesis conditions. Some other examples of poorly reproducible processes can be found in the literature.^{91–93}

Traditionally, the dynamics of chaotic systems have been studied using time-series analysis, which involves observation of changes in a certain experimentally measured parameter. This approach allows determination of the type of system's behaviour (*e.g.*, chaotic one) and obtaining valuable information on the system's dynamics. However, specific features of solid-phase systems sometimes preclude measurements of characteristic dependences of their parameters on time (*e.g.*, for growth of single crystals). At the same time, it's quite an easy matter to obtain statistical data on the results of repeated experiments carried out under identical (within the limits of experimental error) conditions.

A procedure for determining fundamental characteristics of a chaotic system from statistical data obtained by repeated reproduction of experiments has been elaborated.⁹⁴ It was assumed that poor reproducibility of experimental results obtained under identical conditions is due to high sensitivity of the system's dynamics to minor changes in the starting parameters. The initial conditions for different experiments can be set to some finite accuracy, which is determined by the accuracy of the equipment used in the experiments. However, if the system under study behaves chaotically, small, experimentally undetectable, differences can have a strong effect on the overall result.

The model chaotic system was described by a differential equation of Duffing's oscillator⁹⁵

$$\frac{d^2x}{dt^2} + 0.05 \frac{dx}{dt} + x^3 = 7.5 \cos t,$$

which has a set of three phase variables, namely, the coordinate x , velocity dx/dt and time t .

Numerical integration of this equation was carried out by the fourth-order Runge–Kutta method. Randomly chosen initial conditions $x_0 = x$ ($t = 0$) were normally or uniformly distributed with different dispersions. All numerical experiments were carried out with the same initial velocities, namely, $dx/dt = 0$ at $t = 0$. Calculations were terminated after a rather long time

($t \geq 470$ arbitrary units) to ensure that the system's trajectory is the strange attractor.

Numerical experiments showed that the distribution of the end points obtained by integration at different initial conditions reflects only the attractor's structure and is independent of the distribution of initial conditions.

More detailed information was obtained by analysing the distributions of two (or more) independent parameters of the system. Fig. 18 *a* presents a correlation between the final values of the variables $\{x, dx/dt\}$ obtained after completion of calculations. In real experiments, the measured parameters can be functions of one or several phase variables. As can be seen, the final values obtained at $t = 470$ are distributed over the Poincaré cross-section of the strange attractor. The visual appearance of this cross-section is independent of the type and dispersion of initial conditions. It should be noted that exactly the same Poincaré cross-section can be obtained by applying a conventional time-series analysis procedure to the $\{x, dx/dt\}$ pair at times $470 + 2\pi n$, where $n = 1, 2, 3$ (Fig. 18 *b*).

Figure 18. Poincaré cross-sections of Duffing's attractor, obtained from reproducibility experiments ($t = 470$, 30 000 points) (*a*) and using conventional time-series analysis ($t_n = 470 + 2\pi n$, 15 000 points) (*b*).

This approach can also be employed in reconstructing the attractor of the system under study. This requires knowledge of the number of dynamic variables. In the case of the Duffing oscillator, the third phase variable is the time t (see above). To reconstruct the attractor, a total of thirty-one Poincaré cross-sections were obtained at different times $t = 470 + 2\pi n/30$; the cross-section at $n = 0$ was equivalent to that obtained at $n = 30$. Each Poincaré cross-section contained a set of 2000 points obtained by numerical integration of Duffing's equation at normally distributed initial conditions. The three-dimensional image of the strange attractor is shown in Fig. 19. In the general case, reconstruction of the attractor of a poorly reproducible system requires that (i) as many parameters of the process under study as possible be measured to be deliberately larger than the number of phase variables; (ii) independent variables be chosen and (iii) a correlation between the independent variables be

Figure 19. Three-dimensional image of the strange attractor of Duffing's oscillator in the $x - \sin x - dx/dt$ coordinates.

plotted. By virtue of the fact that the fundamental phase variables for the system are usually unknown, the shape of the reconstructed attractor can be distorted. This is also a standard situation for conventional reconstruction of an attractor using time-series analysis.

Thus, even by measuring a single parameter of the system one can say whether or not the poor reproducibility is due to chaos in the system. In this case, it is possible to determine fundamental characteristics of the chaotic system, such as the fractal dimension of the Poincaré cross-section, D_P , and then calculate the fractal dimension of the strange attractor (usually, this parameter equals $D_P + 1$). The possibility of using the reproducibility data for determining other dynamic properties of chaotic systems (*e.g.*, Lyapunov indices,⁹⁶ K-entropy,⁹⁷ *etc.*) is still to be clarified.

Yet another important problem concerns the number of experimental points necessary to obtain correct results. From the aforesaid it follows that even a thousand experimental points can appear to be insufficient. This is a serious impediment, since carrying out, *e.g.*, a thousand of syntheses of single crystals is usually impracticable. However, a way to obtain more than a single point in one experiment should be pointed out. In particular, each experiment on melt growth of superconducting cuprates gives nearly a hundred single crystals with (usually) different parameters (size, composition, *etc.*). Another method for solving this problem involves analysis of statistical data on quality control in large-scale productions. This is of considerable value for these productions, since an intimate relationship between poor reproducibility and chaos makes possible significant improvements in reproducibility of the characteristics of end products by suppression of chaos using known methods.^{98,99}

The examples considered above do not exhaust the list of materials science problems that can be solved using nonlinear dynamics approaches. In particular, such problems include studies of phase boundaries as self-organising systems. The phase boundary was treated¹⁰⁰ as an open nonequilibrium system comprising a number of interacting subsystems. A feature of the system is nonlinear interactions between subsystems and the presence of feedbacks. An example of a self-organisation related phase boundary is provided by the semiconductor/electrolyte interface. This interface comprises the ionic electrolyte layer adjacent to the semiconductor surface, the region of 'alien' surface phases, the region with the changed or broken crystal structure of the semiconductor and the space charge region, which retains the crystal structure of the bulk semiconductor but has different electronic characteristics. Specific properties of such a surface are determined by the processes occurring within all the above-mentioned regions and by their interactions. A salient feature, which serves as a prerequisite for self-organisation, is that the interface is formed as a result of nonlinear interaction between the

electronic subsystem of the semiconductor and the ionic subsystem of the electrolyte. Most often, the polarisation of semiconductors and adsorption of molecules on their surfaces are accompanied by phase transitions, which cause a jumpwise change in the charge of the interface. Sometimes these processes are accompanied by irreversible change in the charge, which is characteristic of the surface of the semiconductors with low density of surface states. This makes possible, *e.g.*, exclusion of pinning of the Fermi level on the GaAs and GaP surfaces and extension of the range of the surface potential values, which can be practically implemented in designing and fabricating metal–insulator–semiconductor transistors.

Of considerable interest are systematic studies on the nonlinear processes accompanying the first-order phase transitions on the surface of solids and on the growth of thin films from multicomponent vapour carried out by Kukushkin and Osipov.^{101,102} These researchers analysed various models for the vapour-phase and melt-solution growth of multicomponent films and proposed efficient methods of control of these processes.

VII. Self-assembly of supramolecular compounds

The evolution of a physicochemical system from atomic vapour to a solid depends on the system's composition. If the system comprises atoms of the same element, the evolution begins with formation of covalently bonded diatomic molecules followed by larger associates, clusters and nanoparticles that are often stabilised in inert matrices in the form of nanocomposites. The assembly is completed with the formation of a covalent (diamond), molecular (iodine) or metal (alkali and alkali-earth metals) crystals as the end product. At any non-zero temperature (in K), the crystal has to some extent a disordered structure, which contains, in the simplest case, point defects (vacancies or atoms occupying the interstitial sites). Thus, the evolution resulting in an elementary crystal as the end product can be represented by the following scheme:

In a more chemically complex system the interactions of different-type atoms cause the formation of molecules bonded through covalent or mixed ionic–covalent interactions. In the latter case the bond ionicity increases as the difference in electronegativity between the constituent elements increases. The next stage of the interaction involves formation of the so-called non-covalently bonded supramolecular ensembles and supramolecular materials. Usually, the formation of supermolecules is assumed to be driven by the system's tendency towards a minimum of the Gibbs free energy (the enthalpy of formation of supermolecules from individual molecules or molecules and ions contributes predominantly in this case). In spite of extensive literature on supramolecular chemistry, from academic monographs (see, *e.g.*, Refs 103–105) to recent publications in scientific journals (see, *e.g.*, Refs 106–110), the nature of the self-organisation of supermolecules and supramolecular crystals has been poorly studied. This uncertainty also covers the terminology of supramolecular chemistry.¹¹¹ First of all, the case in point is the so-called self-assembly and self-organisation processes, which are sometimes (but not always) treated as different. The term self-assembly can be used in a broader sense. It relates to all types of spontaneous binding of components through both covalent and noncovalent forces. According to Lehn,¹⁰³ self-organisation

(1) involves the interactions between systems, which can experience spontaneous ordering in space and/or time;

(2) involves spatial (structural) and temporal (dynamic) order in both the equilibrium and nonequilibrium dissipative structures;

(3) concerns only the noncovalent, supramolecular level of structural organisation; and

(4) results in the formation of polymolecular ensembles due to specific acts of molecular recognition of components.

The higher the extent of spatial organisation of fragments, the more substantiated the reasons for their treatment as self-organised (molecular layers, membranes, micelles, colloids, liquid crystals, molecular crystals). Thus, self-organisation extends to the interactions between fragments and the integration of these interactions, which are responsible for the collective behaviour of the system, as is observed during, *e.g.*, phase transitions or creation of spatial and temporal waves).

The interrelation between conservative and dissipative self-organisation during the evolution of physicochemical systems involving formation of supermolecules has not been studied as yet. We believe that such an evolution is possible due to a complex combination of these factors based on chance and necessity, respectively. According to Müller *et al.*,²⁸ conservative self-

organisation processes play a crucial role in the formation of supermolecules. On the other hand, Lehn pointed out that 'the inclusion of dissipative nonequilibrium processes, like those present in the living world, constitutes a major goal and challenge for supramolecular chemistry'.³¹ An important role in the formation of supermolecules is played by prehistory, or the topochemical memory, as well as the template effect of the central ion or molecule towards other fragments of supermolecules formed. Self-assembly of supermolecules can be employed to prepare advanced functional materials.¹¹²

Let us consider the self-assembly of comb-like supermolecules *via* formation of primary and secondary structures as an example.¹¹³ The simplest case is a flexible polymer having free binding sites along its main chain (component A in Fig. 20). Usually, the main chain is polar, while non-polar side groups can be connected by complementary bonds, thus leading to comb-like supermolecules, which then self-organise. The side chains are bonded to the main polymer chain by hydrogen or coordination bonds.¹¹⁴ Ionic

Figure 20. Self-assembly of comb-like supermolecules involving primary and secondary polymer structures (for details, see text).¹¹³

interactions in polyelectrolyte–surfactant complexes were also used to form comb-like supermolecules.¹¹⁵ The resulting self-organised multidomain structures can be transformed into single-domain ones.¹¹⁶ The properties of the latter group of structures can be tuned by varying the nature of the side chains. For instance, partial fluorination of the side chains reduces the surface energy and the friction coefficient of the material.¹¹⁷

If the main chain consists of the double helix of DNA, self-organisation can be achieved by ionically bonding liposomes or cationic surfactants to the anionic phosphate sites.^{118,119} This allows for materials design possessing unusual biochemical properties. For instance, colour centres can be intercalated into the DNA helices, thus suppressing their aggregation. Such structures can be used as templates for photonic applications.¹¹⁹ The main polymer chain can have two sorts of binding sites to which fragments of different nature can be bonded (component B in Fig. 20).

The side chains can also have different functional groups. For example, in addition to the side chains required for self-organisation, the system can contain acid groups that act as dopants for the conjugated polymer (*e.g.*, polyaniline), which leads to electronic conductivity.¹²⁰ An additional degree of freedom is introduced when polyaniline is first doped with, *e.g.*, camphorsulfonic acid and subsequently connected to hexylresorcinol molecules (component C in Fig. 20) through two H-bonds.¹²¹ The alkyl chains of the hexylresorcinol molecules act as plasticisers, thus making the infusible polymer thermoplastic. Camphorsulfonic acid doped polyaniline chains confined within nanoscale cylinders improve the material's conductivity. This technique also allows modification of rigid-rod polymers similar to polypyridine, which consists of *para*-linked heteroatomic rings. The optical properties of such polymers can be controlled by doping them with camphorsulfonic acid. Subsequent bonding to alkylresorcinol leads to comb-like supermolecules, which self-organise into lamellae in such a way that the material becomes fluid even without solvents.¹²² Such an unusual fluid contains rigid polymer 'rods' and allows processing towards monodomains with aligned 'rods.'

Finally, the plasticising alkylresorcinol molecules can be removed by evaporation *in vacuo*, thus interlocking the chains in solid stable polymer films (product D in Fig. 20). As a result, polarisation-induced luminescence is achieved.¹²² It is also possible to combine different self-organisation and recognition mechanisms within the same polymeric material. For instance, block copolymeric self-organisation fragments of lengths 100 to 200 Å can be combined with amphiphilic self-organisation fragments of length 10 to 60 Å (component E in Fig. 20).^{114,123} After selective doping of one block, the material's conductivity can be changed by using a sequence of phase transitions.¹¹⁴ Three-dimensional conductivity can be achieved by ordering the local structure.¹²⁴ There is a vast variety of phases,¹²³ such as lamellae-within-cylinders (product F in Fig. 20), which, by analogy with the product D, also permit selective cleavage of the constituent fragments that form the supermolecules. For instance, starting from polystyrene-*b*-poly(4-vinylpyridine), in which pentadecylphenol is hydrogen bonded, one can obtain a structure in which the glassy polystyrene matrix contains cylindrical pores with poly(4-vinylpyridine) 'brushes' on the walls (product G in Fig. 20).¹²⁵ By choosing different block copolymers and amphiphiles it is possible to tune the thickness of the pore walls. In principle, the shape of 'nanobrushes' can be controlled by selecting appropriate polymer and solvent. For instance, Saito¹²⁶ cross-linked the poly(4-vinylpyridine) slices using an original method for preparation of nanoscale colloidal disks (product H in Fig. 20). Other shapes of nanoparticles can also be obtained, *e.g.*, polymer 'rods' (product I in Fig. 20).¹²⁷

Complex self-organised supermolecules open up prospects for targeted variation (tuning) of many physical parameters. The possibility of using such molecules in design of advanced biomaterials is particularly attractive, which was successfully dem-

onstrated taking DNA and self-organising fungal proteins as examples.¹²⁸

Rotaxane molecules that are active in redox processes were used to create 'molecular switches', which can act as logical gates.¹²⁹ The rotaxane molecule consists of a dumb-bell chain and a macrocycle mechanically strung on the dumb-bell.

The dumb-bell fragments of the molecule comprise charged bipyridine moieties while the macrocycle consists of crown-ether chains. The molecules of rotaxane are formed as a monolayer and located between the metal and metal oxide electrodes. Passage of electric current causes oxidation of the rotaxane molecules and induces conformational changes, which lead to an increase in the resistance. In fact, the rotaxane molecules behave as a molecular switch. Switching on (oxidation of rotaxane) is a reversible process, while the resistance difference between the on and off states is readily detectable (resistance changes by a factor of 15 to 30).

VIII. Self-organisation in nanosystems

A decrease in the particle size in a dispersed system down to the nanometre scale is accompanied by changes in the bulk properties of the system, including the crystal lattice parameters (sometimes, also the lattice type), melting temperature, electric and heat conductivity, *etc.* This changes the character of interparticle interaction, thus providing a way to various nanostructures possessing unique optical, magnetic, catalytic properties and reactivity.^{130,131} The closer the particle size to the atomic scale, the more pronounced these changes and effects.¹³²

Nanoparticles are divided into two types. The first group comprises nanoclusters or nanocrystals, which consist of at most a thousand atoms, have ordered structure and are of size 1 to 5 nm. The second group comprises nanoparticles consisting of 10^3 to 10^6 atoms having diameters from 5 to 100 nm.¹³³ However, this classification is correct only for isotropic (spherical) particles. Whiskers and plate-like particles can comprise a much larger number of atoms and their linear dimensions (one or even two) can much exceed the threshold value, but the properties of these objects remain typical of matter in the nanocrystalline state. Based on the ratios of linear dimensions, nanoparticles can be treated as one-, two- or three-dimensional (1D-, 2D- and 3D-nanoparticles, respectively).¹³⁴ If a nanoparticle has a complex shape and structure, the linear dimension of the structural element rather than the entire particle is taken as the characteristic size. Such

particles are usually called nanostructures; their linear dimensions can be much larger than 100 nm. Depending on the predominant type of the anisotropy of structural elements, nanostructures are also divided into one-, two- or three-dimensional ones.

The most important feature of nanosystems is manifestation of quantum size effects. From the classical standpoint, as the particle size in the system decreases, the specific surface area of the particles increases. The effect of the particle size on the thermodynamic properties of the system is included by introducing an additional term, γds (γ is the size-independent surface tension coefficient and s is the surface area), into the expression for the free energy. According to Thompson's equation, a decrease in the particle size is accompanied by an increase in the equilibrium vapour pressure and solubility and by changes in the temperatures of melting and other phase transitions. At the same time, a number of extensive parameters of the system, related to surface processes (e.g., adsorption and catalysis), are proportional to the specific surface area. The role of the specific surface area of nanoparticles becomes much more important as their sizes approach the atomic scale. This is due to a considerable increase in the number of surface atoms.

On the other hand, many properties of materials (including magnetic, optical and electrical properties) are due to co-operative interactions in solids that are not retained on going from the bulk material to nanoparticles. In this case the properties of materials cannot be rationalised solely by an increase in the specific surface area and the number of surface atoms without considering quantum size effects. This can be exemplified by the formation of quantum dots in those cases where the sizes of the semiconductor particles are comparable with the de Broglie wavelength of the electron, by a change in the width of the band gap due to localisation of excitons and by transition of ferromagnetic materials to the superparamagnetic state. Sometimes the size effect manifests itself as a dramatic enhancement or reduction of catalytic activity (or reactivity) per metal atom with a decrease in the particle size. This effect is usually most pronounced for nanoclusters.

The magnetic, electrical and optical properties of matter also significantly change as the particle size decreases from 5–10 nm downward.^{135, 136} The properties of nanoclusters depend non-monotonically on the cluster size (i.e., the number of atoms).¹³⁶

Unique properties of nanoclusters are likely due to the limited number of constituent atoms. In most cases the cluster core is formed following the close packing principle. The number of atoms in a regular dodecahedral core is given by the expression

$$N = \frac{10n^3 + 15n^2 + 11n + 3}{3},$$

where n is the number of shells surrounding the central atom. Thus, the smallest close-packed cluster core comprises a total of thirteen atoms (a central atom and twelve atoms of the first outer shell). As a result, one gets a set of 'magic' numbers $N = 13, 55, 147, 309, 561, 923, 1415, 2057, 2869, \text{etc.}$, which correspond to the most stable cluster cores.^{136, 137} A tendency towards formation of cores containing 'magic' numbers of atoms can be followed taking metal clusters as examples. A number of gold, rhodium, platinum and palladium compounds were synthesised, containing from thirteen {e.g., $[\text{Au}_{13}(\text{diphos})_6](\text{NO}_3)_4$; diphos is $\text{PPh}_2\text{CH}_2\text{PPh}_2$ } to a total of 2057 metal atoms [e.g., $\text{Pd}_{2057}(\text{phen})_{840-1600}$].¹³⁸ It should be noted that clusters comprising non-'magic' numbers of atoms are also formed. The existence of more energetically favourable 'magic' clusters provides an explanation for non-monotonic dependence of the properties of nanoclusters on their sizes.¹³⁹ On going from nanoclusters to nanoparticles this effect becomes less pronounced. Detailed studies of gold and palladium clusters revealed that their conductivities, heat capacities and magnetic susceptibilities are significantly different from the corresponding properties of bulk metals.¹⁴⁰ It was established that, unlike the orbitals of metal atoms in bulk samples, those of the

metal atoms of the cluster core are not delocalised and form discrete energy levels that differ from molecular orbitals. On going from a bulk metal to nanoclusters and then to molecules and single atoms the metallic band structure (conduction band formed by delocalised s- and d-electrons) turns into discrete energy levels formed by localised electrons in cluster and then into molecular and atomic orbitals. The appearance of discrete electronic energy levels in clusters causes single-electron transitions that are characteristic of single atoms.

Very interesting quantum size effects were observed in studies of the magnetic susceptibility and heat capacity of nanoclusters.¹⁴¹ It was shown that the magnetic susceptibilities of both the Pd_{2057} cluster and a bulk palladium sample are temperature independent (the absolute value of a cluster's susceptibility is much lower than that of the bulk sample). With inclusion of magnetic effects this means that the Pd_{2057} cluster is a Pauli paramagnetic and similar to the bulk metal. A decrease in the cluster size down to Pd_{1415} causes an increase in the low-temperature magnetic susceptibility, which is in good agreement with the results of quantum-mechanical calculations and is associated with a decrease in the density of states near the Fermi level. At the same time, increasing the cluster size leads to an increase in the specific magnetic susceptibility, which reaches a value typical of bulk metal at a particle size of nearly 30 nm. Nanoclusters exhibit a quadratic (or more complex) temperature dependence of the heat conductivity (cf. a linear dependence for bulk material and larger nanoparticles). The quadratic temperature dependence of the heat conductivity is typical of amorphous solids; in the case of nanosystems it is associated with tunnelling effects.

We have considered only a few examples of specific properties of small nanoparticles. Due to the small number of atoms these properties can be reasonably described using quantum-mechanical approaches. However, many fundamental properties of matter in the nanocrystalline state are different from the properties of bulk materials over a rather wide range of particle sizes (up to hundreds of nanometres).¹⁴² In this case one can use both statistical and thermodynamic methods that allow for the excess surface energy.¹⁴³

Unique physicochemical properties of nanoparticles and nanostructures make the design of functional nanomaterials based on them a quite interesting research avenue. Recently, particular emphasis has been placed on the magnetic and semiconductor nanomaterials. This is due to great practical value of these classes of materials for the development of information technologies. For instance, superparamagnetic materials based on transition-metal (e.g., Fe, Co, Ni) nanocrystals are used in memory devices with ultrahigh recording density.¹⁴⁴ Nanomaterials based on, e.g., $\text{A}^{\text{IV}}\text{B}^{\text{VI}}$ and $\text{A}^{\text{IV}}\text{B}^{\text{VI}}$ semiconductors possess unique optical properties and are thought to be promising for active elements of tunable lasers, nonlinear optical elements and devices for nanoelectronics.¹⁴⁵

Advances in studies of nanosystems are closely related to the improvement of field-ion, tunnelling, atomic force and high-resolution electron microscopies that allow visualisation and determination of the properties of individual nanoparticles and to the development of computational methods that would permit computer simulation of molecular motions in large molecular ensembles.

Summarising the investigations of nanosystems,¹⁴⁶ the following conclusions were drawn.

1. Modern theoretical concepts of nanosystems are too rough to underlie the practical use of nanosystems. Essential development of the theory of nanosystems is required. Most nanosystems are far from the equilibrium state; their state is continuously changed with time. That is why the establishment of laws of the physicochemical evolution of nanosystems is of crucial importance. The available data on this evolution are scarce as yet.

2. Methodologically, the properties of nanosystems should be studied by combining experimental studies and mathematical modelling. It is a combination of 'full-scale experiments and

computer simulation' that was used to obtain essential, unambiguously interpretable information on nanosystems.

3. Characterisation of nanosystems is still a challenge. Quantitative data on the properties of individual nanoparticles are hard to obtain. Information on the behaviour of nanoparticles in the measuring devices is of great importance. The most informative studies have been carried out by those research groups, which not only use but can also modify their measuring devices and adjust them in the course of measurements.

4. Currently, the emphasis has been placed on the following avenues of research on nanosystems:

- elaboration of theoretical foundations of preparation and operation of nanomaterials including superstrong metals and alloys, ceramics, film compositions and materials possessing specific optical, magnetic and electrical properties;

- elaboration of physicochemical foundations of nanotechnologies, including development of methods for preparation and characterisation of technological nanosystems and investigation of their behaviour under the operating conditions;

- development of nanopharmacology and nanomedicine, including elaboration of methods for the synthesis and characterisation of ultradispersed forms of pharmaceuticals and investigations of the mechanisms of their interaction with living organisms;

- creation of ecological nanophysicochemistry, which would study the mechanisms of formation and transformations of natural and technogenic air and water pollutants (aerosols and hydrosols, respectively); development of methods for cleaning the environment of nanoparticles.

Experiments with hydroxyapatite, acetylsalicylic acid and phthalocyanines showed that going to ultradispersed forms of these compounds causes dramatic changes in their therapeutic effects and opens up prospects for the formation of pharmaceuticals immediately inside invaded tissues. Therefore, the development of concepts of physicochemical evolution of ultradispersed pharmaceuticals from their formation in chemical reactors or in tissues to complete excretion is of paramount importance. Melikhov¹⁴⁶ posed a problem of development of physicochemical evolution of nanopharmaceuticals, which should provide methods for solving the following applied tasks.

1. Creation of materials possessing osteoinductive properties (inductors of osteogenesis), osteoporosis remedies and carriers for pharmaceuticals based on ultradispersed hydroxyapatite. For instance, the 'Ostim-100' osteoplastic material (ultradispersed form of hydroxyapatite) was proved to be highly efficient in acceleration of bone tissue regeneration. This opens up prospects for preparation of compositions containing this material and hormones or broad-spectrum antibiotics. However, this requires that hydroxyapatite nanoparticles be capable of forming 'complexes' with macromolecules of different nature.

2. Creation of 'nanofluids' based on hydroxyapatite and hydroxalcite doped with iron oxides for magnetic-field driven, directed transportation and delivery of pharmaceuticals in organisms. Preliminary experiments showed that both the interplanar space of hydroxalcite microcrystals and the aggregates of two-dimensional hydroxyapatite crystals can be intercalated with large amounts of various pharmaceuticals and with magnetic nanoparticles of iron oxides, thus making such materials magnetically sensitive. Therefore, studies on the possibility of creating pharmaceuticals based on these composites would be appropriate.

3. Development of methods for the preparation of nanostructured alloys based on nitinol to create materials for implants and medical instruments. Experiments revealed significant improvement of the consumer properties of the products made of nanostructured alloys. However, to meet all medical requirements, one should study the physicochemical evolution of the alloy.

4. Elaboration of methods for tumour therapy by sonostimulated inhibition and destruction of malignant cells using ultradispersed substances; search for compounds which can selectively crystallise and accumulate within malignant cells. There are experimental grounds to believe that tumour cells containing a rather

large amount of phthalocyanine nanoparticles can be killed by exposing to a weak acoustic field. Studies on crystal sensorics revealed that the frequency of formation of solid nanoparticles in cells can increase upon minor variations of the compositions and molecular structures of the substances present in the cells. Therefore, a promising avenue of pharmacological research consists in search for compounds, which can selectively form nanoparticles in tumour cells and thus provide a route to cell destruction using acoustic fields that is innocuous for normal tissues.

Returning to the role of nonlinear processes and self-organisation in the chemistry of nanomaterials, it should be emphasised that self-organisation is possible in different stages of their synthesis and exploitation, from the formation of nanocrystallites or nanoclusters to long-term operation of nanostructures in various technical, technological and biomedical systems.^{147, 148}

Indeed, in most cases nanoparticles (nanoclusters) are formed under strongly nonequilibrium conditions, which provides the necessary ratio of the rate of spontaneous nucleation to the seed growth to particular sizes. Historically, nanoparticles were first prepared using methods of colloid chemistry, which allowed the synthesis of particles of size 1 nm to 100 μm . In Fig. 21 we compared the linear dimensions of various colloidal systems, which are most often used in practice.

In 1968, Stöber, Fink and Bohn¹⁴⁹ first demonstrated that polycondensation methods are also efficient in the preparation of monodispersed silica particles. They hydrolysed a solution of tetraethylorthosilicate in alcohol at high pH values and obtained homogeneous spherical particles of amorphous SiO_2 . The particle size could be varied from 50 nm to 2 μm by varying only one parameter (reagent concentration). Matijevic *et al.*^{150–154} and the authors of Refs 155–157 also have made large contributions to the development of polycondensation methods. Methods of preparation of colloidal particles using polycondensation in solutions both in the presence and in the absence of surfactants (inhibitors of aggregation) have also been analysed.¹⁵⁸

The next group of methods for the preparation of nanoparticles comprises high-energy methods based on rapid condensation of vapours under such conditions that exclude aggregation and growth of the particles thus formed. These methods mainly differ in the procedures employed for evaporation of the starting compound and stabilisation of nanoparticles. Evaporation can be achieved by plasma excitation, laser methods, arc melting, heat treatment, *etc.*^{159–161} Condensation can occur either in the presence of a surfactant (adsorption of surfactant on the surfaces of particles hampers their growth) or on a cold substrate (here, the growth of particles is limited by diffusion rate).¹⁶²

Yet another group of methods involves the use of spatially confined systems, or the so-called synthesis in nanoreactors (micelles, droplets, films, *etc.*).¹⁶³ Here, one deals with the synthesis in reversed micelles, Langmuir–Blodgett films, adsorption layers, *etc.*^{164–167} Clearly, the particles thus obtained cannot be larger than the size of the corresponding nanoreactor; therefore, these methods allow preparation of monodispersed systems.¹⁶⁸ Biomimetic and biological approaches, which involve the use of biomolecules (proteins, DNA, *etc.*) as nanoreactors,^{169–171} can also be placed into this group.

Synthesis in colloidal nanoreactors permits not only the preparation of nanoparticles with very narrow and controllable size distribution but also particles of different shape and anisotropy (including small particles) as well as coated particles. This technique can be employed to prepare virtually all classes of nanostructures, from single-component metal to multicomponent oxide nanostructures.^{172–174}

It should be noted that the use of free nanoparticles as materials is strongly complicated by the fact that matter in the nanocrystalline state exhibits metastable properties. As mentioned above, this is due to an increase in the specific surface area of particles with decreasing linear size down to the nanometre scale, which leads to an increase in the reactivity of a compound and enhanced aggregation of nanoparticles. The method most

Figure 21. Linear dimensions of various colloidal objects.

widely used to solve this problem involves fabrication of nanocomposites (*i.e.* nanoparticles encapsulated in a chemically inert matrix).¹⁷⁵ This approach provides a way to eliminate aggregation of nanoparticles and protect them from external conditions (*e.g.*, from oxidation by air oxygen), which significantly facilitates the practical use of nanomaterials.

Nearly ten methods of matrix isolation of nanoparticles have been proposed to date. They can be conventionally divided into two groups. The first group comprises methods for the preparation of free nanoparticles followed by their incorporation into an inert matrix. The second group includes methods of formation of nanostructures in the bulk of the matrix during its chemical modification.^{176, 177} Methods from the first group are simple but impose strong limitations on the choice of matrix. Usually, organic polymers are employed as matrices, but these substances do not possess high thermal stability and sometimes do not exhibit the necessary physical properties (*e.g.*, high optical transparency).¹⁷⁸ Besides, incorporation of nanoparticles does not exclude their aggregation.¹⁷⁹ The second approach not only allows one to eliminate these problems but also provides a way of controlling the parameters of nanoparticles immediately in the matrix during their formation and even changing these parameters in the course of exploitation of the material. In this case, the matrix must contain some structural voids, which can be filled with appropriate compounds; subsequent modification of these fillers should cause the formation of nanoparticles in the voids.¹⁸⁰ In other words, these voids should confine the zone of the reaction involving the incorporated compounds, *i.e.*, act as a specific kind of nanoreactor. Clearly, by choosing compounds with different shapes of structural voids it is possible to synthesise nanostructures with different morphologies and anisotropies.

The best known example for this approach is the synthesis of nanomaterials using porous oxide matrices (usually, SiO₂ or Al₂O₃).^{181, 182} In this case, pores are filled with various compounds, which are then chemically modified. However, disordered porous structure and broad pore size distribution preclude preparation of good nanosystems. As a rule, such materials are used in catalysis, where the requirements imposed on the particle size distribution and particle morphology are not too strong.¹⁸³ A possible solution to the problem is provided by using porous materials with ordered pore structure, such as mesoporous silica and zeolites having 1D-channels or 2D-voids.^{184–186} In this case, it is possible to obtain whiskers, plate-like or spherical nanoparticles (depending on the type of the porous structure) with narrow particle size distribution.^{187, 188} Sometimes, rapid directed

formation of nanoparticles in the matrix is achieved by exposing the system to, *e.g.*, sonication, microwave and laser irradiation.^{189–191} However, a rigid porous structure precludes variation of the particle size and morphology during synthesis. As a rule, these parameters are strongly dependent on the pore size and morphology.¹⁹²

The use of structures with variable void sizes seems to be a convenient version of this method. A recently proposed technique involving compounds with layered aluminosilicate structures also seems to be promising.¹⁹³ In these compounds the layers are linked together through weak van der Waals forces, which allows one to change the volume of the interplanar space with ease. Besides, a layered structure permits considerable acceleration of gas diffusion in the interplanar space, thus facilitating chemical modification of layered compounds.^{194, 195}

Several tens of communications on the preparation of nanocomposites *via* layered compounds have been reported so far.^{196–200} Most of them are concerned with aluminosilicates, which have negatively charged layers and cations located in the interplanar space. However, these compounds usually have non-stoichiometric compositions and are highly hydrated and cross-linked, which strongly complicates the synthesis of nanomaterials and has a negative effect on the reproducibility of their properties.^{201, 202}

A large surface area and, hence, an excess surface energy of nanoclusters make aggregation processes unavoidable. They are directed towards a decrease in the Gibbs free energy, occur spontaneously and can be described in the framework of the model of conservative self-organisation in the absence of kinetic difficulties. Figure 22 presents a micrograph of a nearly spherical colloidal gold particle obtained after spontaneous aggregation of nanocrystals of average size 35 ± 5 nm.²⁰³ It was quite correctly pointed out²⁰⁴ that formation of nanostructures from nanoclusters is similar to the formation of bulk crystals from atoms, but the fundamental difference between these processes is that, unlike atoms, clusters are characterised by real surfaces and intercluster boundaries. What is more, cluster-cluster interactions produce strain as well as excess energy and excess pressure at the cluster boundaries. The excess energy per dislocation can be calculated by the formula

$$E_d = \frac{Gb^2}{4\pi(1-\nu)} \ln \frac{r}{r_0}$$

Figure 22. Micrograph of a colloidal gold particle formed upon spontaneous aggregation of nanocrystallites of average size 35 ± 5 nm.

where G is the shear modulus, b is the Burgers vector, which characterises the displacement of the edge dislocation, ν is the Poisson coefficient (usually, $\nu = 0.3$), r is the range of the effect of dislocations and r_0 is the minimum dislocation size. Assuming that the concentration of dislocations in the cluster is determined by the surface-to-volume ratio, the density of the excess energy of a cluster is given by the following expression

$$\varepsilon = \frac{Gb^2}{4\pi(1-\nu)R} \ln \frac{r}{r_0},$$

where R is the cluster size.

Thus, the density of the excess energy decreases with an increase in the cluster size R and equals zero for the bulk material.

Considering the effect of defects and dislocations on the properties of nanosystems comprised of nanoclusters of arbitrary sizes, one should start from the thermodynamic concentration of defects and dislocations, which includes the chemical potential and excess energy of the cluster surface. The excess energy causes the production of excess pressure, which can be estimated at $\sim 10^9$ Pa for clusters of size 1 nm.¹³⁶ Ignoring the difference between the pressure within the cluster and at its surface, the concentration of defects in the cluster (c_0) can be calculated by the formula

$$c_0 = \frac{a(3R^2 - 3aR + a^2)}{R^3},$$

where a is the thickness of the surface layer.

Taking into account the difference between the pressure within the cluster and at its surface, the following expression was derived¹³⁶

$$c = c_0 \exp \left(-\frac{2\alpha V/R}{kT} \right),$$

where α is the surface stress and V is the volume of the defect.

The dependence of c on the cluster size is plotted in Fig. 23. The maximum in the c - $f(R/a)$ curve is observed at $R/a = 25$, which corresponds to $R = 10$ – 50 nm. This range of cluster sizes provides the maximum concentrations of defects and excess energies, and such clusters are involved in the formation of nanosystems.

Nanostructures comprised of molecular clusters CO_2 , N_2 and SF_6 exhibit an increase in strain with increasing cluster size.²⁰⁵ X-Ray diffraction studies of nanosystems revealed the effect of the cluster size and interfacial strain on the structure of nanosystems.²⁰⁶ Analysis of nanocrystalline samples of Al, Ru, Cu and

Figure 23. Defect concentration in clusters plotted vs. cluster size.

AlRu showed^{207,208} that their deformations lie between 1% and 3%, which much exceeds the deformation of coarse-grain metals. Small clusters do not contribute to elastic deformation of the crystal lattice, which is due to interfacial dislocations.²⁰⁹ The major contribution comes from large nanoclusters. Hence, there is some intermediate range of cluster sizes, corresponding to maximum effect of interfacial strain, which is in agreement with the conclusions drawn based on the thermodynamic model of the influence of structural defects.

Nanosystems possess unusual mechanical properties. At room temperature, their microhardness is 2–7 times higher than that of the corresponding bulk materials. The Vickers microhardness of a cluster is given by the expression²¹⁰

$$H_V \approx H_0 + kR^{-1/2}$$

and increases with a decrease in the cluster size R . Experiments showed that a decrease in the size of Ag, Cu, Pd, Fe and Ni clusters is accompanied by an increase in the hardness of nanosystems.²¹¹ The microhardness of a nanosystem also depends on the treatment conditions, which affect the interface structure, cluster–cluster interactions and the cluster size. For instance, relaxation and annealing of interfacial defects at a constant size of $\text{Al}_{98.5}\text{Mg}_{1.5}$ clusters ($R \approx 150$ nm) cause a decrease in the microhardness from 1.7 to 1.45 GPa.²¹² However, annealing has a much more pronounced effect on R . In particular, heat treatment of a nanosystem comprised of palladium clusters at 475–600 K results in an increase in the cluster sizes and, correspondingly, in a nearly three-fold decrease in the microhardness of the system.

Yet another remarkable feature of nanosystems is their superplasticity, which was observed²¹³ for nanocrystalline Ni and Ni_3Al at 470 and 450 °C, respectively (this is nearly one third of the melting temperatures of these compounds). Superplasticity of oxide ceramics is of considerable interest for both theoretical studies and practical implementation. This property manifests itself at cluster sizes lying between 1 nm and 1 μm; the cluster size should not change on heat treatment.²¹⁴ The presence of amorphous phases can influence the superplasticity effect.²¹⁵

Structural transformations in nanosystems also attract considerable attention. It was established²¹⁶ that nanoclusters comprised of thermodynamically unstable γ -Fe phase are stable even at room temperature, whereas bulk samples are stable only at 800 °C. Cadmium sulfide nanoclusters with a rock salt structure are also known;²¹⁷ a bulk sample of CdS with the same structure is stable at high pressure only. Stabilisation of nonequilibrium (at a given temperature) structures due to formation of small clusters ($R < 10$ nm) can be explained by the effects of the surface energy and the surface pressure, which can be as high as several GPa for clusters of size 1–2 nm.

Thermodynamic features of the behaviour of nanosystems including surface phenomena, phase transformations and aggregation of free molecules or ions into various supramolecular structures have also been studied.^{218,219}

IX. Fractal, epitaxial, template structures and nanocomposites

The evolution of any physicochemical systems existing under nonequilibrium conditions can involve formation of various structures (including fractal, epitaxial and template ones) and nanocomposites.

Formation of fractal structures in macroscopic and nano-systems is due to manifestation of dissipative self-organisation under such conditions where the driving force of the process (*e.g.*, the temperature or chemical potential gradient) exceeds a critical value corresponding to the bifurcation point. Many materials have fractal structures in different stages of preparation and exploitation.^{220, 221} A classical example is provided by the formation of fractal particles during aggregation in solutions and gases.^{222–224} The formation of dendritic structures in the course of, *e.g.*, nonequilibrium electrochemical deposition of metals, solidification of alloys under strong supercooling conditions or phase separation processes is also well known.^{224–227} The surface structures of many catalysts and adsorbents are also described in terms of fractal geometry.²²⁸ Finally, cracks and surfaces, which develop on fracture of many materials, also have a fractal structure.^{229–231} Clearly, periodic geometric patterns characteristic of fractal objects strongly affect their behaviour in various physicochemical processes, among which the most important for materials science are heat treatment processes, catalytic and surface phenomena and solid-phase reactions. The fractal structure also influences the characteristics of diffusion in such objects.

The main laws and peculiarities of diffusion processes and reactions in fractal media, which do not involve changes in the fractal structure, have been studied in considerable detail.^{232–235} Much less attention has been paid to the effects of excess surface energy and to significant geometric nonuniformity on the thermodynamic and kinetic properties of fractal objects (in particular, on their behaviour during ageing, sintering, *etc.*). Here, of particular interest for materials science is the evolution of dendritic inclusions on annealing, as well as crack healing in ceramic materials, structural changes in composites at elevated temperatures, *etc.* A common property of these processes is that they occur with a constant amount of matter in the system (*i.e.*, at a conserved order parameter). This differs from dissolution of particles in reactive media or etching.

A computer simulation of the evolution of fractal particles in systems with a conserved order parameter during ageing and sintering has been reported.²³⁶ The fractal cluster was generated by the diffusion limited aggregation (DLA) mechanism with preset joining probabilities assuming that the change in the density at each point of the cluster is described by the Cahn–Hilliard equation

$$\frac{dc}{dt} = \nabla^2 c - V(c),$$

where c is the dimensionless density ($0 \ll c \ll 1$); $V(c) = K(c^2 - c)^2$ is the potential whose minima correspond to the bulk ($c = 1$) and free ($c = 0$) phases and K is a constant. At different stages of evolution, the geometry of the structure of the particles thus obtained was characterised using the box-counting method and by analysing the correlation functions. It was found that the observed evolution pattern is strongly dependent on the geometry of the seed particles, which is prescribed by the ratio of the upper and lower fractality boundaries, $R_{\max}/R_{\min}$, and by the fractal dimension D .

It was also found²³⁶ that, depending on the self-similarity range of the ‘seed,’ the evolution of the fractal cluster can occur in different manners, namely, with and without fragmentation of the initial particles (long-range and short-range cases shown in Figs 24 and 25, respectively).

The principle of orientational and dimensional correspondence, which was first formulated by Konobeevskii and then by

Figure 24. Evolution of a fractal cluster involving fragmentation.

Dankov (see Ref. 237), serves as the basis for the growth of epitaxial structures. According to this principle, the shape and orientation of the seeds of new phases crystallising in an anisotropic medium should correspond to the free energy minimum, which is achieved when the patterns of atomic arrangement in adjacent faces of the new and old phases are best matched. The condition for oriented crystallisation has the form of inequality

$$A + E - Z \leq A_1,$$

where A and E are respectively the work of formation and the energy of two-dimensional nucleus for oriented crystallisation; Z is the work of adhesion (adhesive forces are responsible for enhanced deformation); and A_1 is the work of formation of a three-dimensional nucleus in the case of spontaneous crystallisation. It was shown^{238, 239} that oriented crystallisation is possible if the parameters of the lattices to be matched differ by at most 18%.

It was established²⁴⁰ that epitaxial stabilisation is often followed by the formation of film structures, which are thermodynamically unstable in the absence of such a stabilisation. This can be exemplified by the formation of thin films of REE-containing nickelates and cobaltites on LaAlO_3 , SrTiO_3 and

Figure 25. Evolution of a fractal cluster involving no fragmentation.

NdGaO₃ substrates, though the changes in the Gibbs free energy of the reactions

are positive and, hence, the bulk phases of the nickelates and cobaltites are thermodynamically unstable.

Stabilisation of epitaxial structures can also be exemplified by the behaviour of bulk samples of REE-containing manganites RMnO₃, which can be divided into two groups, namely, samples with a perovskite structure (*Pnma*) for the early REE (*R* = La–Dy) and samples with hexagonal structures (*P6₃mc*) for the late REE (*R* = Ho–Lu). Figure 26 presents the $\Delta_r G^\circ$ of the reaction

plotted vs. the ionic radius of REE, which confirms the above-mentioned structural evolution.²⁴¹

Figure 26. Plot of $\Delta_r G^\circ$ for reaction (1) vs. ionic radius of REE.²⁴¹

However, it is possible to grow thin films of (i) manganites of the late REE with the perovskite structure on substrates with the perovskite structure and (ii) manganites of the early REE with a hexagonal structure on substrates with the hexagonal structure under conditions of epitaxial growth. In other words, the oxide substrate can ‘force’ the film of the REE-containing manganite to grow following the epitaxial pattern, which is atypical of the manganite film under the equilibrium synthesis conditions.²⁴¹

It should be noted that heteroepitaxy of the vapour and liquid phases on single crystals or biaxially textured substrates is efficient only when preparing oriented films of thickness at most 1 μ m. Epitaxial effects dramatically weaken as the film thickness increases. Usually, thin epitaxial films exhibit record values of specific characteristics (e.g., the maximum critical current densities for superconducting cuprates). However, they cannot be

used to achieve high absolute values of operating parameters, as is the case of bulk ceramics, which, unfortunately, possesses poor mechanical properties (first of all, it is highly brittle). A way out was to use a hybrid method elaborated by researchers from the Aachen Centre for solidification in space (Germany) and the Department of Chemistry, M V Lomonosov Moscow State University. To obtain textured thick (50 to 100 μ m) superconducting films, the orientational effect of the substrate (formally, it is similar to the epitaxial effect in the case of thin films) was combined with the melt growth of large grains, which is typical of bulk materials.²⁴² Here, the substrate had an artificial symmetrical relief, which matched the symmetry (grooves or a square grid) and typical sizes (0.1–1 mm) of the crystallising YBa₂Cu₃O_x phase (Fig. 27), instead of short-range orientational effect (molecular epitaxy). By creating such a surface relief using strips made of cheap, untextured commercially available polycrystalline silver as the substrate it is possible to obtain up to 90% of the *ab*-biaxially textured, melt grown crystallites of high-temperature superconductors.

The origin of texture formation is based on various physico-chemical phenomena including wetting (some specific aspects), surface tension, meniscus, heterogeneous nucleation, redistribution of melt components, capillary effects, effects of crystallisation pressure and topographic wall effect of relief elements.^{242, 243} By analogy with ‘graphoepitaxy’ (a well-known thin-film process),^{243, 244} a ‘graphotexturing’ technique was developed, which can be employed in studies of various materials and arbitrary substrates. This approach can lead to virtually complete texturing of a polycrystalline layer in accord with the relief symmetry. The process occurs as a ‘self-assembly’ of the crystallite layer at the mesoscopic level. All tape fragments behave identically, so that the length of the tape crystallising per unit of time can be infinitely long provided that the entire sample is heat treated in the furnace.

Porous structures with pore sizes ranging from 10 nm to 10 μ m can be formed using template synthesis,^{245–248} which is exemplified by Fig. 28. Structural units of the matrix to be formed self-organise into a continuous framework around the template particles. The structure obtained after post-synthetic removal of the template contains channels, which exactly match the size and shape of the template. Once the framework is formed, the template (most often, polystyrene or silica beads) is removed. Namely, polystyrene beads are burnt out in air or dissolved in toluene, while silica beads are etched with hydrofluoric acid. Typical examples of template porous structures are shown in Fig. 29.²⁴⁹ Template synthesis is convenient for preparation of mesoporous, metal,^{250, 251} metal oxide,^{252–254} chalcogenide,^{255, 256} polymeric²⁵⁷ and silica^{253, 258} materials. This method is of prime interest for the formation of photonic crystals (periodic structures comprised of fragments with different dielectric constants). The most important feature of photonic crystals is the forbidden photon energy band, which excludes passage of photons with a particular wavelength through the crystal. Photonic crystals are similar to semiconductor crystals but manipulate photons rather than electrons, thus opening new prospects for development of photonic applications.

In contrast to semiconductor crystals that are characterised by spontaneous formation of periodic atomic structure, photonic

Figure 27. Biaxial texturing of superconducting phase YBa₂Cu₃O_x on a silver substrate with artificial relief.

Figure 28. Scheme of the template synthesis of porous structures.

Figure 29. Typical examples of porous template structures in polyurethane-based polymeric materials (a–c) and in ceramics based on SiO₂ (d), SnO₂ (e) and TiO₂ (f).

crystals are produced artificially using specific methods of template synthesis. The 'lattice' constant of a photonic crystal is comparable with the wavelength of light (of the order of 1 μm), which is more than three orders of magnitude larger than typical lattice constants of 'normal' crystals. At the same time, this value is nearly two orders of magnitude smaller than the diameter of a human hair. A version of template synthesis of photonic silicon crystals elaborated by Vlasov *et al.*²⁵⁹ is illustrated in Fig. 30. The technique is based on self-organisation of colloidal spherical silica particles that act as an ordered template. The starting point is ordered, temperature gradient driven self-organisation of silica particles on the surface of a vertical silicon plate due to surface tension by evaporation of solvent (Fig. 30 a). The temperature gradient permits minimisation of undesired sedimentation processes. The space between spherical silica particles is uniformly filled with silicon using a CVD technique (Fig. 30 b). Then, silica is etched with hydrofluoric acid to leave a photonic crystal, *i.e.*, a periodic three-dimensional structure comprised of a porous silicon framework adjacent to the silicon chip (Fig. 30 c). Thus, self-organisation processes play a key role in the formation of template structures including photonic crystals.²⁶⁰ Two-dimensional photonic structures, *e.g.*, alumina films (Fig. 31), are also of interest. Here, the ordered pore system is formed as a result of self-organisation of alumina films during the oxidation of aluminium.²⁶¹

As mentioned in the preceding Section, nanocomposites (*i.e.*, composites comprised of nanoparticles encapsulated in a chemi-

Figure 30. Scheme of the template synthesis of photonic silicon crystals (for details, see text).

Figure 31. Micrographs of porous alumina film prepared by anodic oxidation of aluminium foil under different conditions. H₂C₂O₄, 40 V (a); H₃PO₄, 140 V (b); and H₃PO₃, 195 V (c).

cally inert matrix) belong to those promising materials whose formation is strongly affected by self-organisation processes. In this case, the matrix allows one to avoid uncontrollable aggregation of nanoparticles and protect them from external factors (*e.g.*, oxidation by air oxygen), thus facilitating practical use of such materials. Considerable attention has been paid to the method for preparation of nanocomposites,^{196, 262–264} which is based on chemical modification of layered double hydroxides (LDH). The LDH are compounds of the compositions $[M_{1-x}^{2+}M_x^{3+}(\text{OH})_2]^{A+} \cdot [(A^{n-})_{A/n} \cdot m \text{H}_2\text{O}]$, where $A = x$ at $z = 2$ and $A = 2x - 1$ at $z = 1$, M^{2+} is the metal in the oxidation state +2 or Li⁺, M^{3+} is the metal in the oxidation state +3 and A^{n-} is any anion incapable of forming stable complexes with these cations.²⁶⁵ The structure of LDH comprises positively charged hydroxide layers $[M_{1-x}^{2+}M_x^{3+}(\text{OH})_2]^{A+}$ and anions present in the interplanar space (Fig. 32), which is usually filled with labile water molecules too. This structure was named hydrotalcite after a natural mineral of the composition $\text{Mg}_{1-x}\text{Al}_x(\text{OH})_2[(\text{CO}_3)_{x/2} \cdot m \text{H}_2\text{O}]$ ($x \sim 0.25$, $m \sim 0.5$). The method for the synthesis of nanocomposites is based on chemical modification of the anions present in the interplanar space of LDH. The reaction zone is confined by the hydroxide layers, which makes the conditions for the synthesis of

Figure 32. LDH structure.

nanophase similar to the conditions for the synthesis in two-dimensional nanoreactors.

Compounds like clays, zeolites and Chevrel's phases also have layered structures; however, only the LDH possess some unique properties that are of great importance for directed synthesis of nanomaterials.²⁶⁶ On the one hand, the LDH containing a very broad range of cations and anions (compounds with $M^{2+} = \text{Mg}^{2+}, \text{Zn}^{2+}, \text{Fe}^{2+}, \text{Co}^{2+}, \text{Ni}^{2+}, \text{Cu}^{2+}, \text{Cd}^{2+}, \text{Mn}^{2+}$ and $M^{3+} = \text{Al}^{3+}, \text{Cr}^{3+}, \text{Mn}^{3+}, \text{Fe}^{3+}, \text{Co}^{3+}, \text{Ni}^{3+}, \text{Sc}^{3+}, \text{Ga}^{3+}, \text{Ln}^{3+}$ have been characterised to date) retain stable layered structures and the interplanar space of the Mg-Al LDH can be intercalated with various anions of sizes 3 to 50 Å. On the other hand, the number of anions present in the interplanar space of the LDH is determined by the M^{2+}/M^{3+} ratio, which can be controlled with ease during the synthesis. This allows preparation of LDH with a prescribed stoichiometric composition and, hence, variation of the concentration of the reactive sites in the matrix. Besides, these compounds can retain the layered structure on thermal decomposition due to high rate of gas diffusion in the interplanar space. This permits chemical reactions involving the anions present in the interplanar space to be carried out at elevated temperatures (*e.g.*, hydrogen reduction, which is necessary for preparation of magnetic nanocomposites) without breaking the matrix that confines the reaction zone.

This synthetic approach was employed for the preparation of various LDH-based functional nanocomposites (*e.g.*, magnetic Fe- and Ni-containing nanocomposites).^{263,267} To this end, the Mg-Al LDH of various cationic compositions were intercalated
