with anionic complexes of these metals [$\text{Fe}(\text{EDTA})^-$ and $\text{Ni}(\text{EDTA})^{2-}$]. The anion-substituted LDH thus obtained were reduced in a hydrogen flow at different temperatures (Fig. 33). It was shown that, depending on the LDH compositions and reduction conditions, the reaction results in one-, two- and three-dimensional metal nanostructures (Fig. 34). An increase in the content of the complex in the LDH matrix causes a decrease in the dimension of the newly formed nanostructures and an increase in the anisotropy factor. It should be noted that lowering the temperature has virtually no effect on the morphology of the nanoparticles thus formed. Namely, an increase in the reduction temperature leads to an increase in the average size of nanoparticles, while the ratio of their linear dimensions (anisotropy factor) varies only slightly. By varying the reduction temperature it is possible to vary the sizes of the newly forming nanoparticles over a rather wide range from several to several tens of nanometres. The results obtained show that magnetic nanocomposites thus obtained can be promising materials for memory devices with ultrahigh recording density.²⁶⁸

The possibility of using the LDH for preparation of semiconductor PbS nanoparticles coated with an amorphous sulfur shell is of considerable interest.^{269,270} The sulfur shell allows a substantial increase in the luminescence intensity and quantum yield. Usually, the preparation of such nanostructures requires multistage synthesis. The use of LDH allowed a single-stage synthesis of matrix isolated PbS/S nanostructures by photochemical modification of Mg-Al LDH intercalated with $[\text{Pb}(\text{S}_2\text{O}_3)_2]^{2-}$ anions (Fig. 35). Nanocomposites thus obtained possess unusual

Figure 33. Scheme of preparation of nanocomposites based on iron or nickel.

Figure 34. Diagrams showing the formation regions of different types of particles in Mg-Al-Fe(EDTA)^- (a) and $\text{Mg-Al-Ni(EDTA)}^{2-}$ (b) systems.

(a): Iron spheres of size 1–10 nm (1), iron plates 10–100 nm long and 1–3 nm thick (2) and iron wires 10–100 nm long and 1–5 nm thick (3); (b): nickel spheres of size 1–10 nm (1), nickel plates 10–70 nm long and 1–3 nm thick (2) and nickel wires 10–150 nm long and 1–5 nm thick (3).

optical properties (increased luminescence intensity, additional exciton bands in absorption spectra) due to modification of the surface of PbS nanoparticles with amorphous sulfur (Fig. 36). The use of Mg-Al LDH as precursors allows exact control of the amount of nanoparticles in the matrix by varying the Mg/Al ratio in the initial stage of the synthesis of LDH. This is of crucial importance for fabrication of optical devices based on quantum dots.

Platinum nanoparticles can be obtained in the LDH matrix in one stage.²⁷¹ Reduction of LDH intercalated with hexahydroxoplatinate(IV) anions is accompanied by the formation of platinum nanoparticles of a size of at most 10 nm. The specific catalytic activity of such nanocomposites in the oxidation of CO, hydrocarbons and alcohols is ten to fifty times higher than the activity of bulk platinum metal. As a consequence, these nanocomposites seem to be promising catalysts for the afterburning of exhaust gases. It should be noted that the approach involving LDH is not limited to preparation of the above-mentioned nanomaterials.

Figure 35. Scheme of the synthesis of PbS nanoparticles in a LDH matrix.

The availability of the starting compounds, simplicity and low cost of synthetic procedure, ease of control of the composition of both intermediates and end products, as well as the possibility of intercalating the LDH structure with various cations and anions make this method rather promising for the preparation of virtually all classes of nanocomposites.

Yet another method for the synthesis of nanocomposites is based on matrix stabilisation of metal and metal oxide nanoparticles of size less than 50 nm as a result of the polymerisation reaction proceeding within the solid phase.^{272, 273} In other words, the technique combines the formation of both nanoparticles and polymer matrix to stabilise them. The process proceeds as copolymerisation of metal-containing monomers that form the polymer matrix. Supramolecular organisation of nanocomposites is achieved as a result of controlled thermal transformation of the metal-containing monomers in an inert atmosphere. The main stages of this transformation are dehydration and thermal copolymerisation including self-propagating frontal polymerisation and controlled pyrolysis of the product obtained.

Figure 36. High-resolution electron micrograph of a PbS–amorphous sulfur core–shell nanoparticle in a LDH matrix.

By varying the copolymerisation conditions and pyrolysis temperature it is possible to prepare both nanoparticles of desired size and the necessary particle size distribution within the polymer matrix with controllable composition and thickness. The nanoparticles thus obtained are chemically bound to the polymer matrix in which they are present. Typical monomers are methacrylate, maleate and acrylamide complexes of d-metals (Co, Ni, Fe, Mn, Ti, Zr, Hf, *etc.*).

When preparing nanocomposites possessing synergistic properties, particular emphasis is placed on co-polycondensation of one or more monomeric metal complexes including both main-group (Ba, Zn, Cd, Pb) and rare-earth (Eu, La, Nd) elements. In particular, controlled thermolysis of $\text{Fe}_2\text{CoAcr}_5$ causes amorphisation of the starting crystalline phases, while the magnetic product (CoFe_2O_4) is formed in the last stage of the process. The nanocomposite thus obtained exhibits unusual properties (*e.g.*, a non-symmetric hysteresis loop and anomalous coupling between the antiferromagnetic and ferrimagnetic phases). Each magnetic particle of the nanocomposite is comprised of a spherical ferrimagnetic core (8–12 nm) and a spin glass shell 8 to 10 nm thick; ensembles of such particles can be an efficient magnetic medium.

A particular group of compounds comprises hybrid nanocomposites, which are formed from organic molecules or macromolecules (templates) and inorganic components containing optically active molecules or ions. Using methods of ‘soft chemistry’ and self-assembly at nanolevel, it is possible to create highly complex hierarchical structures with unique optical properties including high light emissive power and photochromic and electroluminescent effects.²⁷⁴

X. Biomimetism as route to advanced materials

One of the most attractive avenues in design of advanced materials involves the use of biomimetic approaches.^{275, 276} A living organism is a complex dynamic system, which exists due to continuous exchange with the environment. The exchange occurs by breathing, nourishment and excretion. In other words, dissipative self-organisation is intrinsic in any living organism.²⁷⁷ However, this does not exclude conservative self-organisation processes in certain regions of a complex system. And though the processes of conservative and dissipative self-organisation are to some extent the reverse of each other (conservative self-organisation is a result of the evolution of the system towards a decrease in the Gibbs free energy, which is achieved at high temperatures due to an increase in entropy, while dissipative self-organisation is a result of the evolution of the system towards a decrease in entropy), they likely co-exist and make different contributions to the vital activity of the complex system.^{30, 31}

Undoubtedly, both geological and biological evolution of matter obey the laws of nonlinear dynamics, but the interrelation between the processes of conservative and dissipative self-organisation changes in favour of the latter on going from inanimate to organised matter.²⁷⁸ Clearly, the pre-biological or geological evolution associated with transition from plasma to molecules, condensed phase and then to formation of simple and complex minerals is determined by processes of conservative self-organisation,²⁷⁹ whereas the phenomenon of life is intimately associated with dissipative self-organisation.²⁸⁰ Time is also of paramount importance for evolution.²⁸¹ Creating more or less complex artificial inorganic or organic structures, researchers accelerate particular processes by varying the temperature, pressure, chemical potentials of reagents, *etc.* Illustrative examples are provided by fabrication of synthetic diamonds, opals, complex oxides with spinel, perovskite, pyroxene, *etc.* structures. Considerable progress has been made towards hydrothermal synthesis of natural minerals,²⁸² which demonstrated high efficiency of approaches based on geomimetism.²⁸³ Some efforts have been undertaken, aimed at ‘adjusting’ nature by creating more perfect biological systems or their fragments by, *e.g.*, cloning. In the course of pre-biological evolution any system tends to reach a state that is most stable towards faults or fluctuations. At the same time, an increase in the complexity of a system accelerates the exchange of matter and energy, *i.e.*, biological evolution. This statement to some extent contradicts inferences about slowing down metabolism during the evolution of living systems in the course of natural selection. Nevertheless, approaches developed to create models of evolution can be employed for chemical engineering of various materials.²⁸⁴

One of the simplest methods involves the use of biomineralisation processes, in which the conditions for nucleation and crystal growth of inorganic phases are determined by the organised surface of an organic matrix. Biomineralisation processes allow preparation of various inorganic materials with nearly identical crystallites of particular compositions and structure at moderate supersaturations and temperatures.^{285, 286} A classical example is provided by the formation of oriented chains of monodomain magnetite crystals²⁸⁷ or metastable ferromagnetic based on iron sulfide involving magnetic bacteria.^{288, 289} This opens up a way towards cryochemical synthesis of advanced magnetic materials. As a rule, particles of the magnetic material are similar in size to one another and often have an unusual metastable structure.

Yet another feature of biomimetism is preferred crystallographic orientation of inorganic material relative to the organic matrix,²⁹⁰ which often represents a supramolecular structure and is comprised of polypeptide layers, polysaccharide matrices or protolipid membranes. Subsequent ordering of such organised inorgano-organic composites often causes formation of hierarchical structures,^{291, 292} which can be exemplified by mollusk shells. For instance, the shell of *Atrina sp.* comprises a layer of calcite crystals coated with an organic sheath and ordered with formation of a coherent structure. This structure is typical of many types of bioceramics and characterised by unusual structural properties. For instance, the tensile strength of bioceramics is several orders of magnitude higher than that of a material of the same composition prepared in a conventional manner.

The mechanism of the effect of an organic matrix on crystallisation of inorganic compounds was initially described in the framework of epitaxial relationships based on crystallographic similarity.²⁹³ More recently,^{294–296} it was shown that the mechanism of the influence of ordered organic matrix on the nucleation of inorganic compounds is more complicated, being a combination of at least three interfacial processes including adsorption and ordering of charged particles on the surface of the organic matrix, transcription of geometric information through ordered cations and the appearance of stoichiometric complementarity between the cations bonded to the head groups of adsorbed monolayer and

Figure 37. Electron micrographs obtained in different stages of morphogenesis of fluoroapatite aggregates. Initial stage, elongated hexagonal prismatic seeds 10 μm long (a); intermediate stages (dumb-bell aggregates) (b–d); and final stages (spheroaggregates) (e, f).³⁰¹

the local coordination environment of ions in the crystal structure of nuclei. Oriented nucleation of inorganic compounds is controlled by molecular recognition of the two-dimensional organic template and the nuclei of inorganic crystals.²⁹⁷

Of crucial interest are the results obtained in a study²⁹⁸ on the morphogenesis of fluoroapatite in denatured collagen (gelatin) matrix, which is in many ways similar to the growth of bone tissue and dentin.^{299, 300} The sequence of morphogenesis stages is shown in Fig. 37. The process begins with elongated hexagonal prismatic seeds, which are then transformed into dumb-bell structures by a fractal self-similarity mechanism, and is completed by the formation of spheroaggregates of size 150 μm . It is noteworthy that the surface of the spheroaggregates is comprised of needle-shaped fragments. Figure 38 presents the results of a two-dimensional computer simulation,³⁰¹ which clearly illustrates the possibility of fractal growth of the system from a seed to a closed fluoroapatite

spheroaggregate. The fractal mechanism of morphogenesis of the fluoroapatite particles was related to the assumption of the existence of intrinsic electric fields that control the crystal growth. This means that both crystalline seeds and products of morphogenesis are permanent dipoles. The polarity of collagen and the structural features of apatites $\text{Ca}_5\text{X}[\text{PO}_4]_3$ ($\text{X} = \text{F}^-, \text{Cl}^-, \text{OH}^-$),³⁰² in which the distribution of the anions X can be varied from centrosymmetrical to non-centrosymmetrical, confirm this model. It should be taken into account that extremely mild biomimetic growth conditions, which must favour a high degree of atomic ordering, cause an asymmetric displacement of the anions X from the equilibrium positions in the mirror plane³⁰³ and a (possible) reduction of symmetry from the centrosymmetrical point group $6/m$ to the pyroelectric point group 6. Finally, the polar organic component and inorganic crystals can exhibit synergism, thus forming an ordered composite structure in

Figure 38. Two-dimensional evolution models of an intrinsic electric field around a growing fluoroapatite spheroaggregate. Each permanent dipole is represented by a combination of black and gray circles denoting the positive and negative charge, respectively; seeds (a); the growing spheroaggregate: seed + 2 generations (b) and seed + 3 generations (c). Arrows denote the directions of the electric field lines.³⁰¹

Figure 39. Electron micrographs of a hexagonal prismatic fluoroapatite seed (a) and its fracture area perpendicular to the seed axis (b).²⁹⁸

which the *c* axis of apatite crystals is oriented parallel to the long axis of collagen fibres.²⁷⁵

Returning to the morphogenesis of fluoroapatite, it should be noted that completion of the fractal growth (formation of spherical particles) is followed by formation of concentric shells comprised of elongated prismatic fluoroapatite seeds with nearly parallel orientation (the maximum diameter of the core + shell particle is 1 nm) and that the structure of the particle has much in common with the structure of dentin. Hexagonal prismatic seeds of fractal aggregates (see Fig. 39) are not single crystals, as is clearly demonstrated in the micrograph of the fracture area perpendicular to the seed axis. The cross-section shows that formation of the hexagonal prism begins with the central seed, which can be formed due to rearrangements of the gelatin molecules, which can serve as active nucleation centres of apatite. The size of apatite crystallites was not exactly determined, it can lie between nanoscale and mesoscopic levels. Thus, the hexagonal prismatic macroscopic seed is an inorgano-organic composite with an ordered hierarchical superstructure rather than a single crystal.

XI. Conclusion

Modern revolutionary changes in chemistry and technology of materials are closely related to the changes in the fundamental concepts of spatio-temporal evolution of materials.³⁰⁴

Self-organisation processes in the physicochemical systems used as precursors are of great importance for the design of advanced materials, since usually their evolution occurs under strongly nonequilibrium conditions. Conservative and dissipative self-organisation, which best manifest themselves in isolated and open systems, respectively, can accompany each other, thus making the description of the evolution of corresponding physicochemical systems much more complicated. Nonlinear patterns of evolution from precursor to the target solid-phase product complicates the optimum organisation of the reaction zone. Ideally, the precursor or the solid-phase intermediate from which

the solid-phase product is formed must be a composite comprised of a highly homogeneous amorphous matrix and a nanotemplate, which provides a necessary direction of bulk crystallisation.

Application of dissipative chaos models to poorly reproducible physicochemical systems allows valuable information on their dynamics to be obtained. Of crucial importance are the self-organisation processes with formation of supramolecular ensembles and supramolecular materials bonded through noncovalent intermolecular bonds.³⁰⁵

Research on self-organisation phenomena in nanosystems¹⁴⁷ provides an insight into the conditions for formation of various structures (from nanocrystals to nanocomposites). Particular emphasis should be placed on the formation of fractal, epitaxial and template structures as well as nanocomposites that are used in the design of functional materials.

The use of models of bio-evolution, biomimetism and biomineralisation opens up attractive prospects for the creation of smart materials that will be highly competitive with natural materials and in some cases be superior to them.^{306–308}

The author of this review would consider the goal sought in writing this review attained if he was able to show that the most promising and 'stylish' avenues of research in the field of materials science, which are associated with the design of seemingly quite different materials, have much in common. This first of all concerns the algorithm of description of complex open physicochemical systems, which exchange energy and matter with the environment but allow control of the evolution from precursors to target solid-phase products.

The author expresses his gratitude to the Corresponding Member of the Russian Academy of Sciences I V Melikhov, D.Sc. (Chem.) E A Goodilin, D.Sc. (Chem.) I P Suzdalev, D.Sc. (Chem.) B R Churagulov and Dr. (Chem.) Yu G Metlin for valuable comments and help in writing the review.

This review has been written with the financial support from the Russian Foundation for Basic Research (Project No. 02-03-33263).

Abstract. The published data on the comparative activities of the nitro group, fluorine and chlorine in aromatic nucleophilic substitution reactions are generalised and systematised. The factors influencing the relative activities of these substituents, viz., the structure of the substrate, the nature of the nucleophile and reaction conditions, are discussed. The synthetic applications and possible mechanisms of nucleophilic substitution of the nitro group, fluorine and chlorine in aromatic compounds are considered. The bibliography includes 265 references.

I. Introduction

Nucleophilic aromatic substitution is still the field of organic chemistry that is the most intensively developed^{1,2} owing to the diversity of reaction mechanisms^{1–4} and high synthetic potentials of these reactions.^{5–7} Nucleophilic substitution of hydrogen (S_N^H) in arenes is an efficient approach to their functionalisation,^{1,2,8,9} but *ipso*-substitution (S_N^{ipso}) of the nucleofugal group in aromatic compounds is of no less importance, since it allows regioselective synthesis of not only *ortho*- and *para*-isomers, but also of their *meta*-derivatives.¹ The present review is mostly concerned with the S_N^{ipso} reactions of arenes under the conditions where the role of a nucleofuge is played by the nitro group or halogens (fluorine and chlorine).^{1,10–12} The popularity of these leaving groups is due primarily to the high accessibility of the corresponding derivatives^{13–16} and activity of these groups in aromatic nucleophilic substitution reactions.^{1,10–12,17}

Some physicochemical characteristics of the Ar–X bonds and the leaving groups X, where X = NO₂, F and Cl, are given in Table 1. The C–F bond is much shorter, more stable and less polarisable than the C–NO₂ and C–Cl bonds. The NO₂ and F groups are characterised by a strong polar effect (*cf.* relatively high values of the constants σ_X and σ_F), but the steric (E_S) and polarisability (σ_X) effects for the NO₂ group are much stronger

than those for fluorine (the minus sign designates an enhancement of the corresponding effect). Chlorine is the most polarisable and the least electronegative among the substituents mentioned. These characteristics of the leaving groups X have a pronounced effect on their relative activities in nucleophilic substitution reactions. The rates and directions of these reactions depend on the structure of the starting arene, the nature of the nucleophile and the experimental conditions. A combination of these factors determines the reaction mechanism.^{11,12,17,23} For this reason, an analysis of kinetic data on the comparative activities of a nitro group, fluorine and chlorine bound to an aromatic ring is very important for the correct choice of the most efficient approaches to the synthesis of functionalised arenes.¹⁶

Nucleophilic substitution of the aromatic nitro group has been reviewed previously²⁴ with the main emphasis on the synthetic results. The present review is devoted to the analysis and systematisation of the data on comparative activities of the NO₂, F and Cl groups in arenes under the action of various nucleophilic agents published in the past 10–15 years. The main emphasis is laid on reactions of NO₂-, F- or Cl-substituted aromatic compounds with anions as nucleophiles.

Table 1. Characteristics of the Ar–X bonds and groups X in substituted arenes.

Parameter	Group X			Ref.
	NO ₂	F	Cl	
Bond length /Å	1.4982	1.305	1.766	15, 18
Bond dissociation energy /kJ mol ^{–1}	298.0	525.4	400.0	19
Refraction of the Ar–X bond /cm ³	6.9	1.43	6.62	20
Constants:				
electronegativity (σ_X)	0.46	0.70	0.16	21
polarisability (σ_X)	–0.26	0.13	–0.43	21
field (σ_F)	0.65	0.44	0.45	21
resonance (σ_R)	0.18	–0.25	–0.17	21
steric (E_S) (see ^a)	–0.75	0.49	0.18	22

^a The constant of the *ortho*-substituent X ($E_S = 0$ for the CH₃ group) is given.

II. Reactions with carbanions

The methods for the formation of a new carbon–carbon bond in arenes, particularly through aromatic nucleophilic substitution of the nitro group, fluorine and chlorine under the action of carbanions, have been discussed previously.^{7,25} We shall dwell only on specific features of carbanions in the reactions from the standpoint of relative activities of the substituents mentioned.

Thus the arylation of 4- and 2-substituted nitrobenzenes **1–4** under the action of a 2,6-di-*tert*-butylphenol anion (**5**), which acts as a C- rather than an O-nucleophile due to steric hindrance, yields 4- and 2-nitro-substituted biphenyls **6** and **7** according to the S_NAr mechanism.

Compound	X	Reaction time /h	Product	Yield (%)
1	4-NO ₂	3	6	77
2	2-NO ₂	17	7	64
3	2-F	18	7	97
4	2-Cl	24	7	71

Although the results of this study are purely qualitative,²⁶ it is nevertheless evident that the activity of fluorine is higher than that of the nitro group or chlorine. Obviously, steric hindrance in the 1,2-disubstituted substrate **2** decreases the activity of the nitro group making it similar to that of chlorine. Therefore, the activity of the nitro group in sterically non-hindered 1,4-dinitrobenzene (**1**) is much higher.²⁶

Under conditions of phase-transfer catalysis, carbanions of disubstituted acetonitriles **8a–c** attack 4-chloro-4'-nitrobenzophenone (**9**) exclusively with the substitution of the nitro group and the formation of the chloro derivatives **10a–c**.²⁷

R = Me (**8a**; **10a**, 75%), Prⁿ (**8b**; **10b**, 78%), Bn (**8c**; **10c**).

Similarly, a higher activity of the nitro group in comparison with chlorine was observed in the reaction of a tricyclic 1-chloro-4-nitrobenzene analogue **11** with the phenylacetonitrile carbanion **8d** (R = H), the yield of 1-chloro-4-(α -cyanobenzyl)anthraquinone (**12**) being twice as high as that of 1-(α -cyanobenzyl)-4-nitroanthraquinone (**13**).²⁸

These results can be explained by the softness of the carbanions **8** which preferentially attack the carbon atom of the C–NO₂ group which makes a more significant contribution to LUMO (orbital control) than the carbon atom of the C–Cl group which bears a higher positive charge (charge control).²⁹

Reactions of pentafluoronitrobenzene (**14**) with perfluoro-*tert*-butyl and trifluoromethyl anions [these are generated from perfluoroisobutylene (**15**) and trifluoromethyltrimethylsilane (**16**), respectively under the action of the fluoride ion] afford formally the substitution products of the nitro group **17** and **18**.^{30–32} However, the mechanism of direct nucleophilic substitution (route *a*) can be argued (Scheme 1).

Scheme 1

X = CF₃ (**17**, 65.5%), F (**18**, 90%).

Indeed, in the reactions of pentafluoronitrobenzene with nucleophilic reagents (hard N- and O- or soft S-anions) it is the fluorine atom in position 2 or 4 that is usually replaced whereas the nitro group remains unaffected.^{33,34} It is therefore more likely that this reaction occurs according to the route *b* where the additionally activated nitro group in the intermediate compounds **19** and **20** is replaced by the fluoride ion resulting in perfluoro-*tert*-butylbenzene (**17**) or perfluorotoluene (**18**).^{30,35} Supporting evidence in favour of this route can be derived from the yields of

compounds **17** and **18**: the yield of a direct substitution product according to the route *a* is smaller for the more nucleophilic perfluorobutyl anion. Moreover, the more electron-withdrawing CF₃ group in the intermediates **19** and **20** significantly facilitates the substitution of F for the NO₂ group.

The nitro group in compounds **1**, **21–24**, which is activated by an electron-withdrawing substituent, is readily replaced even by weakly basic nitroalkane anions in aprotic polar solvents to give compounds **25–29**.^{36–38}

EWG = NO₂ (**1**, **25**), CN (**21**, **26**), SO₂Ph (**22**, **27**), CO₂Me (**23**, **28**), CPh (**24**, **29**).

The bulky tetrabutylammonium cation can be used as a counterion for accelerating these reactions and promoting better separation of the ion pairs.^{39,40} A similar effect is observed when the reactions of compound **1** with stabilised carbanions of different basicities are carried out in liquid ammonia;⁴¹ this reaction gives nitroarenes **30a–e**.

R = CH₂COMe (**a**), CH(Me)COEt (**b**), CH₂CO₂Et (**c**), CH₂CN (**d**), CH(Ph)CN (**e**).

As a rule, the reactions of carbanions with substitution of the nitro group, fluorine and chlorine in arenes proceed according to the S_NAr mechanism with formation of a σ-complex in the limiting step. This is corroborated by the results of kinetic studies of reactions of 9-substituted fluorenyl anions with *para*-halonitrobenzenes in DMSO, the activities of the leaving groups changing in the following order: F > Cl > Br ≈ I; the ratio of the reaction rate constants (*k*_F/*k*_{Cl}) is 3.5–8.0 (see Ref. 42). Free ions or solvent-separated ion pairs are more reactive than contact ion pairs (for reactions in THF).⁴³

The formation of stable anionic σ-complexes at unsubstituted positions of the aromatic ring is a distinguishing feature of reactions of some carbanions with substituted halogeno- and nitroarenes; their further conversions yield S_N products as a result of oxidation or vicarious nucleophilic substitution with retention of the nucleofugal groups.^{9,25,44} This route is realised not only for low-active substrates, such as nitro-⁴⁵ and 1,3-dinitrobenzenes,²⁶ 1-nitro-^{46,47} and 1,8-dinitronaphthalenes⁴⁸ and 9-nitroanthracene,⁴⁹ but also for substrates with highly reactive nitro groups and halogens, *e.g.*, 1,3,5-trinitrobenzene,⁵⁰ 4-nitrophthalonitrile,⁵¹ 4-chloro- (**31**) and 4-fluoronitrobenzenes (**32**), 1,4-dinitrobenzene (**1**), halo-2,4-dinitrobenzenes^{25,44,52,53} and 3,6-dichloropyridazine as well as 2-chloro-3- and -5-nitropyridines.⁵⁴ The direction of the substitution of the leaving group or hydrogen in arenes under the action of carbanions depends not only on the structure of the substrate but also on the nature of the nucleophile and the reaction conditions. Thus compound **31**, in contrast to the 1,4-dinitro derivative **1**,⁴¹ reacts with some stabilised carbanions in liquid ammonia or THF with substitution of hydrogen rather than halogen. In this case, the starting nitro compound seems to serve as an oxidant of the corresponding σ-complex.^{55,56}

R = CH₂COMe, CH(Me)COPh, CH₂CN, CH₂CO₂But⁴¹;

Similarly, the main reaction product of 2-acetylnaphthalene anion with 2-fluoro-6-nitrobenzonitrile (**33**) in DMSO retains all the functional groups in the benzene ring, *viz.*, 2-fluoro-3-(2-naphthoylethyl)-6-nitrobenzonitrile (**34**).⁵⁷

The activated nitro group is unaffected under these conditions, which may be ascribed to the steric effect.

Under conditions of vicarious nucleophilic substitution (VNS), the substrates **1** and **32** containing reactive NO₂ and F groups react with chloromethylphenyl sulfone according to both VNS and S_NAr mechanisms. At the same time, 4-nitrochlorobenzene **31** reacts exclusively according to the vicarious route (Scheme 2).^{44,52}

In those cases where VNS is to be employed for the preparation of products with preservation of nucleofuges in the aromatic ring, it is desirable that the starting arene contains neither activated nitro group nor fluorine.

In conclusion it may be mentioned that reactions of structurally different carbanions with arenes most often result in the substitution of the most active nucleofuges NO₂ and F according to the S_NAr mechanism. The substitution of chlorine in arenes under the action of the same C-anions according to the S_N^{ipso} mechanism proceeds at a much slower rate and shows a tendency for hydrogen substitution (the S_N^H mechanism).

III. Reactions with N- and P-anions

Like carbanions, N- and P-anions naturally manifest certain specificity with respect to the substitution of the nitro group, fluorine and chlorine in arenes. The differences in the activity, *i.e.*, the ratios of the rate constants of the substitution reactions[†] of fluorine and chlorine in arenes under the action of N-anions **39a,b**, are usually of about two orders of magnitude (Table 2)⁴² and the activity of fluorine in these reactions is similar to that of the nitro group.⁵⁸ Presumably, steric hindrance in the N-anion should decrease the activity of the bulky nitro group in arenes and make it similar to the activity of chlorine. Thus the reactions of N-anions of 4-cyanoaniline (**40**) or 4-nitroaniline (**41**) with 4-substituted nitrobenzenes **1**, **31** and **32** afford di- (**42**, **43**) and triarylamines (**44**, **45**); their ratios depend on the nature of the leaving group X (Table 3).^{58–60}

EWG = CN (**40**, **42**, **44**), NO₂ (**41**, **43**, **45**);

:B is base; X = NO₂ (**1**), Cl (**31**), F (**32**).

Under the action of the N-anions of anilines **40** and **41**, the relative activities of the leaving groups X in compounds **1**, **31** and **32** decrease in the following order: F ≥ NO₂ > Cl.⁵⁹ However, the activities of the same substituents under the action of the N-anions of diarylamines **42** and **43** decrease in the following order: F ≫ NO₂ ≈ Cl.⁵⁸ The sharp (in comparison with the activity of fluorine in the latter reaction) decrease in the activity of the nitro

Table 2. Basicities of N-anions (pK_B)

and the rate constants for the halogen substitution reactions in compounds **31** and **32** (DMSO, 25 °C; the counterion is K⁺).⁴²

Anion	R	pK _B	Compound	X	k ₂ /litre mol ⁻¹ s ⁻¹	k _{rel} = k ₂ ^F /k ₂ ^{Cl}
39a	H	22.72	31	Cl	9.95 × 10 ⁻³	94.5
			32	F	0.941	
39b	Cl	20.79	31	Cl	4.35 × 10 ⁻⁴	214
			32	F	9.31 × 10 ⁻²	

group, which is similar to that of chlorine, seems to be due to its steric (but not polar) effect⁵⁸ (see Table 1).

Obviously, it is for this reason that the reactions of the N-anions generated from aniline (**46**) and 2-aminopyridine (**47**) with 1,4-dinitrobenzene (**1**) give exclusively diarylamines **48** and **49** in high yields.⁴¹

Ar = Ph (**46**, **48**), 2-Py (**47**, **49**).

Reactions of the dimethylamide anion (from HMFTA) with *ortho*-substituted nitrobenzenes corroborate the fact that in the absence of steric hindrance in the N-anion the activity of the nitro group is high and comparable to that of fluorine.⁶¹ In this case, the activities of the NO₂, F and Cl groups were determined from the degree of conversion of the starting compounds **2–4** after 5 h (GLC and NMR).

Compound	X	Conversion of compounds 2–4 (%)	
		GLC	NMR
2	NO ₂	93	86
3	F	84	83
4	Cl	41	40

Steric hindrance in the N-anion changes the direction of the reaction, which sharply decreases the yields of the substitution products of the nitro group. Thus the substitution of the nitro group in the reaction of lithium *tert*-butylamide with 1,4-dinitrobenzene (**1**) proceeds with a rather small yield (10%), while the substitution of the hydrogen atom occurs to a larger extent. In this case, the nitrite ion generated in the S_N^{ipso} Ar reaction⁶² behaves as an oxidant of the corresponding σ-complex in the substitution of the hydrogen atom.⁶² This occurs in parallel with partial reduction of the nitro compound formed by the hydride ion liberated in the reaction and condensation with *tert*-butylamine.

[†] This parameter is always indicated for identical conditions.

Table 3. Ratios of the yields of di-(**42**, **43**) and triarylamines (**44**, **45**) in the reaction of 4-substituted anilines **40** and **41** with nitrobenzenes **1**, **31** and **32**.^{58–60}

Nitroarene	X	Aniline	:B	Solvent	Temperature /°C	Time /h	Reaction products [yield (%)]	
							diarylamine	triarylamine
1	NO ₂	40	K ₂ CO ₃	DMSO	120–130	5	42 (50)	44 (3)
32	F	40	K ₂ CO ₃	DMSO	120–130	5.5	42 (5)	44 (64)
31	Cl	41	K ₂ CO ₃	DMSO	145–150	5	43 (71)	45 (1–2)
31	Cl	41	NaH	DMF	100	2	43 (38)	—

Substitution reactions of hydrogen in (het)arenes, which occur with retention of the halogens and/or the nitro group in the ring, are very typical of N-anions. They involve the intermediate formation of a σ^H -complex which can react with an external oxidant to give a substituted (het)arene.^{2,63} Thus the reaction of 6-chloro-3-methoxy-4-nitropyridazine *N*-oxide (**50**) with potassium amide yields a σ -complex at the unsubstituted position 5 of the ring; this complex is further oxidised to the aromatic amine **51**.⁶⁴

Other examples of nucleophilic hydrogen substitution with retention of the nitro group and the chlorine atom in the azine ring have been described.^{2,63}

Intramolecular oxidation of a σ -complex is also possible. Thus the oxidation of the σ -complex **52** by the nitro-group oxygen is the main direction in the reaction of the anilide ion with nitrobenzene.⁶⁵

The conversion of the σ -complex can also proceed according to the vicarious substitution route. In this case, the N-nucleophile should contain a good leaving group, e.g., a triazole,⁶⁶ an ammonium⁶⁸ or a sulfide group.⁶⁹ However, in contrast to chlorine, the substitution of fluorine in arenes follows the S_NAr mechanism rather than VNS. The formation of compounds **53–55** is an example.⁶⁹

R = 2,4,6-Cl₃C₆H₂.

Compound	X	Products [yield (%)]
31	Cl	53 (60), 55 (0)
32	F	54 (7), 55 (66)

The relative activities of the nitro group, fluorine and chlorine in reactions of arenes with the azide ion change in the following order: NO₂ ≥ F ≫ Cl (see Ref. 11, p. 165; Refs 70 and 71). This dependence was established for the substitution of the 4-nitrobenzene derivatives **1**, **31**, **32** and **56–59** (Table 4):

1, **31**, **32**, **56–59**

R = H: X = NO₂ (**1**), Cl (**31**), F (**32**), I (**56**);

R = NO₂: X = F (**57**), Cl (**58**), I (**59**).

The nitro group activated by the electron-withdrawing substituents in the arene is readily replaced by a small-size azide ion in *N*-methyl-3,5-dinitroththalimide,⁷² 3-nitrothioxanthone deriva-

Table 4. Rate constants for the reactions of 1-X-4-nitrobenzenes (**1**, **31**, **32**, **56**) and 1-X-2,4-dinitrobenzenes (**57–59**) with the azide ion.^{11,70,71}

tives,⁷³ 2,5-dinitro-4-trifluoromethyl- and 5-chloro-2-nitrobenzonitriles⁷⁴ and 2-chloro-1-nitroanthraquinone.⁷⁵ In the case of 1-chloro-2-nitro- and 2-chloro-3-nitroanthraquinones containing a less active nitro group, it is only chlorine that is substituted.⁷⁶

Some ambident ions (NO₂⁻, SCN⁻) react as N-anions in S_NAr reactions. The activities of the substituted groups in 1-X-4-nitrobenzenes **1**, **31** and **32** in their reactions with the nitrite ion decrease in the following order: F > Cl ≈ NO₂,[‡] while those in 1-X-2,4-dinitrobenzenes **57**, **58** and **60** change as follows: NO₂ > Cl > F (Table 5).^{77,78} The reason for the change in the activities of substituents is that the limiting step of the reaction of low-reactive substrates with the nitrite ion is the formation of the σ-complex, in the reaction with highly reactive substrates it is its decomposition.⁷⁸ Thus, it is reasonable to use chlorine as a leaving group (especially in the case of highly reactive arenes) for the introduction of the nitro group into arenes according to the S_NAr mechanism. This has recently been demonstrated for the synthesis of 1,2,4-trinitrobenzene (**60**) from 2,4-dinitrochlorobenzene (**58**) and KNO₂ under the conditions of phase-transfer catalysis (yield 71%).⁷⁹ Substitution of the nitro group for fluorine is especially efficient in the case of low-reactive arenes, *e.g.*, penta- or hexafluorobenzenes.⁸⁰

Table 5. Rate constants for the reactions of 1-X-4-nitrobenzenes **1**, **31** and **32** and 1-X-2,4-dinitrobenzenes **57**, **58** and **60** with the nitrite ion (DMSO).^{77,78}

Compound	X	Temperature /°C	$10^2 k_2$ /litre mol ⁻¹ s ⁻¹	$k_{\text{rel}} = k_2^{\text{X}}/k_2^{\text{Cl}}$
1	NO ₂	100	158	0.89
32	F	100	1290	7.25
31	Cl	100	178	1
60	NO ₂	25	680	17
57	F	25	3.2	0.08
58	Cl	25	40	1

In the case of the thiocyanate ion, the activities of the leaving groups in the S_NAr reaction with 2,4-dinitrobenzenes **57**, **58** and **60** change in the following order: F ≈ NO₂ > Cl (Table 6).⁸¹ The formation of the σ-complex is the limiting step of this reaction.

P-Anions react with nitro- and haloarenes to form preferably hydrogen substitution products rather than functional-group substitution products. Hydrogen substitution is observed not only for activated arenes, *e.g.*, trinitrobenzene⁸² and 1-chloro-4-nitronaphthalene,⁸³ but also for less reactive substrates, such as 1-amino- and 1-methoxy-4-nitronaphthalenes⁸⁴ and 1-nitronaph-

Table 6. Rate constants for the reactions of 1-X-2,4-dinitrobenzenes **57**, **58**, **60** with the thiocyanate ion SCN⁻ (DMSO, 75.2 °C).⁸¹

thalene.⁸⁵ However, S_NAr-substitution of fluorine and chlorine in activated polyhaloarenes **14**, **18**, **61** and **62** under the action of the dialkyl phosphite ions **63** is also possible in moderate yields.^{86,87} These reactions are usually carried out in weakly polar aprotic solvents (*e.g.*, ethers, hydrocarbons).

EWG = NO₂ (**14**), CF₃ (**18**), CN (**61**); R = Me (**63a**), Et (**63b**).

Thus the N-anions of amines and the P-anions of dialkyl phosphites replace hydrogen in reactions with arenes, which is mainly due to steric factors. Compact inorganic azide, nitrite and thiocyanate ions readily replace the nitro group, fluorine and chlorine in activated arenes according to the S_NAr mechanism; in the case of the nitrite ion, the electrophilicity of the substrate determines the limiting step of the process.

IV. Reactions with O- and S-anions

The majority of papers devoted to nucleophilic substitution of the nitro group, fluorine and chlorine in arenes deal with their reactions with O- and S-anions. Many such reactions have been reviewed previously,^{1,7,10–12,20,24} but a series of important kinetic studies in this area has appeared only in the past 10–15 years. The main differences in the relative activities of aromatic substituents under the action of hard O- or soft S-anions are determined by the different nature of the nucleophiles.^{20,88} S-Anions are much more reactive in both S_N2⁸⁹ and S_NAr reactions^{20,42} carried out in solutions than O-anions with similar basicities. This is due to the smaller solvation of S-anions in comparison with O-anions;^{90,91} therefore, the reactivities of S- and O-anions of equal basicities in the gas-phase S_N2-reactions differ only insignificantly.^{92,93} Consequently, the enhanced reactivity of S-anions in solution is not their intrinsic property (*cf.* Ref. 89).

Unfortunately, there are still no literature data on the quantitative aspects of nucleofugicities of leaving groups in arenes in the gas phase (with the exception of fluorine).^{94,95} Therefore, comparative activities of the aromatic nitro group, fluorine and chlorine with respect to the O- and S-anions are discussed exclusively for reactions carried out in solutions.

The data on the relative activities of the nitro group, fluorine and chlorine in structurally different arenes in their reactions with O- and S-anions are given in Table 7. The table contains both the kinetic characteristics and the most interesting synthetic results which altogether provide more detailed information about the dependence of the nucleofugicities of these groups on various factors.

First of all, it is worth comparing the activity series of the nitro group, fluorine and chlorine for those cases where substitution occurs according to the S_NAr mechanism with σ-complex for-

‡ The substitution of the nitrite ion for the nitro group is an example of a degenerate reaction.

Table 7. Activities of the leaving groups X = NO₂, F and Cl in the reactions of ArX with O- and S-anions.

mation in the limiting step. For O-anions, the activities of the leaving groups decrease in the following order: $F > NO_2 > Cl$ (Table 7, entries 1–3, 16, 18, 44, 75–77, 91, 92, 97), whereas those for S-anions change as follows: $NO_2 > F > Cl$ (entries 14, 30, 47, 78, 82, 84, 86–88, 93, 94, 100). The activity series of the leaving groups NO_2 , F and Cl present no peculiarities for various derivatives of 2- and 4-nitrobenzenes, 2,4- and 3,5-dinitrobenzenes, 3,5-bis(trifluoromethylsulfonyl)benzenes, 1- and 2-anthraquinones, 1-methyl-5-nitropyrroles and 5-nitrothiophenes and are attributable to different polarisabilities of O- and S-anions.²⁰ At the same time, in the case of 3-nitrobenzene, 3- and 4-cyanobenzene, 4-trifluoromethylsulfonylbenzene and 3- and 4-phthalimide derivatives (entries 26, 28–30, 34, 38, 40, 41, 81–86), the activity series of the leaving groups are the same for both O- and S-anions: $NO_2 > F > Cl$. However, for some compounds of this group the differences in the relative activities of the nitro group and fluorine for S-anions are more significant: $NO_2 \gg F$.^{123, 141, 142}

It is known that in some compounds of the benzene series the electron-withdrawing substituents favour the replacement of the leaving group by the O- and S-anions in the order: *ortho* $\geq$ *para* $>$ *meta* (entries 5 and 20, 12 and 22, 15 and 23, 34 and 38). The degree of activation depends not only on the electronic properties of the substituent in the *ortho*- or *para*-positions relative to the leaving group (entries 2 and 40, 14 and 41, 6 and 36, 97–99), but also on the steric effect of the *ortho*-substituent. Thus steric hindrance due to the *ortho*-nitro group is smaller than that of the *ortho*-nitro group in 2-substituted 1,4-dinitrobenzenes. Therefore, substitution of the methoxy group for the nitro group occurs faster in nitrile derivatives (entries 44 and 51). The activating effects of electron-withdrawing substituents in the *meta*-position of the benzene ring are strong enough for the substitution of the nitro group, fluorine and chlorine by both O- and S-anions (entries 25, 26, 28–32, 38, 39). In the case of simultaneous activation of the nitro group and chlorine by electron-withdrawing substituents in the *ortho*- and/or *para*-position(s) of the benzene ring, the activity of the nitro group exceeds markedly that of chlorine for both O- and S-anions (entries 52–59).

Substitution in the case of activation by electron-withdrawing substituents in the *meta*-position of the benzene ring has a number of specific features. Thus substitution of the nitro group under the action of methoxide occurs more easily in the case of activation by *meta*-CN or $-CF_3$ substituents than by *meta*- NO_2 - or $-SO_2CF_3$ groups in 5-derivatives of 1,3-dinitrobenzenes (entries 67, 70, 72, 73). The situation is different if the leaving group is fluorine. The activation by a *meta*- NO_2 substituent is more efficient than that by the *meta*- CF_3 group in the same reaction (entries 66 and 74). The reason for the reversal of the substituent effects is the formation of more stable σ -complexes at the unsubstituted positions of the benzene ring **64a–d** (especially for EWG = NO_2 and SO_2CF_3) in comparison with the σ -complexes **65a–d** (see Ref. 148; pp. 173, 276 and 292).

EWG = NO_2 (a), SO_2CF_3 (b), CN (c), CF_3 (d).

The σ -complexes **65a–d** are significantly less stable; therefore, the activation occurs in an ordinary way in accordance with the Hammett constant, which reflects the effect of the electron-withdrawing *meta*-substituent (EWG) on the reaction centre (σ_M). The greater ease of substitution of the thiolate anion for the nitro group in 1-nitro-3,5-bis(trifluoromethyl)benzene in comparison with 1,3-dinitro-5-trifluoromethylsulfonylbenzene in the same

reaction (entries 71 and 80) and the greater activity of fluorine in 3-nitro-5-trifluoromethylfluorobenzene in comparison with 3,5-bis(trifluoromethyl)fluorobenzene in the reaction with sodium methoxide (entries 74 and 79) can be explained in a similar way.

The lower activity of chlorine in comparison with the nitro group is also observed in the case of their simultaneous activation by an electron-withdrawing *meta*-substituent. Thus only the nitro group is substituted in 3,5-dinitrochlorobenzene under the action of methoxide (entry 68). Moreover, the nitro group in 1,3-dinitrobenzene (**66**) can be substituted under the action of the phenolate ion resulting in 3-nitrodiphenyl ether (**67**). The phenolate ion, being an ambident anion, also acts as a C-nucleophile and attacks the non-substituted position of the benzene ring to yield 2,4-dinitro-4'-hydroxybiphenyl (**68**) (entry 27).²⁶ In the latter case, the starting dinitrobenzene **66** acts as an oxidant of the intermediate σ -complex.²⁶

There are some other examples of the dependence of the direction of the substitution reaction on the nature of the nucleophile. Thus the reactions with O-anions result in the substitution of the nitro group in 2,4- (entries 60 and 61) and 3,5-dinitro-1-trifluoromethylsulfonylbenzene (entry 70), whereas reactions with S-anions result predominantly in the substitution of the trifluoromethylsulfonyl group in these compounds (entries 62, 71). The orientation of the substitution reactions in 1-chloro-4-nitroanthraquinone and 1-chloro-5-nitroanthraquinone also depends on the nature of the nucleophile: chlorine is predominantly substituted by O-anions, whereas the nitro group is substituted by S-anions (entries 93–95). Similarly, in 4-chloro-3,5-difluoronitrobenzene fluorine is substituted under the action of sodium methoxide, whereas chlorine is substituted under the action of the benzenethiolate anion.¹⁴⁹ The change in the reaction route on going from hard O-anions to soft easily polarisable S-anions seems to be caused by a transition from charge control to orbital control.^{29, 149, 150} However, fluorine is more easily replaced in 1-fluoro-4-nitroanthraquinone irrespective of the nature of the nucleophile, which is consistent with charge control of the reaction.^{29, 145}

The ease of substitution of the nitro group, fluorine and chlorine is also determined by the structure of the substrate. Thus the activities of these substituents in reactions with both O- and S-anions are much higher for 3-substituted phthalic acid derivatives than for 4-substituted derivatives (entries 83–88). This is corroborated by the selective substitution of the 3-nitro group in 3,5-dinitro-*N*-arylphthalimide under the action of both O- and S-anions (entries 89 and 90). The activities of the nitro group and fluorine in 2-substituted anthraquinone are somewhat higher than in the 1-isomer, whereas those of chlorine are virtually identical in these compounds (entries 91 and 92). It was found also that the nitro group in 5-chloro-1-methyl-3-nitro-1,2,4-triazole is almost 300 times less active than chlorine in a reaction with methoxide (entries 101 and 102). These data corroborate the fact that different activities of substituents with respect to the same nucleophile are determined by different electronic and steric effects in the substrate.

The data on the activities of the nitro group, fluorine and chlorine in the above-described reactions with O- and S-anions are

related to the S_NAr mechanism with the σ -complex formation as a limiting step. If the limiting step is the decomposition of the σ -complex, the activities of the leaving groups in reactions with O- and S-anions will be as follows: $NO_2 > Cl > F$ (entries 48 and 49). This series corresponds to the increase in the dissociation energy of the $Ar-X$ bond on going from $X = NO_2$ to $X = F$ (see Table 1).

In some substitution reactions by aryloxide anions, the nitro group manifests higher activity (entries 7–9) than fluorine and chlorine (entries 6 and 8). However, the addition of a radical trap to a reaction mixture containing 1,4-dinitrobenzene (**1**) and the 2,6-dibromo-4-cresolate anion inhibits completely the substitution of the nitro group. Presumably, the substitution of the nitro group in compound **1** occurs predominantly according to the electron transfer mechanism.¹⁰⁵

It is known that the energies of bimolecular S_NAr reactions depend on the nature of the leaving group and the nucleophile,¹ whereas the reactivities in these processes are under enthalpy control.¹¹ Entropy control itself is effective in fast bimolecular reactions occurring in solution involving radicals ($k_2 = 10^6$ – 10^8 litre mol⁻¹ s⁻¹ from -85 to -10 °C),¹⁵¹ carbenes ($k_2 = 10^4$ – 10^9 litre mol⁻¹ s⁻¹ at 25 °C)¹⁵² or carbocations ($k_2 = 10^{-1}$ – 10^8 litre mol⁻¹ s⁻¹ from -70 to -30 °C)¹⁵³ where the contribution of enthalpy is either very small or constant as a result of which the transition state is shifted to earlier position on the reaction coordinate.^{152, 153}

Recently, it has been found that the selectivity of substitution of the nitro group and fluorine in S_NAr reactions is connected with entropy control,^{154, 155} although bimolecular S_NAr reactions occur at a relatively slow rate ($k_2 = 10^{-4}$ – 10^{-1} litre mol⁻¹ s⁻¹ at 25 °C in DMSO or DMF).¹⁵⁶ However, the relative activities of the nitro group and fluorine in the competitive reactions between nitrobenzotrifluorides **69** and **70**, phenols **71a–d** and arenethiols **72** in the presence of K_2CO_3 in DMF (40 – 95 °C) are controlled by the entropy of the activation, since $T\Delta S^\ddagger > \Delta\Delta H^\ddagger$ in all cases (Table 8).^{154, 155} It was shown¹⁵⁷ that compounds **71** and **72** yield complexes **73** and **74** of the type $(2 ArYH) \cdot K_2CO_3$ in the reaction with K_2CO_3 in DMF. The structures of these complexes depend on the nature of the substituent in the benzene ring.

Compound	Y	R	Compound	Y	R
71a, 73a	O	H	72a, 74a	S	H
71b, 73b	O	4-Cl	72b, 74b	S	4-MeO
71c, 73c	O	3-NO ₂	72c, 74c	S	3-CF ₃
71d, 73d	O	4-CN	72d, 74d	S	4-NO ₂

As the changes in the entropy $\Delta\Delta S^\ddagger$ are positive, the reactions of the fluoro derivative **70** with complexes **73** and **74** are more organised in comparison with analogous reactions of the dinitro-substituted compound **69**. Therefore, the S_NAr -substitution of the nitro group in compound **69** is characterised by an earlier

Table 8. Relative activities of the nitro group and fluorine and the activation parameters for the competitive reactions of compounds **69** and **70** with phenols **71a–d** and arenethiols **72a–d** in the presence of K_2CO_3 (DMF, 70 °C).^{154, 155}

transition state on the reaction coordinate than the substitution of fluorine in compound **70**.^{154, 155}

Summing up the results of the discussion of the reactivities of O- and S-anions, special mention should be made of the following items. First of all, it is obvious that the reactions of O- and S-anions are very sensitive to the nature of both the substrate and the leaving group in the arene. Soft S-anions usually react with those centres in the arene which carry highly polarisable leaving groups owing to the orbital control of the reaction. The reactions of hard O-anions are characterised by charge control. As a result, the activity series of the leaving groups changes from $NO_2 > F > Cl$ (RS^-) to $F > NO_2 \geq Cl$ (RO^-) within the framework of the same reaction mechanism. It should be stressed that the selectivity of substitution of the nitro group and halogens under the action of O- and S-anions may depend on the transition from enthalpy to the entropy control as the nature of the nucleophile is changed.

V. Reactions with hydride and halide ions

S_NAr substitution of the nitro group and halogens in arenes under the action of hydride and halide ions has been described in a number of reviews.^{7, 148, 158} Here, it seems expedient to emphasise only some peculiarities of activities of aromatic substituents with respect to these nucleophiles.

The activity of the nitro group is somewhat higher than that of chlorine in the reaction of *para*-substituted nitrobenzenes with the hydride ion in DMSO,¹⁵⁹ which is also characteristic of other hard anions, *e.g.*, N- and O-anions (see Sections III and IV). However, the nucleofugicity of the nitro group in arenes is increased drastically if it becomes non-coplanar with the aromatic ring under the influence of steric factors. Thus only the nitro group is replaced by hydrogen in the reaction of pentachloronitrobenzene (**75**) or 1,3,5-trichloro-2,4,6-trinitrobenzene (**76**) with sodium borohydride.^{160, 161}

$X = Cl$ (**75**), NO_2 (**76**).

The enhanced activity of the aromatic nitro group (in comparison with fluorine and chlorine) with respect to the hydride ion may be due to a predominant attack on the unsubstituted position of the aromatic ring. Thus the reaction of compounds **57** and **58** with sodium borohydride in DMSO occurs *via* the anionic σ^H -complexes **77**–**80**. It is noteworthy that the conversion of the

σ -complexes **77** and **78** into halonitrobenzenes **31** and **32** proceeds as the intramolecular substitution of the hydride ion for the nitro group.¹⁵⁹

Owing to such a vicinal attack, the yield of the substitution product of the nitro group (compound **31**) in the case of the chloro derivative **58** markedly exceeds the yield of the substitution product of chlorine (compound **66**),¹⁵⁹ which is formed upon a significant increase in the reaction time.

Recently, it has been shown that reactions of nitroarenes with the hydride ion (NaBH_4) strongly depend on the spatial structures of the substituents adjacent to the reaction centre.^{162, 163} Moreover, one should not rule out the possibility that the predominant substitution of the nitro group in comparison with halogens in the reactions of halonitroarenes with the borohydride anion is due to the steric features of the nucleophile.

Substitution of chlorine and the nitro group in arenes under the action of the fluoride ion is a main route to the introduction of fluorine into the aromatic ring;^{14, 15, 164} this approach has a

considerable preparative significance.^{165–169} The nucleophilicity of the halide ions in $\text{S}_{\text{N}}\text{Ar}$ reactions occurring in dipolar aprotic solvents changes in the following order: $\text{F} \gg \text{Cl} > \text{Br} > \text{I}$.^{77, 78, 170} Thus the rate of the substitution of the fluoride ion (DMSO, 25 °C) for the nitro group in compound **60** exceeds 320-fold the rate of an analogous reaction with the chloride ion.⁷⁷ The halogen exchange in 2,4-dichloro- (**81**) and 2,4-difluoro-nitrobenzenes (**82**) under the action of KF and KCl, respectively (DMF, 125 °C) is yet another example of a higher nucleophilicity of the fluoride ion.¹⁷¹

If the substitution of chlorine for fluorine in compound **82** does not take place, compound **81** reacts with KF to give product **82** in a quantitative yield; the rate constant of this pseudo-first order reaction (k_1) is $3.43 \times 10^{-4} \text{ s}^{-1}$ (125 °C).¹⁷¹ This value is similar to the value of the rate constant ($k_1 = 1.1 \times 10^{-4} \text{ s}^{-1}$) for the substitution of fluorine for chlorine in 3,4-dichlorobenzotrifluoride (**83**)

under the action of KF (sulfolane, 180 °C) in the presence of Ph_4PCl .¹⁷² However, the nucleophilicity of the chloride ion in the substitution of the nitro group in compound **76** (LiCl in acetone) is high enough [$k_2 = 0.525 \text{ litre mol}^{-1} \text{ s}^{-1}$ (25 °C)].¹⁷³ The high substitution rate and the low activation energy of the latter reaction are due to alleviation of steric strain on going from the starting compound to the intermediate σ -complex.¹⁷³

Relative activities of the nitro group, fluorine and chlorine in various disubstituted arenes with respect to the fluoride ion are listed in Table 9. The activity series of these substituents in the

reactions of 1,4-disubstituted benzenes **1**, **31** and **32** with Rb¹⁸F (DMSO, 150 °C) changes in the following order: NO₂ > F >> Cl (Table 9, entry 1).³⁵ However, the activities of the nitro group and fluorine in an analogous reaction of 1,2-disubstituted benzenes **2** and **3** are markedly approximated (entry 7).³⁵ A comparison of the activation parameters ($\Delta H^\ddagger$ and $\Delta S^\ddagger$) for the substitution of the nitro group and fluorine in compounds **1** and **32** under the action of the ¹⁸F-labelled fluoride ion in DMSO showed that the selectivity of substitution of these groups ($k^{\text{NO}_2}/k^{\text{F}}$ ratio) is controlled by the entropy of activation.^{176, 177} Obviously, in this case, too, the substitution of the nitro group in compound **1** is characterised by an earlier transition state on the reaction coordinate than the substitution of fluorine in compound **32** (cf. Refs 154 and 155). At the same time, the substitution of the nitro

group in 1,4-dinitro- (**1**) and 1-cyano-4-nitrobenzenes (**22**) under the action of the fluoride ion in DMSO (entries 4 and 21) is subject to enthalpy control despite the fact that a decrease in the electrophilicity of the substrate **22** results in a more positive value of $\Delta S^\ddagger$ in comparison with compound **1** (see Ref. 176).

The data listed in Table 9 corroborate the fact that fluorode-nitration is an efficient procedure for the introduction of fluorine into the aromatic ring in both activated (entries 2, 4, 8, 11, 20, 21, 23, 25, 27–29) and low-reactive substrates (entries 13–16, 18, 19 and 30).

Some synthetic implications of reactions of complex chloro-(nitro)aromatic compounds with the fluoride anion are presented in Table 10; these are analysed in subsequent paragraphs with regard to the previously established kinetic, thermodynamic and

^a R₃N is hexamethylenetetramine (urotropin). ^b TPDF is tetrafluorophthaloyl fluoride.

topological peculiarities. High yields of fluoro derivatives can be achieved by varying the source of the fluoride ion (Table 9, entries 11, 18, 19, 28 and 29), solvents and traps for the leaving nitrite ion (Table 9, entries 15, 16 and 30).¹⁶⁴

The lower activity of chlorine in comparison with the nitro group (Table 9, entries 11, 17, 21, 30 and 31) allows selective fluorodenitration in nitrochloroarenes where these substituents are additionally activated by an electron-withdrawing group (Table 10, entries 1–17). Under these conditions, the effect of the phase-transfer catalyst on the exchange of the nitro groups and chlorine is more pronounced in weakly polar aprotic solvents than in strongly polar solvents.¹⁹² Using the reaction of 2-chloro-6-nitrobenzonitrile (**84**) with KF as an example, a number of solvents were tested to ensure the highest selectivity of substitution of the nitro group in comparison with chlorine: DMSO > NMP > sulfolane > MeCN > 1,2-dimethoxyethane (1,2-DME).¹⁹³ The order of substitution of the NO₂ and Cl groups in chloronitroarenes containing no activating group changes to the opposite (Table 10, entries 18–22). In this case, both functional groups are substituted for fluorine.¹⁶⁴

In polychloronitroarenes, the rate of substitution of the nitro group increases under the action of the fluoride ion due to both its exit from the plane of the aromatic ring and the inductive effect of chlorine (entries 24–26).¹⁷⁹ Naturally, the fluorodenitration reaction proceeds especially smoothly in nitroarenes where the nitro group is activated by more than one electron-withdrawing substituent (entries 27–33).

The relative nucleofugicities of the nitro group and chlorine within the same molecule were studied using semi-empirical methods (AM1 and PM3) for the reaction of 2,4-dichloronitrobenzene (**81**) with a free fluoride ion and a fluoride ion bound to

the counterion Me₄N⁺. A comparison of the transition state enthalpies for these reactions demonstrated a certain preference for fluorodenitration in the case of the free fluoride ion,¹⁹⁴ whereas fluorodechlorination occurs preferentially with Me₄N⁺ as a counterion. In addition, it was found experimentally^{187, 194} that the effect of the solvent on the predominant substitution of the nitro group or chlorine under the action of Me₄NF in 2,3,5,6-tetrachloronitrobenzene (**85**) can be used for estimating the contribution of solvation effects to the structure of the transition states of these reactions.

VI. Reactions with amines

Among other neutral nucleophiles used for aromatic substitution of the nitro group and halogens, only amines have been studied in detail.^{1, 165, 195–199} In contrast to reactions with charged nucleophiles, S_NAr reactions with primary and secondary amines can be catalysed by bases; the role of a base can be played by the second molecule of the amine.

The experimental second-order rate constant k_A is calculated from the conventional mechanism of S_NAr reactions with amines at a steady-state concentration of the σ -complex **86**.^{1, 195, 196}

$$k_A = \frac{k_1(k_2 + k_3[B])}{k_{-1} + k_2 + k_3[B]}$$

Depending on the ratio of the rate constants k_1 , k_{-1} , k_2 and $k_3[B]$ in reactions with amines, the following variants are possible:

(a) if $k_2 + k_3[B] \gg k_{-1}$, there is no catalysis and $k_A = k_1$, *i.e.*, the formation of the σ -complex **86** is the limiting step;

(b) if $k_2 + k_3[B] \ll k_{-1}$, the rapid formation of the intermediate **86** is followed by the rate-determining step of its decomposition, and the expression for k_A appears as $k_A = k_1 \times k_2 / k_{-1} + k_2 \times k_3[B] / k_{-1}$, which predicts that the basic catalysis will be characterised by a linear dependence of k_A vs $[B]$;

(c) if $k_2 + k_3[B] \approx k_{-1}$, the dependence of k_A on $[B]$ will be more complex, *viz.*, at low $[B]$, the dependence of k_A on $[B]$ will be linear, whereas at high $[B]$ it will reach a plateau where $k_A = k_1$. Depending on the nature of the aromatic compound, the amine, the base and the solvent, different substitution mechanisms of the nitro group, fluorine and chlorine in arenes under the action of amines will be realised,^{1, 195, 196, 200, 201} as a result of which the substitution rate constant k_A for these groups will change substantially.

The data on the relative activities (rate constants k_A) of the nitro group, fluorine and chlorine in various arenes under the action of primary and secondary amines in protic, aprotic polar and nonpolar solvents are given in Table 11. The activity series of the leaving groups in reactions of 1,4-disubstituted nitrobenzenes **1**, **31** and **32** with piperidine in aprotic dipolar solvents appear as: $F \gg NO_2 > Cl$ (Table 11, entries 1–3). This order is obviously preserved in reactions of more electrophilic 1-X-2,4-dinitrobenzenes (**57**, **58**, **60**) with piperidine in both protic (MeOH) and aprotic polar solvents (MeCN): $F > NO_2 \gg Cl$ (entries 10 and 11). Presumably, this order of the relative activities of the leaving groups is observed in the absence of the amine catalysis where $k_A = k_1$ and the formation of the intermediate **86** is the limiting step.^{1, 211, 217}

At the same time, the differences in the activities of the nitro group, fluorine and chlorine in reactions of compounds **1**, **31** and **32** with piperidine in aprotic weakly polar solvents are less

apparent, and the order of their activities varies from $F > Cl > NO_2$ (Table 11, entry 4) to $F > NO_2 > Cl$ (entry 5). The activity series of the leaving groups on going to more electrophilic arenes **57**, **58** and **60** in reactions with piperidine under identical conditions appear to be different: $NO_2 > F > Cl$ (entries 12 and 13).

The reason for such variations in the relative activities of these groups is the change of the limiting step of the reaction. If the reaction of compounds **58** and **60** with piperidine in benzene is not subject to catalysis by the amine, the formation of the σ -complex **86** is the limiting step of the reaction.^{205, 213} The reaction of 1-fluoro-2,4-dinitrobenzene (**57**) is catalysed by piperidine.^{211, 214} This is confirmed by the observation of a kinetic isotope effect in a reaction where deuteriopiperidine²¹⁴ and the ¹⁸F-labelled starting compound **57** were used.²¹⁸ Obviously, in this case the decomposition of the σ -complex of the type **86** is the limiting step of this reaction.^{211, 214} A comparison of k_A values for the substitution of fluorine and chlorine in reactions of compounds **57** and **58** with piperidine revealed that the k_A^F/k_A^{Cl} ratio was rather small.^{211, 214} Quite probably, the small values of the $k_A^{NO_2}/k_A^{Cl}$ and k_A^F/k_A^{Cl} ratios in the reactions of nitrobenzenes **1** and **32** with this amine also suggest that the decomposition of the σ -complex **86** is the limiting step in the substitution of the nitro group and fluorine (entries 4 and 5).

The relative activities of the leaving groups in reactions of di- and trinitrobenzenes **57**, **58** and **60** with the primary aromatic amine, *viz.*, aniline, in ethanol decrease in the following order: $NO_2 > F > Cl$,²⁰⁹ which becomes $NO_2 \gg F \gg Cl$ for an analogous reaction of more electrophilic arenes, *viz.*, 2,6-dinitro- (**87–89**) and 2,4,6-trinitrobenzenes **90–92** (entries 16 and 17).

X = NO₂ (**87**, **90**), F (**88**, **91**), Cl (**89**, **92**).

^a The experimental value for the nitro group was calculated relative to chlorine. ^b Substitution of the nitro group. ^c Substitution of fluorine.

For polynitroarenes, the higher activities of the nitro group (compounds **60**, **87** and **90**) and fluorine (compounds **57**, **88** and **91**) in comparison with chlorine (compounds **58**, **89** and **92**) are due to the fact that the limiting step of these reactions is the formation of the σ -complex **86**.^{1, 10, 199, 205} The activity of the nitro group in compounds **87** and **90** is higher than that of fluorine (compounds **88** and **91**) due to the steric effect of two *ortho*-nitro groups in the vicinity of the reaction centre (*cf.* entries 9, 16 and 17).²¹⁶ The weaker spatial effect of a primary amine in comparison with the secondary amine causes a reversal of the relative activities of the nitro group and fluorine in reactions of compounds **60** and **57** with aniline and piperidine in alcohols where the formation of the intermediate **86** (entries 9 and 10) is the limiting step.²¹⁷ Moreover, steric effects in amines can even change the limiting step of the substitution in arene **57** with a small-sized leaving group (the fluoride ion). Thus the reaction of the ¹⁸F-labelled compound **57** with 2-methylaniline (DMSO, 30 °C) manifests a pronounced kinetic isotope effect which suggests the abstraction of the fluoride ion at the rate-determining step.²¹⁹ However, no such effect is observed in an analogous reaction with 4-methylaniline where the formation of the σ -complex **86** is the limiting step²¹⁹ (*cf.* Ref. 220). Naturally, the steric effects of primary and secondary amines in their reactions with arenes in weakly polar media disappear, if the decomposition of the σ -complex **86** is the limiting step. The low values of the k_A^F/k_A^{Cl} ratio in reactions of compounds **59** and **60** with piperidine and 4-anisidine in benzene where the former undergoes catalysis by the corresponding amine (entries 13 and 14) is supporting evidence for this hypothesis.^{214, 215}

The reasons for the higher activity of fluorine in reactions of arenes with amines in weakly polar media in comparison with chlorine under conditions of basic catalysis were discussed in some recent publications.¹⁹⁹ The formation of a hydrogen bond with the amino group is a possible explanation for the faster abstraction of the fluoride ion from the σ -complex **86**. This means that the abstraction of the fluoride ion requires an additional molecule of the amine, *i.e.*, a catalytic step takes place.¹⁹⁹ This is confirmed by a decrease in the activity of fluorine in comparison with chlorine in reactions of halogeno-2,4-dinitrobenzenes **57** and **58** with *N*-methyl-4-anisidine in benzene; the efficiency of catalysis in the reaction of compound **57** (X = F) with a secondary amine markedly decreases due to increased stability of the intermediate **93**.²¹⁵

The formation of a molecular complex of an arene and an amine that is more reactive than the arene itself may be regarded as yet another reason for the higher activity of fluorine in comparison with chlorine under catalytic conditions. This is supported by high negative values of ρ obtained in the analysis of the Hammett equation for the reaction of compound **57** with substituted anilines.¹⁹⁹ Both molecular complexes of reactants and aniline dimers, which are more reactive nucleophiles^{221, 222} may be formed on the reaction coordinate of compounds **57** and **58** with aniline in a weakly polar solvent.

It should be emphasised that the activities of the nitro group, fluorine and chlorine in *ortho*-substituted benzenes **2–4** exceed those of the *para*-substituted compounds **1**, **32** and **33** in reactions

with piperidine in weakly polar solvents due to intramolecular solvation in the transition state of the reaction, *i.e.*, in the intermediate **94** (Table 11, entries 4, 5 and 6).^{1, 206, 208}

The reactions of compounds **2–4** with amines are not catalysed by a base and the formation of the σ -complexes **86** is the limiting step.^{205, 206, 208} In contrast, similar reactions of compounds **1**, **32** and **33** are catalysed by a base and decomposition of the corresponding σ -complexes is the limiting step. The amine-catalysed reaction of 1,2-dinitrobenzene (**2**) with piperidine in non-polar *n*-hexane is an exception.²⁰⁷ The kinetics of this reaction involves the equilibrium constant K_S for the formation of the π - π electron-donor complex **95** prior to the formation of the σ -complex **96**; the decomposition of the latter is the limiting step of this reaction (entry 7).²⁰⁷ Recently, it has been shown that no complexes of the type **95** are formed upon substitution of benzene for *n*-hexane, which results in the deceleration of the reaction of arene **58** with amines.²²³

Thus, the substitution reactions of the nitro group, fluorine and chlorine in arenes under the action of amines under various reaction conditions are multistep processes. In-depth studies of their mechanisms in weakly polar and nonpolar media are currently under way.^{224–228} Such reactions are also being investigated for five-membered heterocycles, *e.g.*, thiophene derivatives.^{229, 230}

VII. The role of the reaction mechanisms

Although the nucleophilic substitution mechanism S_NAr (addition–elimination) in arenes and heteroarenes has become classical in organic chemistry long ago,^{1, 7, 10, 11} some alternative mechanisms can also be used. These may be divided into several groups, *viz.*, electron-transfer reactions (SET),³ photochemical reactions,^{6, 231–233} vicarious hydrogen substitution reactions (VNS),^{2, 9} *kine*- and *tele*-substitutions,^{6, 234} ring opening–closure reactions, mainly for heterocyclic compounds (ANRORC)^{2, 64} and reactions catalysed by transition metals.^{235, 236}

It is known that the formation of σ -complexes of the type **97** at nonsubstituted positions of activated aromatic rings proceeds much faster and the stabilities of these complexes strongly depend on the nature of the nucleophile, the substrate and some other factors.^{1, 2, 5, 9, 25, 44, 148} Therefore, S_N^H and S_N^{ipso} substitutions always compete with one another due to the reversibility of formation of the σ -complexes **97** and **98**.

If σ -complexes of the type **97** can be transformed further (e.g., according to VNS or an oxidative route^{2,9}), the S_N^H route will prevail over S_N^{ipso} substitution. Such a competition has already been discussed in this review (Sections III–V) (see also Ref. 237). It is of note that steric and electronic factors can also influence the regioselectivity of substitution of the nitro group, fluorine and chlorine.^{5,20} Thus compounds **90** and **92** react with the hydroxide

Compound	X	k_1 /litre mol ⁻¹ s ⁻¹	k_3 /litre mol ⁻¹ s ⁻¹
90	NO ₂	1450	140
91	F	50	750
92	Cl	6	0.40

ion in water more readily according to the S_N^H route than according to the S_N^{ipso} route, whereas picryl fluoride **91** undergoes preferably *ipso*-substitution in this reaction.^{238,239} Presumably, the stereo-electronic effects in the reaction of compound **91** with the hydroxide ion in the *ipso*-position favour fast formation of the picrate ion **99** (Scheme 3).^{5,20}

Steric effects in a nucleophile may become crucial as regards the regioselectivity of substitution. Thus compounds **3** and **4** react with the 2-phenylthio-1,3-dithiane carbanion exclusively according to the VNS mechanism.²⁴⁰ Recently, it has been shown that the S_N^H substitution becomes prevalent over S_N^{ipso} substitution in reactions of 1,3-dinitrobenzene (**66**) and its 5-fluoro- and 5-chloro derivatives with potassium methoxide with an increase in the excess of the nucleophile relative to the substrate.²⁴¹ The competition between the S_N^{ipso} and S_N^H routes may result in *kine*- and *tele*-substitution due to faster conversion of the σ -complex of the type **97**. Various *kine*- and *tele*-substitution reactions of the nitro group were generalised in the reviews.^{6,234}

Aromatic nucleophilic substitution reactions are characterised by an immense diversity of intermediates formed (Scheme 4). Introduction of a nitro group into the aromatic ring significantly facilitates the formation and increases the stability of the corresponding radical anions because of a decrease in their LUMO energy. As a rule, *para*-substituted aryl halides **100** (X and/or Z = Hal) produce intermediate structures **101** and **102** and then free radical anions of the type **103**, which undergo fragmentation into aryl radicals and halide ions and can serve as substrates for $S_{NR}1$ reactions (routes *a* + *b*).^{3,242–244} The $S_{NR}1$ mechanism is uncommon for nitro- and halogenonitroarenes. It was shown that substitution of fluorine and chlorine in compounds **57** and **58** under the action of a sterically hindered ethyl α -cyanophenylacetate carbanion in DMSO is induced by a solvated electron and occurs according to the $S_{NR}1$ mechanism.²⁴⁵ Previous studies have

Scheme 4

shown^{246, 247} that substitution of fluorine and chlorine in compounds **31** and **32** under the action of ethyl cyanoacetate carbanion in DMSO follows a non-chain radical mechanism (routes *a* + *c*) (cf. Ref. 105). However, it is believed²⁴⁸ that in the latter case the reactions proceed presumably with an electron transfer (route *d*) with an intermediate formation of the radical pair **102** inside the solvent cage. Subsequent coupling of the radical anion and the radical inside the cage yields the σ -complex **104**. The S_NAr mechanism (route *e*) cannot be excluded either.²⁴⁸

There is a great body of evidence in favour of the *ipso*-substitution mechanism in nitro- and halogenonitroarenes under the action of charged and neutral nucleophiles, which proceeds via an intermediate $n-\pi$ donor-acceptor complex of the type **101**. This is followed by an electron transfer resulting in the formation of the radical pair **102**.^{242, 243, 249–251} The further fate of the radical pair **102** depends largely on the nature of the nucleophile, although its further conversion according to the route *d* + *f* prevails.²⁵¹ Since the routes *d* and *e* leading to the formation of the reaction product **105** are kinetically indistinguishable, the S_NAr substitution mechanism is not ruled out either.²⁴⁸ If the radical pair **102** leaves the solvent cage, free radical anions of the type **103** can be detected by ESR.^{244, 249–252} The hypothesis that these radical anions lie on the coordinate of nucleophilic S_{NR2} substitution of the nitro group, fluorine and chlorine (route *g*)^{253, 254} met sound criticism on kinetic,^{255, 256} electrochemical^{256, 257} and theoretical grounds.^{3, 243} Most probably, the formation of radical anions of the type **103** and the substitution via the σ -complex **104** may occur in parallel and independently of one another.²⁴⁴ Using the reaction of 1,4-dinitrobenzene **1** with the cyanide ion in oxygen-free DMF as an example, it was shown that the radical anions **103** can be generated by homolytic fragmentation of the σ -complex **104** (route *h*)²⁵⁸ (cf. Ref. 257). Therefore, the *ipso*-substitution of the nitro group, fluorine and chlorine in nitro- and halogenonitroarenes follows mainly the SET or the S_NAr mechanism (routes *d*, *e* and *f*) (cf. Ref. 259).

Photochemical substitution reactions of fluorine and chlorine in arenes have been reviewed previously;²³¹ their mechanisms strongly depend on the nature of the arene and the nucleophile. However, photosubstitution of the nitro group in arenes has been little studied. It was shown²³¹ that the reaction of 4-nitroanisole with glycine ethyl ester occurs upon an attack of the substrate in the excited state by the nucleophile (the S_NAr^* mechanism).²⁶⁰ The SET mechanism is realised to a lesser degree²⁶⁰ (cf. Ref. 261). It is of note that photochemical transformations are more efficient for S_N^H substitution reactions in nitroarenes which proceed according to the VNS mechanism.^{232, 233}

Reactions according to the ANRORC mechanism are mostly related to S_N^H rather than S_N^{ipso} substitution.^{2, 63} The S_N^{ipso} reactions catalysed by transition metals (Cu, Ni, Pd, etc.), are of extreme importance and are being developed dynamically; they were studied mostly for the substitution of chlorine, bromine and iodine.^{168, 235, 236, 262–265}

* * *

A vast body of evidence has been accumulated on the activities (including relative activities) of the nitro group, fluorine and chlorine in aromatic nucleophilic substitution reactions in relation to the structure of the substrate, the type of the nucleophile and the medium and the reaction mechanism. This review is an attempt at a state-of-the-art generalisation of the results obtained in this area. The need for such generalisation is due to the fact that significant progress in the development of methods for functionalisation of arenes has become possible owing to the use of convenient nucleophilic *ipso*-substitution reactions ($S_N^{ipso}Ar$).

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 01-03-32909).

Reactions of phosphorus ylides with acyl chlorides: pathways and preparative potential

V N Listvan, V V Listvan

Contents

I. Introduction	705
II. Acylation of phosphorus ylides. Transylidation	705
III. Reactions and preparative value of acylated ylides	708

Abstract. Data concerning the reactions of phosphorus ylides with acyl chlorides that occur by different pathways depending on the nature of the ylide or acyl chloride and on the reaction conditions are summarised and systematised. The products of these reactions are of interest as building blocks for the synthesis of other classes of compounds. The bibliography includes 131 references.

I. Introduction

Phosphorus ylides (or alkylidenephosphoranes, phosphonium methylides)^{1,2} are compounds with a P=C bond. They possess great synthetic potential and are used to obtain other classes of compounds. It is mostly triphenylphosphine derivatives, such as methylenetriphenylphosphorane (**1**) and substituted alkylidenephosphoranes **2** and **3**, that find practical use. The P=C bond in these compounds is polarised considerably in such a way that the electron density is shifted from the phosphorus atom to the carbon atom (structure **A**).

R¹, R² = Alk, Ar, COAlk, COAr, CO₂Alk, CN.

The presence of partial negative charge on the ylide carbon atom makes these compounds highly reactive, primarily with respect to electrophilic reagents.

Phosphorus ylides **2** and **3** containing alkyl or aryl substituents at the ylide carbon atom are the most reactive. They are sensitive to moisture and atmospheric oxygen; therefore, they are not isolated in pure form but are obtained in anhydrous solvents, usually in an inert atmosphere, just prior to the reaction. If electron-withdrawing groups (COR, CO₂R, CN) are present as substituents at the ylide carbon atom and the negative charge is partially shifted to them, the reactivity of the ylides decreases. Such compounds can be isolated in a free state and stored under ordinary conditions. Some of them are available commercially, e.g., acetylmethylenetriphenylphosphorane (**2**, R¹ = COMe), benzoylmethylenetriphenylphosphorane (**2**, R¹ = C(=O)Ph),

ethoxycarbonylmethylenetriphenylphosphorane (**2**, R¹ = CO₂Et), etc.

The reaction of phosphorus ylides with aldehydes (the Wittig reaction) is the most famous; it is widely employed in syntheses of unsaturated compounds. The Wittig reaction has been described in detail in a number of reviews and monographs,^{3–12} including one recent review¹³ dedicated to the 100th anniversary of this reaction's creator.

Wide circles of chemists are less aware of reactions of alkylidenephosphoranes with other electrophilic reagents, *inter alia*, acyl halides. Depending on the nature of the starting compounds and sometimes on the reaction conditions, the reactions of phosphorus ylides with acyl halides occur by different pathways and give different products. In the future, some of these transformations affording interesting organic products^{1,2,14} may become preparative methods for their synthesis. As of now, several examples of reactions of phosphorus ylides with acyl chlorides for possible preparative use are known: the formation of acylated ylides followed by their thermolysis into acetylene compounds or oxidation to give polycarbonyl derivatives; synthesis of allene compounds; synthesis of enol esters, etc.

Since the publication of the review by Bestmann and Zimmermann¹ and the monograph by Kolodyazhnyi² which cover the literature on reactions of phosphorus ylides with acyl chlorides reported before 1990, a lot of new publications have appeared that require generalisation and systematisation. Therefore, it seems expedient to cover this aspect of the chemistry of alkylidenephosphoranes in a separate review. The authors of this review tried to cover, as thoroughly as possible, the literature on reactions of phosphorus ylides with acyl chlorides for the period from 1990 to 2002. Moreover, the review considers the most significant publications of the preceding years.

II. Acylation of phosphorus ylides. Transylidation

Acylation occurs most readily with acyl chlorides and alkylidenephosphoranes **3**, which contain no hydrogen atoms at the ylide carbon atom: the acyl residue adds to the ylide carbon atom to give C-acylated phosphonium salts **4**.^{15–17} Alkaline hydrolysis of the latter results in ketones.

R¹, R² ≠ H.

Reduction of *C*-acylated phosphonium salts **4** with sodium borohydride occurs *via* intermediate betaines, which quickly eliminate triphenylphosphine oxide to give alkenes.¹⁶

$\text{R}^1 = \text{Me}$; $\text{R}^2 = \text{Me, Ph}$; $\text{R}^3 = \text{Ph, MeC}_6\text{H}_4$.

A similar reaction of acyl chlorides with phosphoranes **3** containing the ester group, followed by cathodic reduction of acylated phosphonium chlorides **5**, provides a method to obtain esters of α -substituted β -oxo acids **6**.¹⁷

$\text{R}^1 = \text{Me, Pr, C}_5\text{H}_{11}, (\text{CH}_2)_2\text{CO}_2\text{Me, Ph, CH}=\text{CHPh, (CH}_2)_2\text{Ph}$;
 $\text{R}^2 = \text{Et, Bu}$.

Monosubstituted alkylidenephosphoranes **2** containing a hydrogen atom at the ylide carbon are conjugated bases, whereas the corresponding phosphonium salts are acids. The position of equilibrium depends on the nature of substituents R^1 and R^2

and is strongly (often, almost completely) shifted to the right if R^1 is a much stronger electron-withdrawing group than R^2 ; in fact, this is the case in acylation reactions.

The phosphonium salts **7** initially formed upon acylation of phosphoranes **1** and **2** are rather strong acids due to the effect of the acyl group. They eliminate HCl under the action of the initial phosphorane molecules to give acylated ylides **8** (weaker bases than the original phosphoranes). Thus, transylation occurs:^{18–21} the phosphonium salt and the ylide react to give a new phosphonium salt and a new ylide. This principle is widely employed in the synthesis of α -acylated ylides **8**.^{22–29}

$\text{R}^1 = \text{H, Me, Et, Pr}^n, \text{Pr}^i, \text{Bu}^n, \text{C}_5\text{H}_{11}, \text{Ph, CO}_2\text{Et}$; $\text{R}^2 = \text{Me, Et, Pr}^n, \text{Pr}^i, \text{Bu}^n, \text{Bu}^i, \text{C}_5\text{H}_{11}, \text{C}_6\text{H}_{13}, \text{cyclo-C}_4\text{H}_7, \text{cyclo-C}_6\text{H}_{11}, \text{CH}=\text{CHMe, Ph, 2-MeOC}_6\text{H}_4, \text{2-MeSC}_6\text{H}_4, \text{CH}_2\text{P}(\text{O})(\text{OEt})_2$.

The usual procedure for the acylation of unstable alkylidene- and arylmethylidenephosphoranes **1–3** ($\text{R}^1, \text{R}^2 = \text{Alk, Ar}$) involves the addition of phenyl- or butyllithium to a solution of the appropriate phosphonium salt in an anhydrous solvent, followed by treatment of the resulting phosphorane with the acylating agent in an inert atmosphere. The process can be simplified considerably by using the two-phase system CH_2Cl_2 –50% aqueous NaOH. These conditions were used to acylate benzylidenetriphenylphosphorane and other arylmethyl-

idenephosphoranes (**2**, $\text{R}^1 = \text{Ar}$)^{30–32} formed upon treatment of the corresponding phosphonium salts **9** with NaOH.[†]

$\text{Ar}^1 = \text{Ph, 4-PhC}_6\text{H}_4, 2,4\text{-Cl}_2\text{C}_6\text{H}_3, 3\text{-FC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4, 4\text{-MeO}_2\text{CC}_6\text{H}_4, 2,3,5,6\text{-Cl}_4\text{-4-MeC}_6, 4\text{-PhCOC}_6\text{H}_4, 4\text{-(4-MeC}_6\text{H}_4\text{N}=\text{N)C}_6\text{H}_4, 1\text{-naphthyl, 2-naphthyl, 4-methyl-1-naphthyl, 9-phenanthryl}$;
 $\text{Ar}^2 = \text{Ph, 4-ClC}_6\text{H}_4, 3\text{-NO}_2\text{C}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4, 2\text{-furyl}$.

The reaction is carried out under conditions of phase-transfer catalysis; the phosphonium salt serves as the carrier of ions from the aqueous phase to the organic phase. This procedure makes acylphosphoranes **10** accessible; the latter are used in syntheses of diarylacetylenes.

This two-phase system can also be used to acylate stable ylides; in this case, there is no need to isolate the free ylide beforehand.³²

The optimum phosphorane-to-acyl chloride ratio in transylation is 2 : 1. Otherwise, the excess acyl chloride can further react with the acylated ylide to give side products.

The reactions of aroylmethylidenetriphenylphosphoranes (**2**, $\text{R}^1 = \text{COAr}$) with *p*-nitrobenzoyl chloride in the ratio 2 : 1 resulted in *C*-acylated phosphoranes **11**, which are crystalline products with sharp melting points.³⁴

$\text{Ar} = \text{Ph, 4-ClC}_6\text{H}_4, 4\text{-MeC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4, 2\text{-thienyl}$.

Later, the *C*-acylation of other ylides with similar structures with *p*-nitrobenzoyl chloride as well as cinnamoyl chloride, furoyl chloride and phenylacetyl chloride was described.^{35,36} However, Nesmeyanov *et al.*³⁷ doubted that it was possible to obtain *C*-acylated products from 2-oxoalkylidenephosphoranes; they believed that *O*-acylation was most probable.

In phosphorane molecules containing a carbonyl group bound to the ylide carbon atom, the electron density is shifted from the ylide carbon atom (structure **A**) to the oxygen atom of the carbonyl group to give structure **B**, as confirmed by spectral methods.^{25,38–40}

$\text{R} = \text{Alk, Ar, OAlk}$.

In such a case, the reaction centre of the 2-oxoylide molecule is transferred to the carbonyl oxygen; this is actually observed in acylation and alkylation reactions. For example, it was shown³⁴ that aroylmethylidenetriphenylphosphoranes (**2**, $\text{R}^1 = \text{COAr}$) react with acetyl chloride and benzoyl chloride in accordance with structure **B** to give *O*-acylated salts **12**.

$\text{Ar} = \text{Ph, 4-BrC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-MeC}_6\text{H}_4$; $\text{R} = \text{Me, Ph}$.

[†] Simultaneously, the concentrated alkaline solution acts as a desiccant for dichloromethane.³³

O-Acylation of phosphoranes was also observed in some other studies.^{35, 41–44}

Treatment of phosphorus ylides with a 2.5–3-fold excess of an acyl chloride under conditions of phase-transfer catalysis results in secondary acylation of the initially formed ylide **10**; this is accompanied by the transfer of the reaction centre to the carbonyl oxygen atom. Subsequently, the *O*-acylated phosphonium salt **13** is cleaved by an alkali to give enol esters **14**.^{45, 46}

Ar¹ = Ph, 4-MeC₆H₄, 4-PhC₆H₄, 1-naphthyl, 2-naphthyl, 4-methyl-1-naphthyl; Ar² = Ph, 2-ClC₆H₄, 4-ClC₆H₄, 2-MeC₆H₄, 4-MeC₆H₄.

Chloroformates react with 2-oxoalkylenephosphoranes with the attack also on the oxygen atom under conditions of phase-transfer catalysis giving *O*-acylated phosphonium salts **15**; the latter are cleaved by an alkali into enol carbonates **16**.⁴⁷

O-Acylated phosphonium salts can be isolated and stored under ordinary conditions, but they are very unstable at elevated temperatures. Probably, *O*-acylated phosphonium salts can serve as acylating agents, with respect to the original phosphorane molecules in particular.

It was shown⁴⁸ that heating of *O*-acylation products results in their slow rearrangement with migration of the acyl residue to the carbon atom, *i.e.*, with formation of *C*-acylation products.

Preparation of *C*-acylated derivatives from 2-oxoalkylenephosphoranes is only possible with acyl chlorides activated by electron-withdrawing groups. In addition to *p*-nitrobenzoyl chlorides, this reaction can be carried out with ethoxalyl chloride, 2-oxoacyl chlorides, 2-furoyl chloride, *etc.*

Halogen-substituted acyl halides (chloroacetyl chloride, bromoacetyl bromide, trichloroacetyl chloride) behave as acylating agents⁴⁹ with respect to alkoxy-carbonyl- and cyanomethylidene-triphenylphosphoranes. The reaction is accompanied by transylidation to give *C*-acylated phosphoranes **17**.

R = CO₂Me, CO₂Et, CN; X = Cl, Br.

The halogen atoms of the α-halogenoketone moiety of the ylides **17** can undergo nucleophilic substitution, although the effect of the phosphoranylidene-methyl group makes them less reactive than in ordinary halogenoketones.

Upon transylidation, half of the starting ylide is present in the reaction mixture as a phosphonium salt. This drawback can be avoided if another base, for example triethylamine, is used to bind the hydrogen halide.^{50–53} Yet another advantage of this method is that preliminary isolation of the starting phosphorane in a free state is unnecessary. One can perform the reaction using an appropriate phosphonium salt and a twofold excess of triethyl-

amine.^{54, 55} Successive transformations of a phosphonium salt gave *C*-acylated ylides **18**.

R¹ = Me, Et, Bu, Bn; R² = CHCl₂, CCl₃, CClF₂, CHF₂, CF₃, C₂F₅, CCl₂Me, Ph, 2-MeC₆H₄, 4-MeC₆H₄, 2-MeOC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄, 2-MeSC₆H₄, C≡CBu, C≡CPh, 2-furyl, 2-thienyl.

It was found⁵⁶ that alkoxy-carbonyl-substituted ylides give unstable *O*-acylated salts **19** at low temperatures, which then undergo spontaneous rearrangement into *C*-acylated phosphonium salts.

R = Me, (CH₂)₂CO₂Me, (CH₂)₂CO₂Bn.

The reaction of acetylmethylidene-triphenylphosphorane (**2**, R = COMe) with ethoxalyl chloride gave ylide **20** with two carbonyl groups and one ester group, whereas the reaction of methoxycarbonylmethylidene-triphenylphosphorane (**2**, R = CO₂Me) gave trioxo ylide **21**, which contains one carbonyl group and two ester groups.⁵⁷

R = COMe (**20**), CO₂Me (**21**).

The low yields of phosphoranes **20** and **21** (9% and 33%, respectively) can be explained by the fact that Koz'minykh *et al.*⁵⁷ used an equimolar phosphorane : acyl chloride ratio. Better results were achieved with triethylamine.^{58, 59}

Tetraoxoylides **22** are formed in reactions of dicarbonyl phosphoranes **23** with 2-oxoacyl chlorides.^{60–62}

R¹, R² = Me, Ph, OMe, OEt.

The reactions of alkylidenephosphoranes with dicarboxylic acid chlorides result in bisylides. In certain studies,^{61, 63, 64} oxalyl chloride was used for acylation. For example, bisylides **24** were obtained by treatment of phosphoranes **2** with oxalyl chloride in the presence of triethylamine.⁶³ Reactions of alkylidenephosphoranes **2** with other dicarboxylic acid chlorides, as well as reactions of monoacyl chlorides with bisylides containing hydrogen atoms at the ylide carbon atoms, result in similar products.⁶⁴

R = Ph, 4-ClC₆H₄, 4-BrC₆H₄, CO₂Me, CO₂Et, CPh.

Furthermore, Aitken and Karodia⁶¹ obtained hexacarbonyl bisylides **25** using the reaction of dicarbonyl phosphoranes **23** with oxalyl chloride.

R = Ph, OMe, OEt.

The reactions of oxalyl chloride with alkylidenephosphoranes containing the thiocarbonyl group resulted in heterocyclic phosphonium salts.⁶⁵

Ar = Ph, 4-MeC₆H₄.

Vinylmethylidenetriphenylphosphorane is acylated at the γ -position; this is accompanied by transylidation.^{66, 67}

R = Me, Prⁿ, Prⁱ, Buⁿ, OMe.

However, vinylmethylidenephosphoranes containing two γ -substituents only undergo α -acylation.⁶⁸

R¹ = Ph, R² = H; R¹ = R² = Me; R³ = Ph, 4-ClC₆H₄, 4-MeC₆H₄, CH=CHPh.

An unusual example of the acylation of phosphorane **26** containing a sulfonyl group was reported.⁶⁹ Its treatment with butyllithium results in deprotonation from the α -position with respect to the sulfonyl group, giving a carbanionic centre which is stronger than the ylide carbon atom. Subsequent acylation with ethyl chloroformate results in the new phosphorane **27**, which can subsequently be used in the Wittig reaction.

Acylated ylides possess biological activity; in particular, they were found to have antimicrobial properties. A short survey of results of studies on the biological action of acylmethylidenephosphoranes and the corresponding phosphonium salts has been published.⁵⁷

III. Reactions and preparative value of acylated ylides

1. Hydrolysis and reduction. Synthesis of ketones and carboxylic acids

Acylphosphoranes **8** can serve as intermediates in the syntheses of other classes of compounds, *e.g.*, ketones, using alkaline hydrolysis,^{15, 18, 70} reductive cleavage in the presence of zinc in acetic acid^{18, 20, 68, 71} or other methods.^{18, 26, 69, 72}

R¹ = H, Me, Pr, Ph; R² = Me, Pr, C₅H₁₁, Ph, CH=CHPh, (CH₂)₂Ph.

Chlorination of phosphoranes **8** with dichloriodobenzene followed by hydrolysis of salts **28** results in α -chloro ketones.²⁶

R¹ = Et, Prⁿ, C₅H₁₁, Bn; R² = Me, Prⁱ, cyclo-C₃H₅, cyclo-C₆H₁₁.

The ester group is introduced in alkylidenephosphorane molecules using alkyl chloroformates as acylating agents;^{66, 69, 73} subsequent hydrolysis of the resulting phosphoranes **29** gives carboxylic acids.

R¹ = H, Me, Et, Pr, cyclo-C₃H₅, cyclo-C₆H₁₁, Ph; R² = Me, Et.

Cyclopropanecarboxylic acid **30** was obtained in 84% yield using this method.⁷³

Alkaline hydrolysis of acylated phosphoranes **31** yielded β -oxo acids, while their acid hydrolysis yielded their esters.⁷⁴

R = Me, Pr, C₅H₁₁, C₁₃H₂₇, Ph, 2-furyl.

2. Oxidation of acylmethylidenephosphoranes

The oxidation of acylated ylides is yet another example of their preparative usage. Different products are obtained depending on the oxidant. It was shown^{75, 76} that oxidation of stabilised acyl ylides with peroxy acids gives diacyl-substituted ethylenes. The best results were achieved in the synthesis of diaroylethylenes **32**. Presumably, the original phosphorane is partly oxidised into arylglyoxal during the reaction; the latter then undergoes the Wittig reaction with other ylide molecules to give diaroylethylenes.

Ar = Ph, 4-BrC₆H₄, 4-MeOC₆H₄, 4-NO₂C₆H₄, 4-MeCONHC₆H₄;
R = Me, C₇H₁₅.

Similar compounds were obtained upon the oxidation of aroylmethylidenetriphenylphosphoranes with selenous acid in dioxane.^{77, 78} Treatment of acyl- and alkoxycarbonylmethylidenephosphoranes with alkene ozonides^{79, 80} results in symmetrical alkenes containing ketone or ester groups. The reaction occurs probably *via* intermediate glyoxals, as was proved⁸¹ by analysing the products obtained upon treatment of aroylmethylidenephosphoranes with ozone at -70°C . Under these conditions, phenylglyoxal (**33**) was obtained from benzoylmethylidenetriphenylphosphorane (**2**, R = C₆H₅) and diketone **34** was obtained from the substituted ylide **8** (R¹ = R² = Ph).

Later, Bestmann *et al.*⁸² showed that it is better to use the ozone–triphenylphosphite adduct for the preparation of diketones from phosphoranes **8**.

$\text{R}^1 = \text{Me}, \text{Bu}$; $\text{R}^2 = \text{Bu}, \text{C}_5\text{H}_{11}, \text{C}_6\text{H}_{13}, (\text{CH}_2)_8\text{CH}=\text{CH}_2$.

Similar α -diketones were obtained using NaIO_4 ,⁸³ OsO_4 and KMnO_4 ⁸⁴ as oxidants. Potassium permanganate was found to be the most suitable for the oxidation of compounds **10** with aromatic substituents into the corresponding non-symmetrical diketones **35** in a two-phase system.⁸⁵

$\text{Ar}^1 = \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, 2\text{-NO}_2\text{C}_6\text{H}_4$; $\text{Ar}^2 = \text{Ph}, 2\text{-MeOC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, 2\text{-MeSC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 2\text{-NO}_2\text{C}_6\text{H}_4, 2\text{-furyl}, 2\text{-thienyl}$.

Acylation of methoxymethylidenetriphenylphosphorane **36** with acyl chlorides involving transylidation followed by oxidation of the products **37** with lead dioxide or lead tetraacetate was recommended⁸⁶ as a method for the synthesis of α -oxo acid esters. The same esters were obtained by oxidation of phosphoranes **38** with atmospheric oxygen.⁸⁷

$\text{R} = \text{Me}, \text{Pr}^i, \text{Bu}, \text{cyclo-C}_3\text{H}_5, \text{cyclo-C}_4\text{H}_7, \text{Ph}, \text{CH}=\text{CHPh}, \text{C}\equiv\text{CPh}, 3\text{-pyridyl}, 2\text{-(2-furyl)vinyl}$.

An original method was proposed for the synthesis of esters and amides of α -oxo acids by oxidative cleavage of acyl(cyano)methylidenetriphenylphosphoranes **39** with ozone⁸⁸ or dimethyldioxirane⁸⁹ in the presence of nucleophiles. Thus the oxidation in the presence of alcohols affords esters **40**, whereas in the presence of amines α -oxo amides **41** are formed, including peptides that are active as inhibitors of hydrolytic enzymes.⁸⁸

$\text{R}^1 = \text{Ph}, \text{amino acid and peptide residues}$;
 $\text{R}^2 = \text{H}, \text{Me}, \text{Bn}$; $\text{R}^3 = \text{Bn}, \text{CH}(\text{CH}_2\text{Ph})\text{CO}_2\text{Et}$.

Tricarbonyl compounds, *viz.*, esters of 2,3-dioxo carboxylic acids **42**, were obtained by oxidation of acylated alkylidene-

phosphoranes **18** with ozone,⁹⁰ magnesium monoperoxyphthalate⁹¹ or dimethyldioxirane.⁹²

$\text{R}^1 = \text{Me}, \text{Bu}^t, \text{Bn}$; $\text{R}^2 = \text{Me}, (\text{CH}_2)_2\text{Cl}, \text{CH}=\text{CMe}_2, \text{CH}=\text{CHOMe}, (\text{CH}_2)_2\text{CH}=\text{CH}_2, (\text{CH}_2)_2\text{CH}=\text{CMe}_2, \text{CH}_2\text{CH}(\text{Me})\text{CH}_2\text{CH}=\text{CMe}_2, \text{Ph}, \text{CH}=\text{CHPh}, 2\text{-furyl}, 2\text{-thienyl}$.

It is unlikely that nitrogen dioxide tested as an oxidant for alkylidenephosphoranes^{93,94} will find preparative use because even small variations in the phosphorane structure result in different product mixtures.

3. Thermolysis. Synthesis of functionalised acetylenes

Of other transformations involving acylated ylides, the Wittig reaction occurring at high temperatures is used most widely. In this reaction, the phosphoranylidene group reacts with the carbonyl group of the same molecule in a α -position with respect to the ylide carbon atom so that the phosphorus atom is bound with the oxygen atom of the oxo group, resulting in elimination of triphenylphosphine oxide and formation of a triple $\text{C}\equiv\text{C}$ bond. If the carbonyl group is more remote from the ylide carbon atom, ring closure through the $\text{C}=\text{C}$ bond can occur. The first examples of this reaction were known back in the 1960s.^{41,50,95} The process was carried out at $200\text{--}280^\circ\text{C}$ at reduced pressure with distillation of the resulting products. In the past decade, Aitken *et al.*^{51,52,58,61–64} developed a higher-temperature version of this reaction (500 and even 700°C), *i.e.*, vacuum flash pyrolysis.

If the phosphorane molecule contains one carbonyl group, the reaction gives alkyl(aryl)acetylenes.^{28,29,41,52}

$\text{R}^1, \text{R}^2 = \text{Alk}, \text{Ar}$.

Selenium-substituted acetylenes **43** were obtained using the following scheme:⁹⁶

$\text{R}^1 = \text{Me}, \text{CF}_3, \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4, 2\text{-thienyl}$; $\text{R}^2 = \text{Ph}, 4\text{-ClC}_6\text{H}_4, 4\text{-Cl-2-NO}_2\text{C}_6\text{H}_3, 3\text{-CF}_3\text{C}_6\text{H}_4$.

Thermolysis of aryl(trifluoroacetyl)methylidenephosphoranes obtained upon acylation of arylmethylidenetriphenylphosphoranes with trifluoroacetic anhydride results in aryl(trifluoromethyl)acetylenes.⁹⁷

$\text{Ar} = \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4$.

Reactions of diphenylchlorophosphine with alkylidenephosphoranes **2,98** including those containing an oxo group,^{99,100} give ylides **44**. Heating of these compounds with sulfur yields diphenylthiophosphoryl-substituted alkylidenephosphoranes. Methylation of the resulting ylides with dimethyl sulfate occurs both at the oxygen and the sulfur atoms. However, *S*-methylation products are so unstable that they undergo *in situ* thermolysis in mild conditions giving salts of phosphorus-containing acetylene derivatives.¹⁰⁰

R = Me, Ph.

Acylation of phosphoranes with cinnamoyl chloride followed by thermolysis of the resulting acylides gave conjugated enynes **45**;¹⁰¹ the use of alkynoyl chlorides as acylating agents followed by thermolysis resulted in diacetylenes **46**.^{50, 63}

R = H, Me, Et, Prⁿ, Prⁱ, Bu, Ph, 2-MeOC₆H₄, 4-NO₂C₆H₄, 2-thienyl, CO₂Et.

R¹ = Ph, CN, CO₂Et; R² = Bu, Ph.

Derivatives **46** were also obtained by high-temperature vacuum flash-pyrolysis of dicarbonyl bisylides **24** containing aromatic substituents. If bisylides **24** incorporate aliphatic substituents, this method fails.⁶³

The thermolysis of phosphoranes is successfully used to synthesise diarylacetylenes. For example, diarylacetylenes **47** with perfluorobenzene rings¹⁰² and with anthracene, phenanthrene, pyrene and chrysene fragments¹⁰³ were obtained by thermolysis of phosphoranes **10** used in the reaction without special purification.

Ar¹, Ar² = Ph, C₆F₅, 1-anthryl, 9-anthryl, 2-phenanthryl, 3-phenanthryl, 9-phenanthryl, 1-pyrenyl, 2-pyrenyl, 6-chrysenyl.

Acylation of anthraquinonylmethylenephosphoranes **48** in a two-phase system followed by thermolysis of the resulting acylides **49** gave diarylacetylenes **50** containing an anthraquinone fragment.¹⁰⁴

R = H, Me, F; Ar = Ph, 4-ClC₆H₄, 4-MeC₆H₄, 3-NO₂C₆H₄, 4-NO₂C₆H₄, 2-furyl.

Diarylacetylenes form a considerable group of organic luminophores, although it is not as abundant as that of diarylethylenes.^{103, 105-107}

The thermolysis of acylated phosphoranes is often used to obtain functionalised alkynes: alkynyl ketones,^{42, 50} alkynonitriles,^{41, 50} esters and amides of acetylenecarboxylic acids.^{51, 53, 74, 108-110} A method was suggested⁹⁵ for the synthesis of alkynoic acids **51** by vacuum thermolysis of acylated ylides **18** followed by hydrolysis of the resulting esters **52**.

R = Me, Ph, 2-ClC₆H₄, 4-ClC₆H₄, 4-MeC₆H₄, 2-MeOC₆H₄, 3-MeOC₆H₄, 3-NO₂C₆H₄, Bn, CH=CHPh, 1-naphthyl, 2-furyl.

A preparative method for the synthesis of ethyl 4,4,4-trifluorobutynoate **53** from ethoxycarbonylmethyltriphenylphosphonium bromide **54** was developed.⁵⁵ Trifluoroacetic anhydride in the presence of triethylamine was used as the acylating agent. The key step of this reaction involves thermolysis of acylated phosphorane **55** to give compound **53** containing a triple C≡C bond.

Later, this method was used to obtain esters of other acetylenecarboxylic acids from phosphonium salt **54** and carboxylic acid chlorides.

Thioesters of polyfluorinated carboxylic acids **56** were synthesised by acylation of ylide **57** containing a methylthiocarbonyl group with polyfluorinated acid chlorides followed by heating of the resulting acylides to 190–220 °C *in vacuo*.¹¹¹

R = CF₃; n = 1, 2, 6; R = Cl; n = 3, 5.

Acetylenedi- and -tricarboxyl compounds were obtained by vacuum flash-pyrolysis. On heating to 500 °C *in vacuo*, phosphoranes **58** give esters of 4-oxoalk-2-ynoic acids **59**.^{58, 59}

$\text{R}^1 = \text{Me}, \text{Ph}, 4\text{-BrC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4, \text{OMe}, \text{OEt};$
 $\text{R}^2 = \text{Me}, \text{Et}.$

Thermolysis of tetracarbonylides **22** resulted in esters of 2-oxopentynedioic acid **60**.^{60, 61}

$\text{R} = \text{Me}, \text{Et}.$

However, vacuum flash-pyrolysis of polycarbonyl bisphosphoranes, such as tetraoxobisylides **24** ($\text{R} = \text{COPh}, \text{CO}_2\text{Alk}$) and hexaoxobisylides **25**, result in deeper destruction of the molecules of these compounds.^{61, 63, 64, 112}

If the carbonyl group in the phosphorane molecule is remote from the ylide carbon atom, its thermolysis results in cyclisation and sometimes in heterocyclisation. Some examples of these reactions are documented.^{113–121}

The thermal decomposition of acylated alkoxy carbonylmethylidenephosphoranes **43** or the respective phosphonium salts in acidic media, which involves the loss of the alkoxy carbonyl group and results in acylphosphoranes, can be of value as a preparative method.^{27, 70, 122} The reaction can be used for the synthesis of acylphosphoranes if the corresponding α -halogenoketones are difficult to access. For example, chiral 2-oxoalkylidenephosphoranes **61** were synthesised by acylation of ylides **2** containing an alkoxy carbonyl group with chiral α -substituted acid chlorides followed by decomposition of intermediates **62** by refluxing in benzene in the presence of *p*-toluenesulfonic acid.²⁷

$\text{R}^1 = \text{Me}, \text{Bu}^t; \text{R}^2, \text{R}^3 = \text{F}, \text{Me}, \text{Bu}, \text{cyclo-C}_6\text{H}_{11}\text{CH}_2.$

4. Synthesis of allenic compounds

The synthesis of allenic compounds is yet another interesting and promising example of reactions of alkylidenephosphoranes with acyl chlorides. Bestmann *et al.*^{123, 124} found that the reaction of acyl chlorides with stable phosphorus ylides **3** containing the α -ethoxycarbonyl group results in esters of allenecarboxylic acids. This involves C-acylation of the ylide, the reaction of the resulting phosphonium salts **63** with a second molecule of the original phosphorane **3** with γ -elimination of a proton and simultaneous elimination of triphenylphosphine oxide to give allenecarboxylic esters **64**.

$\text{R}^1 = \text{Me}, \text{Pr}, (\text{CH}_2)_2\text{Ph}; \text{R}^2, \text{R}^3 = \text{H}, \text{Me}, \text{Et}, \text{Pr}, \text{Bu}, \text{C}_5\text{H}_{11}, \text{Ph}, \text{Bn}, \text{CH}_2\text{CO}_2\text{Me}.$

Esters of other allenecarboxylic acids were obtained under the same conditions.¹²⁵ If phosphorane molecules contain hydrogen atoms at the ylide carbon atoms, acylation involves transylidation and allenecarboxylic esters are not formed.

Lang and Hansen^{126, 127} proposed that the reaction be performed in the presence of triethylamine. This also made it possible to obtain allenic derivatives from phosphoranes containing α -hydrogen atoms. In addition, this method allows one to use the corresponding phosphonium salts instead of phosphoranes. The reaction mechanism changes in the presence of triethylamine. Acyl chlorides no longer behave as acylating agents. In the presence of triethylamine, they eliminate HCl to give ketenes, which subsequently undergo the Wittig reaction with phosphoranes.

$\text{R}^1, \text{R}^2 = \text{H}, \text{Me}, \text{Et}, \text{Bu}^t, \text{C}_5\text{H}_{11}, \text{Ph}, \text{CO}_2\text{Me}, \text{Cl}.$

This approach was used to synthesise other ethyl¹²⁸ and aryl¹²⁹ allenecarboxylates; the latter were also obtained by independent syntheses from ketene.

$\text{Ar} = \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-Bu}^t\text{C}_6\text{H}_4, 4\text{-Bu}^i\text{C}_6\text{H}_4, 3\text{-MeC}_6\text{H}_4, 2\text{-MeC}_6\text{H}_4, 2\text{-Bu}^n\text{C}_6\text{H}_4, 3,5\text{-Me}_2\text{C}_6\text{H}_3, 2,4\text{-Me}_2\text{C}_6\text{H}_3, 2,3\text{-Me}_2\text{C}_6\text{H}_3, 2,5\text{-Me}_2\text{C}_6\text{H}_3, 2,6\text{-Me}_2\text{C}_6\text{H}_3, 2,3,5\text{-Me}_3\text{C}_6\text{H}_2, 2,4,6\text{-Me}_3\text{C}_6\text{H}_2, 2,3,6\text{-Me}_3\text{C}_6\text{H}_2.$

Phenylacetyl and diphenylacetyl chlorides react with acetyl-methylidenephosphorane in the presence of triethylamine to give allenyl ketones.¹³⁰

$\text{R} = \text{H}, \text{Ph}.$

Silicon-substituted allenes were obtained¹³¹ from phosphoranes and silicon-containing ketenes.

* * *

It should be noted in conclusion that the reaction of phosphorus ylides with acyl chlorides is not the only example of the chemistry of these compounds. Reactions of phosphorus ylides with acyl chlorides are not solely of theoretical interest; they also open new prospects for the synthesis of other classes of compounds that cannot be synthesised by other methods. In particular, it seems promising to synthesise allenic compounds from alkylidenephosphoranes, although this direction has been developed insufficiently yet and there are few publications in this field. Thus, the practical value of alkylidenephosphoranes is not limited to their use as components of the Wittig reaction.

Lignin. Structural organisation and fractal properties

A P Karmanov, Yu B Monakov

Contents

I. Introduction	715
II. Conformational properties and topological structure of lignin	716
III. Lignin macromolecule as a fractal object	721
IV. Supramolecular structure of lignin	730
V. Conclusion	732

Abstract. The results of investigations of the topological and supramolecular structures of lignins are considered. The experimental data on the hydrodynamic and conformational properties of dilute solutions of hardwood and softwood lignins are generalised. The relationship between hydrodynamic and fractal properties of lignin macromolecules is analysed and the applicability of various fractal concepts is discussed. Good prospects of using the fractal approach for the study of amorphous polymers with complex topological and supramolecular structures are demonstrated. The bibliography includes 174 references.

I. Introduction

Lignins are polyfunctional biopolymers of plant origin. They are formed upon enzymic dehydrogenation polymerisation of a number of methoxylated derivatives of hydroxycinnamic alcohols (guaiacyl-, syringylpropenol, *etc.*).^{1,2}

R = H (guaiacylpropenol), OMe (syringylpropenol).

Two main classes of these biopolymers are distinguished, namely, the guaiacyl type lignin, typical of conifers, and the guaiacyl-syringyl type lignin, which is formed in deciduous plants. The unique character of lignin as a high-molecular-mass compound is due to the diversity of the structural units (dilignols) that constitute the structure and to diverse types of bonds between them.^{3,4} More than twenty types of dilignols are currently known. The key types of dilignols incorporated in the lignin structure are

shown in Fig. 1. In natural lignins, structural elements with β -O-4-bonds predominate [$C(\beta)-O-C(4)$, ~25%]. This type of dilignol, 1-(4-hydroxy-3-methoxyphenyl)-2-(2'-methoxyphenyloxy)-1,3-propanediol (**1**, β -guaiacyl ether of guaiacylglycerol), is often used as a dimeric compound modelling the natural softwood lignin.

The rules of distribution of various dilignols in the polymer chain are unknown, most likely, they are non-deterministic, which is due to the absence of genetic control during the biosynthesis, at the stage of assembly of the lignin macromolecule.^{1–4} It should, however, be noted that this point of view has lately been criticised. A new concept of lignin biosynthesis based on the view of existence of regio- and stereochemical control of the recombination of monolignols has been proposed.⁵

The structural organisation of lignin as a biopolymer can be represented as a set of hierarchical levels differing in complexity, namely, the chemical, topological, supramolecular, and ultra-structural ones.⁶ The last-mentioned level is inherent in native lignin. The achievements and problems related to the study of the chemical structure of lignin have been analysed in a review.⁷ In recent years, substantial advances have been made in the study of the topological and supramolecular organisation of lignin. This is largely due to the development of new approaches to the research of polymers based on the use of the concepts of deterministic chaos and synergetics, the fractal theory, and non-linear dynamics.

This review gives an analysis of the data accumulated to date on the hydrodynamic and conformational properties of lignin macromolecules in solutions and on the topological structure and properties of lignin as a fractal object.

The topicality of research into lignin is dictated by the significant role it plays in the chemical processing of wood to produce cellulose, paper or cardboard. The production technology of cellulose-containing materials from one or another plant raw material is determined, first of all, by the structure and properties of the lignin it contains. Fragmentation and subsequent dissolution of softwood lignin, composed mainly of guaiacyl type dilignols, require the most drastic pulping conditions. In this case, alkaline delignification procedures are used, in particular, sulfate and soda pulping. Lignin of hardwood trees or herbaceous plants is delignified rather easily, which is due to its specific structural features, namely, the guaiacyl-syringyl structure. Cellulose is produced from these plant raw materials using a number of organosolvate pulping processes.

Depending on the production method, soluble lignins are classified into technical and slightly decomposed lignins. Technical lignins include alkaline lignins resulting from treatment of wood or stalks of herbaceous plants with sodium hydroxide or a mixture of sodium sulfide and hydroxide (alkaline and sulfate pulping) and lignosulfonates,[†] which are formed as side products upon treatment of the plant raw material with aqueous solutions of oxo compounds of sulfur (the sulfite pulping procedure).⁸ The slightly decomposed lignins can be isolated from plant raw materials under relatively mild conditions.

If the reserves of traditional organic raw materials are exhausted, lignin can become the main source for the production of diverse organic compounds,⁹ which is due to specific features of the chemical structure of lignin and virtual inexhaustibility of the natural plant resources.

II. Conformational properties and topological structure of lignin

Elucidation of the topological structure of lignin macromolecules is one of the most complicated problems of the physical chemistry of lignin. Historically, the views on the topological structure (configuration) of lignin macromolecules have been based on and have varied to follow the views on its chemical structure. Up to the mid-20th century, it was taken for granted that lignin, like cellulose, is a linear polymer. Later, after the publication of studies by Freudenberg and co-workers on lignin biosynthesis *in vitro* and elucidation of the main principles of the growth of polydignols, the views were revised, and, as a consequence, lignin was assigned to the class of branched polymers (see Ref. 1 and references cited therein). Currently, the concept of a network structure of natural lignin proposed by Goring predominates in wood chemistry.^{10–12}

A classical approach to determining the topological structure of polymers includes investigation of the conformational properties of macromolecules in dilute solutions. The conformational properties of macromolecules show themselves, first of all, in the translational and rotational friction processes; therefore, they are

studied using methods of molecular hydrodynamics, in particular, velocity sedimentation, isothermal translational diffusion and capillary viscosimetry. These methods allow one to estimate the size and conformation of the macromolecular coils, which are of crucial significance for determination of the topological structure of polymers. Hydrodynamic methods still remain the experimental basis for virtually all studies of the topological structure of lignin.

Previously,^{1,2} lignosulfonates (LS) have been considered to be the most appropriate lignin specimens for determination of the macromolecular structure of natural lignin, because only the weakest α - and β -ester bonds are hydrolysed during the nucleophilic sulfitation and the degree of side condensation reactions is low. In addition, unlike many other lignin preparations, lignosulfonates are readily soluble in aqueous solutions. Therefore, many studies dealing with the physical chemistry of lignin have been carried out using LS.

Gardon and Mason have studied the hydrodynamic properties of industrial specimens of guaiacyl type LS (silver fir).^{13,14} The measurements of the intrinsic viscosity and the translational diffusion coefficients carried out in brines provided the conclusion that in aqueous solutions, the LS macromolecules occur as the Gaussian impermeable coil conformation. This conclusion was based on analysis of the correlations between the intrinsic viscosity ($[\eta]$), the diffusion coefficient (D), and the molecular mass (M), which were described by Mark–Kuhn–Houwink (MKH) type dependences:

$$[\eta] = K_{\eta} M^a,$$

$$D = K_D M^b,$$

where K_{η} and K_D are empirical constants; a and b are the MKH scaling indices. The a and b values equal to 0.47 and -0.56 , respectively, point to a linear topological structure of LS macromolecules. A similar value for b , equal to -0.57 , has been obtained for a spruce LS specimen in a 0.02 M solution of NaCl.¹⁵ According to another publication,¹⁶ low-molecular-mass LS fractions ($M < 5 \times 10^3$) consist of linear chains, whereas macromolecules with a higher molecular mass have a branched structure.

Studies performed by Goring and co-workers^{11,17} deserve particular attention, because they crucially changed the views on the topological structure of lignins existing at that time. To study the hydrodynamic properties, Goring used LS specimens prepared by laboratory sulfite pulping of spruce wood. It was found that LS has a high polydispersity index [the ratio of the weight-average molecular mass (M_w) to the number-average molecular mass (M_n) reaches 5–7 or even more]. One specimen was fractionated to give nine fractions, whose molecular mass varied from 37.0×10^3 to 1.3×10^6 . According to Goring's opinion, aqueous solutions of LS in a 0.1 M solution of NaCl are molecular disperse systems. The Mark–Kuhn–Houwink scaling indices a and b were found to be 0.32 and -0.33 , respectively, *i.e.*, the hydrodynamic behaviour of the LS macromolecules corresponded to neither the Gaussian impermeable coil nor the Einstein sphere. The set of obtained results led Goring to the conclusion¹¹ that LS macromolecules, like those of other soluble lignins, represent fragments of the three-dimensional network of natural lignin *in situ*. The destruction of the three-dimensional network of natural lignin during its isolation from the plant tissue yields microgel particles of an arbitrary shape, whose hydrodynamic behaviour corresponds to the properties of slightly swollen spherical particles. The intrinsic viscosity of LS is fairly low, which is due to the small hydrodynamic radius of cross-linked particles. After the publication of Goring's studies, the concept of the cross-linked structure of natural lignin has gained wide acceptance among researchers; however, no convincing evidence supporting this hypothesis has been obtained so far.

A similar study, but using industrial lignosulfonates has been carried out by Afanas'ev *et al.*^{18–20} These publications present the results of measurements of the hydrodynamic characteristics of

[†] Lignosulfonates belong to the class of polyelectrolytes, due to the presence of strong acidic groups CO_2H and SO_3H in the chain.

Table 1. Hydrodynamic and molecular characteristics of liginosulfonates in a water–salt buffer solution (pH 6.85).²⁰

$[\eta]$ /cm ³ g ⁻¹	$10^7 D_0$ /cm ² s ⁻¹	dn/dc (see ^a)	$10^{-3} M_w$	M_w/M_n

^a Increment of the refractive index.

spruce LS in aqueous and aqueous salt solutions at various pH values (Table 1 presents experimental values for some hydrodynamic parameters of LS obtained at pH 6.85). The researchers demonstrated the satisfiability of the scale invariance principle over a broad range of molecular masses — from 6×10^3 to 82×10^3 . Analysis of the viscosimetry ($a = 0.22$) and diffusion ($b = -0.44$) data led to the conclusion²⁰ that the LS macromolecule is a chaotically branched chain rather than a microgel particle.

Due to the inconsistency of experimental data on the hydrodynamic properties of LS in solutions, the problem of the conformation of LS macromolecules remains debatable. Goring and co-workers¹² believe that LS exists in aqueous solutions as dense globular particles similar to Einstein spheres. However, in this case, the scaling indices a and b should be equal to 0 and -0.33 , respectively, which contradicts the experimental data. The viscosimetric properties of samples and the scaling indices $a > 0.2$ imply that the shape asymmetry of the macromolecular coil changes with the growth in the molecular mass and that the macromolecule can be modelled by an ellipsoid of revolution. Rebinder²¹ believed that LS molecules exist in solutions as spheroids with fairly large aspect ratios.

Among other reasons, the diversity and inconsistency of the data on the conformations of LS (Table 2) are related to the chemical structure of this polymer, which refers to the class of polyacids (polyanions). The presence of ionogenic groups (carboxy and sulfo groups) capable of a variety of interactions results in LS acquiring some properties atypical of natural lignin. Thus dilution of solutions of liginosulfonates to concentrations of $(1-0.5) \times 10^{-2}$ g cm⁻³ usually entails an increase in the reduced viscosity (η_{sp}/c), instead of the expected decrease, which is due to electrostatic effects.²⁸ The addition of monomeric electrolytes which shield electrostatic interactions in the chain does not always produce linear dependences of the reduced viscosity on the LS concentration (Fig. 2).²⁹

The conformational characteristics of LS are dictated by the degree of ionisation of acid groups, which depends on the nature and properties of the solvent, the type of low-molecular-weight additives, the ion strength of the solution, and so on. The solution temperature and pH are also important factors influencing the hydrodynamic properties of LS. In the pH region of 5.5–7.5, the hydrodynamic size of LS molecules dramatically increases as a result of polyelectrolyte swelling; the efficiency of ionisation depends on the molecular masses of fractions according to a complex pattern.²⁰ Evidently, this is due to the inhomogeneity of fractions as regards the number and the nature of acidic, first of all, sulfur-containing groups. The degree of sulfonation of the fractions for field LS specimens varies over a wide range, namely, from 0.5 to 0.96. Therefore, it is clear that the chemical inhomogeneity of LS has an ambiguous influence on the results of hydrodynamic measurements and the conclusions drawn.

An essential factor complicating the research and interpretation of the results of hydrodynamic measurements for liginosulfonates is the aggregation of macromolecules (even in dilute

Table 2. Mark–Kuhn–Houwink parameters for samples of technical lignins isolated from wood.

solutions). According to a publication,³⁰ the molecular mass of softwood LS measured by the translational diffusion method decreases 6-fold on passing from a 0.1 N aqueous solution of KCl to anhydrous ethanol and decreases 12.5-fold on passing to methanol.

Associates of macromolecules have also been detected in dilute (in particular, aqueous) solutions of LS by velocity sedimentation techniques.^{18,20} The hydrodynamic radius of the aggregates determined by these methods is equal to

**Figure 2.** Reduced viscosity of liginosulfonates η_{sp}/c vs. concentration upon dilution of solutions of liginosulfonates with brines having different molar concentrations.²⁹ NaCl concentration in brine /mol litre⁻¹: (1) 0.00001, (2) 0.001, (3) 0.01, (4) 0.1, (5) 1.

150–200 nm. Raising the solution temperature to 60 °C induces partial decomposition resulting in a more than twofold decrease in the hydrodynamic radius of the aggregates. It should be noted that the formation of ion associates is a typical feature of not only LS but also other polyelectrolytes.³¹

Lignosulfonates are known to be surfactants. The chains of phenylpropane units form hydrophobic fragments of the macromolecules, while highly acidic sulfo groups constitute the hydrophilic shell. It cannot be ruled out that the hydrophilic properties of LS play a significant role in the structural organisation of the macromolecular coil and, correspondingly, influence the hydrodynamic properties of this polymer in aqueous solutions.

Sokolov and co-workers^{27,32,33} have carried out a series of studies dealing with the polymeric properties of alkaline lignins. It was found that both sulfate and alkaline lignins have high polydispersity indices ($M_w/M_n \approx 3-10$). The molecular mass of sulfate lignins varies from 1×10^3 to 34×10^3 . As a rule, alkaline lignins isolated from hardwood have a lower molecular mass than softwood lignins. According to Sokolov,²⁷ the intrinsic viscosity of fractions of sulfate lignin from spruce wood in DMSO varied from 7.4 ($M_w = 1.3 \times 10^3$) to $13.3 \text{ cm}^3 \text{ g}^{-1}$ ($M_w = 38.7 \times 10^3$). The dependence of $\log[\eta]$ on $\log M_w$ is linear (the slope ratio, equal to the scaling index a , is 0.15), *i.e.*, macromolecules of the sulfate lignin are impermeable coils with a high degree of globularity; in the researcher's opinion, they can be modelled by rigid spheres impermeable to the solvent.

This conclusion is at variance with the results obtained by Mayer,²⁵ who gives a higher value of the viscosimetric parameter for sulfate lignin, $a = 0.69$ (see Table 2). This value corresponds to the conformation of a swollen impermeable coil for a linear macromolecule. It should be noted that this study was performed with hardwood lignin. The differing origin of lignin appears to be the most likely reason for the divergence of results obtained in the studies cited above.^{25,27}

Thus, analysis of early publications dealing with the macromolecular structure of lignin attests to a substantial inhomogeneity of sulfate lignins, which is due to specific features of pulping processes.¹⁻³ A brief survey of publications devoted to technical lignins leads to the conclusion that the use of these polymers for elucidating the topological structure of natural lignin does not give unambiguous results. This is due to the substantial transformation of lignin during isolation from the plant tissue.

More successful studies (as regards gaining information on the structural organisation of natural lignins) have been carried out with another group of specimens, which belong to the class of slightly decomposed lignins. The greatest number of publications deal with the hydrodynamic and conformational properties of dioxane lignins (DL) and milled wood lignins (MWL). These lignins can be isolated from plant tissue under relatively mild conditions, which restricts the undesirable oxidation and condensation processes or modification of the chemical and topological structure of macromolecules. The MWL macromolecules do not contain highly acidic functional groups (see Ref. 24) and this eliminates the influence of the solvent, solution pH, *etc.* on the conformations of the specimens in solutions. Therefore, standard hydrodynamic methods of investigation provide fairly reliable information on the conformational characteristics of slightly decomposed lignins. Analysis of published data^{1,2,5} shows that the M_w value for non-fractionated MWL preparations usually does not exceed 30×10^3 for the polydispersity index $M_w/M_n > 1.5$ (the molecular masses of DL are usually higher and the molecular-mass distributions are broader than those of MWL).

The molecular-mass distribution parameters are substantially dependent on the botanical and anatomical origin of lignin as a living natural object. In particular, lignins isolated from different types of wood or even from different parts (the stem, the roots, branches or leaves) of the same plant can differ appreciably in both the chemical structure⁵ and the physicochemical properties including the molecular-mass distribution. Detailed studies of

macromolecular, in particular, hydrodynamic and conformational, properties of lignins of different taxonomic origins are virtually absent. The necessity of performing such works has not been evident until recently, as it has been generally believed that, irrespective of the origin, natural lignins (and celluloses) are biopolymers with the same topological structure for any plant. However, in recent years, we have obtained new data concerning the macromolecular and conformational properties of slightly decomposed lignins of various botanical origins. This allowed us to hypothesise that the topological structure of natural lignins is polyvariant.

Before proceeding to the analysis of experimental data obtained for different lignin specimens, one should note some specific features of these polymers, which are to be taken into account when interpreting the hydrodynamic results. The first one is relatively low molecular masses of all known types of soluble lignins; therefore, some fractions are classified as oligomers. According to a number of publications (see, for example, Refs 31, 34 and 35), the oligomer molecules, unlike the molecules of high-molecular-mass polymers, are characterised by conformational inhomogeneity (depending on the degree of polymerisation) and an enhanced significance of the terminal functional groups. The excluded volume effects[‡] for oligomer fractions can also depend on the degree of polymerisation.³¹ These features can, in principle, violate the scaling relationships and bring about certain difficulties in the research of even slightly decomposed lignins.

The macromolecular properties of methanol lignin isolated from poplar wood have been studied.²⁴ Plotting the dependence of the intrinsic viscosity on the molecular mass showed that the coefficients a present in the MKH equation differ markedly for high and low molecular masses of methanol lignin. For oligomeric fractions, the a value exceeds 0.4 (in a good solvent), while for polymeric fractions, it decreases to 0.3. This regularity also holds in a Θ -solvent, although the values of the coefficients somewhat decrease (by 10%).

An increase in the a values with a decrease in the lignin molecular mass has been noted in several other studies.³⁶⁻³⁸ Pavlov *et al.*³⁹ showed that in the low-molecular-mass region [$M = (0.8-5.8) \times 10^3$], the slope of the dependences of $[\eta]$ and D on the molecular mass of MWL fractions increases, the a and b values approaching 0.5 and -0.5 , respectively. However, most often, experimental data indicate a straight-line dependence $\log[\eta] - \log M$.

It should be noted that the change in the scaling on passing from one region of characteristic sizes to another is usual for any polymer, which is due, first of all, to conformational transitions.^{31,40} Features of the topological structure of some polymers can hamper their transitions from one conformational state to another. In these cases, the region of a universal hydrodynamic behaviour of the molecule is extended. In any case, the macromolecules of soluble slightly decomposed lignins obey the scale invariance principle over a rather wide range of molecular masses $(3-5) \times 10^3 - 100 \times 10^3$,⁴¹ which justifies the application of traditional approaches to the analysis of conformations of these macromolecules, despite the unique features of the chemical structure of lignins.⁴²

The influence of the terminal functional groups on the conformational properties of slightly decomposed lignins is expected to be insignificant, taking into account their chemical structure (the absence of highly acidic functional groups).^{2,5} However, some researchers adhere to a different opinion, based on the fact that the Flory linear swelling coefficient for low-molecular-mass fractions of dioxane lignin ($M_w < 3 \times 10^3$) in a good solvent barely differs from unity.⁴¹ The authors believe that

‡ The excluded volume effect is related to the fact that two polymer chain units should necessarily occupy two physically different sites in space; this effect influences the conformation of the polymer chain in solution.

12	2.0	21.3	—	—	0.8	—	5.3

this is due to the interaction of the polymer functional groups, resulting in the formation of densely packed weakly solvated coils. The influence of other factors caused by the low molecular mass of the polymers cannot be ruled out either. This influence shows itself as a divergence of the experimental scaling indices obtained by different researchers under analogous conditions. For example it has been noted³⁷ that the Stockmayer–Fixman dependence of $[\eta] \times M^{-0.5}$ on $M^{0.5}$ at $M \rightarrow 0$ found for dioxane lignin isolated from pine wood deviates from a straight line towards higher $[\eta] \times M^{-0.5}$ values, whereas in another publication,²⁴ an almost perfect straight line was obtained.

The greatest number of publications are devoted to softwood lignins, which belong to guaiacyl type lignins. Some of these studies have been considered in a review.⁴³ Detailed investigation of lignins from milled pine wood in DMSO has been reported.³⁹ A sample of this lignin was thoroughly separated into 12 fractions for which velocity sedimentation (S), translational diffusion (D) and intrinsic viscosity ($[\eta]$) coefficients were determined (Table 3).

Attention is drawn by high values and a substantial scatter of the Huggins coefficients (k_H) over the fractions. Earlier studies usually did not report or discuss the k_H values because the interpretation and the physical meaning of the Huggins constant have been and still remain obscure. It is known that typical polymers with a linear topology of macromolecules in good solvents are characterised by $k_H \approx 0.2–0.3$.⁴⁴ Guaiacyl lignins differ from guaiacyl-syringyl lignins or linear polymers by great fluctuations of the Huggins parameter (in some cases, by more than an order of magnitude). In our opinion,⁴⁵ this is due to the specific fractal structure of the macromolecules of softwood lignins. The relationship between the Huggins parameter and the fractal dimension of macromolecules for a number of flexible- and semirigid-chain polymers in dilute solutions has been analysed by Kozlov *et al.*⁴⁶

Turning back to the discussion of the results obtained by Pavlov *et al.*,³⁹ it should be mentioned that the dependences of the hydrodynamic characteristics S , D and $[\eta]$ on M_{SD} and $M_{D\eta}$ were approximated by straight lines with a linear correlation coefficient of not less than 0.91. Shkaeva⁴⁷ has obtained an unexpectedly

high viscosimetric Mark–Kuhn–Houwink parameter for a pine wood lignin ($M_w = 27 \times 10^3$) ($a = 0.79$), which corresponds to the conformation of an impermeable swollen coil for linear polymers in a good solvent. Apparently, this result requires further investigations by sedimentation and diffusion techniques. The Mark–Kuhn–Houwink parameters determined for guaiacyl lignins by different investigators^{37, 39, 43, 48–51} are summarised in Table 4.

These results show that the softwood guaiacyl lignins are distinguished by low intrinsic viscosity and low magnitudes of the Mark–Kuhn–Houwink parameter a , which is indicative of compact shape of the lignin macromolecules, related, in all probability, to their branching. The lowest parameter a found is 0.10;¹¹ however, most often, publications give a value of ~ 0.25 or somewhat higher (see, for example, Refs 48–50). This value coincides with the theoretical value for chaotically branched macromolecules.³¹ The parameters b for a variety of softwood lignin specimens in various solvents found from translational diffusion data fall in a rather narrow range, $b = -(0.3–0.4)$.⁴³

A number of publications report the values for the Tsvetkov–Klenin hydrodynamic invariant (A_0),^{39, 50–52} normally calculated using the equation

$$A_0 = (R[D]^2[S][\eta])^{1/3},$$

where R is the universal gas constant; $[D] = D\eta_0/T$, $[S] = S\eta_0/(1 - \bar{v}\rho_0)$ ($\bar{v}$ is the specific partial volume of the polymer, ρ_0 is the density of the solvent).

For impermeable spherical particles, the theoretical A_0 value is $\sim 2.9 \times 10^{-10}$ erg mol^{-1/3} K⁻¹ (see Ref. 53). For synthetic flexible-chain and moderately rigid-chain polymers, A_0 is normally higher, being equal to $(3.2 \pm 0.2) \times 10^{-10}$ erg mol^{-1/3} K⁻¹. For the milled pine wood lignin, the average value of the Tsvetkov–Klenin hydrodynamic invariant amounts to 3.7×10^{-10} erg mol^{-1/3} K⁻¹ (the range is from 2.99 to 4.08, see Table 3).³⁹ Other researchers reported lower A_0 values for this lignin. For lignin of milled spruce wood, the A_0 values were, on average, 2.95×10^{-10} erg mol^{-1/3} K⁻¹ (see Ref. 51). The following values of the hydrodynamic invariant A_0 have been obtained:⁵⁰ the average value for the pine wood DL is

$2.9 \times 10^{-10} \text{ erg mol}^{-1/3} \text{ K}^{-1}$ and that for MWL in DMF is $3.0 \times 10^{-10} \text{ erg mol}^{-1/3} \text{ K}^{-1}$. It is noteworthy that published data concerning the experimental determination of A_0 are rather scanty and are actually limited to the above examples.

Generally, analysis of the experimental data on hydrodynamic and conformational properties of slightly decomposed lignins isolated from softwood shows that the macromolecules of these lignins are characterised by high diffusional mobility and low intrinsic viscosity. These features, in combination with data on the Mark–Kuhn–Houwink scaling parameters, the hydrodynamic invariant, and the Huggins parameters, attest to a branched structure of the macromolecules of softwood lignins. Obviously, these lignins refer to the class of chaotically branched polymers.

The degree of branching of a macromolecule can be characterised by the so-called g -factor. The magnitude of the g -factor is determined by the ratio of the radii of gyration of the branched (R_b^2) and linear (R_l^2) chains with identical molecular masses and thermodynamic flexibilities

$$g = \frac{R_b^2}{R_l^2}.$$

Analysis of the resulting g -factors shows^{20, 33, 43, 54, 55} that this value depends on the molecular mass of lignin (Fig. 3). The g -factor decreases from 1 (for the lowest-molecular-mass fractions) to 0.3–0.5 (for the fractions with $M > 25 \times 10^3$). A similar pattern of dependence of g on M is observed for synthetic chaotically branched polymers.³¹ Running a few steps forward, we would like to note that an absolutely different pattern of dependence has been found for hardwood lignins, in particular, the g -factor increases with an increase in the lignin molecular mass.

In recent years, guaiacyl-syringyl type lignins have aroused enhanced interest in researchers;^{56, 57} this is related to solution of

Figure 4. Mark–Kuhn–Houwink dependences plotted for a milled birch wood lignin.⁵⁸

purely applied problems associated with the involvement of new types of plant raw materials, *i.e.*, annual plants and hardwood, instead of softwood, in the manufacture of cellulose materials. It was found that the polymeric properties of lignins isolated from angiosperms differ appreciably from the properties of lignins isolated from gymnospermous plants, which is related to specific features of biosynthesis and, as a consequence, to differences in the topological structures of macromolecules.

Table 5 contains the hydrodynamic characteristics that we determined for a lignin specimen from milled aspen wood.⁵⁸ Comparison of the experimental data demonstrates that the aspen wood lignin has a higher intrinsic viscosity and much lower values of the Tsvetkov–Klenin hydrodynamic invariant compared to those of softwood lignins. Study of a series of samples of guaiacyl-syringyl lignins isolated from birch and aspen wood has shown^{58–61} that hydrodynamic characteristics of these lignins follow linear dependences on their molecular masses (Fig. 4). As shown by calculations, the control relations

$$(1 - c) = |b| = \frac{a + 1}{3}, \quad (1)$$

$$K_\eta^{1/3} K_D = \frac{A_0 T}{\eta_0}, \quad (2)$$

$$K_\eta^{1/3} K_S = \frac{A_0(1 - \bar{v}\rho_0)}{\eta_0 R}, \quad (3)$$

hold for these lignin samples within the bounds confined by the root-mean-square errors of scaling indices. This indicates that the equivalence principle is obeyed in the translational and rotational friction processes. Therefore, it was concluded that, irrespective of the size, the lignin macromolecules are topologically similar, and, hence, the scale invariance principle, fundamental for polymers, holds. Table 6 presents the Mark–Kuhn–Houwink parameters, which allow one to determine the conformation of the macro-

molecule. For a number of specimens of guaiacyl-syringyl lignins, the scaling indices a , b and c are equal to 0.6 ± 0.1 , -0.5 ± 0.05 and 0.5 ± 0.05 . These are usual values for linear flexible-chain polymers. Upon analysis of the scaling indices, one can infer that the macromolecules of hardwood lignins in dilute solutions ($c[\eta] \leq 1$) acquire the conformation of a swollen impermeable coil. This demonstrates that hardwood lignins belong to a universal class of polymers with a linear macrochain topology. However, the intrinsic viscosities of these specimens are much lower than those for typical linear flexible-chain polymers with the same molecular mass. The average values for the Flory–Mandelkern hydrodynamic invariants $[\Phi^{1/3}P^{-1}] = (1.7-2.3) \times 10^6$ are lower than the theoretical values for linear Gaussian macromolecules (2.7×10^6) and correspond to the hydrodynamic invariants for branched polymers. Noteworthy is the fact⁶⁰ that in the case of DL, the pattern of dependence of the hydrodynamic invariant $\Phi^{1/3}P^{-1}$ on the molecular mass is similar to that found for regularly branched polymers, in particular, lactodendrimers (Fig. 5), but differs from the pattern of dependence typical of chaotically branched polymers.

Analysis of the published data dealing with the properties of guaiacyl-syringyl lignins shows that the hydrodynamic behaviour of the macromolecules of lignins isolated from the secondary xylem of deciduous trees differs from the behaviours of both flexible- and rigid-chain linear polymers and also from the behaviour of typical chaotically branched polymers, although some criteria are satisfied. In our opinion, soluble hardwood lignins should be attributed to the class of star polymers. The linear structure of the branches of star macromolecules ensures the maintenance of scaling parameters typical of a linear topology; however, the presence of the branching unit — the star centre — decreases appreciably the hydrodynamic dimensions of the macromolecule. This results in abnormally low intrinsic viscosity and

in a decrease in the Flory–Mandelkern and Tsvetkov–Klenin hydrodynamic invariants, which are sensitive to the degree of branching.

This assumption is supported by the results of simulation of the growth of polydisperse polymer stars with linear branches within the framework of the self-avoiding random walk (SARW) model.⁶² According to this model, one-centre star tri- and tetra-functional macromolecules form impermeable coils with a Mark–Kuhn–Houwink diffusional parameter b close to -0.5 and a fractal dimension d_f equal to 2.⁸ It is pertinent to recall that Flory⁶³ has shown theoretically that the viscosimetric parameters a for star and linear macromolecules coincide. Later, this result was confirmed experimentally⁶⁴ in relation to polystyrenes. A star-like polymer structure in a good solvent should have, in conformity with the logic of the excluded volume effect, the fractal dimension of $5/3 < d_f < 2$. Experimental results reported by Belyaev *et al.*⁵⁹ confirm the validity of assignment of the macromolecules of guaiacyl syringyl-lignins to the star type.

III. Lignin macromolecule as a fractal object

The use of classical physicochemical methods of polymer science for the study of dilute solutions of lignin made it possible to elucidate the key hydrodynamic characteristics of its macromolecules, namely, intrinsic viscosity, diffusion and sedimentation coefficients, scaling indices and hydrodynamic invariants. The properties and structure of lignin were found to depend on not only the method used to isolate it from the plant tissue but also on the taxonomic origin. Analysis of the hydrodynamic characteristics of guaiacyl-syringyl lignins showed that the macromolecules of hardwood lignins have a star-like structure, their conformational properties being determined by the linear topology of branches. The hydrodynamic behaviour of guaiacyl lignins differs substantially from the behaviour of polymers with a linear topology of macromolecules.

Despite the long-term studies and a rather vast amount of experimental data on the hydrodynamic properties of lignins of different origin, the task of establishing the topological structure of the macromolecules of natural lignins still remains unsolved. There are grounds for suggesting that traditional approaches and methods are inadequate for obtaining exhaustive information on the structure of macromolecules of natural lignins. The discovery of deterministic chaos, dynamic self-organisation and strange attractor phenomena in the lignin biosynthesis^{65–67} indicates that solving the problem of structure organisation of lignin generally and its topological structure specifically requires resorting to new approaches.

It has been found in recent decades that the structure of a substance formed under conditions far from thermodynamic

Figure 5. Flory–Mandelkern hydrodynamic invariant vs. the molecular mass of polymer fractions with different topological structures. Polymer: (1) birch wood DL,⁶⁰ (2) dendrimer,⁵³ (3) pine MWL,⁵⁰ (4) chaotically branched polyphenylquinoxaline.⁶⁰

§ The fractal dimension of a macromolecular coil in solution is determined by two types of interaction, namely, the interaction of the coil elements with each other and polymer interaction with the solvent.

equilibrium can be described in terms of the mathematical body of fractal geometry and synergetics.^{68–70} The synthesis of polymers, including natural ones, takes place most often under such non-equilibrium conditions. This ultimately results in the formation of fractal structures at one or another level of the polymer structural organisation. It has been stated⁷¹ that any polymer that does not exist in the crystalline state should necessarily have a fractal structure over some scale range. This opinion is confirmed by numerous experimental data.^{46, 72, 73} This is why synergetics and fractal analysis are used more and more extensively to study polymers with complex topological structure, for example, cross-linked polymers and chaotically branched polymers.

In 1986, the possibility of describing the supramolecular structure of lignin within the bounds of the fractal concept was hypothesised for the first time.⁷⁴ By the end of the 20th century, the fractal theory had gained wide application in natural sciences, including polymer science. Below we consider the main properties of fractal objects of differing nature and discuss the experimental data on the fractal properties of lignin.

1. Structure and fractal properties of polymers

Examples demonstrating the scope and prospects of the application of fractal concepts to description of the macromolecular properties of polymers are documented.^{75–80} The key properties of the polymer fractals include self-similarity, fractional dimensions, size dependence of the density, and restricted (regarding the size) domain of existence.^{75, 77} Polymers possess statistical self-similarity but over some limited scale range.⁷¹

A macromolecule is often considered as a fractal cluster assembled from monomer units.⁸¹ The mass M and the density ρ of such a macromolecule are described by the following relation:

$$M = m_0 \left(\frac{R}{a_0} \right)^{d_f},$$

$$\rho = \rho_0 \left(\frac{R}{a_0} \right)^{D-d_f},$$

where m_0 , a_0 and ρ_0 are the mass, the size and the density of a monomer unit; R is the size of the macromolecule; d_f is the mass fractal dimension; D is the dimension of the Euclidean space.

Important characteristics of a macromolecular coil include the radius of gyration R_g and the hydrodynamic radius R_H , which are derived from the results of viscosimetric or diffusion measurements. These parameters depend on the molecular mass (M) and the way it is distributed in space (the latter characteristic is taken into account by the index ν , which is equal to 0.5 for the Θ -state)

$$R_g \sim M^\nu, R_H \sim M^\nu. \quad (4)$$

The fractal dimension of a single macromolecule is determined by both the topological structure (configuration) and the conformational state. For example, a linear macromolecule can possess different fractal properties depending on the number and the size of monomer units, quality of the solvent, temperature and the concentration of macromolecules, *i.e.*, on those factors that dictate the conformation of the macromolecule.

Baranov *et al.*⁸² considered the fractal properties of various conformational states of a linear macromolecule in 3D space (Table 7).

The fractal dimension of a macromolecule is determined by the relation $d_f = 1/\nu$ (see Ref. 83); thus, the fractal dimension of a

macromolecular coil in a Θ -solvent is 2. In a good solvent, $\nu = 3/5$ and, correspondingly, $d_f = 1.67$.

For the globular state, $\nu = 1/3$ and $d_f = 3$, *i.e.*, the globular conformation is not fractal. A globule is characterised by a distribution of the ‘everywhere dense’ type (this does not mean, however, that globular structures are absolutely compact, because the macromolecule bulk contains some amount of the solvent). For a rod-like conformation of the macromolecules, the topological dimension coincides with the fractal dimension and $d_f = 1$; in this conformation, the macromolecule is not a fractal either. Finally, for a permeable coil, $\nu = 2/3$ and $d_f = 3/2$. In this case, the macromolecule is a fractal.

Thus, the fractal properties of linear polymers are determined by their conformational characteristics and a macromolecule can be a fractal object only in three cases: when it acquires the conformation of a Θ -coil, a permeable coil, or a coil in a good solvent. The main criteria of fractality, namely, a fractional dimension and the scale invariance principle, are satisfied for these conformations. The configuration of macromolecules of natural lignin is not linear, as was shown in Section II; therefore, it is pertinent to consider theoretical models that allow one to study the fractal properties of branched structures.

a. Models of the percolation cluster and ‘lattice animals’ clusters

The model of percolation cluster (percolation theory) proposed by Broadbent and Hammersley⁸⁴ is a mathematical model that allows one to study the regularities of the formation of branched polymeric structures. This model is underlain by a lattice composed of a number of points and bonds. Bonding of the lattice points to each other forms a cluster (a branched macromolecule), which is a fractal characterised by a quite definite fractal dimension dependent on the lattice structure and dimension, the growth mechanism and the p value (p is the probability that a lattice point belongs to the cluster). The percolation cluster model is characterised by universal behaviour of various parameters near the percolation threshold when $p = p_c$ (transition from a finite cluster to an infinite cluster after a critical concentration of points has been attained).[¶] The fractal dimension of an infinite critical cluster depends on the lattice dimension and is equal to 1.89 for two-dimensional and 2.5 for three-dimensional lattices.⁸⁵ The structure of percolation clusters above the transition point ($p > p_c$) is characterised as uniformly bound, and $d_f = D$, where D is the dimension of the Euclidean space.

When $p < p_c$, there exist a set of clusters that correspond to a universal class of ‘lattice animals’. These simulate the statistical behaviour of branched polymers in solutions and represent an ensemble of clusters for which any configuration of a specified size is equally probable. Clusters that refer to the type of ‘lattice animals’ have the following fractal dimensions:⁸⁶ $d_f = 1.55 \pm 0.05$ for the two-dimensional case and 2.00 ± 0.05 for the three-dimensional case. A study of the influence of the mechanism of growth of branched macromolecules on their topological structure and fractal characteristics has been reported.⁸⁷ It was found that the applicability of the ‘lattice animals’ cluster model is limited to particular classes of branched polymers.

b. Models of particle–cluster and cluster–cluster type diffusion-limited aggregation

The model of diffusion-limited aggregation of the particle–cluster type (DLA P–C) is the best known kinetic model of irreversible growth of fractal clusters. This model has been developed by Witten and Sander⁸⁸ and has been used subsequently to study the growth of colloid particles of differing nature, electrolysis and polymerisation processes, hydrodynamic structures of the ‘viscous finger’ type, *etc.* All these processes and structures are subject to the same mathematical description under certain conditions.

¶ The formation of an infinite cluster is a phase transition.

Table 7. Characteristics of a linear macromolecule as a fractal object.⁸²

Conformation	ν	a	d_f
Θ -coil	1/2	1/2	2
Swollen coil	3/5	4/5	5/3
Permeable coil	2/3	1	3/2

The DLA P–C model has been considered in detail in the books.^{76,80}

If the Brownian (random) motion of particles involved in the Witten–Sander model is replaced by rectilinear motion, the resulting cluster will represent a compact aggregate with a dimension d_f equal to the dimension of the fractal lattice (the Wald–Sutherland model).⁸⁹ Compact clusters are also produced in other aggregation models of the particle–cluster type, namely, in the ‘rain’ model and in the Eden model.⁹⁰

The model of diffusion-limited aggregation of the cluster–cluster type (DLA C–C) is the most plausible model of the growth of aerosol particles.^{91,92} It was also used to study dehydropolymerisation of monolignols.⁷⁴

The fractal dimension of the clusters assembled from monodisperse particles is equal to 1.78 ± 0.05 . The polydispersity of particles barely changes the fractal dimension of the cluster. The influence of the growth conditions of clusters (diffusion velocity, the probability of addition upon collision, process reversibility) on their structural characteristics has been studied.⁹³ A decrease in the probability of addition was found to entail the formation of denser aggregates, the fractal dimension of the clusters being increased to 2.0 ± 0.06 .

c. Fractal dimensions

The conformational state of a macromolecule in solution is determined by the solvent quality, the solution temperature, the polymer concentration, *etc.* A change in the polymerisation conditions may entail conformational transitions accompanied by a change in scaling indices, the Mark–Kuhn–Houwink parameters and the critical index ν . The nature of transitions between these states can be different. Some transitions correspond to the ‘disorder–disorder’ or ‘fractal- $d_f^i \leftrightarrow$ fractal- d_f^j ’ transitions.⁸² Determination of fractal dimensions using the scaling indices from data of hydrodynamic measurements allows one to establish reliably the macromolecule conformation. However, it is evident that macromolecules possess not only conformational fractal properties but also configurational fractal properties caused by mutual arrangement of topological elements — knots, side branches, subchains, cross-links, rings, *etc.* Therefore, the use of only Hausdorff type dimensions, applied most often to describe fractal objects, is, apparently, inadequate for unambiguous description of the structural organisation of a polymer molecule because these dimensions do not allow one to have an idea of its configuration.⁷¹ According to Mandelbrot,⁹⁴ more accurate description of a complex structure requires the use of a larger number of fractal dimensions.

The connectivity of the structure elements, *i.e.*, the configuration of a macromolecule, can be estimated using the so-called spectral (or fracton) dimension d_s , proposed⁹⁵ to characterise the natural vibrations of fractals. The fracton dimension can be determined from the equation describing the vibrations of a random network, which differs from the equation describing the random walk of a particle across a fractal lattice (with the dimension d_w) only by the order of the derivative.⁸⁵ The d_s value can be found from the relation

$$d_s = \frac{2d_f}{d_w},$$

where $d_w = 2 + \delta$ (δ is the scaling index of abnormal diffusion). For macromolecules with any configuration other than linear, $\delta > 0$.

The fractal and fracton dimensions calculated within the bounds of various cluster models are presented in Table 8.

A specific feature of the fracton dimension is independence of its value of the way of insertion of a fractal object into the Euclidean space. In other words, the fracton dimension, unlike the fractal dimension of the Hausdorff type, does not depend on the conformational state of the macromolecule and is dictated

Table 8. Fractal (d_f), fracton (d_s) and chemical (d_l) dimensions for branched structures in terms of different cluster models.

Model	D	d_s		d_f		d_l	
		value	Ref.	value	Ref.	value	Ref.

only by its topological structure. The fracton dimension of a linear macromolecule is equal to unity.

Along with the fracton dimension d_s , the topology of a macromolecular cluster can be characterised by the chemical dimension (connectivity parameter) d_l which takes into account the arrangement of all chemical bonds occurring between cluster particles. The chemical fractal dimension of the cluster is determined by the expression¹⁰³

$$N \sim l^{d_l},$$

where N is the number of cluster species (monomer units if a polymer fractal is considered); l is the so-called chemical distance, *i.e.*, the shortest distance between two knots of the macromolecule. The chemical dimension reflects the internal connectivity in the polymeric fractal; therefore, in some cases, it is called the internal dimension. It follows from the connectivity position that $d_l \geq 1$. For a linear polymer chain, the chemical dimension is equal to unity. For a chaotically branched structure formed by the Witten–Sander model (the DLA P–C model), the chemical and fractal dimensions coincide ($d_l = d_f$). As opposed to this, structures formed by the DLA C–C mechanism are less branched, which is manifested as a decrease in the chemical (internal) dimension with respect to the fractal dimension (see Table 8).

d. Multifractal formalism

The models considered above describe objects as monofractals. Biopolymers are usually distinguished by a complicated structural hierarchy with numerous structural sublevels, and each of these can be characterised by particular order parameters. In addition, even at one level of structural organisation, fractal ensembles that reflect the structure of a real compound often require that a spectrum of dimensions rather than a single dimension be used. The differences between them serve as a measure of the degree of inhomogeneity of the object under consideration. This circumstance stipulated the necessity of introducing the concept of the multifractal. A multifractal can be presented as a combination (superposition) of monofractals with different fractal dimensions.

Olemskoi and Flat¹⁰⁴ considered the formalism permitting one to derive the regularities of structure formation from the set of monofractals. The applicability of the multifractal formalism to investigations of structural organisation of objects and physical processes is associated with considering the Renyi dimensions D_q .^{72,75,105} The Renyi dimensions are determined from the equation

$$D_q = - \frac{\lim_{\varepsilon \rightarrow 0} K_q(\varepsilon)}{\ln \varepsilon},$$

where ε is the size of a cell into which the phase space was split; $K_q(\varepsilon)$ are generalised entropies calculated from the equation

$$K_q(\varepsilon) = \frac{\ln \sum P_i(\varepsilon)}{1 - q}$$

$[P_i(\varepsilon)]$ is the probability that a particle gets into an i th cell; $q = 0, 1, 2, \dots, n$.

By definition, D_0 ($q = 0$) is a self-similarity dimension, D_1 ($q = 1$) is the information dimension and D_2 ($q = 2$) is the correlation integral index. For homogeneous sets that obey the relation $P_i(\varepsilon) \sim \varepsilon^D$, the Renyi dimensions of different orders coincide. Apparently, the multifractal formalism concept can prove fairly useful in the study of cross-linked polymers and processes (including chemical ones) accompanied by the formation of temporal fractals.

2. Fractal properties of lignin macromolecules

Due to the progress in the development of fractal theory, it became possible to begin the search for new approaches to the investigation of plant biopolymers with intricate structures, first of all, lignin. It has been demonstrated^{106,107} that the fractal theory can be used to characterise lignin and its biosynthetic analogues, *i.e.*, dehydropolymers. Dehydropolymerisation of monomer precursors of lignin *in vitro* is initiated by the peroxidase–hydrogen peroxide enzymic complex. Freudenberg and co-workers developed two methods for laboratory biosynthesis of lignin, namely bulk and end-wise polymerisation (see references cited in Ref. 1). According to Sarkanen,¹ bulk and end-wise dehydropolymers differ from each other in both the chemical and topological structures. Analysis of the conditions of synthesis of various biosynthetic lignins and comparison of them with the growth conditions of fractal clusters made it possible to hypothesise that the bulk and end-wise polymers correspond to definite universal classes of fractal objects.

The end-wise polymerisation is performed by 100-h continuous feeding of a highly dilute solution of the monomer into a large volume of a fairly dilute (10^{-7} mol litre $^{-1}$) solution of enzymic complex. The monomer diffusion is considered to be the rate-determining step of the polymerisation of monomeric lignin precursor. Under these conditions, the macromolecule grows through successive addition of the monomer phenoxyl radicals to those few macromolecules that have formed at the initial stages of reaction. Comparison of the end-wise protocol with the known theoretical models of fractal growth led Ozol-Kalnin⁷⁴ to the conclusion that end-wise polymers belong to the class of Witten–Sander fractal clusters (the DLA P–C model).

In the case of bulk polymerisation, unlike end-wise polymerisation, a rather concentrated solution of the monomer is injected in the reaction area as one portion. Under these conditions, in the opinion of Ozol-Kalnin and co-workers,^{74,90} numerous polymerisation centres appear immediately and the macromolecules grow according to the DLA C–C model.

In order to verify this hypothesis, we synthesised bulk and end-wise dehydropolymers on the basis of a guaiacyl type monomer precursor, namely, ferulic acid ($C_{10}H_{10}O_4$).¹⁰⁸ The fractal dimension of the macromolecule was determined from the data of hydrodynamic measurements in dilute solutions of dehydropolymers in thermodynamically good solvents (DMSO, dioxane). It was found that the hydrodynamic radius of the macromolecule satisfies scaling relation (4). The fractal dimension $d_f = 1/\nu$ (according to translational diffusion data) for the bulk polymer was found to be 2.35 and that for the end-wise polymer was 1.51. The velocity sedimentation coefficients and the intrinsic viscosity also showed a scaling dependence on the molecular mass of the dehydropolymers. This made it possible to calculate the fractal dimension by two more independent methods. The data¹⁰⁸ indicate that bulk lignin corresponds to the DLA P–C model, while end-wise lignin, to the DLA C–C model, as regards their fractal dimensions (see Table 8).

It is noteworthy that the applicability of the DLA C–C model to the description of fractal properties of end-wise lignin gives rise to certain doubts. The fracton and chemical dimensions of clusters

in the DLA C–C model are greater than 1, which implies branching, whereas the Mark–Kuhn–Houwink parameters of the end-wise lignin ($a = 0.8$, $b = -0.58$, $c = 0.45$) and the Flory–Mandelkern hydrodynamic invariant ($\Phi^{1/3}P^{-1} = 2.7 \times 10^{-6}$) obtained in the study cited¹⁰⁸ attest to a linear structure. It is more likely that the fractal properties of this polymer correspond to its conformational state in a good solvent.

One achievement of fractal geometry is elucidation of the relationship between the statistical and fractal properties of polymer chains.⁷⁶ It was shown¹⁰⁹ that the equilibrium statistics of linear polymers is adequately modelled by SARW paths, which demonstrate the fractal properties. The key factors that determine the analogy between the descriptions of a macromolecule and the path of a randomly walking particle are the chain structure and the excluded volume effect.

The conformational characteristics of a linear macromolecule depend on only two parameters, the number of units in the chain (N) and the size of the monomer unit (a_0). Thus, according to the Flory theory, the size of the macromolecule (R) is described by the following scaling relation

$$R \sim a_0 N^{\nu_F},$$

where ν_F is the critical index in the Flory theory, which depends on the dimension of the Euclidean space D :¹¹⁰ $\nu_F = 3/(d+2)$ for $D < 4$ and $\nu_F = 1/2$ for $D > 4$.

According to the SARW model, the average squared distance between the start and the end of the path whose length is N steps obeys the equation

$$\langle R^2(N) \rangle \sim AN^{2\nu_c},$$

where A is a coefficient depending on the lattice dimension and the length of the walk path; ν_c is the critical index in the SARW model.

Mimicking of the Brownian (random) walk on lattices with different dimensions gave¹⁰⁹ the following values for the critical index ν_c : $\nu_c = 0.749$ for $D = 2$; $\nu_c = 0.592$ for $D = 3$; $\nu_c = 0.5$ for $D > 4$.

It can be easily seen that the critical indices ν_F (in the Flory theory) and ν_c (in the SARW model) virtually coincide. This suggests⁷⁶ that the asymptotics of the path of the self-avoiding random walk and the polymeric chain in a thermodynamically good solvent belong to one class of universality, the path itself being a fractal whose self-similar dimension d_f can be determined from the relation

$$\nu_F = \nu_c = \frac{1}{d_f}. \quad (5)$$

Thus, the problem of belonging of the macromolecule of end-wise lignin to fractal objects can be solved unambiguously and refers to metrics, *i.e.*, the mode of arrangement of monomer units in space, rather than to topology ($d_t = 1$). Relations (4) and (5) imply the possibility of determining the fractal dimensions of polymers on the basis of experimentally measurable parameters that characterise, in one way or another, the relationship between the degree of polymerisation N or the molecular mass M and the size of the macromolecule. According to Frenkel' and co-workers,⁸²

$$\nu_F = \frac{1+a}{3}.$$

In this case, if the equivalence principle is obeyed in the translational and rotation friction processes, the known equalities (1)–(3) hold between the hydrodynamic scaling indices. Therefore, the fractal dimension d_f of a macromolecule in solution can be estimated by usual molecular hydrodynamics methods.

Analysis of the published data on the hydrodynamic properties of various lignins (Table 9) and comparison of these data with fractal models led to the hypothesis that the supramolecular structure of lignins *in situ* is an infinite network composed of fractal clusters linked to one another.¹¹¹ When lignins are isolated

Table 9. Fractal dimensions of some lignins.⁹⁰

Lignin specimen	Solvent	$d_f = 3/(a+1)$	$d_f = 1/ b $

	2 M NaCl	2.27	3.0
	0.02 M NaCl	—	1.79

from the plant tissue, the inhomogeneous fractal network is destroyed and its fragments pass to the solution as fractal clusters. Relying on the hydrodynamic characteristics of dioxane lignins in solutions determined by Pla and Yan,¹¹² Ozol-Kalnina and co-workers¹¹¹ concluded that lignin can be assigned to fractals of the DLA P–C type. The fractal dimension calculated from the scaling relation

$$g = CM_w^{3/d-3/2},$$

was equal to 2.439 ± 0.007 , which is consistent, in the first approximation, with the dimension of Witten–Sander fractal clusters. However, for other lignin specimens (see Table 9), quite a substantial scatter in the fractal dimensions is observed, which evidently depends on the pre-history and the molecular-mass distribution of the samples under study and on the chosen solvent.

The rather low fractal dimensions of lignosulfonates refer, in the opinion of Ozol-Kalnina *et al.*,¹⁰⁶ to the lignin structure modified upon the chemical reactions that take place during wood cooking rather than to the initial structure of natural lignin. It has also been assumed not without reason^{90, 106} that lignins of various classes of universality can be localised in different structural elements of the cell wall, in particular, the possibility of formation of ‘dense’ Eden type structures with $d_f = d_l = d$ during lignin biosynthesis has not been considered improbable. Thus, the researchers were unable to draw unambiguous conclusions concerning the concordance of the structure of these lignins to particular classes of fractals.

In our opinion, the most reliable data on the fractal properties of lignosulfonates are presented in two publications^{113, 114} dealing with lignin obtained by sulfite pulping of softwood. The molecular mass of these specimens was determined by the non-established equilibrium technique and by laser correlation spectroscopy. The fractal dimensions determined by three independent methods were, on average, 2.44 ± 0.18 .¹¹⁵

The scaling and fractal properties of the macromolecules of MWL isolated from the pine-tree xylem have been studied.¹¹⁶ The investigation of the macromolecular properties of a number of fractions of this lignin in dilute DMSO solutions confirmed that the main criteria of fractality, namely, the scale invariance principle [in the range of molecular masses $(0.5–64) \times 10^3$] and a fractional dimension, are met. The fractal structure of the macromolecule is manifested in the pattern of mass distribution in space being given by relation (4); this allows one to find the fractal dimension d_f from the plot $\log R_H - \log M$ constructed for each lignin fraction using experimental data (Fig. 6). In the case of MWL, the d_f value proved to be 2.32. The fractal dimensions of MWL specimens calculated from the velocity sedimentation coefficients and intrinsic viscosity were 2.32 and 2.40; thus, they can be classified as fractal objects of the DLA P–C type.

A similar conclusion has been drawn in a study of hydrodynamic and scaling properties of another MWL specimen isolated from pine wood (see Table 4). In this case, the polymer was separated into 9 fractions in the range of molecular masses of $(1.7–14.6) \times 10^3$, for which the scaling principle was found to hold. The results of studies of the molecular hydrodynamics by

**Figure 6.** $\log R_H$ vs. $\log M$ for pine wood lignin specimens.¹¹⁶

Specimen: (1) MWL in DMSO, (2) DL in DMSO, (3) DL in dioxane.

different methods proved to be almost identical; the fractal dimension was 2.32 ± 0.02 .

The macromolecules of the Pepper lignin (DL-1–DL-4) (Table 10) are also typical fractal objects with a fractional dimension in any of the studied solvents including dioxane, DMF and DMSO. The self-similar properties are obeyed in the range of molecular masses $(3.0–100) \times 10^3$ (Fig. 7).

Thus, the fractal dimensions of slightly decomposed lignins isolated from softwood are mainly in the range of 2.3–2.8, the isolation procedure having little influence on the fractal properties of the specimens. The data reported in the literature indicate that macromolecules of softwood lignins refer to the versatile class of DLA P–C type fractals.

The numerical values of the fractal dimension d_f characterise the growth of the fractal cluster, in this case, the dehydropolymerisation of monolignols. It is of prime interest to study the effects of different factors (for example, the degree of branching, intramolecular cyclisation) on the microstructure of the cluster and to elucidate the relationships between these factors and the fractal dimension, which is known to be a global property of the cluster.

It has been proposed⁵⁵ to simulate various versions of dehydropolymerisation using a modified model[†] of the growth of fractal aggregates of the DLA P–C type.

Unlike the classical Witten–Sander model of diffusion-limited aggregation, this model has been supplemented by the parameter P describing the probability of addition of a monomer unit to the growing aggregate upon collision. The probability of addition simulates the chemical reactivity and indicates which process (diffusion or chemical reaction) predominates in the irreversible formation of bonds. The free path of particles in the walk on a lattice, the probability P and the space geometry were shown to influence the formation of the microstructure of the fractal macromolecules constructed in terms of this model.

It has been proposed¹¹¹ that, depending on the conditions, one can observe the formation of either a ‘fractal forest’ or a separate ‘tree with bushes’, which corresponds to the growth of a branched lignin macromolecule in a cell wall in the narrow space between the cellulose fibrils. Since the growth of branches is restricted by the walls, the resulting cluster will possess a much lower effective branching than that produced in the case of unrestricted growth in all directions. The hydrodynamic behaviour of such a macromolecule, especially if it contains a rather large number of rings, will differ substantially from the behaviour of fractal macromolecules of the Witten–Sander type. The possibility of formation of ‘bushes’ within the bounds of the fractal growth procedure implies that the presence of the so-called sol fraction in natural lignin (Brauns lignin) cannot serve as evidence supporting the assumption of the network structure of lignin.

An important topological feature of network and branched polymers is the presence of intramolecular rings. It was found that chaotically branched fractal clusters formed in terms of the modified diffusion-limited aggregation model also contain cyclic structures. According to the publication,¹¹⁷ the procedure of counting intramolecular rings is reduced to counting the number of particles n that close the rings during the growth of the fractal cluster. Figure 8 shows the dependence of the degree of intramolecular cyclisation Y on the probability of addition of a particle to the growing aggregate for several free paths L . The Y value is defined as the ratio of the number of particles n closing the rings to the total number of particles N in this cluster. It should be borne in mind that the Y value defined in this way gives, most likely, a somewhat underestimated degree of cyclisation, because the

[†] Some other models of this type were also proposed earlier,⁷⁸ since the basic Witten–Sander concept is characterised by exceptional versatility and is applicable to investigation of diverse physical phenomena and processes.

Figure 8. Degree of cyclisation (Y) vs. probability of the addition (P) of a particle to the growing cluster for different free paths L .¹¹⁷ Free path L : (1) 1000, (2) 100, (3) 5.

addition of one particle to the cluster can give rise to two or more (for a lattice with an arbitrary dimension) rings. The number of intramolecular rings depends on various factors including the addition probability P , the free path of particles L and the lattice dimension. The smallest number of rings is found in the clusters formed at $L = 1$ and $P = 1$, i.e., within the framework of the classical DLA P–C model.

It should be noted that accumulation of cyclic structures during the growth of the fractal aggregate obeys the Hurst statistics with an R/S index equal to 0.8 (Fig. 9). This means that simulation of the polymer structure by the diffusion-restricted aggregation technique can give information not only on the structure but also on the dynamics of fractal processes. This aspect is discussed in Section III.3.

In a study of structural features of the fractal cluster,¹¹⁸ the mechanism of surface diffusion of monomer particles was taken into account. It was shown that the combination of Brownian and surface diffusions with variation of the free walk length allows one to model the growth of aggregates of various universal classes. The fractal properties of the clusters were studied by analysing the generating function (measure) of the cluster[‡] within the multifractal approach.

Study of the physicochemical properties of guaiacyl-syringyl lignins has shown^{60,61} that the macromolecules of hardwood

Figure 9. Accumulation of intramolecular cyclic structures during the growth of the Witten–Sander type fractal cluster⁶² according to the Hurst equation: $R/S = (A\tau)^H$ (R is the range of the accumulated deviation from the average value, S is the standard deviation equal to the square root of the variance, τ is the time span, A is constant, in this particular case, $A = 1/2$).

[‡] Generating functions are used in the probability theory to simulate random processes.

lignins, like those of softwood lignins, are structures with a fractional dimension. The d_f values for the macromolecules of hardwood lignins found by different methods are presented in Table 10.

The dimension of the macromolecule d_f is often determined from the slope of the straight line $\log M = f(\log R_\eta)$, where R_η is the hydrodynamic radius calculated from the equation

$$[\eta] = \frac{10\pi N_a R_\eta^3}{3M},$$

(N_a is the Avogadro number).

On average, the fractal dimensions of hardwood lignins ($d_f = 1.84 - 1.98$) are much lower than those for softwood lignins ($d_f = 2.3 - 2.8$). Whereas the fractal dimensions of softwood lignins¹¹⁶ are consistent with the d_f values for the three-dimensional fractal clusters formed in the Witten–Sander model, the d_f values of hardwood lignins are close to the fractal dimensions of the clusters formed in terms of the SARW models.

Lignins of herbaceous plants have been least studied. Table 11 contains the fractal dimensions of lignins for a monocotyledonous plant family of Gramineae determined from the results of investigation of the hydrodynamic properties of these lignins in dilute solutions in DMF (good solvent).⁶¹ The d_f values of dioxane lignins isolated from the herb stalks occur in the range from 1.5 to 1.8. Judging by these data, the macromolecules of herbaceous and hardwood lignins should be attributed to different universal classes (according to the chemotaxonomic classification generally accepted in lignin chemistry, these lignins belong to the same type of guaiacyl-syringyl lignins).

Table 11. Fractal dimension (d_f) of the macromolecules of dioxane lignins of herbaceous plants of the Gramineae family according to sedimentation and diffusion analyses and viscosimetry (DMF as the solvent).⁶¹

Plant	d_f determined by		
	viscosimetry	sedimentation analysis	diffusion analysis
Rye (<i>Secale sp.</i>)	1.80	1.72	1.50
Oats (<i>Avena sativa</i>)	1.72	1.69	1.69
Barley (<i>Hordeum sp.</i>)	1.77	1.64	1.69
Wheat (<i>Triticum sp.</i>)	1.73	1.64	1.68

It follows from analysis of the macromolecular properties of birch and aspen lignins that the macromolecules are star-like. The simulation of growth of polydisperse polymer stars with linear branches within the framework of the SARW model has shown⁶² that one-centre star-like tri- and tetrafunctional macromolecules form impermeable Gaussian coils with Mark–Kuhn–Houwink parameters (a , b , c) close to 0.5 and a fractal dimension of ~ 2 (2.02–2.04). It is noteworthy that these values do not coincide with the values obtained in terms of the SARW model for linear chains ($a = 0.78$, $d_f = 1.67$). Although the results of the theoretical simulation of star polymers remain debatable, they are still consistent with the known statement^{63,64} that the Mark–Kuhn–Houwink parameter a (and, hence, d_f) for these polymers does not depend on the quality of the solvent. Since the d_f values of the hardwood lignins studied differ insignificantly from the value 2.0, which was found for the clusters formed according to the model of ‘lattice animals’, ultimate determination of the fractal structure of the macromolecules of guaiacyl-syringyl lignins requires further investigations.

Further progress in solving the problem of the fractal structure of lignin is apparently related to estimation of the fracton

dimension d_s , which describes the connectivity, *i.e.*, characterises directly the topological structure of the macromolecule.^{71,72} Determination of the fracton dimension is based on the study of the spectra of natural vibrations of fractals. The notion of fractons, *i.e.*, localised vibrational states in fractal materials, was introduced in the study of wave phenomena in fractal materials.⁹⁵ The function describing the density of frequency distribution of fractons is a power function,⁷² because the scaling principle is obeyed for fractal objects. The mathematical power is determined by the fracton (spectral) dimension, which functions as a space dimension in the low-frequency asymptote of the density of vibrational states.

Using the fracton theory, one can determine the vibrational spectrum of a fractal object and estimate its fracton dimension. The properties of fractons can be studied only in the region of fractal behaviour of real materials. For polymers, the characteristic sizes do not exceed the optical wavelength in the visible spectrum. Therefore, Raman light scattering and inelastic neutron scattering are the key spectral methods used to study fractons. However, these methods have not yet found wide application in the study of polymers. At present, the fracton dimensions have been determined only for proteins,⁷¹ poly(methyl methacrylate)¹¹⁹ and epoxy polymers.¹²⁰ It should be noted that both theoretical and experimental methods for determination of the fracton dimension are at an early stage of development.^{104,121} Probably, this accounts for the inconsistency of obtained results.⁷¹ As regards lignins, their fracton spectra have not yet been studied; however, in view of the complexity of the topological structure of lignins, the necessity of such studies is beyond doubt.

3. Fractal properties of lignin biosynthesis

To continue the discussion of the fractal properties of lignins, one should note that the results of investigations outlined above are based on representing lignins as fractal objects arising in some aggregation processes. However, the concept of fractals has been markedly extended in recent years. Fractal structures of not only objects but also processes have been considered.^{122,123} It was found that many chemical systems can be represented as complex dynamic systems of a finite dimension with a chaotic behaviour.^{124–126} The mathematical image of the dynamic (deterministic) chaos is represented by the so-called strange attractor, which is characterised by the fractal structure of its paths in the phase space.^{127–130}

In chemistry, the Belousov–Zhabotinskii system is the best known example of a complex system involving any conceivable type of complex dynamic behaviour.^{68,131} Studies of the Belousov–Zhabotinskii reaction revealed diverse chaos and self-organisation phenomena giving rise to periodic space–time structures.

Dynamic self-organisation phenomena have been discovered in the enzymic dehydrogenation polymerisation of monolignols during lignin biosynthesis *in vitro*.^{132,133} Conduction of monolignol dehydropolymerisation under one-dimensional diffusion conditions has been shown¹³⁴ to result in space–time dissipative structures.

Chaotic and periodic oscillations of chemiluminescence intensity have been detected^{135,136} in a study of lignin oxidation processes in alkaline media.

Karmanov *et al.*⁶⁵ reported the first attempt to study the dynamics of dehydropolymerisation of monomeric lignin precursors in relation to ferulic acid; they demonstrated the possibility of existence of the dynamic mode of the ‘strange attractor’ type. The process was monitored by the redox method in the ‘two-dimensional’ variant of the lignin biosynthesis *in vitro*. The redox potentials were determined from the ratio of oxidised and reduced forms of the substrate and the initiator of the polymerisation. This method for determination of redox potentials has been used previously in the study of chemical transformations of the reduced nicotinamide adenine dinucleotide (NADH), ascorbic acid and other compounds.¹³⁷ It should be noted that the redox method does not possess sensitivity with respect to any of the compounds

involved in the reaction. Nevertheless, it yields a function of state of the reaction system, which is directly related to the reactant concentrations. The dynamics of the system which undergoes dehydrogenation and thus evolves with time is obtained as a time series of redox potentials, which constitutes a database suitable for analysis and identification of the dynamic behaviour of the system by means of non-linear dynamics methods.

Thus, by obtaining a chronologically ordered series of redox potentials, one can elucidate characteristic features of the process dynamics, identify the presence or absence of nontrivial phenomena (symmetry violation effect, correlations at the macroscopic scales, *etc.*), which can be indicative of the occurrence of dynamic self-organisation processes.

The formation of chaotic modes of dehydropolymerisation has been observed in a study of the dynamics of the coniferyl alcohol–hydrogen peroxide–horse-radish peroxidase system.⁶⁶ The dynamic modes implemented during lignin biosynthesis *in vitro* were identified using the strategy of time series analysis based on the deterministic chaos concept.^{68–69} This concept is underlain by methods of non-linear dynamics of non-equilibrium systems and the theory of fractal ensembles.^{68, 75} It was found that chaotic oscillations can differ in their properties; this leads unambiguously to differences in the structure and properties of the corresponding attractors.¹²²

The dynamics of polymerisation of monomer precursors of lignin was studied in several stages. The first stage was the construction of a geometrical image (attractor) of the process in multidimensional phase spaces; this was followed by analysis of multidimensional pseudo-phase paths with identification of the boundaries of the scaling region and the scaling indices (dimensions) and analysis by the attractor topology with estimation of its correlation dimension; subsequently, the dimension of the space of embedding was determined. The research showed^{66, 67} that the time dependences of redox potentials during polymerisation of guaiacyl monolignols obey all the main criteria of deterministic chaos, namely, the ‘continuous spectrum’ criterion and scaling and fractional dimension of the phase paths.

The ‘continuous spectrum’ criterion (the fast Fourier transform spectrum, FFT) discerns chaotic and periodic spectra, as the former are responsible for a continuous FFT spectrum, while the latter, for a discrete spectrum.

The criterion of a fractional dimension of the phase paths allows one to distinguish between deterministic chaos and structureless chaos. The dimension of the phase path for a process accompanied by dynamic self-organisation is known¹³⁸ to be strictly smaller than two (for a two-dimensional case) or strictly smaller than three (for a three-dimensional space). This is due to restriction of the phase space. It can be stated with confidence that polymerisation of monolignols shows an ordered (structured) dynamic behaviour. Structureless chaos is characterised by a distribution of the ‘everywhere dense’ type; therefore, the phase path dimension coincides with the space of embedding dimension.

The next stage of investigation of the polymerisation of coniferyl alcohol included quantitative evaluation of the phase paths of the process; usually, they are constructed using the Packard time delay method.¹³⁹ Figure 10 shows the two-dimensional pseudo-phase portrait of the dynamics of enzymic polymerisation of coniferyl alcohol in the horse-radish peroxidase–hydrogen peroxide system constructed using this method.

The features of the distribution of points in the phase paths in space (point sets, as the path is a set of N points) were estimated and the path convergence to some attractor $C(r)$ was established using the Heaviside integral correlation function¹⁴⁰

$$C(r) = \frac{1}{N^2} \sum_{i,j=1}^N \Theta(r - |x_i - x_j|), \quad (6)$$

where N is the number of points in the path; $\Theta(r)$ is the Heaviside function; r is the specified distance across which the points are counted; x_i is a point in the phase path with the coordinates $[h(x)$,

Figure 10. Pseudo-phase portrait of the dynamics of the enzymic polymerisation of coniferyl alcohol in the horse-radish peroxidase–hydrogen peroxide system. $E(t)$ and $E(t + \Delta t)$ are the redox potentials at instants t and $t + \Delta t$, respectively.

$h(x + \Delta x)$, $h(x + 2\Delta x)$, ..., $h(x + (D - 1)\Delta x)$; $|x_i - x_j|$ is the distance from an i th point to a j th point. The function $\Theta(r) = 1$ if $r > 0$ and $\Theta(r) = 0$ if $r \leq 0$.

It was found that the Heaviside function is an invariant measure for the systems under study, because in this case, the scaling principle is obeyed. The correlation dimension of the attractor d was determined from the equation $\log C(r) = d \log r$.¹⁴¹ For polymerisation of coniferyl alcohol, the d index was found to be 1.93 (for another monomeric precursor, ferulic acid, $d = 1.7 - 1.8$). Since all the criteria of deterministic chaos are fulfilled, it was concluded that the dynamic behaviour of the coniferyl alcohol–hydrogen peroxide–peroxidase and ferulic acid–hydrogen peroxide–peroxidase systems has a certain internal order — a structure with fractal properties. The researchers believe that the last-mentioned circumstance^{66, 67} implies that under the chosen conditions, the time evolution of the chemical systems under study is a stable dynamic state called strange attractor.

It is noteworthy that there is a certain relationship between characteristics of the attractor of the dehydrogenation system and the topological structure of the macromolecule of the reaction product (dehydropolymer). It was found that the Mark–Kuhn–Houwink scaling indices calculated from dynamic data are in satisfactory agreement with the results of hydrodynamic measurements.¹⁴² In particular, the parameter a for ferulic acid and coniferyl alcohol is in the range $0.17 < a < 0.38$. These values of scaling indices are normal for the macromolecules of biosynthetic analogues of softwood lignin and correspond to fractal clusters of the Witten–Sander type.

Karmanov and Matveev¹⁴³ have studied the dynamic features of lignin biosynthesis using a different approach based on the self-organised criticality theory.¹⁴⁴ A system functioning in the self-organised criticality mode is known to generate so-called flicker-noise vibrations. The main feature of systems with flicker noise is the fact that their power spectrum is described by the dependence¹⁴⁵

$$A(f) \sim \frac{1}{f^v},$$

where A is the spectral density of the autocorrelator of the dynamic variable, f is frequency, v is the mathematical power. The power spectrum ($1/f$ spectrum) is a function that shows how the energy is distributed over frequencies.

It was shown¹⁴³ that simulation of polymerisation of coniferyl alcohol is subject to a dependence characteristic of the flicker noise (Fig. 11) with $v = 0.8$ (the usual value for a typical flicker noise is $v = 0.8 - 1.3$, see Ref. 146).

Figure 11. Power spectrum ($1/f$ spectrum) of oscillations of the redox potential during lignin biosynthesis *in vitro* in the coniferyl alcohol–hydrogen peroxide–horse-radish peroxidase system.¹⁴³

Figure 12. Duration of the laminar phase (Δt) in the dehydropolymerisation of coniferyl alcohol as a function of chronologically ordered fluctuations of redox potentials (n is the ordinal number of the fluctuations).

Yet another feature of the system functioning in the self-organised criticality mode is generation of temporal fractals. Figure 12 shows the dependence of the duration of the laminar phase (Δt is the time delay between fluctuations with numbers $n-1$ and n) of dehydropolymerisation of coniferyl alcohol in the hydrogen peroxide–horse-radish peroxidase system on the function of chronologically ordered fluctuations of redox potentials. Mathematical analysis of this dependence leads to the conclusion that fluctuations of the redox potentials are mutually time-correlated, *i.e.*, in this case, an ordered temporal structure of the fractal type exists. This fact was confirmed by identification of the scale invariance and a fractional dimension of the pseudo-phase portrait of the process dynamics. This proves that the concept of self-organised criticality describes adequately the dynamics of the generation–recombination process of phenoxyl radicals, giving rise to the macromolecules of biosynthetic lignin.

Timashev and co-workers¹⁴⁷ have performed a theoretical investigation of the formation and recombination of radicals. It was shown that the number of free radicals in the steady-state stage of the process fluctuates around some constant value. The Fourier transform spectrum of the temporal series of the number of radicals has a flicker noise characteristic; hence, the process dynamics fits in the self-organised criticality concept. The total dimensions of the attractor of lignin biosynthesis *in vitro* estimated according to the deterministic chaos theory and the self-organised criticality theory are markedly different (Table 12); this means that the dynamics of lignin biosynthesis needs to be further investigated.

The presence of fractal structure in the processes of monolignol polymerisation is confirmed by determination of the H value in the Hurst equation (see the caption to Fig. 9), which is a

Table 12. Characteristics of the chaotic attractor of the lignin biosynthesis *in vitro*.

statistical characteristic of the structure calculated using the equation

$$\frac{R}{S} = \left(\frac{\tau}{2}\right)^H.$$

Analysis of the parameters of the Hurst equation (Table 13) confirms that the processes involved in lignin biosynthesis possess a fractal structure.[§]

[§] Systems with deterministic chaos, *i.e.*, those having a fractal ordering, are characterised by $0.5 < H < 1$. For random processes, the Hurst value H is 0.5.

IV. Supramolecular structure of lignin

The supramolecular structure of polymers is known to define the mutual arrangement of macrochains and their aggregates. The relevant quantitative characteristics include the size and shape of aggregates and the degree of ordering stipulated by the level of intramolecular interactions. The methods used most often to study the supramolecular structure include X-ray diffraction, electron diffraction and electron microscopy.

Studies dealing with the supramolecular structure of lignins are few. Evidently, the reason is that lignins, which are amorphous polymers, do not usually contain any ordered supramolecular structures such as crystallites, spherulites, *etc.* One more reason is the low efficiency of classical structural methods in the study of amorphous objects.

The wide-angle X-ray scattering provides little information when applied to amorphous polymers. Only in especially favourable cases is it possible to reveal the diffraction effects caused by chemical periodicity of the chain and mutual orientation of the chains. Since lignins are biopolymers with irregular chemical structure, a large set of primary microstructure elements and a rather complex topological structure, the X-ray diffraction pattern obtained for lignins (irrespective of the pre-history of specimens) is expected to represent an amorphous halo. Indeed, this was the case in an X-ray diffraction study of milled spruce wood lignin.¹⁴⁹ Therefore, the results obtained by Pilipchuk *et al.*,¹⁵⁰ who investigated milled wood lignin by electron diffraction, were surprising. These researchers used 2% solutions of lignin in dioxane and acetone and monitored the changes that took place in solutions and films during evaporation of the solvent. After evaporation of dioxane from the solution for 20 h, specific patterns typical of polycrystalline samples were observed on the lignin film thus formed. Further research confirmed the presence of ordering in the structure of films obtained from the dioxane solution; they gave rise to electron diffraction patterns typical of crystalline substances with a long-range order. The pictures of these films obtained by means of an electron microscope showed the presence of symmetrical aggregates consisting mainly of spherical particles of virtually identical sizes. Presumably, during the formation of dioxane films under the experimental conditions, dynamic self-organisation processes take place to give ordered dissipative structures. However, new research is needed to confirm these results. Unlike films obtained from the dioxane solution, the films formed from the acetone solution were fully amorphous.

Most often, the supramolecular structure of lignin is studied using various modifications of electron microscopy. The purpose of a series of studies was to identify individual macromolecules in the photomicrographs obtained by transmission electron microscopy. According to Fengel *et al.*,² lignin of milled spruce wood and ethanol lignin form spherical particles (globules 10 to 100 nm in diameter), the particle shape being independent of the sample preparation procedure. It cannot be ruled out that the smallest of the visible particles are single macromolecules; however, they might also be aggregates, as globules tend to form associates.

Study of lignosulfonates revealed the presence of globular structures 20 to 50 nm in diameter and larger aggregates of an irregular shape. Unlike lignosulfonates, sulfate lignin of pine wood forms substantially smaller particles.² However, in another study,¹⁵¹ the formation of much larger globular particles of sulfate lignin, with a size of 40–100 nm, has been detected. Taking into account that the molecular mass of this lignin did not exceed 1×10^4 , one can suggest that these particles are aggregates composed of several macromolecules. In the presence of electrolytes, sulfate lignin coagulates to give coarse aggregates of an irregular shape. It is clear that to observe separate macromolecules by electron microscopy, new, more rigorous methods for sample preparation need to be worked out. In this connection, noteworthy is the study by Lebedev,¹⁵² who proposed to solve this problem using vacuum atomisation of highly dilute solutions of polymers in mixtures of a solvent and a precipitating agent.

Another group of studies is concerned with the supramolecular organisation of lignins by scanning electron microscopy (SEM). Andersons *et al.*,¹⁵³ who studied the spruce MWL, found spherical domains with a size ranging from 0.5 to several micrometers after evaporation of DMSO. It should be noted that the morphology of lignin films depends on a whole series of factors, in particular, the presence of carbohydrates and the nature of the solvent and the support. If the film is prepared by dispersing a dioxane solution of lignin in an aqueous solution of hemicelluloses, no spherical domains are detected after solvent evaporation and removal of hemicelluloses from the film. In a study of biosynthetic lignin¹⁵⁴ obtained by the end-wise method on the basis of ferulic acid ($M_w = 3 \times 10^4$), spherical particles with a size of 3–5 μm were detected. Study of the dynamics of formation of the supramolecular particles during polymerisation of coniferyl alcohol, ferulic acid, eugenol and isoeugenol has shown¹⁵⁵ that the growth of macromolecules of the dehydropolymer proceeds through the formation of intermediate supramolecular particles with a size of 0.2 to 1.45 μm . In the presence of hemicelluloses, the size of these particles does not exceed 0.3 μm .

The structure of lignins in a scale range of 0.1–10 μm is mainly determined by exogenous factors including temperature and the thermodynamic quality of the solvent used to form the film. It has been found¹⁵⁶ that evaporation of a good solvent gives rise to two types of globular structures in the films of dioxane lignin from pine wood. The diameter of particles of one type does not exceed 1 μm , while that for the other particle type, $\sim 5 \mu\text{m}$. When a poor solvent is evaporated, the loose arrangement of particles, typical of the former case, is replaced by a rather dense packing of the polymer with a structure indiscernible by the SEM method. Mechanical drawing of the specimen plasticised by a good solvent induces the formation of pseudo-fibrils, which are aggregates stretched along the drawing direction of the globule. The formation of oblong aggregates from primary globules of the polymer (polyether acrylate) and their adjustment to one another have also been described in other studies.^{157, 158}

The supramolecular structure of two types of dehydropolymers based on coniferyl alcohol synthesised by enzymic and photochemical methods has been studied.^{159–161} The polymer prepared by the traditional method using peroxidase is composed, as shown by raster-tunnel microscopy, of virtually perfect globular microparticles with a rather narrow size distribution with a maximum at about 500 nm. The globular supramolecular structures tend to form regular macrostructures shaped like triangles, hexagons or helices. Apparently, the geometry of the macrostructures is determined by the nature of the substrate. The most perfect structures were formed on the graphite surface. The photochemical procedure also yields globular supramolecular microparticles. However, in this case, no ordered aggregates are formed (irrespective of the substrate type).

A number of publications^{162–164} are devoted to the supramolecular structure of natural lignin, *i.e.*, lignin of the cell walls of the tree xylem. The most weighty results concerning the structural organisation of natural lignin were obtained using transmission electron microscopy combined with the lignin skeleton method. It was found¹⁶² that lignin of the secondary cell wall has a loose network-like structure formed by globular particles bunched into aggregates of different shapes and sizes. In the central layer, the average size of the supramolecular aggregates is equal to 38 nm. In the outer layers of the secondary cell walls, lignin is present as oblong particles ~ 45 nm wide arranged at right angles to the cell axis. In the primary shell of the pine wood tracheids, lignin occurs as a dense finely grained material,¹⁶³ whereas lignin of the central layer consists of oblong particles oriented along the cellulose microfibrils. The results of investigations suggest the formation of lignin with an ordered structure in cell walls, which is related to the formation of various supramolecular structures during lignin biosynthesis, including fibril-like particles, lamellae and globular structures.

Bogomolov and co-workers¹⁶⁴ studied supramolecular structures formed in the pine wood lignin skeletons before and after partial delignification. The research revealed the presence of (i) structureless lignin in all morphological elements of the cell wall and blind pits; (ii) lamellar lignin in the primary shell, blind pits and the inner layers that line the tracheid cavity; (iii) oblong particles of the type of bars in the secondary shell. The researchers noted different behaviours of these supramolecular structures during alkaline delignification. Conversely, according to other researchers,^{2,165} lignin in the wood is totally amorphous and nonstructured, the shape of lignin particles being determined by the shape of spaces between cellulose microfibrils that are filled during lignification of plant cells.

The inconsistency of the results may be due to specific features of the methods used to obtain lignin skeletons. As a rule, this is done by hydrolysis of wood by various acids (sulfuric, hydrochloric or hydrofluoric), the duration of acid treatment needed to dissolve cellulose and hemicelluloses reaching 3–4 months. During the treatment, the acid concentration is gradually increased and, at the final stages, it is brought to 70%–80%. In the opinion of some researchers,^{2,7,12} high acid concentrations can be responsible for modification of the native structure of lignin.

A promising method for the preparation of lignin specimens is periodate oxidation¹⁶⁶ based on the ability of periodic acid to selectively oxidise and dissolve the polysaccharide components of cell walls. The periodate method for the preparation of lignin skeletons is favourably distinguished from other procedures by mild treatment conditions [neutral pH, low concentration of the reactant (0.08 M), relatively short period (7 days)], which minimise undesirable changes in the structural organisation of the initial lignin.

This method has been successfully used to confirm⁵⁵ the globular morphology of lignin in the central layer of the secondary cell wall of the pine wood tracheid. Meanwhile, the outer layers of the cell membrane were found to contain substantial amounts of oblong and fibril-like supramolecular structures. It was found that globular lignin of the central layer, unlike other lignin forms, is readily soluble in acetic acid after cryochemical treatment of the plant material; however, the reasons for the different behaviours of these lignins remain obscure: this may be due either to structural inhomogeneity or to unequal accessibilities of layers in the cell membrane.

Many researchers have mentioned the clearly disordered pattern of the supramolecular organisation and distribution of lignin in all layers of the cell wall including the intercellular layer—the median plate. This circumstance implies the need for extending the range of physicochemical techniques used to study lignin. A study by Raman spectroscopy has shown¹⁶⁷ that the arrangement of the chains of lignin macromolecules in the cell membranes of spruce wood obeys a certain order. The anisotropy of the paramagnetic properties of the natural lignin of spruce wood pointing to predominant orientation of lignin macrochains along the plant cell axis has been detected by EPR spectroscopy.¹⁶⁸ A γ -photon scattering study of the structural organisation of the plant tissue¹⁶⁹ has shown the presence of fractal order in the packing of polymer chains of both cellulose and lignin.

Solution-free diagnostics of the topological structure of polymers based on thermomechanical analysis is a new method in the study of the supramolecular structure of polymers.^{170,171} The data obtained for hydrolytic lignins led Ol'khov *et al.*¹⁷² to the conclusion that lignins contain partly amorphous and partly crystalline supramolecular structures in which the amorphous blocks have a pseudo-network structure with branching points of a physical nature, these roles being played by crystallites. The degree of crystallinity was found to be dictated by the pre-history of lignin specimens.

Yet another procedure proposed¹⁷³ for investigating the supramolecular structure of lignin is a combination of electron microscopy and densitometric analysis of photomicrographs of the lignin skeletons of pine wood tracheids. The mathematical

processing of densitograms has revealed a certain order in the lignin distribution along the radial direction of the wood cell, which had a self-similarity fractal dimension equal to 1.5.⁵⁵ More recent studies¹³³ indicate that this value is somewhat underestimated. A further development of this method^{142,148} has been the use of non-linear dynamics, fractal geometry and synergetics methods for the analysis of the images obtained by electron microscopy. The following procedure was proposed for the analysis of the electron-microscopy images of lignin polymers. First, so-called spatial series characterising the concentrations of lignin in the radial and tangential directions of a plant cell were constructed and then pseudo-phase portraits were obtained by the Packard method. Second, the integral correlation functions were calculated. Third, the dimensions of the pseudo-phase paths in the spaces with different dimensions were found. The realisation of this algorithm allows one to distinguish between chaotic and ordered structural organisations of the polymer and to establish the order parameters if the system proves to be ordered.

The research showed that the correlation function $C(r)$ of the electron-microscopic images of lignin polymers under analysis is an invariant measure and the distribution function of the ensemble of points in the pseudo-phase space, which reflects the mutual positions of the supramolecular microparticles in the secondary cell wall, is a power function, $C(r) \sim r^{-d}$ (d is a fractional number, $2 < d < 3$). In the researchers' opinion, this implies¹⁴⁸ that the supramolecular organisation of the cell membrane lignin should be described as being scale invariant, *i.e.*, natural lignin has an ordered structure on a scale of 0.01–10 μm .

Table 14 presents some order parameters for the supramolecular structure of lignin, namely, fractal (correlation) dimensions d and the Hurst indices H . A similar fractal type ordering has been established for the supramolecular structure of a number of polyamide acids and polyamides,^{71,174} whose fractal dimension varies in the range of 1.70–1.91 depending on the thermal pre-history of the specimens.

Table 14. Order parameters of the lignins of pine and poplar wood cell membranes.¹⁴⁸

Plant	Specimen	Hurst parameter H	Correlation dimension d for	
			$D = 2$	$D = \infty$
Pine (<i>Pinus silvestris</i>)	xylem	0.88	1.85	5.17
	tracheid			
	xylem tracheid after sulfate pulping	0.90	1.90	5.05
Poplar (<i>Populus nigra</i>)	fibre of the xylem	0.74	1.75	—
	libroform			

The results of studies of the supramolecular structure of lignin indicate that lignification of cell membranes is accompanied by dynamic self-organisation processes, giving rise to self-organised structure of the fractal type. It should also be noted that quantitative analysis of the photomicrographs of cell membranes revealed a power size distribution function for the number of supramolecular elements, $N(r) \sim r^{-n}$, which is typical of systems with self-organised criticality.

A topical problem of the wood chemistry is quantitative characteristics of the structural changes of cell membrane lignin during the production of cellulose. A study of the structure of pine wood lignin at different stages of delignification has been reported.¹⁴² The order parameters of the supramolecular structure of lignin before and after sulfate pulping remain virtually the same, indicating that the structural organisation of lignin as a

fractal object is retained during delignification. However, the size of the supramolecular particles varies depending on the degree of wood delignification. These data demonstrate that the chemical processes that accompany the sulfate pulping of wood are not related to any non-linear self-organisation processes.

V. Conclusion

Despite the vast experimental material accumulated in lignin chemistry, the problem of structural organisation of this natural biopolymer still remains topical. The topological structures of lignin macromolecules are studied using traditional methods of polymer chemistry, which are based on the study of conformational characteristics of the macromolecules by molecular hydrodynamics, namely, capillary viscosimetry, velocity sedimentation and translational diffusion. However, analysis of the relevant publications shows that the problem of determining the topological structure of natural lignin remains unsolved in terms of traditional approaches.

In recent years, a new system approach to the study of lignin structure has been proposed. This approach creates the theoretical grounds for further research into not only topological but also chemical and supramolecular structures. The strategy is to elucidate the genesis of the deterministic chaos and to establish the quantitative criteria of the order arising at different levels of lignin structural organisation upon self-organisation during lignin biosynthesis. These experimental and theoretical studies are based on modern concepts of synergetics, non-linear dynamics and fractal theory.

The experimental data on the conformational and fractal properties of macromolecules of natural lignins obtained in this way are inconsistent with the existing view of the network structure of lignin. Study of the topological and supramolecular structure of natural lignins of different taxonomic origins, *i.e.*, softwood, hardwood and herbaceous lignins, demonstrated that macromolecules of guaiacyl (softwood) lignins are chaotically branched fractal structures whose parameters correspond to the universal Witten–Sander class of fractals, while macromolecules of guaiacyl-syringyl (hardwood) lignins are star-like structures whose scaling parameters are determined by the linear topology of branches. This provided grounds for a new concept which defines the topological structure of lignins as polyvariant. It was found that the topological structure of lignins depends on the functional groups of monomer precursors, polymerisation conditions and dynamic self-organisation.

The fractal properties of lignin at both the topological and supramolecular levels are due to non-linear self-organisation and are related to a dynamic mode of a strange attractor type. Reconstruction of chaotic attractors in terms of the non-linear dynamics of non-equilibrium systems within the framework of chemical synergetics provided data on the dimension of enzymic polymerisation of the basic monolignols of the guaiacyl type.

New methods for the study of the supramolecular structure of lignin were developed. Quantitative characteristics for the structural changes of the lignin of cell membranes of plant tissues during the production of cellulose were obtained.

The authors are grateful to L S Kochev for active participation in the preparation of the review.

The work was supported by the Russian Foundation for Basic Research (Project No. 01-03-96402).

Abstract. The state-of-the-art theory of solvation in polar liquids is considered. The main molecular models and protocols for the calculation of solvation are presented. The protocols based on advanced electrostatic models of solvation, the use of correlation functions found by solving the integral equations of statistical physics and the numerical modelling of solvation processes using Monte Carlo and molecular dynamics methods are described. Attention is focused on the application of the above models to the thermodynamics of the solvation of ions and hydrophobic and polar molecules. Peculiarities of the modelling of processes related to solvation such as electron transfer, conformational and tautomeric equilibria, and solvatochromic shifts in the electronic spectra of the solvated molecules are discussed. The bibliography includes 325 references.

I. Introduction

The character of interaction of a solute with the solvent during solvation depends on the physicochemical properties of solutions and liquid-phase associates. Vast experimental material on the solvation of various molecular objects has been accumulated to date; numerous data on the effect of the solvent on the structural and spectral parameters of the solute molecules, the kinetics and mechanisms of chemical and biochemical reactions are documented. Suffice it to say that in only one monograph¹ devoted to the solvation effects in organic chemistry, does the number of

references exceed 2500. According to the Institute of Scientific Information (Philadelphia, USA), more than 10 000 papers on the topic 'solvation' are published annually in scientific journals.

Solvation of molecules is accompanied by various physico-chemical processes.^{2,3} A solvation shell is formed around each molecule. The physical properties of the solvent can substantially change — dissociation or association of molecules can take place, and the conformations and the electronic structures of both solvated species and solvent species can be affected. This gives rise to diverse specific solvation effects. On the basis of the enormous body of experimental data, a large number of solvation models have been constructed, which are used for interpretation of different solvation effects.

Starting with the Born model,⁴ theoretical studies of solvation for one-atomic ions have long been based on the continuum model of the medium. In recent years, considerable advances have been made along this line related to the improvement of the existing and development of new protocols for the calculation of solvation effects. The general trend is to take into account the molecular structure of the solvent. Description of the solvent at the molecular level can be implemented either within the bounds of continuum approximations, which are vivid and simple as regards the calculations, or on the basis of a consistent statistical theory (the method of integral equations). A special place belongs to the numerical simulation of the solvation effects by molecular dynamics (MD) or Monte Carlo (MC) techniques, which are used more and more often as the computing machinery develops.

The improvement of the simple continuum solvation schemes proposed previously gives rise to an hierarchy of phenomenological approximations, intermediate between these simplest schemes and true molecular theories of solvation. Particular applications of the theory of solvation make use (not always critically) of the whole range of the available methods of this theory. The purpose of this review is to analyse and describe systematically the results obtained using the molecular models of solvation proposed recently.

The review can be divided conventionally into three parts that include Sections II – V, VI – IX and X – XII, respectively. The first part outlines the general scheme for the calculation of solvation

Received 4 October 2002

Uspekhi Khimii 72 (9) 827–851 (2003); translated by Z P Bobkova

and describes the calculation of solvation processes on the basis of upgraded continuum models and integral equations. Since voluminous literature on the MD and MC numerical simulation techniques is available (see, for example, Refs 5–14), we have not discussed here their principles and engineering implementations, but, as an exception, have touched upon the problems of taking into account the electrostatic interactions within the framework of these methods and have briefly considered the calculation of the change in the thermodynamic functions upon solvation — this aspect is especially important for chemical and biological applications. The second part dealing with hydrophobic effects provides a brief description of thermodynamic integration, which is an efficient up-to-date algorithm of such calculations, and considers typical objects to which various methods of solvation theory are applied, depending on the conditions. These objects can be represented by hydrophobic molecules, ions, polar molecules and quantum particles (solvated electrons, bipolarons and positronium). The third part is devoted to the study of processes related to solvation (electron transfer, conformational and tautomeric equilibria and solvatochromic shifts in the electronic spectra). The prospects for using the molecular models of solvation in polar liquids are considered in the Conclusion.

In order to maintain a reasonable relationship between the coverage of information and the logics of narration, we restricted the scope of this review to analysis of the key methods of the solvation theory and did not dwell on detailed discussion of the results obtained.

II. General scheme for the calculation of solvation

The choice of the intermolecular interaction potentials plays a crucial role in the theory of solvation. In most solvation theories, particles of the solute¹⁵ and the solvent (both atoms and molecules) are considered within the framework of classical mechanics. The set of methods and calculation algorithms involved are often referred to as ‘molecular mechanics’ (MM).^{16,17} In this case, it is suggested most often that these potentials can be represented as sums of effective atom–atom pair potentials

$$U(\mathbf{R}^{(N)}) = \sum_{I \neq J}^N u(|\mathbf{R}_I - \mathbf{R}_J|).$$

Here $U(\mathbf{R}^{(N)})$ is the potential energy of the solute–solvent system, N is the total number of atoms in the system, $\mathbf{R}_I$ and $\mathbf{R}_J$ are the radius-vectors of atoms I and J , respectively. The summation covered every possible pair of atoms where both atoms belong to either the solute or a solvent molecule, or one atom belongs to the solute and the other one, to the solvent molecule. The indices I and J imply simultaneously the type and the number of an atom. An advantage of this approach is the possibility of finally reducing the problem to the study of only radial atom–atom potential functions. However, even in this approximation, parametrisation of the interatomic force fields is very complicated. This requires specification of the functional form of each potential containing adjusting parameters, which are selected by comparing the results of trial calculations with the experimental data on the structure and thermodynamic properties of one-atomic and molecular liquids. A number of parametrisation protocols for the intra- and intermolecular force fields (AMBER,¹⁸ CHARMM,¹⁹ OPLS,²⁰ GROMOS,²¹ GROMACS,²² etc.) have been developed. These techniques make use of the partial charges of atoms q_i for parametrisation of the Coulomb interaction and the Lennard-Jones model for parametrisation of the non-Coulomb contribution to atom–atom potentials.

The main phase in the calculation of classical molecular models is determination of the equilibrium ensemble of atomic configurations

$$\bar{\mathbf{R}}^{(N)} = \bar{\mathbf{R}}_1 \bar{\mathbf{R}}_2 \dots \bar{\mathbf{R}}_N$$

in a chosen volume of the medium either by solving dynamic equations (MD method) or using the MC method. In both cases, the final outcome is the calculated atom–atom (AA) correlation function (CF) $g_{AB}(|\mathbf{R}_1 - \mathbf{R}_2|)$, which is related to the conditional probability that one atom A of some molecule will be found at point $\mathbf{R}_1$ provided that atom B of another molecule occurs at point $\mathbf{R}_2$.²³

The presence of chemical bonds gives rise to correlations that are specified by intramolecular correlation functions (IMCF). For rigid molecules, IMCF depends only on the molecular geometry, while for non-rigid molecules, averaging of these functions over all molecular conformations should be carried out. The atom–atom correlation functions (AACF) and the IMCF provide full information on the local microscopic structure of the solution and the solvated complex. All thermodynamic values (Gibbs energy of solvation ΔG , chemical potential μ and so on) can also be calculated from the correlation functions and the intra- and intermolecular interaction potentials.²³

More detailed investigations of real solvation systems require a quantum-mechanical (QM) calculation of electron density distribution $\rho_e(\mathbf{r})$ and many-electron wave function $\Psi(\mathbf{r}^{(n)})$ (n is the number of electrons). However, the quantum-chemical calculations from ‘primary principles’ are very laborious and can now be carried out only for systems consisting of several tens of atoms. For systems comprising hundreds of atoms, semiempirical methods are employed. Therefore, hybrid (QM/MM) methods, i.e., calculation protocols that use simultaneously the equations of quantum and molecular (classical) mechanics, are now actively used to study solvation. All molecules of the solution are divided into two subsystems, namely, the solute (for which the quantum calculations are carried out) and the solvent, which is described on the basis of classical molecular models. Correspondingly, quantum (Q), classical (M) and mixed (QM) contributions to the intermolecular potentials are distinguished. The full Hamiltonian H of the system includes each of these contributions.

$$H = H_Q + H_{QM} + H_M, \quad (1)$$

$$H_Q = \sum_i \frac{\mathbf{P}_i^2}{2m_i} + \sum_{ij} \frac{Z_i Z_j}{|\mathbf{R}_i - \mathbf{R}_j|} + \langle \Psi | H_e | \Psi \rangle,$$

$$H_{QM} = \sum_{iI} \left[\frac{Z_i q_I}{|\mathbf{R}_i - \mathbf{R}_I|} - \left\langle \Psi \left| \frac{q_I}{|\mathbf{r}_i - \mathbf{R}_I|} \right| \Psi \right\rangle + V(|\mathbf{R}_i - \mathbf{R}_I|) \right],$$

$$H_M = \sum_I \frac{\mathbf{P}_I^2}{2m_I} + \sum_{IJ} u(|\mathbf{R}_I - \mathbf{R}_J|).$$

Here, the subscripts i, j, I, J refer to atoms of the quantum and classical subsystems, respectively; $\mathbf{P}_i, \mathbf{P}_I$ and $\mathbf{R}_i, \mathbf{R}_I$ are the impulses and coordinates (radius-vectors) of atoms; Z_i, m_i are the charge and the mass of the solute nuclei, H_e is the electron Hamiltonian (we do not write it out in an explicit form) and the brackets $\langle \Psi | \dots | \Psi \rangle$ mean averaging over the electronic configuration of the solute with coordinates of the electrons $\mathbf{r}_i$. The operator H_{QM} contains both the electrostatic (the first two terms) and non-electrostatic (V) contributions.

The use of Hamiltonian (1) implies the calculation of the many-electron wave function Ψ and the equilibrium configuration $\bar{\mathbf{R}}^{(N)}$ of the solvent molecules. In terms of the method of correlation functions, the problem of solvation can be reduced to the investigation of the effective Hamiltonian H_{ef} , which governs the behaviour of the quantum subsystem in the external field $V_{\text{ef}}(\mathbf{R})$ created by solvent molecules at point $\mathbf{R}_i$,

$$H_{\text{ef}} = H_Q + V_{\text{ef}} = \sum_i \frac{\mathbf{P}_i^2}{2m_i} + \sum_{ij} \frac{Z_i Z_j}{|\mathbf{R}_i - \mathbf{R}_j|} + \langle \Psi | H_e | \Psi \rangle + \sum_{AB} \int g_{AB}(\mathbf{r}) u_{AB}(|\mathbf{r} - \mathbf{R}|) d\mathbf{r}, \quad (2)$$

where $g_{AB}(\mathbf{r})$ is the AACF between atoms of the solvated complex and the solvent and $u_{AB}(\mathbf{r})$ are the corresponding atom–atom potentials. The free Gibbs energy of solvation of the system (per solute species) is given by the equation

$$\Delta G = \langle \Psi | H_{\text{ef}} | \Psi \rangle - \langle \Psi_0 | H_Q | \Psi_0 \rangle + \mu, \quad (3)$$

where $\Psi_0(\mathbf{r}^{(n)})$ and $\Psi(\mathbf{r}^{(n)})$ are many-electron wave functions of the solute in vacuum and in the solvent, respectively, μ is the chemical potential of the solvent, which can be expressed in terms of the CF. Since the AACF is determined by the equilibrium configuration of the solvent molecules, which also depends on the electron density distribution $\rho_e(\mathbf{r})$, self-consistent calculation of Ψ and $g_{AB}(\mathbf{r})$ is required. The calculation procedure is as follows. Some initial approximation is taken for the wave function Ψ and for the spatial configuration of the solute. The next stage is to calculate the charge distribution on the solute atoms, to find the equilibrium configuration $\mathbf{R}^{(N)}$ and $g_{AB}(\mathbf{r})$, to calculate the external field and, finally, to correct Ψ by calculating the electron density distribution in this external field. This procedure should be repeated until full self-consistency is attained. Various modifications of this procedure are related to the choice of methods for calculating $g_{AB}(\mathbf{r})$ (MD, MC or integral equations) and Ψ . The allowance made for electron polarisation of the solvent molecule changes appreciably the whole calculation scheme.

In the general case, the calculation of the equilibrium configuration of the solute + solvent system, like the calculation of the AACF, is labour-consuming; therefore, additional simplifications are used in continuum models. The approximations based on the linear response theory²⁴ allow one to reduce the problem to the calculation of the wave function Ψ in the reactive self-consistent field (SCF) V_{ef} , which depends on the dielectric constant of the liquid and charge distribution in the solute. Thus, using continuum models (CM), one can calculate the energy of solvation and the electron density distribution on the solvated molecule without calculating the correlation functions. Actually, this requires only an additional self-consistent calculation of V_{ef} , which can be naturally included into standard quantum-chemical procedures.²⁵

III. Continuum models

The linear response approximation in the theory of solvation appears to be justified for considering the electrostatic interactions in the system consisting of a solute and the solvent. It is widely used for systems where such interactions predominate, *i.e.*, for charged and highly polar solutes in polar solvents. This approximation forms the basis for the continuum theory. It is formulated as a relationship between the charge distribution on the solute $\rho_Z(\mathbf{r})$, which depends on the charge of the atomic nuclei and the electron density distribution $\rho_e(\mathbf{r})$, *i.e.*,

$$\rho_Z(\mathbf{r}) = \sum_i Z_i \delta(\mathbf{r} - \mathbf{R}_i) - \rho_e(\mathbf{r}),$$

and the field of the medium ‘response’ $V(\mathbf{r})$, *i.e.*, electrostatic field

$$V(\mathbf{r}) = \hat{K} \rho_Z = \int \rho_Z(\mathbf{r}') K(\mathbf{r}, \mathbf{r}') d\mathbf{r}'. \quad (4)$$

Here $\hat{K}$ is the linear integral operator with a symmetric nucleus $K(\mathbf{r}, \mathbf{r}')$ (the Coulomb Green function, which has the following form for the case of electrostatic potential in vacuum: $|\mathbf{r} - \mathbf{r}'|^{-1}$). Within the linear theory, the Helmholtz free energy of solvation is equal to

$$\Delta F = \frac{1}{2} \int \rho_Z(\mathbf{r}) V(\mathbf{r}) d\mathbf{r} = \frac{1}{2} \int \rho_Z(\mathbf{r}') K(\mathbf{r}, \mathbf{r}') \rho_Z(\mathbf{r}) d\mathbf{r}. \quad (5)$$

In the simplest case of a homogeneous medium, the charge distribution $\rho_Z(\mathbf{r})$ is related to the induction field $\mathbf{D}(\mathbf{r})$ by the Poisson equation

$$\nabla \mathbf{D} = 4\pi \rho_Z(\mathbf{r}), \quad (6)$$

and the polarisation $\mathbf{P}(\mathbf{r})$ of the medium is equal to

$$\mathbf{P}(\mathbf{r}) = \frac{1}{4} \pi \left(1 - \frac{1}{\epsilon_0} \right) \mathbf{D}(\mathbf{r}), \quad (7)$$

$$\mathbf{D} = \epsilon_0 \mathbf{E},$$

where ϵ_0 is the static dielectric constant of the solvent, $\mathbf{E}$ is the electric field. A variable polarisation arises in a homogeneous medium as the response field. This simple model has found wide application in early versions of the electron transfer theory.

To describe the solvation effects at an up-to-date level, one should take into account the discrete (atomic) structure of the solvated molecule. There appears a boundary separating the region occupied by the solute (the ‘cavity’ in which the dielectric constant ϵ is taken to be unity) from the surrounding area filled with a continuous medium with $\epsilon = \epsilon_0$. With such boundary conditions, it is inconvenient to use the variables $\mathbf{P}(\mathbf{r})$ and $\mathbf{D}(\mathbf{r})$, and transition to the general relations (4) and (5) is expedient. In this case, the response nucleus $K(\mathbf{r}, \mathbf{r}')$ is defined as the function ϵ_0 . The numerical implementation of this procedure is equivalent to the solution of the Poisson equation with the appropriate boundary conditions, which can be different depending on the particular method used to specify the boundary of the cavity accommodating the solute. Some of these methods are mentioned below.

A more general formulation of electrostatic equations is proposed in non-local electrostatics.^{26,27} For a homogeneous medium, simple relations (6) and (7) are replaced by the relation

$$\mathbf{P}(\mathbf{r}) = \int \mathbf{E}(\mathbf{r}') \chi(\mathbf{r} - \mathbf{r}') d\mathbf{r}'. \quad (8)$$

Here $\chi(\mathbf{r} - \mathbf{r}')$ is the non-local generalised dielectric susceptibility. In the standard phenomenological approach,^{26–29} it is expressed in terms of the dielectric function $\chi(\mathbf{k})$ [Fourier transform of the function $\chi(\mathbf{r})$], which is in turn related to the dielectric susceptibility $\epsilon(\mathbf{k})$ in the following way:

$$\chi(\mathbf{k}) = \frac{1}{4\pi} \left[1 - \frac{1}{\epsilon(\mathbf{k})} \right]. \quad (9)$$

This approach allows one to take into account the structure of the medium in the continuum theory. As an example, we consider the model function $\chi(\mathbf{k})$ for the isotropic case where it depends only on the length of the vector $\mathbf{k}$. In the simplest variant, this model has the form^{24–30}

$$\chi(\mathbf{k}) = \chi_0 + \frac{\chi_1}{1 + k^2 \varsigma^2}. \quad (10)$$

Here χ_0 and χ_1 are constants, the former determining the local, while the latter, the non-local components of the susceptibility; $k = |\mathbf{k}|$; the model parameter ς is the correlation length. After the backward transformation, the Fourier function (10) gives rise to a ‘susceptibility kernel,’ which depends only on the distance between the points $\mathbf{r}$ and $\mathbf{r}'$

$$\chi(|\mathbf{r} - \mathbf{r}'|) = \chi_0 \delta(\mathbf{r} - \mathbf{r}') + \frac{\chi_1}{4\pi \varsigma^2 |\mathbf{r} - \mathbf{r}'|} \exp(-\varsigma^{-1} |\mathbf{r} - \mathbf{r}'|), \quad (11)$$

where δ is the Dirac delta function.

In conformity with relation (8), the response $\mathbf{P}(\mathbf{r})$ decays exponentially with an increase in the distance $|\mathbf{r} - \mathbf{r}'|$, and the dielectric shielding of the solute charge is efficient only at distances not exceeding ς . In the description of the orientational polarisation of the medium, the ς value is of the order of the characteristic size of the solvent particles.

The applicability of local models is restricted by the limited case $\varsigma \lesssim \varsigma_0$, where ς_0 is the characteristic size of the solvated molecule. By introducing multimodal model functions as the sums of Lorentzian functions (10) with different parameters $\varsigma_1, \varsigma_2, \dots$, equation (10) can be generalised to describe the structure of the solvent around the solute in more detail.^{24–28} The non-local models for an inhomogeneous medium are complex and have

been developed only for spherically symmetric systems,^{30–33} although the equations describing them are also known for the general case.^{31–33} In these models, linear relation (4), and, finally, (leaving aside the technical complexity), the response nucleus $K(\mathbf{r}, \mathbf{r}')$ can be expressed in terms of the function $\chi(\mathbf{k})$ or $\varepsilon(\mathbf{k})$.

This type of approach can be extended to time-dependent effects by introducing the functions $\chi(\mathbf{k}, \omega)$ or $\varepsilon(\mathbf{k}, \omega)$ that depend on the frequency ω . In the absence of spatial dispersion, they are reduced to the functions $\chi(\omega)$ and $\varepsilon(\omega)$, which are complex values.³⁴ For example,

$$\varepsilon(\omega) = \varepsilon_1(\omega) + \varepsilon_2(\omega),$$

where the terms ε_1 (real) and ε_2 (imaginary) are even and odd functions of ω , respectively. The transition to time functions is performed by the Fourier inversion.

Relation (4) also holds for molecular theories if the applicability conditions of the linear response are met. Then the nucleus $K(\mathbf{r}, \mathbf{r}')$ can be calculated within the framework of one or another microscopic model. In the classical limit, the Kirkwood formula holds,^{34,35} which expresses the nucleus of the integral operator $\hat{K}$ in terms of the correlation function $\langle \Delta V(\mathbf{r}) \Delta V(\mathbf{r}') \rangle_{\rho_Z T}$ of fluctuations of the microscopic electric field

$$K(\mathbf{r}, \mathbf{r}') = -\beta \langle \Delta V(\mathbf{r}) \Delta V(\mathbf{r}') \rangle_{\rho_Z T}, \quad (12)$$

where $\beta = (k_B T)^{-1}$, k_B is the Boltzmann constant; averaging involves an ensemble with fixed charge density distribution ρ_Z and temperature T . Relation (12) allows one to perform MC or MD simulation of the nucleus $K(\mathbf{r}, \mathbf{r}')$ on the basis of calculations of the correlation function $\langle \Delta V(\mathbf{r}) \Delta V(\mathbf{r}') \rangle$. Finally, it becomes possible to transfer the approaches developed in the continuum theory to molecular models.

Of all the existing computation schemes, the continuum theory most simply, although roughly, takes into account the solvation effects. Owing to the simplicity of the numerical procedure, continuum models have been widely distributed and underlie a large number of applied computer programs. Here, we only briefly touch on different versions of continuum models, because voluminous literature devoted to this topic is available.^{36–43}

Continuum models can be classified in terms of the procedure of calculation of the reactive self-consistent field V_{ef} acting upon the solute [see Eqn (2)]; in terms of the method of inclusion of the short-range contribution V_s ; or in terms of the numerical procedure used to calculate the wave functions Ψ . In addition, in the calculations that are meant to provide the semiquantitative agreement with the experiment, the cavity accommodating the solute should have a complex shape 'adjusted' to the real solute structure; hence, a procedure for finding this cavity is also required.

Quantum-chemical calculations for the solvated complex use most often *ab initio* computations based on the Hartree–Fock (HF) approximation supplemented by some scheme for taking into account the electron correlations.^{44–49} In many publications, the Ψ functions are calculated in terms of the density functional theory (DFT).^{50–53}

Comparison of the data obtained by different methods shows a substantial scatter of the results (Table 1), which is, however, due not only to the calculation scheme chosen but also to the use of different parameters for the interatomic interaction potentials. The results of both HF and DFT calculations are in almost equally satisfactory agreement with the experimental data.

The ways of taking into account the short-range contribution V_s depend on the way of parametrisation of the van der Waals interactions. Most often, the Solvent Accessible Surface (SAS) approximation is used according to which the contribution of short-range forces to ΔG (ΔG_s) is proportional to the solute surface area accessible to the solvent molecules. If the SAS has a complex shape, it is considered as consisting of separate S_i fragments, which correspond to the solute atoms, and ΔG_s is calculated as the sum over the fragments⁶⁰

Table 1. Experimental and calculated [by DFT, MM, HF, SMx (Solvation Model) and CM methods] values of free energy ΔG (kcal mol^{−1}) for the hydration of amines and amides.

Solute	Experiment (see ⁵⁴)	Calculation by the method					
		DFT (see ⁵³)	MM (see ⁵⁵)	HF (see ⁵⁶)	SMx (see ⁵⁷)	MM (see ⁵⁸)	CM (see ⁵⁹)
NH ₃	−4.3	−4.8	−4.0	−5.1	−4.3	−4.2	−6.3
CH ₃ NH ₂	−4.6	−3.0	−3.7	3.5	—	−3.5	−4.5
(CH ₃) ₂ NH	−4.3	—	−1.2	—	−4.3	−1.9	−2.7
(CH ₃) ₃ N	−3.2	—	−0.6	—	−2.6	0.4	−1.2
Acetamide	−9.7	−9.0	−11.9	−9.2	—	—	−9.8
NMA ^a	−10.1	—	−9.3	—	—	—	−7.8
NNDMA ^b	−8.5	—	−7.3	—	—	—	−6.3

^a NMA is *N*-methylacetamide; ^b NNDMA is *N,N*-dimethylacetamide.

$$\Delta G_s = \sum_i A_i S_i, \quad (13)$$

where A_i is a coefficient expressed in the surface tension units. According to the Generalised Born Surface Area (GBSA) model,^{61,62} it is assumed that the A_i value is determined only by the type of atom. In more advanced SMx models,^{63,64} it depends additionally on the type and length of the bonds and (implicitly) on the charge of the i th atom. Attempts have been made to parametrise the separate contributions related to the repulsion of atoms and to their attraction due to dispersion interactions. The complexity of such calculations is obvious, due to the fact that these contributions have opposite signs and partially neutralise each other. In some cases, these contributions are expressed *via* one- and two-electron integrals for the corresponding atomic orbitals and are included in the calculation scheme as a component of the self-consistent field acting on the solute.⁶⁵ The repulsion contribution contains a temperature-dependent 'non-potential' component, namely, the cavitation energy (see Section VI). Other methods for the parametrisation of ΔG_s also exist. Comparative analysis of the existing methods showed⁶⁶ that, with appropriate thoroughness, they all provide similar estimates of ΔG_s .

A number of modifications of continuum models exist, depending on the procedure of calculation of the self-consistent field, which is dictated by the method used to solve the Poisson equation for the electrostatic potential V_{ef} created by the charge distribution $\rho_Z(\mathbf{R})$

$$\nabla \varepsilon(\mathbf{R}) \nabla V_{\text{ef}}(\mathbf{R}) = -4\pi \rho_Z(\mathbf{R}). \quad (14)$$

This equation corresponds to the most general case where the dielectric constant of the (inhomogeneous) medium $\varepsilon(\mathbf{R})$ depends (unlike ε_0) on the spatial coordinates $\mathbf{R}$. Equation (14) can be numerically solved by using various finite-difference schemes or the finite-element method. This way of solving the equation is, however, labour-consuming, because elucidating the details of field distribution $V_{\text{ef}}(\mathbf{R})$ requires the use of a three-dimensional network with a large number of points.⁶⁷ In some cases, poor convergence is observed during the solution. Despite these drawbacks, this approach has quite a lot of supporters, especially among researchers engaged in molecular biology,⁵⁹ which is due to the availability of the relevant program packages for the solution of the Poisson–Boltzmann⁶⁸ and Poisson⁶⁹ equations.

Most often, the cavities of the solute excluded volume are considered, the dielectric constant being a stepwise function

$$\varepsilon(\mathbf{R}) = 1$$

inside the cavity and

$$\varepsilon(\mathbf{R}) = \varepsilon_0$$

outside the cavity. Then for a spherical cavity with the radius a , the solution of Eqn (14) can be written as a multipole expansion into spherical harmonics $Y_l^m(\psi, \theta)$ ^{38, 70}

$$V_{\text{ef}}(R > a) = \sum_{l=0}^{\infty} \frac{2l+1}{l+(l+1)\epsilon} \frac{1}{R^{l+1}} \sum_{m=-l}^l B_{lm} Y_l^m(\psi, \theta),$$

$$V_{\text{ef}}(R \leq a) = V_0(\mathbf{R}) + V_{\sigma}(\mathbf{R}) = \sum_{l=0}^{\infty} \frac{1}{R^{l+1}} \sum_{m=-l}^l B_{lm} Y_l^m(\psi, \theta) + \sum_{l=0}^{\infty} \frac{(l+1)(\epsilon-1)}{l+(l+1)\epsilon} \frac{1}{a^{2l+1}} \sum_{m=-l}^l B_{lm} Y_l^m(\psi, \theta), \quad (15)$$

where $R = |\mathbf{R}|$, B_{lm} are the expansion coefficients. In relation (15), the contributions $V_0(\mathbf{R})$ and $V_{\sigma}(\mathbf{R})$ represent the potential created by the charge distribution on the solute in vacuum and the response field created by the induced charge of the surface of the sphere, respectively. In the case of a solute with an arbitrary shape, one can use a multicentred multipole expansion.³⁸ In this case, the whole surface of the solute is first split into spherical fragments for which expansion (15) is performed, while the self-consistent field $V_{\text{ef}}(\mathbf{R})$ is calculated as a superposition of the contributions of all centres. An essential drawback of this approach is poor convergence of series (15); as a consequence, it is difficult to control the number of terms of the series needed to ensure the specified precision. For small molecules, an accuracy of not less than 93% is attained at $l_{\text{max}} = 8$ (see Ref. 71), whereas for large molecules, l_{max} increases linearly with an increase in the distance from the expansion centres. The case where only the terms with $l_{\text{max}} = 0$ are considered corresponds to the Born approximation⁴ and $l_{\text{max}} = 1$, to the Onsager approximation.⁷² The two last-mentioned protocols are embodied in a large number of computer programs. The former underlies the GBSA model (generalised Born model taking into account the accessible surface),⁶⁰ which is actively used for 'classical' calculations of the solvation energy of biomacromolecules⁷³ or the energy of binding of a ligand to a protein.⁷⁴ Yet another example is represented by SMx models⁶² where this approximation is used for the quantum-chemical calculation of solvation. Note that the results of calculations in terms of these models are highly sensitive to the choice of the a radius.

An alternative method for solving the Poisson equation is the popular Polarised Continuum Model (PCM).^{75–78} According to this model, the solute is immersed in a cavity with a complex shape which is constructed as a combination of (overlapping) spheres drawn around each of the solute atoms. The radii of the spheres are expressed in terms of the van der Waals radii of atoms by introducing a scaling multiplier, which is a method parameter. Equation (14) with the function $\epsilon(\mathbf{R})$, which acquires different constant values inside and outside the cavity, is reduced to the integral relation

$$V_{\sigma}(\mathbf{R}) = V_{\text{ef}}(\mathbf{R}) - V_0(\mathbf{R}) = \int_S \frac{\sigma(\mathbf{R}')}{|\mathbf{R} - \mathbf{R}'|} d\mathbf{R}'. \quad (16)$$

Here, S is the surface area of the boundary of the cavity around the solute over which the corresponding surface integral is calculated.

It follows from electrostatics equations that the surface charge $\sigma(\mathbf{R}')$ on the boundary of the cavity is related to the field strength $E(\mathbf{R}')$ by the relation

$$\sigma(\mathbf{R}') = \frac{1 - \epsilon_0}{4\pi\epsilon_0} \mathbf{n}(\mathbf{R}') E(\mathbf{R}') = \frac{\epsilon_0 - 1}{4\pi\epsilon_0} \mathbf{n}(\mathbf{R}') \nabla [V_0(\mathbf{R}') - V_{\sigma}(\mathbf{R}')], \quad (17)$$

where $\mathbf{n}(\mathbf{R}')$ is the unit vector of the inward normal to the surface S . Equations (16) and (17) taken in combination provide the

possibility of obtaining a closed-loop iterative scheme for the calculation of $\sigma(\mathbf{R}')$ and $V_{\sigma}(\mathbf{R}')$.

The key integral equation of the PCM determines the surface charge $\sigma(\mathbf{R})$ (see Ref. 79)

$$\sigma(\mathbf{R}) = \frac{1 - \epsilon_0}{4\pi\epsilon_0} \left[\int_V a(\mathbf{R}, \mathbf{R}') \rho_z(\mathbf{R}') d\mathbf{R}' + \int_S a(\mathbf{R}, \mathbf{R}') \sigma(\mathbf{R}') d^2\mathbf{R}' + 2\pi\sigma(\mathbf{R}) \right], \quad (18)$$

$$a(\mathbf{R}, \mathbf{R}') = \frac{\partial}{\partial \mathbf{n}(\mathbf{R})} \left(\frac{1}{|\mathbf{R} - \mathbf{R}'|} \right),$$

where a is the normal derivative of the Coulomb potential.

The right-hand part of Eqn (18) is the sum of volume and surface integrals.

Iterative algorithms are used most often to solve Eqns (16) and (17) for $V_{\sigma}(\mathbf{R})$ and $\sigma(\mathbf{R}')$ or the equivalent equation (18) for $\sigma(\mathbf{R})$. The function $\sigma(\mathbf{R})$ is approximated by the network of its values on small segments of the surface S . In some existing alternative (non-iterative) calculation schemes, the set of the $\sigma(\mathbf{R})$ values on the segments of the cavity surrounding the solute is considered as a vector and the Eqns (16), (17) and (18) that determine it are reduced to a high-dimension matrix equation (see the review³⁶ and the references cited therein).

The PCM model is represented by a large number of versions whose comparative analysis has been reported.³⁷ A recent version⁸⁰ makes it possible to carry out the calculation of solvation in liquid crystals and salt solutions. A simplified modification of the PCM is the Conductor-Like Screening Model (COSMO),⁸¹ which assumes that highly polar liquids such as water ($\epsilon_0 = 80$) can be regarded as conductors ($\epsilon_0 = \infty$). The corresponding equation for the charge surface density obtained in terms of this model is solved by the matrix method mentioned above. This scheme is considered to be attractive for calculating the solvation of large biomacromolecules.⁸²

To conclude the Section, let us turn back to the problem of applicability of the linear response theory to the description of solvation. The linear approximation is basic for the use of continuum models; its adequacy was verified by comparing the results of calculations in terms of these models with the results of MD or MC calculations.^{83–85} Comparison showed a substantial deviation of the response from linearity. The deviation is smaller for charged solvated molecules than for polar molecules; in addition, the non-linearity of the real response increases with a decrease in the solute charge. Before the publications,^{83–85} it was believed that non-linear effects should arise in strong electric fields (dielectric saturation). Calculations^{84, 85} revealed an absolutely different effect of purely molecular nature generated in weak fields. It was found that linearity of the dielectric response is violated due to solvent structuring in the near environment of the solute caused by short-range van der Waals interactions. As the strength of the external electric field increases, a 'phase transition' takes place and the linearity is restored. However, studies were carried out only for aqueous solutions, and it is unknown whether this effect is significant for non-aqueous systems.

Apparently, continuum models cannot provide a calculation accuracy above 80% for either free or potential energy, or for the electrostatic potential, irrespective of the way of parametrisation of the non-electrostatic contribution or the shape of the solute cavity. One more shortcoming of the continuum models is that they do not allow one to estimate temperature dependences of the energy of solvation or to study the change in the local structure of the solution near the solute. Nevertheless, due to the relative simplicity of the calculation of ΔG and the possibility of estimating the changes in the electronic structure of the solute, the continuum models appear rather attractive for applications, especially in the field of biochemistry and molecular biology.

IV. Method of integral equations

The MC or MD calculation of the correlation functions is associated with a great amount of computation. By using the CF formalism, it is possible to reduce the problem to a simpler investigation of Ornstein–Zernike type equations.^{23,86,87} These equations relate the atom–atom radial distribution function $g(r)$ to the ‘direct’ correlation function $c(r)$, which plays an important role in the statistical mechanics and determines the two-particle spatial correlations (medium density) caused by the interatomic potential $u(r)$ so that $c(r \rightarrow \infty) \rightarrow -\beta u(r)$. In the case of an infinitely dilute solution where a monoatomic solute in a monoatomic liquid is considered, the equation for the $h_{AB}(r) = g_{AB}(r) - 1$ (see [†]) is written in the form

$$\gamma_{AB}(R) = h_{AB}(R) - c_{AB}(R) = \rho \iint c_{AB}(r) h_{BB}(|r - R|) dr, \quad (19)$$

where ρ is the average solution density, $h_{BB}(r)$ is the full correlation function of the pure solvent. The integral equation (19) connects two functions, h and c , and, hence, it can be supplemented by the ‘closure’ condition. This condition can be obtained as the dependence of the function c_{AB} on the ‘bridge’ functional B

$$c_{AB} = \exp[-\beta u_{AB} + \gamma_{AB} + B(\gamma_{AB})] - \gamma_{AB} - 1.$$

No exact expression for the bridge functional has yet been found; however, a large number of approximate expressions have been obtained for simple liquids by the diagram expansion method;^{88,89} the applicability of such expressions is limited to the $u(r)$ type of interaction. For example, the hyperchain (HC) approximation (HCA) with $B[\gamma(r)] = 0$ is used for long-range interactions and $B[\gamma(r)] = \ln[1 + \gamma(r)] - \gamma(r)$ corresponds to the Percus–Yevick (PY) approximation, which is used for short-range potentials.

In the case of molecular solutions, unlike simple liquids, it is impossible to relate unambiguously the behaviour of the atom–atom potential to the type of closure; therefore, the closure conditions for the atom–atom functions are not rigorously deduced but are also expressed in the HC or PY approximation. This idea has been developed extensively in the Reference Interaction Site Model (RISM) theory,⁹⁰ in which the CF are related by the integral relations

$$\rho H_{AB}(R) = \sum_{CD} W_{AC}(r) C_{CD}(r - r_1) X_{DB}(|r_1 - R|) dr dr_1. \quad (20)$$

Here ρ is the average density of the solvent; H and C are matrices whose elements are the h_{AB} and c_{AB} functions for atoms of different types, respectively; C and D are additional subscripts for the solute and solvent atoms, respectively; W_{AC} is the ‘structural matrix’ composed of the solute correlation functions w_{AC} , and

$$X_{DB}(r) = W_{DB}(r) + \rho H_{DB}(r) \quad (21)$$

is the generalised susceptibility of the pure solvent. Here, matrices are introduced instead of three scalar integral equations for the solute–solute, solute–solvent and solvent–solvent correlation functions. The X_{DB} matrix can be calculated by the MC or MD methods or using integral equations. Like the structural matrix for the complex solute W_{AD} , this matrix specifies the input structural data for Eqn (20). As regards the mathematical statement, the equations of the RISM theory are similar to Eqn (19) and differ only by the presence of an additional weighting factor W caused by intramolecular bonds. The large number of discrepancies

[†] The function h is the full CF. From the standpoint of a mathematician, this function is more convenient, as $h(r \rightarrow \infty) \rightarrow 0$ and the integrals that include $h(r)$ are finite, while $g(r \rightarrow \infty) \rightarrow 1$. In addition to these CF, the ‘indirect’ CF is also used: $\gamma \equiv h - c$.

between the asymptotic estimates of various physical properties and the conclusions drawn in terms of the RISM models are due to the approximate character of this analogy.^{86,91} In particular, for polar liquids, the RISM model substantially underestimates the dielectric constant and, for example, for water, it does not predict adequately thermodynamic and structural properties.⁹² More rigorous approaches also exist;⁹³ however, these are seldom used to study solvation due to the complexity of numerical implementation.⁹⁴

As noted above, all the thermodynamic characteristics of solvation can be found in terms of the AACF. The form of the relevant relations depends on the type of closure. The simplest relations are obtained in the case of the HC approximation where the excess chemical potential μ in the limit of an infinitely dilute solution is determined from the equation⁹⁵

$$\beta\mu = \rho \sum_{AB} \int \left[\frac{1}{2} h_{AB}^2(r) - c_{AB}(r) - \frac{1}{2} \sum_{CD} \int c_{AC}(r) X_{CD}(|r_1 - R|) c_{DB}(r)(|r - r_1|) dr dr_1 \right] \quad (22)$$

By using standard thermodynamic relations, one can also calculate the energy E , the enthalpy H and the entropy Γ of solvation⁹⁶

$$\begin{aligned} E &= \left. \frac{\partial(\beta\mu)}{\partial\beta} \right|_{\rho}, \\ H &= \left. \frac{\partial(\beta\mu)}{\partial\beta} \right|_{\rho}, \\ \Gamma &= \frac{\mu - H}{T}. \end{aligned} \quad (23)$$

The subscripts $|\rho$ and $|\rho$ mean that the derivatives are calculated at a constant density and pressure, respectively.

The RISM equations with allowance for closure, like Eqn (19), are heterogeneous Fredholm integral equations of the second kind in the unknown function $\gamma_{AB}(r)$. The numerical investigation is done using iterative methods. First, some indirect correlation function $\gamma^{in}(r)$ is specified. Then the $c_{AB}(r)$ function is determined using the closure conditions. For the resulting function, the Fourier transform is found and used in the integral equation written in the k space for the calculation of the $\gamma_{AB}(k)$ function. The Fourier inversion is performed for the $\gamma^{out}(k)$ function found, and the process is repeated once again. The procedure of convergence can be accelerated by using various algorithms based on the Newton–Raphson method.^{97,98}

The integral equations can be analytically solved only for a very limited set of potentials and closures.⁹⁹ Despite the small number of such analytical solutions, they are useful for the modelling of structural and thermodynamic properties of solutions on the basis of simplified models. The most important example for polar liquids is represented by the Mean Spherical Approximation (MSA) in which the closure is described in the following form

$$\begin{aligned} h(r < d) &= -1, \\ c(r > d) &= -\beta u(r) \end{aligned} \quad (24)$$

where d is the diameter of the solid sphere.

With this closure, analytical solutions were obtained for solid spheres having an electric charge or a dipole moment.¹⁰⁰ The properties of the MSA allow one to obtain analytical expressions for the free energy of solvation and other thermodynamic values in ion–dipole systems.¹⁰¹ The model can be successfully used to study solvation in water–salt solutions.

In recent years, new calculation schemes have been developed (Three-Dimensional Interaction-Site Model, 3DRISM)^{102–108} in which the structure of the solvent near the solvated molecule is

Figure 1. Isovalse surface of the propane–oxygen of the MACF $g(r) = 1.5$ around the propane molecule.¹⁰²

determined by the molecular–atomic correlation functions (MACF) $g_B(r)$. These functions characterise the probability that atom B of the solvent molecule is found at point r , which is specified in the system of coordinates related to the solvated molecule. Figure 1 shows the sectional view of the MACF $g(r)$ isovalse surface for the propane molecule in water.¹⁰² An equation similar to Eqn (20) can be written for MACF,

$$\rho h_B(r) = \sum_A \int c_B(r) X_{AB}(|r - R|) dR, \quad (25)$$

where $c_B(r)$ is the ‘direct’ molecular–atomic CF. For $c_B(r)$, the HCA closure is constructed to relate $c_B(r)$ to $g_B(r)$. In fact, this assumes the additivity of action of the solvated molecule on separate atoms of the solvent molecule. Although $X_{AB}(r)$ is a radial function, the interaction potentials $u_B(r, \Omega)$ and $c_B(r, \Omega)$ depend, in the general case, not only on the distances but also on the orientation Ω with respect to the solvated molecule. The relations involved in the 3DRISM model, unlike the integral equation (20), represent a set of three-dimensional integral equations. The algorithm for the solution of the 3DRISM equation is similar to that described above and differs only by the fact that it requires performing calculations on a three-dimensional network and using the three-dimensional Fourier transform in order to find $\gamma(k_x, k_y, k_z)$.

Yet another modification of the method of integral equations is the study of the molecular correlation functions (MCF) $g_{AB}(r, \Omega)$,^{109, 110} which depend on both the distance between the centres of the molecules and the relative angular orientation of molecules. A ‘molecular’ integral equation similar to Eqn (19) can be written for MCF

$$\begin{aligned} \gamma(r, \Omega) &= h(r, \Omega) - c(r, \Omega) = \\ &= \rho \int h(r - R, \Omega_1) c(R, \Omega - \Omega_1) dR d\Omega_1. \end{aligned} \quad (26)$$

With this type of notation, one can avoid the problems caused by the choice of closure, because the diagram expansion method is naturally extended to the MCF. However, this gives rise to new problems associated with the increase in the dimension of integration in Eqn (26), which leads to a pronounced increase in the number of network points in the numerical approximation of the function $\gamma(r, \Omega)$. As a consequence, it becomes virtually impossible to find an analytical solution to Eqn (26). One way of avoiding the integration by angles is to expand the orientation-dependent CF into a series in eigenfunctions of the rotation operator $D_{\mu\nu}^{mnl}(\Omega_1, \Omega_2, \Omega_R)$. The presence of a particular symmetry group for the solvent particles can reduce significantly the number of expansion terms. In some cases, rather fast convergence of the series ensures a good result even with a relatively small number of terms.¹⁰⁹ Comparison of these results with the results of MC

Figure 2. Carbon–methyl correlation functions for acetonitrile;¹⁰⁹ (1) solution of the molecular integral equations, (2) calculation using the RISM equations, (3) MC calculation.

calculations showed close agreement of the data for acetonitrile (Fig. 2). However, the scope of this approach is limited; it can be successfully used only for highly symmetrical solvated complexes.

The main difficulty involved in the use of the method of integral equations is the complexity of its numerical implementation on a computer. In each particular case, it requires designing of special subroutines for different types of closure, potentials, *etc.*; moreover, there is no assurance that the developed algorithm will ensure convergence of the iteration procedure. However, the method of integral equations has also a number of advantages over the MC and MD calculations. For equally complex systems, the amount of calculation is 2 to 3 orders of magnitude smaller in this method than in the two other methods. Since the correlations that are calculated are considered to decay rapidly with an increase in the distance between the particles, the method can be formulated for finite spatial areas. The method does not imply the choice of a periodic spatial cell during the modelling, and the results are not subject to the influence of the boundary conditions. Using modern versions of the method of integral equations, calculations of the solvation can be performed for macromolecules comprising up to 10^3 atoms. Owing to the possibility of re-normalisation of the sought-for correlation functions, this method is also applicable to systems that are difficult to treat in terms of the MC or MD calculations. Examples are systems that incorporate solutes of complex shape or with a large electric charge, electrolyte solutions with low ion strengths, *etc.*

V. Electrostatic interactions in the Monte Carlo and molecular dynamics methods

The complexity of MC and MD calculations of the solvation in polar liquids is due to the fact that calculations are carried out for some limited volume of space (a cell); this may be associated with substantial errors due to the long-range character of the Coulomb forces. The use of periodic boundary conditions requires ‘cutting off’ the Coulomb potentials (usually, at a distance about half of the cell size). This distortion of the potential has only a weak influence on the radial dependence of the CF; however, it can change significantly the behaviour of the orientation correlations. The characteristics of cutting off the Coulomb potentials have been studied rather long ago. The interest in this effect was enhanced after publication of the paper¹¹¹ in which it was shown that this procedure gives rise to a false pattern of interaction of hydrated iron ions. With the cut-off Coulomb potential, likely charged ions were attracted at long distances, whereas calculation by the Ewald method⁸⁵ correctly predicted the asymptotic behaviour of the ions.

The Ewald and reactive field calculations are currently the best methods for taking into account the electrostatic interactions in solvation systems.^{112–114} The Ewald method first developed for the calculation of Coulomb interactions in ion crystals¹¹⁵ is considered to be the most consistent in the calculation of electrostatic potentials. In its modification for periodic molecular systems, the electrostatic energy (U) is expressed through the periodic Ewald pair potential $\varphi(\mathbf{R})$ (see Ref. 85)

$$U = \sum_{I < J} \sum_{\alpha\beta} q_{I\alpha} q_{J\beta} \varphi(|\mathbf{R}_{I\alpha} - \mathbf{R}_{J\beta}|) + \sum_{IJ} \sum_{\alpha < \beta} q_{I\alpha} q_{J\beta} \left[\varphi(|\mathbf{R}_{I\alpha} - \mathbf{R}_{J\beta}|) - \frac{1}{|\mathbf{R}_{I\alpha} - \mathbf{R}_{J\beta}|} \right] + \sum_{I\alpha} \frac{q_{I\alpha}}{2} \lim_{R \rightarrow 0} \left[\varphi(\mathbf{R}) - \frac{1}{R} \right]. \quad (27)$$

The subscripts α and β designate different atoms in different molecules I, J (of the solute or the solvent). The first two terms in this equation correspond to inter- and intramolecular electrostatic contributions to U . The last sum (this term is also called self-action) is a correction, which is necessary because in the point charge limit, the Ewald potential does not reproduce accurately enough the Coulomb potential within an area of the finite size. The sum of partial charges $q_{I\alpha}$ of all atoms disappears for electrically neutral systems. In this case, the use of the Ewald potential is the most justified. For charged solute–solvent systems, the self-action term turns into a constant which can be estimated from the condition

$$\lim_{R \rightarrow 0} \left[\varphi(\mathbf{R}) - \frac{1}{R} \right] = \frac{\zeta}{L},$$

where ζ is a constant equal, for example, to ~ 2.837297 for a cubic cell, L is the linear size of the modelling cell. The appearance of the constant ζ dependent on the modelling conditions is a flaw of the Ewald calculations and the problem related to it is still debated.^{116–121} However, for many applications, it is sufficient to calculate the energy U to within this constant.

The Ewald potential $\varphi(\mathbf{R})$ itself can be written down as a sum of two rapidly converging series

$$\varphi(\mathbf{R}) = \sum_n \frac{\text{erfc}(\eta|\mathbf{R} - n\mathbf{L}|)}{|\mathbf{R} + n\mathbf{L}|} + \sum_k \frac{4\pi}{k^2 L^3} \exp\left[-\frac{k^2}{4\eta^2} + ik\mathbf{R}\right] - \frac{\pi}{L^3 \eta^2}, \quad (28)$$

where η is a shielding parameter which controls the convergence and the relative contributions of the series. However, formally, the Ewald potential does not depend on the selection of this parameter, *i.e.*,

$$\frac{\partial \varphi(\mathbf{R})}{\partial \eta} = 0,$$

while the cell-averaged value of this potential is also equal to zero

$$\int_{L^3} \varphi(\mathbf{R}) d\mathbf{R} = 0.$$

The difference between the Ewald potential and the reactive field potential (see below) is in the way the charge distribution which compensates the total charge of the solvation system is specified. In the case of the Ewald potential, this charge is uniformly distributed over the cell chosen for calculations, whereas in the reactive field method, it lies on a sphere with the radius R_c around the solvated ion under consideration. The calculations^{85, 116–118} showed that in practice, the Ewald potential approximates rather closely the electrostatic interaction.

In the reactive field method, the electrostatic interaction is approximated by using the potential^{112–114}

$$\varphi(R < R_c) = \frac{1}{R} - \frac{1}{R_c} + \frac{(2\epsilon_0 - 1)(R^2 - R_c^2)}{(2\epsilon_0 + 1)R_c^3}, \quad (29)$$

$$\varphi(R > R_c) = 0.$$

The cut-off (at $R > R_c$) Coulomb interaction is modified by adding a surface field borrowed from the continuum theory. Actually, $\varphi(R)$ is the solution of the Poisson equation for the point charge located at the centre of a spherical cell with the size R_c immersed in a dielectric medium with the permeability ϵ_0 and the compensating surface charge on the cell surface. This approximation is used in the MD simulation of an ensemble of solvent molecules surrounding the solute.^{21, 22} In the calculation of the medium response field, the problem of finding the solvation energy is reduced to a hybrid computation (MD/CM) in which some of the molecules of the liquid (inside the chosen cell) are calculated (in the explicit form) by the MD method, while other molecules (outside the cell) are calculated using continuum models. Detailed description of the calculation algorithms on the basis of this hybrid discrete and continuum approach has been reported.¹²² The researchers have found that this protocol allows one to calculate the electrostatic contributions to the free energy of solvation to an accuracy of several kilocalories per mole.

VI. Hydrophobic effects

Noble gases and hydrocarbons are typical examples of hydrophobic solutes. Their poor solubility in water is due to the entropy loss related to the entropy of hydration, which counterbalances or exceeds the benefit in enthalpy.¹²³ The main difference between the hydrophobic and hydrophilic solutes is the fact that the former have no charged or polar groups, which shows itself as the absence of electrostatic contributions to intermolecular potentials.

Study of the hydration of hydrophobic solutes is associated with two problems.¹²⁴ First, adequate simulation of hydrophobic effects requires detailed information on the microstructure and thermodynamic state of water. This information is used as the input data for calculating the hydration. Water has a number of abnormal properties compared to other polar liquids; therefore, in the simulation of hydrophobic solutes, the choice of the molecular model of water and the calculation of its properties should be carried out with special care. The microscopic models of water specially designed for this purpose allow one to calculate rather accurately the thermodynamic parameters of solvation for simple hydrophobic solutes.¹²⁵ Figure 3 shows the temperature dependences of the chemical potential (μ) and its enthalpy (h) and entropy (s) contributions for a methane molecule hydrated under atmospheric pressure. It can be seen that calculated and experimental data agree both qualitatively and quantitatively.

Figure 3. Temperature dependences of the chemical potential (I, I') and its enthalpy ($2, 2'$) and entropy ($3, 3'$) contributions for a methane molecule hydrated under atmospheric pressure; ($I-3$) calculation,¹²⁵ ($I'-3'$) experiment.¹²⁶

The second characteristic feature of hydrophobic solutes is related to geometric factors and excluded volume effects. Depending on the size of the solute, these effects can be manifested in different ways.¹²⁷ For small hydrophobic solutes (such as atoms of noble gases) at low concentrations, the packing effects are associated with reorganisation of water around the solute without rupture of a large number of hydrogen bonds. For mesoscopic hydrophobic solutes (for example, globular proteins), solvation can result in the cleavage of a large number of hydrogen bonds, giving rise to a nonwetting area near the hydrophobic surface of the solute where water occurs in the vapour state.

As an example, we shall consider a spherical model of the solute with a large radius R , which resides in the excluded volume cavity having the same radius. For macroscopically large cavities, Gibbs free energy of solvation is described by the expression^{128, 129}

$$\Delta G \sim \frac{4\pi R^3 p}{3} + 4\pi\sigma R^2, \quad (30)$$

where p and σ are the hydrostatic pressure and the liquid–vapour surface tension coefficient, respectively.

By parametrisation,^{130, 131} this relation can be extrapolated to microscopic cavities which arise upon solvation of molecular species. The first term in relation (30) becomes negligibly small at normal pressures, and the σ value remains the only significant parameter to determine ΔG . In early publications (see, for example, Ref. 128), this parameter has still been interpreted as macroscopic surface tension, although a consistent formulation¹²⁹ interprets σ as a model parameter dependent on the solvent and the cavity size and shape. This approach, called the scaled particle theory, was modified to be applied to non-spherical cavities.^{132, 133} The modern version is based on the density functional theory,¹²⁷ where the free energy of solvation is expressed in terms of generalised water susceptibility $X(r, r')$ [see Eqn (21)]. The free energy of cavity formation in the solvent is called the cavitation energy. It is mainly of the entropy nature. In the absence of electrostatic interactions, the total energy of solvation consists of the cavitation and van der Waals contributions. The latter contribution is due to short-range interactions (which are usually described using Lennard-Jones parametrisation) and is largely an enthalpy effect. The peculiarity of the situation is that the cavitation and van der Waals contributions have opposite signs (Fig. 4). The magnitude of each contribution grows with an increase in the size of the cavity¹³⁴ (often, they are regarded as being proportional to the surface area of the cavity¹³⁵), whereas the overall effect is small ($\sim 2-3$ kcal mol⁻¹) and barely depends on the size of the cavity (at least, for hydrocarbons with a number of carbon atoms ranging from 1 to 6).

Yet another molecular model of the hydrophobic effect is formulated on the basis of the Pratt and Chandler theory¹³⁶ in terms of the integral equation method. This theory reduces determination of ΔG to the calculation of the AACF. It is closely related to the most developed molecular model of hydrophobic solvation, based on the information theory^{124, 137} and is actually a cavitation effect model. With this approach, the free energy of solvation ΔG of a non-polar solid particle is determined in terms of the probability p_0 of formation of a cavity with the corresponding size and shape in the bulk of the liquid

$$\beta\Delta G = -\ln p_0. \quad (31)$$

The probability p_0 can be found by computer simulation^{138–150} or in terms of many-particle correlation functions.¹³⁰ The following simple procedure is also efficient.^{149–152} One should consider the probability distribution $\{p_n\}$ for which the case $n = 0$ corresponds to the probability of formation of an excluded volume cavity [see Eqn (31)]. The p_n values for $n \neq 0$ are interpreted as the probabilities that n solvent (water) molecules are situated in the cavity. The zero, first and second probability moments $\{p_n\}$

Figure 4. Experimental values of the entropy (a), free energy (b) and enthalpy (c) contributions to the hydration of isobutane (1), 2-methylbutane (2), neopentane (3), cyclopentane (4) and cyclohexane (5); the line shows the approximation of the discrete values by some dependence.¹³⁴

$$\langle 1 \rangle = \sum_n p_n,$$

$$\langle n \rangle = \sum_n n p_n,$$

$$\langle n^2 \rangle = \sum_n n^2 p_n,$$

respectively, can be expressed in terms of values that can be measured experimentally, namely, the density and the generalised susceptibility of water. The distribution $\{p_n\}$ is simulated in the form

$$p_n = p_{0n} \exp(\lambda_0 + \lambda_1 n + \lambda_2 n^2), \quad (32)$$

where p_{0n} is the simplest ‘primer’ distribution, $p_{0n}(n < n_{\max}) = \text{const}$ and $p_{0n}(n > n_{\max}) = 0$, where the maximum number of particles in the cavity $n_{\max}$ is the distribution parameter.¹⁴⁵ The additional parameters, $\lambda_0, \lambda_1, \lambda_2$, are found from the condition of reproducing the three first probability moments $\{p_n\}$, which are specified as noted above. Expression (32) corresponds to the maximum of informational entropy with additional constraints imposed on the moments.¹⁴⁹ By constructing the entropy functional in such a way that the zero, first and second probability moments corresponded to experimental data, Vener *et al.*¹²² have found an expression for the free energy of hydration of noble gas atoms

$$\beta\Delta G \approx \frac{\rho^2 v^2}{\delta n^2}, \quad (33)$$

where ρ is the density of solvent (water) particles, v is the volume of the excluded volume cavity, $\rho v = \langle n \rangle$ is the average number of solvent particles in the cavity, $\delta n^2 = \langle n^2 \rangle - \langle n \rangle^2$ is the variance of the number of particles in the cavity. According to this approximate relation, the temperature dependence of the cavitation energy is determined by two factors, namely, the dependences $\langle n \rangle(T)$ and $\delta n^2(T)$. Relation (33) was confirmed by computer simulation of small-sized solutes;¹²⁴ however, the result is deteriorated with an increase in the size of the excluded volume cavity,¹³⁴ apparently, due to the excessively simplified (‘planar’) form of the function p_{0n} , chosen according to Eqn (32). The MC-

and MD-based simulation shows that, generally, the theory described above reproduces qualitatively the hydrophobic effect but does not provide a quantitative estimate of the temperature dependence of cavitation free energy for solutes of an arbitrary size.

Direct MD and MC calculations of thermodynamic functions are complicated and cumbersome. There are several algorithms efficient for the calculation of free energy, namely, the Umbrella Sampling, Thermodynamic Perturbation, and Thermodynamic Integration methods.^{16, 139–141} The last two methods are used most often; they are useful for the calculation of cavitation effects.^{134, 146} They differ only in procedural points and give the required result after a sequence of consecutive standard MC or MD calculations.

Let us consider, as an example, the use of thermodynamic integration for determining the change $\Delta G = \Delta G_{XY}$ of the free energy of a solvation system

$$G = \beta^{-1} \langle \exp(-\beta U) \rangle$$

caused by its transition from the initial state X to the final state Y upon transfer of a solute particle from the gas phase to the solution. Here U is the potential energy of interactions between the solute and solvent particles and interactions of solvent particles with one another. This value is regarded as a function of the coordinates of solvent particles. Averaging $\langle \dots \rangle$ should be carried out over an equilibrium ensemble of solvent configurations in the presence (Y) and in the absence of the solute (X). To carry out this calculation, an additional parameter λ , equal to zero in the state X and equal to unity in the state Y , is introduced in the potential U . This parameter acquires discrete values $\lambda_i = 0, \lambda_1, \lambda_2, \dots, \lambda_i, \dots, 1$ in the segment $(0, 1)$. Thus the change in the free energy ΔG can be calculated as follows

$$\Delta G = -\frac{1}{\beta} \sum_i \ln \langle \exp\{-\beta[U(\lambda_{i+1}) - U(\lambda_i)]\} \rangle_{\lambda_i} = \int_0^1 \left\langle \frac{\partial U(\lambda)}{\partial \lambda} \right\rangle_{\lambda} d\lambda, \quad (34)$$

where $U(\lambda)$ is the potential considered as a function of λ . Analogous relations can be obtained for the enthalpy and entropy contributions to ΔG . The change in the entropy ΔS is determined by the formula

$$-\Delta S = \beta \int_0^1 \left[\left\langle U(\lambda) \frac{\partial U(\lambda)}{\partial \lambda} \right\rangle_{\lambda} - \langle U(\lambda) \rangle_{\lambda} \left\langle \frac{\partial U(\lambda)}{\partial \lambda} \right\rangle_{\lambda} \right] d\lambda. \quad (35)$$

Thus, calculation of thermodynamic values includes a series of MC or MD computations with fixed λ_i followed by numerical integration according to Eqn (34) or (35). The values of the parameter λ can be varied not only by deterministic choice of the intermediate λ_i values but also in a stochastic way during the solution of MD equations^{153, 154} in which the variable λ is included as an additional degree of freedom.

The above-described thermodynamic integration method has been used to study the temperature dependence of the thermodynamic characteristics of the hydration of hydrocarbons.^{143, 144, 155} The functional dependence of the binding energy on the distance between the solute and solvent molecules has also been studied.^{156, 157} Computations performed by various researchers have now been reported^{134, 155, 158} where thermodynamic perturbation and thermodynamic integration procedures have been used for systematic study of the changes in the free energy, the enthalpy and the entropy upon hydration of lower alkanes containing one to six carbon atoms. The results of these calculations were compared with experimental results. However, it was found that the results of MC and MD computations can deviate from experimental thermodynamic data (Table 2), although generally they provide an adequate estimate of the relative changes in ΔG . For hydrophobic molecular solutes, the results of calculations can

Table 2. Experimental and calculated [by 3DRISM, XSOL (Extended Solvation), SMx, SCF and MC methods] values of free energy of hydration ΔG (kcal mol⁻¹) for various solutes.

be substantially improved by using the 3DRISM procedure and an additional empirical calibration of closure conditions.¹⁰⁴

To conclude the Section, we would like to note that, despite the many years of investigation of hydrophobic effects and the advances made due to the development of molecular models for the hydrophobicity phenomenon,^{124, 127, 129–136} the theory is still far from being completed because in the general case, hydrophobic behaviour is due not only to the type of interaction potentials or the solute geometry, but also to collective effects related to the entropy factor.¹⁶¹

VII. Solvation of ions

Solvation of ions is a trial for various molecular models, as it allows one to reveal the scope and drawbacks of one or another approach. The classical MC and MD models of solvation of monoatomic ions, as well as molecular solutes, make it possible to calculate the microstructure of the solvent around the ion; however, in the case of solvation energy, agreement with the experimental results is less satisfactory. Even accurate MD calculations based on the Ewald potential give deviations of up to 20% of the experimental values.¹⁶² Therefore, in recent years, calculations based on either hybrid and combined protocols (Table 3) or classical polarisation models have been actively carried out. In these procedures, the calculation of the solvation of monoatomic ions is a test routine for verification of the calculation scheme. The quantum corrections usually result in smoother AACF and smaller coordination numbers of the solvated ion (Fig. 5). Quantum calculations also give lower potential barriers for proton or electron transfer. This is clearly seen in relation to the hydrated proton (Fig. 6).

The spherical symmetry of monoatomic ions allows one to derive analytical expressions for the solvation energy within the bounds of different models of the medium. Comparison of these expressions clearly demonstrated the influence of the structure of

the solvent on the solvation effects. Let us consider particular examples of the calculation of free energy of solvation of an ion with the charge Q in a spherical cavity with the radius a .

According to Born,⁴ the medium around the cavity is characterised by an invariable dielectric constant, ϵ_0 , while the free energy of solvation is determined by the following relation:

$$\Delta G = -\frac{Q^2}{2a} \left(1 - \frac{1}{\epsilon_0} \right). \quad (36)$$

In this equation, the cavity radius a should be considered as some effective value. Direct use of crystallographic ionic radii gives unsatisfactory results. It has been shown¹⁷⁰ that for ions

Figure 5. Dependences of the atom-atom (Na-Na) correlation function $g(I, I')$ and the coordination number $n(2, 2')$ on the distance between the centres of the sodium ions solvated in ammonia.¹⁶⁸ The dashed line corresponds to the classical MD calculation and the continuous line shows the QM/MM calculation.

Figure 6. Free energy ΔF of the hydrated proton vs. its coordinate R relative to the midpoint of the O-O bond.¹⁶⁹ (1) energy at 300 K, (2) QM calculation, (3) MD calculation.

with a rather large size, relation (22) is converted into the Born formula with $a = r_{\text{max}}$, where r_{max} is the distance from the ion centre to the first maximum of the radial distribution function $g(r)$. The difference between the values of free energy of hydration of spherical ions found using the Born approximation and by direct solution of the RISM equations for Cl^+ and Cl^- ions is less than 12%.¹⁶⁰ By applying various corrections to formula (36), one can attain a satisfactory agreement between the calculation data and experimental results for a large number of monoatomic ions.^{50, 160, 171} The situation regarding the separation of the enthalpy ΔH and entropy $T\Delta S$ contributions to the Gibbs free energy

$$\Delta G = \Delta H - T\Delta S. \quad (37)$$

is less successful.

Even in complex calculations of the solvation effects, the use of experimental data on the temperature and pressure dependences of the dielectric constant $\epsilon_0(T, P)$ makes it possible to reach quantitative agreement with experimental thermodynamic data (see Table 3).

Direct MD and MC calculations for the free energies of solvation of polyatomic ions with non-spherical shapes have been reported.^{12, 172, 173} Successful implementation of these calculations requires that thorough parametrisation of the Lennard-Jones interaction between atoms of the solute and solvent particles be carried out. Apparently, the dependence of this parametrisation on the partial electric charge on atoms of the ionic solute should also be carried out.¹⁷⁴ However, the problem of selection of appropriate parameters is appreciably complicated by great scatter of experimental data obtained by different researchers for ionic systems.

For qualitative understanding of the solvation effects at the molecular level, it is expedient to continue with the discussion of the solvation models of spherical ions. In doing this, one can see that explicit allowance made for the molecular structure of the solvent changes the theoretical views on the free energy of solvation.

Figure 7 shows the scheme of the concentric two-sphere model of solvation.¹⁷⁵⁻¹⁷⁷ Inside a cavity with the radius a_1 , the dielectric constant is equal to unity, while in the outer region, outside the sphere with the radius a_2 , the dielectric constant is determined by the solvent and is equal to ϵ_0 . The intermediate space between the inner and outer boundaries contains a layer with ϵ_∞ (the optical dielectric constant). For this model, the free energy of solvation is equal to

Figure 7. Scheme of the two-sphere model of solvation.

$$\Delta G = -\frac{Q^2}{2} \left[\left(1 - \frac{1}{\varepsilon_\infty} \right) \frac{1}{a_1} + C \frac{1}{a_2} \right], \quad (38)$$

where C is the Pekar factor,

$$C = \frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_0}. \quad (39)$$

In the non-local extension of the Born model, the dielectric constant is specified by the function $\varepsilon(k)$. In this case, the following approximate relation holds:^{24–29}

$$\Delta G = -\frac{Q^2}{\pi} \int_0^\infty dk \frac{\sin^2 ka}{k^2 a^2} \left[1 - \frac{1}{\varepsilon(k)} \right], \quad (40)$$

while for the simple Lorentzian model of the dielectric function $\chi(\mathbf{k})$ [see Eqn (10)] with $\chi_0 = (1 - \varepsilon_\infty^{-1})/4\pi$, the following exact expression has been derived:³¹

$$\Delta G = -\frac{Q^2}{2} \left(1 - \frac{1}{\varepsilon_\infty} \right) - \frac{CQ^2}{2} \frac{1 + \sqrt{\varepsilon_0/\varepsilon_\infty} [\coth(a/\zeta) - \zeta/a]}{1 + \sqrt{\varepsilon_0/\varepsilon_\infty} [\coth(a/\zeta) - \zeta/a] + \sqrt{\varepsilon_\infty/\varepsilon_0} (\zeta/a)}. \quad (41)$$

In the MSA theory, according to which the solvent molecules are modelled as hard spheres with dipole moment m , the free energy of solvation is given by^{101, 178}

$$\Delta G = -\left(1 - \frac{1}{\varepsilon_0} \right) \frac{Q^2}{2a + \zeta}, \quad (42)$$

where a is the effective radius of the solute, ζ is the correction to radius a , which depends on the temperature and is expressed in terms of m or ε_0 as the solution of the non-linear Wertheim equation.¹⁷⁹

Relations (38)–(42) clearly demonstrate the influence of the solvent structure. In particular, in the last three models, the expression for the free energy of solvation is reduced to the Born formula (36) in the limit where the characteristic size of the solvent particles (the correlation length in the non-local models or the radius ζ in the MSA model) is much smaller than the radius of the solvated ion. The opposite limit is also of certain interest. Detailed discussion of these asymptotic expressions and their comparison with experiment have been reported^{176, 177, 180, 181} and supplemented by qualitative interpretation on the basis of molecular modelling.^{182, 183}

The solvation of polyatomic ions is also studied on the basis of integral equations using the RISM method. The calculations based on the molecular integral equations (25) are laborious and it was not until recently that they started to be actively used to study the solvation of polyatomic ions.¹⁸⁴ Note that even for an infinitely dilute solution, the standard RISM model should be modified for well-posed allowance for the dielectric shielding effects, because it results in a false estimate of the dielectric constant of the solvent. To eliminate this drawback, in the XRISM model,¹⁸⁵ it is proposed to renormalise the Coulomb interaction of ions in solution assuming that

$$u_c(r_{AB}) = \frac{Aq_A q_B}{r_{AB}}.$$

Here, the constant A is selected in such a way as to provide finally the required dielectric constant ε_0 . In practice, the constant A is determined from experimental data. Usually, it differs little from unity (for water, $A \simeq 0.98$), and this modification of the Coulomb potentials has only a slight influence on the thermodynamic parameters of the liquid. The XRISM calculations of the hydration of various ions provide qualitative agreement between the theory and experiment (see Table 3). Generally, these calculations give reliable information concerning various structural characteristics of hydrated ions. The activation energy ΔE for transfer of a water molecule from the region near the ion to the region of pure solvent has been calculated.¹⁶³ These data are consistent with experiment.¹⁶⁴

In the case of finite concentrations of solvated ions, the standard RISM and XRISM models lead to incorrect results, because the approximation of the linear response of the system to the external field created by a solvated molecule is violated. At low concentrations of ions, the plasma parameter

$$\zeta = \frac{l_B}{r_D}$$

[$l_B = e^2/(ek_B T)$ is the Bjerrum length, r_D is the Debye radius] is small and the linear response approximation is plausible. However, at high concentrations of solvated ions, the plasma parameter is no longer small (for NaCl concentrations of about 0.05 mol litre⁻¹ in water, $\zeta \simeq 0.5$). Hence, the ion-induced potential does not follow a linear dependence on the ion concentration and cannot be taken into account by mere renormalisation of the Coulomb interaction. For this case, the DRISM (Dielectric RISM) model has been developed;¹⁸⁶ in this model, the dielectric constant is included in the closure equation as the initial data. The calculations carried out using this model make it possible to estimate rather adequately the free energy and the salting-out coefficients for various concentrated salts.¹⁸⁷ It is noteworthy that DRISM calculations are needed in those cases where microscopic changes in the interaction of ions with a solvated macromolecule give rise to conformational rearrangements in the molecule, which involve rather large space.

In recent years, attempts have been made to use the 3DRISM models^{104, 107} or the method of molecular integral equations¹⁸⁸ to take into account the effect of the orientational correlations on the solvent structure near a polyatomic ion. Figure 8 shows the local structure of water around the Na⁺–Na⁺ ion pair calculated in terms of the 3DRISM model.¹⁸⁹ The deviation of the results obtained on the basis of this model from the results of MC and MD calculations is insignificant. Apparently, more accurate calculations could be carried out with appropriate calibration of the interaction potentials. Yet another promising route is to take into account the changes in the electronic structure of solvated ions caused by interaction with the solvent.

Figure 8. Molecule-atom ion-oxygen (a) and ion-hydrogen (b) correlation functions for the $\text{Na}^+ - \text{Na}^+$ pair in water.¹⁸⁹ The x, y, z coordinates of the sodium ions are $\pm 2.05, 0$ and 0 , respectively.

VIII. Polar molecules

The calculations of solvation for polar molecules are carried out in the same way as for ions. In the case of polar solutes, the effects of cutting-off the Coulomb interactions are usually neglected on the ground that the resultant electric field decays rather rapidly for these systems, *i.e.*, its potential

$$\varphi(R \rightarrow \infty) \propto R^{-n}, \quad n \geq 3,$$

Figure 9. Electrostatic potential φ near the polar solute in water.⁸⁵ (1) calculation by the Ewald method, (2) calculation for the cluster of 1024 water molecules by the standard MD method.

and the errors caused by the cutting-off effects are insignificant. However, accurate calculations for polarisable solutes¹⁹⁰ have shown that the way of cutting-off the potential $\varphi(R)$ still influences, although to a lesser extent, the induced charge of the solvent molecule and, hence, the calculated thermodynamic and structural properties of the system. Figure 9 shows the electrostatic potential around a polar solute in water.⁸⁵

The modern trends in such studies take into account the many-particle interactions caused by the solute-induced polarisation of the solvent and turn to polarisable models of polar liquids (see, for example, Refs 191–193). These models (unlike non-polarisable ones) permit well-posed simulation of various processes in biological systems: electron transfer, solvatochromic changes of the electronic and vibronic spectra, *etc.* The results of computation of various characteristics of water in terms of polarisable and non-polarisable models of the solute and those found experimentally are summarised in Table 4. Richardi *et al.*¹⁸⁸ carried out computations within the framework of the same molecular model of water but on the basis of different methods. It can be seen that approximation (29) simulates rather closely statistic and dynamic characteristics of liquid water; the calculation of pressure is faced with difficulties because this value is determined by the balance of repulsion and attraction forces between molecules and is sensitive to the way of cutting-off the Coulomb potentials.

Currently, the most reliable estimates of the free energy of solvation of polar molecules are based on continuum models. Comparison of the theoretical and experimental data has shown

that the difference between these values does not exceed 20%. This result is attained due to thorough parametrisation of models. However, at present, the continuum approaches tend to be upgraded, the modern phase in the modelling of solvation being characterised by active use of hybrid schemes. These schemes may include QM/MM computations²⁰² or the calculations in which some of the water molecules are explicitly taken into account, while other water molecules are taken into account in terms of a continuum approach.²⁰³ The results point to a higher efficiency of hybrid procedures compared to the conventional procedures of the continuum theory (see Table 2). For instance, calculations of the solvation of the $\text{Cl}^+ \cdots \text{Cl}^-$ complex based on a hybrid MD/CM model made it possible to estimate the electrostatic contribution to the free energy of solvation to within 1 kcal mol⁻¹ (see Ref. 122).

General equation (34) of the thermodynamic integration method can be regarded as an estimate for the change in the free energy related to the transition of the solvation system from one state to another; this change is described by the parameter λ . The selection of λ is rather free. It can be described as a multidimensional vector whose components correspond to different contributions to the free energy of the system. With this interpretation, thermodynamic integration is widely used for estimating the role of Coulomb contributions to the free energy of solvation (see, for example, Refs 83, 85). It can also be applied for estimating the changes in the free energy caused by quantum effects. For example, this procedure has been used²⁰⁴ to assess the quantum corrections to ΔG_s relying on the data of classical modelling as the initial conditions.

The method of integral equations also allows one to calculate the structural characteristics of solvation of polar molecules; however, the accuracy of the results obtained using the standard integral equations described above is much lower than in the MC or MD computations. This drawback is partially compensated by the relative ease of calculation of the solvation of large biomacromolecules. Thus for a fixed double helix conformation, RISM computations of hydration of a DNA fragment composed of 315 atoms²⁰⁵ and a mellitin molecule containing 436 atoms have been carried out.²⁰⁶ A calbindin molecule containing 722 atoms has been considered in a similar way.²⁰⁷ In the general case, the conformation of a biomacromolecule can be found by a self-consistent procedure based on hybrid calculations of the IMCF by the MC method and numerical solution of the RISM equations.^{208–211} At present, such calculations are carried out for peptides containing ~ 20 to 200 atoms. Figure 10 shows one of the conformations found for the hydrated C-peptide of ribonuclease A.²¹¹

Yet another version of hybrid calculations are those done for solvated molecules in which the electronic structure of the solute is calculated by quantum chemistry techniques, while the spatial

structure of the solvent is determined by the method of integral equations.^{212–220} Table 2 shows the results of calculations of ΔG_s on the basis of SCF–RISM computations (XSOL).¹⁵⁹ In this case, as in MC calculations, only qualitative agreement with experimental data is attained. As noted above, this is due to an ill-posed allowance made for the molecular orientations in the standard RISM procedure. Apparently, the results could be markedly improved by using the 3DRISM model or by solving the molecular integral equations. The conduction of such hybrid calculations has started only recently.^{217,218}

IX. Solvated quantum particles

In a study of solvation of a light quantum particle, an excess electron is considered most often. The interest in this type of studies is caused by two factors. First, such a quantum-and-classical hybrid system is convenient for demonstrating the potential of various hybrid schemes. Second, development of experimental procedures and the large amount of accumulated data on the behaviour of solvated electron (e_s) in various media²²¹ resulted in considering e_s as a unique test particle for testing the solution microstructure.

Early investigations of the solvated electron were based on the continuum approach;²²² it was assumed that e_s exists in a cavity surrounded by a dielectric medium with the constant ϵ . With this definition, the problem was reduced to the solution of the Schrödinger equation in the self-consistent field V_{ef} for the single-electron wave function $\phi(r)$. An alternative approach is to calculate the e_s characteristics on the basis of methods of the MC^{223–226} or MD quantum model (QMD).^{227–233} The application of these methods is based on the fact that the problem of the behaviour of a quantum particle in a liquid can be reduced to the equivalent problem of calculation of a classical polymer chain.²³⁴ A large number of calculations for the solvated electron in water,²²⁷ ammonia²²³ and metal–ammonia solutions²³⁵ have been reported. The results obtained are in good agreement with one another and correspond to experimental estimates. The modern studies also include SCF calculations, which take into account the discrete description of the solvent based on the method of integral equations.^{236–239} Detailed discussion of the application of these approaches has been reported;^{237,240} we will give only a brief outline of the calculation scheme. The interaction of the electron with molecules of the liquid results in redistribution of the solvent molecules, which is found from the electron–atom correlation functions $h_{\text{es}}(\mathbf{r})$ by solving integral equations²⁴¹

$$\rho h_{\text{es}}(\mathbf{R}) = \sum_j \int \int \omega_e(\mathbf{r}) c_{ej}(|\mathbf{r} - \mathbf{r}'|) \chi_{sj}(|\mathbf{r}' - \mathbf{R}|) d\mathbf{r} d\mathbf{r}', \quad (43)$$

where $\omega_e(\mathbf{r})$ is the electronic CF, which is a quantum analogue of the IMCF; $c_{ej}(\mathbf{r})$ is the direct electron–atom CF, $\chi_{sj}(\mathbf{r})$ is the generalised susceptibility of the pure solvent. The electron correlation function $\omega_e(\mathbf{r})$ is related to the electron wave function as²³⁷

$$\omega_e(\mathbf{r}) \simeq \phi^2(\mathbf{r})$$

and can be calculated by the variation method^{241,242} or by solving the Schrödinger equation with the potential V_{ef} .²³⁷ These studies of the hydrated electron (e_h) provide estimates for the energy and structural characteristics,^{241,242} which are in good agreement with experimental data: the calculated chemical potential e_h (see Ref. 241) differs from the experimental one²⁴³ by only 1%.

Yet another interesting example of the solvation of quantum particles is study of the bipolaron — two excess electrons that form a bound state — a ‘quasi-molecule’. Apparently, Feng *et al.*²⁴⁴ were the first to investigate this problem in detail for a number of liquids on the basis of the continuum approach. The numerical investigations by the MC method for water²⁴⁵ and for metal–ammonia solutions²³⁵ have shown that the bipolaron states are stable in water and in metal–ammonia solutions at a metal concentration of < 1%. As the concentration increases, the

triplet state of the bipolaron decays, which is observed experimentally as a sharp decrease in the magnetic susceptibility.²⁴⁶ On further increase in the metal concentration, bipolarons are clustered and the electrons become delocalised.^{235, 247}

Both solvated electrons and bipolarons were studied using a hybrid approach which included the calculation of the electron structure by the density functional method and the solvent structure by the method of integral equations.²³⁸ Table 5 presents the main energy parameters of the hydrated electron and bipolaron calculated by various methods, while Fig. 11 presents the electron–solvent correlation functions $g(r, \theta = 0)$ for a singlet bipolaron and an electron solvated in a model polar liquid consisting of hard spheres. Qualitative analysis has shown²⁴⁸ that in the general case, the free energy functional includes various factors. The entropy contribution involved in the excluded volume cavity around the solute decreases the average radius of the bipolaron and favours an increase in its bond energy. The contribution caused by dielectric shielding produces an opposite effect. The competition of two contributions determines the stability condition for the bipolaron. The electron–electron correlations also result in an increase in the entropy factor due to the effects related to the formation of an ‘exchange-correlation hole’ and finally promote an increase in the bond energy. The calculations showed that bipolaron singlet states are stable in most polar liquids under normal conditions (Fig. 12).

The simplest example of a solvated quantum particle is positronium (Ps). This neutral quasi-atom consists of an electron and a positron. Like atomic hydrogen, positronium has two spin states separated in energy, namely, a singlet state (parapositro-

**Figure 11.** Electron–solvent correlation function $g(r, \theta = 0)$ in the spherical coordinates for an electron (1) and a singlet bipolaron (2) solvated in a polar liquid as solid spheres with the radius $\sigma = 3.15$ Å and the dipole moment $m = 1.6$ D with the value $\rho\sigma^3 = 0.9$ (ρ is the average density of the solvent) at $T = 233$ K.²³⁸**Figure 12.** Diagram of bipolaron decomposition into single solvated electrons.²³⁸

Bipolarons are stable in the regions below the lines and decompose with temperature rise.

$\rho_0\sigma^3$: 0.8 (1), 0.9 (2), 1.0 (3).

nium) and a triplet state (orthopositronium). The interest in the study of this quasi-particle is related to the fact that, due to its electroneutrality, this particle can serve as a ‘probe’ for determining the character of molecular surfaces, the orientation of molecules in the liquid, and so on. Most often, continuum models are employed in the calculations of positronium. For example, a model taking into account the molecular structure of only the first coordination sphere of Ps has been considered.^{249, 250} Monte Carlo calculations for positronium solutions²⁵¹ and for distribution of the Ps density in water have also been carried out.²⁵² A hybrid scheme for the calculation of hydrated positronium including self-consistent DFT computations of the distribution of the Ps density and the calculation of water microstructure by the method of integral equations has been developed.²⁵³ The obtained results are consistent with experimental data. Figure 13 shows the Ps–H and Ps–O atom–atom correlation functions calculated for normal conditions. The form of these functions is typical of neutral solutes; however, in the case of positronium, they are smoother than in the case of neutral atoms. The procedure similar to that described in the study cited²⁵³ is fairly versatile and can be used for solving a broad range of problems related to the study of solvated positronium.

**Figure 13.** Correlation functions Ps–H (1) and Ps–O (2) for the positronium hydrated at room temperature.²⁵³

X. Tautomeric and conformational equilibria

The main goal of most molecular models of solvation is to study the conformational, tautomeric and other transformations of the solutes and to elucidate the conditions of formation of their dimers or other complexes. The scope of application of molecular models is very broad; therefore, without going into details, we

would only note characteristic features of the computation protocols involved.

Examples of application of the molecular models of solvation were given in the review.⁴⁰ This list is not exhaustive but continuum approaches clearly predominate. They are included in most packages of quantum-chemical programs and are most important in the study of binding of various ligands to the solute and in the studies related to the problem of 'recognition' in biomacromolecular reactions.^{254, 255}

In the case of continuum methods, several preferable schemes can be distinguished. Comparison of the calculations of the conformations of various peptides has shown²⁵⁶ that the GBSA model and the continuum calculations based on the solution of the Poisson – Boltzmann equation are best suited for the modelling of conformations. The corresponding estimates of the energy of conformational transitions give an error not exceeding 1–2 kcal mol^{−1} (see Ref. 256). The continuum models with distance-dependent $\epsilon(r)$ are less suitable for these purposes. The accuracy of calculations in terms of the GBSA model depends appreciably on the approximation of the cavity.⁴⁰ The calculations in which the whole region occupied by the solute is approximated as a single spherical or ellipsoidal cavity produce unrealistic results.

At present, various hybrid methods are used in which the electronic structure of the solute is calculated without taking into account the medium, then charge distribution on the solute is determined and, finally, the local structure of the solvent for the resulting charge distribution is calculated in terms of the MD or MC procedures.²⁵⁷ Unlike the continuum approaches, these calculations allow, in principle, not only estimation of the energy of conformational transitions and stability of the conformers but also determination of the enthalpy and entropy contributions to ΔG and the temperature dependence of the conformational transitions. They also provide the possibility of determining the accuracy of the classical molecular models. Comparison of the calculations using classical and hybrid models has shown, in particular, that the former give unsatisfactory results in the study of solvation of transition metal ions and polarisation of the solute molecule, while the latter produce more realistic results.²⁵⁸

In recent years, studies have been reported (see, for example, Refs 212–214) in which solvation was calculated in terms of a hybrid self-consistent procedure where the electronic structure of a conformer or a tautomer was calculated by quantum-chemical methods and the solvent microstructure was calculated by solving integral equations. These RISM – SCF models allow one to study chemical reactions in molecular liquids. The calculations were carried out for solute isomerisation in water^{213, 220} and tautomerisation in acetylacetone.²¹⁹ The absolute values of the solvation parameters determined on the basis of integral equations do not always correspond to experimental data; however, such estimates

are rather efficient for predicting thermodynamic and structural characteristics of the solvated complexes in various reactions (Table 6). In general, they are markedly more accurate than continuum models and almost as accurate as hybrid methods.

XI. Electronic spectra and solvatochromic shifts

The most detailed simulation of electronic spectra was carried out for the solvated electron. The absorption spectra of the solvated electron in ammonia,²²⁴ methanol,²⁵⁹ water²²⁵ and heavy water²³² were calculated. The resulting dependences of the absorption maximum and the peak width on the temperature and solvent density are in quantitative agreement with experimental results. The isotope effects²³² and the dynamics of variation of the spectrum²⁶⁰ have been studied in terms of nonadiabatic²⁵⁹ and adiabatic²²⁴ MD calculations. Simulation of the spectra of the solvated electron by the method of integral equations has been reported. These calculations also reproduce adequately the influence of temperature and ion concentration on the pattern of the absorption spectrum.²⁶¹ Figure 14 shows the calculated and experimental values for the shift of the absorption maximum of the hydrated electron in aqueous solutions of LiCl, MgCl₂ and LiClO₄.

Figure 14. Shift of the maximum in the absorption spectrum of the hydrated electron in water – salt solutions depending on the salt concentration;

(1) calculation,²⁶¹ (2) experiment.²⁶²

Study of the solvatochromic shifts occupies an important place, especially in organic chemistry. There exists a correlation between the solvatochromic shift and the rates of chemical reactions in polar solvents.^{1, 263} The possibility of constructing polarity scales and using chromophores as probes for determining the relative polarity of the solvent has long been discussed.¹ The data obtained in this way provide much more detailed knowledge of the intermolecular potentials than conventional dielectric measurements, as solvatochromic shifts are sensitive to both electrostatic and short-range interactions.

We will briefly discuss some features of calculation of these shifts using betaine-30 as an example. The simplest approach used is based on the mean-spherical approximation,²⁶⁴ according to which the solvatochromic shift (ν_s) and the free energy of solvation (ΔG) are related as follows

$$\nu_s = \Delta G \frac{m_e(m_g - m_e)}{a^3}, \quad (44)$$

where m_e and m_g are the dipole moments of the solute in the ground and excited states, respectively. The free energy of solvation depends, in turn, on the size of the solute a and the dielectric constant of the liquid

$$\Delta G = f(\epsilon, a),$$

Table 6. Thermodynamic characteristics (kcal mol^{−1}) of some reactions for solute molecules.

Reaction	Solvent	ΔG	ΔH	$T\Delta G$	Ref.
Tautomerisation of acetylacetone	H ₂ O	−1.37 (−0.98)	−6.05 (2.7 ± 0.3)	−4.6 (3.7)	219
	DMSO	0.14 (0.29)	0.55 (1.8 ± 0.2)	0.41 (1.5)	219
	CCl ₄	0.11 (1.74)	1.02 (2.5 ± 0.3)	0.91 (0.8)	219

Note. The values in parentheses are experimental results.

the calculation of the function $f(\epsilon, a)$ according to the MSA method presents no difficulty.²⁶⁵ Using this approximation and relation (44), the solvatochromic shifts of betaine-30 in 110 solvents were found;²⁶⁴ the average deviation of the calculated values from experimental ones did not exceed 10%. It should be emphasised that two important points were taken into account, namely, the change in the dipole moment of the solute upon optical excitation and the predominant role of electrostatic interactions between the solute and the solvent.

It was shown using simple estimates²⁶⁶ that the contributions of the dispersion and induction interactions are also significant for the calculation of solvatochromic shifts. However, the results of calculation for betaine-30²⁶⁷ where these interactions were taken into account indicate that electrostatic interactions play crucial role in the appearance of this shift, which is mainly determined by the change in the dipole moment of the solute. The simplest approximation that assumes proportionality between the solvatochromic shift and the dipole moment²⁶⁷ leads to satisfactory results consistent with experimental data, although it is less accurate than hybrid calculations (Table 7). Shoeib *et al.*¹⁷² have attempted to include additionally the contribution of the electron polarisation of the solute by means of an appropriate renormalisation of the free energy of solvation. However, comparison of the data obtained by Chong and Hirata¹⁶³ with the results of hybrid calculations²⁶⁷ has shown that for this method, the role of electron polarisation is overestimated. According to calculations,²⁶⁷ the contribution of the electron polarisation to the solvatochromic shift does not exceed 5%.

Table 7. Solvatochromic shift (cm^{-1}) for betaine-30 in various solvents according to experimental data²⁶⁸ and calculations by various methods.^{172, 267}

Solvent	Experiment	Calculation by		Calculation by Eqn (44)

Ethanol	2170	3070	—	2110
Methanol	2140	3570	2930	2510

^a Semiempirical quantum-chemical calculation.

In some publications, the solvatochromic shifts have been studied in terms of hybrid models.^{269–271} Detailed self-consistent calculations²⁷¹ demonstrated that accounting of the solvent can be restricted to the first coordination sphere of the solute (Fig. 15).

Finally, we will consider the dynamics of Stokes shifts. Continuum models are successfully used to study the dynamics of solvation phenomena; the complex dielectric constant $\epsilon(\omega)$ is used in these cases as a dynamic characteristic. Simple models^{272–274} have used the Debye parametrisation

$$\epsilon(\omega) = \epsilon_{\infty} + \frac{\epsilon_0 - \epsilon_{\infty}}{1 - i\tau_D\omega},$$

where ϵ_0 and ϵ_{∞} are the static and optical dielectric constants of the solvent, τ_D is the Debye relaxation time for the spherical approximation of the shape of the solute. There are different ways of modernisation of the Born model: more complex multimode parametrisation of the dielectric function, allowance made for the non-spherical shape of the solute molecule, account taken of the non-local electrostatic effects (as noted above, the last-mentioned point allows one to include the molecular structure of the solvent in the calculation scheme). The influence of the solute shape on the dynamics of Stokes shifts was first studied for the ellipsoidal cavities around the solute molecule^{275, 276} and then for cavities

Figure 15. Calculated solvatochromic shift (Δ) vs. the number of solvent molecules (N) included in the quantum-chemical calculation.²⁷¹ (1) H_2O , (2) cyclo- C_6H_{12} , (3) C_6H_6 , (4) CCl_4 ; the dark dots show the data for the first coordination sphere of the solute.

having an arbitrary shape.^{277, 278} The molecular structure of the solvent was studied within the framework of the MSA method^{279–281} and by other methods,^{282, 283} and also using non-local models.²⁸⁴ However, in all of these calculations, the solute was assumed to be spherical. Early studies were mainly concerned with the asymptotic behaviour of the temporal correlation functions and the possibility of determining these functions from experimental data using the Stokes shift.^{272, 273, 276, 282, 283} The calculation could be improved if the data on the behaviour of the dielectric function in the region of medium and high frequencies, especially in the far infrared range, were available.^{275, 278, 285} An upgraded continuum model has been used to perform a systematic study²⁸⁶ of the influence of various factors on the dynamics of the Stokes shifts. In particular, the influence of the solute shape was studied in terms of single- and two-sphere models of the cavity surrounding the solute;¹⁷⁷ the intermediate spherical layer simulated the first coordination sphere of the solute. Yet another factor affecting the Stokes shift is related to the non-local effect.^{31, 33} The simpler models of the cavity predict simple monoexponential kinetics of the shift for Debye solvents where a single relaxation mode of the medium is considered.^{273, 274} This drawback is eliminated by taking into account either non-sphericity of the cavity^{275, 276–278} or the multimode relaxation of the medium. In the latter case, the kinetics²⁸⁶ is polyexponential and the results of calculations based on the local approach depend only slightly on the shape of the cavity. These calculations adequately reproduce the experimental data in the case where detailed information on the change in the dielectric constant is used as the input information.^{275, 278, 286}

A more complex situation arises when the MSA model and the non-local theories are used. Even for Debye solvents and spherical solutes, the calculations lead to polyexponential kinetics.^{279–281, 286} The local and non-local models produce different results. In non-local models, the oscillations of the correlation functions in the $0.1 \text{ ps} < t < 1 \text{ ns}$ range are smoother than in local approaches. These oscillations, which are not typical of the changes in the Stokes shifts observed experimentally, arise in all local models irrespective of the approximation of the solute shape. Another important difference is related to the asymptotic behaviour of the correlation functions. Non-local models yield much longer relaxation times than local models.²⁸⁶

XII. Electron transfer

Electron transfer plays a key role in many chemical and biological processes,²⁸⁷ and study of the electron transfer occupies an important place among applications of the molecular models of

solvation. The most important characteristic of this process is the rate constant for transfer K_{et} . In the Frank–Condon approximation in which the matrix element of the electron transition V_{et} does not depend on the nuclear coordinates, the constant can be found from the following equation:^{287–289}

$$K_{\text{et}} = V_{\text{et}}^2 \sqrt{\frac{\pi\beta}{E_{\text{r}}}} \exp\left[-\frac{\beta(\Delta F^\circ + E_{\text{r}})^2}{4E_{\text{r}}}\right], \quad (45)$$

where E_{r} is the reorganisation energy, ΔF° is the free energy of the reaction. The reorganisation energy is composed of the inner-sphere (*i.e.*, related to the internal degrees of freedom of the solute) and the outer-sphere (*i.e.*, related to the rearrangement of the solvent structure) components. In the continuum approach for spherically symmetrical charge distributions on the donor and the acceptor, outer-sphere reorganisation energy is often found from the equation²⁸⁷

$$E_{\text{r}} = C\Delta q^2 \left(\frac{1}{2a_{\text{A}}} + \frac{1}{2a_{\text{D}}} - \frac{1}{R_{\text{DA}}} \right), \quad (46)$$

where C is the Pekar factor, Δq is the charge being transferred, a_{D} and a_{A} are the effective radii for the donor and the acceptor, and R_{DA} is the distance of transfer. There exist numerous procedures for extending expressions (45) and (46) that take into account the real shape of the solute, quantum effects, deviations from the Frank–Condon approximation, and so on.²⁹⁰ In particular, for the intramolecular transfer of an electron, the influence of high-frequency quantum modes of the solute is commonly taken into account in an explicit form.^{291–298} However, in this case, too, the reorganisation energy E_{r} and the matrix element V_{et} still remain the key characteristics of the electron transfer. The problem is to elucidate the dependence of these values on the molecular and thermodynamic parameters of the surrounding medium. Here we discuss only aspects of the electron transfer concerned with its simulation on the basis of microscopic models and upgraded continuum theories.

Some effects cannot, in principle, be taken into account within the bounds of the continuum electrostatic models of the medium. These include, for example, the temperature dependence of the reorganisation energy. It can be included in a standard continuum calculation only through the temperature dependence of the dielectric constant of the solvent. However, this type of modelling is inefficient: the reorganisation energy really decreases with temperature rise,²⁹³ whereas the theoretical estimate based on the data on the dielectric constant predicts an increase in this energy. The error of calculation is due to neglect of the temperature dependence of the size of the cavity occupied by the solute. The size and the shape of the cavity are fixed in the continuum calculation and only transition to the molecular description of the solvent provides the possibility of reproducing the desired effect.

The continuum theory (in the local electrostatic variant) also cannot explain the presence of a noticeable outer-sphere reorganisation energy in non-polar solvents (benzene, dioxane, *etc.*), whose molecules are devoid of a permanent dipole moment. In these media, $\varepsilon_\infty = \varepsilon_0$ and the Pekar factor C is equal to zero, while the reorganisation energies found experimentally are equal to 0.1–0.2 eV.²⁹³

The simplest way of correcting the continuum calculations is to use the mean-spherical approximation for the solute model as hard spheres with an electric charge (on the solute) or a dipole moment (for solvent molecules). This approximation allows one not only to calculate the reorganisation energy but also to estimate correctly its temperature dependence (Table 8); however, its use is restricted by the assumption concerning the spherical shape of the solute inherent in the MSA theory. This version of the MSA model has also been used^{296,297} to study the reorganisation energy for the same solute (approximated by a sphere) in a series of solvents with different polarity including non-polar solvents.^{296,297} An alternative way of upgrading the continuum theory²⁹⁸ is to detail

Table 8. Calculated and experimental temperature characteristics of the free energy of solvation (ΔG) and reorganisation energy (E_{r}) for (tetrahydro-4H-thiopyran-4-ylidene)propanedinitrile dissolved in acetonitrile.²⁹³

Model	$a/\text{\AA}$	$\Delta G/\text{eV}$	$\frac{T\partial E_{\text{r}}}{\partial T}/\text{eV}$	$\frac{T\partial \Delta G}{\partial T}/\text{eV}$
Continuum	4.52	4.64	0.03	0.10
MSA	4.50	4.39	−0.19	0.37
Experiment	—	—	−0.23	0.32

the dielectric model of the medium. The solute is assumed to be surrounded by two cavities with different dielectric constants, namely, high-frequency and static ones (see Fig. 7). The cavities are constructed in the same way as in the PCM method. The modernised model explicitly takes into account the electronic structure and the real shape of the solute and implicitly, the molecular structure of the solvent in terms of the parameters of the cavity, *i.e.*, the dielectric constants and the atom radii r_∞ and r_{in}

$$r_\infty = kr_{\text{vdW}}, \quad (47)$$

$$r_{\text{in}} = \delta + r_\infty,$$

where k is a universal scale factor, r_{vdW} is the van der Waals radius, and δ depends on the particular solvent. This model can be used to calculate the reorganisation energy and the matrix element of transfer if these values depend little on the details of molecular structure around the solute. The optimal k and δ values are found by comparing the theoretical and experimental values for the free energy of solvation of small polyatomic ions.²⁹⁸ The k and δ values obtained in this way were used to calculate the reorganisation energies for many reactions of intramolecular electron transfer in steroid compounds.²⁹⁹ The results of calculations are consistent with experimental data,²⁹¹ which cannot be reproduced in the single-cavity model.^{300–302} However, like other continuum theories, this method cannot describe the temperature dependence of the reorganisation energy.

The method of integral equations also allows one to take into account, in an explicit form, the discrete pattern of charge distribution on the solvent molecules. The reorganisation energy E_{r} was calculated, in terms of the RISM theory,¹⁷² for betaine-30 solvated in various polar liquids. The results of calculations¹⁷² are in qualitative agreement with experimental data. Yet another line in the research into electron transfer related to the effect of the molecular structure of the solvent on the reorganisation energy is represented by studies performed by MD calculations.^{303–306} These works dealt with calculations of the diabatic surfaces of free energy, whose intersection area determines the transfer rate. In the macroscopic Marcus theory,³⁰⁷ the potential surfaces of the reactants and products are parabolic. The MD calculations³⁰⁵ have shown that the free energy surfaces found are close to parabolic surfaces, but under certain conditions, the reaction system behaviour can markedly deviate from the predictions of the Marcus theory [see Eqns (45) and (46)]. The deviations are great in the case of polarisation of neutral solutes,^{308–310} *i.e.*, in charge separation processes. They have also been observed for charged asymmetrical systems with different structures of the donor and acceptor centres.³¹¹ The deviations are assumed to be due to two compensative factors, namely, electrostriction and dielectric saturation, both being dependent on the charge of the reactants.³¹² The MD calculations of the reorganisation energy have now been carried out for several simplified model systems of electron transfer^{311–316} and for complex systems that mimic the electron transfer in proteins.^{317,318} Compared with routine MD calculations, these calculations require accurate handling of Coulomb interactions (see Section V) and taking into account electron polarisation. The latter is usually simulated by renorm-

alisation of the reorganisation energy by changing the Pekar factor C .³¹⁷

The calculation of the matrix element V_{et} requires thorough quantum-chemical calculations.^{292, 319} The result is sensitive to the choice of the initial and final diabatic electronic states between which the transition takes place. It is recommended to localise these states by the generalised Mulliken–Hush method according to which they are determined by diagonalisation of the matrix of the dipole moment of the electron transition.^{290, 320} An alternative method invariant with respect to the choice of the basis states has also been formulated.²⁹⁹ For complex biochemical objects, direct quantum-chemical calculation of the matrix elements V_{et} is impossible; therefore, it was proposed to estimate this matrix element by calculating the quasi-classical tunnelling flow of probability.^{321–324}

The number of works dealing with the effect of the solvent on the matrix element V_{et} is relatively low (see the review²⁹²). These calculations are based on upgraded continuum models²⁹⁹ or molecular schemes,³¹⁷ which allow one to determine the contribution of the effect of the molecular structure of the solute (conformation and effective radius) on the V_{et} value. This is exemplified in Table 9, which presents the results of calculation of characteristics of the electron transfer for a number of model $(\text{CH}_2)_n^-$ anions. The results confirm the tendency of V_{et} for exponential decrease following an increase in the distance R_{DA} between the donor and the acceptor, which has been discussed in the literature.²⁹⁰

Table 9. Calculated characteristics of electron transfer for a number of model $(\text{CH}_2)_n^-$ anions with the linear structure.²⁹⁹

n	E_{r}/eV	$\Delta F/\text{eV}$	$10^3 V_{\text{et}}/\text{eV}$	$R_{\text{DA}}/\text{\AA}$

XIII. Conclusion

The examples considered above of the use of molecular models for the study of solvation in polar liquids permit one to estimate qualitatively and, in some cases, even quantitatively the influence of the solvent on the change in the structural and thermodynamic properties of solvated particles and to study the physicochemical processes that accompany solvation. In essence, the molecular approach is meant to take into account two factors. The first one is mainly of entropic origin and is related to the excluded volume effect and the packing of molecules in the nearest environment of the solute particles. It is a consequence of the finite size of these particles. The second factor is due to the finite size of the solvent particles that interact with the solute. Both factors were ignored in the early solvation theories. In the modern continuum theories, the former factor is consistently taken into account, in particular, the size and shape of the solute are considered explicitly by specifying an excluded volume cavity in the continuum medium. This description is valid in the asymptotic limit

$$\frac{\text{size of the solvent particles}}{\text{size of the solute particles}} \ll 1$$

The theories that are commonly called molecular are beyond the scope of this restriction.

In the simplest molecular models of solvation, the solute and solvent particles are considered to be spherical, with point charges or dipoles at the centre of the sphere. At this level of description, it is usually possible to obtain analytical expressions or semianalytic

algorithms for the calculation of the response field, the solvation energy and other values. Abandoning of the spherical approximation, which is absolutely necessary for calculating real systems, inevitably converts the model physical theory into a cumbersome computation procedure. The computations are least cumbersome in the continuum approximation, whereas the use of ‘truly’ molecular calculations (MC or MD) increases the computational burden by a factor of 10^3 or more. The calculations of the correlation functions by the method of integral equations occupy an intermediate position, as regards laboriousness, in the series of modern computational methods of the solvation theory.

It is noteworthy that the structure of the medium can be ignored if the difference between the solute and solvent particles is much greater than the size of solvent particles. In this case, one can use hybrid schemes, which smoothly ‘sew together’ the continuum and molecular modes of the description of solvation effects and thus reduce the computational burden without substantial decrease in the reliability of the results obtained.

It is shown using particular examples that molecular models can be efficiently utilised to study various solvation systems ranging from salt solutions to dissolved biomacromolecules. The possibility of developing hybrid schemes in order to take into account changes in the conformation and the electronic structure of molecules in the solvent extends the scope of application of molecular models. The prospects of nanotechnology are associated with the study of a large number of complex liquids, which are characterised by high microheterogeneity and diverse supramolecular architecture which arises on the mesoscopic scale.³²⁵ The molecular models can serve as peculiar probes in the study of these mesoscopic structures, and new interesting results may be expected in this field.

IV. Supramolecular concept in the theory of eutectics	765
V. Conclusion	767

Abstract. The main concepts of the theory of eutectics are analysed. The most essential results of investigations on eutectic alloys of inorganic compounds are surveyed. Evidence in favour of the supramolecular concept of eutectics is presented. This concept takes into account interactions of incommensurate substructures and gives an insight into the mechanisms of formation of supramolecular eutectic assemblies in boundary regions ('non-autonomous phases'). Using the static one-dimensional Frenkel–Kontorova model for finite systems, it is shown that the consideration of these mechanisms in terms of supramolecular chemistry simplifies analysis of the behaviour of inorganic eutectic systems in the course of crystallisation under conditions both close to and far from equilibrium, including crystallization upon quenching and under external actions. The supramolecular concept bridges gaps between the definitions 'compound', 'eutectic' and 'solution' in physicochemical analysis. The bibliography includes 83 references.

I. Main concepts and state-of-the-art in the theory of eutectics

Theoretical views of the nature of eutectic alloys were formed more than 80 years ago. Since then these views have gained wide acceptance. However, authors of a number of papers and monographs (see, for examples, Refs 1 and 2) stated their justified belief that the theory of eutectics is inconsistent with up-to-date knowledge. Thus, this theory fails to explain the fact that eutectics have low melting points, leaves unexplained the mechanism of the initial step of melting and gives no clear answer to the question as to why a 'mixture' of crystals of two compounds is molten and crystallises at the same temperature.² A sharp increase in the mutual solubility of components as the eutectic temperature passes through the liquidus line is inconsistent with the known

data that melting leads to only small changes in interatomic distances (melting of many metals and salts is even accompanied by a decrease in interatomic distances³).

Numerous studies of eutectics can be divided into three main groups. The first group involves data on the structures and morphology of eutectics (including attempts to classify eutectics). The second group includes theoretical studies of possible mechanisms of solidification of eutectic materials of different types. Results of recent studies of interphase and intergrain boundaries and structures of melts belong to the third group. Micromorphological structural features of eutectic composites ('eutectic grains' or 'colonies'^{4–6}) were most extensively studied in the 1920s–1980s.

Different classifications of eutectic structures were proposed. These classifications were presented in many reviews (see, for example, Refs 1, 4 and 5). However, attempts to combine these classifications into a single system failed because all known reviews were based on phenomenological data, which, generally, ignore many important factors, such as the chemical nature and structures of individual compounds, the degree of their chemical interaction, temperature and concentration parameters, conditions of crystallisation and cooling. That is why much recent attention has been focussed on investigations of particular objects. Nevertheless, early studies revealed certain general formal tendencies. For instance, it was demonstrated⁴ that crystal nucleation of eutectic phases occurs separately in organic systems solidified at relatively small supercooling: '...both crystals grow as though these processes were independent and crystal growth proceeds until the liquid completely disappears'.⁴ The so-called 'rough conglomerate of phases' is thus formed. In the second mode of growth typical of inorganic systems, nuclei appear at the contact interface of both phases. In the latter case, the basic phase gives rise to a coupled growth of colonies on a bicrystalline base. Taran¹ believed that this idea carries 'the germ of correct understanding' of the whole process of formation of a eutectic colony, *e.g.*, the colony is a product of crystal formation occurring in contact, *i.e.*, of cocrystallisation of two eutectic phases.

The best known classifications are those proposed by Brady,⁷ Portevin,⁸ Scheil⁹ and Hant and Jackson.¹⁰ Scheil's classification has gained wide acceptance. In this classification, the author attempted to take into account both morphological features and the assumed differences in the mechanism of crystallisation of eutectic alloys. All structures are classified into three groups, *viz.*, normal, degenerate (or separated) and anomalous. All eutectics characterised by the ordered arrangement of phases, *viz.*, lamellar, rod and globular, are assigned to normal structures. These eutectics have a colony structure, and individual colonies can

always be separated by boundaries. The order appears due to the coupled growth of phases. The eutectic class depends on the rate of cooling. Very slow cooling can lead to 'degeneration of coupled growth', and eutectic phases crystallise separately to form degenerate (or separated) structures. Finally, there are systems in which coupled growth cannot take place at all (anomalous eutectics).⁹

In recent years, the terminology proposed by Brady⁷ has found ever-increasing application to the description of the eutectic morphology. Brady took the surface tension of components as the main classification criterion and classified eutectics as globular (both components have high but different surface tensions), lamellar (both components have high and approximately equal surface tensions), polygonal (one of the components has a substantially higher surface tension than another component) and crystalline (both components have low surface tensions). In the discussion of the morphology and structures of eutectic alloys, let us cite the conclusions made by Taran¹ after detailed analysis of the available classifications and abundant factual data. These conclusions concern not only the structures of eutectic colonies but also the mechanisms of their formation for interacting systems.

1. A colony can occur as a finely crystalline mixture of two phases (*i.e.*, a 'mechanical mixture of phases').

2. A colony can consist of a matrix built from the basic phase and inclusions of numerous crystallites of another phase. The basic phase is characterised by high entropy of melting and, correspondingly, by high surface tension at the interface with the melt. The development of a colony is accompanied by coupled growth of dispersed crystals and the matrix.

3. A colony contains two intergrown branched crystals of eutectic phases. The centre of the colony is the site of primary contact between the nucleated crystals. The formation of colonies occurs through their coupled growth.

As mentioned above, the structural features of crystallised eutectic alloys depend on the conditions of crystallisation of the system. The classical theory of crystallisation is based on studies by Gibbs and Volmer,^{11–13} who introduced the notion of metastable systems and constructed the apparatus of thermodynamics of phase interfaces. This theory is beyond the scope of the present review because it has been outlined in numerous handbooks and monographs. Let us only note that the Gibbs–Volmer theory does not allow one to predict the structures of crystallised multi-component alloys and determine the morphology of co-crystallised phases. This theory did not find application in the theory of eutectics, although the consideration of a eutectic alloy as a mechanical mixture of phases and the views of the separate crystal growth of each phase are seemingly consistent with the model implied in this theory. In our opinion, the reason is that the real crystallisation conditions very rarely satisfy the requirements of the thermodynamic model.

Presently, the less known concept of the phase field is used in many studies (including those devoted to the mechanisms of crystallisation of eutectic alloys). This concept has been proposed approximately simultaneously with the classical Gibbs–Volmer theory of phase interfaces. The phase-field approach is based on the assumption that a liquid–solid interface is determined as a gradual change in extensive quantities (continuous continuum^{14,15}).

For the solid and liquid phases in the system to be distinguished at any instant, the so-called order parameters describing the 'phase field' are introduced. The concept of the phase field was developed for modelling processes of solidification of two-component systems. According to these models, the free energy of the system depends on the temperature, phase field and concentrations of all components (*i.e.*, on the phase diagram). Computer simulations of solidification of eutectic alloys with different morphology (dendrite,¹⁶ lamellar,^{17–21} *etc.*^{18,21}) demonstrated that the theoretical model is in satisfactory agreement with experimental data. The drawbacks of the cited studies are the cursory consideration of the morphology and lack of information

on the structures of interphase boundaries. Besides, this model provides no clear explanation as to why the melting point of a eutectic is equal to its solidification temperature and it does not include parameters allowing for the description of distinctive specific properties of eutectic composites.

Obviously, the theories of phase interfaces and phase field, which include thermodynamic potentials as the initial parameters, can be used only if the system under consideration is close to thermodynamic equilibrium. Taking into account that an alloy can occur under conditions far from equilibrium (quenching), physical schemes were developed, which relate the morphological features of an alloy to diffusion processes. Considerations are carried out within the framework of stationary and non-stationary problems of diffusion. According to Chalmers and Weingard (Fig. 1),^{22,23} the appearance of periodic structures of eutectics (lamellar or rod) is determined by distances between the phase interface OA and two solid–liquid interfaces OB and OC in the vicinity of the point O. The width of lamellae depends on the rate of their growth and the influence of two opposite tendencies. One of these tendencies consists in the fact that the thicker is the lamella OB, the larger is the distance for which the structural components of the phase OC, which diffuse in the cross direction, should be moved and, correspondingly, the stronger is the driving force of diffusion. The latter is equal to $\Delta G^T(\text{melt}) - \Delta G^T(\text{cr})$, where $\Delta G^T(\text{melt})$ and $\Delta G^T(\text{cr})$ are the Gibbs free energies in the melt and crystal, respectively. At the same time, the thinner is the lamella, the stronger is the resistance to this force (determined by the contact surface OA). Therefore, diffusion is favoured by a small thickness of lamellae, whereas the principle of minimisation of the energy of the phase interface, by contrast, facilitates thickening of the lamellae. It can easily be concluded that a change in the rate of cooling should lead to a change in the mechanism of crystallisation due to the difference in the diffusion rate. Evidently, the above-considered mechanism is consistent with the Brady–Scheil classification (see above) and conclusions made in the studies.^{11,12}

In recent years, the Jackson–Hunt theory of formation of periodic structures upon crystallisation of eutectics^{24,25} has gained recognition. This theory takes into account the parameters of a phase diagram, surface tension and the rate of motion of the interphase boundary. Many studies were devoted to the development of the Jackson–Hunt model (see, for example, Ref. 26). Among these studies, noteworthy are investigations on the application of this theory to calculations of particular systems.²⁷ In a number of studies, account was taken of differences in the phase density,²⁸ the presence of external pressure,¹⁵ temperature gradient,²⁹ effect of electromagnetic fields³⁰ and differences in thermal conductivity of both components.³¹

An analogous approach was used in the study of the mechanisms of crystallisation of eutectics with rod or dendrite structures.³²

Figure 1. Mechanism of formation of lamellar eutectics according to Chalmers and Weingard.^{22,23}

The effects of rapid cooling (diffusion retardation) upon crystallisation of eutectics were investigated.^{20, 32, 33}

In spite of the fact that the results of calculations of particular eutectic structures with the use of the above-described models are in good agreement with the experimental data, it can be stated that the essential drawback of the available approaches is that they poorly describe interactions between components at the interface. In the review,² it was noted that it is this presence of an interface and solid–liquid interactions that are responsible for specific properties of eutectic alloys: ‘In a liquid eutectic alloy, the ‘structural complementarity’ between the dispersed medium and dispersed phase (the dimensional compatibility of the atomic arrangement at the interface) is better than that in a solidified alloy’. And later: ‘The eutectic composition corresponds to the phase ratio self-established in the melt at which the dispersed medium (melt) occurs in the state of solvation shells of dispersed particles. This specific nature of eutectics is responsible for their melting and crystallisation at a certain and constant temperature. A sacrifice in the dimensional compatibility of the atomic arrangement that occurs upon crystallisation is responsible for the elastic deformation of conjugated crystal lattices and a high elastic energy of the interphase surface’.²

These conclusions are confirmed by theoretical statements made by various authors at different periods of time. Commenting on the study by Bochvar,⁴ Taran¹ emphasised that ‘the fundamental idea is that two different crystals must be in contact with each other’. Based on the results of analysis of the structures of numerous eutectic alloys, Taran assumed that in the case of ‘the crystal-chemical difference between phases typical of the vast majority of eutectics,... the consideration of one of the phases as the basic one seems to be justified’.¹ This phase should possess ‘...a more complex crystal-chemical nature... The surface tension at the interface between this phase and the melt is high, which provides the possibility of nucleation and growth... of the second phase...’.¹ This basic phase can be determined with the use of the theorem of minimum entropy production in non-equilibrium processes. It was confirmed that this theorem is also applicable to particular simple eutectic structures, for example, to lamellar structures.³⁴ However, in a number of studies, this criterion was demonstrated to be insufficient. In the investigation,³⁵ the latter was attributed to the fact that characteristics of ‘pure’ phases are considered, whereas the presence of the second component is ignored, in particular, the entropy of mixing, which depends on interactions between the molecules of the components, is not taken into consideration. To characterise these interactions, new parameters, for example, the ‘parameter of surface roughness’ were introduced.³⁵

It should be noted that processes attendant on melting of crystals of different types (ionic, molecular, with different structures, etc.) were studied and described in detail.³⁶ The complexity of these processes in the pre-melting period (for example, positional and orientational disorder, the dependence on the type of unit cell of the initial crystal and its imperfection) suggests that the situation can become strongly complicated in the case of a mixture of interacting phases. In our opinion, all these changes should concern primarily the model of positional disorder because disordering of interacting structural units upon melting can be accompanied by their self-organisation giving rise to associates or something resembling a compound.³⁶

The concept of ‘interacting phases’ was supported by abundant experimental evidence. For example, interatomic interactions at the interface in crystallised eutectics were investigated. Analysis of X-ray emission and photoelectron spectra of eutectic alloys in the Al–Ge, Ag–Si, Ag–Ge (see Ref. 37) and Fe (Co,Ni)–Ge (see Ref. 38) systems demonstrated that the energy state of atoms in boundary layers of eutectic phases differs substantially from the state of atoms in the bulk of these phases and in the corresponding individual crystals. This specific state of boundary atoms is said to be ‘chemically active’.³⁶ These con-

clusions were made in studies of thin layers of eutectic alloys on substrates.³⁹

Let us discuss in more detail the remarkable and reliable experimental fact, viz., the orientational structural preference upon crystallisation of lamellar eutectics (the detection of this phenomenon was the aim of many investigations). In particular, it was proved⁴⁰ that the contact of phases along two crystallographic planes, viz., (111)Al–(211)CuAl₂ and (101)Al–(120)CuAl₂, is favourable for Al–CuAl₂ eutectics in the course of growth of a lamellar single crystal upon very slow cooling.

The consequences of interactions between components of eutectics in a molten state were also studied in sufficient detail. Thus, it was established^{41–47} that melts of eutectic systems in a particular temperature range above the liquidus line are characterised by ‘dynamic inhomogeneity’ manifested in the presence of ordered microregions, which are similar in composition and structure to eutectic colonies that form a structure of an alloy in the solid state. These ordered regions are called clusters, microgroups, cybotaxes, associates, dynamic short-lived complexes, heterophase complexes of atoms (or molecules), quasimolecules and fragments.² Hereinafter, we shall use the term ‘non-autonomous phase’ to refer to these ordered regions.

Many liquid alloys with eutectic compositions were studied by X-ray diffraction methods, which confirmed the presence of such non-autonomous phases. Studies of eutectic systems containing an intermediate phase revealed microgroups of atoms, which are similar in composition and structure to a chemical compound existing in the solid state (in the Tl–Te,⁴² Mg–Bi,⁴³ Fe–Si,⁴⁴ In–Sb,⁴⁵ etc. systems). For some binary amalgam systems, the substantiated conclusion was made that ordered structures, which are similar to chemical compounds, are retained in a melt.⁴⁷ In several studies, continuous series of solid solutions or metastable intermediate phases were detected in simple eutectic alloys obtained upon melt quenching.² These results are consistent, for example, with the conclusions⁴⁸ that eutectic melts are difficult to devitrify as well as with the data^{49, 50} that metastable solid solutions or compounds can exist after mechanochemical activation of eutectic alloys.

At the same time, it is known that microregions self-organised in a melt (non-autonomous phases) can be destroyed by external actions. For example, it was reported that the concentration in a eutectic melt changed under the action of centrifugal forces.²

When discussing the current state of the theory of eutectics, it should be noted that analogies between eutectics and chemical compounds were found. For example, Antipin and Vazhenin⁵¹ analysed two points of view, which are, in their opinion, of most importance. The first and most justified point of view consists in that eutectics are similar in nature to chemical compounds. The main argument is that most of eutectics obey the law of multiple ratios. The compositions of eutectics in melts of selected salts are given in Table 1.⁵¹

Table 1. Compositions of eutectics in molten salts.⁵¹

System	Chemical formula of the eutectic	Content of the second component (mol.%)	
		experiment	calculations
NaF–NaCl	NaF·2 NaCl	66.6	66.6
NaF–SrF ₂	2 NaF·SrF ₂	33.3	33.3
SrCl ₂ –NaCl	SrCl ₂ ·NaCl	50.0	50.0
LiCl–BaCl ₂	3 LiCl·BaCl ₂	25.0	25.0
KF–KI	KF·2 KI	66.0	66.0
NaF–KF	2 NaF·3 KF	60.0	60.0
NaF–LiF	2 NaF·3 LiF	61.0	60.0
KCl–KPO ₃	3 KCl·KPO ₃	20.0	20.0
KBr–KOH	KBr·3 KOH	75.0	75.0

It should be mentioned that Antipin and Vazhenin⁵¹ noted that more complex ratios (for example, $\text{NaCl} \cdot 14 \text{NaNO}_3$, $2 \text{NaF} \cdot 9 \text{NaI}$, $\text{NaCl} \cdot 6 \text{LiNO}_3$, *etc.*) were observed in some cases. These ratios could be considered as artificially selected. They referred to the data obtained by Geveling, who calculated that of 22 potassium halides, which form eutectics with other salts, 12 substances exactly correspond to multiple molar ratios. For three substances, the discrepancy is several tenths of a molar percentage. The remaining eutectics are not described by simple formulae. The authors of the cited monograph noted⁵¹ that 'this fact does not provide reason to reject certain stoichiometric ratios but can be indicative of their complexity' and believed that upon heating of a mechanical mixture of compounds forming eutectics, the liquid phase corresponding to the composition of the eutectic appears at a specified temperature only if certain ratios and conditions for contact between crystallographic planes of both substructures occur at the contact site. Antipin and Vazhenin⁵¹ concluded that, unlike chemical compounds characterised by the closest packing, a eutectic can be considered 'as the most weakly packed combinations of its constituent ions and atoms' and, hence, external actions, in particular, the pressure, 'can make the packing denser, *i.e.*, can, in the limit, give rise to a specific structure of a chemical compound'.⁵¹ In addition, studies were cited in which phase diagrams of either a eutectic or a chemical compound were obtained by varying the crystallisation conditions. Figure 2 illustrates the disappearance of a chemical compound and the appearance of a eutectic in the 2-chloronaphthalene–antimony trichloride system under certain experimental conditions.⁵¹

Figure 2. Phase diagram for the 2-chloronaphthalene–antimony trichloride system in the case of equilibrium and non-equilibrium crystallisation (c is the concentration of SbCl_3).⁵¹

Recently, the composition of a vapour over a eutectic melt was investigated.^{52, 53} Complex molecules of the MLnCl_4 and M_2LnCl_5 types ($\text{M} = \text{Rb}$ or Cs) were reliably detected in the vapour by high-temperature mass spectrometry. These results indicate that interactions in a melt, whose eutectic composition corresponds to the simple component ratio of 1 : 1, can be strong to an extent that congruent evaporation of the compound corresponding to the eutectic composition becomes possible. Therefore, the results of the above-mentioned studies can be considered as important experimental evidence in support of the proposed concept.

An alternative point of view consisting in that eutectics are heterogeneous mixtures, in the opinion of Antipin and Vazhenin,⁵¹ is based on two facts. First, the dependence of the eutectic composition on the external action, for example, on the pressure, can be attributed to a 'weak packing'. Second, a strong effect of the composition of impurities on the properties of eutectic alloys

cannot be explained within the framework of the concept presented in the monograph.⁵¹ However, it should be noted that the influence of impurities on the properties of eutectics has been considered in detail by Rebinder,⁵⁴ who explained this influence using the classical Gibbs–Volmer postulates and concepts of colloid chemistry.

To conclude this section, we cite one of the most recent definitions of the phenomenon of eutectics: 'The eutectic is a specific alloy (solution), whose components are partially miscible in the solid and liquid states and spontaneously form a thermodynamically equilibrium lyophilic dispersed system at certain temperatures. This system is characterised by substantial inter-phase interactions and solvation as well as by sedimentation stability. The composition of a eutectic corresponds to the ratio between eutectic phases, which is self-established in the melt and at which the dispersed medium completely occurs in the state of solvation shells of dispersed particles'.² It can be seen that the specific features of the formation of non-autonomous phases in eutectic alloys are described with the use of the notion of lyophilic systems characterised by interactions between dispersed particles. The terminology of colloid chemistry can eliminate particular contradictions in the theory of eutectics but it does not give a clear understanding of the mechanisms of processes occurring during melting and crystallisation of eutectic alloys. In our opinion, it seems more logical to use concepts of supramolecular chemistry for the determination of the nature of eutectic alloys and processes taking place during their formation. The formal possibilities of this approach will be considered in the next section. The drawbacks of the available notions can be to a large extent eliminated, first, by taking into account interactions between incommensurate substructures and, second, by developing a model, which describes mechanisms of these interactions and in which possible deformations and defects upon self-organisation of non-autonomous phases should be considered as a product of these interactions.

II. Main concepts and objects of inorganic supramolecular chemistry

J-M Lehn described supramolecular chemistry as the next step toward complexation of systems under study from molecules to supramolecules and organised supramolecular systems held together by non-covalent interactions.⁵⁵ This field of science deals with the chemistry of supramolecular assemblies and intermolecular interactions. Lehn assigned coordination bonds with metal ions as well as Coulombic, hydrogen, van der Waals and donor-acceptor interactions to intermolecular interactions.⁵⁵ The main property of self-organised supramolecular systems is their ability to perform molecular recognition. Recognition of components implies complementarity, *i.e.*, the mutual correspondence, both geometric and at the level of formation of intermolecular bonds, between the participants of the assembly (substrate and receptor). Although supramolecular chemistry has its roots in organic synthesis, coordination chemistry and studies of bioorganic and complicated organometallic complexes, Lehn particularly noted some objects of inorganic supramolecular chemistry admitting that the situation observed for these objects is rather inhomogeneous. In the study,⁵⁵ it was emphasised that intercalates, clathrates and host–guest structures exist only in the solid state. In the strict sense of the word, these structures are not discrete supramolecules but belong to solid supramolecular assemblies. Extended supramolecular assemblies (guests in extended[†] host structures) and discrete supramolecules occupy a special place.

[†] By 'extended' structures are meant one-, two- or three-dimensional infinite or semi-infinite crystalline substances with ionic or covalent bonds.

A more detailed classification of objects of inorganic supramolecular chemistry was presented in the review.⁵⁶ Among these objects are intercalates containing guests of different sizes in the host lattice, clathrates, framework silicates and complex molybdenum and vanadium phosphates. Because of the lack of the commonly accepted definitions and notions, the range of these objects is outlined very roughly.

In the present review, we restricted ourselves to the discussion of host–guest compounds as objects of inorganic supramolecular chemistry. These compounds allow one to study supramolecular assemblies in which the guest molecules form rather strong bonds with extended structures, factors influencing their complementarity (in particular, the geometric and topological complementarity between the components) and characteristic features of self-organisation. Extended assemblies enable one to consider the consequences of possible violations of the principle of complementarity and reveal the structural features of assemblies resulting from these violations. As will be demonstrated below, investigations of such objects can help in elucidating the mechanisms of formation of eutectic alloys.

It is known that formation of inorganic supramolecular assemblies can lead to violation of the principle of geometric and topological complementarity. Layered intercalates (in layered dichalcogenide matrices, graphite or clays) were particularly noted⁵⁶ as typical host–guest compounds examined in inorganic supramolecular chemistry. In all the above-mentioned cases, layers in the host lattice are linked by van der Waals interactions. Upon incorporation of guest molecules, the layers are pushed apart. It is known⁵⁷ that a change in the interlayer distance is an indication of the formation of an intercalate. This change depends on the size of the guest and can be 3–5 times larger than the initial crystallographic parameter of the host lattice. However, the ratio between the sizes of the guest molecules and cavities in the host lattice is not the only factor responsible for the limiting stoichiometry of an intercalate. It was demonstrated^{58,59} that the limiting stoichiometry of the intercalates A_aMX_2 (A is metal and MX_2 is a layered dichalcogenide matrix) is determined by the conditions of the matrix conduction band filling with electrons of the donor A (i.e., by electron stabilisation of the A_aMX_2 structure as a whole). The geometric factors are of secondary importance, as unambiguously evidenced by the small sizes of the M atoms in the A_aMX_2 systems, the absence of changes in the interlayer distances, the small limiting value of the parameter a and the dependence of a on the valence states of the A and M atoms.

The synthesis schemes for suprastructures developed in the study⁵⁶ consist in the following: the structure of a host should be constructed in such a way that it can be adapted to the structure of a guest. Successful examples of these retrosyntheses were cited in the study.⁶⁰ It should be noted that the so-called matrix crystals, which belong to a new type of inorganic supramolecular assemblies, have been discovered very recently.⁶⁰ Single crystals of synthetic opal were grown. These crystals contain cavities of a certain size, which form a regular cubic sublattice. The cavities were filled (from a melt under pressure) by crystalline and amorphous selenium as well as by sodium chloride. It was established that guest molecules always form quasilattices with unusually large parameters. Therefore, the geometric incommensurability of the sublattices is compensated by deformation of one of them (in this case, by deformation of the guest sublattice). Misfit compounds, which are a variety of intercalates in a layered dichalcogenide matrix, provide another example of incommensurability between the guest and host. Such compounds can also be assigned to objects of supramolecular chemistry. These are complex chalcogenides of the general formula $(AX)_{1+x}(MX_2)_y$ ($A = \text{Sn, Pb, Bi, Sb, Ln}$; $M = \text{Ti, V, Nb, Ta, Cr}$; $X = \text{S, Se}$; $x = 0.08–0.28$; $y = 1, 2, 3, \dots$) consisting of layers of two substructures, viz., AX (guest) and MX_2 (host). The guest layer (Q layer) forms a pseudocubic NaCl-type lattice. The host layer (H layer) occurs as a sandwich composed of hexagonal networks of the X atoms in which the M metal atoms have a trigonal-prismatic

(Nb, Ta) or octahedral (Ti, V, Cr) environment formed by the X atoms. The Q and H layers are incommensurate along one of the crystallographic directions (along one of the axes of the layer plane), the incommensurability being determined by the limiting value of x (at $y = 1$). Data on misfit compounds were generalised in the review⁶¹ in which it was noted that high thermodynamic stability of such compounds calls for revision of the topochemical laws of construction of supramolecular structures.[‡] Besides, it was hypothesised that in the process of organisation of supramolecular assemblies with incommensurate elements, the forces responsible for the retention of substructures (and their molecular recognition) compete with the forces linking these substructures.⁶¹ This can lead to morphological distortions of crystals and the appearance of different structural defects. The widespread opinion that the properties of misfit compounds are additive with respect to the properties of their constituent substructures was disproved in the study.⁶³ Numerous phase transitions were observed by measuring thermal capacity. The authors of the cited study⁶³ believed that these phase transitions are caused by temperature- and incommensurability-dependent defects of suprastructures.

Theoretical analysis^{64,65} confirmed the possibility of self-organisation of suprastructures from structures incommensurate along one crystallographic direction. Mechanisms of this self-organisation were proposed in the studies.^{64,65} The results of these investigations are briefly surveyed in the next section. Here it should be noted that (as will be demonstrated below) a consideration of eutectics, which, in the limiting case, are incommensurate along all three crystallographic directions, in terms of supramolecular chemistry allows one to answer many questions and eliminate unclear facts, which we have mentioned in the discussion of the available concepts of eutectics.

III. Static Frenkel–Kontorova model for finite systems

Interactions between substructures characterised by one-dimensional incommensurability (misfit compounds) were proposed to be considered as the behaviour of an elastic and less strong chain of finite length (guest) in the field of a rigid substrate (host) inducing a periodic potential (U)^{64,65} for elements of the chain (Fig. 3). This approach is a static version of the known Frenkel–Kontorova model.⁶⁶

A method was developed^{64,65} for the numerical solution of the problem of a search for energy minima of systems, which are composed of an elastic chain consisting of $N + 1$ atoms (i.e., containing N bonds) and a substrate, provided that the position of the chain on the substrate is determined by only one parameter (position of its end or beginning), whereas all other geometric elements of the chains are calculated according to recurrent equations. In calculations, the incommensurability parameter of subsystems $\gamma = b/h$ (b is the bond length in the free chain) and the ratio between their characteristic energies $z = 2\pi A/(kh^2)$ ($kh^2/2$ is the energy of stretching of the bond in the chain by a period of the substrate) are used as parameters of the problem. For convenience of discussion, the dimensionless potential energy (E) of chain–substrate systems (in units $kh^2/2$) per degree of freedom was introduced in the form $\varepsilon = E/(N + 1)$. In calculations, the incommensurability parameter of subsystems (γ) was varied within 0.5–1.5, and the optimum region of variation of the dimensionless

‡ It should be noted that the term ‘misfit’ is rather widely used in the literature. In particular, misfits between the parameters of crystal lattices of components of alloys are generally considered in metallurgy. For instance, in the study devoted to the development of compositions of high-temperature nickel alloys,⁶² the misfit characteristics were determined and the influence of these characteristics on processes of ordering and liquation depending on the morphological structural features were investigated.

Figure 3. Frenkel–Kontorova model for a chain of a finite length;⁶⁶ y_0 is the position of the beginning of the chain; y_i is the dimensionless coordinate of the i th element of the chain ($i = 0, 1, \dots, N$) in units h , where h is the period of the potential of the substrate; Y_i is the absolute coordinate of the i th element of the chain; A_i is the length of the i th bond in the chain in units h ; k is the rigidity of the bonds in the chain; U is the potential energy; A is the amplitude of the potential of the substrate.

energy parameter z was determined from the real values of the corresponding constants for inorganic compounds. Leaving aside mathematical procedures (analytical and numerical solutions of

this problem were reported in detail in Refs 64 and 65), let us consider the most important conclusions drawn from the dependences obtained.

1. For different z and γ , the energy of the system in the ground state per degree of freedom (ε) increases as the number of bonds (N) increases. This indicates that beginning with a particular number of bonds, fragmentation (cleavage of the chain) becomes favourable. Obviously, in each particular case, the gain in energy upon fragmentation must be compared with the real bond energies in the corresponding substructure. Typical plots of the relative maximum bond deformations for a chain in the ground state [$\delta = (1/\gamma - 1) \times 100\%$] and the corresponding energies per degree of freedom (ε) vs. the number of bonds (N) at different incommensurability parameters γ and energy parameters z are shown in Figs. 4 *a–f*. It can be seen that an increase in N leads to a change in the configuration of the ground state. For example, if $\gamma = 1.1$ (see Fig. 4 *a*) and $z = 0.030$, the rigid chain is strongly stretched (or cleaved) on going from $N = 12$ to $N = 13$. If $\gamma = 0.9$ (see Fig. 4 *c*), a strong chain contraction occurs at the same parameters of the system.

2. The probability of fragmentation sharply increases as the initial incommensurability increases as well as upon the formation of strong chain–substrate bonds. For example, if $\gamma = 0.6$ (see Fig. 4 *e*), the deformation of one bond reaches 20% already at $z = 0.15$.

Figure 4. Plots of the maximum relative bond deformation (δ) in the chain in the ground state (*a*, *c*, *e*) and the energy per degree of freedom (ε) of the system (*b*, *d*, *f*) vs. the number of bonds (N) in the chain for $z < z^*$ and $\gamma = 1.1$ (*a*, *b*); 0.9 (*c*, *d*); 0.6 (*e*, *f*).⁶⁵ See comments in the text.

Figure 5. Estimation (1) and calculated (2) plots of z^* vs. γ . The region in which the ground state of the chain has the 1 : 1 configuration is dashed.⁶⁵

3. For chains with any rigidity and for a given incommensurability between the chain and substrate, there is the energy parameter z^* such that if $z > z^*$, the system occurs in the ground state (corresponding to the ratio of 1 : 1), i.e., $\gamma = 1.0$ (Fig. 5).

4. Excited metastable states of the system (conformers) also possess some interesting features. Calculations demonstrated that these states should be very stable. Regions of contraction or stretching in incommensurate systems are developed analogously to those in commensurate systems ($\gamma = 1.0$). This fact allows one to state that the deformation and fragmentation of substructures in real eutectic alloys depend substantially on the conditions of the synthesis (crystallisation).

5. The proposed one-dimensional model provides the answer to the question as to the mechanisms of mechanochemical actions on interacting substructures. The preliminary longitudinal contraction or stretching of the chain influences the incommensurability parameter γ , whereas the forces acting in the perpendicular direction affect the parameter z (via the dependence of the parameter A on the chain–substrate distance). The above-mentioned changes can lead to the formation of a suprastructure in the metastable state for non-excited γ and z .

Although these conclusions were made based on the results of investigations, which were far from completion, it is believed that they are of importance for an understanding of the mechanisms of formation of eutectic suprastructures from elements, which are, in the limiting case, incommensurate along all three crystallographic directions.

First, calculations demonstrated that the formation of assemblies from incommensurate elements cannot differ substantially from the formation of assemblies from commensurate elements if the synthesis conditions imply the presence of excited states. This is yet another argument in favour of the statement that the topological and geometric complementarity between the guest and host is not necessary, and, consequently, eutectics can be assigned to objects of supramolecular chemistry.

Second, one can follow the changes in the parameters of the model (as yet one-dimensional) depending on the external conditions (the effect of the temperature on the interaction potential, rigidity and bond energy, mechanical actions, etc.).

Third, the mechanism of fragmentation of interacting incommensurate substructures, i.e., the formation of thermodynamically stable nanocomposites, was established. In our opinion, the conclusions made for a one-dimensional model can be used for explaining certain phenomenological results of studies of eutectic alloys.

IV. Supramolecular concept in the theory of eutectics

As mentioned above, poorly defined terms in inorganic supramolecular chemistry arise from the fact that intercalated host–guest compounds are assigned to solid supramolecular structures according to the available nomenclature. Therefore, the term ‘compound’ is set equal to the term ‘supramolecular assembly’. At the same time, in solid-state chemistry it is generally agreed that compounds have individual structures. In our opinion, there is an approach eliminating these uncertainties. If an interaction between the initial substructures leads to their destruction giving rise to a new structure typical of a particular compound, conditions for the molecular recognition are violated. These objects fall outside the scope of supramolecular chemistry and the problems considered in the present review. However, if the energy released upon interaction between the initial structural elements is insufficient for their radical rearrangement, it can be used for production of various structurally less stable supramolecular assemblies. We believe that any alloys (eutectics, solid solutions, etc.) can serve as examples of such supramolecular assemblies. This provides the basis for our approach. Undoubtedly, these assemblies are consistent with the principle of molecular recognition because the initial structures are not destroyed. Evidently, the Gibbs energies of such assemblies should depend on their architecture and mutual arrangement of sublattices. For example, the fulfilment of the principle of complementarity depends to a lesser or greater extent on the incommensurability and rigidity parameters, the presence of defects and analogous factors. In syntheses under different conditions (for example, under different temperature modes of alloy solidification), the self-organisation of a suprastructure should be accompanied by the emergence of hierarchy of assemblies of different types. The main type (possessing the lowest energy under particular thermodynamic conditions) should correspond to the case of the limiting self-organisation, whereas all other types are non-equilibrium or metastable. A change in the synthesis conditions should lead to a change in the energy hierarchy of suprastructures.

Organisation of suprastructures from incommensurate elements can proceed according to three schemes. In the first scheme, we deal with rigid substructures, which rather weakly interact with each other. Since the energy effects are small, the self-organisation[§] is also insignificant. In a certain approximation, we arrive at the term ‘mechanical mixture of phases’ whose properties are additive with respect to the properties of its constituent structural elements.

According to the second scheme, non-rigidity of interacting substructures or external mechanical actions compensate insignificant incommensurability between these substructures upon the formation of a suprastructure. In this case, stresses giving rise to a change in the crystal morphology should appear in the resulting suprastructure, and the non-additivity of the thermal capacity and some other physicochemical properties can be observed. Apparently, this scheme can be used for explaining the formation of limited solid solutions. It is worthwhile to cite the reasoning of the authors of the study⁶⁹ who believed that the regions of existence of solid solutions in phase diagrams cannot be described in the context of classical thermodynamics because of their imperfection. These phases are non-equilibrium and, consequently, they must decompose as the system approaches equilibrium. It has long been noticed that some alloys quenched from a solid-solution region appear to be decomposed (the so-called ‘tweed’ or modulated structure is formed).^{70–73} In the study,⁷⁴ this phenomenon was interpreted as follows: ‘The concentration at which noticeable

[§] The meaning and differences of the terms ‘self-organisation’ and ‘self-assembling’ are extensively discussed in the literature. Cases when the initial components have different incommensurability and rigidity parameters were also described.^{67,68}

deviations from perfection take place in a particular solution depends substantially on the nature of the compounds involved in this solution. Solutions for which deviations from perfection cannot be observed throughout the concentration range are exceptionally rare and exist only if their components have similar chemical structures, possess similar thermodynamic characteristics, similar atomic sizes, identical crystal structures, *etc.* If atoms differ in size by more than 14%, a solid solution cannot be formed because the deformation energy of the crystal lattice substantially increases'. It was also noted that if only two types of interactions, *viz.*, attraction (tendency to ordering) and repulsion (tendency to phase separation), occur between components, two types of regions in which these tendencies are manifested should be observed in phase diagrams.^{74, 75} In the studies,^{76, 77} the thermodynamic, kinetic and morphological aspects of decomposition of substitution solid solutions characterised by either the positive or negative energy of ordering were considered. Using a model of free energy relaxation for separation and ordering, a method was developed⁷⁶ for the computer simulation of such transformations, including calculations of the effects of induced elastic stresses.

Therefore, the problems discussed in the present review, *viz.*, the possibility of self-organisation and defect formation in systems with interacting incommensurate structural elements, are directly related not only to eutectic alloys but also to solid solutions. Based on the available data, it can be assumed that the difference between the eutectic type of formation of an alloy in a binary system and the formation of a solid solution consists in the following.

In the case of small incommensurability, the molten components A and B are mutually soluble. The release of thermal energy responsible for the conditions of formation of a solution can be favoured by mechanical actions (thus, it was experimentally demonstrated⁷⁸ that these actions allow one to extend sharply the concentration region of existence of single-phase alloys; the mechanochemical synthesis of metastable solid solutions from eutectic phases was carried out in the studies^{49, 50}). If the components A and B have more substantial incommensurability and do not interact with each other (the negative energy of ordering), they undergo phase separation.

However, if the components A and B interact with each other, it is worthwhile to consider the third scheme associated with the mechanisms of structural compensation in the course of active self-organisation of assemblies, which are composed of incommensurate substructures, in eutectic alloys. This is true for cases when the potential of interactions between substructures is rather high and their non-rigidity and incommensurability lead to critical deformations or fragmentation of one of the substructures. The formation of assemblies can be accompanied by the appearance of various defects, nanocomposite structures, non-additivity of properties and morphological changes during crystal growth.

Evidently, eutectic supramolecular assemblies are generated as non-autonomous phases, *i.e.*, as phases formed in the vicinity of the contact surface of interacting substructures. However, under certain conditions, this non-autonomy can, in principle, turn into the organisation of the structure as a solid solution. Therefore, the proposed concept allows one to bridge the gap between the terms 'eutectic' and 'solid solution'. Obviously, non-autonomous phases in a molten state differ from those in the solid state because processes of self-organisation of substructures depend substantially on the temperature (crystal lattice parameters,⁷⁹ bond energies, interatomic distances² and rigidity are changed). Consequently, like in the case of solid solutions, the ground states of a supramolecular system and a set of excited states are functions of the temperature. In our opinion, estimation of the changes in the parameters of the system in the proposed one-dimensional theoretical model will enable one to predict the characteristic features of eutectic suprastructures formed in the quenching mode. As mentioned above, alloys prepared by quenching can retain the structure of assemblies formed at high temperature as long as is

wished due to thermodynamic stability of the conformers. Stability of eutectic suprastructures is responsible for the necessity of the constancy of their compositions and melting–solidification temperatures. The fact that eutectics have low-melting points and possess specific physiochemical properties can easily be explained taking into account that interactions between incommensurate structural elements are associated with bond deformation and considering that under particular conditions the total amount of defects in a non-autonomous phase should be approximately constant.

Measurements of heat capacities and the determination of their temperature dependences for a series of oxide eutectic alloys provided evidence that these non-autonomous phases play different roles in such systems. The GaSe–GaSe_{1.5} system was studied in the Se concentration range of 50%–60%, where the homogeneity region of gallium monoselenide and simple eutectics occurred.⁸⁰ For this purpose, samples, which were quenched from a melt and slowly cooled, were used. We studied the temperature dependences of the heat capacity⁸¹ for the PbO–ZnO (eutectic, 89 mol.% of ZnO, $T_m = 1134$ K),⁸² PbO–Y₂O₃ (eutectic, 95 mol.% of Y₂O₃, $T_m = 1103$ K)⁴⁸ and MoO₃–PbO (eutectic, 59 mol.% of MoO₃, $T_m = 933$ K) systems.⁸³ A special procedure was developed, which made it possible to decrease an error of the measurements of heat capacity to approximately 0.5%. The crystallographic characteristics of substructures and eutectic alloys were studied. It appeared that the heat capacities of eutectics, like those of misfit compounds, deviated toward the values calculated according to the additive scheme (by 4.0%–4.5% for PbO–ZnO and by 9%–10% for PbO–Y₂O₃ and PbO–MoO₃). The devitrification and crystallisation temperatures in the region of eutectic compositions and in the nearby concentration regions were also investigated. The results of these investigations demonstrated that there are no substantial difference between the structures of the 'host–guest' type, which fall into the category of supramolecular compounds and are consistent with the principle of molecular recognition, and eutectic assemblies.

In the context of the proposed concept, the orientational ordering in eutectic alloys (see above) can easily be explained. If the system is incommensurate along two or three crystallographic directions and the incommensurability parameter γ along different directions has different values, energetically most favourable positions will be chosen upon interaction between substructures of two components (A and B) in the course of self-organisation of assemblies.

Mechanochemical treatment of substructures can also lead to changes in the parameters of the system determining the self-organisation of assemblies.

Finally, the proposed concept provides an alternative insight to the mechanisms of modification of eutectics by adding the third component.

The known descriptions of quasi-equilibrium crystallisation of melts are based on the genetic relations between the phase diagrams of eutectics and solid solutions. A scheme of formation of a eutectic-type phase diagram after superposition of two phase diagrams of solid solutions is shown in Fig. 6. Weingard believed²³ that at the solidification temperature (T_{cr}), a melt with eutectic composition can be considered as if it were present on two liquidus lines. The liquid is in equilibrium with the solid phase with composition C₁ and another solid phase with composition C₂. Both solid phases are formed from the liquid with composition C_E. This mixture of two different solid phases is called a eutectic. It should be noted that the genetic relation between the state of a solid solution and eutectics is consistent with the conclusions drawn from the proposed theory. Recall that the results of analytical and numerical studies of the static one-dimensional Frenkel–Kontorova model eliminate sharp differences between commensurate and incommensurate substructures upon the formation of excited states of a suprastructure. At the same time, the supramolecular concept involving this theory

Figure 6. Scheme of formation of a eutectic-type phase diagram after superposition of two phase diagrams of solid solutions. See comments in the text.²³

bridges the gap between the notions of compound and solution by introducing a ‘supramolecular eutectic assembly’ as an intermediate.

As can be seen from Fig. 7, different composites can occur in a two-component (consisting of the phases A and B) eutectic alloy depending on the parameters of the system and external actions. This can be a mechanical mixture of phases (see Fig. 7, line 1), an associated solution (curve 2) or a supramolecular assembly (curve 3). The minimum of the potential corresponds to the ground state. The presence of excited states (conformers; region 4) implies an uncertainty in the composition and structure of the assembly. The exact concentration ratios can take place only upon the formation of a compound with an individual structure (point 5).

Figure 7. Types of interactions in a two-component A + B system; (1) a mechanical mixture of components, (2) an associated solution, (3) a supramolecular assembly, (4) a region of existence of metastable conformers (C_E^0 is a eutectic, the ground state), (5) a compound with an individual structure.

It can be stated that the proposed supramolecular concept in the theory of eutectics does not reject the classical views. The only difference is that the abstract thermodynamic criteria, such as the surface energy or surface tension, are changed for real parameters of interacting substructures, viz., the incommensurability, rigidity and interaction potential. These parameters are generally not used in supramolecular chemistry but are included in the static Frenkel–Kontorova model, which we propose for the description of different modes of self-organisation of systems characterised by one-dimensional incommensurability.

It should be noted that some of the notions used in the present review are discussed not for the first time. Thus, the terms

‘assembly’, ‘size dimensionality factor’ and ‘crystallographic factor’ have been used by Hume-Rothery *et al.*⁵

One would expect that the further development of theoretical approaches (primarily, the development of the two-dimensional static Frenkel–Kontorova model for finite systems) and the target studies of the dependences of the parameters of the model and structural features of the resulting suprastructural eutectic assemblies will allow one to accumulate data, which will make it possible to predict unambiguously properties of eutectic alloys.

V. Conclusion

The results surveyed in the present review provide evidence in favour of the supramolecular concept in the theory of eutectics. This concept is based on the assumption that a eutectic alloy containing the autonomous phases A and B (in a two-component system) must be studied with consideration for interactions between these phases. These interactions can be responsible for the formation of ordered microregions (non-autonomous phases) analogous to supramolecular assemblies. Depending on the interaction potential, incommensurability between the crystal lattices of the substructures A and B, their rigidity and extension, external mechanical actions, the conditions can be provided for the formation of defect composites, viz., non-autonomous phases with changed lattice parameters. The existence of such phases is confirmed by the data published in the literature and our experimental results. The mechanisms of self-organisation of such assemblies are discussed using the one-dimensional static Frenkel–Kontorova model. It was demonstrated that a change in the parameters of the model can lead to the formation of limited solid solutions. The relationships between the mechanisms of formation and ordering in metastable solid solutions and processes of formation of supramolecular assemblies in eutectic alloys are discussed. Along with the ground state of a non-autonomous phase (corresponding to the maximum level of self-organisation), there are a large number of excited states (conformers), which are similar in energy and whose transitions to the ground state should be kinetically hindered. At low interaction potentials and in the case of substantial rigidity of substructures A and B, eutectic alloys should be similar in properties to mechanical mixtures of the phases. The specific properties of eutectic alloys and the dependence of their structures on the synthesis conditions (temperature, rate of cooling, mechanical actions) depend on the amount of a non-autonomous phase and the degree of its organisation. Analysis of the results of investigations devoted to the structures and properties of eutectic alloys provided evidence that the proposed concept is consistent with abundant phenomenological data and is not contradictory to the classical theoretical notions.

We acknowledge Academician I I Moiseev for help in formulating the problem and valuable advice and Academician A M Kutepov for comprehensive encouragement.

VII. Conclusion	784

Abstract. The published data on the methods for the synthesis of vinyl sulfides are considered and generalised. The main attention is given to methods based on electrophilic sulfenylation of unsaturated compounds. The bibliography includes 173 references.

I. Introduction

Vinyl sulfides play a prominent role in synthetic organic chemistry. They are extensively used as synthetic equivalents of enolate ions¹ and acyl anions.² In addition, vinyl sulfides are valuable intermediates in the synthesis of oxetanes,³ spirocyclic systems⁴ and other organic compounds.^{5–10} Vinyl sulfides also present interest as candidate pesticides and bactericides.^{11,12}

Among numerous methods for the synthesis of vinyl sulfides that have been described in the literature, three main groups can be selected: (1) electrophilic sulfenylation of unsaturated compounds; (2) nucleophilic addition of the RS group and nucleophilic substitution at the unsaturated carbon atom; (3) synthesis *via* radical intermediates. Other methods for the synthesis of vinyl sulfides can be illustrated by only a few examples, which include addition of hydrogen halides to alkynyl sulfides, elimination of various fragments from sulfur-containing compounds, reduction of sulfoxides, the Wittig–Horner reactions of arylthio-substituted phosphonates and the Peterson reaction.

Some examples of the synthesis of vinyl sulfides can be found in reviews devoted to the synthesis of sulfides,¹³ applications of sulfonyl chlorides in organic synthesis¹⁴ and metal-catalysed formation of C–S bonds.¹⁵ A recently published review is devoted to the synthesis of fluorine-containing alkyl(aryl)vinyl sulfides.¹⁶ However, to the best of the authors' knowledge there are still no reviews devoted to the synthesis of vinyl sulfides. The present review is intended to bridge this gap. Here, we generalise

and analyse the data on the methods for the synthesis of vinyl sulfides published in the last 15–20 years. Besides, we thought it expedient to mention some other methods that were developed much earlier, but are still widely used.

II. Electrophilic sulfenylation of unsaturated compounds

1. Electrophilic sulfenylation of alkynes

Electrophilic addition of divalent sulfur derivatives to alkynes is the most popular method for the synthesis of vinyl sulfides.

The addition of sulfur dichloride to alkenes and alkynes was studied in some detail back in the 1970's.^{17–21} Reactions of alkenes^{18–21} with SCl_2 afford chloroalkanesulfonyl chlorides which, in turn, react with the second alkene molecule to yield sulfides. It might be supposed that reactions of acetylenes with SCl_2 occur in a different manner and result in the formation of thiiranes, the addition products of the sulfonyl chloride group of the alkenesulfonyl chloride formed to the double bond.

However, it was found that SCl_2 reacts with hex-3-yne in dry ether in the same way as with alkenes to afford divinyl sulfide **1**. The latter is formed as a result of sulfenylation of an alkyne by the alkenesulfonyl chloride formed in the first step.¹⁷

At the same time, the reaction of diphenylacetylene with sulfur dichloride in Et_2O results in 3-chloro-2-phenylbenzothiophene

Received 6 November 2002

Uspekhi Khimii 72 (9) 864–883 (2003); translated by R L Birnova

(2). The structure of the latter was established on the basis of its spectral characteristics and was confirmed by its conversion into the known 2-phenylbenzothiophene, although the reaction in dichloromethane gives divinyl sulfide **3** in high yield.¹⁷

The stereo- and regioselectivity of the addition of sulfur dichloride to phenylacetylene have been studied.¹⁷ It was found that the reaction of equimolar amounts of phenylacetylene and sulfur dichloride in Et_2O yields an anti-Markownikoff adduct with a *trans*-configuration of the substituents, whereas Markownikoff and anti-Markownikoff products are formed in acetic acid. 1-Phenylpropyne reacts with SCl_2 in a similar way.

In highly polar solvents, *e.g.*, in acetic acid, the addition preferably occurs in accordance with the Markownikoff rule, while in less polar solvents, such as ethyl acetate, anti-Markownikoff adducts are preferably formed. It was thus suggested that this reaction occurs *via* one of the three intermediates **A–C** depending on the ion-stabilising characteristics of the solvent.

Steric factors compete successfully with the solvent effect.

Sulfenyl chlorides are one of the few sulfenic acid derivatives that add to multiple bonds without additional activation.

The first paper devoted to acetylene sulfenylation was published as early as 1946 within the framework of a search for methods for the synthesis of yperite and its analogues.²² The addition of 2-chloroethanesulfonyl chloride to acetylene was studied. *trans*-Configuration was ascribed to the monoadduct **4** formed.

Later, it was shown²³ that the reaction of acetylene with chloromethanesulfonyl chloride yields an addition product of two sulfonyl chloride molecules to one acetylene molecule.

The reaction of acetylene with ethane-1,2-disulfonyl chloride underlies the synthesis of sulfur-containing heterocyclic compounds.²⁴

The reaction of 2,4-dinitrobenzenesulfonyl chloride with symmetrical acetylenes in glacial acetic acid yields exclusively *trans*-addition products.²⁴

It was found that sulfonyl chloride reacts with acetylene in dichloroethane only in the presence of catalytic amounts of AlCl_3 .²⁵ The following reaction mechanism has been proposed:

However, in the case of higher acetylene homologues, *e.g.*, but-2-yne, hex-3-yne and diphenylacetylene, the presence of aluminium chloride is unnecessary.

As could be expected, electron-withdrawing groups deactivated the triple bond with respect to electrophilic reagents, while electron-donor groups activated it. Thus acetylenedicarboxylic acid does not react with sulfonyl chloride,²⁵ although methyl propiolate adds methane-, benzene- and *p*-substituted arenesulfonyl chlorides on heating.²⁶ Methanesulfonyl chloride adds to alkylthiovinylacetylenes exclusively at the triple bond.²⁷ The ratio of 1-trimethylsilylbut-3-en-1-yne adducts with methanesulfonyl halides (**5a**: **6a** and **5b**: **6b**) depends on the nature of the halogen atom in the sulfonylating reagent.²⁸

$\text{Hal} = \text{Cl}$ (**5a**, 90%; **6a**, 10%), Br (**5b**, 75%; **6b**, 25%).

Functionalised trimethylsilylvinylacetylenes $\text{Me}_3\text{Si}-\text{C}\equiv\text{C}-\text{CH}=\text{CRX}$ ($\text{X} = \text{CN, COMe, CO}_2\text{Et}$; $\text{R} = \text{H, Me}$) react with methanesulfonyl chloride at the triple bond.²⁹ Reactions of methane-, ethane- and *p*-toluenesulfonyl chlorides with nitroynes and their functional derivatives also involve exclusively the triple bond.³⁰

The effect of substituents in the benzene ring of diarylacetylenes on the addition of sulfonyl chlorides has been studied.³¹

The reaction of *p*-toluenesulfonyl chloride with diphenylacetylene in chloroform yields the monoadduct **7a** in quantitative yield. The reaction with *p*-methoxy-substituted diphenylacetylene proceeds in a similar way. Compound **7b** is the only reaction product (no isomer **8b** was found †).

X = H (**a**), 4-MeO (**b**), 3-Cl (**c**), 4-Cl (**d**).

At the same time, the reaction of this sulfenylating agent with chloro-substituted diphenylacetylenes yields both isomers: for X = 3-Cl, the **7c**:**8c** ratio is 1:4, whereas for X = 4-Cl the **7d**:**8d** ratio is 3:2. Thus, the outcome of electrophilic addition of sulfonyl chlorides to substituted diphenylacetylenes is determined by the polar effects of the substituents.

The rates of addition of sulfonyl halides to acetylenes and the structures of the reaction products depend on the nature of substituents in both the acetylene substrate and the starting sulfonyl halide. Thus the rate of addition of *para*-substituted arenesulfonyl chlorides to acetylene decreases in the following order: OMe > Me > H > Cl > NO₂. The methyl group and the chlorine atom in the *ortho*-position have little effect on the reaction rate, whereas the presence of a nitro group in the same position causes a 2000–3000-fold decrease in the reaction rate.³²

Studies on the kinetics of the addition of 2,4-dinitrobenzenesulfonyl chloride to hex-3-yne and phenylacetylene in acetic acid have shown that both reactions are overall second order and first order with respect to each reactant; the reaction products are represented exclusively by *trans*-isomers. In the case of acetylene, the addition product is formed exclusively according to the Markownikoff rule.³³

The effects of solvents on the ratio of Markownikoff and anti-Markownikoff addition products in reactions of sulfonyl chlorides with acetylenes have been studied.^{25,33,34} It was shown in particular that the reaction of *p*-nitrobenzenesulfonyl chloride with phenylacetylene in ethyl acetate gives predominantly the anti-Markownikoff adduct **9a**, whereas the same reaction in acetic acid yields predominantly the adduct **9b**.³⁴

The reaction product ratios of arenesulfonyl chlorides **10a–c** with phenylacetylene and but-1-yne in various solvents are presented in Table 1.³⁵

R¹ = Et, Ph; R² = 4-Me (**a**), 4-NO₂ (**b**), 2-NO₂ (**c**).

All of the adducts formed are *trans*-addition products. A reaction scheme has been proposed³⁶ where a complex of the chloride ion with the thiirenium cation is formed in the first step. Further transformations of this ionic complex depend on the nature of the solvent and the structure of the cation; these determine the quantitative ratio of the reaction products. Thus conversions within tight ion pairs result in anti-Markownikoff

† It is worth mentioning that formation of the adduct **8b** in this reaction cannot completely be excluded. Apparently, it is present, but in insignificant amounts (< 5%).

Table 1. Yields of the adducts **11** and **12** prepared by sulfenylation of but-1-yne and phenylacetylene.³⁵

R ¹	R ²	Solvent	Yield (%)	
			11	12
Ph	4-Me	EtOAc	100	0
	4-Me	CHCl ₃	65	35
	4-Me	AcOH	29	71
	4-NO ₂	EtOAc	85	15
	4-NO ₂	CHCl ₃	65	35
	4-NO ₂	AcOH	20	80
	4-NO ₂	MeCN	67	33
	2-NO ₂	EtOAc	57	43
	2-NO ₂	CHCl ₃	45	55
	2-NO ₂	AcOH	11	89
Et	4-NO ₂	EtOAc	100	0
	4-NO ₂	AcOH	100	0
	2-NO ₂	EtOAc	80	20
	2-NO ₂	CHCl ₃	67	33
	2-NO ₂	AcOH	58	42

adducts, while the dissociation into a chloride anion and an organic cation yields Markownikoff products.

Catalytic amounts of trifluoroacetic acid and hydrogen chloride added to the reaction mixture have different effects on the structures and ratios of the reaction products of *p*-nitrobenzenesulfonyl chloride with phenylacetylene in ethyl acetate.³⁷ In the presence of hydrogen chloride, the ratio of Markownikoff and anti-Markownikoff *trans*-isomers changes simultaneously with the formation of *cis*-isomers. It has been found³⁷ that *cis*-isomers are formed as a result of isomerisation of the original *trans*-adducts. It is noteworthy that the nature of the acid influences neither the course of the reaction of but-1-yne with *p*-nitrobenzenesulfonyl chloride nor the ratio of the isomers formed.

The formation of *cis*-isomers in the chlorosulfenylation of certain alkynes has been observed earlier.³⁸ *cis*-Addition products have also been obtained in the reaction of benzenesulfonyl chloride with *tert*-butylacetylene.³⁹

These studies have shown that compounds **13** and **14** are converted into a thermodynamically more stable isomer **15** upon heating or UV irradiation in benzene.

Later, it was found^{40,41} that reactions of sulfonyl chlorides with alkynes are *trans*-stereospecific and afford a mixture of Markownikoff [adduct (*E*)-A] and anti-Markownikoff products

R¹ = Prⁱ, Buⁿ, Bu^t, Ph; R² = Me, C₆H₄Me-*p*, C₆H₄Cl-*p*.

[adduct (*E*)-**B**] which are converted into Markownikoff *cis*-isomers (*Z*)-**A** in the presence of an excess of sulfenyl chloride or catalytic amounts of trifluoroacetic acid.

Aldehydes and ketones can in principle be prepared^{40,41} from β -chlorovinyl sulfides synthesised upon acid hydrolysis.

A method for electrophilic sulfonylation of alkynes with phthalimidosulfonyl chloride, which can be regarded as a synthetic precursor of sulfenic acid derivatives, has been developed.⁴² The nucleophilic substitution of the phthalimide group at the sulfur atom enables the preparation of hitherto unavailable vinyl sulfides and alkenesulfenamides. Some of them manifest pesticidal and bactericidal activities.¹¹

$\text{R}^1 = \text{R}^2 = \text{Me, Ph}$; $\text{R}^1 = \text{Bu}^n, \text{R}^2 = \text{H}$; $\text{R}^1 = \text{Ph, R}^2 = \text{H}$;
AIBN is azobisisobutyronitrile.

Yet another convenient approach to the synthesis of vinyl sulfides has been described.⁴³ Complexes **16** formed in the reaction of lithium acetylides with trialkylaluminium were used as the starting substrates. The reactions of these complexes with benzenesulfonyl chloride afford the intermediates **17** which yield vinyl sulfides upon hydrolysis or on treatment with allyl halides.

$\text{R}^1 = \text{n-C}_5\text{H}_{11}$; $\text{R}^2 = \text{Me, Et, Bu}^i, \text{n-C}_8\text{H}_{17}$; $\text{R}^1 = \text{n-C}_{10}\text{H}_{21}, \text{R}^2 = \text{Et}$.

The formation of side products, such as $\text{R}^1\text{C}\equiv\text{CR}^2$, $\text{R}^1\text{C}\equiv\text{CSPH}$, PhSSPH and PhSR^2 , is a disadvantage of this reaction.

Vinyl sulfides can also be synthesised in a reaction of acetylene with alkylolithium cuprates.⁴⁴

$\text{R}^1 = \text{Et, Bu}^n, \text{n-C}_7\text{H}_{15}$; $\text{R}^2 = \text{Me, Bu}^i, \text{Ph, Bn}$;
HMPA is hexamethylphosphoramide.

It is of note that in many studies devoted to electrophilic addition various selenium and tellurium derivatives were investigated along with sulfenyl chlorides. Thus reactions of areneselenenyl and arenesulfonyl chlorides containing 4-MeO, 4-Me, 4-Cl, 4-Br, 3-Br, 4-NO₂ and 3-NO₂ groups in the benzene ring with various unsaturated compounds have been studied.⁴⁵ It was shown⁴⁶ that the addition of sulfonyl and selenenyl halides (Hal = Cl, Br) to the triple bond of 1,4-dichlorobut-2-yne and subsequent dehydrohalogenation can be used for the synthesis of novel 1,3-disubstituted butadienes.

It was found⁴⁷ that reactions of areneselenenyl chloride and bromide with silver trifluoroacetate yield reactive complexes which are added to alkynes to give α -arylseleno-substituted esters. Hydrolysis of the latter yields α -arylseleno-substituted ketones.

$\text{R}^1 = \text{Ph}$; $\text{R}^2 = \text{H, Me}$; $\text{R}^1 = \text{R}^2 = \text{Et}$.

Later,⁴⁸ fluoroselenenylation of a vast variety of alkyl- and dialkyl acetylenes was performed using sonication of an alkyne–phenylselenenyl bromide–silver fluoride mixture.

$\text{R}^1 = \text{R}^2 = \text{Et, Pr, Bu, Ph}$; $\text{R}^1 = \text{Et, R}^2 = \text{Ph}$;
 $\text{R}^1 = \text{Pr, iso-C}_5\text{H}_{11}, \text{R}^2 = \text{Me}$.

The addition of sulfonyl, selenenyl and tellurenyl halides to phenylacetylene has been studied and their reactivities have been compared.⁴⁹ It was shown that the reaction rate decreases in the following order: $\text{AlkSHal} > \text{AlkSeHal} > \text{AlkTeHal}$. If the reaction is carried out in chloroform, a mixture of addition products is formed, whereas addition–elimination products are formed under conditions of phase-transfer catalysis (KOH–crown ether–PhMe).

$\text{R} = \text{Me, Et, Pr}^i, \text{Bu}^n$; $\text{X} = \text{S, Se, Te}$; $\text{Hal} = \text{Cl, Br, I}$.

Much attention in the majority of papers devoted to reactions of sulfonyl chlorides with alkynes is given to the nature of reaction intermediates. The reaction of 2,4-dinitrobenzenesulfonyl chloride with 1-phenyl-prop-1-yne in CHCl_3 yields exclusively *trans*-addition products; the reaction mixture contains 94% of the Markownikoff adduct.⁵⁰ It was found that this reaction is second order and occurs in two steps. The first, rate-determining step is the formation of a cyclic intermediate (a thiirenium ion); the second step consists of its opening. The second reaction is *trans*-stereo-

specific rather than regioselective. The predominance of one of the isomers in the reaction mixture testifies to a non-symmetry of the cyclic intermediate.

Further studies^{51–54} of chlorosulfonylation of substituted acetylenes by sulfonyl chlorides in various solvents, *e.g.*, tetrachloroethane,^{51,52} acetic acid⁵³ and SO₂ (see Ref. 54), revealed that the effects of the alkyl substituents at the triple bond on the rate of ArSCL addition are adequately described by the Taft correlation equation. Steric factors prevail over electronic ones only in the case of *tert*-butyl-substituted alkynes. The effects of aryl substituents at the triple bond are not so unambiguous. The data obtained^{51–54} have made it possible to propose a theory for the cyclic structure of the reaction intermediate **A** and to postulate the role of the benzene ring in the delocalisation of the positive charge in the thiirenium ion (structure **B**) (see also Refs 17 and 20).

More recent studies⁵⁵ into kinetic isotope effects of the solvent in addition of 4-chlorobenzenesulfonyl chloride to alkenes and alkynes in AcOH and AcOD corroborated the earlier proposed mechanism.^{50–54}

The kinetic aspects of reactions of arylacetylenes and styrenes with arenesulfonyl chlorides have been studied in detail; the rate constants and the activation barriers have been established.^{56,57}

The isolation of trimethylthiirenium hexachloroantimonate (**18**) formed in a reaction of di(methylthio)methylsulfonium hexachloroantimonate with an excess of but-2-yne provided direct evidence for the role of thiirenium intermediates in the addition of sulfonyl chlorides to acetylenes.⁵⁸ This salt retained stability in liquid SO₂ at temperatures up to –60 °C.

The ¹H NMR and ¹³C spectra of compound **18** and the corresponding spectra of 2,3-diethyl-1-methylthiirenium ion isolated from hex-3-yne could be recorded.⁵⁸

The use of alkynes containing bulkier substituents, *e.g.*, [di(*tert*-butyl)acetylene, 3-methyl-1-phenylbut-1-yne and 3,3-dimethyl-1-phenylbut-1-yne] increased the stabilities of thiirenium ions, and 1-methyl-2-phenyl-3-(*tert*-butyl)thiirenium and 1-methyl-2,3-di(*tert*-butyl)thiirenium hexachloroantimonates and tetrafluoroborates were isolated as white crystals at 20 °C.^{59,60} The structures of 1-methyl-2,3-di(*tert*-butyl)thiirenium hexachloroantimonate, tetrafluoroborate and hexafluorophosphate were established using X-ray diffraction analysis.⁶¹ The

nucleophilic stereo- and regiospecific Markownikoff attack of the chloride ion on the sulfur atom of the thiirenium ring in the absence of stabilising non-nucleophilic anions (SbCl₆[–], BF₄[–]) yields the corresponding (*E*)-chlorovinyl sulfides.⁶⁰

The structures, stabilities, reactivities and rearrangements of thiirenium and thiiranium ions have been studied by a group of Italian investigators.^{62–66}

¹H NMR studies have shown⁶² that compounds **19a,b** containing thiirenium rings are quantitatively isomerised in deuteriodichloromethane into thietene derivatives **20a,b** within several hours.

R = Me (**a**), C₆H₄Cl-*p* (**b**).

It is believed^{63,64} that the rearrangement mechanism (S_N2-Vin) of thiirenium cations is similar to that of their saturated analogues, *viz.*, thiiranium ions.

The S_N2-Vin mechanism implies an attack of the nucleophile (Nu) lying in the plane of the molecule from the side opposite to the leaving group (LG). This results in the formation of a planar transition state which resembles that in S_N2.

Theoretically, the rearrangements of the thiirenium ion may proceed according to two routes (Scheme 1, routes *a* and *b*). Route *a* leads to the linear intermediate **21** for which a 1,2-methyl shift is possible. This shift yields *Z*- and *E*-isomers of carbenium ions **22** and **23**. It is of note that only one of these isomers, *viz.*, the isomer **22**, can be converted into thietene derivatives **20a,b**, whereas the second ion (isomer **23**) reacts with a nucleophile or a base to give addition or dissociation products. Route *b* is no other than the S_N2-Vin mechanism, which yields exclusively compounds **20a,b**.

The quantitative conversion of compounds **19a,b** into compounds **20a,b** is in favour of a rearrangement according to route *b*.

Later, it was found⁶⁵ that thiirenium hexachloroantimonates react with dialkyl disulfides at 20 °C to yield substitution products.

Scheme 1

R = Me (**a**), C₆H₄Cl-*p* (**b**); B is a base.

$R^1 = \text{Me}, \text{C}_6\text{H}_4\text{Cl-}p$; $R^2, R^3 = \text{Bu}^t, \text{Ph}, \text{Ad}$ (Ad is adamantyl);
 $R^4 = \text{Me}, \text{Et}, \text{Pr}^i$.

Steric hindrances created by substituents at the sulfur atom and the carbon atoms of the thiirenium ring strongly affect the reaction rate. An analysis of the kinetic data has led to a hypothesis that attack on the sulfur atom occurs in the plane of the ring parallel to the C=C bond. Such a direction corresponds to the maximum electron density of the lowest unoccupied molecular orbital (LUMO) of the thiirenium ions (*ab initio* calculations data^{65,66}). Taking into account the effects of the substituents on the reaction rate and the calculated data, Fachini *et al.*⁶⁵ put forward a hypothesis that nucleophilic substitution at the sulfur atom in thiirenium ions follows an addition–dissociation mechanism *via* a sulfurane-like intermediate rather than the $\text{S}_{\text{N}}2$ mechanism.

o-Sulfonylarene sulfonates react with unsaturated hydrocarbons like sulfonyl chlorides to give *trans*-adducts (1 : 1).⁶⁷

$R^1 = \text{H}, \text{Me}$; $R^2 = \text{Ph}$; $R^3 = \text{Me}, \text{Ph}, 4\text{-MeC}_6\text{H}_4$;
 $\text{Ar} = 2,4,6\text{-(NO}_2)_3\text{C}_6\text{H}_2, 2,4\text{-(NO}_2)_2\text{C}_6\text{H}_3, 4\text{-NO}_2\text{C}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4$.

The orientation of substituents in the products of this type of reaction suggests that their mechanisms are similar to the mechanism of addition of sulfonyl halides to the triple bond.

The addition of weak electrophilic reagents to the multiple bonds requires the presence of activating reagents. A search for such agents has led to a vast variety of novel sulfonylating systems. Thus the use of readily available inorganic Lewis acids, *e.g.*, sulfuric anhydride and its complexes with pyridine,⁶⁸ thionyl and sulfonyl chlorides⁶⁹ as well as phosphorus halides and oxyhalides,^{70,71} zinc, magnesium and tin iodides,⁷² as activating reagents has made it possible to perform electrophilic addition reactions with sulfenamides and sulfonates,^{68–72} thio- and dithio-bisamines,^{69,70,72,73} disulfides⁷⁴ and many other sulfur-containing compounds, which themselves cannot add to the multiple bond. This has made it possible to extend the range of reactants and to develop novel methods for one-step synthesis of substituted vinyl sulfides which cannot be prepared by other methods. The activation of arenesulfenamides by sulfuric anhydride is one of such reactions.^{68,75}

$R = \text{H}$ (13%–15%), Ph (12%–14%).

It is sulfonyl sulfamate that is formed upon insertion of sulfuric anhydride at the sulfur–nitrogen bond that adds to the

triple bond. However, this reaction has not gained wide acceptance for the preparative synthesis of aryl β -sulfamatovinyl sulfides because of low yields and side processes.

The studies by Italian investigators^{76–83} were devoted to reactions of arenesulfenamides with unsaturated compounds in the presence of boron trifluoride. The synthetic applications of these reactions have been investigated. It was found in particular that the reaction of *p*-nitrobenzenesulfenamide with alkynes in the presence of boron trifluoride (20 °C) can be used for the preparative synthesis of β -substituted vinyl derivatives. It was found that BF_3 converts inactive arenesulfenamides into highly reactive species (presumably into reactive BF_3 –sulfenamide complexes⁷⁸) which undergo nucleophilic substitution at the sulfur atom to give thiirenium ions **24** (Scheme 2).

Scheme 2

$\text{Ar} = \text{Ph}, \text{C}_6\text{H}_4\text{Me-}p, \text{C}_6\text{H}_4\text{OMe-}p, \text{C}_6\text{H}_4\text{Cl-}p, \text{C}_6\text{H}_4\text{NO}_2\text{-}p$;
 $R^1 = \text{H}, \text{Me}$; $R^2 = \text{H}$; $R^3 = \text{Pr}^n, \text{Bu}^n, \text{Bu}^t, \text{Ph}$;
 $R^2 = \text{Me}$; $R^3 = \text{Me}, \text{Pr}$; $R^2 = R^3 = \text{Et}$.

The nucleophilic opening of the thiirenium ring in the intermediate **24** is *trans*-stereospecific and highly regioselective and yields vinyl sulfides according to the Markownikoff rule. The ring opening in nucleophilic solvents, such as acetonitrile^{75,78} and acetic acid,⁷⁹ is accompanied by formation of β -amidino- (**25**) and β -acetoxyvinyl sulfides (**26**),^{78,79} respectively, in good yields. Compounds **25** and **26** are convenient starting reagents for the synthesis of β -oxosulfides.⁸²

The addition of PhSSPh in non-nucleophilic solvents, such as dichloromethane and benzene, results in bisulfides **27**.⁸⁰ Alkyl-substituted acetylenes react with thiirenium cations in the presence of ArNHBF_3^- to give β -fluorovinyl sulfides **28**.⁸⁰ In all cases studied, diphenyl disulfide **29** and substituted anilines **30** are formed along with the main reaction products.

The reaction of boron trifluoride-activated *p*-nitrobenzenesulfenamide with alkyl- and arylacetylenes in chlorobenzene (80 °C) occurs *trans*-stereospecifically and regioselectively and yields β -fluorovinyl sulfides **28**.⁸⁰

If the sulfenamide molecule contains nucleophilic sites involved in the opening of the thiirenium ring, heterocyclic compounds are formed.⁸³

Ar = C₆H₄NO₂-*p*.

The activation of arenesulfenamides by Lewis acids, such as AlCl₃ or AlBr₃, affords *E*-isomers of β-halogenovinyl sulfides.⁸³

X = Cl (55%), Br (35%).

The *p*-nitrobenzenesulfenamide–HBr system was recommended as a bromosulfenylating reagent.^{83,84} The sulfenyl bromide formed adds *trans*-stereoselectively and regioselectively to alkenes and alkynes against the Markownikoff rule. The mechanism of this reaction seems to be similar to the mechanism of addition of sulfenyl chlorides to multiple bonds.

Ar = C₆H₄NO₂-*p*; R¹ = H: R² = Prⁿ, Buⁿ, Bu^t, Ph;
R¹ = Me, R² = Ph; R¹ = Et: R² = Et, Ph.

Arenesulfenamides activated by phosphorus oxyhalides are promising sulfenylating reagents for alkynes.^{85–87} It is believed that the role of reactive sulfenylating species in this reaction is played by complexes of the type **31**; the positive charge on the sulfur atoms is higher than that on the starting sulfenamide.⁸⁸

Ar = Ph, C₆H₄NO₂-*p*, C₆H₄NO₂-*o*; Hal = Cl, Br.

The complexes **31** react with alkynes according to the electrophilic substitution mechanism. In the final addition step, the halogen atom of phosphorus oxyhalide acts as a nucleophile; this reaction yields β-halogenovinyl sulfides.^{71,85,87}

According to kinetic data, no sulfenyl chlorides are formed in reactions of arenesulfenamides with phosphorus oxychlorides. The data presented in Table 2 suggest that the reaction time of

Table 2. Addition of sulfenyl chlorides and arenesulfenamides to unsaturated hydrocarbons.

Alkyne or alkene	Sulfenyl chloride or arenesulfenamide	Activating reagent	Reaction time	Ref.
H ₂ C=CH ₂	2,4-(NO ₂) ₂ C ₆ H ₃ SCl	—	16 h	89

POCl₃-activated *N*-(4-nitrophenylthio)morpholine with alkynes is much less than that of nonactivated sulfenyl chlorides.

The rates of dehydration of sulfenyl bromides into disulfides often exceed the rates of their addition to multiple bonds, which decreases the yields of the final products.^{22,90} At the same time, arenesulfenamides activated by phosphorus oxybromide react readily with alkenes,⁷¹ alkynes^{85,86} and dienes⁸⁸ to give high yields of bromosulfides. No new stable compounds are formed upon mixing of sulfenamides with POCl₃ or POBr₃ in dichloromethane in the absence of alkenes (TLC data).⁸⁷

The reaction of POHal₃-activated arenesulfenamides with acetylene and its derivatives in dichloromethane chloride is *trans*-stereospecific.^{85,87}

R¹ = R² = H, Prⁿ; Ar = Ph, C₆H₄NO₂-*p*, C₆H₄NO₂-*o*, C₆H₄Me-*p*;
Hal = Cl, Br.

The addition of arenesulfenamides to terminal alkynes yields a mixture of isomeric aryl β-halogenovinyl sulfides (total yield 50%–90%), which represent addition products formed both against (**32**) and according to the Markownikoff rule (**33**).^{85,87} The anti-Markownikoff product **32** prevails.

R = Prⁿ, Buⁿ, n-C₅H₁₁; Ar = C₆H₄NO₂-*p*, C₆H₄NO₂-*o*.

The *cis*-isomers of aryl β-halogenovinyl sulfides (*Z*)-**35** are formed in reactions of arenesulfenamides with phenylacetylene along with the *trans*-addition products (*E*)-**34** and (*E*)-**35**.^{85,87}

Ar = Ph, C₆H₄NO₂-*p*, C₆H₄NO₂-*o*; Hal = Cl, Br.

2-Arylthio-1-halogenoalk-1-enes (*E*)-**32**, the products of anti-Markownikoff halogenosulfenylation of terminal alkynes,

undergo isomerisation into 2-arylthio-1-halogenoalk-2-enes (*E*)-**36** and (*Z*)-**36** under the action of catalytic amounts of protic acids.^{85, 87}

R = Prⁿ, Buⁿ, n-C₅H₁₁; Ar = C₆H₄NO₂-*p*, C₆H₄NO₂-*o*.

The following mechanism for the acid-catalysed isomerisation of 2-arylthio-1-halogenoalk-1-enes has been proposed:⁸⁶

R = Prⁿ, Buⁿ, n-C₅H₁₁.

Here, the protonation of the double bond in compounds **32** and subsequent deprotonation with the formation of a mixture of isomeric alkenes is the key step. The ratio of the isomers is determined by their relative thermodynamic stabilities.

It should be emphasised that only one of the initially formed halogenovinyl sulfides, *viz.*, the anti-Markownikoff isomer **32**, undergoes isomerisation under conditions of acid catalysis to give a mixture of *E*- and *Z*-isomers of 2-arylthio-1-halogenoalk-2-ene **36** with the predominance of the *Z*-isomer. Under these conditions, the Markownikoff adduct (*E*)-**33** is partly converted into a *Z*-isomer. Apparently, the formation of more thermodynamically stable alkenes is the driving force of the isomerisation in both cases.

2. Electrophilic sulfonylation of allenes

It is of note that reactions of sulfonyl halides with conjugated and non-conjugated dienes do not usually afford vinyl sulfides; therefore, electrophilic sulfonylation of these unsaturated compounds is not considered in this review. Here, only the sulfonylation of cumulated dienes, *i.e.*, allenes, will be discussed in detail.

In 1960, Jacobs and Johnson⁹¹ established that 2,4-dinitrobenzenesulfonyl chloride reacted with allene to give 3-chloro-2-(2,4-dinitrophenylthio)prop-1-ene as an addition product (yield ~ 80%). In the authors' opinion, this reaction occurs regioselectively with the anti-Markownikoff attack by the electrophilic sulfur atom on the central atom of the allenic system. Such a regioselectivity is not unexpected, since the addition of sulfonyl chlorides to alkenes largely occurs against the Markownikoff rule. Small amount of a compound with a tentative structure of 2-chloro-3-(2,4-dinitrophenylthio)prop-1-ene could be isolated.

Later, it was found⁹² that reactions of allenes with other sulfonyl chlorides always yield mainly anti-Markownikoff products. Bisadducts (up to 20%) are formed in small amounts along with monoadducts.

A classical mechanism including the intermediate formation of the episulfonium ion has been proposed for these reactions.^{91, 92}

The addition of 2,4-dinitrobenzenesulfonyl chloride to various allenes has been studied.⁹³ It was shown that adducts of the type **37** containing a 2,4-dinitrophenylthio group at the double bond are the main reduction products; regioisomeric compounds of the type **38** were formed in smaller amounts and with only some of the substrates studied.

In early studies, stereochemical aspects of reactions of sulfonyl chlorides with allene derivatives have not been considered; the first paper⁹⁴ devoted to the detailed analysis of this problem appeared only in 1979. Evidently, addition of a sulfonyl chloride to a tetrasubstituted allene containing four different substituents may afford four stereoisomers **A–D**.

It was shown⁹⁴ that electrophilic species always attack only the central atom of the allenic system. The stereochemistry of the addition reaction is determined by steric factors, which favour the predominant formation of (*E*)-isomers. The formation of Markownikoff products of the type **38** was explained by the rearrangement of the adducts of the type **37** formed under conditions of kinetic control.

The kinetics of addition of sulfonyl chlorides to allenes and the effects of substituents in sulfonyl chlorides on the rate and stereochemistry of the reaction have been studied.^{95–97} It was found that steric and electronic factors have little effect on the addition of sulfonyl chlorides to allenes.⁹⁷ It was therefore concluded that steric effects are critical only in the case of arenesulfonyl chlorides containing *ortho*-substituents in the benzene ring. It was even suggested⁹⁶ that specific intermediates **E** are formed in reactions of allenes with *o*-nitrobenzenesulfonyl chloride; however, this hypothesis has not been strictly proven.

In a more recent study,⁹⁸ using the example of the reaction of 1,1-dimethylallene with various sulfonyl chlorides it was shown that the ratios of the products **39** and **40** strongly depend on the reaction conditions and the nature of the aryl substituent in the sulfonyl chloride. Thus the adduct **39** is mainly formed in C₂H₂Cl₄ at 20 °C, whereas the adduct **40** is mainly formed in CH₂Cl₂ at –78 °C. As far as the nature of the aryl substituent in a sulfonyl

chloride is concerned, the adducts **40** are almost exclusively formed for Ar = Ph, 4-MeC₆H₄, while a mixture of the adducts **39** and **40** (2:1) is formed for Ar = 4-ClC₆H₄ and 2,4-(NO₂)₂C₆H₃, respectively.

Ar = Ph, 4-MeC₆H₄, 4-ClC₆H₄, 2,4-(NO₂)₂C₆H₃.

Similar conclusions were made with respect to the reaction of 1-methoxyallene with arenesulfonyl chlorides.⁹⁹ Treatment of chlorosulfonylation products of 1-methoxyallene with water yields α -arylthiosubstituted aldehydes.

Ar = 4-MeC₆H₄, 4-ClC₆H₄, 2,4,5-Me₃C₆H₂.

Chloro- and bromoselenenylation reactions of allenes¹⁰⁰ were found to be very similar to the sulfonylation reactions.

3. Electrophilic vinylsulfonylation of alkenes

As mentioned above, the addition of sulfur dichloride to alkynes usually results in divinyl sulfides. However, it was possible to isolate¹⁷ an intermediate product, *viz.*, 2-chloro-1,2-diphenylethenesulfonyl chloride (**41**), upon treatment of diphenylacetylene with SCl₂ and to investigate its properties.

It was shown, in particular, that this compound adds to cyclohexene.

There is very little evidence on reactions of α,β -unsaturated sulfonyl chlorides, which may be attributed to their inaccessibility and low stability.¹⁷ It is known, for example, that chlorination of some benzyl, perfluoroalkenyl and perfluorocycloalkenyl sulfides results in the chlorolysis of the C–S bond with retention of the double bond in the fluorinated substituents.¹⁰¹ The perfluoroalkene- and perfluorocycloalkenesulfonyl chlorides formed are efficient sulfonylating reagents, which easily add to multiple bonds.

Later, a new method for electrophilic vinylsulfonylation of alkenes by ethenesulfenamides in the presence of activating reagents, such as sulfuric anhydride and its complexes with tertiary amines (Py·SO₃, Et₃N·SO₃) or ammonia, was proposed.^{102, 103} Ethenesulfenamides were prepared from readily available dithiobisamines.

The insertion of sulfotrioxide into the S–N bond of vinylsulfenamides has enabled the sulfamatovinylsulfonylation of some cage alkenes.^{102, 103}

An attempt to perform vinylsulfonylation of conformationally labile alkenes, such as cyclohexene and hex-1-ene, was unsuccessful, since the products formed appeared to be extremely unstable.¹⁰⁴

Similar results were obtained in the electrophilic vinylsulfonylation of alkenes by ethenesulfenamides activated by phosphorus oxyhalides.⁸⁷ Thus stable compounds (*e.g.*, product **42**) were obtained in reactions with cage alkenes (norbornene, norbornadiene, camphene, dimethyl 5,6-di-*endo*-norbornenedicarboxylate), while the vinylsulfonylation products of conformationally labile alkenes, *e.g.*, cyclohexene, could not be isolated because of their low stability.⁸⁷

The feasibility of conjugate addition was demonstrated in the example of a reaction of phosphorus oxychloride-activated ethenesulfenamides with dimethyl 5,6-di-*endo*-norbornenedicarboxylate.⁸⁷

4. Electrophilic sulfonylation of alkenes with subsequent α,β -elimination

Electrophilic sulfonylation of alkenes with subsequent α,β -elimination is yet another convenient method for the synthesis of vinyl sulfides. Both reaction steps are carried out under mild conditions and give fairly good yields of reaction products.^{105–109}

B is a base.

Sulfenyl halides are usually precursors of reactive species RS^+ . Dehydrohalogenation is carried out with different bases, *e.g.*, sodium methoxide, potassium *tert*-butoxide (in diethyl ether, DMSO or THF),¹⁰⁵ triethylamine,^{106, 107} sodium carbonate,¹⁰⁸ potassium fluoride (in DMSO or THF)¹⁰⁹ and silver trifluoroacetate.¹⁰⁹ A convenient method for the *in situ* synthesis of starting arenesulfonyl chlorides, which excludes isolation and purification of sulfenyl chlorides, has been described.¹⁰⁸

There are two possible directions of elimination, which yield allylic or vinylic sulfides. In many cases, the formation of allylic rather than vinylic sulfides is more preferable. Thus it has been shown¹⁰⁵ that 1-alkylthio-2-chlorocyclohexanes **43a** undergo elimination with great difficulty and give exclusively 3-alkylthiocyclohexenes **44a**. The formation of alkenes containing an allylic RS group proves that *anti*-elimination is more preferable for cyclohexane systems with a diaxial arrangement of the hydrogen atom [at C(3)] and the leaving group (the chlorine atom). The proton at C(1) is in a *gauche*-position relative to the chlorine atom in any conformation of cyclohexane **43a** which is unfavourable for the elimination.¹⁰⁵

$n = 2$ (a), 1 (b); $R = \text{Me, Et}$.

On the other hand, the dehydrohalogenation of sulfenylation products of cyclopentene **43b** occurs more smoothly and yields a mixture of 3-alkylthio- (**44b**) and 1-alkylthiocyclopentenenes (**45b**) (1 : 1). The equal probability of formation of allylic and vinylic thioethers suggests that *syn*-elimination is the most probable route for this system.

syn-Elimination is the only route for the chlorosulenylation products of the cage alkene **46**, which gives a quantitative yield of vinyl sulfide **47**.

Dialkyl disulfides can also be used as electrophilic sulfenylating species. Their reactions with *C,N*-lithiated tosylhydrazones and subsequent α,β -elimination lead regioselectively to vinyl sulfides; the yields of the latter depend on the nature of substituents in the starting tosylhydrazones.¹¹⁰

III. Synthesis of α -halogenovinyl sulfides by electrophilic hydrohalogenation of alkynyl sulfides

Regioselective addition of hydrogen halides (HCl, HBr, HI) to alkynyl sulfides is also related to the class of electrophilic reactions. However, it can be placed in a separate group, because it is not accompanied by the formation of a new C–S bond. This reaction is the simplest and most efficient approach to the synthesis of α -halogenovinyl sulfides (see Ref. 111 and references cited therein).

Reactions of aqueous hydrohalic acids (37% HCl, 48% HBr, 51% HI) or saturated hydrogen halides in benzene with alkynyl sulfides are regioselective and yield mixtures of *Z*- and *E*-isomers that are difficult to separate.

The recently developed procedure for the synthesis of α -halogen-substituted vinyl sulfides and vinyl ethers by addition of a hydrogen halide generated *in situ* from a trimethylsilyl halide in dry methanol at low temperature is devoid of this defect.¹¹² This reaction is highly regioselective and affords nearly quantitative yields of vinyl sulfides.¹¹³

$R^1 = \text{Me, Ph}$; $R^2 = \text{Bu}^n, n\text{-C}_7\text{H}_{15}, \text{cyclo-C}_6\text{H}_{11}, \text{BnCH}_2$;
 $X = \text{Cl, Br, I}$.

IV. Methods for the synthesis of vinyl sulfides based on nucleophilic reactions

1. Nucleophilic thiolation of alkynes

Nucleophilic thiolation of alkynes is one of the oldest, but nevertheless valuable methods for the synthesis of nonsymmetrical unsaturated sulfides. On the whole, this reaction can be described by the following scheme:

Thiols and alkali metal thiolates are most commonly used as thiolating reagents^{114–116} with proton as the electrophile. The use of thiolates enables the synthesis of stereochemically pure products. Thus reactions of phenylacetylene and but-2-yne with various thiolates occur exclusively as *trans*-addition.¹¹⁶

R = Me, C₆H₄Me-*p*.

Such a stereoselectivity can be attributed to the fact that this reaction proceeds *via* a carbanion in which the negative charge on the carbon atom (the free electron pair) and the lone electron pairs on the sulfur atom tend to be arranged as far as possible from one another.

R¹ = H, Me, Ph; R² = Me, C₆H₄Me-*p*.

Thiols add to non-symmetrical alkynes in a non-stereoselective manner.¹¹⁷

A reaction described by Trofimov and co-workers¹¹⁸ can also be regarded as a convenient method for the synthesis of alkyl (β-substituted vinyl) sulfides. It was found that thiolation of phenylacetylene by thiolate anions generated from *S*-alkylisothiuronium salts under the action of alkali occurs smoothly under mild conditions in both protic (ethanol) and aprotic (DMSO, DMF, *N*-methylpyrrolidone) solvents. The yields of alkyl styryl sulfides in dimethyl sulfoxide reached 98%.

R = Me, Prⁿ, All; Hal = Br, I.

The *in situ* generation of thiolate anions from *S*-alkylisothiuronium salts in the presence of alkali excludes the use of free thiols and, as a consequence, the occurrence of competing free-radical reactions.¹¹⁸

Alternative methods for the *in situ* generation of thiols include decomposition of xanthates and dithiocarbonates¹¹⁹ and alkylthioimidinium salts.¹²⁰ Electrochemical generation of thiolate anions is carried out in the absence of alkali. It is possible to synthesise sulfides by this method in up to 97% yields.¹²¹

The salient advantages of alkyne thiolation by elemental sulfur in the presence of potassium hydroxide and catalytic amounts of water required for the proton transfer are simplicity of the procedure, availability of reactants and high yields of divinyl sulfides.¹²²

R = H, Ph.

The reaction is carried out at 80–120 °C exclusively in aprotic dipolar solvents (DMSO, HMPA), which are rather stable on heating in the presence of strong bases. In other solvents (*e.g.*, dioxane), the reaction does not occur or proceeds with low efficiency. It was shown¹²² that at higher temperatures (130–170 °C) the potassium thiosulfate formed can also react with acetylene thereby increasing the yield of the final product.

R = H, Ph.

The reactions of acetylene and its derivatives with ethylene chlorohydrin and aqueous sodium sulfide afford 2-hydroxyethyl vinyl sulfides **48** and 2-vinyloxyethyl vinyl sulfides **49**.¹²³

R = H, Ph.

If the reaction in DMSO is carried out in a flow reactor, it can be stopped at the stage of formation of sulfide **48**. Taking into account the accessibility of the starting reagents, this synthetic procedure can sometimes be rather convenient despite low (5%–20%) yields of the reaction products. This approach was used in the synthesis of *p*-nitrophenyl and *p*-aminophenyl vinyl sulfides.¹²³

2. Nucleophilic substitution at the unsaturated carbon atom

Nucleophilic substitution at the unsaturated carbon atom is yet another popular synthetic procedure.

Vinyl halides (X = Cl, Br, I) are most commonly used as substrates, while thiols¹²⁴ and alkali metal,^{125–127} copper¹²⁸ and magnesium⁶ thiolates serve as a source of thiolating species.

Thus tetrachloroethylene reacts exothermally with sodium thiolates as suspensions in aprotic solvents (*e.g.*, DMF, DMSO, HMPA) at atmospheric pressure to afford tetra[alkyl(aryl)thio]ethylenes in 60%–80% yields. Tri[alkyl(aryl)thio] derivatives are formed as side products.¹²³

R = Et, Prⁿ, Prⁱ, C₆H₁₃, C₈H₁₇, (CH₂)₂OH, Ph.

Substitution at the double bond occurs more easily in the presence of catalysts, such as Ni (see Ref. 126) and Pd complexes.¹²⁷ Nonpolar aprotic solvents (benzene, toluene, dimethoxyethane) are used in catalytic reactions, whereas alcohols are usually used in the absence of catalysts.

Reactive thiolating species can also be generated *in situ*, if the reaction is carried out in alkaline media. Alkali metal hydroxides (NaOH, KOH)¹²⁹ or potassium carbonate in acetone¹²⁴ are most often used as deprotonating reagents.

Similar reactions were used in the synthesis of vinyl selenides.¹²⁶ High (70%–80%) yields of vinyl sulfides and vinyl selenides is a salient advantage of this method.

A highly stereospecific method for the synthesis of vinyl sulfides from alkynes, boranes and magnesium thiolates has been developed.⁶ This approach can be used for the synthesis of a broad range of vinyl sulfides.

$\text{R}^1 = \text{Bu}^n, n\text{-C}_6\text{H}_{11}$; $\text{R}^2 = \text{Me}_2\text{CHCHMe}$; $\text{R}^3 = \text{Bu}^n, \text{Bu}^t, \text{Ph}, \text{Bn}$.

All reagents used in this reaction are readily available and relatively inexpensive; moreover, all reactions can be carried out in a one-pot procedure.

3. Addition of thiols to the C=O bond of carbonyl compounds

In recent years, the method based on addition of thiols to ketones under conditions of acid catalysis followed by dehydration of the hemiketals formed has been widely used for the synthesis of vinyl sulfides. Both protic¹³⁰ and Lewis acids [AlCl_3 ,¹³¹ P_2O_5 (see Refs 131 and 132), *etc.*] are used as catalysts.

Thus heating of a mixture of a cyclic ketone, a thiol and a catalyst in benzene afforded the corresponding vinyl sulfides in up to 80% yields.¹³²

$\text{R}^1, \text{R}^2 = \text{H}, \text{Me}, \text{Pr}^i$; $\text{R}^3 = \text{Et}, \text{Pr}^n$; $n = 1, 2, 3$;
(a) $\text{PhH}, \text{AlCl}_3, \Delta, 15 \text{ min}$; (b) $\text{PhH}, \text{P}_2\text{O}_5, \Delta, 1 \text{ h}$

This approach¹³³ was used for the synthesis of di(alkylthio)alkenes from a series of cyclic and acyclic α -chloro ketones; the former are starting compounds in [4+2]-cycloaddition reactions used for the synthesis of novel acetylene compounds.¹³⁴

$n = 1, 2$; $\text{R} = \text{Et}, \text{Pr}, \text{Bu}$.

$\text{R}^1 = \text{Me}, \text{Et}, \text{Pr}^n, \text{Bu}^n, \text{Bu}^t, \text{Ph}$; $\text{R}^2 = \text{H}, \text{Me}, \text{Et}, \text{Pr}^n$; $\text{R}^3 = \text{Et}, \text{Pr}, \text{Bu}$.

The Michael addition of thiols to cyclic α, β -unsaturated carbonyl compounds, such as 3-oxo-2,3-dihydrothiophene 1,1-dioxides, with subsequent opening of the ring also affords vinyl sulfides (see Section VI).

4. Nucleophilic vinylthiolation

Much attention has recently been given to methods based on nucleophilic vinylthiolation. In many reactions, nucleophilic species are generated *in situ*, *e.g.*, upon treatment of aldehydes with Me_3SiCl and H_2S in pyridine.¹³⁵

$\text{R}^1 = \text{H}$; $\text{R}^2 = \text{Me}, \text{Et}, \text{Pr}^i$; $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_5$;
 $\text{R}^3 = \text{Ph}(\text{CH}_2)_2, \text{Bn}, \text{cyclo-C}_6\text{H}_{11}, \text{Pr}^n, \text{Bu}^n$; $\text{Hal} = \text{Cl}, \text{Br}, \text{I}$.

The vinylthiolating species can easily be generated through the opening of the thiophene ring under the action of organolithium compounds^{136, 137} or metals (Li, Na) in liquid ammonia in the presence of alcohols.¹³⁸

$\text{X} = \text{Br}, \text{I}$; $\text{R}^1 = \text{H}, \text{Me}, \text{Et}, \text{Bu}^t, \text{Ph}$; $\text{R}^2 = \text{H}, \text{Me}$; $\text{R}^3 = \text{H}, \text{Me}, \text{Et}$,

Bu^t, Ph ,  ($\text{R}^5 = \text{Me}, \text{R}^6 = \text{H}$; $\text{R}^5 = \text{Pr}^i, \text{R}^6 = \text{Me}$);

$\text{Alk} = \text{Et}, \text{Bu}$; $\text{R}^4 = \text{Et}, \text{Bu}, \text{CO}_2\text{Et}, \text{CH}_2\text{CO}_2\text{Me}, \text{Bn}$; $\text{Hal} = \text{Cl}, \text{Br}$.

The cleavage of the thiophene ring takes place under the action of solvated electrons; subsequent alkylation of the thiolate formed gives rise to various unsaturated sulfides which are further converted into the corresponding ketones.^{138, 139}

$\text{R}^1 = \text{H}, \text{Me}$; $\text{R}^2 = \text{Me}, \text{Et}, \text{C}_9\text{H}_{19}, (\text{CH}_2)_2\text{NEt}_2, (\text{CH}_2)_4\text{NEt}_2, (\text{CH}_2)_6\text{NEt}_2$; $\text{R}^3 = \text{Me}, \text{Et}, \text{Bu}^n, (\text{CH}_2)_4\text{CO}_2\text{Et}, \text{CH}_2\text{COPh}$,

$\text{CH}_2\text{CH}(\text{Me})\text{OH}, \text{CHCH}_2\text{OH}, \text{CH}_2\text{CHCH}_2\text{O}$; $\text{Hal} = \text{Cl}, \text{Br}, \text{I}$.

In the last step, epoxides can be used as alkylating reagents.¹³⁹

The opening of the thiophene ring in thiophene-3-carboxylic acids¹⁴⁰ results in enolthiolate; its benzylation and subsequent esterification give high yields of alkyl (Z)-4-benzylthio-2-methyl-alk-3-enoates.

$\text{R} = \text{H}, \text{Me}$.

V. Methods for the synthesis of vinyl sulfides based on reactions occurring *via* radical intermediates

1. Addition of thiols to alkynes

The addition of thiyl radicals to multiple carbon–carbon bonds is a well-known reaction, which has found wide acceptance in organic synthesis. Normally, thiyl radicals are generated from thiols or disulfides by thermolysis, photolysis¹⁴¹ or treatment with radical initiators.^{142, 143} The radical addition of thiols to alkynes occurs regioselectively against the Markownikoff rule and yields a mixture of stereoisomers.

Reactions of thiols with acetylenes are catalysed by nickel,^{15, 144} platinum,^{144–146} palladium,^{144, 146} rhodium^{144, 147, 148} and ruthenium complexes.¹⁴⁸

The addition of benzenethiol to various alkynes has been studied in detail.^{144, 147} The effects of the structure of the starting substrate, the nature of the catalyst and the solvent on the yields of reaction products have been investigated. Using the reaction of oct-1-yne with benzenethiol as an example, it was demonstrated¹⁴⁷ that the addition follows the Markownikoff rule in the presence of palladium(II) acetate and yields compound **50**. However, reactions catalysed by other divalent palladium complexes, *e.g.*, PdCl₂(PhCN)₂ or PdCl₂(MeCN)₂, afford the anti-Markownikoff product **51** and the double-bond-migration product **52**.

ML_n = Pd(OAc)₂, PdCl₂(PhCN)₂, PdCl₂(MeCN)₂, Pd(PPh₃)₄, Pt(PPh₃)₂(CH₂=CH₂), RhH(CO)(PPh₃)₃, RhCl(PPh₃)₃.

Both Markownikoff and anti-Markownikoff adducts are formed in the presence of RhH(CO)(PPh₃)₃ and the Wilkinson complex RhCl(PPh₃)₃. However, in-depth studies of the addition of benzenethiol to oct-1-yne in the presence of RhCl(PPh₃)₃ have shown that in ethanol only the *E*-isomer of the anti-Markownikoff product is formed. Thus different regioisomers can be prepared from the same starting compounds (alkyne and thiol) by varying the solvent and the catalyst.

It was also found that the double bond in addition products of thiols to alkynes migrates in the presence of metal complex catalysts. Thus the Markownikoff adducts (*e.g.*, compound **50**) formed in reactions of alkynes containing propargyl hydrogen atoms with benzenethiol in the presence of PdCl₂(PhCN)₂ are further isomerised under the action of the catalyst to give alkenes of the type **52** containing a non-terminal double bond. The following reaction scheme has been proposed:

L = PhCN, n = 2.

It was also shown that isomerisation does not take place if alkynes contain no propargyl hydrogen atoms. Moreover, the presence of an amino group in the alkyne molecule prevents the migration of the double bond.

The addition of various thiols to substituted acetylenes in the presence of a ruthenium complex catalyst has been studied.¹⁴⁹ This reaction yielded a mixture of *cis*- and *trans*-alkenes; their ratio varied depending on the nature of substituents in the starting alkyne.

2. Substitution at the unsaturated carbon atom

The replacement of the halogen at the double bond by an arylthio or an alkylthio group yields vinyl sulfides and may occur as both nucleophilic substitution and *via* radical intermediates. These reactions are usually carried out in the presence of initiators (*e.g.*, benzoyl peroxide^{146, 150, 151}) or upon UV irradiation.^{152, 153} In this case, the formation of side products (diaryl disulfides) is insignificant.

For the first time, radical chlorovinylation of benzenethiol and 4-toluenethiol with trichloroethylene in the presence of benzoyl peroxide (BP) was used for the synthesis of aryl β,β-dichlorovinyl sulfides in 1966.¹⁵⁴

Ar = Ph, C₆H₄Me-*p*.

It has been shown¹⁵¹ that aryl β,β-dichlorovinyl sulfides are formed as the main products in reactions of trichloroethylene with arenethiols irrespective of the nature of the substituent in the benzene ring.¹⁵¹ Diaryl disulfides are formed as side products, but their content is not very high. Saturated sulfides of the type ArS(Cl)CHCHCl₂ are not formed at all.

X = H, 4-MeO, 4-Me, 3-Me, 4-Cl.

Free-radical chlorovinylation of aliphatic thiols by trichloroethylene also results in β,β-dichlorovinyl sulfides.¹⁵¹ UV irradiation of reaction mixtures is optimum for thermolysis; the trichloroethylene : thiol ratio varies from 3 : 1 to 4 : 1.

Reactions of 1,2-dichloroethylene with thiols upon UV irradiation yield β-chlorovinyl sulfides RSCH=CHCl and disulfides RSCH=CHSR in addition to saturated products.¹⁵¹

A similar UV-induced reaction of tribromoethylene with benzenethiol yields β,β-dibromovinyl phenyl sulfide.¹⁵³ A general scheme for the substitution of the thiol group for the halogen atom in trichloro- and tribromoethylenes has been proposed:^{151, 153}

Initiation

Chain growth

Chain termination

It should be noted that some reactions of thiols with tribromoethylene yield aryl monobromovinyl sulfides as side products,¹⁵³ similar reactions with trichloroethylene do not give aryl monochlorovinyl sulfides.¹⁵¹

VI. Miscellaneous methods for the synthesis of α,β -unsaturated sulfides

1. Elimination from sulfur-containing compounds

a. α,β -Elimination from dithioacetals and dithioketals

The method for the synthesis of vinyl sulfides based on α,β -elimination of thiols from dithioacetals and dithioketals has found wide acceptance owing to the ease of preparation of the starting compounds. Usually, thiols are eliminated from dithio compounds by treatment with Simmons–Smith reagent,¹⁵⁵ phosphorus iodides,¹⁵⁶ mono- or divalent copper salts^{157,158} or mercury trifluoroacetate.¹³² The main disadvantage of these reactions is their nonstereoselectivity.

Phosphorus iodides, copper salts and thionyl chloride are widely used for α,β -elimination of thiols from acetals, α -hydroxy-, α -alkoxythio(seleno) ketals and orthothioesters.^{159,160}

X = S, Se; R¹ = n-C₅H₁₁, n-C₇H₁₅, cyclo-C₃H₅, Ph; R² = H, Me; R³ = H; R⁴ = Me, Ph; Cat = P₂I₄, PI₃, CuY, CuY₂, SOCl₂.

Yet another approach to the conversion of dithioketals into vinyl sulfides has been proposed.¹ It consists of treatment of thioacetals and thioketals with benzenesulfonyl chloride and subsequent elimination of HCl from the α -chloro sulfide formed.

High yields and applicability of this method for a broad range of substrates make it extremely promising.

b. Elimination of sulfur dioxide from the Michael adducts of thiols to 3-oxo-2,3-dihydrothiophene 1,1-dioxides

Boiling of 3-oxo-2,3-dihydroxythiophene 1,1-dioxide **53** (R¹ = H) with benzenethiol in toluene in the presence of catalytic amounts of pyridine results in the elimination of SO₂ and the formation of a 5:1 mixture of *Z*- and *E*-isomers of 4-phenylthiobut-3-en-2-one.¹⁶¹ In THF, this reaction occurs in the absence of a base.¹⁶² The reaction of substituted 3-oxo-2,3-dihydroxythiophene 1,1-dioxides with aliphatic thiols proceeds in a similar way.¹⁶²

Although the mechanism of this reaction has not been strictly proven, it is believed¹⁶² that it occurs as a cheletropic disrotatory conversion **53** → **54** (Scheme 3), although a two-step mechanism with the initial formation of the sulfinate anion and a subsequent loss of SO₂ is not excluded. Exclusive formation of the *E*-isomer of compound **55** (R¹ = H, R² = Ph) upon heating of the intermediate **54** in ethanol is the supporting evidence in favour of a

R¹ = H, Me; R² = Ph, Bu, (CH₂)₂CO₂Me.

concerted mechanism. The *Z*-isomers **55** are formed in subsequent conversions of *E*-isomers.

c. Decarboxylation of α -methylthiocarboxylic acid salts

Regioselective syntheses of terminal vinyl sulfides can be implemented using mild decarboxylation of (α -methyl)(α -methylthio)alkanoic acids **56** with *N*-chlorosuccinimide (NCS) and sodium hydride in dimethoxyethane (DME).¹⁶³

LDA is lithium diisopropylamide; Ar = Ph, 3-MeOC₆H₄, 3,4-(CH₂O₂)C₆H₃; n = 2–5.

No regioisomer with a non-terminal double bond was found in this reaction. However, it was concluded¹⁶³ that reactions in protic solvents, *e.g.*, Bu^tOH, lead to the reduction of the oxidative potential of *N*-chlorosuccinimide and the establishment of a rapid equilibrium between the regioisomers, as a result of which the regioselectivity of the reaction decreases.

2. Reduction of sulfoxides with subsequent α,β -elimination

Reduction of sulfoxides to sulfides usually occurs under mild conditions and with good yields and does not require any complex equipment. Trimethylsilyl iodide in combination with bis(trimethylsilyl)amine or sterically hindered tertiary amines is one of the most efficient reagents for the reduction and subsequent α,β -elimination of sulfoxides.¹⁶⁴

R = n-C₆H₁₃.

Treatment of α -chloroalkyl sulfoxides with trifluoroacetic anhydride and sodium iodide in acetone at low temperatures affords vinyl sulfides in high yields.²

Trimethylsilyl trifluoromethanesulfonate (Me₃SiOTf) can be used in the synthesis of α -cyano- and α -alkoxycarbonyl-substituted vinyl sulfides.⁵

R = H, Et, Prⁿ, cyclo-C₆H₁₁; X = CN, CO₂R.

Sulfoxides containing a halogen or a hydroxy group in the α - and β -positions easily undergo reductive elimination in diethyl ether under the action of Zn and TiCl_4 .¹⁶⁵

$\text{R}^1, \text{R}^2 = \text{H, Alk, Ar}; \text{X} = \text{H, OH}; \text{Y} = \text{H, Cl, Br}; \text{Z} = \text{H, Cl}.$

A method for the reduction of sulfoxides containing hydrogen atoms in α - and β -positions was developed in 1995,¹⁶⁶ which involves their treatment with *in situ* generated magnesium amide $\text{Mg}(\text{NH}_2)_2$.

$\text{R}^1 = \text{Bu}^n, \text{Ph}, 4\text{-MeC}_6\text{H}_4; \text{R}^2 = \text{H, Me, Ph}; \text{R}^3 = \text{H, Me, Et, Ph};$
 $\text{R}^4 = \text{H, Me}; \text{R}_2^5\text{NH} = 2,2,6,6\text{-Me}_4\text{C}_5\text{H}_6\text{NH}, \text{Pr}_2^i\text{NH}.$

3. Methods for the synthesis of vinyl sulfides based on the Wittig–Horner and Peterson reactions

a. Synthesis of vinyl sulfides using the Wittig–Horner reaction

The Wittig reaction using sulfur-containing reagents can be used for the synthesis of vinyl sulfides.¹⁶⁷

$\text{Ar} = \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4;$
 $\text{R} = \text{Me, Et, Ph}, 4\text{-NO}_2\text{C}_6\text{H}_4, \text{PhC}\equiv\text{C}, 2\text{-NO}_2\text{C}_6\text{H}_4\text{CH}=\text{CH}.$

However, the Wittig–Horner reactions where phosphonates are used instead of phosphonium salts have found wider application in the synthesis of α,β -unsaturated sulfides.^{3, 168, 169} This reaction is carried out in the presence of strong bases, such as NaH (see Ref. 3) or Bu^nLi .^{168, 169}

$\text{R}^1 = \text{Me, Ph}; \text{R}^2 = \text{H, Et, Pr}^i, \text{Bn}; \text{R}^3 = \text{H}; \text{R}^4 = \text{Ph, n-C}_6\text{H}_{13},$
 $4\text{-MeOC}_6\text{H}_4, \text{PhCH}=\text{CH}, 3,4\text{-(CH}_2\text{O}_2\text{)}_2\text{C}_6\text{H}_3; \text{R}^3 = \text{Me},$
 $\text{R}^4 = 4\text{-MeOC}_6\text{H}_4\text{CH}_2; \text{R}^3 = \text{R}^4 = \text{Ph, Bn}; \text{R}^3 - \text{R}^4 = -(\text{CH}_2)_4-,$

Sometimes, these reactions require BF_3 for their completion.¹⁶⁹ They can also be carried out under conditions of phase-transfer catalysis.¹⁷⁰

$\text{R}^1 = \text{Me, Ph}; \text{R}^2 = \text{Ph}, 4\text{-Me}_2\text{NC}_6\text{H}_4.$

Quaternary ammonium bases and crown-ethers are used as catalysts in phase-transfer reactions. In this case, the ratio of (*E*)- and (*Z*)-vinyl sulfides formed varies depending on the catalyst.¹⁷⁰

High yields of vinyl sulfides are an indisputable advantage of the given method; however, in some cases the synthesis of sulfur-containing Wittig reagents presents a complicated synthetic problem.

The use of the Wittig–Horner reaction enables the synthesis of some thio(telluro)acetals of substituted ketenes where the aryltelluro groups can be readily and selectively modified.¹⁷¹

$\text{R}^1 = \text{Me, Ph}; \text{R}^2 = \text{Ph}, \text{Bu}^n; \text{R}^3 = \text{H, Ph}, 2\text{-furyl}, 4\text{-MeC}_6\text{H}_4,$
 $4\text{-ClC}_6\text{H}_4, \text{Pr}^n, \text{Pr}^i; \text{E} = \text{H}_2\text{O, MeI, PhCHO}; \text{E}' = \text{OH (62\%),}$
 $\text{Me (86\%), PhCHOH (85\%).}$

b. Synthesis of vinyl sulfides using the Peterson reaction

The Peterson reaction, *i.e.*, the synthesis of vinyl sulfides from α -metallo-silanes, plays an important role in organic synthesis. Thus lithium derivatives of arylthiomethyltrimethylsilanes react with ketones to give vinyl sulfides.¹⁷² Various carboxylic acid derivatives, *e.g.*, amides, can be used for the synthesis of β -substituted vinyl sulfides instead of ketones.

$\text{R}^1 = \text{Me, Ph}; \text{R}^2 = \text{H, Bu}^t, \text{Ph}; \text{R}_2^3 = \text{Me}_2, (\text{CH}_2)_2, (\text{CH}_2)_5.$

A method for the synthesis of vinyl sulfides has been developed which is based on the reaction of epoxysilanes with lithium phenylsulfide and subsequent Peterson *syn*- α,β -elimination.¹⁷³ This method is distinguished for high yields, regio- and stereo-specificity.

$\text{R}^1 = \text{H, Bu, Ph, SiMe}_3, \text{SiMe}_2\text{Ph}; \text{R}^2 = \text{Me, Ph}.$

VII. Conclusion

The choice of a method for the synthesis of vinyl sulfides is determined by the nature of the substrate as well as by the stability and availability of the starting reagents. Some of the methods considered in this review, e.g., the addition of sulfonyl chlorides to acetylenes or nucleophilic substitution for the thiolate ion, were developed as early as the middle of the last century, but are still widely employed owing to the simplicity of equipment and experimental procedures. However, the yields of such classical reactions are not always satisfactory, which stimulates the search for more complex, perhaps, but nevertheless more efficient methods for the synthesis of vinyl sulfides.

Among a variety of methods recently developed for the synthesis of vinyl sulfides, reactions of arenesulfenamides with alkynes in the presence of phosphorus oxyhalides hold especially great promise.^{69–74} The simplicity of equipment, the availability of starting reagents and high yields of reaction products make this method a reasonable alternative to the existing chloro- and bromosulfenylation procedures. Addition of thiols to alkynes in the presence of metal complex catalysts is yet another promising approach,^{15, 144–149} which allows regioselective sulfenylation of nonsymmetrical alkynes. The success of the synthesis of the target regioisomer depends on the choice of a metal complex catalyst.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 02-03-33347) and the Foundation 'Universities of Russia' (Project No. UR.05.03.005).

I. Introduction	787
II. 1,2-Thiaphosphiranes	787
III. 1,2-Thiaphosphetanes	791
IV. 1,2-Thiaphospholanes and 1,2-thiaphosphinanes	793
V. Ring-chain tautomerism in the series of 1,2-thiaphosphacyclanes	798
VI. Structural features of 1,2-thiaphosphacyclanes	798
VII. Conclusion	801

Abstract. Synthetic routes to 1,2-thiaphosphacyclanes bearing both tri- and tetracoordinate phosphorus atoms, and their reactivity and structural features based on data from X-ray diffraction analysis are discussed. Particular emphasis is placed on the rare case of ring-chain halogenotropic tautomerism in the series of 1,2-thiaphosphacyclanium salts and related compounds. The bibliography includes 107 references.

I. Introduction

In recent years, there has been an increase in the interest in the chemistry of heterocyclic compounds, development of synthetic routes and investigation of properties of novel types of heterocycles, mostly due to their practical applications, *e.g.*, in agrochemistry and pharmaceutical chemistry. In full measure, this applies to phosphorus-containing heterocyclic compounds. Noteworthy is the known peculiarity of phosphorus-containing heterocyclic compounds compared to their acyclic analogues, which is manifested in the unusual structures (conformational and stereochemical) of the reaction products. Cyclic phosphorus compounds are often invoked with the purpose of studying the mechanisms of chemical transformations of organophosphorus compounds, moreover, they are effectively used as synthons in organic synthesis. Phosphorus-containing heterocyclic compounds, in particular, phosphates, play an important role in biochemical processes.

Among fairly numerous phosphorus-containing heterocyclic compounds known presently, saturated and unsaturated phosphacyclanes¹ and polyheterophosphacyclanes^{2–6} have been investigated in most detail. General synthetic procedures have been proposed for the synthesis of 1,3,2-diheterophosphacyclanes based mostly on the interaction of phosphorus acid chlorides with nucleophiles (polyhydric alcohols, thiols and amines). Mono-

heterophosphacyclanes are represented in the literature mainly by 1,2-oxaphosphacyclanes. Basic publications concerning the synthetic routes to these compounds date from the 1960–1980. 1,2-Oxaphosphacyclanes have found wide industrial application, particularly as non-inflammable hydraulic fluids and plasticisers,^{7,8} additives to lubricants,⁹ flame retardants,^{10,11} thermostabilisers of synthetic fibres^{12–14} and surfactants.¹⁵ Some P,O-heterocyclic compounds are used as synthons for hard-to-reach compounds.^{16–19}

1,2-Monoheterophosphacyclanes having other heteroatoms in the ring, *e.g.*, sulfur or nitrogen, have been investigated to a far lesser extent because of the absence of convenient preparative methods to obtain them. At the same time, cyclic P,S-containing systems represent a highly promising class of organophosphorus compounds. In particular, it is known that some P,S-heterocycles are used as antioxidant additives in motor oils, polymers and agrochemicals,^{20–22} and also as co-monomers for polymers possessing complexation properties²³ and ligands for metal complex catalysts.²⁴ Cyclic esters of phosphorus thioacids are widely used in biochemical studies and as sulfur analogues of nucleotides.^{25,26} Some saturated P,S-heterocyclic compounds, such as 2,4-bis-(4-methoxyphenyl)-1,3-dithia-2,4-diphosphetane 2,4-disulfide²⁷ (currently known as the Lawesson reagent, LR), are of great utility in organic synthesis as mild thiylating agents for carbonyl and phosphoryl compounds and also as reagents in the synthesis of unsaturated 5- and 6-membered heterocyclic compounds containing a P,S-moiety.^{28,29}

Though the number of publications concerning the saturated 1,2-thiaphosphacyclanes is rather limited, it seemed expedient to summarise the information on this topic available in the literature taking into account the clear prospects of these compounds. We have paid attention to the synthesis, structural features and tautomerism of this interesting but still poorly investigated class of heterocyclic compounds.

II. 1,2-Thiaphosphiranes

Three-membered saturated P,S-heterocycles, *i.e.*, 1,2-thiaphosphiranes, became available only when synthetic approaches to stable dicoordinate phosphorus compounds were developed.

1. Synthesis of 1,2λ⁵-thiaphosphiranes

The only general synthetic route to 2-thioxo-1,2λ⁵-thiaphosphiranes presently known is based on the addition of elementary sulfur to methylenephosphines. Niecke and Wildbrecht³⁰ were the first

Uspekhi Khimii 72 (9) 884–901 (2003); translated by I L Odinets

to obtain a compound with such a heterocycle starting from [bis(trimethylsilyl)amino]trimethylsilylmethylidene- $\sigma^2\lambda^3$ -phosphine (**1**).

This reaction proceeds in two steps: the addition of one equivalent of sulfur affords $\sigma^3\lambda^5$ -methylidene(thio)phosphorane **2** in high yield (90%), which reacts with the second equivalent of sulfur according to the [1 + 2]-cycloaddition affording 2-thioxo-1,2 λ^5 -thiaphosphirane **3**. A small amount of the latter as a by-product is formed in the first step. If the reaction of methylidene-phosphine **1** is carried out directly with two equivalents of sulfur the desired 2-thioxo-1,2 λ^5 -thiaphosphirane **3** is obtained in virtually quantitative yield.

It should be noted that not all cases of the reactions of phosphalkenes with sulfur result in the formation of stable $\sigma^3\lambda^5$ -methylidene(thio)phosphoranes, the pentavalent tricoordinate phosphorus compounds. In particular, the reaction of 2,4,6-tri-*tert*-butylphenyl(dimethylaminomethylidene)phosphines **4** with sulfur yields metadithiophosphonate **5**^{31,32}, which does not dimerise to the corresponding analogue of the Lawesson reagent because of the bulky aryl moiety.

Ar = 2,4,6-Bu₃C₆H₂, R = H, Me.

No thiaphosphiranes were also found among the addition products of the sulfur to 2,6-dimethylphenyl(diphenylmethylidene)phosphine (**6**) in boiling ethanol,[†] though in this case methylidene(thio)phosphorane **7** is really formed in the first step.^{32,33} It was not possible to isolate phosphorane **7** because of its extreme instability, but its formation was confirmed by NMR and mass spectrometry techniques and also by its reaction with ethanol affording *O*-ethyl 2,6-dimethylphenyl(diphenylmethyl) thiophosphinate **8** (Scheme 1, path *a*, attack on the lone electron pair of the phosphorus atom).³² Concurrently with the addition of one equivalent of sulfur leading to the phosphorane **7** (path *b*), cleavage of the P=C multiple bond in the starting methylidene-phosphine takes place (path *b*), as the energies of these reactions are similar. Such a cleavage results in thiobenzophenone (15%), and after addition of ethanol to an unstable intermediate **A**, *O*-ethyl H-phosphinothioate **9** (15%).

However, if this reaction is carried out in benzene, it is possible to obtain the desired addition product of two sulfur atoms, 2-thioxo-1,2 λ^5 -thiaphosphirane **10**. Refluxing of methylidene-phosphine **6** with 5.7 equivalents of sulfur in benzene for 3 h provided the maximum yield of the product **10** (34%).³² With a lesser amount of sulfur, a mixture of methylidene(thio)phosphorane **7** and the starting methylidene-phosphine **6** was formed containing only traces of 1,2 λ^5 -thiaphosphirane **10**. An increase in the temperature up to 90–100 °C (sealed tube) afforded an analogue of the Lawesson reagent, *i.e.*, compound **11**, which is the dimerisation product of arylmetadithiophosphonate **12**, and

[†] No reaction of 2,6-dimethylphenyl(methylidene)phosphine with sulfur occurs in EtOH or benzene at room temperature.³²

Scheme 1

Ar = 2,6-Me₂C₆H₃.

prolonged heating under the above-mentioned conditions gave a mixture of eleven unidentified phosphorus-containing compounds.

Ar = 2,6-Me₂C₆H₃.

Obviously, the stability of methylidene(thio)phosphoranes like the stability of 2-thioxo-1,2 λ^5 -thiaphosphiranes depends on the nature of substituents at the phosphorus atom and at the methylene carbon atom. On the whole, the set of these substituents is rather limited and comprises bulky groups [(Me₃Si)₂N, (Bu^t)(Me₃Si)N, Ph, 2,4,6-Me₃C₆H₂, 2,4,6-Bu₃C₆H₂, 2,6-Me₂C₆H₃, SiMe₃], which stabilise both the starting methylidene-phosphine and the addition products of sulfur. The trimethylsilyl group at the methylene carbon atom and bis(trimethylsilyl)amino-³⁰ and mesityl (Mes)^{34,35} groups at the phosphorus atom manifest the greatest stabilising effect.

The reaction of mesityl[bis(trimethylsilyl)methylidene]phosphine (**13**) with sulfur gives methylidene(thio)phosphorane **14** and the corresponding 1,2 λ^5 -thiaphosphirane **15**, which were obtained in the crystalline form for the first time. This made it possible to carry out the X-ray diffraction investigation (see below).³⁴

Later, by the example of 2,4,6-tri-*tert*-butylphenyl(diphenylmethylene)phosphine (**16**) it was shown that the use of bases [e.g., 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)] allows one to perform the addition of sulfur to triarylphosphaalkenes under very mild conditions (under room temperature) and to obtain the corresponding 2-thioxo-1,2λ⁵-thiaphosphirane **17** in virtually quantitative yield.³⁶ At higher temperatures, the yield of the cyclic product decreases significantly due to its instability under these conditions.³⁷

It may be suggested that the presence of different substituents at the methylene carbon atom of methylenephosphine would result in the formation of λ⁵-thiaphosphiranes as a mixture of two stereoisomers, and this was observed in one study.³⁸

The reaction of (*E*)-benzylidene(2,4,6-tri-*tert*-butylphenyl)phosphine (**18**) with sulfur afforded 1,2λ⁵-thiaphosphirane **19** as a mixture of isomers differing in the mutual arrangement of aryl groups. Taking into account the possible steric repulsion of the bulky aryl groups, the authors ascribed the *trans*-configuration to the major isomer.

One might also expect the formation of two geometric isomers for the aforementioned 3-trimethylsilyl-2-bis(trimethylsilyl)amino-2-thioxo-1,2λ⁵-thiaphosphirane (**3**),³⁰ and for λ⁵-thiaphosphirane **20**, which is the reaction product of 1-[bis(trimethylsilyl)amino]phosphadiene (**21**) with sulfur.³⁹

Nevertheless, in these cases the products were isolated as single isomers; their configurations were not discussed by the authors. Evidently, cycloaddition of sulfur to the intermediate methylenethio(phosphorane) is the step determining the type of the λ⁵-thiaphosphirane isomer formed. Most likely, this process is stereoselective and results in the sterically least hindered product.

2-Imino-1,2λ⁵-thiaphosphiranes **22** are also available by [1 + 2]-cycloaddition of sulfur to methylenethio(phosphorane) **23**.⁴⁰

R = SiMe₃ (**a**, 72%), Bu^t (**b**, 77%).

Compounds **22** were also obtained starting from methylenethio(phosphorane) by independent synthesis, which involved the addition of trimethylsilyl azide followed by the thermal decomposition of the Δ¹-triazaphospholene **24** (R² = SiMe₃) formed.⁴⁰ It is noteworthy that the photochemical decomposition of the adduct **24** (R² = Bu^t) yields 2-thioxo-λ⁵-azaphosphirane **25**.

R¹, R² = SiMe₃, Bu^t.

An unusual reaction of 2-acetyl-5-methyl-1,2,3-diazaphosphole (**26**) with phenyl isothiocyanate (**27**) afforded a fused 2-thioxo-1,2λ⁵-thiaphosphirane **28**.⁴¹ The latter can be obtained either upon prolonged heating of the equimolar mixture of reactants or in the presence of a catalytic amount of triethylamine. Changing the reaction conditions (UV-irradiation) causes a change in its direction: the acetyl group at N(2) atom of the starting phosphole is substituted for the phenyl group of phenyl isothiocyanate, giving the product **29**, which is partially dimerised during the reaction affording compound **30**.

2. Synthesis of 1,2λ³-thiaphosphiranes

As was mentioned above, the addition of one equivalent of sulfur to methylenephosphine usually gives rise to methylenethio(phosphorane) rather than to thiaphosphirane or to their mixture with the former predominating. Nevertheless, exceptions from this rule are documented. Thus the reactions of ethynylphosphaalkene **31** with sulfur and selenium do not result in methylenethio(phosphorane) (**32a**) and methylenethio(selenophosphorane) (**32b**), but occur as a [2 + 1]-cycloaddition yielding 1,2λ³-thiaphosphirane (**33a**) and 1,2λ³-selenaphosphirane (**33b**);⁴² the latter do not react with the second equivalent of sulfur.

X = S (**33a**, 55%), Se (**33b**, 50%).

Analogously, in the reaction of tricyclic phosphalkene **34** with sulfur (or selenium)⁴³ the sulfur (or selenium) atom adds stereoselectively to the P=C bond with the formation of tetracyclic λ^3 -thiaphosphirane (**35a**) [(or λ^3 -selenaphosphirane (**35b**)] where the sulfur (or selenium) atom is located *trans* relative to the bridging oxygen atom. However, in this case treatment of the sulfur-containing λ^3 -thiaphosphirane with the second equivalent of sulfur under the same conditions readily gives the corresponding 2-thioxo derivative **36**.

X = S (**35a**), Se (**35b**).

It should be noted that the use of a base (Et₃N) enables one to perform the above reaction under very mild conditions.

The reaction of 5-methyl-1,3,4-oxathiazol-2-one (**37**) with *P*-chloromethylidene phosphine **38** afforded, instead of the expected thiazaphospholenes **39**, a mixture of *E*- and *Z*-isomers of 2-chloro-1,2 λ^3 -thiaphosphiranes **40** (it is of note, that the interaction of 5-aryl-substituted oxathiazole with phosphines **38** yielded the corresponding thiazaphospholene).⁴⁴

R = Ph (total yield 32%, *E* : *Z* = 75 : 25), SiMe₃ (22%).

With general considerations in mind, one could suggest desulfurisation of the corresponding 2-thioxo-1,2 λ^5 -thiaphosphiranes as a possible approach to 1,2 λ^3 -thiaphosphiranes. However, 2-mesityl-3,3-bis(trimethylsilyl)-2-thioxo-1,2 λ^5 -thiaphosphirane (**15**) yields the corresponding methylenethiophosphorane **14** rather than the expected λ^3 -thiaphosphirane under the action of tributylphosphine.^{34,35}

Desulfurisation of 2-thioxo-1,2 λ^5 -thiaphosphirane **20** obtained from 1-phosphadiene **21** (see above) with triphenylphosphine affords phosphacyclobutene **41**,³⁹ which is the intramolecular cyclisation product involving C=C and P=C bonds in the intermediate methylenethiophosphorane **42**. The formation of the latter in the reaction was confirmed by ³¹P NMR spectroscopy.

At the same time, 2-thioxo-2-(2,4,6-*tert*-butylphenyl)-3,3-diphenyl-1,2 λ^5 -thiaphosphirane (**17**) is desulfurised readily giving the corresponding 1,2 λ^3 -thiaphosphirane **43**.^{36,37} Different phosphines were tested as desulfurisation agents; tris(dimethylamino)-phosphine proved to be the most efficient.

It is believed³⁷ that the distinction in the results of the reaction of different 2-thioxo-1,2 λ^5 -thiaphosphiranes suggests that the desulfurisation affording 1,2 λ^3 -thiaphosphirane^{36,37} is governed by kinetic control, while the reaction giving more stable methylenethiophosphorane^{34,35} is governed by thermodynamic control.

It should be noted that triaryl-substituted 2-thioxo-1,2 λ^5 -thiaphosphirane **17** is unstable and decomposes in deuterated benzene yielding arylmetadithiophosphonate **5**, thiobenzophenone and the corresponding λ^3 -thiaphosphirane **43**.³⁶

Ar = 2,4,6-Bu₃C₆H₂.

In many respects, the special interest in 1,2λ³-thiaphosphiranes is caused by the existence of valence isomerism between σ³λ⁵-phosphoranes (**A**) and σ³λ³-phosphiranes (**B**).

Thus thermodynamic conversion of methyldene(imino)phosphorane Pr₂NP(=CHBu^t)(=NBu^t) (< 110 °C) and dimethyldene-phosphorane (Me₃Si)₂NP(=CHSiMe₃)₂ (190 °C) to the corresponding azaphosphirane⁴⁵ and phosphirane⁴⁶ as well as the reverse transition of diazaphosphiranes (R = Pr₂N, Bu₂N; X = Y = NBu^t; 50 °C) to diiminophosphorane⁴⁷ have been reported earlier. Thermal or photoinduced isomerisation of sterically hindered diphosphene-*P*-sulfide (R = 2,4,6-Bu₃C₆H₂; X = S, Y = 2,4,6-Bu₃C₆H₂P) to λ³σ³-thiadiphosphirane has been described earlier.^{48,49}

Yoshifuji and co-workers^{36,37} were the first to obtain both valence isomers **A**(σ³λ⁵) and **B**(σ³λ³) in the individual state and to investigate in detail interconversions of 2,4,6-tri-*tert*-butyl-phenyl(dimethyldene)(thioxo)phosphorane (**44**) and the corresponding 1,2λ³-thiaphosphirane **43**. Being irradiated by the light of a mercury³⁶ or xenon³⁷ lamp, phosphorane **44** gave λ³-thiaphosphirane **43** as the main reaction product.

Ar = 2,4,6-Bu₃C₆H₂.

Irradiation by the Hg lamp (followed by flash chromatography and recrystallisation) and the Xe lamp, yielded 35% and 86% of compound **43** respectively.

The thermal transition of the linear form **44** to the cyclic form **43** for such a type of σ³λ⁵-phosphoranes was not observed. Thus, no traces of the cyclic isomer **43** could be detected upon refluxing of methyldene(thioxo)phosphorane **44** in toluene in the absence of light for 6 days.^{36,37} On the contrary, the reverse thermally induced transition of λ³-thiaphosphirane **43** to methyldene(thioxo)phosphorane **44** did occur.

Investigation of the temperature- and time-dependent transition **43** → **44** showed that the maximum yield of phosphoranes **44** (32%) was achieved upon 16-h reflux of a solution of λ³-thiaphosphirane **43** in *m*-xylene in the dark. More prolonged heating of compound **43** under these conditions resulted in the decomposition of the methyldene(thioxo)phosphorane **44** that was formed. A decrease in the reaction temperature down to 100 °C along with a simultaneous increase in the heating time (7 days) gave no positive result: the yield of the linear isomer **44** was only 10%. Irradiation of λ³-thiaphosphirane **43** by the mercury lamp afforded methyldene(thioxo)phosphorane **44** in 5% yield or as traces in a mixture with other unidentified products.

Ar = 2,4,6-Bu₃C₆H₂.

Thus, in the case of methyldene(thioxo)phosphoranes the conversion of the linear form to the cyclic one is only possible upon irradiation, while the reverse process can be both thermally and photochemically induced, though in the latter case to an considerably lesser extent.

III. 1,2-Thiaphosphetanes

The number of publications devoted to the synthesis of 4-membered 1,2-thiaphosphacyclanes, *i.e.*, 1,2-thiaphosphetanes, is very limited, all the known methods provide only 2-thioxo-1,2λ⁵-derivatives.

Thus the reaction of alkyl aminocrotonates **45** with P₄S₁₀ gives 2-thioxo-1,2-thiaphosphetan-4-ones **46**.⁵⁰ However, being heated in benzene (for more than 30 min) or upon chromatographic purification on silica gel the latter rearrange spontaneously to the isomeric oxaphosphetanes **47**. The authors suggested that the possible reaction mechanism involves the addition of a PS₂ fragment and substitution of sulfur for the carbonyl oxygen (intermediate **48**), electrophilic attack by the phosphorus atom of the PS₂ group on the thiocarbonyl sulfur atom with the closure of the P,S-heterocycle **49** and a series of successive rearrangements resulting in migration of the alkyl radical from the oxygen atom to sulfur (intermediates **50**, **51**). Taking into account data from IR spectroscopy (using deuterium exchange), which show that the intramolecular hydrogen bond stabilizing the isomeric heterocycles formed is stronger by far in the thiocarbonyl product **47**, it was proposed that the thiaphosphetane **46** represents a product of kinetic reaction control and the isomeric oxaphosphetane **47**, of thermodynamic control. It should be noted that this method cannot be considered as a preparative one, since the product yields are only 1%–4%.

R¹ = Me, Prⁿ; R² = Me, Et.

Two approaches to the synthesis of tetrafluoro-1,2-thiaphosphetanes **52** are described.⁵¹ One of them is based on the reaction of [bis(trimethylsilyl)]phosphines **53** with 1,1,2,2-tetrafluoroethane-1,2-bisulfenyl chloride (**54**), which has found application in the preparation of partially fluorinated heterocycles,^{52–54} and the second one makes use of the reaction of dichloro(methyl)phosphine with 4,4,5,5-tetrafluoro-2,2,7,7-tetramethyl-3,6-dithia-2,7-disilaoctane (**55**).

R = Me (**a**), Bu^t (**b**), Ph (**c**), 2,4,6-Bu^t₃C₆H₂ (**d**).

The latter reaction proceeds extremely readily at low temperature and results in the desired heterocycle **52a** in 68% yield, but since the fluorinated agent **55** used in this reaction was obtained in turn from 1,1,2,2-tetrafluoroethane-1,2-bisulfenyl chloride (**54**),⁵¹ the overall yield of the perfluorinated heterocycle **52a** according to this procedure is somewhat lower.

The application of the Lawesson reagent for the synthesis of unsaturated 5- and 6-membered P,S-heterocycles has already been mentioned. This is based on the reactions of the LR with alkenes,²⁰ the simplest 1,3-dienes^{55–58} and α,β-unsaturated ketones.^{27, 59}

The ability of the LR to enter into cycloaddition reactions with multiple bonds of different types is believed to be connected with its existence in solution^{60, 61} or at elevated temperatures^{28, 31} (and all the above reactions take place under rather drastic conditions) in an equilibrium with metadithiophosphonate.^{31, 32, 62} The latter is often referred to as dipolar dithiophosphonium ylide, since its reactivity is similar to that of the Wittig reagents.

The addition of the Lawesson reagent to the double bond of dicyanomethylidene compounds **56** aiming at obtaining 2-thioxo-1,2-thiaphosphetanes **57** was investigated.⁶³ This was the first example of the application of LR for such a purpose. The putative

R = C₆H₄OH-*o*, C₆H₄OMe-*p*, C₆H₄NO₂-*p*, 2-thienyl.

reaction mechanism involves nucleophilic attack by the monomeric LR fragment on the sp²-carbon atom resulting in the intermediate **58**, which undergoes intramolecular cyclisation (Scheme 2).

Unsaturated thioamides **59** are formed in this reaction in parallel (as a result of partial hydrolysis of one cyano group in compound **56** under the reaction conditions followed by the substitution of sulfur for the oxygen atom in compound **60** under the action of LR). In the case of benzyldenemalonodinitrile (**56**, R = Ph), the latter reaction pathway is the only one (see Scheme 2).

An effective straightforward synthesis of fused 2-thioxo-1,2-thiaphosphetanes has been proposed⁵⁸ based on the addition of dithiaphosphetane disulfides R₂P₂S₄ to sterically hindered alkenes. Thus exo-[2+2]-cycloaddition of R₂P₂S₄ to the multiple bond of norbornadiene (NBD) results in a series of stable tricyclic 2-thioxo-1,2-thiaphosphetanes **61**.

R = 4-MeOC₆H₄ (**a**), 3-Bu^t-4-OBu^tC₆H₃ (**b**), (C₅H₅)Fe(C₅H₄) ≡ Fc (**c**), (C₅H₄Me)Fe(C₅H₃Me) (**d**).

The rate of this reaction is determined mostly by the solubility of the starting dithiaphosphetane. Thus bis(methylferrocenyl)dithiaphosphetane — [(C₅H₄Me)Fe(C₅H₃Me)]₂P₂S₄ reacts with NBD at room temperature to give the [2+2] adduct **61d** in virtually quantitative yield in 14 h (CDCl₃, NMR experiment). The ferrocenyl derivative **61c** is obtained upon heating the reactants in the absence of a solvent at 80 °C for 16 h (the product yield is 69%). The reactions of bis(3-*tert*-butyl-4-*tert*-butoxyphenyl)dithiaphosphetane and the Lawesson reagent itself with NBD afford the target tricyclic compounds **61b** and **61a** in 44% and 13% yields, respectively.

Using Fc₂P₂S₄ as an example, an attempt was undertaken to evaluate the scope of the method proposed. The cycloaddition of Fc₂P₂S₄ to cyclohexene, norbornene and hexamethylbi-

Scheme 2

cyclo[2.2.0]hexa-2,5-diene was investigated.⁵⁸ As cyclohexene did not react with $\text{Fc}_2\text{P}_2\text{S}_4$, the authors supposed that only sterically strained alkenes are able to react according to the cycloaddition scheme under such mild conditions giving products of the type **62**.

In conclusion it should be mentioned that the main methods for obtaining 1,2-thiaphosphetanes, excluding the perfluorinated rings, involve the addition of phosphorus pentasulfide and the Lawesson reagent to various unsaturated substrates.

IV. 1,2-Thiaphospholanes and 1,2-thiaphosphinanes

The first representatives of the 5- and 6-membered saturated 1,2-thiaphosphacyclane family have been obtained upon exhaustive replacement of oxygen atoms by sulfur in the well-known 2-oxo-1,2-oxaphosphacyclanes.^{24, 64, 65} Such a replacement occurs under the action of an excess of phosphorus pentasulfide on the parent compounds, *e.g.*, 2-oxo-1,2-oxaphospholanes **63**, under drastic conditions (at 160–250 °C). Under milder conditions (reflux in benzene⁶⁴ or toluene^{24, 65}), only the phosphoryl oxygen atom is replaced affording 2-thioxo-1,2-oxaphospholanes **64**. Their yields range from 17% to 58% depending on the substituent R^1 at the phosphorus atom. The intermediate 2-thioxo-1,2-oxaphospholanes **64** are thermally stable,⁶⁴ in particular, upon distillation (80–130 °C) they do not undergo thione–thiol rearrangement, which would result in the migration of the sulfur atom into the ring. Replacement of the oxygen atom in the oxaphospholane ring by sulfur requires heating of compounds **64** with P_4S_{10} either at 120–130 °C (2 h without a solvent,⁶⁴ 6 h in chlorobenzene⁶⁵) or in an autoclave at 250 °C (in toluene).²⁴

$\text{R}^1 = \text{Me, Et, Ph}; \text{R}^2 = \text{H, Me}.$

Using this procedure, Polozov and Cremer⁶⁶ have performed exhaustive replacement of oxygen atoms by sulfur in both fused 1,2-oxaphospholane rings of the *cis*-isomer of 2,10-dioxaphosphabicyclo[4.4.0]decane 1-oxide **65** (P_4S_{10} , pyridine, reflux).

It was found that the stereochemistry of the starting bicycle can be changed during the reaction; the corresponding trithio derivative **66** was obtained as a mixture of *cis*- and *trans*-isomers in a 1.6 : 1 ratio. A milder thiylating agent, LR, enables only a partial replacement of the oxygen atoms in the substrate **65**, and the configuration of the initial *cis*-isomer is retained.

Numerous methods to obtain various 5- and 6-membered 2-oxo-1,2-oxaphospholanes is described in the literature. Evidently, the corresponding 2-thioxo-1,2-thia derivatives may be synthesised from them using phosphorus pentasulfide.

A method different in principle to obtain 2-thioxo-1,2-thiaphospholanes was proposed by Wing.^{21, 67} It is based on direct reaction of an unsaturated hydrocarbon, phosphorus pentasulfide and thiophosphoric acid halide under drastic conditions (autoclave, 150–200 °C, 10–18 h). When cyclic alkenes (*e.g.*, cyclohexene) are used as the starting substrates, bicyclic compounds are formed with one of the rings representing 1,2-thiaphospholane. These reaction products are used as antioxidant additives for motor oils, polymers and agrochemicals.

$\text{R} = \text{H, Me, Et}; \text{X} = \text{Cl, Br}.$

$\text{X} = \text{Cl, Br}.$

Conjugated 2-thioxo-1,2-thiaphospholanes **67** substituted in the ring were obtained by the reaction of the Lawesson reagent with a sterically crowded cyclohexyldienecyclopropanone **68**.⁶⁸ Nominally, this reaction may be considered as the insertion of the LR monomeric fragment (dithiophosphonium ylide) into the strained C–C bond of the starting cyclopropanone.

2,9-Dithia-1-thioxophosphabicyclo[4.3.0]nona-3,7-dienes **69** should be mentioned as precursors of another type of fused 2-thioxo-1,2-thiaphospholanes; these are formed in the reaction of α,β -unsaturated ketones with P_4S_{10} in the presence of

$\text{X} = \text{O, S}; \text{Ar} = \text{Ph, 4-ClC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4; \text{R}^1 = \text{Bu}^t, \text{Ph, 4-ClC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4; \text{R}^2 = \text{CN, Ph, OBU}.$

Et_3N .^{69–71} Thermolysis of such compounds in benzene occurs with the generation of 2-thioxo-1,2-thiaphospholes **70**, which act as cyclic heterodienes in [4 + 2]cycloaddition reactions with acrylonitrile,^{69, 70} styrene,⁷⁰ butyl vinyl ether⁷⁰ and norbornene.⁷⁰ In most cases, the cycloaddition products are obtained as mixtures of *exo*- and *endo*-isomers **71** or *exo-exo*- and *endo-exo*-isomers (in the case of norbornene), usually with the *endo*-isomer (when $\text{R}^2 = \text{CN}, \text{Ph}$) and *exo-exo*-isomer for the norbornene derivative predominating. The configuration of these compounds was established using NMR spectroscopy^{69, 70} and X-ray diffraction analysis.⁷¹ For butoxy-substituted polycarbocycles, it was not possible to establish the geometry of the molecule.

(*E*)-Arylmethylidene-1,2,3,4-tetrahydronaphthalen-1-one can be used as an α, β -unsaturated ketone, too.⁷⁰

$\text{Ar} = \text{Ph}, 4\text{-ClC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$.

Some processes can be applied for the preparation of both 1,2-oxaphosphacyclanes and their 1,2-thia analogues. Thus an intramolecular thermal isomerisation of the Arbuzov rearrangement type is characteristic of 1,3,2 λ^3 -diheterophosphacyclanes **72** ($\text{X} = \text{O}, \text{S}$); this occurs with a ring contraction.^{24, 63} The reaction occurs more readily and in higher yields for the corresponding oxygen derivatives.

$\text{X} = \text{O}$ (**72a**), S (**72b**).

In the case of 1,3,2 λ^3 -dithiaphosphinane **72b** ($\text{X} = \text{S}$), both 2-thioxo-1,2-thiaphospholane (**73**) and 2-thioxo-1,3,2-dithia-

phosphinane (**74**) are formed, the latter being the addition product of sulfur to the substrate. This result is explained by the possible reaction of 1,3,2 λ^3 -dithiaphosphinane **72b** with 2-thioxo-1,2 λ^5 -thiaphospholane **73** under drastic reaction conditions.

However, the second reaction product, viz., 2-phenyl-1,2 λ^3 -thiaphospholane (**75**), was not isolated and the authors failed to detect it by spectroscopic methods. Nevertheless, in the reaction of 2-thioxo-1,2 λ^5 -thiaphospholane **73** with $\text{Fe}_2(\text{CO})_9$ such a P(III) heterocycle was obtained as a ligand bound to the iron atom. The reaction proceeds in two steps. First, the complex **76** is formed having bridging $\text{Fe}-\text{S}-\text{Fe}$ and $\text{Fe}-\text{P}-\text{Fe}$ bonds, which then reacts with the second molecule of 1,2 λ^5 -thiaphospholane **73**. As a result of selective reduction of the $\text{P}=\text{S}$ group in compound **73**, the complex **77** is formed comprising the 1,2-thiaphospholane ligand.⁷²

It should be emphasised that the aforementioned synthetic routes to 5- and 6-membered 1,2-thiaphosphacyclanes are limited by the possibility of obtaining products with only a thiophosphoryl group.

An alternative general method for the formation of 1,2-heterophosphacyclic structure has been proposed by Kobayashi and co-workers^{23, 73} who obtained P,O- and P,S-heterocycles **78–81** bearing a three-valent phosphorus atom. This method involves the synthesis of *O*- or *S*-(ω -chloroalkyl) phenylphosphonochloridites followed by their intramolecular cyclisation under the action of metallic lithium.

Compound	X	n	Yield (%)
78	O	3	37
79	O	4	18
80	S	3	10
81	S	4	5

Independent of the nature of the X atom, 1,2-heterophospholanes ($n = 3$) are formed in higher yields than 1,2-heterophosphinanes ($n = 4$); in each class of compounds the yields of oxygen derivatives are higher than those of the sulfur-containing ones. Though in general the yields of both 1,2 λ^3 -oxaphosphacyclanes **78, 79** and 1,2 λ^3 -thiaphosphacyclanes **80, 81** in this reaction are moderate, the reaction is rather simple to perform. Compounds **78–81** were used as monomers in polymerisation.^{23, 74} The polymerisation occurs upon either the action of cationic initiators or heating and is accompanied by ring-opening.

The poly(phosphine oxides) and poly(phosphine sulfides) obtained possess good chelate-forming properties including high extraction capacity towards the ions of some heavy metals.²³ Poly(phosphine sulfides) extract Pd^{2+} and Hg^{2+} cations quantitatively from solutions in a wide range of pH, Cu^{2+} ions are extracted more efficiently in weakly alkaline media. The chelating capacity of poly(phosphine sulfides) exceeds that of the corresponding poly(phosphine oxides) towards Pd^{2+} and Hg^{2+} ions and is comparable for Hg^{2+} ions and significantly lower for uranyl ions UO_2^{2+} .

Fused 2-chloro-1,2 λ^3 -heterophospholanes **82a–c** ($\text{X} = \text{O}, \text{S}, \text{Se}$) are formed as a result of the intramolecular cyclisation of 2,4-di-*tert*-butyl-6-(methylheteromethyl)phenyldichlorophosphines **83a–c**.⁷⁵ It should be noted that the ease of formation of such heterocyclic compounds decreases in the order $\text{Se} > \text{O} \gg \text{S}$.

Compound	X	Cyclisation conditions	
		$T/^\circ\text{C}$	t/h
82a	O	25	10
82b	S	25	144
		66	3
82c	Se	< 0	—

2-Thioxo-1,2 λ^5 -analogues of such fused heterocycles (compounds **84a,b**) were obtained by an intramolecular rearrangement of $\sigma^3\lambda^5$ -metadithiophosphonates **85a,b**, obtained in turn by sulfur addition to the corresponding primary phosphines **86a,b** in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene.[‡]

$\text{X} = \text{S}$ (a), Se (b).

In this case, too, the cyclisation rate of methylselenomethyl-substituted derivative **85b** was much higher than for its sulfur analogue **85a**. The same applies to the formation of compounds **85a,b**. Thus the reaction of the phosphine **86b** with sulfur proceeds within 1 day at ambient temperature resulting in 2-thioxo-1,2-selenaphospholane **84b** in virtually quantitative yield. The formation of dithioxophosphorane **85b** could be observed only by NMR spectroscopy due to its rapid cyclisation. In the preparation of the corresponding 1,2 λ^5 -thiaphospholane **84a**, the intermediate stable metadithiophosphonate **85a** was isolated in the pure state and its cyclisation proceeded either upon heating of the solution in toluene in a sealed tube for 1 h or on heating without the solvent

for 1 min at 180 $^\circ\text{C}$ (above the melting point of 171–173 $^\circ\text{C}$). As the chemical shifts of metadithiophosphonates **85** [$\delta_{\text{P}} = 159.9$ ($\text{X} = \text{Se}$) and 161.8 ($\text{X} = \text{S}$) in CDCl_3] in ^{31}P NMR spectra are significantly shifted upfield in comparison with the signal of the 2,4,6-tri-*tert*-butylphenyl analogue, 2,4,6- $\text{Bu}_3^t\text{C}_6\text{H}_2\text{PS}_2$ ($\delta_{\text{P}} = 298.2$ in CDCl_3), the authors suggested the existence of a strong interaction between phosphorus and chalcogen atoms in the methylthio(seleno)methyl substituent as shown below.

To obtain 2-oxo-1,2 λ^5 - (**87, 88**) or 2-oxo-1,2 λ^5 -thiaphosphacyclanes (**89, 90**), one may use an intramolecular alkylation of ω -chloroalkylphosphinous (**91, 92**) and -thiophosphinous acids occurring in the presence of triethylamine.^{76, 77} Virtually no side products are formed during this cyclisation and the reaction kinetics is approximately first order. In this case, too, the five-membered heterocyclic products were formed more rapidly than their six-membered analogues: the ratio of the rate constants for 5- and 6-membered heterocycle formation ($k^5:k^6$) is 4.3 (for the phosphinate anion) and 30 (for the thiophosphinate anion). It should be noted that despite cyclisation of thiophosphinous acids proceeding under mild conditions and 2-oxo-1,2-thiaphosphacyclanes **89, 90** being formed in fairly high yields (85%–90%), the starting thioacids **93, 94** as such were obtained by multi-step procedures complicated by numerous side reactions from the corresponding phosphoryl analogues **91, 92** in low yields and of 90%–95% purity only.

$\text{Hal} = \text{Cl}, \text{Br}; n = 0$ (**87, 89, 91, 93**), 1 (**88, 90, 92, 94**);

(a) $(\text{COCl})_2$; (b) P_4S_{10} , HCONMe_2 (Cat.), dioxane, reflux;

(c) H_2O , acetone.

Harger and co-workers^{78, 79} carried out the comparative investigation of acid-catalysed cyclisation of ω -hydroxy- (**95, 96**)⁷⁸ and ω -mercaptoalkylphenylphosphinous (**97, 98**) acid anilides.⁷⁹ In this case, the sharp distinction in reactivities of HS and HO groups was observed. Thus oxaphospholanes (**87**) and oxaphosphinanes (**88**) were readily formed in both methanol and chloroform [$k^5:k^6 = 70$ (in CHCl_3) and 50 (in MeOH), at 20 $^\circ\text{C}$, the cyclisation time for the anilide **95** is 1 min and 15 min for the anilide **96**]. At the same time, in MeOH the anilides **97, 98** were converted into the corresponding esters **99, 100** due to the nucleophilic substitution of the methoxy group for the anilide residue. In CHCl_3 in the presence of gaseous HCl , the cyclisation of anilides **97, 98** leading to 1,2-thiaphospholane **89** (yield $\sim 75\%$) and 1,2-thiaphosphinane **90** (yield $\sim 2\%$) takes place. It should be noted, that such a cyclisation proceeds *via* the intermediate

[‡] Phosphines **86a,b** were obtained by reduction of the corresponding aryldichlorophosphines **83** or *O*-ethyl aryldichlorophosphinates with LiAlH_4 .

formation of phosphinic chlorides **101**, **102**, which were detected in the reaction mixtures by NMR spectroscopy.

X = O: $n = 0$ (**87**, **95**), 1 (**88**, **96**);

X = S: $n = 0$ (**89**, **97**, **99**, **101**), 1 (**90**, **98**, **100**, **102**).

Extensive research to the development of a general approach to 1,2-monoheterophosphacyclanes of diverse structures has been performed by Mastryukova and co-workers in recent years. The method is based on the intramolecular E-alkylation of ω -halogenoalkyl-substituted compounds of tetracoordinate phosphorus bearing a P = E group.

R = Alk, Ar; E = S, O, NR'; Hal = Cl, Br, I; $n = 3, 4$.

For the first time, this reaction has been employed for the synthesis of 2,2-diphenyl-1,2,4⁴-thiaphosphacyclanium iodides **103a,b** (E = S, $n = 3, 4$; Hal = I), which were obtained by refluxing solutions of the thermally stable ω -chloroalkyldiphenylphosphine sulfides **104a,b** in either acetone or acetonitrile with NaI.⁸⁰ The reaction proceeds *via* the formation of the corresponding ω -iodoalkyldiphenylphosphine sulfides **105a,b**, which was confirmed by ³¹P NMR spectroscopy. In contrast to ω -chloro-substituted derivatives **104a,b**, ω -bromoalkylphosphine sulfides **106a,b**, obtained from the corresponding hydroxy derivatives **107a,b** and isolated in a pure state, underwent rather easy transformations into cyclic thiaphosphacyclanium bromides **103a,b** (Hal = Br) (heating at 100 °C without a solvent).^{81, 82} Starting from these compounds, one could prepare the corresponding perchlorates and tetrafluoroborates **108a,b** by an exchange reaction.⁸³

The ease of formation of the cyclic salts **103a,b** (Hal = Cl, Br, I) is determined first of all by the nature of the halogen atom and

$n = 3$ (**a**), 4 (**b**); X = ClO₄, BF₄.

the length of the alkyl chain in the linear starting compound. Thus other conditions being equal, the iodides **105a,b** undergo cyclisation more rapidly than bromides **106a,b**, whereas chlorides **104a,b** do not undergo the intramolecular S-alkylation upon either refluxing in acetone or on heating in the absence of a solvent (140 °C, 1.5 h). The 1,2-thiaphospholanium salts (**103a**, $n = 3$) are formed more rapidly than 1,2-thiaphosphinanium salts (**103b**, $n = 4$). It should be noted that a tautomeric equilibrium between the cyclic form and the starting linear compound is established in solutions of 1,2-thiaphosphacyclanium salts, which is a rare case of ring-chain halogenotropic tautomerism (see below).

Intramolecular S-alkylation of ω -iodoalkyl-substituted thiophosphoryl compounds bearing an alkoxy group at the phosphorus atom **109a,b** obtained *in situ* from the corresponding chloro derivatives **110a,b**,[§] dealkylation of the quazi-phosphonium salt formed takes place according to the second step of the Arbuzov rearrangement resulting in 2-oxo-1,2-thiaphosphacyclanes **112a,b**.^{83–85} In this case, too, five-membered heterocyclic compounds ($n = 3$) are formed more rapidly than the six-membered ones ($n = 4$) ($k^5 : k^6 \approx 2$). In addition to the alkyl chain length, the solvent used influences the cyclisation rate: the reaction is faster in acetonitrile than in acetone, which may be connected with both the higher polarity and higher boiling point of MeCN. The nature of the substituent R at the phosphorus atom influences the cyclisation rate to a lesser extent (it decreases in the order Et > Ph > OEt). The yield of 1,2-thiaphosphacyclanes **112a,b** is 82%–96% (according to the ³¹P NMR data obtained for the reaction mixture) and 55%–71% (after isolation by chromatography or recrystallisation).

$n = 3$ (**a**), 4 (**b**); R = Et, Ph, OEt, NEt₂.

The mechanism of the reaction was established quite reliably as the authors succeeded in isolating the intermediate quazi-phosphonium salt bearing the ethoxy group starting from compound (EtO)EtP(S)(CH₂)₃Cl if the nucleophilic chloride anion is replaced by the perchlorate anion.^{84, 85} It should be noted that this is the first case where the intermediate product of the thione–thiol rearrangement of a phosphorus thioacid ester was isolated as an individual compound.

Thus, intramolecular S-alkylation represents a general method for the preparation of thiaphosphacyclanes. A wide range of thiophosphoryl compounds bearing a ω -halogenoalkyl moiety in the molecule undergo the above-mentioned intramolecular transformation. In particular, cyano-substituted mono- and bicyclic 1,2-thiaphosphacyclanes were obtained from ω -halogeno-

§ Chloroalkyl-substituted thiophosphinates and thiophosphonates **110** are thermally stable liquids that can easily be distilled (b.p. = 105–165 °C/2–3 Torr). 3-Chloropropyl(phenyl)thiophosphinate (R = Ph, $n = 3$) is the only exception, it undergoes the intramolecular thione–thiol rearrangement into 2-oxo-2-phenyl-1,2-thiaphospholane upon distillation *in vacuo* (160–170 °C/2 Torr).

As one would expect, the introduction of an electron-withdrawing cyano group at the α -position with respect to the phosphorus atom results in a decrease in the nucleophilicity of the thione sulfur atom and an increase in the stability of the linear form of cyano-substituted ω -halogenoalkyl sulfides (even the ones with a terminal iodine atom). Thus if non-functionalised ω -iodoalkylphosphine sulfides **105** undergo cyclisation *in status nascendi* under the action of NaI on chloro derivatives **104**, the cyano-substituted analogues **113** cyclise very slowly and in the equilibrium position the proportion of the corresponding phosphacyclanium salt **114** does not exceed 15%.⁸⁹

However, the α -CN group favours subsequent dealkylation in the phosphacyclanium salts formed (the intramolecular thione–thiol rearrangement) with at least one alkoxy substituent at the phosphorus atom. Thus, ω -chloroalkyl derivatives **115a,b** undergo cyclisation to the 3-cyano-2-oxo-1,2-thiaphosphacyclanes **116a,b** upon distillation *in vacuo*.^{86–90,93} Under these conditions, the cyano-substituted thiaphospholanes **116a** were formed faster and in higher yields than thiaphosphinanes **116b**. It should be noted, that the radical R^3 at the carbon atom influences sufficiently the yields of the target products (if $R^3 = \text{Alk}$, the yields decrease drastically), while the radical R^1 at the phosphorus atom virtually has no influence on the product yields. The cyclisation of the corresponding ω -iodoalkyl-substituted thiaphosphorylacetonitriles **117a,b**, formed *in situ* from the chloro derivatives proceeds under milder conditions. The yields of 3-cyano-2-oxo-1,2-thiaphosphacyclanes obtained in this way are usually higher than those of the same compounds prepared by distillation. If the starting substrate represents the thiophosphonate ($R^1 = \text{OAlk}$), the cyclisation of chloro derivatives **115a,b** carried out in the presence of an excess of NaI is accompanied by dealkylation of both alkoxy groups at the phosphorus atom and leads to the formation of sodium salts of the corresponding cyclic acid **118a,b** in virtually quantitative yields.^{89,93}

Cyano-substituted thiaphosphacyclanes **116a,b** were formed as mixtures of two stereoisomers differing in the mutual disposition of the cyano group and the phosphoryl oxygen atom relative to the ring plane (*cis*- $R_P^*R_{C^*}$ and *trans*- $R_P^*S_{C^*}$). The isomer ratio varies from 7 : 3 to 3 : 7 depending on the cyclisation method.⁸⁹ In most cases, the mixtures were separated into individual isomers

The reversible diastereomeric transformations were found to be a characteristic feature of 3-cyano-2-oxo-1,2λ⁵-thiaphosphinanes **116b** where R³ = H. Thus, the isomeric mixture obtained upon cyclisation transforms with time into a single isomer with the most favourable arrangement of the substituents as regards the general anomeric effect (*cis*-isomer for R¹ = OAlk and *trans*-isomer for R¹ = Me). In benzene solution, the isomer isolated in the pure state gradually transforms into an equilibrium mixture of both isomers.⁸⁶ Since no transformation of an isomeric mixture of **116b** R³ = Alk into an individual isomer and the reverse transformation of any individual isomer into an equilibrium mixture were observed, a carbanion mechanism was suggested for such diastereomeric transformations.^{88,90,93} It is believed that the process involves dissociation of a rather acidic hydrogen atom at position 3, the formation of a flattened carbanion and subsequent proton addition with the inversion of configuration of the asymmetric carbon atom in the ring.

$$\begin{array}{ccc} \begin{array}{c} \text{O} \\ \parallel \\ \text{R}^1-\text{P}-\text{S} \\ | \quad | \\ \text{R}^3 \quad \text{CN} \\ | \\ (\text{CH}_2)_{n-2} \end{array} & \xrightarrow[\text{C}_6\text{H}_6, \Delta]{\text{HSiCl}_3} & \begin{array}{c} \text{O} \\ \parallel \\ \text{R}^1-\text{P}-\text{S} \\ | \quad | \\ \text{R}^3 \quad \text{CN} \\ | \\ (\text{CH}_2)_{n-2} \end{array} \end{array}$$

An efficient route to 6-cyano-2-oxa-10-thia(oxa)phosphabicyclodecane 1-oxides, which were previously accessible with difficulty, was elaborated based on thermal cyclisation of bis(3-chloropropyl)phosphoryl- and -thiophosphorylacetonitriles **120**. This proceeded by an intramolecular P=E alkylation (E = O, S) mechanism.^{90–93} 6-Cyano-2,10-dioxaphosphabicyclodecane 1-oxide (**121**) was obtained as a single *cis*-isomer,⁹¹ while its thio analogue with two different cyclic moieties **122** formed as a mixture of *cis*- and *trans*-isomers in a 2.3 : 1 ratio.⁹² Both isomers of 6-cyano-2-oxa-10-thia(oxa)phosphabicyclodecane 1-oxide **122** were found to be conglomerates (racemic mixture of homochiral crystals) undergoing spontaneous resolution[¶] upon crystallisation.⁹²

It should be mentioned, that the intramolecular P=S alkylation (followed by dealkylation of the alkoxy group at the phosphorus atom) proceeds also in the series of *N*-(ω -halogenoalkyl)thiophosphonamidates **123**^{94–100} and *S*-(ω -halogenoalkyl)

¶ Crystals are formed enriched in one enantiomer.

dithiophosphorates and -phosphonates **124**,¹⁰¹ to give 1,3,2-diheterophosphacyclanes **125** and **126**, respectively.

$n = 2, 3$; $\text{R}^1 = \text{Me, Ph}$; $\text{R}^2 = \text{Me, Et, Pr, Bu}$; $\text{R}^3 = \text{Me, Et, Ph}$.

$n = 2, 3$; $\text{R}^1 = \text{Me, OPr}$; $\text{R}^2 = \text{Et, Pr}$.

Thus, the intramolecular *S*-alkylation is apparently inherent in various types of thiophosphoryl compounds with an ω -halogenoalkyl fragment. Therefore, there is good reason to believe that the method for the preparation of 2-oxo-1,2-thiaphosphacyclanes by the intramolecular thione–thiol rearrangement is the most common and is of practical importance.

V. Ring-chain tautomerism in the series of 1,2-thiaphosphacyclanes

It was reported,^{80–84} that cyclic phosphonium salts **103a,b**, called 1,2 λ^4 -thiaphosphacyclanium salts, exist in solutions as equilibrium mixtures of a cyclic form (**A**) and a linear ω -halogenoalkylphosphine sulfide (**B**). Such a tautomeric equilibrium belongs to a type of ring-chain anionotropic tautomerism, which occurs in organic chemistry much more rarely than the prototropic one.¹⁰² Moreover, even in cases where both tautomers could be isolated in the individual state, the tautomeric equilibrium in solution is rarely observed especially in the absence of a catalyst.¹⁰²

$\text{X} = \text{Cl, Br, I}$.

For the first time, the existence of such a tautomeric equilibrium $\text{A} \rightleftharpoons \text{B}$ was detected for 2,2-diphenyl-1,2 λ^4 -thiaphospholanium iodides (**103a**, $\text{Hal} = \text{I}$) and 2,2-diphenyl-1,2 λ^4 -thiaphosphinanium iodides (**103b**, $\text{Hal} = \text{I}$).⁸⁰ However, halogenotropic tautomerism in the series of 1,2-thiaphosphacyclanium salts was investigated in more detail by the example of the corresponding bromides, both the linear (**106a,b**) and the cyclic (**103a,b**) tautomers of which ($\text{Hal} = \text{Br}$) were isolated in the pure state and investigated by X-ray diffraction analysis.^{80,81} It was shown that the equilibrium position is attained starting from either the linear or cyclic tautomer. Thus, according to the ³¹P NMR data, keeping a solution of a five-membered cyclic bromide **103a** ($\text{Hal} = \text{Br}$) (or its linear tautomer **106a**) in CH_2Cl_2 at 20 °C yields an equilibrium mixture of the same composition comprising 38% of the cyclic (**A**) and 62% of the linear (**B**) tautomer. In the case of the six-membered bromide **103b** ($\text{Hal} = \text{Br}$) (or its linear tautomer **106b**), it takes *ca.* 25 days for the equilibrium to be attained in CH_2Cl_2 and the equilibrium mixture contains 48% of the cyclic (**A**) and 52% of the linear (**B**) tautomers. Thus, with the other conditions being the same (the solvent and temperature), the equilibrium is established faster for five-membered heterocyclic compounds than for the six-membered ones.

The effect of solvent polarity, ring size and the nature of the anion on the position of the tautomeric equilibrium $\text{A} \rightleftharpoons \text{B}$ was investigated in detail.⁸¹ As is evident from the data in Table 1, the position of the equilibrium shifts from the linear form to the cyclic one in going from Cl to Br and I. Thus only minor amounts of the cyclic form **A** were determined in acetonitrile solutions of ω -chloroalkyldiphenylphosphine sulfides **104a,b** after storage for 6 months, while only the cyclic form **B** was found after keeping the solutions of the corresponding iodides **105a,b** in the same solvent. As would be expected for perchlorates, the equilibrium is completely shifted to the cyclic tautomer **A** independent of the solvent polarity. Under the same conditions (solvent, temperature, time), usually an increase in the content of the form **A** is observed in equilibrium mixtures on going from the 1,2-thiaphospholanium salts to 1,2-thiaphosphinanium salts. This fact was explained^{80–82} by the higher strain in the five-membered ring.

Table 1. The content of the cyclic form **A** (%) in solutions of 1,2 λ^4 -thiaphosphacyclanium salts **103a,b** ($\text{Hal} = \text{Cl, Br, I}$) and **108a,b** ($\text{X} = \text{ClO}_4$) according to ³¹P NMR data.

Solvent	Hal = Cl		Hal = Br		Hal = I		X = ClO ₄	
	$n = 3$	$n = 4$	$n = 3$	$n = 4$	$n = 3$	$n = 4$	$n = 3$	$n = 4$
CH_2Cl_2	0	0	38	48	70	85	100	100
CHCl_3	0	0	65	85	87	92	100	100
MeCN	9	3	82	82	100	100	—	—

It was also established that the proportion of the cyclic tautomer **A** increases with a decrease in temperature,^{80,81} *i.e.*, as in other ring-chain tautomeric systems,¹⁰² the transition of a cyclic form into the linear one is an endothermic process.

A similar equilibrium was described by Kobayashi *et al.*,²³ who studied the mechanism of polymerisation of 1,2 λ^3 -thiaphosphacyclanes, where the initiation step involves the reaction of the latter with RX .

$n = 3$ (**80**), 4 (**81**); $\text{RX} = \text{MeOTf, MeI, BnBr}$.

A mixture of the starting monomer with an equimolar amount of MeOTf, MeI or BnBr in CDCl_3 was monitored by ³¹P NMR and the formation of the corresponding linear form at 80 °C was observed in the cases where halide serves as a counterion. At lower temperature (35 °C), the linear form was not detected. However neither regularities of this process were investigated nor the corresponding tautomers were isolated.

As mentioned above, the decrease in the nucleophilicity of the sulfur atom in linear ω -halogenoalkyl-substituted phosphine sulfides due to the introduction of an electron-withdrawing substituent (*e.g.*, the cyano group) into the α -position relative to the phosphorus atom resulted in the deceleration of the cyclisation, the proportion of the product **114** in the equilibrium mixture not exceeding 15%.⁸⁹

VI. Structural features of 1,2-thiaphosphacyclanes

In a number of papers devoted to 1,2-thiaphosphacyclanes having different ring sizes their structural features revealed from X-ray studies are discussed in detail. Therefore we considered it reasonable to summarise these data. Table 2 presents the principal geometric parameters of 1,2-thiaphosphacyclanes as obtained from X-ray data.

Table 2. The principal bond lengths and bond angles for 1,2-thiaphosphacyclanes according to the literature data.

^a Parameters for two independent molecules. ^b The compounds represent conglomerates, which undergo crystal-induced spontaneous resolution (data for the major enantiomer are shown). The structures are disordered due to superposition of two enantiomers (7 : 3 for *trans*-**122** and 17 : 3 for *cis*-**122**).

The structures of two 1,2-thiaphosphiranes **43** and **15**, with a tri-^{36,37} and tetracoordinate³⁴ phosphorus atom, respectively, were investigated by X-ray diffraction analysis. In λ^5 -derivative **15** with the phosphine sulfide group, the P—C and P—S bond lengths in the three-membered ring are somewhat shorter than in the λ^3 -derivative **43**, which results in the corresponding elongation of the S—C bond in compound **15**. Presumably, this is connected with the presence of bulky trimethylsilyl groups at the carbon atom in compound **15**. It is interesting to note that with allowance for the difference in the chemical structure, *i.e.*, with the presence of the sulfur atom in the ring, compound **15** is virtually isostructural with its precursor, methylidene(thioxo)phosphorane **14** Mes—P(S)=C(SiMe₃)₂.³⁴

In the series of 1,2-thiaphosphetanes, the representatives of the smallest group of 1,2-thiaphosphacyclanes, only for two ferrocenyl-substituted thiophosphoryl compounds **61c** and **62b**^{58,103} are X-ray data available. In these compounds, the four-membered ring is part of a fused cage system, both compounds being represented by *exo*-isomers. The four-membered ring in both compounds is flattened (the maximum deviation from the plane PCCS is 0.05 and 0.14 Å for **61c** and **62b** respectively). The minor deviation from planarity in compound **62b** is caused by steric hindrance due to methyl substituents. The increase in the S=P—C angle in **62b** is evidence for this fact.

X-Ray diffraction studies of the iron complex **77** with the 1,2,3-thiaphospholane P-monodentate ligand was carried out.⁷² The ligand is characterised by the longest P—C_{cyclo} bond (1.907 Å) of all the 1,2-thiaphosphacyclanes shown in Table 2. In addition, the P—S bond length in this compound (2.087 Å) also exceeds the analogous bond lengths in other 1,2-thiaphospholanes with the exception of compound **71** (Ar = Ph, R¹ = Bu^t, R² = CN)¹⁰⁴ having a norbornene structure, where the five-membered ring may be considered as a 1,2-thiaphospholane only formally (the sulfur atom serves as a bridge between the bridgehead phosphorus and carbon atoms). The parameters of the 1,2-thiaphospholane ring in

compound **71** are similar to the expected values with the exception of the P—S—C angle (82.3° and 82.6°) due to considerable steric strain in the bicyclic skeleton. It should be noted that in this case the values of the angle are similar to those in phosphetanes.

According to X-ray data for 5- and 6-membered 1,2-thiaphosphacyclanium salts **103a** (Hal = I, Br), **108a** (X = ClO₄) and **103b** (Hal = I, Br)^{80,81,83} differing only in their anions, these compounds are isostructural. In addition, the orientation of the two phenyl rings bound to the phosphorus atom relative to the planes of both the 5- and 6-membered rings is practically the same in all compounds. Thus, their structures do not depend on the nature of the anion or packing character. In all the structures under investigation, the phosphorus atom has a slightly distorted tetrahedral configuration with an endocyclic angle reduced to 100.3(2)° and 108.1(2)° in the thiaphospholane and thiaphosphinane rings, respectively.

Five-membered rings in 1,2-thiaphosphacyclanium salts **103a** (Hal = I, Br) and **108a** (X = ClO₄) have envelope conformations with an average deviation of the C(4) atom from the plane formed by the other atoms of 0.6 Å. 1,2-Thiaphosphinanium salts **103b** (Hal = I, Br) possess chair conformations. On going from five-membered to six-membered rings contraction of the P⁺—S bonds (on average, from 2.065 to 2.050 Å) and S—C bonds (from 1.846 to 1.835 Å) is observed.

The presence of shortened contacts of the type 'cation—halide anion' (P⁺—S...Hal[−]) is a characteristic feature of these compounds, and analysis of the known structural data showed that such contacts with the halide ions in compounds containing the P⁺—S bond were previously unknown. In compounds **103a** (Hal = I, Br), **108a** (X = ClO₄) and **103b** (Hal = I, Br), the phosphorus, sulfur and halogen atoms are virtually colinear [the average value of the P—S—Hal bond angle is 175.3(1)°], which points to the directionality of the contact. Taking into account the difference in the van der Waals distances, the contact strength for the same ring is virtually independent of the nature of the halogen.

Thus the difference in the $S \cdots \text{Hal}^-$ distances in five-membered rings for the bromide **103a** ($\text{Hal} = \text{Br}$) and the iodide **103a** ($\text{Hal} = \text{I}$) (0.16 Å) almost coincides with the difference in van der Waals radii for Br and I (0.17 Å). Owing to these contacts, the sulfur atom in such structures acquires a trigonal configuration. On going from five- to six-membered thiaphosphacyclanium halides, significant contraction of the $S \cdots \text{Hal}^-$ distance is observed (this correlates with the interion contact strength) by 0.19 and 0.18 Å in iodides and bromides, respectively. Based on the correlation of the $\text{P}-\text{S}$ and $S \cdots \text{Hal}^-$ bond lengths with the ring size, it was suggested that this contact is caused by the donor–acceptor interaction of the halogen lone electron pair with the antibonding orbital of the $\text{P}-\text{S}$ bond ($n-\sigma^*$ -interaction).

Despite the similarity on the whole of the geometric parameters of five-membered phosphonium salts **103a** and **108a** with those of cyano-substituted *cis* and *trans*-2-oxo-1,2λ⁵-thiaphospholanes **116a**,⁸⁹ the elongation of the $\text{P}-\text{S}$ bond and contraction of the $\text{S}-\text{C}$ bond in the latter should be mentioned. The same regularity is observed when comparing the bond lengths in salts **103b** ($\text{Hal} = \text{I}, \text{Br}$) with those in 2-oxo-1,2λ⁵-thiaphosphinane **112b** ($\text{R} = \text{Ph}$).⁸⁴

The introduction of the cyano group in position 3 of the 2-oxo-1,2-thiaphosphinane ring^{86,88,89} resulted in the contraction of the $\text{P}-\text{S}$ bonds (*cf.* structures **112b** and **116b** with different substituents R^1 and R^3 , Table 2). At the same time, the $\text{P}-\text{S}$ bond in 3-cyano-2-oxo-1,2-thiaphosphinanes **116b** ($\text{R}^1 = \text{OEt}$, $\text{R}^3 = \text{Me}$; $\text{R}^1 = \text{Me}$; $\text{R}^3 = \text{H}$, Me ; $\text{R}^1 = \text{Ph}$, $\text{R}^3 = \text{H}$) is longer[†] than the $\text{P}-\text{S}$ bond in the corresponding thiaphosphinanium salts **103b** ($\text{Hal} = \text{I}, \text{Br}$). It should be mentioned also that in both five- and six-membered rings the presence of the cyano group leads to a significant elongation of the $\text{P}-\text{S}$ bond, especially in the case of transoid arrangement of the phosphoryl oxygen atom and the CN fragment.

According to an X-ray investigation⁹² of single crystals of *cis*- and *trans*-isomers of phosphabicyclo[4.4.0]decane 1-oxide **122**, these compounds represent conglomerates (racemic mixture of homochiral crystals) which undergo the crystal-induced spontaneous resolution. Thus in the crystals of both isomers, the superposition of two enantiomers P_R and P_S (7:3 for *trans*-**122** and 17:3 for *cis*-**122**) is observed. On the whole, the geometry of compounds obtained is similar to that of the known phosphabicyclo[4.4.0]decane 1-oxides with two symmetric 1,2-oxaphosphinane rings.^{91,105–107} The $\text{P}(\text{I})\text{O}(\text{2})\text{C}(\text{4})\text{C}(\text{8})$ torsion angles in compounds *cis*-**122** and *trans*-**122**, which characterise the mutual disposition of the phosphoryl and cyano groups, are equal to -48.4° and 179° , respectively.

In conclusion, it may be mentioned that in general the length of an ordinary $\text{P}-\text{S}$ bond in 1,2-thiaphosphacyclanes independent of the ring size and coordination number of the phosphorus atom varies within a rather narrow range 2.049–2.095 Å. The longest $\text{P}-\text{S}$ bond was detected in 1,2-thiaphosphirane **43** (2.113 Å) and phosphetane **61c** (2.102 Å), and the shortest one in phosphabicyclo[4.4.0]decane 1-oxide **122** (2.02 and 2.04 Å). The $\text{P}-\text{C}$ bond length also varies insignificantly: the shortest $\text{P}-\text{C}$ bond was found in 1,2-thiaphosphirane **15** and in five- and six-membered 1,2-thiaphosphacyclanium salts **103b** ($\text{Hal} = \text{I}, \text{Br}$) and **108a** ($\text{X} = \text{ClO}_4$). The bond angles $\text{S}-\text{P}-\text{C}$ in all compounds shown in Table 2 are in keeping with the regular values corresponding to the size of the heterocycle (in three- and four-membered cycles, the bond angles decrease in compliance with the normal tendency connected with the presence of strained small rings).

VII. Conclusion

The material presented in this review is evidence of the essential progress in the field of synthesis of 1,2-thiaphosphacyclanes having the phosphorus atom in different valence states and

coordination. Such general synthetic routes should be noted as sulfur addition to methylenephosphines resulting in 2-thioxo-1,2λ⁵-thiaphosphiranes; the addition of phosphorus pentasulfide or the Lawesson reagent to a variety of unsaturated substrates leading to 2-thioxo-1,2λ⁵-thiaphosphetanes; the reaction of phosphorus pentasulfide with available five- or six-membered 2-oxo-1,2-oxaphosphacyclanes yielding 2-thioxo-1,2λ⁵-thiaphospholanes and -thiaphosphinanes; and intramolecular *S*-alkylation of ω-halogenoalkyl-substituted thiophosphoryl compounds, which give easy access to a wide range of mono- and bicyclic 2-oxo-1,2λ⁵-thiaphosphacyclanes, including those functionalised in the ring. The existence of convenient synthetic routes may open prospects for the further use of this type of organophosphorus compounds in fine organic synthesis, agriculture and some technical areas.

VI. Conclusion	821

Abstract. Methods for the synthesis of chiral organophosphorus compounds based on natural optically active compounds (hydroxy acids, amino acids and their derivatives, mono- and disaccharides, mono- and diterpenoids, steroids) are discussed. Particular attention is given to the synthesis of bisphosphines and bisphosphinites. These compounds serve as ligands for transition metal complexes, which catalyse asymmetric hydrogenation. Data on the enantioselectivity of hydrogenation of unsaturated precursors of amino acids and unsaturated prochiral acids as well as on the enantioselectivity of hydrosilylation of ketones are surveyed. The bibliography includes 77 references.

I. Introduction

Chiral organophosphorus ligands are widely used in the synthesis of metal complex catalysts. It is these transition metal complexes with mono- and bidentate chiral phosphines and phosphinites that made it possible to perform important industrial reactions such as hydrogenation of prochiral unsaturated carbonyl compounds in preparative yield and with high enantioselectivity ($\geq 90\%$).

A large number of optically active phosphorus-containing ligands have been synthesised and used for the preparation of transition metal complexes exhibiting high catalytic activities resulting in high enantioselectivities.^{1–5} Chiral organophosphorus ligands are prepared either by enantiospecific transformations of native optically pure compounds or by transformations of prochiral compounds followed by resolution of racemates. Among natural compounds, hydroxy and amino acids as well as

carbohydrates are most commonly used for the synthesis of such ligands (more rarely, terpenoids and steroids, are employed).

Syntheses of chiral organophosphorus ligands with the use of natural compounds have not been systematically surveyed in the literature. The aim of the present review is to close this gap.

II. Organophosphorus ligands based on hydroxy acids

1. Synthesis of ligands

One of the first ligands used in asymmetric metal complex catalysis was DIOP, viz., (–)-*trans*-4,5-bis(diphenylphosphino-methyl)-2,2-dimethyl-1,3-dioxolane (**1**),

which was prepared by stereospecific transformations of (+)-(2*R*,3*R*)-tartaric acid (**2**).⁶ The synthesis of **1** was preceded by unsuccessful attempts to prepare chiral bisphosphine **3** from intermediate dichloride **4** by the reaction of the latter with nucleophilic reagents, viz., diphenylphosphine or diphenylphosphides MPPH_2 ($\text{M} = \text{Li}, \text{Na}, \text{K}$). However, in all cases only optically inactive phosphine oxide was isolated from the reaction mixtures.

An approach based on transformations of diethyl L-tartrate (**5a**) first into acetone, then into diol **6** and, finally, into ditosylate **7** appeared to be more efficient. Compound **7** was transformed into the target product (–)-DIOP (**1**) using sodium diphenylphosphide (Scheme 1).⁷

An analogous approach was used in the synthesis of dithoxybisphosphine **8**.

Unlike dimethoxy derivative **8**, DIOP is a crystalline compound due to which its isolation and additional purification can be substantially simplified. In addition, an essential advantage of ligand **1** over its acyclic analogue **8** is the conformational rigidity of the chelate ring formed upon its coordination to a transition metal atom due to the presence of *trans* substituents in the dioxolane ring. Metal complex catalysts thus prepared exhibit high stereoselectivity.⁷

In the syntheses of chiral phosphines from natural compounds, the phosphine group is introduced by nucleophilic displacement of the toluenesulfonyl (methanesulfonyl) group or the halogen atom with alkali metal phosphides. There are two main procedures for the preparation of the latter compounds. One procedure (*in situ* synthesis of phosphides) is based on the reactions of chlorophosphines $\text{R}^1\text{R}^2\text{PCl}$ ($\text{R}^1, \text{R}^2 = \text{Ar}, \text{Alk}$) with alkali metals (Li, Na, K) in dioxane or tetrahydrofuran. Another widely used method involves the cleavage of the $\text{P}-\text{C}(\text{Ar})$ bond in tertiary phosphines by alkali metals followed by isolation of the resulting diarylphosphides.⁸ To improve the efficiency of the synthesis, one or another modification of phosphinylation is often required. Thus, high yields were achieved in all steps of the above-considered procedure for the synthesis of DIOP (see Scheme 1) except for the step of phosphinylation, which decreased the total yield of the product to 27%.⁷ Murrer *et al.*⁸ suggested that phosphinylation of ditosylate **7** should be performed with the diphenylphosphide anion, which is formed *in situ* in the reaction of triphenylphosphine with an alloy of Na and K. The use of this expedient made it possible to increase the yield in the last step of the reaction to 72% (the total yield of the ligand was 49%).

Other analogues of compound **1** were synthesised by the target replacement of substituents at the phosphorus atoms as well as by acetalisation of free hydroxy groups, which are generated upon hydrolysis of acetonide, with different carbonyl compounds.

For example, the reactions of ditosylate **7** with lithium diarylphosphides afforded symmetrical bisphosphines **9a–f**.^{9–11}

$\text{Ar} = 2\text{-MeC}_6\text{H}_4$ (**a**), $4\text{-MeC}_6\text{H}_4$ (**b**), $2,5\text{-Me}_2\text{C}_6\text{H}_3$ (**c**),
 $4\text{-MeO-3,5-Me}_2\text{C}_6\text{H}_2$ (**d**), $4\text{-Me}_2\text{NC}_6\text{H}_4$ (**e**);

Unsymmetrical analogues of (–)-DIOP, *viz.*, compounds **10a,b** containing various aryl substituents at the phosphorus atoms, were synthesised in two steps. First, ditosylate **7** was treated with a particular lithium diarylphosphide (1 equiv.) and then the resulting monophosphines **11a,b** were treated with another diarylphosphide.¹⁰

Compound	Ar ¹	Ar ²	Yield (%)
11a	Ph	—	44
11b	3-MeC ₆ H ₄	—	52
10a	Ph	4-MeNC ₆ H ₄	51
10b	3-MeC ₆ H ₄	4-MeNC ₆ H ₄	52

Alkyl derivatives of bisphosphine **1** were prepared from ditosylate **7** through intermediate difluoride **12**. The reactions of the latter with lithium dialkylphosphides afforded bisalkyl-bisphosphines, *viz.*, (–)-EtDIOP (**13a**), (–)-PrⁱDIOP (**13b**) and (–)-CyDIOP (**13c**).¹²

$\text{R} = \text{Et}$ (**a**, 83%), Pr^i (**b**, 34%), cyclo-C₆H₁₁ (**c**, 74%).

Unsymmetrical chiral bisphosphine (–)-DIOCP **14** containing cyclohexyl groups at one of the phosphorus atoms and bearing phenyl groups at another phosphorus atom was prepared from 2,3-*O*-isopropylidene-L-threitol (**6**) by the multistep synthesis.¹³

$\text{Ms} = \text{MeSO}_2$.

The introduction of substituents containing highly polar functional groups, which can form salts, into bisphosphine molecules gives rise to water-soluble organophosphorus ligands.¹⁴ Groups providing solubility of structural analogues of (–)-DIOP in water can be present not only in the aromatic fragments of the ligand (for example, quaternised compound **9e**) but also in the dioxolane ring. For example, among compounds **15a–e**, which were prepared from condensation products of diol **16** with various aldehydes or ketones,^{9, 15, 16} polyoxadioxolanes **15d,e** are soluble in water.

$R^1 - R^2 = (\text{CH}_2)_4$ (**a**), $(\text{CH}_2)_5$ (**b**); $R^1 = \text{H}$; $R^2 = \text{Ph}$ (**c**), $\text{CH}_2\text{O}(\text{CH}_2\text{CH}_2\text{O})_5\text{Me}$ (**d**), $\text{CH}_2\text{O}(\text{CH}_2\text{CH}_2\text{O})_{16}\text{Me}$ (**e**).

Bisphosphines **17** synthesised in the study¹⁷ are soluble in water due to the presence of hydroxy-containing substituents in the dioxolane ring.

Tf = CF_3SO_2 .

Compound 17, 18	R^1	R^2	R^3	Yield (%)	
				18	17
a	Ph	Me	Me	80	79
b	Me	CH_2OAc	CH_2OH	89	52
c	H	2-AcOC ₆ H ₄	2-HOC ₆ H ₄	70	76
d	H	4-AcOC ₆ H ₄	4-HOC ₆ H ₄	73	82

Ligands **17a-d** were prepared from the corresponding ditosylates **18a-d** by the reactions with lithium diphenylphosphide, which were accompanied by elimination of acetyl groups. Phosphinylation of ditosylate **18b** afforded bisphosphine **17b** in substantially lower yield compared to those achieved in all other cases because this reaction gave rise to phosphine **17b** along with bicyclic ether ketal **19** (43%).¹⁷

When performing analogous transformations of ditosylate **18e** ($R^1 = \text{Ph}$, $R^2 = \text{CH}_2\text{OAc}$), the acetyl group was replaced by the tetrahydropyranyl group to prevent undesired cyclisation in the final step of the synthesis. Subsequent transformations of ester **20** produced the target bisphosphine **17e**.¹⁷

THP is tetrahydropyranyl.

Attempts to subject diethyl tartrate **5a** to acetalisation with butane-2,3-dione monoketals **21** led to the formation of 1,4-dioxane **23** instead of the expected dioxolane **22**. Compound **23** served as the starting compound for the synthesis of chiral bisphosphines of new structural types **24** and **25**.^{18, 19}

$R = \text{Me}$ (**a**), Et (**b**).

Yet another procedure for the preparation of C_2 -symmetrical ligands involves structural transformations of (+)-(-)(2*R*,3*R*)-tartaric acid (**2**) into pyrrolidine-type 1,2-bisphosphines. For example, heating of acid **2** with benzylamine afforded cyclic imide **26**, which was reduced by NaBH_4 to form dihydroxy-pyrrolidine **27**. The latter served as the starting compound for the synthesis of the DEGUPHOS ligand (**28a**), its derivatives (**28b,c**) and the PYRPHOS ligand (**29**). The presence of the amino group in these compounds substantially facilitates both their isolation from the reaction mixtures as hydrochlorides and subsequent purification.²⁰⁻²²

$M = \text{Na}$ (for **28a**), Li (for **28b,c**);

$\text{Ar} = \text{Ph}$ (**a**), 4-Me₂NC₆H₄ (**b**), 4-MeO-3,5-Me₂C₆H₃ (**c**).

Treatment of imide **26** with chlorodiphenylphosphine in pyridine produced bisphosphinite **30**.²³

Acylation of the secondary amino group in bisphosphine **29** made it possible to prepare compounds **31a–g**, including C_2 -symmetrical ligands **31f,g**, viz., oxalic and terephthalic acid diamides.²¹

Reagent	Product	R	Yield (%)
PhCOCl	a	Ph	89
$(\text{Boc})_2\text{O}$ (Boc = $\text{Bu}^t\text{OC}(\text{O})$)	b	OBu^t	96
	c	$(\text{CH}_2)_3\text{CO}_2\text{H}$	100
$\text{MeO}(\text{CH}_2)_2\text{OCH}_2\text{COCl}$	d	$\text{CH}_2\text{O}(\text{CH}_2)_2\text{OMe}$	83
$\text{MeO}(\text{CH}_2\text{CH}_2\text{O})_3\text{CH}_2\text{COCl}$	e	$\text{CH}_2(\text{OCH}_2\text{CH}_2)_3\text{OMe}$	80

Y is a bond (**f**, 83%), C_6H_4 -*p* (**g**, 88%).

Cyclic monophosphites were synthesised based on derivatives of tartaric acid. For example, the reaction of diisopropyl tartrate **5b** with ethyl bis(dimethylamino)phosphinite produced compound **32**.²⁴

Bidentate organophosphorus ligands are derived also from natural α -hydroxycarboxylic acids. However, the general procedure for the preparation of chiral 1,2-bisphosphines based on these ligands involves the reaction of vicinal ditosylates with alkali metal organophosphides, which is difficult to reproduce. In this step of the synthesis, the $\text{S}_{\text{N}}2$ reaction is generally accompanied by competitive elimination giving rise to intermediate oxiranes. The latter are subjected to the repeated nucleophilic attack by the phosphide anion to produce a mixture of undesired hydroxy-monophosphines. Under certain conditions, the latter reaction becomes the major process, which substantially decreases the yield of the target bisphosphines. Nevertheless, bisphosphines (*R*)-PROPHOS (**34a**) and (*R*)-PHENPHOS (**34b**) were prepared from (*S*)-(+)-lactic (**33a**) and (*S*)-(+)-mandelic (**33b**) acids in 10 and 20% yields, respectively. The reaction with (2*R*,3*R*)-butanediol (**35**) afforded C_2 -symmetrical 1,2-bisphosphine (*S,S*)-CHIRAPHOS (**36**). The (*R*)-CYCPHOS ligand (**34c**) was synthesised from (*S*)-(+)-hexahydromandelic acid (**33c**), which was generated by hydrogenation of (*S*)-(+)-mandelic acid (5% $\text{Rh}/\text{Al}_2\text{O}_3$ as the catalyst). Unlike the (*R*)-PHENPHOS compound (**34b**) isolated in pure form, bisphosphines (*R*)-PROPHOS (**34a**), (*R*)-CYCPHOS (**34c**) and (*S,S*)-CHIRAPHOS (**36**) were contaminated with by-products. To purify the latter bisphosphines, they were transformed into insoluble complexes with

NiCl_2 and then optically pure ligands were regenerated by treatment with sodium cyanide.^{25–28}

R = Me (**a**), Ph (**b**), Cy (**c**).

The introduction of highly polar substituents into the aromatic fragments of the (*R*)-PROPHOS (**34a**) and (*S,S*)-CHIRAPHOS (**36**) ligands gave rise to water-soluble derivatives. The reaction of chiral ligand **36** with oleum produced the tetrasulfonated analogue of (*S,S*)-CHIRAPHOS (**37**). Under the same conditions, sulfonation of bisphosphine **34a** proceeded much more slowly and with lower selectivity. The tetrasulfonated analogue of (*R*)-PROPHOS (**38**) was isolated only as a mixture with trisulfonated phosphine and phosphine oxide (in 55%, 35% and 10% yields, respectively).²⁹

34a: $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{R}^3 = \text{H}$; **36**: $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{R}^3 = \text{Me}$; X = 3- SO_3Na .

Mono-, bi- and tridentate chiral phosphine ligands in which only one diphenylphosphine group is directly bound to the asymmetric centre were synthesised starting from L-malic acid (**39**). Reduction of acid **39** with the borane dimethyl sulfide complex followed by the two-step treatment of triol **40** with tosyl chloride and lithium diphenylphosphide afforded 1,2,4-trisphosphine **41**.³⁰

Trisphosphine **41** can selectively form nickel complex **42** involving only the vicinal phosphine groups. This made it possible to modify the remote phosphine group giving rise to ligands **43a,b**.³¹

X = O (**a**, 63%), S (**b**, 77%).

Chiral 1,3-bisphosphine **44** was synthesised starting from triol **40**, which was prepared by reduction of dimethyl L-malate.³² The reaction of compound **40** with formaldehyde produced a mixture of cyclic acetals **45** and **46**. The latter was subjected to mesylation without separation. The major isomer **47**, which was isolated from the mixture of the resulting methanesulfonates, was transformed into the target bisphosphine **44** in five steps. The reaction product was characterised as the stable bisquaternary salt **44a**.

The synthesis of chiral monophosphines **48a,b** from L-malic acid (**39**) was based on transformations of intermediate hydroxypyrrolidine **49**. The latter was prepared without epimerisation of the chiral centre either by the two-step synthesis (heterocyclisation followed by reduction) through imide **50** or by the six-step

R = Bn (**a**, 75%), Boc (**b**, 70%).

synthesis (reduction followed by heterocyclisation) through protected triol **51**.³³

In the study,³⁰ bisphosphine **52** was synthesised starting from natural optically active pantolactone **53**. Tosylation of triol **54** followed by phosphinylation of the tosylates yielded bisphosphine **55** instead of the expected trisphosphine.

The phosphorus-containing ligands thus prepared were used for the synthesis of metal complex catalysts.

2. Use in asymmetric synthesis

The stereodifferentiating abilities of ligands and catalysts are most often estimated and compared using catalytic asymmetric hydrogenation, for example, asymmetric hydrogenation of unsaturated α -amino acids and their derivatives.

R¹ = Alk, Ar; R² = Alk, Ar, COAlk, COAr; R³ = OH, OAlk, NAlk₂.

Metal complexes with DIOP exhibit high catalytic activities in hydrogenation with enantioselectivity varying from moderate to high depending on the structure of the substrate subjected to hydrogenation. It appeared that the enantiomeric purities of the hydrogenation products of free *N*-acylaminocinnamic acids are much higher (*ee* = 25%–81%) than those of the hydrogenation products of their esters on the same catalysts (*ee* = 5%–55%).⁴

The products were obtained with an enantiomeric excess of 90%–92% by reduction of certain enamides using the cationic complex [Rh(COD)(DIOP)]⁺ClO₄[−], where COD is cyclooctadiene.³ The methyl substitution in the *meta* position of the aromatic ring of the ligand made it possible to achieve an enantiomeric purity of 88% in the asymmetric synthesis of 3-(3,4-dihydroxyphenyl)alanine derivatives.⁹

Analogues of DIOP containing electron-donating substituents at the phosphorus atom were also successfully used as catalysts for asymmetric hydrogenation of electron-deficient alkenes and carbonyl compounds. Thus, reduction of itaconic acid and its β -aryl derivatives catalysed by Rh(I) complexes with ligands **9d,e** afforded products with an enantiomeric purity of 91%–96%, whereas the enantioselectivity of reduction of these substrates in the presence of the Rh(I) complex with unmodified DIOP was at most 58%.¹¹

The Rh(I) complexes with chiral bisphosphines **13a–c** were successfully used in hydrogenation of α -oxo amides and *N*-oxo-acylamino acid esters. It was demonstrated that the activity and enantioselectivity of the catalyst increases as the size of the alkyl substituent at the phosphorus atom in the ligand increases. The enantiomeric excess of up to 77% was achieved in hydrogenation of *N*-benzylphenylglyoxylamide catalysed by the Rh(I) complex with CyDIOP ligand **13c**.¹² The Rh(I) complex with DIOCP ligand **14** appeared to be a better stereodifferentiating catalyst for asymmetric hydrogenation of α -ketopantolactone than the Rh(I) complexes with the DIOP and CyDIOP ligands. The enantiomeric purities of the products prepared with the use of these catalysts were 72%, 52% and 45%, respectively.¹³

Rhodium catalysts containing DIOP derivatives with dibenzophosphole groups (compound **9f**) as ligands proved to be less

enantioselective in hydrogenation of α -acetamidocinnamic acid than Rh catalysts with unmodified bisphosphine ligands (*ee* decreased from 81% to 28%). At the same time, the use of ligand **9f** in a Pd(II) complex made it possible to increase the enantiomeric purity of the product of asymmetric hydroesterification of α -methylstyrene to 44% (in the case of DIOP, *ee* = 9%).⁴

Modifications of the acetal groups of DIOP (compounds **15a–c**) do not change the structure of the coordination centre of the catalyst and, consequently, have only a slight effect on the stereoselectivity of the reaction.^{9,15} The enantioselectivity of hydrogenation of unsaturated acids catalysed by Rh(I) complexes with hydroxy-containing ligands **17b–e** is increased due, apparently, to additional interactions between the substrate and functional groups of the ligand remote from the coordination centre.¹⁷ Hydrogenation of methyl (*Z*)-2-*N*-benzamidocinnamate on Rh(I) complexes with ligands **24** and **25** proceeded with moderate enantioselectivity. The highest enantiomeric excess (54%) was obtained in hydrogenation catalysed by the Rh(I) complex with ligand **24b**.¹⁹

The synthesis of water-soluble chiral bisphosphine ligands enables one to solve some problems of homogeneous catalysis. In particular, the use of water-soluble rhodium phosphine catalysts for asymmetric hydrogenation in two-phase (aqueous–organic) systems substantially simplifies separation of the reaction products present in the organic phase from the catalyst. The rhodium phosphine complex that remains in the aqueous phase can be repeatedly used without substantial loss of efficiency. As mentioned above, water-soluble ligands are prepared by introducing highly polar functional groups into the bisphosphine structure. These groups can be present both in the phosphine and alkyl fragments of the molecule. For example, quaternisation at the nitrogen atoms of ligand **9e** [tetraamino analogue of (–)-DIOP] in the Rh complex afforded water-soluble chiral complexes **56a,b**.¹⁴

NBD is norbornadiene; R = H (**a**), Me (**b**);
RX = HBF₄ (for **a**), Me₃O⁺BF₄[–] (for **b**).

Quaternisation of the amino group of bisphosphine ligand **57** (prepared from PYRPHOS **29**) in the rhodium complex gave rise to water-soluble catalyst **58**.²⁰

However, the enantioselectivity of hydrogenation in the presence of water-soluble Rh catalysts was found to be much lower than that of hydrogenation performed with Rh catalysts based on unmodified DIOP. Besides, the use of complexes **56a,b** led to a change in the sign of asymmetric induction. These results suggest that ammonium substituents in aromatic fragments of the DIOP ligand substantially influence the conformation of the chelate ring in the catalysts.¹⁴

The use of Rh(I) catalysts with water-soluble polyoxabisphosphines **15d,e** in hydrogenation of *N*-acylaminocinnamic acids in water led to a decrease in the enantiomeric purity of the product to 30% (hydrogenation on the same catalysts in ethanol gave *ee* = 75%).¹⁶ The enantioselectivity of hydrogenation of *N*-acylaminocinnamic acids in water catalysed by the cationic Rh(I) complex with ligand **17a** was also no higher than 34%. However, the addition of sodium dodecyl sulfate as an amphiphilic agent to the reaction mixture made it possible to increase the enantioselectivity of the reaction to 77%.³⁴

Hydrogenation of (*Z*)- α -acetamidocinnamic acids on Rh(I) complexes with bis(diphenylphosphino)pyrrolidine-type ligands proceeded with high enantioselectivity [92%, 94% and 96% for ligands **29** (PYRPHOS) and **28b,c**, respectively].^{21,22} The use of catalyst **58** for hydrogenation of sodium α -acetamidocinnamate in water made it possible to prepare (*S*)-*N*-acetylphenylalanine with an enantiomeric purity of 90%.²⁰

The Rh(I) complexes with the (*R*)-PROPHOS (**34a**), (*R*)-PHENPHOS (**34b**), (*R*)-CYCPHOS **34c** and (*S,S*)-CHIRAPHOS (**36**) ligands serve as highly efficient catalysts for enantioselective hydrogenation of unsaturated precursors of amino acids. The enantiomeric purities of the products prepared with the use of these catalysts were higher than 80%. The best result (*ee* = 100%) was achieved in hydrogenation of acetamidoisopropylacrylic acid catalysed by the Rh(I) complex with (*S,S*)-CHIRAPHOS.^{25–28} The Rh(I) complex with ligand **37** [water-soluble analogue of the (*S,S*)-CHIRAPHOS ligand] also showed high enantioselectivity (*ee* up to 94%) in reduction of unsaturated amino acids both in water and a two-phase aqueous-organic system.^{14,29}

The enantioselectivity of catalytic hydrogenation of precursors of amino acids catalysed by the Rh(I) complexes with ligands **41** and **44** appeared to be low. For example, reduction of (*Z*)- α -acetamidocinnamic acid using Rh(I) complexes with trisphosphine **41** afforded the target product with an enantiomeric excess of 25%.³¹ The enantiomeric purity of the reduction product prepared with the use of the Rh(I) complex with ligand **44** was no higher than 20%.³² The replacement of one phosphine group in ligand **44** by phosphine oxide or phosphine sulfide (compounds **43a,b**) led to a substantial enhancement of enantioselectivity of the catalyst. For example, the use of the Rh(I) complexes with ligands **43a,b** in the hydrogenation of (*Z*)- α -acetamidocinnamic acid made it possible to increase the enantiomeric purities of the products to 72%–74%.³¹

III. Organophosphorus ligands based on amino acids

1. Synthesis of ligands

A large number of efficient chiral phosphorus-containing ligands were prepared starting from natural and synthetic amino acids. For instance, readily accessible 4-hydroxy-L-proline (**59**) can be used as the starting compound for the synthesis of the above-mentioned ligands. The first hydroxyproline derivatives to be prepared were 1,4-bisphosphines (2*S*,4*S*)-BPPM (**60**) and (2*S*,4*S*)-PPM (**61**).³⁵

The synthesis of the optical antipode of bisphosphine **60**, viz., the chiral ligand (2*R*,4*R*)-BPPM, required successive epimerisation of two chiral centres of 4-hydroxy-L-proline (**59**).³⁶

Later on, various derivatives of bisphosphinopyrrolidines **61**, viz., amides **62**, carbamides **63** and carbamates **64a,b**, were prepared.³⁷

Reagent	Product	R	Yield (%)
HCO ₂ H, AcOH	62a	H	65
MeCOCl, Py (or Et ₃ N)	62b	Me	70
Bu ^t COCl, Py (or Et ₃ N)	62c	Bu ^t	75
PhCOCl, Py (or Et ₃ N)	62d	Ph	91
MeNCO	63a	MeNH	95
Bu ^t NCO	63b	Bu ^t NH	73
PhNCO	63c	PhNH	76
MeOCOCl	64a	MeO	91
PhOCOCl	64b	PhO	99

The synthesis of bisphosphines **65–69** containing various combinations of cyclohexyl and phenyl groups at the phosphorus atoms offers wide possibilities in the design of pyrrolidine-type ligands.^{38,39} Multistep transformations of 4-hydroxy-L-proline (**59**) produced phosphine oxides **70** and **71**. Bisphosphine **65** was derived from compound **70** (Scheme 2).

Phosphine oxide **71** was used for the preparation of the target ligands **66–69**.

An analogous sequence of transformations was employed in the synthesis of ligand **72**, in which the stereocentres have configurations opposite to those in bisphosphine **65**. The ligand

Scheme 2

72 was prepared starting from 4-hydroxy-*N*-(methylsulfonyl)-D-prolinol (**73**), which was generated by epimerisation of the chiral centres of 4-hydroxy-L-proline (**59**) according to the method used for the synthesis of the ligand (*R,R*)-**60**.⁴⁰

Chiral bisphosphines **74** and **75a–c** were generated from bisphosphine **60**.¹²

R = *OBu*^t (**74**, 54%), *NHPh* (**75a**, 78%), *NHCy* (**75b**, 75%), *NHBu*^t (**75c**, 89%).

Various ligands **76a–g** containing functional substituents in aromatic rings of the bisphosphine fragments were synthesised from other analogues of (*2S,4S*)-BPPM.^{41–43}

Ar¹ = Ar² = 2-MeOC₆H₄ (**a**), 3-MeOC₆H₄ (**b**), 4-MeOC₆H₄ (**c**), 4-MeO-3,5-Me₂C₆H₂ (**d**), 4-Me₂NC₆H₄ (**e**); Ar¹ = Ph, Ar² = 4-Me₂NC₆H₄ (**f**); Ar¹ = 4-Me₂NC₆H₄, Ar² = Ph (**g**).

Alcohol **77**, which was prepared by decarboxylation of 4-hydroxy-L-proline (**59**), was transformed into chiral mono-phosphines **78a–c**. The optically pure ligands **78a,b** were isolated in the individual form after treatment of palladium complexes **79a,b** with potassium cyanide. It should be noted that reduction of

phosphine amides **80a,b** with lithium aluminium hydride giving rise to phosphine amines **78a,b** proceeded smoothly without elimination of the diphenylphosphine group at the chiral centre. By contrast, analogous reduction of bisphosphine **80c** was accompanied by elimination of the activated phosphine group to form monophosphine **78c** instead of the expected tridentate P,N,P ligand.³³

R = Ph (**a**), 4-MeC₆H₄ (**b**).

Chiral trisphosphine **81** and bisphosphine **82** were derived from L-glutamic acid **83** (Scheme 3).³⁰

Phosphine oxide **84a** and phosphine sulfide **84b** were synthesised using a known procedure, which required the additional preparation of intermediate Ni complex **85** from trisphosphine **81**. Oxidation or sulfonation of the free phosphine group in compound **85** produced complexes **86a,b**, respectively. Regeneration with sodium cyanide completed the synthesis of the target ligands.^{30, 31}

X = O (**a**, 63%), S (**b**, 31%).

Enantiospecific transformations of natural and synthetic amino acids were employed for the preparation of chiral 1,2-

Scheme 3

Scheme 4

R = (S)-Me (a), (S)-Et (b), (S)-Prⁱ (c), (S)-Bu^t (d), (R)-Bu^s (e), (R)-Bu^t (f), (R)-Cy (g), (S)-Bn (h), (R)-Bn (i), (R)-Ph (j); M = Li, Na, K.

bisphosphines, aminophosphines and phosphinoaminophosphinites (Scheme 4). The synthesis of bisphosphines was preceded by the transformation of the amino group in the starting amino acid into the hydroxy group under the action of HNO₂. For example, hydroxy acids **88c,h** derived from (S)-valine (**87c**) and (S)-phenylalanine (**87h**), respectively, were transformed into chiral bisphosphines **89c,h** according to a conventional procedure.⁴⁴

Chiral ligands **90a,c-h,j,k** were synthesised starting from (S)-alanine (**87a**), (S)-valine (**87c**), (S)-leucine (**87d**), (S)-isoleucine (**87e**), (R)-tert-leucine (**87f**), (R)-cyclohexylglycine (**87g**), (S)-phenylalanine (**87h**), (R)-phenylglycine (**87j**) and (S)-proline (**87k**), respectively, by successive transformations involving N,N-dimethylation, reduction and chlorination in different orders. It should be noted that the key β-dimethylamino alcohols **91g,h,j** were synthesised in higher yields by N,N-dimethylation of amino alcohols **92g,h,j** prepared by reduction of the corresponding amino acids. Aminophosphine **93** was produced by the thermal rearrangement of chloro derivative **94a** followed by phosphinylation in the presence of potassium *tert*-butoxide.^{23, 45, 46}

After N-formylation and reduction with LiAlH₄, amino acids **87a-d,i** were transformed into N,O-bisphosphinylaminoethanols **95a-d,i** (see Scheme 4).⁴⁷⁻⁴⁹

(S)-Prolinol (**96**) produced by reduction of (S)-proline (**87k**) was used as the starting compound for the synthesis of phosphinoaminophosphinites containing identical (**97a-d**) or different (**97e-j**) substituents at the phosphorus atoms.^{50, 51}

R¹ = R² = Prⁱ (a), cyclo-C₅H₉ (b), Cy (c), Ph (d); R¹ = Prⁱ, R² = Cp (e); R¹ = Cp; R² = Prⁱ (f), Cy (g), Ph (h); R¹ = Cy, R² = Cp (i); R¹ = Ph, R² = Cp (j).

Tridentate phosphinoaminobisphosphinite **99** was derived from (2S,3R)-threonine (**98**).⁵²

The sequence of transformations of this compound is analogous to that used for transformations of amino acids **87a-d,i** into phosphinoaminophosphinites **95a-d,i** (see Scheme 4).

2. Use in asymmetric synthesis

Catalysts based on pyrrolidine-type bisphosphines BPPM (**60**) (proline derivatives) were used in hydrogenation of various substrates. Generally, such reactions proceed at 50 atm. For hydrogenation products of α-acetamidoacrylic acids, good results were obtained (enantiomeric purity up to 91%) in the presence of Rh(I) complexes with the unmodified (2S,4S)-BPPM ligand and its optical antipode, *viz.*, (2R,4R)-BPPM.^{35, 36} The enantioselectivity of hydrogenation of (Z)-2-acetylaminocinnamic acid was increased to 98% by introducing the methoxy group in the *ortho* position of the benzene rings of this ligand (compound **76a**). The use of the Rh(I) complex with ligand **76c** containing the methoxy groups in the *para* positions of the benzene rings made it possible to increase the [substrate]:[catalyst] ratio from 10³ to 10⁴.⁴¹ Hydrogenation of derivatives of (Z)-2-acetamidoacrylic acids on the Rh catalyst with ligand **76d** afforded products with *ee* = 99% (*p*_{H2} = 20 atm, [substrate]:[catalyst] = 10⁴).⁴² These results are consistent with the assumption^{41, 42} that an increase in the enantioselectivity of the catalyst results from the steric effect of the *o*-MeO substituents in the aromatic fragments of the ligand. The electron-donating substituents in the benzene ring also substantially influence the reaction rate, the best result being achieved for compounds containing the *p*-MeO groups.^{41, 42}

Hydrogenation of ketopantolactone catalysed by the Rh(I) complexes with the BPPM ligand proceeded with an enantioselectivity of 87% (50 °C, *p*_{H2} = 50 atm).⁴ Of Rh(I) complexes with cyclohexyl analogues of the BPPM ligand, the metal complex with ligand **68** containing both the cyclohexyl and phenyl substituents

at the phosphorus atom provided the highest enantiomeric yield (*ee* up to 91%) in this reaction. The Rh(I) complexes with this bisphosphine and its analogue containing only the dicyclohexylphosphine groups (compound **74**) exhibited much higher catalytic activities in this reaction as compared to the catalyst prepared based on the unmodified BPPM ligand (the [substrate]:[catalyst] ratio increased from 10^2 to 10^4 ; see Refs 38 and 39). Hydrogenation of ketopantolactone in the presence of the Rh(I) complex with bisphosphine ligand **75c** containing the carbamoyl substituent proceeded under substantially milder conditions, *viz.*, at room temperature and under normal H_2 pressure. However, the enantioselectivity of this reaction was at most 66%.¹²

Of the three types of rhodium catalysts with *N*-substituted pyrrolidinebisphosphines **62–64**, the Rh(I) complexes with *N*-carbamoyl ligands **63a–c** proved to be most efficient in the hydrogenation of 2-methylidenesuccinamic acid. The use of these catalysts led to an increase in the enantioselectivity to 77% at normal H_2 pressure, whereas hydrogenation catalysed by the Rh(I) complexes with ligands **62a–e** and **64a,b** proceeded only under an H_2 pressure of 30 atm, the enantiomeric purities being 43%–64% and 53%–66%, respectively.³⁷

The introduction of the *p*-Me₂N group into the benzene ring of the BPPM ligand (compounds **76e–g**) led to an increase in the activity and stereoselectivity of the Rh catalyst for the hydrogenation of dimethyl itaconate. The best results (*ee* = 93%, the conversion was 100%) were achieved in the presence of the Rh(I) complex with ligand **76f** (for comparison, hydrogenation catalysed by the complex with unmodified BPPM afforded the product with an *ee* of 5% and a conversion of 36%).⁴³

The Rh(I) complexes with tris- (**81**) and bisphosphines (**82**) exhibited moderate enantioselectivity in hydrogenation of (*Z*)- α -acetylaminocinnamic acid (*ee* = 31%–36% and 54%–58%, respectively). The transformation of one of the phosphine groups into phosphine oxide (compound **84a**) or phosphine sulfide (compound **84b**) led to an increase in the enantioselectivity of the catalyst for hydrogenation of (*Z*)- α -acetylaminocinnamic acid. Thus, the enantiomeric purities of the hydrogenation product prepared in the presence of the Rh(I) complexes with ligands **84b** and **84a** were 54%–58% and 85%–89%, respectively.^{31, 32}

Rhodium complexes with bisphosphines **89c,h** were successfully used in enantioselective hydrogenation of (*Z*)- α -acylaminoacrylic acids to form the corresponding α -acylamino acids (*ee* = 85%–99%).⁴⁴ Unlike Ni(0) complexes with β -dimethylaminomethylphosphines **90a,c–h,j**, Ni(0) complexes with ligands of this type proved to be less efficient in catalytic asymmetric cross-coupling. The highest enantiomeric purity (*ee* up to 80%) of the products of this reaction was achieved with the use of Rh(I) complexes prepared based on ligands **90c,e,h,j**. It was demonstrated that an increase in the stereoselectivity of hydrogenation in the presence of catalysts containing aminophosphines of the structural type **90** as ligands is favoured by an increase in the volume of the substituent at the chiral β -carbon atom directly bound to the dimethylamino group. For example, *ee* of 25% and 38% were achieved in hydrogenation catalysed by the Ni(0) complexes with ligands **93** and **90e**, respectively.^{45, 46} In asymmetric hydrosilylation of acetophenone, Rh(I) complexes with phosphinoaminophosphinites **95a,c** showed low enantioselectivity (*ee* = 10%–26%), which depended on the structure of the silane used.⁴⁸ Hydrogenation of *N*-acetylaminocinnamic acid in the presence of the Rh(I) complex with phosphinoaminophosphinite **95i** afforded products with *ee* = 60%.⁴⁹

Cationic Rh(I) complexes based on ligands **97** were used as catalysts for asymmetric hydrogenation of activated ketones, the best results (*ee* = 85%) being achieved with the complex based on phosphinite **97j**.^{50, 51}

Asymmetric hydrovinylation of 1,3-cyclohexadiene catalysed by Ni(0) complexes with ligand **99** afforded products with *ee* = 93%, whereas the enantioselectivity of the same reaction in the presence of Ni(0) complexes with phosphinoaminophosphinites **95a,c** was no higher than 50%.⁵²

Therefore, the above-considered examples demonstrate that metal complexes with chiral organophosphorus ligands based on both natural and synthetic amino acids show promise as catalysts.

IV. Organophosphorus ligands based on carbohydrates

1. Synthesis of ligands

Carbohydrates and their derivatives are readily accessible, optically pure and contain several functional groups at the asymmetric centres with different configurations, which can be readily transformed. Hence, these compounds are attractive for the synthesis of chiral heteroorganic ligands. The synthesis of diastereomeric bisphosphines **100a,b** and bisphosphinites **101a,b** from α -D-glucose **102** was described in the study.⁵³ In this synthesis, 3-*O*-benzyl-1,2-*O*-cyclohexylidene- α -D-glucopyranose **103** (Scheme 5) was generated as an intermediate.

D-Glucopyranoside **102** was transformed into glucosyl bromide **104**, from which aryl- and alkyl-*O*-glucosides **105a–i** were generated. The latter compounds were used in the synthesis of chiral 2,3-bis(diphenylphosphinites) **106a–i**.

R = α -OMe (**a**), α -OPh (**b**), β -OBn (**c**), β -OPh (**d**), β -OC₆H₄Me-2 (**e**), β -OC₆H₄Me-4 (**f**), β -OC₆H₄NO₂-2 (**g**), β -OC₆H₄NO₂-4 (**h**), β -OC₁₀H₇-2 (**i**).

Treatment of 2,3,4,6-tetra-*O*-acetyl- α -D-glucopyranosyl bromide **104** with zinc in acetic acid afforded tri-*O*-acetyl-D-glucal **107**, which was used for the synthesis of 3,4-bisphosphinite **108**.

Tr is trityl, TBDMS is *tert*-butyldimethylsilyl, Im is imidazole.

Scheme 5

Phosphinite **110** was derived from methyl-2-deoxy- α -D-glucopyranoside **109**.⁵⁴

Analogous bisphosphinite **111** was generated from 2-acetyl-amino- β -methyl-2-deoxy-D-glucopyranoside **112**.⁵⁴

3,4-Bis(diphenylphosphinites) **113a,b** were prepared by selective acylation of methyl- α -D-glucopyranoside (**114**) followed by phosphinylation.⁵⁴ The same glycoside **114** was used for the synthesis of the 2,4-bisphosphite of 3,6-anhydroglucopyranoside **115** containing bulky substituents, viz., derivatives of *o,o'*-biphenylene **116**.⁵⁵

$\text{R}^1 = \text{COBu}^t$ (**a**), COPh (**b**); $\text{R}^2\text{P} = \text{Bu}^t$ (BMOPP).

Methyl- α -D-mannopyranoside **117** was transformed into 3,4-bisphosphinite **118**, 2,4- (**119**) and 4,6-bisphosphites **120** and **121** employing different procedures for the protection of the hydroxy groups.^{54,55}

$\text{RP} = \text{BMOPP}$.

Bisphosphinite **122**, which was synthesised from D-xylopyranose **123** through di-*O*-acetyl-D-xylal **124**, was isolated as a complex with $\text{Cu}(\text{I})$ and then purified.⁵⁶

Ligands **125a,b** containing the bulky *o,o'*-biphenylene substituents were prepared by the reactions of 1,2-*O*-isopropylidene-D-xylofuranose **126** with phosphorochloridites.⁵⁵

R¹P = BMOPP; R²P = R¹P (**a**, 53%), P(2-Bu¹-6-MeC₆H₃O)₂ (**b**, 27%).

Chiral 2,4-bisphosphite **128** was synthesised in several steps from D-galactose **127**.⁵⁵ The same compound was used for the preparation of monophosphine **129**.¹⁵

RP = BMOPP.

Unlike pyranosides, the synthesis of 3,5-bisphosphines based on furanosides presented difficulties. Thus, an attempt to synthesise bisphosphine **130** from 1,2-*O*-isopropylidene-D-xylofuranose **126** through ditosylate **131** led to the formation of a mixture of monophosphines **132a,b**.⁵⁷

R = H (**a**, 27%), Ts (**b**, 6%).

It was hypothesised⁶⁰ that attempts to synthesise compound **130** failed due primarily to steric overcrowding of the 1,2-*O*-isopropylidene-3,5-di-*O*-tosyl-D-xylofuranose molecule (**131**). The α -attack of the diphenylphosphide anion on the C(3) atom of the furanoside ring of compound **131** is hindered by steric effects, and the S_N2 reaction with sodium diphenylphosphide does not proceed. To relieve steric hindrances, attempts were made to synthesise bisphosphine ligands **136** from monotosylate **134** through alkene intermediates **135a,b**. The latter were prepared by the reaction of 3-oxofuranose **133** with α -cyanomethylidene-triphenylphosphorane. The reactions of isomeric nitriles **135a,b** with sodium diphenylphosphide afforded the same bicyclic product **137** instead of the corresponding bisphosphines **136**. Reduction of compound **137** with LiAlH₄ gave rise to phosphinoamine **138** (Scheme 6).⁵⁷

Chiral polyoxabisphosphines of the general formula **139** were synthesised from D-mannitol (**140**). Intermediate polyoxadioxolanes **141** were prepared according to two procedures, viz., by the reactions of chlorides with isopropylidenglycerol **142** under conditions of phase transfer catalysis or by the reactions of chloro ethers **143** with the corresponding alkoxides. Sodium alkoxide of *N,N*-diethylaminoethanol was used for the synthesis of dioxolane **144**, which was transformed into the target bisphosphine **145** (Scheme 7).⁵⁸

Acetonide **146** derived from D-mannitol (**140**) was used as the starting compound in the synthesis of diastereomeric epoxides **147a,b**, which were reduced to the key diols **148a,b** (Scheme 8). The latter served as the starting compounds in the synthesis of chiral organophosphorus ligands.

Examples of the use of diol **148a** in the synthesis of chiral bisphosphinites **149a,b**, bisphosphine **150** and phospholanes **151** and **152** were given in the study.⁵⁹ Diastereomers of these compounds were prepared from diol **148b** according to an analogous scheme (Scheme 9).

Examples of the use of oligosaccharides as the starting chiral compounds for the synthesis of organophosphorus ligands are much fewer in number as compared to monosaccharides. For

Scheme 6

R¹ = CN, R² = H (**a**, 67%); R¹ = H, R² = CN (**b**, 24%)

Scheme 7

$p = 1-3, n = 1-5, m = 1, 2, q = 0-2$.

Scheme 8

Scheme 9

$\text{R} = \text{Ph}$ (**a**, 66%), 3,5- $\text{Me}_2\text{C}_6\text{H}_3$ (**b**, 42%); $\text{X} = \text{PPh}_2$; DMAP is 4-dimethylaminopyridine.

instance, phosphines **153a,b** were prepared from disaccharide α,α -trehalose (**154**) according to the standard sequence of reactions employed in carbohydrate chemistry. This procedure made it possible to synthesise the key intermediates **155a** (or **155b**), which were then transformed into the target ligands **153**.⁶⁰

R = Me (**a**), Bn (**b**).

Bisphosphinites **156a,b** were prepared from α,α -trehalose (**154**) through the formation of alkylidene derivatives **157a,b** whose isolation involved successive acetylation–deacetylation steps.⁶¹

R = Me (**157a**, 14%; **156a**, 63%),

R – R = (CH₂)₅ (**157b**, 63%; **156b**, 65%).

Unnatural carbohydrate β,β -tetrahalose (**158**) was produced from 2,3,4,6-tetra-*O*-acetyl- α -D-glucopyranosyl bromide (**104**) and used in subsequent transformations into bisphosphinite **159**.⁶¹

NIS is *N*-iodosuccinimide.

Several procedures were developed for the synthesis of 2,2'-bisphosphine **160**. These procedures are associated with the choice of protective groups, which can selectively protect hydroxy groups in the starting carbohydrate, viz., α,α -trehalose (**154**) (Scheme 10). Two derivatives of this disaccharide, viz., benzylidene (**161**) and diisopropylidene (**162**) derivatives, were prepared. Compound **161** was transformed into bis(epoxide) **163** in two steps. Treatment of the latter with sodium diphenylphosphide afforded phosphine **164**. Attempts to prepare 2,2'-bisphosphine **160** by direct hydrogenolysis of compound **164** on the Pd/C catalyst failed. An attempt to reduce intermediate phosphine oxide **165** with trichlorosilane was also inefficient. The procedure for the preparation of polyhydroxybisphosphine **160** through acetone **162**

Scheme 10

proved to be more successful. Hydrolysis of phosphinylated compound **166** with pyridinium *p*-toluenesulfonate produced the target ligand **160** (see Scheme 10).⁶²

The above-considered examples demonstrate that a broad spectrum of chiral organophosphorus compounds can be synthesised based on carbohydrates. The compounds thus prepared were used for the synthesis of metal complex catalysts.

2. Use in asymmetric synthesis

Hydrogenation of a series of unsaturated acids and their esters in the presence of Rh(I) complexes with bisphosphines **100a,b** and bisphosphinites **101a,b** afforded the corresponding saturated products with an enantiomeric excess of 67%. Hydrogenation catalysed by the Rh(I) complexes with ligands **100a** and **101a** produced compounds having the (*R*) configuration, whereas hydrogenation in the presence of the Rh(I) complexes with their diastereomers **100b** and **101** yielded products with the (*S*) configuration.⁵³

Study of the behaviour of the Rh(I) complexes with chiral organophosphorus ligands **106a–i** in hydrogenation reactions demonstrated that the presence of equatorial substituents in the glucopyranoside ring of the ligand leads to a decrease in the enantioselectivity of the catalyst. For example, hydrogenation of methyl (*Z*)-2-acetamidocinnamate catalysed by the Rh(I) complexes with β -anomeric ligands **106c–i** afforded products in enantiomeric yields of 91%–92%, whereas the enantioselectivity of analogous transformations on the Rh(I) complexes with α -anomers **106a,b** was no higher than 71%. Asymmetric hydrogenation of *N*-acetylaminoacrylic acids in the presence of the Rh(I) complex with ligand **106d** proceeded with *ee* = 96%–99%. Hydrogenation of esters of these acids catalysed by the same complex proceeded with somewhat lower enantioselectivity (*ee* = 91%).

With the aim of studying the effect of intramolecular hydrogen bonds on the structure of a complex catalyst and its behaviour in enantioselective hydrogenation, the protective benzylidene group of ligand **107d** in rhodium complex **A** was subjected to hydrolysis.^{63–65}

The use of Rh catalysts with ligands **106a–j** made it possible to carry out the successful synthesis of (*S*)-amino acids. By contrast, hydrogenation in the presence of complexes with 3,4-bisphosphinites **108**, **110**, **111**, **113**, **118** and **122**, in which the configurations of the carbon atoms [C(3) and C(4)] in the chelate ring of the catalysts are opposite to the configurations of the chiral centres [C(2) and C(3)] of the chelate ring of the catalysts with ligands **106a–j**, gave rise to (*R*)-amino acids. As in the case of ligands **106a–i**, the presence of equatorial substituents in the pyranose ring leads to a substantial decrease in the enantioselectivity of the catalyst.

The best results (*ee* = 93%–98%) were achieved in the presence of the complex with ligand **111** containing only axial substituents.^{56–56}

The Rh(I) complex with monophosphine ligand **129** exhibits moderate enantioselectivity (*ee* = 54%) in the hydrogenation of α -acetylaminoacrylic acids.¹⁵ Asymmetric hydrogenation of α -acetamidocinnamic acid proceeded with good enantioselectivity (92%) on the Rh(I) complex with monophosphine **137**, whereas hydrogenation in the presence of the Rh(I) complex with reduced ligand **138** afforded the reaction products with an enantiomeric purity of 39%.⁵⁷ Hydrogenation of dehydroamino acids on the Rh(I) complexes with ligands **139** and **145** proceeded with enantioselectivity of no higher than 86%.⁵⁵

When performing hydroformylation of styrene on Rh(I) complexes with bisphosphite ligands (compounds **115**, **119**, **120**, **121**, **125a,b** and **128**), the best stereochemical result (*ee* = 64%) was achieved in the presence of the Rh(I) complex with ligand **121**.⁵⁸

The Rh(I) complexes with disaccharide bisphosphines **153a,b** were used as catalysts for the hydrogenation of α -(*N*-acetylamino)acrylates. The enantioselectivity of hydrogenation catalysed by the Rh(I) complex with ligand **153b** containing benzyl groups appeared to be much higher (*ee* = 82%) than that of hydrogenation on the Rh(I) complexes with methylated analogue **153a** (*ee* = 10%).⁶⁰ Water-soluble cationic Rh(I) complex **167** was synthesised from bisphosphinites **156a,b** based on trehalose.

R = Me (**a**), R–R = (CH₂)₅ (**b**); BCOD is bicyclooctadiene.

The Rh(I) complex with structurally similar ligand **159** was produced analogously. These catalysts prepared *in situ* showed high enantioselectivity (99%) in the hydrogenation of *N*-acetylaminoacinnamic acids and their esters both in water and a two-phase aqueous-organic system.⁶¹

Analogous water-soluble transition metal complexes suitable for catalytic asymmetric reactions in organic and aqueous media can be prepared based also on other chiral organophosphorus ligands containing free or protected hydroxy groups, *viz.*, bisphosphinites **149**, bisphosphine **150**, phospholanes **151** and **152**, their diastereomers and polyhydroxy-2,2'-bisphosphine **160**.^{59, 62} Investigations of the enantioselectivity of hydrogenation catalysed by metal complexes with organophosphorus ligands based on carbohydrates are being continued.

V. Organophosphorus ligands based on terpenoids and steroids

Syntheses of chiral ligands based on terpenoids are remarkable in that they use secondary metabolites of the plant origin (L-menthol, α -pinene, Δ^3 -carene, levopimaric and dehydroabietic acids) as the starting compounds. These compounds are comparable to the above-considered hydroxy acids, amino acids and carbohydrates (L-tartaric acid, D-glucose, D-xylose, L-arabinose, L-phenylalanine, *etc.*) in accessibility, optical purity and structural diversity.

Chiral phosphonite **169**¹⁵ and phosphine **170**⁶⁶ were prepared from L-menthol (**168**) according to rather simple procedures. Phosphine **170** was also generated by phosphinylation of L-menthyl chloride (**171**).

Neomenthol **172** was also used as the starting compound in the synthesis of chiral organophosphorus ligands. For example, treatment of L-neomenthyl chloride **173** with sodium phosphide containing different substituents afforded a mixture of diastereomers **174** possessing an additional asymmetric centre at the phosphorus atom. These diastereomers were purified and separated through chromatographically stable phosphine oxides **175**. After separation, all individual stereoisomers were reduced with phenylsilane to the corresponding menthylmethylphenylphosphines (*S_P*)-**174** and (*R_P*)-**174**. It was noted that, unlike the stable (*S_P*) isomer, the (*R_P*) isomer underwent partial epimerisation at the phosphorus atom (~13%–25%) under the reaction conditions.⁶⁷

Ligands **176** and **177** were synthesised from L-menthyl chloride (**171**) by nucleophilic hydrophosphinylation. The reaction of chloride **171** with sodium phenylphosphide afforded a mixture of diastereomeric secondary phosphines **178**, whose coupling with phenylvinylphosphines gave rise to the desired ligands **176** and **177**. Individual stereoisomers of these compounds were isolated by recrystallisation.⁶⁸

Mono- (**179a,b**) and bicyclic (**180a,b**) phosphines were prepared by radical hydrophosphinylation of limonene (**181**) with phosphine PH_3 . Bicyclic phosphines **180a,b** were oxidised to stereoisomeric phosphinic acids **182a,b**.⁶⁹

$\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Me}$ (**a**); $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$ (**b**);
AIBN is azobis(isobutyronitrile).

In the study,⁷⁰ the PHELLANOPHOS ligand (**183**) was derived from (–)- α -phellandrene (**184**) and used as a chiral diene in the Diels–Alder reaction with *trans*-vinylenebis(diphenylphosphine sulfide). Adduct **185**, which formed stereospecifically, was reduced to the target bisphosphine **183** by refluxing with sodium metal in toluene.

Chiral zinc organometallics **186** and **187**, which were prepared from β -pinene (**188**) and (+)-longifolene (**189**), respectively, by successive hydroboration and transmetalation, served as the starting compounds for the synthesis of the corresponding bidentate phosphines **190a,b** and **191a,b**. The latter were characterised as complexes with BH_3 . These phosphines were used for preparing ruthenium complexes. The latter catalyse hydrogenation of 2-methyl-3-phenylpropenol with moderate enantioselectivity (*ee* = 45%).^{71, 72}

1,3-Bis(dimethylphosphino)maleic anhydride **192** and substituted maleimides **193a,b** were synthesised by the reactions of dimethyl(trimethylsilyl)phosphine with 2,3-dichloromaleic anhydride or 2,3-dichloromaleimides, respectively.⁷³

R is L-menthyl; **X** = O (**192**), NMe (**193a**), NPh (**193b**).

First syntheses of chiral organophosphorus ligands from diterpenoids were described in the studies.^{74,75} The authors of the cited studies used the known adducts of levopimaric acid (**194a**) with maleic anhydride (compound **195**) and diethyl fumarate (compound **196**) as well as the adduct of the benzyl ether of levopimarol (**194b**) with diethyl fumarate (compound **197**).

Reduction of adduct **195** produced triol **198**. Protection of all hydroxy groups in compound **198** gave rise to compound **199**, from which the target bisphosphine **200** was prepared according to standard procedures.

Adduct **196** was transformed into aminodiol through the formation of the morpholine derivative. Successive tosylation and phosphinylation of the aminodiol afforded bisphosphine **201**. Reduction of benzyl ether **197** with LiAlH_4 followed by standard transformations gave rise to analogous bisphosphine **202**.

R = CO_2H (**194a, 196**), CH_2OBn (**194b, 197, 202**), $\text{CH}_2\text{N}(\text{CH}_2\text{CH}_2)_2\text{O}$ (**201**).

The reactions of bisphosphines **200**–**202** with di- μ -chloro-bis(1,5-cyclooctadiene)dirhodium and NaBF_4 produced complexes of the $[\text{Rh}(\text{COD})\text{L}]^+\text{BF}_4^-$ type. Rhodium complexes with phosphine **200** catalyse hydrogenation of (*Z*)-*N*-acetylaminocinnamic acid to give *N*-acetylphenylalanine in quantitative yield with *ee* = 37%. The optical purity of 3-(3,4-dihydroxyphenyl)-alanine prepared by hydrogenation of the corresponding precursor on this complex was 27%.

The Rh(I) complexes with phosphines **201** and **202** substantially accelerated hydrogenation of the above-mentioned unsaturated amino acids; however, these reactions gave rise to optically inactive products.

In the study,⁷⁶ chiral steroidal organophosphorus ligands were synthesised from cholestan-3-one (**203**). Alkylation of the latter compound with methyl bromoacetate afforded keto ester **204**, which was reduced to isomeric diols **205** and **206**. Then dimesylates were produced and used in the final step of the synthesis for the preparation of bisphosphines **207** and **208** using sodium diarylphosphides. 2-Formylcholestanone **209** was transformed into 1,4-bisphosphine **210** in several steps. 1,6-Bisphosphine **212** is rather readily generated from the oxidation product of cholestanone, *viz.*, seco acid ester **211**. The synthesis of monophosphine derivative **213** from diol **205** was also described in the study⁷⁶ (Scheme 11).

Phosphorus-containing derivatives of monoterpenes were used as chiral ligands in the hydrogenation of a series of prochiral substrates catalysed by Rh(I) complexes. Hydrogenation of (*E*)- β -methylcinnamic acid in the presence of the Rh(I) complex with ligand **170** produced (*S*)-(+)-3-phenylbutyric acid with an enantiomeric purity of 61%.⁶⁶ The rhodium catalysts with ligands (*S*_P)-

Scheme 11

174a and (*R_P*)-**174b** showed higher enantioselectivity (*ee* was 71% and 67%, respectively) in reduction of the same substrate. It should be noted that the use of these diastereomeric ligands made it possible to prepare both enantiomers of 3-phenylbutyric acid.⁶⁷ The Rh(I) complexes with diastereomeric bisphosphine ligands **176** catalysed the asymmetric hydrogenation of α -acylaminocinnamic acids. The enantioselectivity of hydrogenation of the latter acids in the presence of these catalysts appeared to be higher (*ee* = 85%) than that of hydrogenation of their esters (*ee* = 31%).⁶⁸ The Rh(I) complex with the PHELLANOPHOS ligand (**183**) exhibits high efficiency in the hydrogenation of unsaturated precursors of α -amino acids. The optical purities of the products prepared with the use of this catalyst were 94%–95%.⁷⁰

The catalytic activities and enantioselectivities of Rh(I) complexes with steroidal ligands derived from cholestan-3-one in the hydrogenation of (*Z*)- α -acetamidocinnamic acid were estimated. The Rh(I) complexes with 1,4- and 1,3-bisphosphines **207a**, **208a** and **210** (*ee* = 75%–86%) appeared to be most efficient. Hydrogenation catalysed by the Rh(I) complexes with ligands **207a** and **210** afforded (*R*)-*N*-acetylphenylalanine, whereas hydrogenation on the complex with ligand **208a** gave rise to the product with the (*S*) configuration. The replacement of the diphenylphosphine groups in the ligands by the benzophosphindole groups leads to a substantial decrease both in the reaction rate and enantioselectivity of hydrogenation catalysed by the corresponding Rh complexes. The enantioselectivity achieved in the presence of Rh catalysts with such ligands (**207b** and **208b**) was 12%–22%.

Low enantiomeric yields of the products (*ee* = 44%) were observed in hydrogenation of (*Z*)- α -acetamidocinnamic acid on the Rh catalyst with 1,6-bisphosphine **212** as the ligand, whereas the Rh(I) complex with monophosphine **213** has no catalytic effect at all.⁷⁶

The Rh(I) complex with bisphosphine **214** of the mixed type, which was prepared from cholestanone and diethyl tartrate, exhibited high enantioselectivity (*ee* = 90%) in the hydrogenation of (*Z*)-*N*-acetylaminophenylpropenoic acid.⁷⁷

DET is diethyl tartrate.

Therefore, natural terpenes and steroids can be used as the starting compounds in the synthesis of chiral organophosphorus ligands for the preparation of metal complex catalysts for asymmetric homogeneous hydrogenation.

VI. Conclusion

The data surveyed in the present review raise the question of whether ligands prepared by transformations of natural molecules can compete with binaphthyl phosphorus-containing ligands of the BINAP type, which are by far the most efficient ligands for enantioselective catalysts.

In this competition, the advantage of the latter ligands is that they have been studied in much more detail as components of highly efficient catalytic systems. The best ligands serve as reference compounds and are used in fine organic synthesis. These ligands are widely advertised (which is also of importance) by manufacturing companies.

However, the most substantial drawback of binaphthyl ligands is their high price, which remains virtually unchanged over a long period of time. Hence, such ligands will find use in industrially promising processes only after the development of supercatalysts based on these compounds such that they can withstand tens and hundreds of thousands of catalytic cycles. As an example we refer to Rh(I) complexes with bidentate binaphthyl phosphines catalysing the enantiospecific shift of the double bond in the synthesis of L-menthol (Takasago process).

The main hopes, which stimulate investigations on the synthesis of chiral organophosphorus ligands based on available natural compounds, are pinned on the development of technological procedures for the preparation of inexpensive ligands, which can serve as components of catalysts for practically important reactions. These studies are in their infancy and, undoubtedly, will be continued.

Abstract. The fractal structures that form in disperse systems are considered. Theoretical models of fractal aggregation and the kinetics of coagulation of fractal aggregates are described. The characteristics of deposited fractal films and of corroded surfaces are considered. The multifractal analysis of colloidal systems and related thermodynamics of fractal aggregates are outlined. The bibliography includes 380 references.

I. Introduction

The concepts of fractal structures or, simply, fractals have been widely used since the 1980s. Fractals are objects that are characterised by a fractional dimension. Pioneering studies on mathematical treatment of objects with fractional geometric dimensions date back to the early 20th century; however, they have rarely been the subject of physicochemical research. It was Mandelbrot who clearly demonstrated in his monographs^{1,2} that many systems in nature can be considered as fractals. This aroused the interest of physicists and chemists in fractal structures.

The most important property of fractal structures is self-similarity. The visual appearance of self-similar structures is identical at different length scales, which allows one to envision the structure of the whole object using a fragment of it. Since this property is also characteristic of many non-fractal structures, the second property of fractals becomes of crucial importance. Namely, the changes in various characteristics (mass, density, surface area, elastic modulus, *etc.*) of a fractal object, which are due to changes in the size of the object or in the corresponding length scale, obey a power law with a fractional exponent. In other words, some relationships established for conventional one-, two- or three-dimensional systems are valid for fractals if we assume that their geometric dimension is not an integer.

The concepts of fractals have provided a better insight into both the structural organisation and the laws governing various

nonequilibrium processes in various physicochemical systems. Simultaneously, many regularities of the changes in the physicochemical parameters with varying spatio-temporal characteristics have been revised.

The new concept of structural organisation of well-known objects gave an impetus to original experimental studies and to the development of novel theoretical models. Considerable efforts have been made in order to find, generate and examine fractal structures. It should be noted that the subjects of a large number of these studies were typical objects of colloid chemistry, namely, particle aggregates, porous media, composite materials and rough surfaces. Therefore, it is quite reasonable that the first reviews and monographs in the field concerned mainly fractal aggregates.

In spite of extensive literature on fractal objects,^{3–23} many issues dealing with the properties of colloidal fractal structures are still to be clarified. Besides, a considerable body of information on the fractal characteristics of various colloidal systems has been accumulated in the last decade. Because of this, it seems appropriate to generalise the results obtained.

In this review, the emphasis is placed on the studies reported in the 1990s and more recently and on a few publications from the 1980s which contain basic results. These are necessary to enhance the integrity of material presented below.

The contents of the review is self-explanatory, so we will not dwell on its structure. Mention can only be made that here we have restricted ourselves to the consideration of (mainly) theoretical models for growth and geometric characteristics of fractal aggregates. Many problems concerning the description of experimental studies on the physicochemical properties of fractal aggregates and their dispersions will be the subject of a separate review, which will be published in the near future.

It seems appropriate to begin with a definition of the fractal dimension, which will be implicitly used throughout the text. The point is that this notion can be introduced in several ways, some of which are mathematically inequivalent. Subtle details of the corresponding mathematical treatment can be found in, *e.g.*, monograph.¹³ From this point on we will consider that the fractal dimension of any physical object can be determined using the following relationship[†]

V I Roldughin Institute of Physical Chemistry, Russian Academy of Sciences, Leninsky prosp. 31, 119991 Moscow, Russian Federation.
Fax (7-095) 952 53 08. Tel. (7-095) 955 46 47.
E-mail: roldugin@phych.ac.ru

[†] Here and in some relationships listed below unity is implied to be a dimensional quantity whose dimension is inverse to that of the expression under the logarithm.

$$d_f = \lim_{\delta \rightarrow 0} \frac{\ln N(\delta)}{\ln(1/\delta)},$$

where N is the number of boxes (spheres) of size δ needed to completely cover a given object (the so-called box-counting technique). Therefore, calculations of d_f in a particular case require the number of boxes of a given size necessary to cover the object to be counted and the limit of the ratio of logarithms with $\delta \rightarrow 0$ to be evaluated. In the case of planar fractal objects one can use squares (disks) instead of boxes. This relationship, adapted to particular systems, is most often used in determining the fractal dimension of physicochemical objects. Some modification of this relation will be given below. It should be noted in advance that here we will not discuss the problems concerning possible differences between the fractal dimensions determined using different relationships because they are of little interest for physical chemists. Besides, the development of fractal theory is accompanied by the introduction of various fractal dimensions, which characterise particular physicochemical properties of objects under study. Some of them will be introduced in the next Sections of the review.

II. Fractal aggregates

Aggregates of colloidal particles were among the first objects described using fractal geometry concepts. The pioneering studies on fractal clusters have been well documented in a number of reviews.^{7,8,12} In this Section we will consider the main stages of development of the fractal concepts.

Interest in fractal aggregates was aroused after publication of two basic studies^{24,25} concerning aggregates of highly dispersed iron particles produced by flash evaporation of induction heated wires. Analysis showed²⁴ that the aggregates can be treated as fractal structures, while numerical experiments using a model of diffusion-limited aggregation of individual particles revealed²⁵ that the process involves formation of aggregates, which possess some properties of fractals. Next, it was found that fractal aggregates can be generated in numerical experiments with various growth models^{26,27} for diverse colloidal systems.^{28–37} These investigations were followed by dramatic increase in the studies on the formation and structure of aggregates of colloidal particles and other fractal objects. To date, fractal aggregates of gold,^{29,34} hematite,^{38,39} silica,⁴⁰ polystyrene⁴¹ and carbon⁴² particles have been obtained. The state-of-the-art in the field of research on fractal structures since 1985 is well illustrated by the book,⁴³ which gives a clear idea of both the expansion of avenues of investigation and diversity of the methods for studying fractals.

Computer simulation has played a significant role in the studies of fractal aggregates. Detailed analysis of the available literature in the field is presented in a monograph.¹⁸ Computer models allow different regimes of particle aggregation to be examined. They also serve as the basis for carrying out real experiments and processing large arrays of experimental data. Now it is appropriate to briefly outline the main models for description of particle aggregation, which are used in numerical simulation. We will often refer to them in the text below.

1. Classical models for fractal aggregation

Numerical experiments began with the simulation of random walk of particles on a lattice. This imposed some limitations. The next step was to simulate the motion in free space instead of the movement of particles over lattice sites. This caused no significant changes in the structure of clusters at longer length scales but led to a more realistic structural organisation of aggregates at short length scales. If numerical simulation concerns the random walk of clusters and particles on a lattice, the corresponding models are called lattice models. Otherwise (motion in continuous space), they are called off-lattice models.

The simplest model of aggregation was proposed by Eden. According to this model, a seed is initially introduced into the

system, which gives rise to a cluster. Growth occurs by attachment of a particle to a randomly chosen, unoccupied nearest-neighbour perimeter site. This repeats during each step of growth simulation. The model generates a dense cluster and is therefore usually considered as a model for growth of dense objects (e.g., crystals).

The ballistic model considers the motion of a pair of clusters (or a cluster and a particle) along randomly chosen linear trajectories. Collisions between clusters causes their aggregation. In the simplest version of the model the structure of the aggregate is determined by the mutual orientation of moving clusters at the instant at which they first contact each other. If the growth of a cluster occurs by attachment of single particles, the model is called the particle–cluster ballistic aggregation model. If the process of aggregation involves not only the primary particles (monomers) but also aggregates, the model is called the cluster–cluster ballistic aggregation model. The Witten–Sander model for diffusion-limited aggregation (DLA) assumes that aggregation occurs by attachment of a particle (or aggregate) to the seed (aggregate). Here, the particle (or aggregate) is introduced into the system at a rather long distance from the seed and experiences Brownian motion before collision with the seed. As particles or aggregates first contact each other, they combine irreversibly. Similarly to the ballistic model, two types of aggregation are considered, namely, particle–cluster and cluster–cluster aggregation in accord with the type of the object introduced into the system (single particle or a cluster).

Among the variety of models proposed to describe the processes of particle aggregation, the reaction-limited cluster–cluster aggregation (RLA) model is most widely used. According to this model, particles and clusters moving *via* Brownian motion must experience numerous collisions before aggregation. In numerical simulation, this is included by setting a low probability, p , of the collisional aggregation of particles. If this probability is rather high or even set to unity, the diffusion transport of particles can appear to be the limiting step and the DLA regime operates. In the limiting case ($p \rightarrow 0$), the reaction-limited particle–cluster aggregation model is transformed into the Eden model.

2. The fractal dimensions and the most important properties of fractal aggregates

Prior to considering some recently proposed, generalised aggregation models, let us give definitions of various fractal dimensions, which are used to describe the growth and properties of fractal aggregates.

The mass fractal dimension, d_f , is the dimensionless exponent in the relationship connecting the number, N , of particles in the aggregate to the linear dimension, R , of the aggregate

$$N = k_0 \left(\frac{R}{a} \right)^{d_f}. \quad (1)$$

The coefficient k_0 is called the prefactor, the structure factor or the first-order lacunarity and a is the size of the primary particles. Usually, the role of linear dimension is played by the radius of gyration, R_g , of the aggregate, which is given by

$$R_g^2 = \frac{1}{N} \sum_{i=1}^N (\mathbf{r}_i - \mathbf{r}_0)^2, \quad (2)$$

where $\mathbf{r}_i$ and $\mathbf{r}_0$ are the coordinates of the i th particle and the centre of mass of the aggregate, respectively.

The fractal dimension of aggregates grown in numerical simulation is determined using relation (1). This requires preliminary generation of clusters of different sizes followed by plotting of the logarithm of the number of particles *vs.* the logarithm of the radius of gyration, R_g ; the slope of this dependence equals the fractal dimension.

The mass fractal dimensions determined for the main models of particle aggregation (see above) are listed in Table 1. As can be

Table 1. The fractal dimensions of aggregates obtained by numerical simulation of cluster growth.^{12, 19}

d	Particle – cluster aggregation	Cluster – cluster aggregation
Diffusion-limited aggregation		
2	1.71	1.45
3	2.50	1.80
Ballistic aggregation		
2	2.0	1.55
3	3.0	1.95
Reaction-limited aggregation		
2	2.0	1.61
3	3.0	2.09

seen, the fractal dimension strongly depends on the dimension, d , of the space in which the aggregate was grown and on the aggregation regime. Hereafter we will use the values listed in Table 1 as references in comparing the results obtained using different models.

The mass fractal dimension is sufficient for characterisation of the properties of nearly spherical aggregates. In some systems, particle aggregates possess pronounced shape anisotropy. They are called self-affine aggregates rather than self-similar ones⁸ and can be described by two (longitudinal, d_l , and transverse, d_t) fractal dimensions given by

$$N = k_L \left(\frac{L}{a} \right)^{d_l}, \quad (3)$$

$$N = k_W \left(\frac{W}{a} \right)^{d_t},$$

where k_L and k_W are the corresponding prefactors and L and W are the longitudinal and transverse linear dimensions of the aggregate, respectively.

When considering anisotropic fractal aggregates, the averaged mass fractal dimension is also used

$$\langle N \rangle = k_M \left[\frac{(LW)^{1/2}}{a} \right]^{d_f}. \quad (4)$$

where the angle brackets denote the averaging over all aggregates characterised by the given length and transverse linear dimension and k_M is the effective prefactor.

Self-affinity of aggregates means that they are invariant with respect to expansion or contraction with different factors, A_L , A_W , for the longitudinal and transverse linear dimensions, respectively

$$L' = A_L L,$$

$$W' = A_W W.$$

By expressing the self-affinity coefficient in the form

$$A = \frac{\ln A_W}{\ln A_L},$$

it is possible to interrelate the three fractal dimensions mentioned above

$$d_l = \left(\frac{1+A}{2} \right) d_f, \quad (5)$$

$$d_t = \left(\frac{1+A}{2A} \right) d_f.$$

Introduction of the trajectory dimension, d_w , of the particles involved in the formation of aggregates (the random walk dimension) appeared to be useful for theoretical analysis. In the DLA regime, particles and clusters experience Brownian motion; the trajectory dimension for a Brownian particle is known¹² to be 2; therefore, $d_w = 2$. Ballistic aggregation is characterised by the motion of particles and aggregates along linear trajectories; hence, $d_w = 1$. For the reaction-limited regime of aggregation, the character of particles motion is of no significance, because particles experience multiple collisions before being added to aggregates and can therefore ‘forget’ their true trajectories (this holds for all particles). Here, the determining role is played by the point to which the particle or aggregate is attached; therefore, the trajectory dimension for the RLA regime is taken to be zero.

Many properties of fractal aggregates, which will be discussed below, are determined not only by the fractal dimension but also by the so-called chemical dimension, d_c , which is introduced as follows. Let R_c be the minimum distance, which should be travelled to pass from the particle i to the particle j without leaving the aggregate. Let a sphere B_c centred at the particle i be a set of particles j of the aggregate, for which $R_c \leq R_0$. Then, the number of particles belonging to B_c increases with increasing R_0 as follows

$$N_c \propto R_0^{d_c}. \quad (6)$$

which gives the chemical dimension of the fractal aggregate.

The growth laws of irregular fractals are to a great extent dependent on the conditions for penetration of particles into these structures. For instance, growth of a cluster in the DLA regime depends on the ability of a randomly walking particle to reach a particular site. If the sites on the surface of clusters are ascribed some ‘masses’ proportional to the probability of attachment of a randomly walking particle, it is possible to introduce a new fractal dimension (harmonic fractal dimension d_h) using the dependence of the total ‘mass’ on the size of the fractal aggregate. This parameter is of crucial importance for determination of various physicochemical characteristics of fractal objects. In particular, knowledge of the distribution of sites possessing activity towards the walking particle is of great importance in studies of adsorption, catalytic reactions, breakdown of dielectrics and dissolution processes.

In contrast to the fractal dimension and chemical dimension, which can be determined using relationships (1) and (6) immediately after aggregation, calculations of the harmonic dimension require either special computations or additional simulation. This parameter can be found by, *e.g.*, solving the Laplace equation for the potential distribution in the space outside of the aggregate at a given surface potential. In this case, the probability of aggregation at a given point is proportional to the surface potential gradient. This problem is too difficult to be solved analytically and therefore the parameter d_h is usually determined using numerical methods.

Meakin⁴⁴ reported a study on two-dimensional clusters grown using the Witten–Sander model for diffusion-limited cluster–cluster aggregation and some other models. The clusters were characterised by significantly different fractal dimensions; namely, the d_f values varied from 1.25 to 1.89. The activities of the growth sites were determined using the probe particles experiencing Brownian motion, *viz.*, the growth probability was assumed to be proportional to the number of contacts between Brownian particles and a given site. It was found that d_h has nearly the same value of 0.925 for all the systems studied. This is in agreement with the analytically predicted value $d_h = 1$ for all two-dimensional objects.⁴⁵ Grassberger⁴⁵ also introduced yet another fractal dimension, namely, the ballistic fractal dimension (d_b), which is determined analogously to the harmonic fractal dimension except that the probe particles are assumed to follow linear trajectories. Unlike the harmonic fractal dimension, d_b strongly depends on the nature of the fractal aggregate.

Generally, the surface of a fractal aggregate requires an infinite hierarchy of fractal dimensions for complete character-

isation,^{46,47} which corresponds to the so-called multifractal description of fractal objects (see Section IV). Moreover, an infinite hierarchy of fractal dimensions also arises⁴⁷ for those non-fractal surfaces which are characterised by a constant fractal dimension in a particular portion of the distribution curve.

Concluding this subsection, we will give some simple relationships, which characterise the properties of fractal aggregates.[‡]

The dependence (1) corresponds to the following radial density distribution in a fractal aggregate

$$\rho(r) \propto r^{d_f-d}, \quad (7)$$

where r is the distance from the centre of the aggregate.

The density distribution of the number of particles in aggregates is usually characterised by the density correlation function

$$C(r) = \frac{\langle \rho(r)\rho(0) \rangle}{\rho(0)^2} \propto r^{d_f-d}, \quad (8)$$

where the angle brackets denote the averaging over different orientation of the aggregate. It should be noted that this form of the correlation function is independent of the choice of the origin of coordinates. Namely, if the origin of coordinates is at any point in the cluster, including a point that is well off its centre, the density correlation function decreases obeying the relation (8). Any change in position of the origin of coordinates will affect only the coefficient on the right of expression (8) rather than the exponent. This property of the structure of fractal aggregates was tested by numerical simulation of clusters grown in the DLA regime.⁴⁸ As will be shown below, this property is responsible for many peculiarities of the physicochemical properties of fractal aggregates.

Running somewhat ahead, mention may be made that the correlation function (8) corresponds to the intensity of small-angle scattering of electromagnetic radiation by fractal aggregates given by

$$I(q) \propto q^{-d_f}, \quad (9)$$

where q is the magnitude of the scattering vector

$$q = \frac{4\pi}{\lambda} \sin \frac{\theta}{2},$$

and λ is the radiation wavelength and θ is the scattering angle. The scattering intensity obeys the relation (9) at

$$qR_g \gg 1 \text{ and } qa \ll 1.$$

Some generalisations will be considered below.

Using relationships (7) and (8) implies an infinite cluster. However, both real and numerical experiments deal with finite clusters. Because of this, the so-called cutoff function is introduced into relations of the types (7) and (8). For instance, the cutoff function $h(r)$ can be introduced into the density correlation function of an aggregate as follows

$$C(r) \propto r^{d_f-d} h\left(\frac{r}{R}\right). \quad (10)$$

The function $h(r)$ must satisfy the following conditions

$$\begin{aligned} h\left(\frac{r}{R}\right) &\approx 1, \quad r < R, \\ h\left(\frac{r}{R}\right) &\rightarrow 0, \quad r > R. \end{aligned} \quad (11)$$

‡ It would be more appropriate to introduce these relationships later but they are necessary for considering the results of some studies concerning the subject of this Section of the review.

In order for fractal dependence of the correlation function on the distance to be valid, the cutoff function should tend to the limiting values faster than power functions.

Knowledge of the cutoff function is required for correct reconstruction of the aggregate size distribution from light scattering data.⁴⁹ It should be noted that to a first approximation the introduction of the cutoff function has no effect on the dependence (9). Different cutoff functions were proposed, *e.g.*, an exponent,⁵⁰ a stretched exponent⁵¹ and a Gaussian function.⁵² A detailed study on the role of the cutoff function in determining the parameters of fractal aggregates has been reported.⁵³

3. Generalisations of classical models

Initially, numerical experiments were performed ignoring interparticle interactions. However, real experiments revealed production of clusters whose fractal dimensions differed from those predicted by simple DLA and RLA models. This was explained by specific features of interparticle forces. Therefore, a number of specific experiments and numerical simulation with inclusion of interparticle forces were carried out. The effect of the dipole–dipole interaction on the structure of fractal aggregates grown in the diffusion-limited cluster–cluster aggregation regime was studied.^{54,55} Taking the three-dimensional system as an example, it was shown that the d_f value gradually varies from 1.78 for weak to 1.35 for strong dipole–dipole interactions. The fractal dimensions obtained were in good agreement with the experimental values.^{56,57}

The effect of the interparticle interaction on the structures of aggregates growing in the reaction-limited cluster–cluster aggregation regime was studied.^{58–63} It was found that the structures and the fractal dimensions of the aggregates depend on the particular form of the interparticle interaction. The fractal dimensions obtained were both greater and smaller than the values determined using the classical models.

It should be noted that restructuring of fractal aggregates, which were preliminarily grown using the classical approaches, also allows the aggregates characterised by greater fractal dimensions (compared to the classical values) to be obtained.^{60,61}

Diffusion-limited aggregation of particles of different kinds was studied.^{64,65} Only particles of different types could bind to each other in a two-species DLA model,⁶⁵ which revealed a specific type of percolation transition. Namely, only finite clusters can grow in the system if the fraction of particles of one sort is small, whereas infinite clusters can grow only if the fractions of particles of each sort exceed some critical values.

The Eden model was generalised⁶⁶ by introducing an additional internal degree of freedom of the particles, the spin. The model assumes a cluster growing in an external magnetic field and the spin–spin interaction between the nearest neighbours. The new model allows two new fractal dimensions characterising particles with different spin orientations to be introduced. It appeared that the fractal dimension is a nonmonotonic function of the parameter characterising the energy of the interparticle interaction. At low and high interaction energies, the fractal dimension approaches the space dimension and passes through a minimum (the minimum d_f value is 1.79) at intermediate energies of the interparticle interaction. At these energies, the aggregation regime changes in such a way that the cluster structure becomes highly porous. The cluster grown at high energies of the interparticle interaction is characterised by a structure with uniform porosity.

The growth of fractal aggregates near surfaces of various nature was studied by numerical simulation.^{67–69} In all cases, aggregates grown in the presence of steric hindrances were characterised by reduced fractal dimensions.

Generalisations of the ballistic model were reported.^{70,71} The effects of biases of the trajectories of the particles following streamlines in the viscous fluid near the growing aggregate⁷⁰ and accretion of particles on seeds of different (finite) sizes were included.⁷¹

In most of the above-mentioned studies on the growth of fractal aggregates they were simulated using ensembles of mono-disperse particles. Studies on the influence of particle polydispersity on the structure and fractal dimension of aggregates^{34, 72–76} revealed that polydispersity has little effect on the fractal dimension even for an ensemble characterised by polymodal size distribution.⁷⁶ However, the local structure of aggregates can significantly change, thus affecting the calculated intensity of small-angle light scattering.^{75, 76} The cutoff function, which includes the finite size of aggregates, weakly depends on the degree of polydispersity.

4. Analytical models of aggregation

Most theoretical studies on the growth of fractal aggregates involve numerical simulation. There is only a few analytical models of the growth of fractal structures. The reason is the complexity of description of the fractal structure using analytical functions. The most interesting results obtained in this field are briefly outlined below.

Based on general considerations, without using any hypotheses of the structure of aggregates grown in the DLA regime of particle aggregation, it was established⁷⁷ that the largest separation between the centre and the most distant point of the aggregate cannot exceed $C_2 N^{2/3}$ for the two-dimensional space and $C_d N^{2/d}$ for the spaces characterised by greater dimensions ($d > 2$), where C_2 and C_d are constants. In fact, these relationships place limits on the growth rate of fractal aggregates. It was pointed out that some of the models proposed earlier predicted a faster increase in the aggregate size.

Formation of fractal aggregates in the DLA regime was also studied^{78, 79} using an approach which is similar to the Flory model for polymer molecules (see Ref. 80). The authors introduced the effective free energies of repulsion between and attraction of the aggregating particles. An equation for the fractal dimension of the growing aggregates was derived from the condition for the free energy minimum. If an aggregate was grown on the substrate with the dimension $d-m$ in the space with the dimension d , the d_f value for the aggregate is given by⁷⁸

$$d_f = \frac{d^2 + 1}{d + 1} - (d - m). \quad (12)$$

The fractal dimensions found using this relationship are in good agreement with the results of numerical simulation for the spaces and substrates of various dimensions.

The fractal dimensions of aggregates were also analytically determined^{81, 82} using the renormalisation group approach (see, e.g., Ref. 83). In this case, the fractal dimension is determined from some recurrent relations rather than from an explicit expression. The fractal dimensions of aggregates thus obtained were also consistent with the values found by numerical simulation.

Sander *et al.*⁸⁴ treated diffusion-limited aggregation as a deterministic process of propagation of the interface due to particle diffusion. In this case, calculations of the cluster's growth were reduced to the solution of the Laplace equation with the corresponding boundary conditions. It should be noted that processes of electrochemical deposition, viscous fluid flow in porous media and the breakdown of dielectrics^{85, 86} are described by similar equations. Numerical solution of the equations derived showed that the front propagation is accompanied by the development of perturbations on the initially smooth surface, thus resulting in the formation of a dendritic structure. The fractal dimensions of the dendrites growing in two-dimensional and three-dimensional systems were in agreement with the fractal dimensions determined by numerical simulation.

This method of simulation of the growth of dendritic structures has been intensively developed over a long period. Not only theoretical studies but also model experiments have been carried out. The initial model was generalised^{87–90} with inclusion of

various effects including the anisotropy of transport coefficients near the interface. Theoretical studies on the morphological stability of the growing dendritic structure were also reported.^{91–93} It was found⁹⁴ that the growing dendritic structures can be characterised by both periodic and random distributions of the secondary branches grown on the primary branch; doubling of the distance between the secondary branches is also possible. The change in the dendrite growth scenario was observed in model experiments. Studies on the growth of ammonium chloride crystals in agar gel revealed⁹⁵ that growth of fractal structures instead of crystals with smooth surfaces begins at particular supersaturations. This was explained by surface reconstruction of the growing face under the action of solvent. Transition from regular to chaotic branch growth in dendritic clusters was realised⁹⁶ in the experiments on quasi-two-dimensional growth of ammonium chloride crystals between two plates in solution at rather high supersaturations.

These investigations were to some extent reviewed in a study⁹⁷ concerned with possible morphologies of the growing structures and conditions for transitions between different scenarios of dendrite growth. Current interest in these models is due to the possibility of using them for growth of structures that do not possess isotropic symmetry (the so-called chiral structures).^{98, 99}

Qualitative analysis of aggregation laws^{100, 101} made it possible to derive an explicit expression relating d_f to the space and random walk dimensions with inclusion of incomplete accommodation of particles on the growing cluster

$$d_f = \frac{d^2 + \varepsilon(d_w - 1)}{d + \varepsilon(d_w - 1)}, \quad (13)$$

where ε is the particle accommodation coefficient. This equation was confirmed¹⁰² by Monte Carlo simulation of aggregation under conditions identical to those reported in the studies mentioned above.^{100, 101}

An analytical model was proposed, which allows one to follow the evolution of diffusion-limited fractal aggregation.¹⁰³ A closed equation was derived for the aggregate density and the concentration of primary particles, which predicted a power-law decrease in the density of the growing aggregate.

This model was extended¹⁰⁴ to the case of incomplete accommodation of particles on the surface of an aggregate, *i.e.*, diffusion-limited aggregation, reaction-limited aggregation and an intermediate regime of aggregation were considered in the framework of a unified model. The equations in the generalised model become somewhat cumbersome but not too complicated. Figure 1 presents the fractal dimension of a three-dimensional aggregate plotted *vs.* the particle accommodation coefficient. As can be seen, the model correctly reproduces the limiting cases. The region corresponding to the inflection in the $d_f(\varepsilon)$ curve has attracted considerable interest. The structures of the aggregates grown under these conditions exhibit two domains, a compact

Figure 1. Fractal dimensions of aggregates growing in the DLA regime *vs.* particle accommodation coefficient.¹⁰⁴

Figure 2. Density distribution for an aggregate grown at intermediate values of the particle accommodation coefficient. Core (1), fractal shell (2) and peripheral area (3).

core and a fractal peripheral area (Fig. 2). The presence of two domains indicates that the initial RLA regime is changed by the DLA regime with time. The change in the aggregation regime occurs almost without exception. Therefore, strictly speaking, fractal aggregates should exhibit a multifractal structure (see below).

A model describing the evolution of regularly branched polymers (dendrimers) also belongs to analytical models of fractal aggregation. Dendrimers are synthetic macromolecules with a definite architecture. They can be synthesised by performing repeated reactions.^{105–107} Successive ‘generations’ of branches are built of polyfunctional monomers, emerge from the same centre and form a dendritic structure.

The first theoretical description of the structure of dendrimers was reported by de Gennes and Hervet,¹⁰⁸ though primitive models of such structures were proposed somewhat earlier.² Different models of dendrimers were considered in a number of studies^{13,43,109} and generalised by McCoy.¹¹⁰ According to the generalised model, a total of Π branches grow at $t = 0$. In contrast to the earlier models, the branches can be characterised by different masses or lengths (some mass distribution of the emerging branches was preset). Then, a total of Π new, smaller branches successively grow at the end of each ‘old’ branch at regular time intervals. The model assumes that the ratio of the average mass of the new branches, m_i^{av} , to the average mass of the branches grown in the preceding step, m_{i-1}^{av} , is a constant

$$\frac{m_i^{av}}{m_{i-1}^{av}} = A. \quad (14)$$

In this case, the dendrimer grown is a fractal aggregate with the dimension

$$d_f = \frac{\ln \Pi}{|\ln(A)|}. \quad (15)$$

As mentioned above, this model is a generalisation of the models proposed earlier. In particular, at $\Pi = 2$ and $A = 1$, it describes the so-called Cayley tree.¹¹¹ The model was used to determine the temporal dependences of the number of branches, the masses and densities of dendrimers and the viscosities of their solutions.

The model of growth of dendritic structures is a particular case of regular models of fractal aggregation. Usually, regular models include some algorithms of generation of self-similar aggregates. One of them is presented in Fig. 3. It is an easy matter to extend this procedure to three-dimensional, self-affine and other aggregates. A comprehensive analysis of regular models of fractal aggregates was reported earlier,⁸ so we will not dwell on them here.

Figure 3. Growth scenario of a self-similar two-dimensional fractal aggregate with the dimension $d_f = \ln 7 / \ln 3 \approx 1.77$.

Concluding this subsection, mention may be made that thermodynamic characteristics are also suitable for the determination of fractal dimensions of different objects.^{112–114} In particular, the fractal characteristics of aggregates were determined using the principle of maximum information entropy production.¹¹³ The size distribution of aggregates was assumed to be lognormal. The fractal dimensions and the standard deviations found using the principle of maximum information entropy production were in agreement with the experimental data.¹¹⁵

In most of the models considered above the fractal dimension is governed by the aggregate growth algorithm. Recently, some models have been proposed,^{116–119} in which the cluster growth algorithm is prescribed by the fractal dimension and the prefactor in order to provide correspondence between the results of calculations and experimental data. In these models, aggregation occurs by attachment of single particles or fractal aggregates and the position of the attached fragment is preset by the fractal characteristics of the growing system. It can be found with ease using relationships (1) and (2) and the prescribed fractal dimension for both particle–cluster and cluster–cluster aggregations of overlapping and non-overlapping spheres.

5. The prefactor

Quantitative description of clusters using improved experimental methods requires the prefactor k_0 to be determined.^{120–123} This coefficient is of particular importance in determining the optical characteristics of clusters (in particular, their scattering power) and their radiating capacities.

Both the prefactor and the fractal dimension can be determined using relationship (1). In contrast to calculations of the fractal dimension, computations of the prefactor initially gave contradictory results. Based on the results of numerical simulation and model experiments, the prefactor was reported to be approximately unity.¹²¹ At the same time, the prefactors measured in studies of soot clusters formed under different regimes of combustion were 1.23 ± 0.07 (see Ref. 120) and 1.66 ± 0.4 .¹²⁴ Numerical simulation for diffusion-limited cluster–cluster aggregation gave¹²⁵ a k_0 value of 1.2 ± 0.15 . Analysis of stereoscopic images of soot agglomerates^{126,127} showed that $k_0 \approx 2.4$ and $d_f = 1.64$.

Probably, the reason for the observed differences between the experimental values of k_0 and d_f is an internal rearrangement and partial sintering of aggregates, which, as was mentioned in Refs 128 and 129, predetermine the change in their fractal dimension. An important fact was pointed out:¹³⁰ interparticle contacts in real systems should not be treated as point contacts. Hence, one deals with seemingly overlapping particles. Simulation of diffusion-limited cluster–cluster aggregation and processing of the data with inclusion of particle overlap showed that both the fractal dimension and the prefactor increase on increasing the degree of particle overlap (Fig. 4). This dependence can be described by the approximate relationship

$$k_0 = \tilde{k}_0 \Delta_d^{d_f}, \quad (16)$$

Figure 4. Fractal dimension (1) and prefactor (2) plotted vs. degree of particle overlap (a_p) in a fractal aggregate.¹²⁹

where

$$\Delta_a = \frac{2a}{2a + a_s}$$

(a_s is the distance between the surfaces of the particles) and $\tilde{k}_0$ is the point-contact prefactor.

It was also confirmed¹³⁰ that even at $d_f < 2$ the fractal dimension of the two-dimensional projection of a three-dimensional cluster is nearly 10% smaller than the fractal dimension of this cluster only for the point contact case. The inclusion of the monomer overlap increases the discrepancy between the fractal dimensions of the three-dimensional aggregate and its projection.

The assumption of the effect of the degree of particle overlap on the fractal dimension and prefactor was experimentally tested¹³¹ taking the coagulation of polystyrene latex particles with adsorption layers of different thicknesses in different regimes as an example. The fractal dimensions and sizes of aggregates were determined by static and dynamic light scattering, respectively. The results of processing of experimental data confirmed the validity of relationship (16).

III. Kinetics of coagulation of fractal aggregates

1. General relationships

Numerical simulation of the growth of fractal aggregates concerns the structure of aggregates and regularities of changes in their size distribution with time. It was shown¹³² that the size distribution, $N_s(t)$, of clusters containing a constant number (s) of primary particles changes with time obeying a self-preserving (or scaling) law

$$N_s(t) \propto s^{-2} f\left[\frac{s}{\langle s \rangle(t)}\right], \quad (17)$$

where $\langle s \rangle(t)$ is the average number of particles in the cluster at instant t , which is given by

$$\langle s \rangle(t) = \left[\sum_{s=1}^{\infty} s^2 N_s(t) \right] / \left[\sum_{s=1}^{\infty} s N_s(t) \right], \quad (18)$$

and f is some universal function.

Relation (17) for asymptotic cluster size distribution was proposed earlier based on the solution of the Smoluchowski coagulation equation, which in the general case has the form

$$\begin{aligned} \frac{\partial n_s}{\partial t} = & \frac{1}{2} \sum_{i=1}^{s-1} Z(i, s-i) n_i n_{s-i} - \sum_{i=1}^{\infty} Z(s, i) n_s n_i + \\ & + \sum_{j=1}^{\infty} Y(s, j) n_{s+j} - \frac{1}{2} \sum_{j=1}^{s-1} Y(j, s-j) n_s, \end{aligned} \quad (19)$$

where n_s is the concentration of clusters comprised of s primary particles, $Z(i, j)$ is the coagulation kernel and $Y(i, j)$ is the fragmentation kernel.

A more general relation obtained for a number of model aggregation kernels has the form

$$N_s(t) \propto s^{-\vartheta} f\left[\frac{s}{\langle s \rangle(t)}\right], \quad (20)$$

where $\vartheta = 2$ for systems characterised by conservation of the total mass.

The aggregation kinetics described by the Smoluchowski equation (19) is governed by the forms of the coagulation and fragmentation kernels (detailed analysis of the solutions to the Smoluchowski equation was reported earlier¹³³). A classification of uniform coagulation kernels was proposed,¹³⁴ which is based on comparison of the probabilities of coagulation of large clusters and of large and small clusters. Depending on which process prevails, it is possible to obtain different laws of aggregation and different cluster size distributions. If aggregation of large and small clusters predominates, no considerable changes in the masses of clusters occur and the size distribution curve becomes bell-shaped. If the interaction of large clusters dominates, small clusters are not involved in the 'battle' and the size distribution curve corresponds to a monotonically decreasing power function.

Two parameters, μ and ν , are responsible for different regimes of growth of the coagulation kernels with increasing cluster size. Namely, $Z(j, j) \propto j^\mu$ for large aggregates and $S(1, j) \propto j^\nu$ for the probability of coagulation of a large aggregate and a small cluster. For the classical Smoluchowski coagulation kernel, $\nu = 1/3$ and $\mu = 0$. For the same coagulation kernel and fractal aggregates, $\nu = 1/d_f$ and $\mu = 0$. It should be noted that the cases $\nu > 1$ and $\mu > 2$ are physically unrealistic. At $\mu > 1$, the Smoluchowski equation predicts that the formation of an infinite cluster takes a finite time (the so-called gel point). At $\mu \leq 1$, no gel transition occurs; the formation of an infinite cluster takes an infinitely long time.

At $\mu > \nu$ and $\mu < 1$ (no gel transition), the cluster size distribution curve is described by a decreasing power function

$$N_s \propto s^{-\tau}, \quad \tau = 1 + \mu,$$

(τ is sometimes called the polydispersity index). Under the same conditions, the mass-average molecular mass is described by an increasing power function

$$M_w \propto t^z,$$

$$z = \frac{1}{1 - \mu}.$$

The radius of gyration, R_g , of fractal aggregates changes with time as follows

$$R_g \propto t^{1/d_f}.$$

For diffusion-limited aggregation with the Smoluchowski coagulation kernel ($\mu = 0$) one has

$$R_g \propto t^{1/d_f}. \quad (21)$$

This dependence was confirmed experimentally. For instance, aggregation of silica particles of size 7 nm was studied by static light scattering.¹³⁵ The d_f value obtained using relation (21) coincided with the fractal dimension determined in the same study by small-angle light scattering.

If a gel transition is possible ($\nu < 1 < \mu \leq 2$), the size distribution of the growing clusters, which are smaller than some characteristic size, is also described by a power function

$$\begin{aligned} N_s & \propto s^{-\tau}, \\ \tau & = \frac{3 + \mu}{2} > 2, \end{aligned}$$

Near the gel point, the mass-average mass of the cluster increases as follows

$$M_w \propto |t - t_g|^{-\gamma},$$

where t_g is the gel transition time and

$$\gamma = \frac{1}{1 - \mu}.$$

At $\mu < \nu$, no gel transition occurs, because $\nu < 1$. In this case, the formation of a broad size distribution is impossible and the size distribution curve has a bell shape.

In a regime, which is intermediate between the regimes mentioned above, where both types of aggregation are equally significant (at $\mu = \nu \leq 1$), no gel transition occurs and the average mass of the cluster increases as follows

$$M_w \propto e^{ct}. \quad (22)$$

Attempts have also been undertaken to obtain an analytical solution to the Smoluchowski coagulation equation for fractal aggregates using some realistic approximations. Coagulation processes are also studied using aerosols. In this case, aggregation can occur in both free-molecular and continuum regimes. The expressions for the coagulation kernels in these two limiting cases are as follows

$$Z(i, j) = \frac{2kT}{3\eta} \left(i^{1/d_f} + j^{1/d_f} \right) \left(\frac{1}{i^{1/d_f}} + \frac{1}{j^{1/d_f}} \right), \quad (23)$$

for the DLA regime and

$$Z(i, j) = \left(\frac{6kT}{m_p} \right)^{1/2} \left(\frac{1}{i} + \frac{1}{j} \right)^{1/2} \left(i^{1/d_f} + j^{1/d_f} \right)^2, \quad (24)$$

for the free-molecular regime, where η is the viscosity of the disperse medium and m_p is the mass of the primary particle.

Correctness of relationship (24) for aerosol particles was the subject of a study¹³⁶ and good agreement with the results of numerical simulation was revealed.

Fractal aggregation in the continuum regime using the Smoluchowski equation with the coagulation kernels for DLA was studied.^{137, 138} Both analytical¹³⁷ (assuming a lognormal cluster size distribution) and numerical¹³⁸ solution of the coagulation equation were obtained. The former solution was reproduced by Park *et al.*¹³⁹ Figure 5 presents the temporal dependences of particle concentrations. As can be seen, the formation of fractal aggregates causes a faster decrease in the particle concentration;

Figure 5. Reduced concentration, N , of aggregates with different fractal dimensions as a function of time.¹³⁹
 d_f : 1.5 (1), 2.0 (2) and 3 (3); N_0 is the concentration of primary particles and τ_0 is the half-coagulation time.

the reciprocal concentration increases linearly with time for different fractal dimensions.

The existence of a self-preserving solution of the Smoluchowski coagulation equation with the coagulation kernels (23) and (24) was confirmed both numerically and analytically.¹⁴⁰ Based on the numerical solution, simple approximate expressions were presented for the self-preserving solution of the Smoluchowski equation.

The possibility for the self-preserving solution of the Smoluchowski equation to exist was also reported^{138, 141–144} for the continuum (DLA) and free-molecular regimes of particle aggregation. The results of calculations^{141–144} were confirmed by experiments¹⁴³ with silicon and silicon nitride aerosol particles. At the same time, numerical calculations¹⁴⁴ showed that no self-preserving solution exists at $\mu > 1$ because of gel transition.

Sintering of particle aggregates^{145–147} and other processes related to the effects of surface phenomena¹⁴⁸ or dispersion composition¹⁴⁹ on the kinetics of particle aggregation¹⁴⁸ only slightly affect the possibility of obtaining the self-preserving cluster size distribution.

2. Coagulation in concentrated dispersions

Recently, considerable attention has been paid to the studies on aggregation in concentrated disperse systems. This is due to advances in computational procedures and to the development of new experimental methods. A feature of concentrated colloidal systems is a significant role of not only the average cluster size and the cluster size distribution but also the structure factor, which is given by (see also the next subsection)

$$S(q) = \frac{1}{N^2} \sum_{j=1}^N \sum_{i=1}^N \exp[iq(\mathbf{r}_i - \mathbf{r}_j)], \quad (25)$$

where $\mathbf{q}$ is the scattering vector, $\mathbf{r}_i$ and $\mathbf{r}_j$ are the coordinates of particles and N is the number of particles in the system. The structure factor characterises both long-range and short-range orders in the particle distribution and predetermines the optical properties of dispersions.

Aggregation in concentrated colloidal dispersions can be considered as a stage of phase[§] decomposition. Phase decomposition in molecular systems is accompanied by definite evolution of the structure factor. Numerous attempts to confirm or reject the validity of these evolutionary relations for colloidal systems have been undertaken.

Kolb and Herrmann¹⁵⁰ seem to have been the first to report significant differences between the aggregation in concentrated dispersions and aggregation in strongly dilute colloidal systems. The subject of their study was the numerical simulation of particle aggregation in two- and three-dimensional systems at high concentrations of clusters. The emphasis was placed on the effect of the diffusion coefficient on the structure of the growing aggregates. The diffusion coefficient was assumed to be a power function of the cluster mass. It was found that three types of aggregation can occur in the system at different values of the exponent and initial concentration of particles. These are (i) growth of fractal clusters whose dimensions vary over a wide range, (ii) growth of dense clusters with fractal surfaces and (iii) growth of dense clusters with smooth surfaces. Particular regimes of aggregation allow growth of infinite clusters (*i.e.*, percolation clusters or gel).

Monte Carlo simulation of diffusion-limited cluster–cluster aggregation of colloidal particles in concentrated dispersions was reported.¹⁵¹ The structure factor was calculated at different instants. The emphasis was placed on verification of the hypothesis of scaling invariance of the dynamical structure factor, according to which

§ The phase state of an ensemble of colloidal particles is kept in mind.

$$S(q, t) = R_g(t)^{d_f} F[qR_g(t)], \quad (26)$$

where F is a universal scaling function, which does not depend on time in an explicit form. Numerical calculations confirmed the scaling invariance of the dynamical structure factor. At the same time, it was pointed out that some details of the evolution of the colloidal dispersion are different from the model of spinodal decomposition, as was found in the model^{152, 153} and numerical¹⁵⁴ experiments. The main difference was attributed to different exponents in the power-law expression for the temporal dependence of the average size of the new-phase domains, namely, the exponent equals $1/3$ for spinodal decomposition while depends on the space dimension and on d_f of aggregates for fractal aggregation.

Scaling invariance of the structure factor was the subject of yet another study, numerical simulation of DLA and RLA in three-dimensional space.¹⁵⁵ Using a structure factor similar to that given by (26), the authors tested the validity of the relationship established¹⁵⁶ for spinodal decomposition

$$S(q, t) = q_m^{-3} F\left(\frac{q}{q_m}\right),$$

where $q_m(t)$ is the wave vector corresponding to the maximum value of the structure factor and d is the space dimension (for fractal aggregates, $d = d_f$). The structure factor was also compared with the pair correlation function and it was shown that the peak of the structure factor arises from the correlations between particles belonging to nearest-neighbour clusters. The exponents that relate the position and the height of the maximum of $S(q)$ to time differ from the spinodal decomposition exponents. Though the $S(q)$ for RLA exhibits no peak at short times, eventually its maximum becomes higher than that for the DLA regime. The final shape of $S(q)$ corresponds to a close packing of the clusters after gelation.

A numerical study on diffusion-limited aggregation in two-dimensional colloidal dispersions of various concentrations was also reported by van Garderen *et al.*¹⁵⁷ Conditions for gel transition in the system were established (see Section VI). In the gel state, the system contains a domain of size $r < \xi$ (ξ is the so-called correlation length, which characterises the spatial range of fractal properties of aggregates). At long length scales, the system is a homogeneous medium. The fractal dimension of the grown aggregates coincided with that found for diffusion-limited cluster–cluster aggregation. Variation of the concentration of primary particles affects only the parameter ξ .

The results obtained for three-dimensional systems were somewhat different.¹⁵⁸ The existence of two domains characterised by different length scales, $r < \xi$ and $r > \xi$, was also pointed out. At short length scales, the system has a fractal structure, while at long length scales, the system is a homogeneous medium. However, an increase in the fractal dimension of aggregates with increasing concentration of primary particles was reported, which contradicts the results of this study by van Garderen *et al.*¹⁵⁷ To eliminate the contradiction, a thorough study of aggregation of colloidal particles in dispersions of different concentrations was carried out.¹⁵⁹ Calculations for the three-dimensional space using the diffusion-limited and reaction-limited cluster–cluster aggregation models with inclusion of the dependence of the particle diffusion coefficient on the particle size showed that for both models the fractal dimension increases with increasing concentration of primary particles. This increase for the DLA and RLA regimes can be approximated by the corresponding relationships

$$d_f = 1.80 + 0.91\varphi^{0.51}, \quad (27)$$

$$d_f = 2.1 + 0.47\varphi^{0.66},$$

where φ is the volume fraction of particles. The cluster size increases as a power function of time for DLA and exponentially

for RLA. The exponent in the former case and the coefficient in the exponential expression in the latter case are also functions of the initial particle concentration. In both cases, self-preserving cluster size distributions were found, which correspond to the above-mentioned relations (20) with a bell-shaped function $f(x)$ for DLA. The corresponding function $f(x)$ for RLA has the form

$$f(x) \propto x^{-\tau} \tilde{f}(x), \quad \tau = 1.5.$$

Diffusion-limited aggregation in concentrated dispersions was analysed¹⁶⁰ by analytical methods using the known mean-field approximation model.¹⁶¹ The conditions for cluster formation and the cluster–cluster correlations were analysed with inclusion of the presence of domains with reduced concentrations of particles (monomers). The temporal evolution of the mean cluster radius coincided with that predicted by solution of the Smoluchowski equation. The angular dependences of the scattering light intensities by dispersions were calculated at different instants. Differences between the light scattering by dispersions characterised by the growth of dense and fractal clusters were pointed out. Model experiments showed that scaling invariance of the type (26) during the whole aggregation process is characteristic only of the scattering intensity calculated for the dispersions of dense clusters. The absence of scaling invariance for fractal clusters was explained by differences between the characteristic times of aggregation and of local changes in the concentration of monomers; namely, aggregation is governed by the fractal dimension while the formation of domains with reduced concentrations of particles (monomers) is governed by the space dimension. Scaling-invariant changes in the scattering intensity can occur only immediately prior to gelation.

3. Systems characterised by fragmentation and rearrangement of aggregates

In most cases, numerical experiments concerning fractal aggregation imply rather strong interparticle interactions. In fact, fragmentation of particles is possible, in particular, because of thermal motion. It was Kolb¹⁶² who pioneered numerical experiments on the growth of fractal aggregates by fragmentation. The inclusion of the possibility of cluster fragmentation can lead to an increase in the fractal dimension of aggregates. For instance, d_f increases from 1.78 in the absence of fragmentation to 2.03 if one assumes a low probability of interparticle bond breaking. An increase in the fractal dimension is readily explicable: most often, aggregates comprising fragments connected through a small number of bonds (*i.e.*, the loosest aggregates) undergo fragmentation. Of course, fragmentation of aggregates produces some mass distribution, but the average cluster mass has a finite value.

The effect of bond energy on the fractal dimension of aggregates grown in the diffusion-limited cluster–cluster aggregation regime was studied.¹⁶³ Using the two-dimensional model, it was shown that the fractal dimension strongly depends on the bond energy of the particles in the aggregate.

If the homogeneous coagulation and fragmentation kernels meet the conditions

$$Z(Ai, Aj) = A^{v_z} Z(i, j), \quad (28)$$

$$Y(Ai, Aj) = A^{v_y} Y(i, j),$$

where v_z and v_y are the homogeneity exponents, the average number of particles in the aggregate is given by¹⁶⁴

$$\langle s \rangle \propto \left(\frac{Z_0}{Y_0} \right)^{1/(2+v_y-v_z)}, \quad (29)$$

where Z_0 and Y_0 are the dimensional coagulation and fragmentation constants, respectively,

$$Z(i, j) = Z_0 \tilde{Z}(i, j),$$

$$Y(i, j) = Y_0 \tilde{Y}(i, j).$$

Here $\tilde{Z}(i,j), \tilde{Y}(i,j)$ are dimensionless functions [usually, $\tilde{Z}(1,1) = \tilde{Y}(1,1) = 1$].

Dimensional relationships (28) and (29) were used to establish the dependence of the average number of particles in aggregates, their average size ($\langle R \rangle$) and concentration (n) on the volume fraction, ϕ , of particles in the system.¹⁶⁵ A criterion for gel transition in the system was also proposed.

The growth of fractal clusters, which can undergo fragmentation induced by thermal motion, and gel transition in two- and three-dimensional systems was studied.^{166–170} The structure factor $S(q,t)$ of aggregates grown in the diffusion-limited cluster–cluster aggregation regime was determined at different instants by numerical simulation.¹⁶⁶ The height of the maximum of $S(q,t)$ is plotted vs. time in Fig. 6. Three main regions in the plot can be pointed out. At short times, the height of the maximum slowly increases [the lower the bond energy, the slower the growth of $S(q_m)$]. At intermediate times, the $S(q_m)$ increases as a power function of time. The duration of this stage is limited by the gel transition, which corresponds to the next, final, stage of the change in the structure factor $S(q_m)$. Here, the $S(q_m)$ slowly increases and reaches a plateau. The higher the bond energy, the slower the increase in the $S(q_m)$. At low bond energies, the plot exhibits no saturation. In this case, the system's behaviour corresponds to the classical pattern for ageing colloidal dispersions, which are characterised by a gradual increase in the size of compact 'droplets' (gel state will be considered in more detail in Section V).

Figure 6. Maximum value of the structure factor, $S(q_m)$, as a function of time for a system of gel-forming aggregates.¹⁶⁶

Concluding this Section, mention may be made of a number of studies concerning the fragmentation of fractal aggregates by different mechanisms. Etching studies of fractal and non-fractal clusters revealed¹⁷¹ that the temporal dependence of the number of fragments passes through a maximum and that the number of fragments and the width of their distribution at maximum exhibit power-law dependences on the mass of the initial cluster and on the average coordination number of particles in the cluster. The corresponding exponents depend on the space dimension, starting geometry of the system and on the temperature (the bond breaking probability was assumed to be proportional to the Boltzmann factor). Simulation of etching of fractal objects (aggregates, surfaces and a porous medium) was carried out¹⁷² for both reaction-limited and diffusion-limited regimes. Each object under study was characterised by its own kinetics of etching, governed by the fractal dimension. For instance, the mass of a fractal cluster M decreases with time as follows

$$M \sim (1 - Kt)^{d_f},$$

while the area of the fractal surface obeys the t^{1-d_f} law. It should be noted that fragmentation of fractal aggregates is similar to fragmentation of percolation clusters, which are known to have a fractal structure. Studies on the fragmentation probability of a percolation cluster *via* random rupture of a finite number of bonds have been reported.^{173–177} It was shown that fragmentation of

such a cluster obeys some scaling relationships; however, they cannot be used in fragmentation studies of conventional fractal aggregates and are therefore not presented here.

IV. Multifractal analysis of fractal aggregates

Some fractal objects cannot be described by one fractal dimension,^{178, 179} so one should introduce a large number of parameters similar to the fractal dimension. In this case, the object under study is said to possess multifractal properties.

Often, the question arises as to the multifractal characteristics. For instance, a study on the motion of a fractal aggregate in viscous fluid showed¹⁸⁰ that the distribution of viscous forces applied to particles obeys multifractal relations. It was pointed out¹⁸¹ that the multifractal approach should be used when analysing the voltage drop distribution at the interparticle contacts in a composite material characterised by near-percolation concentration of the conducting phase. This methodology was also used to study the crack structure distribution in solids¹⁸¹ and the fluid flow distribution in a porous medium.¹⁸²

Let us consider the multifractal characteristics in more detail. We will examine a fractal object following a conventional formalism by tiling the space of the object into small boxes. Let any box have a unit mass. This allows the mass, M , and the density of the object of linear dimension L to be determined

$$\rho = \frac{M}{L^d}.$$

An increase in the linear dimension of the object by a factor of A causes the mass to increase by a factor of A^{d_f} and the density to decrease by a factor of A^{d_f-d} . Generally, we can write

$$M \sim L^{d_f}, \quad \rho \sim L^{d_f-d}.$$

Since all boxes have equal masses, the changes in the characteristics of the object, which are due to the change in its linear dimension, can be described using one parameter, namely, the fractal dimension d_f . Such an 'equality' of the masses (or other characteristics) of boxes not necessarily corresponds to the physical essence of the object under study. In the example considered above (see Section II), the characteristics of the perimeter of the growing cluster were determined with inclusion of the attachment probability of a new particle to a certain perimeter site. It was shown that different perimeter sites are characterised by different attachment probabilities p . Therefore, it is possible to introduce a probability distribution, $n(p)$, for different perimeter sites. In this way, other elements of the fractal object can also be described by some probability distributions. Like any other probability distribution, the distribution $n(p)$ can be characterised by moments of the order q [¶]

$$Z(q) = \sum_p n(p)p^q = \sum_i p_i^q. \quad (30)$$

Summation in the first sum is performed over the probabilities while summation in the second sum is performed over all the perimeter sites characterised by the corresponding probabilities.

Any parameter suitable for quantitative comparison of different regions of a fractal object can be used instead of the probability. Often, the parameters p_i are meant as generalised measures. Examples of the normalised quantities (measures) will be presented below.

Fractal objects belong to the so-called critical structures. According to the theory of critical phenomena, the probability

[¶] Literal designation of the moments as q is commonly accepted in the literature. Here, it should be recalled that the letter ' q ' has already been used in the review for notation of another quantity (see above).

distribution must be characterised by two critical indices only.¹⁸³ This means that it is impossible to obtain additional information on the system by examining the higher moments, because the $(q + 1)$ th moment is determined by the exponent, which is found from the q th moment, and some increment Δ . Let the moment be related to the linear dimension L by a power dependence with the exponent $\tau(q)$

$$Z(q) \sim L^{-\tau(q)}. \quad (31)$$

Then, $\tau(q)$ must be a linear function because only two numbers (critical indices) are required to find the dependence $\tau(q)$ (see above). Both numerical simulation and model experiments on many real fractal objects revealed that in the general case the relation between τ and q significantly differs from a linear dependence, which points to multifractality of these objects.

The generalised fractal dimension, D_q (more rigorously, the dimension spectrum), is given by the following relationship

$$(q-1)D_q = \tau(q). \quad (32)$$

As can be seen, $\tau(q)$ equals zero at $q = 1$.

Usually, yet another two characteristics are introduced. These are the so-called Hölder exponent

$$\alpha_m = \frac{d\tau}{dq}, \quad (33)$$

and the Legendre transformation of the function $\tau(q)$, or the multifractal spectrum

$$f(\alpha_m) = q\alpha_m - \tau(q). \quad (34)$$

For true fractal structures, this difference and the parameter D_q are constants.

The physical meaning of these characteristics can be understood taking the aggregation problem as an example. Assuming that the probability of particle attachment to some site changes with the change in the linear dimension of the aggregate (namely, decreases because of the lengthening of the perimeter) as follows

$$p \sim L^{\alpha_m}, \quad (35)$$

from relations (30), (32) and (34) the probability distribution density is given by

$$n(p) \sim C(\alpha_m)L^{f(\alpha_m)}, \quad (36)$$

where $C(\alpha_m)$ is a function independent of the length scale.

When analysing real objects using the multifractal approach, a number of characteristic parameters corresponding to $q = -\infty$, 0, 1 and $+\infty$ are usually considered. At $q \rightarrow \infty$, the parameter $\tau(q)$ equals the proportion of the multifractal set, which is characterised by the highest probability, and D_∞ equals the minimum α_m value for the system in hand. And *vice versa*, at $q \rightarrow -\infty$, $\tau(q)$ equals the proportion of the multifractal set, which is characterised by the lowest probability, and $D_{-\infty}$ equals the maximum α_m value. At $q = 0$, the parameter D_0 , which is equal to the maximum value of the function $f(\alpha_m)$, characterises the dimension of the measure carrier (*i.e.*, the multifractal object itself). For a monofractal object, D_0 equals the fractal dimension of the object. Finally, at $q = 1$, the parameter D_1 is equal to the dimension of information entropy (generally, it can be considered equal to the dimension of the generalised Renyi entropy).

Typical dependences $D_q(q)$ and $f(\alpha_m)$ are shown in Figs 7 and 8. Real systems can exhibit marked deviations from these dependences.

There is an analogy between the multifractal and thermodynamic formalisms. Let us re-write relationship (30) in the form

$$Z(q) = \sum_p e^{F(p)}, \quad (37)$$

Figure 7. Typical fractal dimension spectrum.¹⁸⁰

Figure 8. Typical multifractal spectrum and its characteristic points.¹⁸⁰

where $F(p) = \ln n(p) + q \ln p$. Suppose that the major contribution to the sum on the right of Eqn (37) comes from the terms with $p = p^*$, where p^* corresponds to the maximum value of the function under the summation sign. Then one gets

$$Z(q) \approx e^{F(p^*)} \propto L^{\tau(q)} = L^{f(\alpha_m) - \alpha_m q}. \quad (38)$$

As can be seen, the function $Z(q)$ formally plays the role of the statistical sum of the thermodynamic system while $\tau(q)$ is the free energy and q is the reciprocal of the temperature. The Legendre transformation $f(\alpha_m)$ is an analogue of the entropy, the parameter α_m is an analogue of the energy while the dependence $f(\alpha_m)$ is easily recognisable as similar to the relation between the entropy and energy of the thermodynamic system. The analogy between the fractal and thermodynamic formalisms has been the subject of a thorough study.¹⁸⁴

The multifractal thermodynamic characteristics of the fractal aggregates grown in the DLA regime have been reported.¹⁸⁵ The generalised Renyi entropies were calculated

$$I_q(L) = \frac{1}{q-1} \ln \sum_i p_i^q, \quad q \neq 1, \quad (39)$$

$$I_1(L) = \sum_i p_i \ln p_i,$$

and their changes during the aggregation simulated using the Brownian dynamics approach were followed.

The Renyi entropies depend on the fractal dimension of aggregates. An increase in the number, N , of particles in the aggregate causes the Renyi entropies to increase in proportion to $\ln N$. The coefficient of proportionality,

$$K_q = \frac{I_q}{\ln N}$$

for this dependence is determined by the fractal dimension of the aggregate and the q value. At $q \leq 1$, the parameter K_q decreases, while at $q > 1$ it increases on increasing the fractal dimension. This coefficient can be used to determine the degree of multifractality of aggregates, which is defined¹⁸⁶ as the entropy difference between the domains corresponding to the maximum ($q \rightarrow +\infty$) and minimum ($q \rightarrow -\infty$) measures, *i.e.*, $K_{-\infty}(N) - K_{+\infty}(N)$. According to calculations, this difference tends to zero as the number of particles in the aggregate increases. Thus, transition to a true monofractal is possible in the limit $N \rightarrow \infty$; the aggregate comprising a finite number of particles possesses multifractal properties.

An attempt has been undertaken¹⁸⁷ to go beyond the scope of a simple analogy between the multifractal and thermodynamic descriptions. The 'thermodynamic' behaviour of multifractal systems was compared with the thermodynamic behaviour of conventional physical objects. The 'thermodynamics' of multifractals was considered in the constant specific heat approximation. This choice is due to the fact that the specific heats of gases and solids remain constant over a rather wide temperature range. In this approximation, the function f should have the form

$$f(q) = a_m - c_m \ln q, \quad (40)$$

where a_m and c_m are constants and q is the constant specific heat. For the generalised dimension from Eqn (32) one has

$$D_q = (a_m - c_m) + c_m \frac{\ln q}{q - 1}. \quad (41)$$

The dependence $f(q)$ is plotted in Fig. 9. As can be seen, the constant specific heat approximation fits well the results of numerical experiments.

Figure 9. Multifractal spectrum calculated for the DLA regime (points)¹⁸⁸ and calculated in the constant specific heat approximation (straight line).

Analogous dependences for the generalised fractal dimension are presented in Fig. 10. The results of numerical simulation are in good agreement with the fractal dimension spectra obtained in the constant specific heat approximation. Interestingly, the slope ratio of the straight lines in Fig. 10, which is equal to the 'specific heat' ratio, is $\sim 3/2$, as in the case of the specific heats of three- and two-dimensional gases. It has been shown¹⁸⁸ that the constant specific heat approximation describes the multifractal spectra obtained by different authors for various systems (*e.g.*, stress distribution for percolation cluster, surface profile of corroding material, turbulent diffusion, *etc.*).

The multifractal analysis of the clusters growing in the DLA regime showed^{190–192} that the clusters are characterised by a more complex structure than could be expected based on the fractal dimension and anisotropy factor only.

Consideration of correlations between the measures of a multifractal object showed¹⁹¹ that the correlation function has the form

$$\langle p(r')^m p(r' + r)^n \rangle \simeq \left(\frac{R}{a}\right)^{d_{m+n}} \left(\frac{r}{a}\right)^{d_m + d_n - d_{m+n}}, \quad (42)$$

Figure 10. Fractal dimension spectra for two-dimensional (1) and three-dimensional (2) DLA¹⁸⁹ plotted in the constant specific heat approximation.

where a and R are respectively the lower and the upper bounds of the fractal behaviour of the measure carrier ($a < r < R$; a is the short cutoff and R is the overall radius of the object), $d_q \equiv (1 - q)D_q - d_f$ and d_f is the fractal dimension of the measure carrier. The existence of a single scaling form over the full range of radius indicates that the multifractal object is a set of blocks similar to those used in polymer physics rather than a superposition of fractal sets.

A similar approach to the description of fractals treats fractal aggregates as sets of 'branches' with certain masses m .¹⁹² For a typical cluster comprised of N particles, the branch mass distribution, $n(m, N)$, was introduced. Processing of a large body of data obtained by numerical simulation of aggregates showed that this distribution obeys the law

$$\frac{n(m, N)}{N} \sim m^{-\beta}. \quad (43)$$

More recently,¹⁹³ it was shown that this power law can be derived from the maximum entropy principle. In this case, the entropy is expressed through information necessary for growing a fractal object with prescribed structure and size. Taking a number of fractal objects, which can be grown iteratively, it was demonstrated that the maximum entropy principle allows, on the one hand, the power laws of changes in some characteristics of fractals to be established, and, on the other hand, the fractal dimension to be calculated without determining the spatial structure of fractal objects.

Theoretical conclusions were confirmed by the data of experiments¹⁹⁴ with polystyrene latex particles of size 600 nm, which floated on the surface of aqueous MgSO_4 solution. The image of the surface fluid with floating particles was tiled into boxes of a particular size δ . Each box was ascribed a measure p_i equal to the ratio of the number of particles in the box to the total number of particles in the system. The multifractal characteristics can be found with ease from the following expressions

$$\tau(q) = \lim_{\delta \rightarrow 0} \frac{\ln \sum_i p_i^q}{\ln \delta}, \quad (44)$$

$$\alpha_m(q) = \lim_{\delta \rightarrow 0} \frac{\sum_i \hat{p}_i \ln p_i}{\ln \delta},$$

$$f(q) = \lim_{\delta \rightarrow 0} \frac{\sum_i \hat{p}_i \ln \hat{p}_i}{\ln \delta},$$

where

$$\hat{p}_i = \frac{p_i^q}{\sum_i p_i^q}. \quad (45)$$

The multifractal spectra of aggregating two-dimensional dispersion at different instants are shown in Fig. 11. Some peculiar features should be pointed out. The maximum in the curve is related to the fractal dimension of the measure carrier, *i.e.*, to the fractal dimension of the substrate regions characterised by the nonzero measure. A large number of empty regions is also present in the system in question; because of this, the fractal dimension of the measure carrier is less than two. The information entropy and the fractal dimension of the measure carrier are plotted *vs.* time in Fig. 12. As can be seen, both dimensions decrease with time. This is typical of two-dimensional aggregation of colloidal particles. A decrease in the entropy dimension is explained by a decrease in the monolayer entropy upon aggregation.

Figure 11. Multifractal spectra of aggregating two-dimensional dispersions at different instants of time.¹⁹⁴
t/s: 122 (1), 613 (2) and 2401 (3).

Using the relations mentioned above implies an all-scale self-similarity of the object analysed using the multifractal approach. Real objects are self-similar at certain length scales. This means that in the general case the multifractal spectrum depends on the length scale. Taking into account this scaling dependence, it is possible to draw some interesting conclusions concerning the length scales appropriate for multifractal analysis of objects.¹⁹⁵ Let us take an ensemble of particle aggregates as an example and analyse it using the multifractal approach.

Let us tile the entire space into boxes of linear dimension δ . Let the proportion of particles in the box i be the measure p_i . Clearly, the sum of the measures over all boxes equals unity. The average measure in the filled boxes equals the reciprocal of the number of the filled boxes

Figure 12. Information entropy (D_0) (1) and fractal dimension of the measure carrier (D_1) (2) plotted *vs.* time.

$$\langle p \rangle = Z(0, \delta)^{-1}. \quad (46)$$

The dispersion of the measure in the boxes is given by

$$\sigma_p^2 = \langle p^2 \rangle - \langle p \rangle^2 = \frac{Z(2, \delta)}{Z(0, \delta)} - \frac{1}{Z(0, \delta)^2}. \quad (47)$$

For monofractal objects one has

$$Z(0, \delta) \sim \delta^{-d_f},$$

$$Z(2, \delta) \sim \delta^{d_f}.$$

As a result, the measure dispersion remains constant upon changing the box size. For multifractal objects, the first term in Eqn (47) is proportional to $\delta^{D_2+D_0}$ and the second term is proportional to δ^{2D_0} ; *i.e.*, the measure dispersion varies with the change in the box size. Therefore, it is possible to find a box size (for a normal multifractal spectrum, where $D_2 < D_0$ on the long length scale, and for an anomalous multifractal spectrum, where $D_2 > D_0$ on the short length scale) such that the measure dispersion becomes equal to zero. Further change in the length scale will not affect the dispersion, because it cannot be negative. So one can say that, from the measure distribution standpoint, the system will be homogeneous beyond the limiting length scales. In the case of colloidal systems the minimum box size nearly equals the particle size or the correlation radius.

Yet another field of application of the multifractal approach is the determination of the fractal dimension of real finite systems. The point is that the use of the relationship given in p. 824 faces some difficulties, because this relation ‘works’ well only in the case of ideal (in the mathematical sense) fractal objects. Real systems are characterised by finite dimensions, which confines the range of fractal behaviour. Therefore, the fractal dimension is usually estimated rather than calculated. The procedures for reliably estimating the fractal dimension have been discussed in the literature.^{196–199} Usually, it is possible to determine several different fractal dimensions. A typical curve for the determination of the fractal dimension of an object, obtained using the box-counting technique, is shown in Fig. 13. The curve degenerates into a straight line only for true fractal object. Otherwise (including multifractal structures), a number of straight-line portions are observed. Usually, region 1 (large δ) characterises the fractal dimension of the space into which fractal objects can be embedded. The slope of the straight line in region 2 (small δ) determines the fractal dimension of the embedded object. Unambiguous interpretation of the intermediate region 3 is impossible, because its pattern is to a great extent determined by the character

Figure 13. Typical curve for determination of the fractal dimension using the box-counting technique.
 (1–3) see text.

of the spatial distribution of fractal objects. It can be treated as the region of the fractal dimension distribution, corresponding to the multifractal properties of the system under study.

V. Fractal gels and emulsions

1. Fractal gels

The size of fractal aggregates increases much faster than their mass during the aggregation process. At a certain particle concentration, which is specific to each fractal dimension value, the aggregates grown can fill the entire space, thus forming a gel structure composed of a network of connected clusters. Colloidal diffusion-limited cluster–cluster aggregation in two-dimensional systems was studied using the Smoluchowski coagulation equation²⁰⁰ and by numerical simulation.²⁰¹ The evolution of the cluster size distribution was followed; the gel was treated as an infinite fractal cluster. It was shown²⁰² that, if the volume fraction of the primary particles exceeds some critical value, φ_c , diffusion-limited cluster–cluster aggregation results in a homogeneous network formed by fractal clusters of size ξ .

There is a large number of models, which describe the transition of colloidal dispersions to the gel state. They are based on the classical fluid theory equations adapted for colloidal systems.²⁰³ The approach employed includes the Brownian dynamics simulation^{204–207} with different potentials of interparticle interactions, *e.g.*, the Derjaguin–Landau–Verwey–Overbeek,^{204,205} Lennard-Jones²⁰⁶ or the depletion potential.²⁰⁷ The molecular dynamics approach²⁰⁸ is also employed in the studies of gelation at the molecular level.

The simplest models of gel formation upon particle aggregation usually assume²⁰⁹ that the fractal dimension of aggregates remains unchanged during their growth under, *e.g.*, the DLA or RLA conditions. The volume fraction of particles in the fractal aggregate can be found with ease from

$$\varphi_a = \left(\frac{R}{a}\right)^{d_f-3}. \quad (48)$$

Gel transition occurs if the volume fraction of particles in the fractal aggregate becomes equal to the volume fraction of clusters in the entire system (at $\varphi_a = \varphi$). All clusters are assumed to have the same mean size $R = \xi$. In this state, there is a region of size $r < \xi$ (see Section III) in the system where the aggregates possess fractal properties. At long length scales, the system is a homogeneous medium whose fractal dimension equals the space dimension. The correlation length, ξ , is determined by the volume fraction of particles and is given by

$$\xi \approx a\varphi^{-1/(3-d_f)}. \quad (49)$$

The simplest model for gel formation can be applied to explain the results of experimental studies on the dynamics of the structure factor of dispersions. Experiments showed^{152,153,210–214} that, if fractal aggregation in the system results in the formation of a gel, the dependence of the structure factor $S(q,t)$ on the wave vector at different instants passes through a maximum. Small-angle neutron, X-ray, and light scattering studies of a broad class of dispersions (aluminosilicate gels,²¹⁰ polystyrene latex particles,^{152,153} polymer gels²¹¹ and monodisperse oil droplets in water^{212,213}) also showed that the position of the maximum, q_m , is inversely proportional to the ξ value at a given instant. This maximum is interpreted as an indication of the transition from the fractal regime of scattering [at intermediate q values corresponding to $S(q) \propto q^{-d_f}$] to the scattering by a homogeneous medium (small q values). It was also established^{152,211,215} that

$$S(q_m, t) \propto \xi^{d_f}, \quad (50)$$

$$q_m \propto S(q_m, t)^{-1/d_f},$$

$$t_g \propto \varphi^{-d_f/(3-d_f)},$$

where t_g is the gel time.

These relationships were tested in the Monte Carlo studies of gel formation in the diffusion-limited cluster–cluster aggregation regime.^{158,216} It was found that in the short-time scale the cluster size changes as follows

$$\xi \propto \left(\frac{t}{t_g}\right)^{1/d_f}.$$

As time passes, the exponent decreases; it should be noted that the higher the concentration of primary particles in the system, the earlier the decrease begins. The power-law relationship between q_m and $S(q_m, t)$ was confirmed with high accuracy; however, the exponent remained constant on increasing the concentration of primary particles, whereas the fractal dimension of the growing aggregates increased substantially. On this basis, it was assumed that the gelating systems are also characterised by the apparent fractal dimension of aggregates, which governs the relation between q_m and $S(q_m, t)$. A detailed review on the kinetics of formation of fractal gels from colloidal particles was reported by Poon and Haw.¹⁷⁰ They considered the processes of gel formation from colloidal particles and from colloidal particles and polymers and analysed the peculiar features of small-angle light scattering by gels of colloidal particles, which are due to the existence of a mesoscopic fractal structure.

In fact, fractal gels have a more complex structure compared to that predicted by the simplest model and the process of gel formation involves several stages.²⁰⁸ At first, clusters are formed from monomers and then grow under DLA conditions. The initial gel network is comprised of the largest aggregates and then smaller aggregates and free particles are included. In this stage, intercluster interactions become increasingly significant. Thus, the formation of a gel network is accompanied by slow changes in the structural organisation of particles.²¹⁷ Breakage of certain bonds and the formation of new bonds induce restructuring of the gel, which is accompanied by an increase in the dimensions of fractal objects. The multistep process of gel formation in colloidal dispersions was confirmed in a series of experimental studies^{218–220} carried out using various methods of analysis of the gel structure, which allowed length scales from several nanometres to 5000 nm to be investigated.

Restructuring of aggregates after formation of a gel network is possible in the systems characterised by rather weak attractive interparticle interactions.^{167–170,221,222} Here, the lifetime of the gel network can be rather long. However, if the interparticle bonds can be broken, the network is restructured because this state of particles in colloidal systems is metastable compared to gas–liquid phase transitions. Usually, such gels are called transient gels,²²³ though in fact all gels of colloidal particles are treated as transient gels (though for some of them the time for transition to the equilibrium state is too long). Numerical simulation of the process of transient gel formation has been the subject of a large number of studies (see, *e.g.*, Refs 205, 206, 222, 224 and 225). Transient gels obey common relations for the pair correlation function, $g(r)$, and the particle density distribution, $n(r)$

$$g(r) = \left(\frac{r}{\xi}\right)^{d_f-3},$$

$$n(r) = n_0 \left(\frac{r}{a}\right)^{d_f}$$

(n_0 is the normalising factor) and for the correlation length; however, the parameters of these distributions (including d_f) change with time.

Modern experimental studies are mainly carried out in order to establish a relation between the parameters of gels and

conditions for gel formation. In particular, the effects of the properties of the disperse medium^{226,227} and of the regime of coagulation of the primary particles^{226,228} on the fractal dimensions and correlation lengths of gels have been studied. The range of substances used for the formation of hydrogels is extended^{229–233} (here, silica undoubtedly ranks first). New experimental procedures for the determination of the sol–gel transition point, kinetics of fractal aggregation and fractal characteristics of gels are elaborated (*e.g.*, rheological^{232,233} and electrical conductivity methods²³⁴).

Studies on the dynamics of the restructuring of gels are a particular avenue of experimental research. Here, the main difficulty is due to the low rate of the process. Nevertheless, interesting results have been reported recently.²³⁵ Experiments were carried out with gels of polystyrene latex particles of size 10 nm dispersed in a light/heavy water mixture, which provided neutral buoyancy of particles. The volume fraction of particles varied from 10^{-4} to 10^{-3} . The fractal dimension of the freshly formed gel was 1.82. It was established that the dynamical structure factors of the gels obtained obeys the law

$$S(q, t) \propto \exp \left[- \left(\frac{t}{\tau_f} \right)^{\beta_g} \right], \quad (51)$$

with $\beta_g = 1.5$ and $\tau_f \propto q^{-1}$. Ageing causes the time τ_f to increase substantially. The temporal dependences obtained for different q can be scaled on a single master curve, with τ_f growing linearly with age. It should be noted that the temporal dependence of type (51) was reported earlier²³⁶ for an identical gel of polystyrene latex particles of size 9.5 nm with a somewhat different β_g value (0.66). No changes in the relaxation time were observed, except for a rather strong dependence of this parameter on the concentration of primary particles.

To explain these observations, a model was proposed, which is based on the syneresis of a gel and on its local shrinkage [the case in point is (i) the compaction of fractal fragments and (ii) restructuring of the gel]. The model allows experimental dependences to be reproduced correctly at a qualitative level. Densification of the central part of aggregates was reported in a study²³⁷ on the evolution of gels formed in methylcellulose solutions.

Until recently, gel formation was observed only in liquid dispersions. The first experiment on the formation of gels initially in the gas phase was reported by Lushnikov *et al.*²³⁸ who prepared the so-called fractal wires. The metal surface was exposed to intense laser radiation; subsequent application of a strong external electric field induced the ‘growth’ of a thick wire formed by fractal clusters attaching to the metal surface. The mechanism of wire formation is rather simple, namely, metal vapours are condensed in the form of nanoparticles which form fractal clusters. The external electric field induces directed aggregation into macroscopic fractal structures. A feature of the process is that the fractal wires at first grow in the gas atmosphere and then are attached to the surface.

Fractal wires from steel, brass and carbon particles have been produced analogously.²³⁹ A thorough examination of the structures showed that the primary particles are 1 to 10 nm in diameter and up to several millimetres long and possessed pronounced anisotropy. The ‘lifetime’ of the wires reached several weeks at zero electric field between the electrodes. The mechanism of formation of these structures is still to be clarified. The point is that one should take into account not only accelerated coagulation of particles but also their deposition on the electrodes. Here, the main contribution comes from Brownian diffusion of the particles and from their motion in the electric field. The nonuniformity of the electric field should also play a significant role. This is unavoidable in the system under study both at the electrode surfaces covered with the deposits and in the space between the electrodes, filled with rather large and readily polarisable aggregates.

The formation of an aerogel from soot particles formed during acetylene combustion has been studied.²⁴⁰ The primary particles of size 10 to 30 nm, which are usually formed in flames, grow (most often, under DLA conditions) into fractal aggregates with the radii of gyration varied between 50 and 100 nm. The experiment involved determination of the structure factor and photography of the upper region of the flame at different flow rates of acetylene. Measurements and observations showed that at sufficiently low flow rates of acetylene the structure factor corresponded to the presence of flame fractal aggregates with a dimension of 1.8. At rather high flow rates of acetylene, the dependence of the structure factor on the wave vector exhibits a maximum and some contacting aggregates of size of at most 5 μm are observed in the system. This indicates formation of a flame aerogel. Estimation of the aggregation rate of soot particles showed that it much exceeds that expected from the Smoluchowski equation. The mechanism of accelerated aggregation is also still to be clarified; mention was only made that studies of the sol–gel transition in the liquid phase also revealed²⁴¹ accelerated aggregation.

2. Fractal emulsions and microemulsions

In studies of the mechanical properties of aqueous emulsions^{242,243} it was conjectured that their spatial structure is characterised by the presence of inhomogeneous regions possessing the properties of fractals. This was confirmed in a quenching study²⁴⁴ of the microstructure of silicate glass in a liquid with low glass affinity (fractal properties were observed at a certain fraction of the dispersed phase). The data were analysed based on the concept of the so-called connected cluster, which is similar to a percolation cluster. However, analysis was performed by inclusion of all particles in the entire system, so the total number of particles much exceeded the number of particles in the connected cluster. Therefore, the fractal structure reported in Ref. 244 cannot be explained by effect of this cluster.

The fractal structure of emulsions was also assumed to have a dynamical nature²⁴⁵ and numerical simulation of a two-dimensional ensemble of disks with short-range attractive interactions was carried out. The type of particle distribution in the system was determined from the relationship between the number of particles in the circle $g(r)$ and the circle size r . For a system of non-interacting particles or at a low energy of interparticle interaction

$$U < kT$$

the particle distribution was uniform. The system with strong interparticle interaction

$$U > 3kT$$

was characterised by the formation of associates followed by separation into two phases. At

$$kT < U < 3kT$$

clustering occurred. The composition of clusters varied with time. The function $g(r)$ for the region occupied by the cluster was found to be a power function with a fractional exponent equal to the fractal dimension of the growing clusters. It was established that the fractal dimension increases on increasing the concentration of disks in the system.

Microemulsions, or surfactant-stabilised, thermodynamically stable homogeneous mixtures of polar (water) and non-polar (oil) liquids, belong to yet another group of colloidal objects with fractal structures. The surfactant molecules are usually distributed over the oil/water interfaces, which confine nanodroplets of water or oil.

Microemulsions are characterised by diverse structural organisations. Here, only three of them will be pointed out. If oil is present in excess, the phase L_2 comprised of water-containing surfactant micelles distributed in oil is usually formed. Otherwise (water-rich compositions), a microemulsion is comprised of surfactant-coated oil droplets dispersed in water (phase L_1). The

presence of water and oil in nearly equal proportions leads to formation of a bicontinuous phase (structure with surfactant-separated interpenetrating domains of the oil and water phases). The phase state of the microemulsions is to a great extent determined by the temperature and salinity of the aqueous solution.

Interestingly, by increasing the water-to-oil ratio it is possible to pass from the phase L_2 to the phase L_1 through the bicontinuous phase. This transition is accompanied by changes in the physicochemical properties of the microemulsion. The most remarkable is a dramatic (by several orders of magnitude) increase in the conductivity of microemulsion, which is usually considered as a percolation transition.^{246–249}

Observation of this transition indicates that microdroplets must form a fractal structure corresponding to the percolation cluster.⁵ At the same time, treatment of microemulsions in the framework of the fractal approach is seldom the case, though the earlier Monte Carlo simulation²⁵⁰ revealed fractal aggregation in microemulsions. It is the concept of fractal aggregation that allowed agreement between the theoretical and experimental temperature dependences of the conductivity of microemulsions on the concentration of the conducting phase to be established.

It was shown²⁵¹ that dynamic light scattering in microemulsions can be described in terms of the fractal aggregation of microdroplets and that the fractal dimension of the percolation cluster (2.5) is quite appropriate to account for the experimental data. This approach was also used²⁵² to describe the temperature dependences of the viscosity and elastic modulus of a microemulsion and of the dependences of the ultrasound velocity, specific heat and viscosity on the concentration of droplets. The great potential of the fractal methodology for the theory of microemulsions was confirmed by the results of experiments on the kinetics of quenching of fluorescent probes²⁵³ and diffusion of water molecules,²⁵⁴ dynamical percolation transitions^{255,256} and fluctuation effects²⁵⁷ in microemulsions near the percolation threshold. The fractal nature of the structure of microemulsions is also indicated by numerical simulation data and analytical calculations of the dynamics of the processes in the oil/water/surfactant systems during the formation of microemulsions from a (initially) homogeneous ternary mixture.^{258–261} This also holds for the interfaces in microemulsions.²⁶² Thus, application of the fractal approach to such interesting systems as microemulsions offers considerable promise.

VI. Two-dimensional fractal structures

Numerical simulation of aggregation processes usually concerns the laws of aggregation in spaces of different dimensions. The case for two-dimensional space is most often studied. This is mainly due to considerable reduction of computational cost, while the results obtained differ from those typical of the three-dimensional systems only quantitatively. However, interest in two-dimensional systems is not only of theoretical but also practical value. Modern technologies require knowledge of the laws of the interfacial behaviour of colloidal particles. These can be, *e.g.*, the water/air or oil/water interfaces; aggregation of particles at the solid/liquid interface is also possible.

Because of the need for research on aggregation in the two-dimensional space, numerical simulation was followed by experimental studies nearly immediately. It should be noted that such experiments have some advantage over the experiments with three-dimensional systems, namely, the structures of two-dimensional aggregates can be observed immediately using various microscopy techniques without distorting the objects under study.

1. Air/liquid interfaces

The pioneering experimental studies on the laws of fractal aggregation at interfaces were reported by Hurd and Schaefer²⁶³ and Onoda.²⁶⁴ They used micrometre-sized, hydrophobised particles of silica²⁶³ and polystyrene²⁶⁴ distributed over the surface of

aqueous salt solution. The experiments were carried out under DLA conditions. The values of the fractal dimensions determined appeared to be close to those found from numerical simulation.

There are three main types of interaction between particles trapped at interfaces. These are the electrostatic repulsion, molecular attraction and capillary interaction, which can be both an attractive and repulsive interaction. The electrostatic and capillary forces can be controlled with ease by adding salts in solution and by changing the extent of modification of the particle surface. The possibility of controlling the interaction forces allows the regime of particle aggregation to be varied. In particular, no changes in the structure of aggregates were observed^{265–267} upon change in the regime of cluster–cluster aggregation of polystyrene latex particles on the surface of water from DLA to RLA.

Studies on the aggregation of glass beads at the water/octane²⁶⁸ and water/air^{269,270} interfaces were carried out in different regimes of particle aggregation including those allowing the aggregates to undergo restructuring. Experiments showed that the aggregates can have either a fractal or non-fractal structure depending on the regime of aggregation. The fractal dimension of the growing aggregates depends on the hydrophobicity of the particle surface and on the concentration of salt in solution. Under particular conditions, rather large aggregates are characterised by the internal structure, as indicated by a break in the plot of the logarithm of the cluster density *vs.* distance to the centre of the cluster. The break was ascribed to the action of capillary forces, which contract the soft peripheral area of aggregates (see below). The interior of the large clusters is characterised by the same fractal dimension as the small aggregates. Considerable attention was paid to the restructuring of the grown aggregates. No quantitative relationships were found, but simple estimation showed that restructuring of aggregates is to a great extent controlled by the repulsive electrostatic forces. This conclusion was confirmed in the experiments on aggregation of polystyrene latex particles on the surface of water. In this case, the possibility of restructuring of aggregates was provided by specific adjustment of the parameters of the colloidal system.²⁷¹ By varying the electrostatic repulsion between particles it was possible to grow both compact aggregates and two-dimensional ‘foam’ formed by chains of particles.

A comparison of the laws of aggregation of rod-like and spherical particles at the water/air interface was reported.²⁷² The experiments were carried out with polydisperse rod-like soot particles 35 μm thick and 140 μm long and monodisperse glass beads 75 μm in diameter with different extent of surface hydrophobicity. The fractal dimension of two-dimensional structures was determined using three methods (box-counting technique, density correlation function and the number of particles–box size correlation). Experiments showed that the shape of particles has no effect on the laws of aggregation because the fractal dimensions of the aggregates of soot particles and of glass beads differed only slightly; at the same time, the fractal dimension of glass beads was affected by the hydrophobicity of their surface. Based on the fact that in both systems the structures of aggregates exhibited the existence of two regions with different fractal dimensions, it was concluded that aggregation was accompanied by restructuring.

Zeiri *et al.*²⁷³ studied a specific process of two-dimensional aggregation, namely, deposition of silver particles, which were distributed over the water subphase/organic liquid interface, on a thin electrode just contacting the water phase. An ensemble of silver particles at the interface (the so-called metallic liquid-like films) was prepared following a special procedure.²⁷⁴ The organic phases were chloroform and dichloromethane and the water subphases were aqueous solutions of silver nitrate with various surfactant additives. The concentration of silver nitrate in solutions was varied over a wide range. The use of solutions with strongly different concentrations allowed silver deposition on the electrode to be carried out in three regimes, *viz.*, electroaggregation of particles, electrochemical deposition of silver in the absence of interfacial particles and a combined regime ‘electro-

aggregation particles/electrochemical deposition of silver'. In the last-mentioned case, aggregation proceeded by a new mechanism, which involved the formation of interparticle bridges due to electrochemical deposition of silver. The preparation of nearly poreless aggregates and wire-like structures revealed the possibility of basically changing the structure of the deposits and their fractal characteristics.

Studies on subtle details of structural organisation of fractal aggregates formed on the liquid surface have been reported^{275, 276} taking aggregation of polystyrene latex particles of size 1 μm , which floated in the surface of aqueous solutions, as an example. Analysis of changes in the structure factor $S(q, t)$ under reaction-limited cluster–cluster aggregation conditions²⁷⁵ revealed a power-law singularity in $S(q, t)$ at $t \rightarrow \infty$, $q \rightarrow 0$. This behaviour corresponds to the so-called self-organised criticality, where in the absence of external factors the system tends to reach a state characterised by the absence of characteristic time and length scales. The system comprises both small clusters and large clusters whose size is comparable with the size of the entire system. In this case, a crucial role is played by co-operative effects, which reflect the long-range order in the ensemble of two-dimensional aggregates.

Experiments with polystyrene latex particles on liquid substrates were accompanied by numerical simulations of two-dimensional aggregation process at rather high particle concentrations under diffusion-limited cluster–cluster aggregation conditions.²⁷⁶ Direct observations of the system's structure [numerical processing of the experimentally measured structure factor $S(q, t)$] and the results of numerical simulation showed that at intermediate times the system has a structure with a six-fold symmetry. The corresponding peaks of the structure factor become strongly diffuse with time. The six-fold symmetry is quite unexpected for the system under study and has no rigorous physical substantiation as yet. It was hypothesised that the instant at which the hexagonal structure is formed corresponds to the instant at which the average cluster size becomes comparable with the half-distance between clusters. At that instant, depletion zones are formed around clusters and weak long-range repulsion between the mobile clusters can provide conditions for the formation of a hexagonal structure. By the way, the authors²⁷⁶ pointed to weak points of this hypothesis.

Control of the interaction between particles located at the interface was a rather complicated task in most experiments considered above. This fact is responsible for the scatter of the fractal dimension values obtained in different experiments. Hansen and Bergström²⁷⁷ proposed a method of controlled variation of the potential of interparticle interaction by varying the extent of particle modification by alcohols and the length of the grafted alkyl chain. Estimates revealed that replacement of octyl by an octadecyl chain causes the bond energy of 2 μm silica particles at the air/toluene interface to decrease from 30 down to 15 kT . Video-enhanced microscopy and image analysis of the particle dynamics showed that the average cluster size and the cluster size distribution obey the scaling relationship (20). The structure of the octyl system is formed in the diffusion-limited cluster–cluster aggregation regime. This is indicated by the fractal dimension of aggregates determined from the dependence of the radius of gyration on the number of particles and using the grid method ($d_f = 1.45$). Aggregation of particles in the octadecyl system resulted in a more dense structure with $d_f = 1.55$. A feature of both systems is the characteristic time corresponding to a transition point between aggregation regimes, which was attributed to convective motion of the clusters at the interface. Convective motion considerably enhances the mobility of large clusters and is believed to be responsible for the transition from diffusion-limited to reaction-limited cluster–cluster aggregation.

Particles can form gel-like structures both at liquid interfaces and in the bulk of the liquid phase. Two- and three-dimensional gels exhibit no fundamental differences in their behaviour; because of this, we will not consider them. The characteristics of

such structures including their rheological properties have been thoroughly studied by Dickinson.²²²

A detailed investigation of two-dimensional aggregation of colloidal particles under the DLA and RLA conditions was reported.²⁷⁸ Numerical simulation was carried out for the rectangular lattice and off-lattice models. The emphasis was placed on the dependence of the fractal dimension on the initial particle concentration, which varied over a range of two and a half orders of magnitude. The relationship established for the fractal dimension was similar to that obtained for three-dimensional systems

$$d_f = d_0 + b_d \varphi^{c_d}.$$

The parameters b_d and c_d in this relationship depend on the aggregation regime and on the model employed. However, the exponent c_d was equal to nearly unity within the limits of the computational procedure. The temporal dependence of the cluster size was also calculated. At a rather long time scale, this is a power law with the exponent z , where z depends on concentration as follows:

$$z = z_0 + b_z \varphi^{c_z}.$$

Here, the values of the coefficients are also governed by the regime of aggregation and the model employed; however, the exponent significantly differs from unity and is close to 0.6.

The subject of the studies considered above was the DLA or RLA regime at the surface of liquid phase. Practical realisation of other mechanisms of aggregation in these systems is a complicated task. The authors of study²⁷⁹ succeeded in implementing a two-dimensional ballistic aggregation of particles. In the experiments, hydrophobic particles were successively placed at the top of a droplet on the substrate. Particles were gravity 'slipped' following 'linear' trajectories towards the peripheral area of the droplet where aggregation occurred (aggregates grew from the periphery towards the centre of the surface of the spherical segment). The surface was nearly completely covered by particles; the fractal dimension of the aggregates thus grown was 1.95. In the case of diffusion-limited cluster–cluster aggregation on a flat surface, the same particles formed fractal structures with a fractal dimension of 1.45.

Particle aggregation on liquid surfaces in specific regimes (neither DLA nor RLA) is accompanied by the formation of various structures including fractal ones.^{280–282}

2. Cluster deposition on substrates

Deposition of nanoparticles on solid substrates is also accompanied by the growth of clusters with fractal structure.²⁸³ Low-energy monodispersed clusters produced by condensation of vapours were vacuum deposited on the substrate, thus forming submonolayers of clusters comprised of several tens to several thousands of atoms. Such clusters do not break down upon collision with the substrate. Larger clusters are characterised by small surface diffusion coefficients; therefore, they virtually do not move across the surface and their aggregation is thus also strongly inhibited. As the number of clusters on the substrate increases, specific structures are formed, which correspond to successive deposition of strongly attaching particles. Most often, structures similar to two-dimensional fractal aggregates are formed. Experimental studies and the results of numerical simulation concerning a broad spectrum of problems related to cluster deposition have been reviewed.^{284, 285} However, a study on the growth of fractal germanium clusters by epitaxial deposition on lead-coated silica surface should be pointed out.²⁸⁶ A remarkable feature of this study is that the cluster structure corresponds to the RLA rather than DLA regime. This indicates the existence of an energy barrier, which precludes aggregation of clusters. The barrier is high enough to provide conditions for transition from the DLA (a common situation for clusters on solid substrates) to RLA regime at small surface diffusion coefficients.

Clusters with fractal structures were produced by pulsed laser deposition of gold vapours on substrate (highly oriented pyrolytic

graphite).²⁸⁷ The possibility of formation of fractal aggregates in similar experiments with a NaCl substrate was suggested earlier.²⁸⁸ The fractal dimension depended on the radiation intensity and on the length of the pulse train. An original model for the formation of fractal clusters was proposed. It is based on consideration of the motion of adatoms across the substrate surface. The model was transformed to the equations corresponding to the formation of Julia sets.¹¹¹ It correctly reproduced value of the fractal dimension of aggregates.

The subjects of studies^{289–294} were various theoretical models for growth of fractal aggregates from particles deposited on solid substrates. The models included the surface diffusion of adatoms²⁸⁹ and clusters²⁹⁰ as well as rotation of clusters²⁹¹ assuming deposition of both monodisperse particles and particles of different size^{292,293} and shape.²⁹⁴ Analysis of aggregation on solid substrates also revealed that the fractal dimension is related to the degree of surface coverage as follows

$$d_f = 1.455 + 1.322 \varphi.$$

Experimental studies in this field^{295–299} were concerned with the deposition of metal vapours on the surface of substances with well-developed crystal structure^{295,296} and on the surface of oil²⁹⁷ and glass.²⁹⁸ Deposition of mesoscopic particles on a solid substrate was reported.²⁹⁹

The fractal structures are formed on the surface not only on deposition of vapours or particles but also in surface chemical reactions. This was observed in the Dy–Co system (see Ref. 300) under the action of a beam in an electron microscope and on the surface of liquid gallium.³⁰¹ The formation of iron oxide clusters of size up to several millimetres on the surface of amorphous iron films several tens of nanometres thick was reported.³⁰² In all experiments, the cluster structures were identical to the structure of the particles grown in the DLA regime. The results of recent search for fractal structures on the surfaces of specially treated polymer films are available.^{303,304}

VII. Viscous fingering

Penetration of fluids into porous solids also produces fractal structures.¹³ Fluid flow in porous media is accompanied by the so-called viscous fingering, *i.e.*, formation of a specific kind of prominence at the interface. Viscous fingering is due to the instability of the propagating interface and usually occurs when the more viscous fluid is displaced from the porous media by the less viscous fluid. The fractal dimension of viscous fingers is determined using the following relationship

$$N_v = k_v R_g^{d_f}, \quad (52)$$

where N_v is the number of pores filled with the more viscous fluid, k_v is the corresponding prefactor and R_g is the radius of gyration of the liquid cluster. Studies on the mechanisms of viscous fingering and formation of related structures have been well documented.^{305,306}

Viscous fingering is most often analysed taking immiscible fluids¹³ and — much more rarely — partially miscible fluids³⁰⁷ as examples. This phenomenon can also occur when dispersions are displaced by neat solvents, because the former liquids are always more viscous than the latter.

The so-called Hele–Shaw flow, or displacement of a viscous fluid from the space confined between two transparent flat plates, is often considered as a model for flow in a porous medium. Transparency of the plates allows the propagation of the interface to be monitored.³⁰⁸ A complete analogy between the development of instabilities of the Hele–Shaw flow and the growth of dendritic structures was established.^{306,309} Stability studies of the Hele–Shaw flow are of great practical value, because the development of instabilities precludes a number of important technological processes related to, *e.g.*, oil displacement from pools. For this reason, attempts to suppress the development of instabilities are under-

taken. Studies on the flow of three immiscible fluids in the Hele–Shaw cell³¹⁰ and on the flow stability considerations in the presence of highly dispersed particles in the displacing fluid³¹¹ showed that under particular conditions it is possible to suppress the development of instabilities in different stages of flow.

There is an analogy between the flow in porous solids and fractal aggregation. In particular, the DLA model and the flow in porous solids are described by identical equations.^{13,312,313} However, this analogy does not necessarily hold. The laws of formation of the viscous interface in the case of porous solids characterised by a broad pore size distribution are significantly different from the laws of clustering under the DLA conditions.³¹⁴

The influence of inhomogeneities in the porous medium on the regularities of the growth of viscous fingers has been studied assuming a Gaussian distribution of the permeability of the porous medium centred at the mean value.³¹⁵ The fractal structure of viscous fingers was not determined. The authors calculated the width of the mixing interface between two fluids for different dispersions of the permeability (see also Section VIII). According to calculations, the width of the interface increases linearly with time.

Viscous fingering related to flow in fractal structures was studied.³¹⁶ This is the case of flow in, *e.g.*, porous media near the percolation threshold (at a small fraction of through pores). Clearly, in this case the fractal system of viscous fingers will also be governed by the structure of the percolation cluster of the porous solid. More sophisticated models for viscous fingering in porous media require the use of the multifractal approach to describe the media³¹⁷ or the self-affine geometry for the pore space.³¹⁸

Viscous fingering accompanied by polymerisation at the interface was simulated.³¹⁹ It was shown that three situations are possible depending on the capillary number

$$N_{Ca} = \frac{\eta v}{\gamma},$$

where η is the viscosity of the displacing fluid, v is the average interface propagation velocity and γ is the interfacial tension. Within some range, the reaction rate affects the interface propagation velocity; at lower reaction rates beyond the range mentioned above, the reaction has virtually no effect on the interface propagation. At higher rates (above the upper bound of the range), the interface propagation slows down. The smaller the capillary number, the wider the range of reaction rates affecting interface propagation.

The theoretical studies considered above were carried out using mainly two-dimensional models of porous media. Numerical solution to the three-dimensional hydrodynamics equations describing viscous fingering in the case of partially miscible fluids was also reported.³²⁰ It was shown that screening, spillover and coalescence of viscous fingers occur at all Peclet numbers in the range studied. At large Peclet numbers, splitting of viscous fingers occurs, similarly to two-dimensional systems. Broadening of the interface at long time scales occurs at a constant velocity, which is independent of the Peclet number. If flow occurs in the regime corresponding to rare splitting of viscous fingers, their number monotonically decreases with time. The authors pointed out that the solution obtained for the two-dimensional model by and large correctly includes peculiar features of the development of the process in three-dimensional systems.

A related study³²¹ dealt with the effect of kinetic fluctuations on the propagation of the interface between immiscible fluids. According to calculations, the width of the interface remains constant for three-dimensional systems. For the two-dimensional model of a porous medium, the interface width logarithmically increases with time.

A more complex process, namely, displacement of a viscous fluid from the porous body by the medium that can react with the body (dissolve it) was also studied.^{322,323} It was found that the

structure of the liquid–liquid interface is similar to the interface structure formed in the DLA regime. The results of simulation of the structure of a soluble porous solid were confirmed experimentally. This problem was also solved analytically³²⁴ in the asymptotic limit using the renormalisation group method. This system is characterised by the existence of two limiting regimes. Under these conditions, the interface structure corresponds to the structure of the DLA-grown clusters and it is possible to observe a successive transition from the interface with the structure of the DLA-grown clusters to a rather smooth interface and then again to the interface with the structure of the DLA-grown cluster.

Studies of the boundary effects on the structure of viscous fingers⁶⁸ revealed that the fractal dimension of viscous fingers in retarded flow is much smaller than in the three-dimensional system. As the bounding surfaces move away, the fractal dimension logarithmically approaches its bulk value.

Fractal structures are also formed when nonwetting fluids displace wetting fluids from porous solids. In particular, this is the case for the conventional mercury porosimetry technique.³²⁵ Simulation is usually carried out using a particular (prescribed) structure of pores and pore necks, which permits the fractal dimension of the growing structures to be varied over a rather wide range. Usually, the entire percolation cluster of the invaded fluid, its branches and the ‘backbone’, which is obtained by cutting the branches off, are considered.^{326–330} The structure of the porous solid has a strong effect not only on the fractal characteristics of different clusters but also on their structure.³²⁹ This holds for the systems both with and without trapping of the displaced fluid.

Viscous fingering was observed during the wetting/dewetting process of a solid surface.³³¹ In the experiments, a droplet of SnPb eutectic alloy at first spilled over an Au/Cu/Cr multilayered film. This droplet etched the Au/Cu films, which was followed by contraction of the droplet, because the chromium substrate was not wetted with the alloy. It was found that contraction of the droplet was accompanied by the formation of fractal structures similar to viscous fingers. At different stages of contraction, fractal structures with different structures were formed. At first, the fractal structure exhibited a DLA pattern, while the final structure was a dendrite-like one. The fractal dimensions of these structures were 1.83 and 1.79, respectively.

The problem of the flow of a fluid along the grain boundaries³³² is similar to the viscous fingering problem. The grain boundaries wetted with the fluid form a fractal cluster, which allows percolation transitions to be observed similarly to the case of fluid invasion into porous media.

VIII. Fractal films

1. Simulation

Recently, considerable attention has been given to the studies of vapour deposition of films.³³³ This is due to two reasons. On the one hand, vapour-deposited metal and semiconductor films are used in various microelectronic devices. On the other hand, development of scanning electron and atomic force microscopies has opened up new prospects for research on the properties of films and on the mechanisms of their growth.

Vapour phase deposition of films is usually accompanied by the formation of granular structures (protrusions of different height and width). Here, significant roles are played by the thermodynamics and kinetics of film growth. Thermodynamics predetermines the growth pattern (layer-by-layer or island-type) of the newly formed structure, while the kinetics prescribes the rates of nucleation and growth of islands (*via* parameters of the surface diffusion of atoms). The formation of a continuous surface layer is followed by the growth of films with rough surface, the roughness being more pronounced with time. This is due to the fact that protrusions ‘mask’ depressions, thus making them less accessible to filling. This mechanism of development of rough surfaces is realised in combination with the smoothing mecha-

nisms of film surfaces, among which the most important is surface diffusion.

Growth of vapour-deposited films is usually described using the ballistic model,³³⁴ according to which particles moving towards the surface follow random trajectories. The surfaces growing by this mechanism possess fractal properties. As mentioned above, fractals can be self-similar or self-affine. Rough surfaces are treated as self-affine objects.

The fractal dimensions of the growing films are usually determined from the dependence of the surface ‘thickness’ on the lateral size of the portion L rather than the fractal dimension of the profile. The surface thickness is calculated as the root-mean-square deviation of the profile over the length L

$$w(L) = \sqrt{\frac{1}{N_L} \sum_{j=1}^{N_L} [h_{ij} - \langle h_f(L) \rangle]^2}, \quad (53)$$

where N_L is the number of points of the profile of length L , h_{ij} is the height at the point j , and $\langle h_f(L) \rangle$ is the average height of profile of length L . Since the height h_f is a function of time, the surface thickness $w(L, t)$ also appears to be time dependent. For self-affine surfaces, $w(L, t)$ changes with increasing L as follows

$$w(L, t) \propto L^\alpha,$$

where α is the roughness exponent. For fractal surfaces, the roughness exponent is related to the fractal dimension

$$d_f = d' + 1 - \alpha,$$

where d' is the dimension of the interface (for non-fractal surfaces, $d' = 2$).

Using the ballistic model³³⁵ and Eden model³³⁶ for particle deposition on the substrate, it was established that the surface thickness is described by a universal (scaling) distribution

$$w(h_f) \sim L^\alpha f\left(\frac{h_f}{L^{\alpha/\beta}}\right), \quad (54)$$

where h is the average height of the layer deposited on the substrate, L is the width of the growing stripe (column in the case of three dimensions) and the function $f(x)$ meets the following conditions

$$f(x) = \begin{cases} x^\beta, & x \ll 1 \\ \text{const}, & x \gg 1 \end{cases}. \quad (55)$$

The parameters in relationship (54) are as follows: $\alpha = 1/2$ and $\beta = 1/3$ for two-dimensional systems and $\alpha = 1/3$ and $\beta = 1/4$ for three-dimensional systems. In the case of the ballistic mechanism, the deposit is a homogeneous medium while the layer deposited has a self-affine ‘surface’ with fractal structure.

Relationships (54) and (55) were verified for various models³³⁷ including those for ‘tree-like’ film growth (Fig. 14). Some additional scaling relationships for the tree height, h_f , tree width, w , and for the number, N_s , of trees of size s (s is the number of particles in the tree) were established. They are as follows

$$w \sim s^{v_1}, \quad (56)$$

$$h_f \sim s^{v_2},$$

$$N_s \sim s^{-\tau},$$

where the exponents are interrelated

$$(d-1)v_1 + v_2 = 1, \quad (57)$$

$$\tau = 2 - v_2,$$

and weakly depend on the deposition model employed.

When analysing the dynamics of film growth, relationship (54) can be re-written in the more general form

Figure 14. Structure of fractal aggregates formed upon deposition of particles on substrates. As can be seen, the number of 'trees' grown on the surface sequentially decreases (one 'tree' is shown in black).

$$w(t) \sim t^{\alpha} f\left(\frac{t}{L^{\alpha/\beta}}\right), \quad (58)$$

where t is time.

Various equations were proposed for analytical description of the film growth during vapour and particle deposition on the substrate. Consider the most important of them.

The simplest model was proposed by Edwards and Wilkinson.³³⁸ Here, the height of the surface is determined from the equation

$$\frac{dh_f}{dt} = v\nabla^2 h_f + \chi(x, t), \quad (59)$$

where $\chi(x, t)$ denotes the fluctuation (noise) contribution of the surface; $\chi(x, t)$ meets the following conditions

$$\langle \chi(x, t) \rangle = 0, \quad (60)$$

$$\langle \chi(x, t) \chi(x', t') \rangle = R \delta(x - x') \delta(t - t'),$$

where the angle brackets denote the averaging over the random variable χ , R is root-mean-square fluctuation of 'noise'.

This model describes smoothing of the surface by the capillary forces governed by the parameter v . The model can also be used to describe the propagation of an interface through a disordered medium and to study how the interface spreads out with time.³³⁹

The parameters of the model are as follows: $\alpha = (3-d)/2$ and $\beta = (3-d)/4$ for a one-dimensional substrate and $\alpha = 1/2$ and $\beta = 1/4$ for a two-dimensional substrate; the width of the surface logarithmically increases with time; for substrates of greater dimensions, the surface of the growing film is considered smooth.

This model was employed³⁴⁰ in calculations of interface growth on a fractal substrate characterised by the dimension d_s . The surface width exhibits the asymptotic behaviour given by expressions (54) and (55) with the parameter β

$$\beta = \begin{cases} \frac{1}{4}, & d' = 1 \\ \frac{1}{4} - \frac{d_s}{4}, & 1 < d_s < 2, \end{cases} \quad (61)$$

where d' is the substrate dimension.

A similar expression was obtained for the parameter α ³⁴¹

$$\alpha = \begin{cases} \frac{1}{2}, & d' = 1 \\ d_f \left(\frac{1}{d_s} - \frac{1}{2} \right), & 1 < d_s < 2. \end{cases} \quad (62)$$

The Edwards–Wilkinson model correctly reproduces the structure of surfaces grown by sedimentation of spherical particles.³⁴² Experiments were carried out with particles of size 440 nm in aqueous solutions. The profile of the sediment surface was determined using an atomic force microscope.

Trapping of polystyrene latex particles of size 0.8 μm at the meniscus of a thin film was studied in experiments on a deposition on a 'one-dimensional' substrate.³⁴³ It was found that $\beta = 0.267$, while the parameter α varied from 0.5 in the initial stage of the 'surface' growth to 0.71 a long time after the beginning of the process. The crossover of the regimes of the surface growth was explained by kinetic reasons. Initially, the 'deposit' moves with the meniscus and particles are deposited ballistically. Then, the deposit slows down and deposition due to Brownian-type particle diffusion is observed.

Kardar, Parisi and Zhang³⁴⁴ proposed a more sophisticated model for film growth, which is described by the following equation

$$\frac{dh_f}{dt} = v\nabla^2 h_f + \frac{\lambda}{2} (\nabla h_f)^2 + \chi(x, t), \quad (63)$$

here λ is the parameter of a model.

The additional term [cf. Eqn (59)] accounts for smoothing of the surface by lateral growth of protrusions. In the case of two dimensions, this model gives the parameters $\alpha = 1/2$ and $\beta = 1/3$, which exactly fulfils the relationship predicted³⁴⁵ for Eqn (63)

$$\alpha + \frac{\alpha}{\beta} = 2.$$

A comprehensive examination of Eqn (63) was reported.^{346,347} The parameters of Eqn (63) were related to the coefficients determining the asymptotic behaviour of the surface width at long time and long length scales

$$w(\infty, t) = C_t t^{1/3}, \quad (64)$$

$$w(L, \infty) = C_L L^{1/2},$$

The possibility of deriving a single-parameter (λ) universal relationship for the coefficients C_t , C_L was shown. Analogous analysis of the model for epitaxial film growth³⁴⁸ is described by the following equation

$$\frac{dh_f}{dt} = -v\nabla^4 h_f + \lambda \nabla^2 (|\nabla h_f|)^2 + \chi(x, t); \quad (65)$$

the model gives the parameters $\alpha = (5-d)/3$ and $\beta = (7+d)/3$ and is consistent with the results of numerical simulation of film deposition at the atomic level.

Various analytical models for film growth and interface propagation were proposed^{349–355} to generalise the models considered above. The model by Kardar–Parisi–Zhang was extended³⁵⁶ to the case for radial growth of spherical surfaces. The surface width is a complex function of time and exhibits a power dependence on a rather long time scale, the parameter β being equal to 1/3. Numerical simulation of the co-deposition of films was carried out³⁵⁷ with inclusion of the interactions between nearest neighbours and more distant particles and different probabilities of the deposition of the particles of a specified type at a given instant. It was shown that the parameters α and β depend on this probability, thus exhibiting a marked deviation from the dependence predicted by Eqn (63).

New models for particle deposition on substrates resulting in the formation of fractal surfaces have also been developed. In particular, an original model was proposed,³⁵⁸ which accounts for hierarchical deposition of debris during particle deposition from the atmosphere (particles reach the surface in order of size, largest first). Both regular and stochastic models for particle deposition on substrates were considered. Numerical simulation revealed that, in contrast to deposition of particles of the same size, in this

model the contour length (or surface area) increase logarithmically rather than obeying the power law as the length scale changes. For instance, the length of a line on the surface increases on decreasing the characteristic probe size δ as follows:

$$L(\delta) = \left(1 + A \ln \frac{1}{\delta}\right) L(1),$$

where A is a constant.

2. Experiments

Experimental studies on the interface growth were carried out using various systems.³⁵¹ The physical meaning of the equations considered above corresponds to the molecular beam epitaxy experiments. Deposition of gold,^{359–362} silver^{359,363} and iron^{359,364–366} films on various substrates was studied. A rather wide scatter of α values was obtained, which is apparently due to the use of different methods of determination of surface roughness. However, the scatter of β values is much smaller compared to that of α values. At the same time, in most cases the results of calculations and experimental data are in good agreement. This can be exemplified by the results of a study³⁶⁷ concerned with the analysis of the evolution of the surface of gold films deposited using the thermal evaporation technique. The characteristics of the surface were determined using scanning tunnelling microscopy; the experimental data were processed using Fourier analysis, which allowed the so-called power spectrum, $S_m(q, t)$, of the protrusion heights to be calculated. It was found that the surface width depends on time as $t^{0.25}$ and the power spectrum

$$S_m \sim q^{-4.1},$$

the parameter α being equal to nearly unity.

The dynamics of the interface growth was studied not only in the film deposition experiments but also in the experiments on paper imbibition,^{368–370} combustion³⁷¹ and tear.³⁷² The experimental results were described by the power dependences (54)–(58) but the values of the exponents differed from those predicted by theoretical models; the numerical values of the exponents obtained in different experiments were also different (for instance, paper imbibition experiments gave close values of the parameters α and β). Yet another feature of the experimental data is the crossover of the growth regimes of the interface width, which manifested itself as a change in the exponents α and β on increasing the time and length scales. No unambiguous explanation for this phenomenon has been reported as yet. It should be noted that some theoretical models include the possibility of changing the interface growth regime (see, e.g., Ref. 350). This change can be due to large-scale fluctuations of the growth direction in the active zone. However, the available models for growth of self-affine surfaces cannot correctly describe this crossover.³⁵⁰ Numerical experiments³⁷³ on epitaxial growth of the surface with inclusion of surface diffusion without desorption of adatoms revealed two growth regimes of the interface width. The regime found for short time scales was changed to that described by the Kardar–Parisi–Zhang equation over a long time scale. The new growth regime at short times is due to the inclusion of surface diffusion and is not observed if diffusion processes are ignored.

The establishment of different growth regimes is a complicated task because modification of models does not necessarily lead to crossover. In this connection, a representative example is provided by the study³⁷⁴ on a modified Eden model in which the growth process began after contact with ‘acceleration sites’, which were spatially distributed at random. The ‘acceleration site’ became an Eden cell immediately after contact with the surface of the growing film. The model revealed a percolation transition, i.e., the existence of some critical concentration of ‘acceleration sites’ corresponding to divergence of the growth rate of the surface area. However, no crossover of the growth regimes was found, even for this, basically modified, model. Moreover, the value of

the exponent α remained constant (0.5) over a wide range of ‘acceleration site’ concentrations.

The problem of etching of metallic surfaces is closely related to the problems considered above. It was reported³⁷⁵ that the perimeters of pits etched in thin aluminium films in NaCl solutions have a fractal structure and that the ‘roughness’ of the perimeter developed only at particular values of the potential applied. Detailed analysis of the corrosion pit profiles (corroded surface of stainless steel rods)³⁷⁶ revealed two different length scales (textural and structural) with different fractal dimensions (1.17 and 1.45, respectively). Further studies confirmed the existence of two characteristic length scales for the corrosion pit profiles in steel rods and aluminium sheets. Two fractal dimensions were also reported³⁷⁷ in a study of corrosion of vapour-deposited nanoscale Al films; the larger fractal dimension corresponded to the longer length scale. It was shown that the pit morphology can be varied over a rather wide range by varying the concentrations of iron and chloride ions in solution.³⁷⁷ Transition from a smooth to rough interface under particular regimes of corrosion is also possible.³⁷⁸ Corrosion of quasi-two-dimensional thin Al films was studied.³⁷⁹ Both model and numerical experiments were carried out. Model experiments were carried out using Al films 50 μm thick with etched end faces. Numerical simulation was performed with inclusion of higher electrolyte concentration in the pit during corrosion. The pit perimeter was characterised by one fractal dimension, which to some extent varied depending on the procedure employed for its determination. The results of the model and numerical experiments were found to be in good agreement.

Numerical (Monte Carlo) simulation of dissolution of a solid was carried out³⁸⁰ taking the case for the dissolution rate controlled by surface reactions as an example. It was shown that the predominance of stochastic lateral dissolution causes broadening of the interface; the parameters of Eqn (58) were found to be $\alpha = 1/3$ and $\beta = 1/4$. The inclusion of surface diffusion of atoms led to an increase in the α value to unity (β value remained unchanged) in the early stages and to transition to unstable interface in the later stages (β value increased from 0.25 to greater than 0.5). The inclusion of nonlocal effects caused an even greater increase in the parameter β .

* * *

In this review we considered the most important characteristics of fractal objects and the main types of fractal structures which can be found in disperse systems. The material presented gives an idea of the diversity of fractal objects and parameters that are necessary to completely characterise them. The large number of parameters reflects the variety of specific properties of fractal structures, which do or do not manifest themselves depending on external conditions. An attempt to present a comprehensive analysis of the properties of even those fractal structures considered in this review could lead to a considerable increase in the size of the text. Because of this, experimental methods for the determination of the fractal characteristics and physicochemical properties of fractal objects will be described separately.

Abstract. Chemical aspects of the formation of microcomposites based on superconducting cuprates are considered. The materials are composed of a superconducting ceramic matrix and micro- or nanoinclusions of the non-superconducting phase, which are uniformly distributed in the matrix. Requirements on the operating characteristics of the superconducting ceramics are described and routes to high critical current densities are outlined. Phase equilibria in the generic systems are considered. Physical and chemical criteria for the choice of phases that can form non-superconducting inclusions are proposed. Methods of preparation and the microstructures and superconducting properties of the composites based on cuprates $\text{RBa}_2\text{Cu}_3\text{O}_{7-\delta}$ (R is the rare-earth element) and on $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ and $(\text{Bi,Pb})_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10+\delta}$ are considered. The bibliography includes 247 references.

I. Introduction

Progress towards preparation and investigation of functional inorganic materials is closely related to complexity of the chemical composition and structure of systems in different levels of a material's organisation. On the atomic scale, advances are due to the preparation of multicomponent chemical compounds and to passage from simple to more complex crystal structures. For the nano- and micrometre-sized systems, the determining factor is an optimum organisation of domains, crystallites and ensembles of microscopic structural defects. The range of values of the operating parameters can be considerably extended by using multiphase composite materials. Some examples of the efficiency of such materials are provided by fabrication of magnets with high coercive force, intermetallide superconductors with high critical current densities, high-strength and heat-resistant ceramics

obtained by eutectic crystallisation, nanocomposites possessing specific optical properties, chemical sensors, *etc.*

Considerable advances in studies on superconductivity have been achieved in the last fifteen years. The discovery of high-temperature superconductivity in oxide ceramics by Bednorz and Müller¹ gave an impetus to expansion of the area of search for novel, chemically complex ceramic superconductors. A number of promising compounds were found, whose superconducting transition temperatures (T_c) much exceeded the boiling temperature of liquid nitrogen. However, the route to practical use of these compounds appeared to be rather long. Severe problems arose due to low efficiency of the magnetic flux pinning, weak intergranular contacts in the polycrystalline materials, brittleness and low mechanical strength of ceramics and the rather narrow range of external conditions for the formation of the superconducting phases.^{2–4} These difficulties can be to some extent resolved by carrying out international research collaboration. In particular, considerable progress has been achieved towards fabrication of silver-sheathed tapes and wires based on Bi-containing cuprates,^{5,6} $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ tapes on bitextured metallic substrates,⁷ thin epitaxial films of various high-temperature superconductors (HTSC),^{8,9} bulk $\text{RBa}_2\text{Cu}_3\text{O}_{7-\delta}$ (R is the rare-earth element) ceramics¹⁰ and $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ rods.¹¹ Advances in development of graphotexturing techniques are also encouraging.¹²

In this review we analyse the currently available results of the studies on the synthesis of microcomposites based on superconducting cuprates containing highly dispersed inclusions of different phases. The significant role of such microcomposites in the development of materials science makes research in this field topical.

II. The problem of design of superconducting materials with high critical current densities

The most important operating characteristic of a superconducting material is the critical current density (J_c). Being considered as a function of the temperature and magnetic field, the J_c value characterises the maximum electric current which can flow through the conductor without energy loss.² The theoretical limit for the superconducting current density in HTSC is $\sim 10^8 \text{ A cm}^{-2}$; this value is due to kinetic energy induced unpairing of charge carriers (electron pairs).¹⁰ In real materials, the J_c values are much smaller. This is due to the fact that the critical current density depends on the force and energy of pinning of the

magnetic vortices present in the superconductor in a nonzero magnetic field and on the intergranular electric contacts in ceramics. Weak pinning in HTSC causes a rapid decrease in the critical current density with increasing magnetic field strength and on raising the temperature. Breakdown of intergranular electric contacts is responsible for the presence of weak Josephson junctions and for the low J_c , which dramatically decreases as the magnetic field increases. Therefore, the design of a material with high J_c requires efficient pinning of magnetic vortices and strong intergranular contacts. Besides, the material should possess a sufficiently high mechanical strength. To this end, the materials are prepared in the form of tapes and wires with a silver alloy core,^{5,6} films on single-crystalline oxide and metallic substrates^{7–9} and bulk composites.^{11,13} Intercrystalline contacts can be improved by forming pure grain boundaries containing no impurity phases and by texturing of ceramics (after, *e.g.*, deposition of epitaxial films or thermomechanical treatment).

The magnetic vortices are pinned to inhomogeneities, such as both point and extended lattice defects and inclusions of alien phases (Fig. 1). Enhancement of pinning can be achieved by forming a material containing micrometre- and nanometre-sized inhomogeneities.

Figure 1. Illustration of pinning of magnetic vortices to non-superconducting inclusions.

The vortex energy decreases if its normal core (with destroyed superconductivity) passes through the non-superconducting inclusion. The vortex is pinned to such inclusions, so that its depinning and displacement require some force (pinning force) to be applied. Depinning and displacement of the vortex are accompanied by loss of energy in the superconductor;

ξ is the coherence length of the Cooper pairs.

According to calculations, the greatest pinning force can be attained if the dielectric inclusions or defects are of the order of the coherence length, ξ , of the Cooper pair^{2,14} (in most cases, several nanometres). In addition, the pinning force is expected to increase on increasing the concentration and, correspondingly, the volume fraction of inclusions up to 40 vol.% in the superconductor matrix.¹⁴ At higher concentration of inclusions, J_c decreases due to a marked decrease in the matrix cross-section area. For HTSC, the maximum J_c value due to a finite value of pinning energy is 10^7 A cm^{-2} .

One to several vortices can be pinned to large inclusions.¹⁵ According to calculations, in this case the pinning force is proportional to the total surface area of the inclusion–matrix interface; inclusions of size about $1 \mu\text{m}$ can provide the critical current densities lying between 10^4 and 10^5 A cm^{-2} .

The pinning centres in a superconducting material can be created using different approaches. The three main methods are as follows:

(1) exposure to accelerated particles and heavy ions, resulting in the appearance of amorphised domains and channels (of size of several nanometres) with destroyed superconductivity;^{16–19}

(2) heat treatment and mechanical treatment, which cause an increase in the density of the lattice defects or result in the formation of a fine-grained material with high concentration of grain boundaries (defects);^{20–25}

(3) introduction of micro- and nanoinclusions of the alien non-superconducting phases or creation of nanoscale inhomogeneities differing in the chemical composition and properties from the matrix phase.^{15,26}

The first method is highly efficient but is mainly applicable to small samples of thickness at most several tens of micrometres. It is often used in studies of the pinning mechanism.²⁷

Enhancement of pinning due to heat treatment and mechanical treatment can be exemplified by the formation of a fine-grained material based on Nb_3Sn (Ref. 20) and epitaxial HTSC films less than $1 \mu\text{m}$ thick. The maximum critical current densities for such films reach nearly 10^5 – 10^6 A cm^{-2} at 77 K, which can be explained by high concentration of dislocations at small-angle boundaries of submicrometre-sized domains.^{21–23} Similar results were also obtained in the experiments on creation of high concentrations of dislocations by mechanical treatment of HTSC.^{24,25}

The third method of pinning enhancement is of prime importance for bulk and long samples. It appeared to be rather promising for engineering of metallic superconductors based on Nb–Ti alloy.¹⁴ Using heat treatment and mechanical treatment (drawing), it is possible to prepare materials with controllable sizes of the second phase inclusions (Ti, Nb, Cu, V, Ni). The size of inclusions varies from several to tens of nanometres and the J_c value can be as high as $4.5 \times 10^5 \text{ A cm}^{-2}$ at a field of 5 T at $T = 4.2 \text{ K}$.¹⁴ Melt processing was used to obtain bulk samples of $\text{RBa}_2\text{Cu}_3\text{O}_{7-\delta}$ ceramics containing microinclusions of R_2BaCuO_5 phases (R is the rare-earth element). The critical current densities for such ceramics reach several tens of kiloamperes per square centimetre at 77 K.^{15,26} Considerable attention has been given to the formation of inclusions in bismuth-containing cuprates, for which the pinning of magnetic vortices is a challenge.^{28,29} Sometimes the critical current density can be increased by creating micro- and nanoinclusions of phases of the generic chemical system (*i.e.*, the system to which a particular superconducting complex oxide belongs) and the phases containing additional chemical elements (dopants). This effect is most pronounced at elevated temperatures ($> 20 \text{ K}$).

Thus, materials with high operating parameters should be composites. Taking into account the necessity of structuring the materials at micro- and nanolevels, we will call them microcomposites.

III. Main methods of preparation of microcomposites

Methodologically, the design of microcomposites is based on the principle of complication of the phase composition of the system,³⁰ according to which the material must be at least a two-phase system, in which the non-superconducting phase is uniformly distributed in the superconducting matrix in the form of micro- or nanoinclusions. These phases should be to the greatest extent chemically inert towards each other, while the entire system should be highly stable towards recrystallisation and segregation of the inclusion phase.

The chemical inertness of the phases in a composite is best achieved when using thermodynamically compatible components, which are in equilibrium at such values of the external parameters (temperature and the partial pressure of oxygen) that correspond to the conditions for the synthesis of the composite or to the operating conditions. Of course, this does not exclude the preparation of microcomposites containing incompatible phases; however, in these instances it is hard to prevent rather intense reactions between the constituents at high synthesis temperatures (850–1000 °C). This was confirmed by numerous observations of reactions between superconductors (and their melts) and the high-melting materials of crucibles and substrates.^{31–38} It should

be noted that inertness of different phases is of importance not only for microcomposites of the superconducting matrix–inclusion phase type but also for other types of materials, in which the superconducting phase immediately contacts some alien solid phases. This can be exemplified by substrate grown (deposited) films,^{7,9} composite wires of the ‘metal-sheathed superconductor’ type^{5,6} and reinforced superconducting composites.^{10,11} The problem of chemical inertness of phases in the composite is closely related to the problem of preparation of the so-called barrier materials, which prevent superconductors from being entered into chemical reactions with the environment during the synthesis and operation of microcomposites.^{31,38}

Sometimes, both the non-superconducting and superconducting phases of the microcomposite belong to the same chemical system, while the formation of the former phase is due to a shift of the system’s composition from the homogeneity region of the superconducting phase to the two-phase or multiphase region at particular values of external parameters. An alternative strategy involves the chemical complication of the system, *i.e.*, introduction of some extra components (chemical elements) to form the non-superconducting phase along with the components of the generic system. This technique has a greater potential for varying the system’s properties and, correspondingly, preparation of a material with the desired microstructure and operating characteristics.

Pinning centres (inclusions) can be created using different approaches (Fig. 2).

Figure 2. Scheme of the choice of system’s composition in the model phase diagram using the first (configurative point *A*) and second (configurative points *B*, *C*) methods of synthesis of microcomposites (see text).

The first method is to choose the chemical composition of the system in the two-phase or multi-phase region of the phase diagram at particular values of external parameters (temperature and partial pressure of oxygen) and to prepare the microcomposite material under these conditions (configurative point *A*).

The second approach involves the synthesis of the starting single-phase material followed by variation of the external parameters in such a way that the figurative point is in the instability region of the superconducting phase. The instability can mean either decomposition of the superconducting phase into non-superconducting phases ($C \rightarrow C_1$) or a change in the composition within the solid solution region without loss of superconductivity ($B \rightarrow B_1, B_2$).

Clearly, the first approach requires the decomposition to be stopped at some intermediate stage to retain the superconducting matrix. In the second case, the process can be carried out up to attainment of the phase equilibrium. A special type of decomposition is provided by separation of the starting superconducting phase into two solid solutions differing in chemical composition and, correspondingly, in the superconducting properties.³⁹ In this

case, structural similarity of the solid solutions allows a spinodal decomposition and formation of very small non-superconducting domains in the material.

Currently, the systems $R\text{--Ba--Cu--O}$ and $\text{Bi--(Pb)--Sr--Ca--Cu--O}$ are most practically valuable. They have been studied in most detail. Here, we will use them to illustrate some chemical problems concerning the design of superconducting microcomposites (see below).

IV. Phase relations in the existence regions of the superconductors $\text{RBa}_2\text{Cu}_3\text{O}_{7-\delta}$, $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ and $(\text{Bi,Pb})_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10+\delta}$

To carry out successful syntheses of ceramic superconducting composites, one should obtain critically important information on the phase relations in the corresponding chemical systems, on the stability regions of the superconducting phases, and on the dependence of the superconducting properties (usually, T_c) on the chemical composition.

The $R\text{--Ba--Cu--O}$ systems containing rare-earth elements of small radii ($R = \text{Y, Dy, Ho, Er, Tm, Yb}$) form stoichiometric (with respect to cations) phases $\text{RBa}_2\text{Cu}_3\text{O}_{7-\delta}$ (R123).^{39–41} The highest superconducting transition temperatures (90–93 K) correspond to some non-stoichiometry with respect to oxygen ($\delta \approx 0\text{--}0.1$), which is usually achieved by annealing at moderate temperatures in oxygen. The Y123 phase has been studied in most detail. In the subsolidus region of the phase diagram ($\sim 900^\circ\text{C}$) in air the Y123 phase is in equilibrium with BaCuO_2 (011), CuO and Y_2BaCuO_5 (211) (Fig. 3). Raising the temperature causes the appearance of melt in the $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}\text{--BaCuO}_2\text{--CuO}$ field. At $1010\text{--}1020^\circ\text{C}$, the Y123 phase undergoes incongruent decomposition into Y211 and melt and at temperatures above $1100\text{--}1200^\circ\text{C}$ the system consists of Y_2O_3 and melt (Fig. 4).⁴² At lower temperatures (below 900°C and elevated pressure of oxygen), two new superconducting phases, $\text{YBa}_2\text{Cu}_4\text{O}_8$ and $\text{Y}_2\text{Ba}_4\text{Cu}_7\text{O}_{14}$, are formed, while the Y123 phase becomes unstable.⁴⁰ Studies of systems containing other rare-earth elements of the yttrium subgroup showed that in the subsolidus region the R123 phases exist in the same compositional triangles ($\text{BaCuO}_2\text{--CuO--R}_2\text{BaCuO}_5$) as the Y123 phase.^{39–41}

The rare-earth elements with large ionic radii ($\text{La, Nd, Sm, Eu, Gd}$) form solid solutions of the type $\text{R}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ (123ss).^{39–41,43} Figure 5 presents the isothermal section of the phase diagram of the Nd--Ba--Cu--O system. The solid solution $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ ($x \approx 0$), which is characterised by the highest T_c , is in equilibrium with BaCuO_2 , CuO , $\text{Nd}_x\text{Ba}_{2-x}\text{CuO}_3$ and

Experiment (1) and calculations (2). Hereafter L stands for melt.

Figure 5. Phase relations in the subsolidus region of the $\text{NdO}_{1.5}$ –BaO–CuO system in air.⁴¹

$\text{Nd}_{4-2x}\text{Ba}_{2+2x}\text{Cu}_{2-x}\text{O}_{10-2x}$ (422). The last-mentioned phase is compositionally analogous to the Y_2BaCuO_5 phase but has another crystal structure.⁴⁴ The polythermal section of the phase diagram of $\text{NdO}_{1.5}$ –BaO–CuO is shown in Fig. 6. The homogeneity region of the $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ phase ($-0.1 < x \leq 1$ at 1000 °C) narrows as the temperature decreases; the process can be accompanied by separation of the solid solution.^{45–47} In the system with $\text{R} = \text{Pr}$ the non-superconducting oxide $\text{Pr}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ ($x \approx 0$) coexists with BaCuO_2 , CuO and PrBaO_3 (Fig. 7). No $\text{RBa}_2\text{Cu}_3\text{O}_z$ compounds are formed in the systems with $\text{R} = \text{Ce}$ and Tb .⁴⁰

The quinary(sextenary) system $\text{Bi}(\text{Pb})$ –Sr–Ca–Cu–O exhibits much more complex phase relations. A considerable body of contradictory data on both the exact phase compositions and the phase fields in this system is available.^{40,48} Figure 8 presents the compositional tetrahedron and its section for the quasi-quaternary system Bi_2O_3 –SrO–CaO–CuO.⁴⁹ It is of importance that the phase diagram exhibits extended regions of solid solutions for both the superconducting phases and the phases coexisting with them and that the superconducting transition temperature is strongly dependent on the cationic composition of the phases and on the oxygen content. The

Figure 7. Phase relations in the subsolidus region of the $\text{PrO}_{1.83}$ –BaO–CuO system in air.⁴¹

system contains three superconducting phases, namely, $\text{Bi}_{2+x}\text{Sr}_{2-x}\text{CuO}_{6+\delta}$ ($\text{Bi}2201$ or $\underline{119x5}$, $T_c \approx 20$ K), $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ ($\text{Bi}2212$, $T_c \approx 90$ K) and $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10+\delta}$ ($\text{Bi}2223$, $T_c \approx 110$ K), which are the first three representatives of the homologous series $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{6+2n+\delta}$. The second and third homologues are of practical value. In $\text{Bi}2223$, bismuth is, as a rule, partially replaced by lead.⁴⁹ The formation of the $\text{Bi}2223$ phase can also be significantly improved upon partial replacement of Bi by V, Nd, Ta (see Ref. 50) or Ga.⁵¹ It is more appropriate to write the formula for the second homologue ($n = 2$) as $\text{Bi}_{2+x}\text{Sr}_{2-x-y}\text{Ca}_{1+y-r}\text{Cu}_{2-r}\text{O}_{8+\delta}$.^{48,49,52–54} This compound is characterised by a relatively broad homogeneity region with respect to the strontium : calcium ratio (Fig. 9), which, according to different authors, can vary from 2.2 : 0.8 to 1.2 : 1.8.^{48,55,56} Strontium can be to some extent ($x \leq 0.2$) replaced by bismuth, while the content of copper can somewhat decrease due to the formation of stacking faults (sublayers of the first homologue). The third homologue has a narrower homogeneity region with respect to the strontium : calcium ratio (from 1.9 : 2.1 to 2 : 2); the content of bismuth (or bismuth and lead together) can exceed the stoichiometric value by $\sim 20\%$.⁴⁹

In air, the phase of the second homologue is stable from ~ 600 °C to the melting temperature (850 – 885 °C depending on the composition).^{48,57–63} The highest melting temperature refers to a composition similar to the stoichiometric composition

Figure 8. Phase relations in the Bi_2O_3 – SrO – CaO – CuO system in air at 850°C .⁴⁹

Compounds in the quaternary system (a) and the section of the compositional tetrahedron by the plane passing through the $(1/3)(2\text{SrO} + \text{CaO})$ – Bi_2O_3 – CuO points (b). The phases in the ternary and quaternary systems are denoted using their cationic compositions ($\text{Bi}:\text{Sr}:\text{Ca}:\text{Cu}$).

Bi2212. Melting and crystallisation processes play a significant role in the preparation of both bulk samples of HTSC (Ref. 64) and sheathed wires (tapes) possessing high critical current densities.⁶⁵ The melting diagram along the Bi2201 – Bi2223 compositional line is schematically shown in Fig. 10.

A great body of information on melting of the Bi2212 phase is available (see, e.g., Refs 48, 59, 63, 66–71). Often, the results obtained by different authors were essentially different. The most plausible order of processes is as follows. In air, Bi2212 undergoes peritectic decomposition into two oxides, $(\text{Sr,Ca})_{4-y}\text{Bi}_2\text{O}_z$ and $(\text{Sr,Ca})\text{CuO}_2$, and melt.^{66, 72, 73} This is accompanied by release of oxygen, which corresponds to reduction of the oxygen content.⁶³ Storage of the melt over a period of 1 h at a temperature which only slightly exceeds the melting temperature leads to crystallisation of yet another phase, Bi2201 .⁶⁷ Further increase in the temperature in the range 900 – 1000°C causes disappearance of the bismuth-containing phases and the following sequence of transformation of the cuprate phase^{66, 68, 72}

Figure 9. Homogeneity region of the Bi2212 phase for the $\text{Bi}_x\text{Sr}_{3-y}\text{Ca}_y\text{Cu}_2\text{O}_{8+\delta}$ composition in air at 800°C .⁴⁹

At temperatures above 1100°C the system consists of a melt only.^{66, 72}

The Bi2223 phase exists in the narrower temperature interval (840 – 890°C). Doping with lead shifts this temperature range towards lower temperatures.^{49, 52, 74} The extent of bismuth replacement by lead depends on the partial pressure of oxygen and can reach 30% for Bi2212 and 15%–18% for Bi2223 .^{48, 49, 52} In air, the $(\text{Bi,Pb})2223$ phase doped with lead oxide melts incongruently at temperatures above 870°C to give strontium–calcium cuprates of different compositions (the melting temperature reducing as the pressure of oxygen decreases).^{52, 75, 76}

Figure 10. Polythermal section of the phase diagram of the Bi_2O_3 – SrO – CaO – CuO system along the Bi2201 – Bi2223 line.⁴⁹

Cooling of the melt causes crystallisation of the second homologue as the major product. This significantly hampers the use of the melt technique in obtaining the third homologue, which is of the greatest interest.

In the temperature range 800–870 °C in air, the Bi2212 phase can be in equilibrium with CaO, CuO, (Sr,Ca)₁₄Cu₂₄O₄₁, Bi_{2.2}(Sr,Ca)_{1.8}CuO_{6+δ}, (Sr,Ca)_{1-δ}BiO_z, (Ca,Sr)₂CuO₃, (Sr,Ca)_{4-y}Bi₂O_z, Bi₄(Sr,Ca)₈Cu₅O_z, Bi₂Sr₂CuO₆, Bi2223 and melt.^{49,52,77–81} Other phases in this system were also found. These are (Sr,Ca)₃Bi₂O₆,⁴⁹ Sr₉Bi₁₁O_{25.5},⁷⁷ Ca_{0.86}Sr_{0.14}CuO₂,⁸⁰ (Sr,Ca)CuO₂ and (Sr,Ca)₆Bi₂O₁₁,⁸¹ which probably also coexist with the Bi2212 phase under particular conditions. Studies of the lead-doped system revealed^{82,83} that at 810–820 °C and $p_{O_2} = 0.075$ the (Bi,Pb)2223 phase is in equilibrium with CaO, CuO, (Bi,Pb)2212, (Sr,Ca)₁₄Cu₂₄O₄₁, (Ca,Sr)₂CuO₃, (Bi,Pb)_{2.2}(Sr,Ca)_{1.8}CuO_{6+δ}, (Bi,Pb)₂Sr₂CuO_{6-δ}, (Sr,Ca)_{4-y}.Bi₂O_z, (Sr,Ca)CuO₂, Ca_{0.86}Sr_{0.14}CuO₂, (Ca,Sr)₂PbO₄ and (Pb,Bi)₃Sr₂Ca₂CuO_z.

Thus, the generic (with respect to the superconducting phases) chemical systems contain a large number of thermodynamically compatible phases, which can be used as inclusions in the superconducting composites.

V. Microcomposites based on RBa₂Cu₃O_{7-δ}

The first method of preparation of composites can be well illustrated by taking the system RBa₂Cu₃O_{7-δ}–R₂BaCuO₅ as an example. Microcomposites are synthesised by crystallising the superconducting phase from a peritectic melt^{10,39} containing micrometre-sized particles of the R₂BaCuO₅ phase, which is partially consumed for the formation of the R123 phase in the reaction

while the remaining fraction of R₂BaCuO₅ forms inclusions in the superconducting matrix. Depending on the synthetic procedure and composition of the starting materials, the average size of the inclusion particles can vary from several fractions of a micrometre to tens of micrometres. The smallest inclusions are prepared by melting a mixture of RBa₂Cu₃O_{7-δ} with highly dispersed R₂BaCuO₅ and subsequent crystallisation of the melt.^{84,85} The R₂BaCuO₅ particles can be trapped with ease by the growing RBa₂Cu₃O_{7-δ} crystals, which leads to a uniform distribution of these particles in the material. However, sometimes (in the case of, e.g., doping with platinum) the distribution of Y₂BaCuO₅ particles over the volume of the Y123 crystal is nonuniform, which is described and explained using the pushing–trapping model.^{86–89}

Coarse-grained, textured composite samples obtained by the melt processing technique and containing 0.1–0.4 mole of R₂BaCuO₅ per mole of RBa₂Cu₃O_{7-δ} are characterised by the critical current densities of the order of 10⁴–10⁵ A cm⁻² at 77 K.^{10,15,90–93} Studies of the dependence of the pinning force (F_p) on the magnetic field (B)

$$F_p(B, T) = J_c(B, T) B$$

revealed a dominant role of the magnetic flux pinning by inclusions (or inclusion–matrix interface).^{94–96} However, the role of R₂BaCuO₅ is not restricted to the pinning effect, namely, the presence of the second phase favours a complete peritectic crystallisation of the superconducting phase.

Introduction of (micro)additives into the R–Ba–Cu–O system can lead to a further increase in J_c . In most cases, this approach results in R123–R₂BaCuO₅–alien phase composites. The efficiency of pinning can be due to the effects of both inclusion phases. Often, it is assumed that this parameter is mainly due to the dopant effect on the size of inclusions of the main non-superconducting phase R₂BaCuO₅. Doping with Pt(PtO₂), CeO₂ and SnO₂ (usually, of the order of a per cent) can cause a substantial increase in the degree of dispersion of the R₂BaCuO₅ phase.^{97–108} Introduction of platinum leads to a decrease in the

energy of the R₂BaCuO₅–liquid interface, thus facilitating nucleation and slowing down the growth of the R₂BaCuO₅ phase. The effect of the cerium and tin oxides is explained by heterogeneous nucleation of R₂BaCuO₅ on microinclusions of products of the reactions of these additives with the melt.⁹⁸

The platinum-doped system contains the following accompanying (and, possibly, thermodynamically compatible with Y123) phases: Ba₄CuPt₂O₉, Y₂Ba₃Cu₂PtO₁₀ and Y₂Ba₂CuPtO₈, which are more likely treated as undesired inclusions.^{100,109,110} Introduction of extra impurity (alumina) causes the formation of large (tens of micrometres in size) Ba₃YAl₂PtO_{9-δ} inclusions.¹¹¹ The addition of SnO₂ results in BaSnO₃,¹¹² YBa₂SnO_{5.5} (see Ref. 113) and YBa₃Sn_{2-x}Cu_xO_{9-δ}.^{101,114} The cubic double perovskite YBa₂SnO_{5.5} phase seems to be the most stable and introduction of platinum or cerium into the system causes the formation of solid solutions Y₂Ba₅(Sn_{3-y-x}Cu_yPt_x)₃O_z (see Ref. 115) and Ba₂(Y_{2/3-x}Cu_x)·(Ce,Sn)_{4/3}O_{6-δ}.¹⁰¹ Tin and platinum are insoluble in Y123, whereas cerium occupies some sites in the Y123 lattice.¹⁰¹

Particular emphasis should be placed on the doping of the Y123 system with oxides of ²³⁵U.^{116–118} In these cases, submicrometre-sized inclusions of the compositions Ba(U_{0.6}Y_{0.4})O₃ or Ba₂Y(U_{0.6}Pt_{0.4})O₈ (in the presence of platinum) are formed in the superconductor crystallites and the corresponding J_c values somewhat increase. Neutron irradiation causes fission of ²³⁵U nuclei and the appearance of numerous tracks in the superconductor matrix, which leads to a subsequent manifold increase in J_c due to the pinning of magnetic vortices to the new defects. This technique was used for preparation of a bulk material characterised by a record J_c value ($\approx 3 \times 10^5$ A cm⁻² at 77 K).¹¹⁷

Reactions of ceria, zirconia and hafnia with R123 result in stable phases (BaCeO₃, BaZrO₃ and BaHfO₃, respectively).^{101,112,119–121} In the case of melt growth of the superconducting phase, particles of these phases are pushed by the growing R123 crystal and segregated in the intercrystalline space, thus impeding the flow of the superconducting current between crystallites. These phases are inert and can therefore be used as barrier materials for crucibles, substrates and coatings in the synthesis of superconductors.^{122–124}

The estimates of thermodynamic parameters¹²³ indicated that the Y123 phase cannot be treated as being in equilibrium in the mixtures with TiO₂, ZrO₂, HfO₂ and CeO₂. This disequilibrium manifests itself in the chemical reaction, which proceeds on heat treatment of the mixture of the corresponding dioxide and Y123 and results in Y211, CuO and compounds of the starting dioxide with (mainly) barium oxide.

Among all metals, only silver is thermodynamically compatible with R123. In the presence of silver the melt crystallisation temperature of Y123 reduces down to 970 °C, while the overall process is described by a monotectic-peritectic reaction

where L1 is the BaO- and CuO-rich liquid and L2 is the Ag-rich liquid.¹²⁵ Crystallisation from oxide melt is accompanied by trapping of silver in the form of spherical or disk-like particles.^{125–128} The introduction of silver improves the mechanical strength of and precludes crack formation in the ceramics.

The second method of preparation of microcomposites is based on the decomposition of a solid solution in the R–Ba–Cu–O system. It can be exemplified by the synthesis of Nd_{1+x}Ba_{2-x}Cu₃O_z ceramics.^{39,129–133} Under particular heat treatment conditions (hypothetically, at a rather low temperature), a solid solution ($x \approx 0$) is separated into two solid phases. One phase is characterised by a high extent of replacement of neodymium by barium and low T_c while the other phase is characterised by a lower extent of replacement and higher T_c (> 90 K). The first phase forms nanometre-sized inclusions in the matrix of the second phase. A feature of such superconductors is the so-called peak effect (J_c first increases with an increase in the magnetic field and then decreases).¹³⁴ This effect is associated with

magnetic field induced destruction of superconductivity in nanodomains, which makes these domains efficient pinning centres at intermediate magnetic fields. The peak effect was also observed in $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ ($\delta > 0$);^{134, 135} however, it was treated as a consequence of phase separation accompanied by the appearance of nanodomains enriched with and depleted of oxygen and, correspondingly, characterised by different superconducting transition temperatures.

The dependence of the pinning force in $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z$ on the reduced magnetic field B/B_{ir} (B_{ir} is the irreversibility field induction) passes through a maximum at $B/B_{\text{ir}} = 0.4-0.5$, which indicates pinning of magnetic vortices to small regions with weakened superconductivity.^{95, 96, 136} For the composites $\text{R}\text{Ba}_2\text{Cu}_3\text{O}_{7-\delta}-\text{R}_2\text{BaCuO}_5$ ($\text{R} = \text{Y}, \text{Yb}$; see Ref. 94), the maximum value of the B/B_{ir} ratio is nearly halved and corresponds to dominant pinning at the interface between the superconducting matrix and inclusions of the second phase. As to the $\text{Nd}_{1+x}\text{Ba}_{2-x}\text{Cu}_3\text{O}_z-\text{Nd}_4\text{Ba}_2\text{Cu}_2\text{O}_{10}$ composite, both interface pinning and pinning to small regions with weakened superconductivity are possible.¹³⁷

Simultaneous introduction of several rare-earth elements into yttrium lattice sites is thought to have considerable promise. The $J_c(B)$ plots constructed for the superconductors $(\text{Nd}, \text{Eu}, \text{Gd})\text{Ba}_2\text{Cu}_3\text{O}_{7-\delta}$ and $(\text{Nd}, \text{Sm}, \text{Gd})\text{Ba}_2\text{Cu}_3\text{O}_{7-\delta}$ exhibit a pronounced peak effect, so that the maximum critical current density reaches a value of 10^5 A cm^{-2} at a magnetic field of about 2 T at 77 K.^{138, 139} It was established that the superconductor crystallites are characterised by fluctuations of the composition (variation of the rare-earth element : barium ratio) in the regions from several to tens of nanometres in diameter. The smaller the 'fluctuation' domain size, the more pronounced the peak effect in the materials. Besides, the character of the inclusion phase, R_2BaCuO_5 , also changes. Melting of $(\text{Nd}, \text{Sm}, \text{Gd})\text{Ba}_2\text{Cu}_3\text{O}_{7-\delta}$ is accompanied by redistribution of the rare-earth elements between the solid and liquid phases in such a way that the composition of the newly formed solid phase approaches $\text{Gd}_2\text{BaCuO}_5$. In the course of subsequent crystallisation the second phase of the composite $(\text{Nd}, \text{Sm}, \text{Gd})_2\text{BaCuO}_5$ first of all reacts with the melt. As a result, the end product contains a large number of small $\text{Gd}_2\text{BaCuO}_5$ inclusions, which are much smaller than the grain size of the second phase. Such a dispersion of the second phase causes an increase in the critical current density at zero magnetic field.

More than a twofold increase in J_c at 77 K was found in the large-domain composites $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}-\text{Y}_2\text{BaCuO}_5$ doped with microscopic amounts (hundredth fractions of a per cent) of zinc oxide.¹⁴⁰⁻¹⁴² It is assumed that the zinc ions replace copper in the crystal lattice and create nanoscale domains with destroyed superconductivity, which act as efficient pinning centres. This is indirectly confirmed by the shift of the maximum in the field dependence $F_p(B/B_{\text{ir}})$ from $B/B_{\text{ir}} = 0.31$ to 0.41 after relevant doping.

VI. Microcomposites based on phases of the Bi-(Pb)-Sr-Ca-Cu-O system

The system Bi-(Pb)-Sr-Ca-Cu-O is characterised by equilibrium between the superconducting phases and a large number of other phases and by extended regions of solid solutions for the superconducting phases. This allows a wider use of both methods of synthesis of composites (see Section III).

Cooling of a peritectic melt permits preparation of $\text{Bi}(\text{Pb})2212-\text{Ca}_2\text{CuO}_3$ (10 mol.%–15 mol.%) composites with the Ca_2CuO_3 inclusions (of size of several micrometres) uniformly distributed in the $\text{Bi}(\text{Pb})2212$ phase. These composites exhibit an increased (by several times) critical current density at $T \geq 20 \text{ K}$.^{143, 144} Magneto-optical studies revealed pinning of magnetic vortices to the Ca_2CuO_3 particles.¹⁴⁵ A considerable increase in J_c within grains of sintered $\text{Bi}2223-\text{Ca}_2\text{CuO}_3$ ceramics was also reported.¹⁴⁶ Single crystals of $\text{Bi}2212$ containing inclu-

sions of CuO (elongated particles 1 μm in diameter and 3–4 μm long) were obtained by melt-solution crystallisation from KCl .¹⁴⁷

Majewski *et al.*¹⁴⁸⁻¹⁵⁰ reported detailed phase diagram studies concerning the possibility of partial decomposition of the solid solution. If a solid solution of a particular composition is heat treated at a lower or, *vice versa*, a higher temperature, it loses homogeneity and submicrometre-sized inclusions of products are formed in the matrix of the starting compound. This approach was used for the synthesis of ceramic $\text{Bi}2212$ samples containing inclusions of the $\text{Bi}2201$, $\text{Sr}_3\text{Bi}_2\text{O}_6$, $\text{Sr}_{14}\text{Cu}_{24}\text{O}_{41}$ and Ca_2CuO_3 phases (see Refs 148 and 149) and of $\text{Bi}2223$ samples containing inclusions of the $\text{Bi}2212$, Ca_2CuO_3 and $(\text{Sr}, \text{Ca})\text{CuO}_2$ phases.¹⁵⁰ A scheme illustrating the trajectory of the figurative point in the phase diagram during heat treatment is shown in Fig. 11. The J_c value inside of the grains of the samples heat treated for a restricted time increases by three to six times at 30 K. Prolonged annealing causes coarsening of the inclusions and a decrease in the critical current density. It was shown¹⁵¹ that annealing of $\text{Bi}2212$ at 550 °C results in precipitation of smaller particles of size 0.02 to 0.1 μm and in greater nonuniformity of the distribution of the components in ceramics.

Figure 11. Section of the phase diagram of the Bi-Sr-Ca-Cu-O system along the $\text{Bi}_{2.18}\text{Sr}_{3-y}\text{Ca}_y\text{Cu}_2\text{O}_{8+\delta}$ composition.¹⁴⁹

Shown are the homogeneity regions of the $\text{Bi}2212$ (2212) phase and the trajectory of the figurative point of the system upon heat treatment (phase-forming annealing at 875 °C–low-temperature annealing at 700 °C).

Separation of the solid solution was found and studied in detail taking $\text{Bi}_{2-x}\text{Pb}_x\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ ($x > 0.4$) samples as examples.^{152, 153} Melt processed single crystals and coarse-grained ceramics exhibited the formation of submicrometre-sized domains (in the form of stripes or closed regions), which were both depleted of and rich with lead. Such samples are characterised by increased irreversibility fields and J_c .

A study on the decomposition of $\text{Bi}2212$ solid solutions characterised by partial replacement of calcium or strontium by rare-earth elements *via* annealing at a reduced temperature has been reported.¹⁵⁴ Precipitation of the second phases was observed

only for the early rare-earth elements ($R = \text{La, Pr, Nd}$). The Bi2212 phase with $R = \text{Pr}$ decomposed much faster than other phases. This was associated with the fact that the starting phase contained praseodymium in the Pr^{3+} state, while annealing in air caused its oxidation to Pr^{4+} with a smaller ionic radius and subsequent destabilisation of the Bi2212 phase.

VII. Microcomposites based on phases of the Bi–(Pb)–Sr–Ca–Cu–A–O system

The best way of preparing superconducting materials with good intergranular contacts is to use melt techniques. However, under these conditions the generic second phases form rather large inclusions (of size greater than $1\ \mu\text{m}$). The reason is that in the melt all components of the system are present in comparable amounts. To improve the efficiency of pinning, one should make the inclusions smaller. This can be achieved by introducing some alien phases containing an extra component A into the system.

Multicomponent systems are extremely complex objects. Because of this, ‘engineering’ methods of doping of the generic system often fail. In most cases the introduction of some high-melting oxide additives is accompanied by partial decomposition of the superconducting phase and by the formation of the accompanying complex oxide phases.²⁸

The authors of this review believe that a consistent method for solving the problem of design of microcomposites based on superconducting cuprates must include:

- searching for new components, which do not destroy the superconductivity in the matrix material;
- establishment of phases which contain the new components and are chemically inert towards the superconductor; and
- elaboration of methods for synthesis of materials containing fine-grained, uniformly distributed inclusions of the above-mentioned phases.

The superconducting phase, which acts as the matrix, must be characterised by a rather high T_c value. The optimum compositions and the heat treatment regimes of such phases have been reported.^{48,49} In the search for various dopants it can appear that the simplest way is to retain the composition of the generic system because of the minimum solubility of the new component in the superconducting phase. As mentioned above, the chemical inertness of the system is best achieved if its components are thermodynamically compatible, *i.e.*, if the impurity and the matrix superconducting phase are in equilibrium at least at such values of the external parameters (temperature and the partial pressure of oxygen) that correspond to the conditions for the synthesis of the composite. Therefore, determination of the compositions of the equilibrium phases is of prime importance. The next stage involves preparation of the composite containing inclusions of the equilibrium phases. Here, one should take into account the effects related to the interface interactions, such as agglomeration and recrystallisation of the particles of the inclusion phase and their effect on the nucleation and growth of crystallites of the superconducting matrix. Besides, in the text below we will show that the presence of the equilibrium phase can change the phase relations in the system in the region above the solidus and, correspondingly, the crystallisation mechanism of the matrix phase.

The thermodynamic compatibility of silver with the superconducting phases in the Bi–(Pb)–Sr–Ca–Cu–O and Y–Ba–Cu–O systems has been established reliably.^{63,155–158} This is of crucial importance for fabrication of flexible sheathed HTSC wires and tapes.^{5,158} The solubility of silver in the solid phases Bi2212 and (Bi,Pb)2223 is at most 1% while its solubility in the corresponding oxide melts is nearly 5%, which leads to reduction of the melting temperature of the superconducting ceramics by $20–30\ ^\circ\text{C}$.^{82,157,159} It was found that the peritectic melt contains the same phases as the melt containing no silver (see Section IV). Because of doping, the melting temperature of metallic silver in the composite decreases by $\sim 10\ ^\circ\text{C}$. Gold also seems to be compatible with the above-mentioned phases.^{6,160–163}

Metallic platinum slowly reacts with the melts of the ceramic matrix and forms complex oxide phases containing alkaline-earth elements and copper along with platinum.^{163,164}

The compositions and properties of the microcomposites based on the superconducting Bi2212 matrix are listed in Table 1.

Apparently, MgO is the only individual oxide which possesses a sufficient chemical inertness towards the superconducting phases. Nevertheless, it was shown^{165,166} that the Bi2212 phase is in equilibrium with the solid solution $\text{Mg}_{1-x}\text{Cu}_x\text{O}$ ($x \approx 0.1$). Pure fine-grained magnesia causes decomposition of the superconductor phase due to partial removal of copper, while coarse-grained MgO does not readily react with either the solid Bi2212 phase or its melt. The solubility of MgO in Bi2212 is at most 1 at.%, so the T_c value of the superconducting matrix remains virtually unchanged.

The introduction of other chemical elements into the Bi–(Pb)–Sr–Ca–Cu–O system results in the formation of complex oxides. Alumina, gallium sesquioxide and oxides of rare-earth elements form two compatible phases with the oxides of the generic system each,^{164,168–172} while oxides of the other elements listed in Table 1 form one compatible phase each.^{28,72,167,172,173,176–182}

In spite of a wide variety of chemical compositions of the Bi2212-compatible complex oxides, some general trends were revealed. At the phase equilibrium, the components of the coexisting phases have the same chemical potentials. To a first approximation the oxide systems can be characterised by the chemical potential of the common component (O^{2-} anion), which reflects the acid–base properties of the system (reduced potential corresponds to an acid medium while increased potential corresponds to a basic medium).¹⁸³ The compatible phase must be stable in a range of chemical potentials of the O^{2-} anion which overlaps with the chemical potential range corresponding to the stability of the superconducting phase. Thus, the strongest acid oxides will form compounds with the stronger basic oxides of the generic system in order to increase the chemical potential of O^{2-} to a value corresponding to the lower boundary of the stability of the Bi2212 phase. Analogously, the basic oxides will form compounds with the stronger acid oxides. Clearly, the interaction between the strongest acid oxides and the strongest basic oxides is most energetically favourable. One should also take into account that the acidity of the oxide increases with increasing oxidation state and decreasing ionic radius of the element.

Analysis of general trends of changes in the compositions of complex oxides (see Table 1) suggests that the oxides characterised by high oxidation state of the corresponding element ($\geq +4$) and, hence, by relatively high acidity usually form compounds with strontium oxide, which is the strongest basic oxide in the generic system. Reduction of the acidity of the extra oxides formed by the triply charged cations leads to the formation of calcium, bismuth and copper oxide constituents of the non-superconducting complex oxide along with strontium oxide. In the case of rare-earth elements with the largest ionic radii, the composition of the complex oxide cannot include strontium oxide (see Table 1), which is consistent with the lowest acidities of the oxides of rare-earth elements. From the standpoint of the acidity criterion, MgO is compatible with the Bi2212 phase. Barium oxide (the strongest basic oxide) forms a compound with bismuth oxide (the strongest acid oxide in the generic system).

Sometimes, the Bi2212 phase contains a minor amount of dopant (less than 1 at.% with respect to all cations), which allows the rather high superconducting transition temperature of the composite to be retained (see Table 1). Small amounts of gallium sesquioxide and titania can be dissolved in the solid phase of the superconductor, which reduces T_c by several degrees. The values listed (~ 2 at.%) correspond to the lower bounds of the solubilities of these oxides in the Bi2212 phase, which is in equilibrium with the non-superconducting oxide phase. It is assumed that titanium occupies sites in the copper sublattice¹⁸⁴ while gallium can replace both copper and bismuth.^{164,171,185,186} It is also

^a $R = \frac{J_c(60 \text{ K}, 10 \text{ mT})}{J_c(5 \text{ K}, 1 \text{ T})}$. This parameter characterises the average pinning energy of magnetic vortices.²⁸ For most composites, the R values increase (by up to hundreds per cent) compared to those of single-phase

superconductors ($R = 0.01$ for bulk samples of the pure Bi2212 phase; $R = 0.03$ for silver-sheathed tapes).²⁸ ^b Corresponds to the lower bound of the solubility in equilibrium with the A-containing phase. ^c Rod-like grains. ^d For Bi2212 – $\text{Sr}_2\text{LnBiO}_6$ composites. ^e Average values for the equilibrium with $\text{Sr}_2\text{LnBiO}_6$. ^f For silver-sheathed tape.

known that rare-earth elements can partially or completely replace calcium in Bi2212.^{187–189} Under particular conditions the equilibrium with the complex oxides containing the late rare-earth elements permits the content of the rare-earth elements in the Bi2212 phase to be limited, thus retaining the high T_c values (e.g., 87 K for the Bi2212–Sr₂YbBiO₆ composite).¹⁷⁴

Figure 12 presents the plots of the critical current density vs. the magnetic field induction for the single-phase Bi2212 sample and the Bi2212–SrZrO₃ composite in the form of silver-sheathed tapes.¹⁷⁹ At low temperature (5 K), the J_c values for both samples are comparable. It is assumed⁹¹ that under these conditions the critical current is governed by the pinning to a large number of small defects (e.g., atomic vacancies) with low pinning energies. Raising the temperature to 60 K causes a dramatic decrease in the efficiency of such pinning centres. At this temperature, the composite is characterised by higher J_c compared to the single-phase Bi2212 sample, the difference being increased with increasing magnetic field induction. Apparently, this indicates that inclusions of the second phase create new high-energy pinning centres, which can efficiently operate at a temperature of nearly 60 K.

Figure 12. Critical current density vs. magnetic field induction for the superconducting silver-sheathed tapes based on pure Bi2212 phase (open circles and open triangles, two samples) and on the Bi2212 phase containing submicrometre-sized inclusions of SrZrO₃ (full circles and full triangles, two samples) at 5 (a) and 60 K (b).¹⁷⁹

Most studies on the superconducting composites were carried out using MgO as the inclusion phase. Magnesia was introduced into the Bi2212 samples in the form of micro- and nanoparticles^{165, 166, 190–193} and aligned whiskers several micrometres^{11, 194, 195} or nanometres¹⁹⁶ in diameter. Usually, MgO particles are uniformly distributed in both polycrystalline ceramics (Fig. 13) and Bi2212 single crystals.^{72, 164, 166, 193} The size of inclusions depends on the preparation procedure and on the dispersion of the starting powder; however, melt processing is accompanied by recrystallisation of the inclusion phase, so that the MgO inclusions in the composite were of submicrometre size

Figure 13. Electron microscopy (BSE) micrograph of Bi2212–MgO composite.

The grey background is the Bi2212 matrix and the dark objects are Mg_{1–x}Cu_xO inclusions.

even when nanocrystalline (~ 10 nm) powder was used. The samples exhibited an increase in J_c , which was most pronounced at elevated temperatures and at high magnetic fields and reached one or two orders of magnitude. For instance, a thick Bi2212 film with perpendicularly aligned MgO whiskers 20 nm in diameter was characterised by a critical current density of $\sim 10^4$ A cm^{–2} at a magnetic field of 0.5 T at 60 K.¹⁹⁶ Introduction of larger (micrometre-sized) MgO whiskers causes significant improvement of the strength of bulk composite samples and favours their texturing.^{11, 194, 195}

Doping with alumina is often used to modify the properties of the generic superconducting system. In this connection, the effect of Al₂O₃ on the superconducting transition temperatures of Bi2212 and (Bi,Pb)2223,^{197–199} on the ability of the phases in the generic system to undergo glass transitions,^{200, 201} on the microstructure of molten Bi2212,¹⁹⁷ on the mechanical properties of a (Bi,Pb)2223-based composite (see Ref. 198) and on the pinning force of the magnetic vortices in Bi2212 (see Refs 202 and 203) was studied. Considerable interest in alumina is due to the remarkable positive effect of this compound on the formation and growth of Bi2212 whiskers.^{170, 200, 204–207} A mechanism of formation of whiskers involving a phase of the Bi–Sr–Ca–Al–O system as a specific kind of microcrucible was proposed.^{204, 205, 207}

Bi2212-based composites with inclusions of compatible Al-containing oxides have been studied in detail.^{164, 168, 169, 208} It was found that the BiSr_{1.5}Ca_{0.5}Al₂O₆ phase is nearly completely segregated in the intercrystalline space of the Bi2212 phase, so that the intergranular electric contacts are broken. At the same time, Sr_{1.7}Ca_{1.3}Al₂O₆ mainly forms inclusions inside of the Bi2212 crystallites and, hence, the superconducting current can flow throughout the whole volume of the sample (Fig. 14). In the presence of BiSr_{1.5}Ca_{0.5}Al₂O₆ the melting temperature of Bi2212 reduces down to 860 °C and the process is described by the following peritectic reaction

A Bi2212–Sr_{1.7}Ca_{1.3}Al₂O₆ composite with substantially (by nearly an order of magnitude) reduced size of inclusions (down to 0.3 μm) was obtained from a glassy precursor (Fig. 14c).²⁰⁸ However, in this case the aluminate grains are partially aggregated in the space between lamellae of the superconducting phase.

If the composite is prepared by a melt technique, particles of the impurity phase (usually, this is the solid phase in the peritectic melt) are either trapped by the growing Bi2212 crystal or pushed by it depending on the energy ratio at the melt–superconducting phase–impurity phase interfaces. If pushing of particles of the impurity phase is energetically favourable, there is a critical growth rate of the crystal, v_c (if the crystal growth rate exceeds

Figure 14. Electron microscopy (BSE) micrographs of Bi2212-based composites with inclusions of Al-containing oxides.

Compositions: Bi2212 + 0.5 BiSr_{1.5}Ca_{0.5}Al₂O₂ (a), Bi2212 + 0.2 Sr_{1.7}Ca_{1.3}Al₂O₆ (b) and Bi2212 + 0.2 Sr_{1.7}Ca_{1.3}Al₂O₆ (c) (prepared from oxide glass). The grey background is the Bi2212 matrix, the light-grey equiaxial objects are the BiSr_{1.5}Ca_{0.5}Al₂O₂ grains and the black equiaxial objects are the Sr_{1.7}Ca_{1.3}Al₂O₆ grains.

v_c , the particles are not displaced) and the extent of trapping by the matrix phase dramatically increases^{86, 88, 89}

$$v_c \sim \frac{\Delta\sigma}{\eta r},$$

$$\Delta\sigma = \sigma_1 - \sigma_2 - \sigma_3,$$

where σ_1 , σ_2 , σ_3 are the energies of the particle–crystal, particle–melt and crystal–melt interfaces per unit of surface area, respectively; η is the melt viscosity and r is the particle radius.

The critical growth rate of the crystal increases with decreasing particle size. This provides an explanation for the fact that small Sr_{1.7}Ca_{1.3}Al₂O₆ particles are aggregated much more than large particles.

It was reported that the lattice parameter of Sr_{1.7}Ca_{1.3}Al₂O₆ is in good agreement with the interatomic distances in the CuO₂ layers of the matrix Bi2212 phase.¹⁶⁸ This means that Sr_{1.7}Ca_{1.3}Al₂O₆ can appear to be a promising substrate material for the preparation of epitaxial superconducting films. A study of the dielectric properties of this aluminate, aimed at using it in HTSC-containing composites, was carried out.²⁰⁹

Gallium sesquioxide additives were also used to obtain superconducting ceramics.^{171, 186} The composite prepared by solid-phase synthesis exhibited a higher J_c value compared to the single-phase sample.¹⁸⁶ The melt processed material contains large inclusions of gallate Bi_{0.2}SrCa_{0.8}Ga₂O₂ (crystallite size of the order of tens of micrometres) and is characterised by reduced T_c and J_c due to insertion of gallium ions into the crystal lattice of the superconductor.¹⁷¹ Melting of Bi2212 in the presence of the equilibrium gallate can be described by the reversible reaction

which is similar to the peritectic reaction involving the aluminate phase (see above). In both cases at temperatures above the melting temperature the systems contain no solid phases (cuprates and bismuthate of the rare-earth element) typical of the pure Bi2212 melt. Contacts with many other compatible oxides do not violate the nature of peritectic decomposition of the Bi2212 phase.²⁸

Bi2212-based composites containing inclusions of perovskite phases Sr(Ca)AO₃ (A = Ti, Zr, Hf, Sn) have been reported.^{176–179, 210} These composites are prepared using a melt technique and crystalline inclusions thus formed are much less prone to recrystallisation compared to MgO and Al-containing phases. Because of this, the size of inclusions is relatively small (~ 0.1 – 0.3 μm). As a rule, a considerable fraction of the second phase is inside of the Bi2212 lamellae in the form of submicrometre-sized inclusions while the space between large lamellae is

filled with relatively small aggregates of SrAO₃ grains, so that some intercrystalline contacts are retained (Fig. 15). Compared to the single-phase material, these composites (except for Ti-containing ones) are characterised by enhanced pinning of magnetic vortices and increased critical current density (by nearly an order

Figure 15. Electron microscopy (BSE) micrographs of composites Bi2212 + 1.6 SrSnO₃ (a) and Bi2212 + 0.5 SrZrO₃ (b).

Figure 16. Electron microscopy (BSE) micrographs of Bi2212– $\text{Sr}_{1-x}\text{Ca}_x\text{SnO}_3$ composites prepared by reactions of molten Bi–Sr–Ca–Cu–O system with Sr_2SnO_4 (a), $\text{Sr}_3\text{Sn}_2\text{O}_7$ (b) and Ca_2SnO_4 (c).

The grey background is the Bi2212 matrix and the dark objects are $\text{Sr}_{1-x}\text{Ca}_x\text{SnO}_3$ inclusions of various shapes. The insets present micrographs of the starting powders of the corresponding tin-containing oxides.

of magnitude at 30–60 K). For instance, at 60 K silver-sheathed tapes of Bi2212– SrZrO_3 composite and pure Bi2212 phase are characterised by $J_c = 1.4 \times 10^4$ and $6 \times 10^3 \text{ A cm}^{-2}$, respectively (see Ref. 178).

It should be noted that the use of precursors of various chemical nature eventually leads to the formation of the same type of Bi2212–perovskite phase composites. In this connection a remarkable example is provided by the preparation of composites from a mixture of nonequilibrium substances *via* a chemical reaction between them.^{211–214} This approach allows modification of the shape and size of inclusions. An intense reaction proceeds between the solid phase containing the component A and the molten oxide precursor of the Bi–Sr–Ca–Cu–O system. For instance, micrometre-sized Sr_2SnO_4 grains are transformed into hollow perforated shells of equilibrium $(\text{Sr,Ca})\text{SnO}_3$; $\text{Sr}_3\text{Sn}_2\text{O}_7$ is transformed into corroded $(\text{Sr,Ca})\text{SnO}_3$ particles, while nearly $1 \mu\text{m}$ Ca_2SnO_4 grains are dispersed into much smaller $(\text{Sr,Ca})\text{SnO}_3$ particles (Fig. 16).^{211,212} When heated above 1000°C in the Bi2212 melt, strontium stannate SrSnO_3 is transformed into the $(\text{Sr,Ca})_3\text{Sn}_2\text{O}_7$ phase, which forms aggregates composed of mutually perpendicular plates located at positions of the grains of the starting stannate (Fig. 17). Cooling of the system is accompanied by the reverse process, *i.e.*, transformation into metastannate, which forms complex-shaped particles.²¹³ Similar particles are also formed as a result of transformations of Sr_2TiO_4 and $\text{Sr}_3\text{Ti}_2\text{O}_7$ into SrTiO_3 and of $\text{Sr}_3\text{Zr}_2\text{O}_7$ into SrZrO_3 .²¹⁴ It is assumed that complex-shaped particles formed during melt processing of a composite are less prone to agglomeration.²¹¹

The inclusion phases mentioned above have isotropic crystal lattices and, as a rule, form equiaxial grains. The crystal lattice of indium-containing oxide $\text{Sr}_{1-x}\text{Ca}_x\text{In}_2\text{O}_4$ has one-dimensional $\text{In}-\text{O}_2-\text{In}$ chains with strong bonds. This compound forms uniaxial particles in the composite matrix. Figure 18 presents the micrographs of Bi2212– $\text{Sr}_{1-x}\text{Ca}_x\text{In}_2\text{O}_4$ composites. Synthesis from nitrate solutions gives the composite containing elongated indate particles of size $1 \times 5 \mu\text{m}$, which are partially agglomerated in-between the Bi2212 lamellae.¹⁷² Synthesis from a glassy oxide causes the formation of more anisotropic indate particles, which are much less agglomerated.²¹⁵ One can expect that an anisotropic particle placed at a large angle with respect to the front of the growing crystal will be more readily trapped by the crystal compared to an equiaxial particle. A possible consequence is a much more uniform phase distribution in the composite.

The Bi2223 superconductor is less stable than Bi2212 (see Ref. 49) and is formed much more slowly. Namely, a complete solid-phase transformation of the precursor requires tens (hundreds) of hours; the Bi2223 phase cannot be crystallised immediately from melt. A vast majority of experiments were carried out using a lead-doped (Bi,Pb)2223 matrix instead of Bi2223, because

Figure 17. Electron microscopy (BSE) micrographs.

Sample prepared by melting of a mixture of Bi2212 and SrSnO_3 followed by annealing; the grey background is the Bi2212 matrix (solidified melt) and the black aggregates are scaly crystals of $(\text{Sr,Ca})_3\text{Sn}_2\text{O}_7$ (inset: starting SrSnO_3 powder) (a); Bi2212– $\text{Sr}_{1-x}\text{Ca}_x\text{SnO}_3$ composite prepared by heat treatment of the sample: the grey background is the Bi2212 matrix and the dark-grey and white objects are the $\text{Sr}_{1-x}\text{Ca}_x\text{SnO}_3$ and Bi2201 inclusions of irregular shapes (b).

phase formation in the former system proceeds much faster and to a greater extent as compared to the undoped system.

Figure 18. Electron microscopy (BSE) micrographs of Bi2212–Sr_{1–x}Ca_xIn₂O₄ composite prepared from nitrate precursor (a) and oxide glass (b).

Table 2 lists the data on the microcomposites containing different inclusion phases, which are thermodynamically compatible with (Bi,Pb)2223. The content of the impurity element in the matrix phase of the composite is at most 1 at.% and T_c varies in the narrow range from 106 to 110 K. A number of Bi2212-compatible phases (see Table 1) are also compatible with (Bi,Pb)2223. However, some phases including (Sr,Ca)₃Al₂O₆ and complex oxides of gallium react with the superconductor.^{164, 219}

At present, methods for preparation of (Bi,Pb)2223-based composite materials include only solid-phase synthesis. The impurity components strongly affect the rate of (Bi,Pb)2223 phase formation. The slowest reaction resulting in the (Bi,Pb)2223 phase proceeds between (Bi,Pb)2212, calcium cuprate and copper oxide.⁴⁹ Taking the reaction of the oxide precursor of (Bi,Pb)2223 with Sr_{1–x}Ca_xZrO₃ as an example, it was shown that during heat treatment the finely dispersed strontium zirconate absorbs the Pb-rich liquid, which is present in the system in small amounts and serves as an important factor of the phase transformation. The absorption slows down the formation of the (Bi,Pb)2223 phase.²²⁴ Acceleration of phase formation observed in the reactions with other additives is associated with the appearance of an additional amount of the liquid phase, which favours diffusion of the components.^{224, 225, 229, 230}

Introduction of submicrometre-sized SrZrO₃ particles into (Bi,Pb)2223 ceramics causes an increase in the current flowing within grains.¹⁷⁶ At the same time, the Ca₂B₂O₅ additive has little effect on J_c ,²¹⁸ while the addition of BiSr_{1.5}Ca_{0.5}Al₂O₇ and vanadium-containing oxide (see Table 2) leads to reduction of J_c , especially at nonzero magnetic fields.^{219, 225}

Table 2. Composition and properties of microcomposites with the (Bi,Pb)2223 superconducting matrix.

Dopant A	A-Containing phase compatible with (Bi,Pb)2223	Effect of dopant on phase formation of (Bi,Pb)2223	T_c /K	Ref.

^a Isostructural to Sr₅(VO₄)₃CuO.²²⁶

Considerable enhancement of magnetic flux pinning was observed upon introduction of MgO in the form of micro- and nanoparticles or nanowhiskers into the (Bi,Pb)2223 ceramics and silver-sheathed tapes.^{75, 231–234} Tapes containing additives of highly dispersed Ca₂PbO₄ were also prepared.²³⁵ Of special note is the doping of superconducting cuprates with uranium prior to neutron irradiation in order to create a high concentration of defects (tracks) as a result of nuclear fission of ²³⁵U.^{227, 228} The interaction of U₃O₈ with the (Bi,Pb)2223 phase is mainly reduced to the reactions with the calcium and strontium oxides. The superconductor phase is in equilibrium with the solid solution (Sr,Ca)₃UO₆ containing nearly equal amounts of strontium and calcium.

It is noteworthy that doping of both bulk (Bi,Pb)2223 ceramics^{236–240} and silver-sheathed wires with some microcomponents^{24, 230, 241, 242} causes significant changes in the grain microstructure and the material's texture and finally results in an increase in the critical current density. It was shown²³⁷ that introduction of nanodispersed TaC (0.1%) is followed by a twofold increase in J_c in the sintered ceramics; a further increase in the TaC content leads to reduction of the critical current density. Analogous changes in J_c were observed upon doping with microamounts of NbC (see Ref. 236) and HfN (see Ref. 238). It was assumed that the effect of these dopants is due to the changes in the content and composition of the intermediate liquid phase and to the formation of impurity phases. It was found²⁴¹ that (Bi,Pb)2223 tapes sheathed with the silver alloy doped with Ti, Zr or Hf exhibit higher J_c and that their microstructures are characterised by the larger size of the (Bi,Pb)2223 lamellae. This effect seems to be associated with the diffusion of micro amounts of dopants from the sheath to the superconducting core of the tape.

Investigations on the preparation of composites based on other high-temperature superconducting cuprates are on the initial stage yet. The introduction of nanoparticles of high-melting oxides into the TlBa₂Ca₂Cu₃O₇ matrix (see Ref. 243) leads to the

formation of inclusions of reaction products (particle size 30 to 100 nm). The product of the reaction with Al_2O_3 was identified as BaAl_2O_4 . Phase formation of the superconductor $(\text{Tl,Bi})\text{Ba}_2\text{Ca}_2\text{Cu}_3\text{O}_x$ in the system containing micrometre-sized LaAlO_3 particles was studied.²⁴⁴

Partial replacement of barium by strontium and of mercury by lead in the superconducting phase $\text{HgBa}_2\text{Ca}_2\text{Cu}_3\text{O}_{8+\delta}$ accompanied by a sharp increase in the irreversibility field at temperatures above 77 K was reported (see Refs 245 and 246). Initially, this effect was associated with a decrease in the anisotropy of the superconducting state due to lattice compression along the c axis.²⁴⁵ A more recent study²⁴⁷ of the material revealed wave-like fluctuations of the Hg and Pb content with a period of tens of nanometres and pinning of magnetic vortices in the regions with weakened superconductivity [similar to the Nd123 and $(\text{Bi,Pb})2212$ phases] was assumed.

* * *

Material presented in this review illustrates the importance of taking into account the chemical properties of components in the design of superconducting microcomposites based on cuprate superconductors. Considerable advances can be achieved only by carrying out basic research on the multicomponent oxide systems, formation of the matrix and inclusion phases and on peculiar features of physicochemical interactions between these phases during the composite formation, which is to a great extent governed by the interface energy.

Further progress in the field of design of superconducting microcomposites is related to thorough choice of additives and conditions for the preparation of microcomposites for each particular generic system in order to retain high superconductivity parameters of the matrix phase, reduction and stabilisation of inclusion size at nanolevel and control of the inclusion shape and distribution in the superconductor matrix. On this basis, the potentialities of the chemical complication of the systems under study are still far from being exhausted. It seems not improbable that multiphase materials containing several additives rather than a single extra component will exhibit optimum operating characteristics.

This review has been written with financial support from the 'Universities of Russia' Programme of the Ministry of Education of the Russian Federation (Project No. UR06.03.003), the State Programme for Support of Leading Scientific Schools, the Ministry of Industry, Science and Technologies of the Russian Federation (Project No. NSH-2033.03.2003) and the State Programme 'Actual Problems of Condensed Matter Physics'.

XI. Conclusion	893

Abstract. Data on circumambulatory rearrangements caused by rapid migrations of substituents formed by Group 13–17 elements around three- to nine-membered cyclopolyenes are generalised and systematised. Depending on the ring size, the nature of the migrating group, substituents in the ring and the medium, the rate constants of circumambulatory rearrangements vary over a wide range from 10^6 to 10^{-8} s $^{-1}$ at room temperature. Particular attention is given to analysis of the mechanisms of these rearrangements ([1,*j*]-, [2,3]- and [3,3]-sigmatropic shifts, haptotropic rearrangements and ionisation–recombination) and to the correlation of these mechanisms with the structural characteristics of the compounds that undergo rearrangements. The bibliography includes 241 references.

I. Introduction

The molecular structure theory is closely related to the notions of space and time continuity. The three-dimensional space is insufficient for a detailed description of molecular structures; the fourth dimension is required to characterise the internal dynamics of a molecule, *i.e.*, the distribution of the times of occurrence of this molecule in different conformational, topomeric or isomeric states. The most detailed information on the internal dynamics can be gained from the data on energy barriers to various intramolecular processes.

Hindered rotations about single bonds and the related conformational transitions characterised by particular energy barriers were among the first dynamic processes which have been

studied extensively due to the development of IR spectroscopy and radiospectroscopy.^{1,2} Internal rotations leave sequences of bonds in molecules unchanged. These rotations are characterised by relatively low energy barriers. An insight into these processes can be gained within the framework of conventional models of molecular structures, including mechanical models. In the 1950s, reports were published on the fluxional behaviour of organometallic and organic compounds associated with rapid and reversible degenerate intramolecular rearrangements, which are accompanied by the cleavage and formation of covalent bonds (some of these rearrangements are characterised by rate constants of 10^6 – 10^9 s $^{-1}$ at room temperature; these processes have been surveyed in Refs 3–7). These data radically change the views of the degree of rigidity of molecular structures. The decisive breakthrough has been achieved due to the development of methods of dynamic NMR spectroscopy,^{3,8–10} which allowed the researchers to reveal the diversity of molecular fluxional structures and mechanisms of main intramolecular processes. It appeared that the stereochemical non-rigidity rather than rigidity of molecules is the most general characteristic of molecular structures. When speaking about NMR spectroscopy as the main method for studying the structural (or stereochemical) non-rigidity, it should be emphasised that the detection of structural non-rigidity is directly associated with the characteristic NMR time scale. It was suggested¹¹ that the term ‘structurally non-rigid molecules’ be used for molecules which undergo reversible rearrangements characterised by energy barriers (ΔG) no higher than the values determined by conventional methods of dynamic NMR spectroscopy ($\Delta G_{25}^\ddagger \leq 25$ kcal mol $^{-1}$).

The structural non-rigidity of the molecules of organometallic compounds was first discovered by Wilkinson and Piper,^{12,13} who described very rapid migrations of the Fe(η^5 -Cp)(CO) $_2$ (Cp is cyclopentadienyl) and Hg(η^1 -Cp) groups around the five-membered ring in the π -cyclopentadienylirondicarbonyl- σ -cyclopentadiene and dicyclopentadienylmercury molecules, respectively. At that time, the techniques at hand did not enable Wilkinson and Piper to observe directly the migration, but they recorded the only averaged signal for the protons of the η^1 -Cp ring and correctly attributed this fact to rapid (on the NMR time scale) migrations of the metal-centred groups around the five-membered ring.

Only ten years later, this assumption was confirmed¹⁴ by the data from complete analysis of line shapes of the temperature-dependent ¹H NMR spectra of the MC₅R₅ compounds (**1**), where M is the migrating group (this discovery has been described in detail in the study¹⁵).

M = Fe(η^5 -Cp)(CO)₂.

Rapid circumambulatory migrations of metal-centred groups M (formed by both transition and main-group metals) around the ring have been found in numerous cyclopentadiene derivatives containing such groups as substituents in the ring.^{4, 15–17} The term ‘circumambulatory rearrangements’ has gained acceptance as the most general term for describing rearrangements in the course of which an atom or a group of atoms migrates around the ring in such a way that they can finally be bound to any carbon atom of the ring.¹⁸ There are also alternative terms for these rearrangements, such as ‘merry-go-round’, ‘walk’, ‘ring-whizzing’, and ‘ring runners’.^{4, 15–18}

The tendency of σ -bound (η^1) cyclopentadienyl derivatives of transition metals **1a–e** to fluxionality correlates well with the polarity of the C_{Cp}–metal bonds, the ease of their ionisation and the ability of transition metal ions to form multicentre bonds. It was demonstrated that rapid circumambulatory rearrangements are typical also of cyclopentadiene derivatives containing covalently bound substituents formed by Group 13–15 elements in the ring (see comprehensive reviews published earlier^{17–22}). Investigations which we carried out in the last decade in cooperation with researchers from Rostov-on-Don, Berlin and Novosibirsk extended the range of fluxional η^1 -cyclopentadienes by including not only derivatives of Group 13–15 elements but also compounds in which migrating substituents are formed by Group 16 and 17 elements.

Circumambulatory rearrangements of cyclopentadiene derivatives belong to one of the most extensively studied areas of the dynamic stereochemistry of structurally non-rigid compounds. By contrast, analogous rearrangements of derivatives of the preceding and following members of the family of conjugated carbocyclic structures, *viz.*, cyclopropene (**2**) and cycloheptatriene (**3**), respectively, were poorly studied. In recent years, our research group has obtained new data on the fluxional behaviour of cyclopropenyl and cycloheptatrienyl derivatives of Group 15 and 16 elements.

Circumambulatory rearrangements are typical also of cyclic carbocationic systems **4** and **5** containing an even number of carbon atoms.

In the present review, particular attention is given to mechanisms of circumambulatory rearrangements, structures and estimates of the relative energies of transition states and intermediates for different reaction pathways. An important role of theoretical simulation in the identification of the major reaction pathway is demonstrated. Compounds in which groups M exhibit high ability to migrate in conjugated rings can serve as convenient carriers of functional groups in intermolecular reactions with substrates possessing higher affinity for migrating groups than the molecules of the starting compound. The possibilities of using compounds **1–5** as efficient soft carrier reagents are illustrated in Section X. The non-degenerate rearrangements of cyclopentadiene derivatives **1** discovered recently extend the range of functionalised Cp ligands involved in metal complexes, which can serve as catalysts for various stereospecific reactions (see Section X).

In the present review, we restrict ourselves to thermal rearrangements of derivatives of compounds **1–5** and some higher cyclopolyenes containing Group 13–17 elements. Data on the rearrangements of analogous derivatives of transition metals are considered only for comparison. Circumambulatory rearrangements of migrating substituents formed by Group 13 and 14 elements (B, Si, Ge, Sn) and phosphorus were studied in detail. Excellent comprehensive reviews^{17–19} devoted to this problem surveyed the data published up to 1985 inclusive. In the discussion of the rearrangements, we focus our attention on nitrogen-, oxygen-, chalcogen- and halogen-centred groups, whose migrations around the periphery of conjugated cyclopolyenes were discovered and studied primarily in the last 10–15 years. For cyclopentadiene derivatives, which belong to the most extensively studied fluxional cyclopolyene systems, the elements serving as centres of migrating groups are given below (according to their positions in the Periodic table); the central atoms of the groups, whose migrations were unknown before the mid-1980s (when we began our investigations) are shaded.

B	C	N	O	F
Al	Si	P	S	Cl

In	Sn	Sb	Te	I

The review is arranged as follows. It is known that the tendency of a molecule to undergo structural rearrangements depends on the presence of several stationary points on the potential energy surface (PES), which are comparable in energy, belong to two or more isomeric forms and are related by trajectories containing low-energy saddle points of transition states. Hence, we begin with the consideration of the structural types of isomers of conjugated cyclopolyenes. The tendency of these structures to undergo ionisation or η^1 – η^n transformations dictates the pathway of circumambulatory rearrangements. Alternative possible pathways of circumambulatory rearrangements of compounds **1–5** depending on the ring size, nature of the migrating group M and substituents in the ring are considered in Section III. In subsequent sections, the experimental and theoret-

ical results are discussed in the order of increasing structural complexity, starting from the smallest cyclopropene derivatives.

II. Structural types of monosubstituted cyclopolyenes

Two main factors responsible for the mutual orientation of the fragments in cyclopolyenyl–M systems **1–5** and the type of the resulting structure are Coulombic and covalent interactions between these fragments. Cyclopentadienyl derivatives of alkali and alkaline-earth metals occur as ionic compounds containing aromatic cyclopentadienyl anions. In the solid state, these salts generally form polymeric structures. By contrast, the C–M bond in cyclopropene derivatives **2** and cycloheptatriene derivatives **3**, which are stable in the cationic form due to requirements for aromaticity, undergoes ionisation only if the group M possesses high electron affinity.

The multicentre mode of binding giving rise to sandwich (metallocene) structures is most common to transition metal complexes with cyclopolyenyl ligands. Although only the s and p orbitals of Group 13–17 elements can be involved in binding with the cyclopolyene fragment, their compounds of general formulae **1–3** are also characterised by considerable structural diversity. The usual covalent two-centre two-electron (2c–2e) binding is the dominant interaction in the cyclopolyenyl–M system. However, numerous stable π complexes with the cyclopentadienyl ligands in which the migrating groups M are formed by main-group elements are known (see the reviews^{23–27}).

Hoffmann and co-workers²⁸ analysed the role of covalent binding for cyclopentadiene derivatives in terms of projections of the centre M bound to the five-membered ring onto the plane of this ring. Taking into account the isolobal analogy,²⁹ this approach allows one to extend analysis to all CpM compounds, where M is a transition metal or a main-group element.²⁶ The position of the projection point is considered as a structural parameter based on which the compound is assigned to one of the η^n structural types (n is the number of p_π centres of the ligand involved in the multicentre bond with the substituent). σ -Bound (η^1) compounds **1** (as well as compounds **2–5**) generally belong to the most stable structural type of cyclopolyenyl derivatives of Group 13–17 elements, and η^2 – η^n structures (for cyclopentadiene derivatives, $n_{\max} = 5$) **6–9** are possible isomeric forms. Different simple models for electronic calculations, which enable one to predict the structures of the energetically most favourable η^n isomers, were developed.^{30, 31}

For some cyclopolyenyl, particularly, cyclopentadienyl, derivatives of Group 13–17 elements, the energy differences between various η^n -isomeric structures are very small. Tris(1,2,3,4-tetramethylcyclopentadienyl)aluminium is a prominent example.³² In the solid state, all three tetramethylcyclopentadienyl ligands in this compound are η^1 -coordinated, but signals in the ¹H and ¹³C NMR spectra of its solutions are completely averaged, which reflects the rapid exchange of the Al centre between all positions of the ligands even at low temperatures (about –110 °C). The results of *ab initio* calculations at the RHF/3-21G* level for model compounds, *viz.*, cyclopentadienylaluminium derivatives, are indicative of the flat potential energy surface in the region of existence of isomers with different modes of η -binding (η^1 , η^2 , η^3 and η^5). Thus, the energy differences between the η^2 and η^5 structures are in the range of 1–2 kcal mol^{–1}.

III. Mechanisms of circumambulatory rearrangements

The structural diversity of cyclopolyenyl compounds of Group 13–17 elements is a prerequisite for their fluxional behaviour. The choice between different mechanisms of rearrangements of a particular compound is determined by the relative stabilities of intermediate or transition state structures with different modes of η -binding as well as by the ease of ionisation of the cyclopolyenyl–M bond. We classify the possible pathways of circumambulatory rearrangements according to the modes of η -binding for energetically favourable transition state structures, including the η^1 – η^2 (η^1 – η^3 , ... η^n) and η^2 – η^3 (η^2 – η^3 , ... η^n) rearrangements, where n is the coordination number of the central atom in the transition state. In addition to haptotropic rearrangements (this term is used for generalisation of all types of $[i, j]$ -sigmatropic rearrangements and isomerisation processes in multicentre π complexes **7–9**¹⁹), an intramolecular shift of the migrating group around the periphery of the cyclopolyene ring can occur due to successive events of the cleavage and recombination of the cyclopolyenyl–M bonds within a tight ion pair generated upon ionisation of this bond. We restrict ourselves to a brief discussion and characteristic examples of each specific mechanism responsible for circumambulatory rearrangements of derivatives of main-group elements in conjugated cyclopolyene systems.

1. Ionisation–recombination mechanism

The ionisation–recombination mechanism is most common to cyclopropene derivatives **2** and cycloheptatriene derivatives **3**, whose ionisation is facilitated by the formation of stable aromatic cations. This mechanism has been proposed for the first time in the study³³ as an explanation of rapid randomisation of the position of the chlorine atom in 3-chlorocyclopropene molecule **2** (M = Cl, R = H). More recent studies of migrations of the azido group (M = N₃) in 3-azido-1,2,3-trimethyl-³⁴ and 3-azido-1,2,3-tri-*tert*-butylcyclopropenes³⁵ demonstrated that the rate of these rearrangements is independent of the concentration of the solution, but it is substantially influenced by the polarity of the solvent. For instance, the energy barrier to the rearrangement of compound **2** (M = N₃, R = Bu^t) in non-polar tetrachloromethane is 16.5 kcal mol^{–1}, whereas this barrier in polar deuteriomethanol is lower by 4.5 kcal mol^{–1}.³⁵ These data provide evidence supporting the ionic mechanism (formation of a tight ion pair), which can be represented as a disordered (random) circumambulatory rearrangement of migrating groups in molecules **2**.

The dependence of the ¹H NMR spectrum of tropylium azide **3** (M = N₃, R = H) on the temperature and solvent was also accounted for by the intermediate formation of the ion pair, *viz.*, tropylium azide ion.³⁶ Randomisation of the position of the isothiocyanate group in the cycloheptatriene ring was also observed in solutions of compound **3** (M = NCS, R = H) in CD₃CN.³⁷

Unlike the cyclopropenyl and cycloheptatrienyl ions, the aromatic cyclopentadienyl ions bear a negative charge. Hence,

the electronic requirements for the ionisation mechanism of shifts of migrating groups *M* around the five-membered cyclopentadiene ring differ from those typical of three- and seven-membered cyclopolyenes **2** and **3**. Ionisation of the Cp–*M* bond is favoured by the presence of substituents, which facilitate delocalisation of the negative charge in the ring, as well as by the presence of groups *M*, which form stable cations *M*⁺. This combination occurs in 5-aryloxy-1,2,3,4,5-pentamethoxycarbonylcyclopentadienes. The latter compounds are the first cyclopentadiene derivatives for which the ionisation–recombination mechanism was observed (see Section VI.3.a).^{38,39}

2. 1,2-Shifts of migrating groups

The migration of the substituent *M* to the adjacent position of the cyclopolyene ring is the most common pathway of circumambulatory rearrangements of compounds **1**–**5** proceeding through a series of successive 1,2-shifts. In terms of sigmatropic rearrangements, 1,2-shifts are classified as [1,*j*]-sigmatropic shifts, where *j* = *n* (*n* is the ring size).

Until recently, examples of 1,2-shifts for sigmatropic rearrangements of cyclopropenyl compounds **2** remained unknown. The evidence supporting this mechanism was presented in the study of the rearrangements of *S*-substituted 1,2,3-triphenylcyclopropenes⁴⁰ (see Section IV.3). By contrast, the 1,2-shift ([1,5]-sigmatropic shift) is the most common and well-studied mechanism of circumambulatory rearrangements of cyclopentadiene derivatives **1**. The 1,2-shift of the hydrogen atom in the cyclopentadiene ring was first described in 1963.⁴¹ Two years later, rapid migrations of Si-, Ge- and Sn-centred groups around the Cp ring were discovered.⁴² Ustynyuk and co-workers^{43,44} made a considerable contribution to investigations of [1,5]-sigmatropic shifts in cyclopentadienylsilanes, -germanes and -stannanes. In the cited studies, it was demonstrated that the shifts of Si-centred groups around the five-membered ring are accompanied by the competitive migration of the hydrogen atom, which should be taken into account to gain a precise estimate of the kinetics of these rearrangements. The cited studies gave impetus to investigations of cyclopentadienes containing methyl, phenyl or methoxycarbonyl substituents in all positions of the ring in view of the fact that their migration ability is lower than that of the hydrogen atom.

According to the Woodward–Hoffmann rules, the [1,5]-sigmatropic shifts in cyclopentadienylsilanes, -germanes and -stannanes proceed with retention of stereochemical configuration of the central atom of the migrating group.⁴⁵ Consequently, transition state structure **10a** should be energetically more favourable than structure **10b** corresponding to inversion of stereochemical configuration of the central atom of the migrating group. This prediction is consistent with the results of semi-empirical calculations for the rearrangement in the cyclopentadienylsilane molecule.⁴⁶ The transition state for 1,2-shifts in cyclopentadiene derivatives is structurally analogous to bicyclo[3.3.0]hexatriene (**10c**), which is the lowest homologue of azulene. The electron density distribution in molecule **10c** gives a clue to an explanation of the influence of the nature of migrating groups and substituents in the ring on the kinetics of rearrangements.⁴⁷

In the case of migrating substituents formed by elements of Groups 13 (B, Al) and 15 (P, As, Sb), the rearrangements also proceed predominantly as 1,2-shifts (see Sections VI.1, VI.3.b and c).

Thermal rearrangements of various cycloheptatriene derivatives caused by 1,2-shifts of the hydrogen atom, which correspond to the mechanism of [1,7]-sigmatropic shift, were described in sufficient detail.¹⁷ In the presence of bulky substituents in the ring, symmetry-allowed suprafacial [1,5]-shifts of hydrogen atoms become energetically more favourable (see Section III.4). However, theoretical and experimental studies demonstrated⁴⁸ that photochemical rearrangements of monosubstituted cycloheptatrienes associated with the migration of the hydrogen atom around the ring proceed as the [1,7]-sigmatropic shift. This mechanism was established also for rapid migrations of the Re(CO)₅ and RuCp(CO)₂ groups around the cycloheptatriene ring.⁴⁹ Recently, ¹H and ¹³C 2D EXSY NMR spectroscopic studies revealed⁵⁰ rapid 1,2-shifts ([1,7]-sigmatropic shifts) of the dipropylboryl group in the [1-4-η⁴-*exo*-7-(dipropylboryl)cycloheptatriene]tricarbonyliron molecules (**11**) (*E*_a = 17 kcal mol^{−1}), which were accompanied by the simultaneous 1,2-shift of the Fe(CO)₃ group.

For the 1,2-shifts of the hydrogen atom and various migrating substituents formed by Group 13–17 elements to occur in rings containing an even number of carbon atoms, it is requisite that the unsaturated portion of the ring should be either ionic or radical. In the four-membered ring of compound **4**, such migrations can be assigned to the η²–η³ type (see Section III.5), whereas the rearrangements in benzenium ions **5** proceed as a series of successive 1,2-shifts to form cations **5a**, **5b**, etc. The kinetics and stereochemistry of this type of rearrangement were studied in detail.^{51–53}

3. 1,3-Shifts

According to the principle of conservation of orbital symmetry for [1,3]-sigmatropic shifts, the suprafacial pathway of the reaction with inversion of stereochemical configuration of the central atom of the migrating group is preferable. The transition state structures for these rearrangements are substantially sterically hindered, and this mechanism is untypical of circumambulatory rearrangements of migrating substituents formed by Group 13–17 elements. As a result, the 1,3-shift of the migrating group generally involves two successive 1,2-shifts (symmetry-allowed suprafacial [1,5]-sigmatropic shifts).^{17,54} As an example we refer to the major mechanism of the rearrangement of tris(3-indenyl)-allylsilane studied by dynamic two-dimensional NMR spectroscopy.⁵⁵ The exceptions are the 1,3-shifts of the dipropylboryl group in 9-cyclononatetraenyldipropylborane⁵⁶ and compound **11**.⁵⁰ In the latter case, the rearrangement, which is presumably accompanied by the inversion of configuration of the boron atom, proceeds more slowly than the 1,2-shifts of the dipropylboryl group.

Studies by ¹³C CP/MAS NMR spectroscopy and the results of magnetisation transfer experiments showed that the 1,3-shifts of the Ti(η⁵-Cp)₂(σ-Cp) group occur in the σ-bound cyclopentadiene rings of the Ti(η⁵-Cp)₂(σ-Cp)₂ compound (**12**) both in the solid state and solution at 165 K.⁵⁷ However, 1,2-shifts

($E_a \approx 7.9 \text{ kcal mol}^{-1}$) are still the major pathway of this rearrangement.

4. 1,4-Shifts and 1,5-shifts

As mentioned in Section III.2, the migration of hydrogen atoms in sterically hindered cycloheptatrienes proceeds according to the mechanism of [1,5]-sigmatropic shifts, *i.e.*, as the 1,4-shift. For this rearrangement to occur, the migrating group must be present in the axial position. This rearrangement proceeds at a higher rate than the ring inversion in cycloheptatrienes **13** whose energy barrier is higher by 25 kcal mol^{-1} .⁵⁸

$R^1 = \text{Ph}; R^2 = \text{Me}, 4\text{-MeC}_6\text{H}_4$.

According to the data from dynamic ^{13}C NMR spectroscopy, the migrations of the triphenylsilyl, -germyl and -stannyl groups in the cycloheptatriene ring also proceed as successive [1,5]-sigmatropic shifts.^{59, 60} In 7-triphenylstannylcycloheptatriene adopting a boat conformation, the $\text{Sn}\cdots\text{C}(5)$ distance ($3.61 \text{ \AA}$)⁶¹ is approximately $0.3 \text{ \AA}$ smaller than the sum of the van der Waals radii of the tin and carbon atoms, which is indicative of the presence of strong attractive interaction between these centres even in the ground state. Recently, the ^1H 2D EXSY NMR spectroscopic study provided evidence that the mechanism of circumambulatory rearrangements in 7-trimethyltin- and 7-chlorodimethyltin-cycloheptatrienes involves a series of rapid successive 1,5-shifts of the tin-centred groups.⁶²

5. η^2 – η^3 -Shifts

Compounds with bicyclic structures **6** (η^2 structures) are prone to undergo [1,3]-sigmatropic shifts resulting in the circumambulatory migration of the group M. One of the first examples of such shifts was presented in the elegant study of the low-barrier ($\Delta G_{25}^\ddagger = 10.1 \text{ kcal mol}^{-1}$) rearrangement of hexamethylbicyclo[3.1.0]hex-3-en-2-yl cation **14a**.⁶³ The major reaction pathway (*a*) corresponds to retention of stereochemical configuration of the migrating carbon centre to form cation **14b**, whereas the pathway involving the inversion of configuration (*b*) to give cation **14c** is energetically less favourable (the energy difference is $4.6 \text{ kcal mol}^{-1}$).

In the transition state structure for the rearrangement, the migrating group is bound to three adjacent atoms of the ring. Hence, this rearrangement can be assigned to the η^2 – η^3 type. It should be noted that an analogous rearrangement in 6-methyl-

idenebicyclo[3.1.0]hexenyl cation **14d** (its energy barrier is $10.6 \pm 0.2 \text{ kcal mol}^{-1}$) proceeds more than 10^7 times faster than that in cation **14a**. This was accounted for by the fact that intermediates with the structures of η^3 -dicyclopropylcarbinyl cations **14e** are readily formed.⁶⁴

The η^3 -transition state structure for the rearrangement of Dewar thiophene derivatives, which leads to a rapid exchange between the positions of the sulfur atom or the $\text{S}=\text{O}$ group in the four-membered ring (see Section V),⁶⁵ was confirmed by semi-empirical calculations using the PRDDO method.⁶⁶

In uncharged systems, the ring-walk η^2 – η^3 rearrangements proceed rather slowly and do not satisfy the condition $\Delta G_{25}^\ddagger \leq 25 \text{ kcal mol}^{-1}$. One way of increasing the rate of such rearrangements is to irradiate a solution with UV light. For example, the photoinduced rearrangement of doubly ^{13}C -labelled cyclopentadiene was attributed⁶⁷ to the migration of the cyclopropane fragment around the four-membered ring in bicyclo[2.1.0]pentene (**15**).

It is believed that many photoinduced migration processes in aromatic five-membered heterocycles proceed as η^2 – η^3 -rearrangements.^{68, 69}

6. σ, π Rearrangements

The mechanism of bond switching in η^1 or η^2 structures with the intermediate formation of isomeric π complexes (η^n structures at $n \geq 3$) belongs to the σ, π type.^{5, 53} However, this mechanism of exchange between the positions of the carbon atoms in antiaromatic cyclopentadienyl cation **16** was not confirmed, although a series of derivatives of the pyramidal $(\text{CH})_5^+$ cation, which has been predicted by Stohrer and Hoffmann,⁷⁰ were prepared (see the study³⁰ and references cited therein).

It should be noted that the σ, π rearrangements resulting in the shift of the migrating group around the cyclopolyene ring are known for cyclopentadienyl complexes of alkaline-earth metals. For example, the beryllium atom in beryllocene is equally disordered over two positions both in the solid state and the gas phase. This corresponds to unique asymmetric structure **17** in which very rapid ligand exchange takes place (see the study^{26, 71} and references cited therein).

Analogous rearrangements were also observed for di(1,2,3,4,5-pentamethylcyclopentadienyl)zinc, which has a 'slip sandwich' structure. In solutions, this compound undergoes very rapid reversible ligand exchange. The ^1H NMR spectrum of this compound has only one sharp singlet common to all methyl groups even at -135°C .⁷² Apparently, this process is controlled by two concerted isomerisation mechanisms with energy barriers of $\sim 1.2\text{ kcal mol}^{-1}$ (for rotation of the ring, which is displaced from the axis passing through the centre of another Cp ring; the so-called gear mechanism) and $\sim 2\text{ kcal mol}^{-1}$ (for the σ,π rearrangements; molecular inversion).

7. π,π Rearrangements

In asymmetric π complexes with the cyclopolyene ligands, the coordination centre can undergo reversible shifts above the plane of the ligands, which is associated with interconversions of isomeric or topomeric π complexes. Haptotropic rearrangements of this type are well-known for transition metal complexes.⁷³ A few examples of such shifts for π complexes of Group 13–17 elements were also described. Of the latter processes, the rearrangements of π complexes of the nitronium cation with arenes have received the most study (see the comprehensive review⁷⁴). High-symmetry (C_{6h}) structure **18a**, which was expected based on experimental data⁷⁵ and *ab initio* calculations,⁷⁶ was in doubt because, according to the results of semiempirical calculations⁷⁷ and calculations by the density functional theory,^{78,79} this structure corresponds not to a minimum but to a hilltop on the potential energy surface of $\text{C}_6\text{H}_6\text{NO}^+$. Structure **18b** with the symmetry C_s is a stable form of the π complex. This structure undergoes rapid topomerisation (the calculated energy barrier is $< 3\text{ kcal mol}^{-1}$) due to sliding of the nitronium cation above the plane of the six-membered ring.

X-Ray diffraction studies of the $\text{NO}^+\text{AlCl}_4^-$ complexes with durene and hexamethylbenzene, the $\text{NO}^+\text{AsF}_6^-$ or $\text{NO}^+\text{SbCl}_6^-$ complexes with hexamethylbenzene and toluene⁷⁴ and the NO^+PF_6^- complex with hexamethylbenzene⁸⁰ demonstrated that the nitroso group in these complexes does not lie on a sixfold symmetry axis. The structure of π complex **18c** corresponds to the η^2 arrangement although the nitroso group deviates from the plane of the ring by approximately 50° . The ^{13}C CP/MAS NMR spectrum⁷⁴ and ^{13}C NMR spectrum of the complex of the nitronium cation with durene revealed a rapid rearrangement ($E_a = 10.2\text{ kcal mol}^{-1}$). This process was described as the rotation of the six-membered ring about the nitroso group.⁸¹ Analogous π complexes of the nitronium cation with fluorene, methyl-substituted naphthalenes⁸² and 1,2-bis(pentamethylphenyl)bicyclo[2.2.2]octene (the latter is called a 'Venus flytrap')⁸³ as well as the triple π complex of the cene type **18d** (see Ref. 84) were prepared and structurally characterised.

18c: R = H, Me.

8. [3,3]-Sigmatropic shifts

If a migrating group consists of three atoms with a terminal π bond, circumambulatory rearrangements can proceed by a mechanism involving concerted [3,3]-sigmatropic shifts of this group around the cyclopolyene ring. This mechanism is supported by the transformations of 3-allylcyclopropene derivative **19a** into isomer **19b** upon heating,⁸⁵ which is indicative of the [3,3]- rather than [1,3]-sigmatropic shift of the migrating group.

The mechanism of [3,3]-sigmatropic shifts is considered as an alternative to the ionisation–recombination pathway for the circumambulatory migrations of the azido group in the cyclopropene ring (see Section III.1). This mechanism is confirmed by the fact that a series of 3-azidocyclopropene derivatives **2** ($M = \text{N}_3$) were transformed into *v*-triazines under mild conditions.^{34,86}

Direct evidence for [3,3]-sigmatropic shifts as a mechanism of migration of the azido group around the seven-membered cycloheptatriene ring was obtained^{87,88} by dynamic ^{15}N NMR spectroscopy (see Section VIII.6).

Rapid circumambulatory migrations of the heteroallyl groups $\text{X}-\text{C}(\text{R}^1)=\text{X}$ ($\text{X} = \text{NR}^2, \text{O}, \text{S}$) around three- and five-membered rings proceeding as successive [3,3]-sigmatropic shifts of these groups are considered in Sections IV.2, VI.3.a, VI.4.a and b.

IV. Circumambulatory rearrangements of cyclopropene derivatives

1. Rearrangements proceeding by the ionisation–recombination mechanism

Section III.1 covers the circumambulatory rearrangements of chloro- and azido-substituted cyclopropenes, involving heterolysis of the $\text{C}-\text{Cl}$ and $\text{C}-\text{N}$ bonds followed by recombination of the resulting ion pairs. Rapid degenerate and non-degenerate intramolecular migrations of the isothiocyanate groups around the three-membered ring in 1,2,3-triphenyl- and 1-(4-methoxyphenyl)-2,3-diphenylcyclopropene derivatives (**20a**) are other examples of this type of rearrangement.⁸⁹ According to the data from ^{13}C NMR spectroscopy in the temperature range of $10-80^\circ\text{C}$, the activation free energies ($\Delta G_{25}^\ddagger$) of the rearrangements of compound **20a** ($\text{X} = \text{NCS}$, $\text{R} = \text{Ph}$) in benzene and chlorobenzene are 15.6 and $14.4\text{ kcal mol}^{-1}$, respectively. The reaction pathways corresponding to the non-dissociative [1,3]-sigmatropic shift and the ionisation–recombination mechanism were simulated^{89,90} by semiempirical AM1 and MNDO/PM3 methods taking into account solvation (polarisation continuum model).⁹¹ It was demonstrated that transition state structure **20b** ($\text{X} = \text{NCO}$, $\text{R} = \text{H}$) for the 1,3-shift is energetically less favourable than tight ion pair **20c** even in non-polar solvents.

The energy barrier ($15.4\text{ kcal mol}^{-1}$; estimated as the relative energy of ion pair **20c**) which was calculated for the randomisation of the position of the isothiocyanate group in the course of the rearrangement $\text{20a} \rightleftharpoons \text{20d} \rightleftharpoons \dots$ ($\text{X} = \text{NCS}$, $\text{R} = \text{Ph}$) in chloroform, is in good agreement with the experimental value $\Delta G_{25}^\ddagger$. The calculations carried out in the studies^{89,90} demonstrated that in

Figure 1. Geometric parameters and heats of formation of the ground state structures of 1-isothiocyanato-1,2,3-triphenylcyclopropene (**20a**) and 1,2,3-triphenyl-1-thiocyanatocyclopropene (**22a**), the transition state for the [1,3]-sigmatropic shift of the isothiocyanate (**20b**) and thiocyanate groups (**22b**), tight ion pairs (**20c** and **22c**) and transition state **21** for the interconversion $20a \rightleftharpoons 22a$ via [3,3]-sigmatropic shifts calculated by the MNDO/PM3 method.⁹⁰

Hereinafter, the bonds in the figures are given in Å; the bond angles and dihedral angles are also presented.

addition to the above-considered reaction mechanisms, the pathway through transition state **21** (Fig. 1) is also possible. The latter pathway corresponds to the [3,3]-sigmatropic shift in the course of interconversions of isomeric isothiocyanate **20** and thiocyanate **22**. Although MNDO/PM3 calculations demonstrated that compound **21** is less stable than isothiocyanate (the energy difference is $4.2 \text{ kcal mol}^{-1}$), it was detected⁸⁹ (0.4%) in the gas phase by mass spectrometry. The calculated relative energy of transition state structure **21** ($49.3 \text{ kcal mol}^{-1}$) is too high and its value depends only slightly on the polarity of the solvent. Therefore, in this case the [3,3]-sigmatropic shift seems to be unlikely.

2. Rearrangements via [3,3]-sigmatropic shifts

For cyclopropene derivatives, rapid circumambulatory rearrangements proceeding through a series of successive [3,3]-sigmatropic shifts were first discovered in the study of the migration of the dithioacyl group $[S-C(OEt)=S]$ around the three-membered ring of 1,2,3-triphenylcyclopropenyl *O*-ethyl dithiocarbonate **23a** ($X = S$, $R^1 = Ph$, $R^2 = OEt$).⁹²

According to the results of X-ray diffraction study, molecule **23a** ($X = S$, $R^1 = Ph$, $R^2 = OEt$) in the crystal is characterised by the *exo* conformation of the dithioacyloxy group with respect to the three-membered ring. Based on the results of MNDO/PM3 calculations, this conformation is energetically more favourable (by $0.7 \text{ kcal mol}^{-1}$) than *endo* form **23b**. The transformation into the latter form requires the migration event. According to the data from NMR spectroscopy, the energy barrier to interconversion of the conformers in solutions is lower than 12 kcal mol^{-1} . The

kinetic parameters of the degenerate rearrangement (Scheme 1), which were determined based on analysis of line shapes in the ^{13}C NMR spectra, are as follows: $\Delta G_{25}^\ddagger$ ($\text{C}_6\text{D}_5\text{CD}_3$) = $17.8 \text{ kcal mol}^{-1}$, $\Delta H^\ddagger = 14.8 \pm 0.2 \text{ kcal mol}^{-1}$, $\Delta S^\ddagger = -10.0 \pm 0.3 \text{ cal mol}^{-1} \text{ deg}^{-1}$, $k_{25} = 0.43 \text{ s}^{-1}$. These parameters

Scheme 1

are virtually independent of the concentration of the solution, which is indicative of the intramolecular character of the migration of the dithioacyloxy group around the cyclopropene ring.

To decide between two possible competitive mechanisms of migration, *viz.*, [3,3]- and [1,3]-shifts, the rearrangements of model compounds **23** ($X = \text{NH}, \text{O}, \text{S}$; $R^1 = R^2 = \text{H}$) were calculated by the semiempirical MNDO/PM3 method^{90,92} and the *ab initio* MP2/6-31G** method.⁹³ Selected results of these calculations are given in Table 1 and Figs 2 and 3.

Table 1. Relative energies ($\Delta E/\text{kcal mol}^{-1}$) and relative heats of formation ($\Delta H_f/\text{kcal mol}^{-1}$) of the structures of intermediates and transition states (TS) compared to the parameters of ground state structure **23a** for the hetero-Cope rearrangements of cyclopropene derivatives **23** ($R^1 = R^2 = \text{H}$).^{90,93}

Structure	X = NH		X = O		X = S	
	ΔE (see ^a)	ΔH_f (see ^b)	ΔE	ΔH_f	ΔE	ΔH_f
24 (TS for [1,3]-shift)	64.9	64.4	47.4	58.2	46.4	43.9
25 (TS for [3,3]-shift)	27.2 ^c	19.9	26.5	42.4	14.5	10.8
26	27.6	19.3	see ^d	see ^d	13.6	9.3
27	25.5	10.8	38.9	34.8	-5.0	-9.2

^a Energies calculated by the *ab initio* MP2 (fc)/6-31G** method.

^b Heats of formation were calculated by the MNDO/PM3 method.

^c Without consideration of zero-point vibrations, the structure of TS **25** ($X = \text{NH}$) is energetically less favourable than structure **26** ($X = \text{NH}$); the energy difference is 0.3 kcal mol⁻¹.

^d The structure was not localised on the corresponding potential energy surface.

It should be noted that the energy barriers predicted for the [3,3]-sigmatropic shifts of the dithioacyloxy group in molecule **23a** ($X = \text{S}$, $R^1 = R^2 = \text{H}$; see Table 1) are in good agreement with the barriers determined experimentally for compound **23a** ($X = \text{S}$, $R^1 = \text{Ph}$, $R^2 = \text{OEt}$), whereas the energies calculated for the migration mechanism involving the [1,3]-shift (with transition state structure **24**) are approximately 30 kcal mol⁻¹ higher and seem to be inconsistent with the results of dynamic NMR spectroscopy. The conclusion that the [3,3]-sigmatropic shift is

Figure 2. Energy profile of the pathway of [3,3]-sigmatropic shifts for the migrations of the allyl and heteroallyl groups around the cyclopropene ring in compound **23** ($X = \text{CH}_2, \text{O}, \text{NH}, \text{S}$).

Figure 3. Geometric parameters of the ground state structures of 1-(*N*-amidinyl)cyclopropene (**23**), transition states for its rearrangements via [1,3]- and [3,3]-sigmatropic shifts (**24** and **25**, respectively), biradical intermediate **26** in the pathway of the [3,3]-sigmatropic shift and tricyclic structure **27** isomeric to structure **26** calculated by the *ab initio* MP2/6-31G** method.⁹³

energetically more favourable is also true for circumambulatory migrations of other heteroallyl substituents in the cyclopropene ring. The energy barriers calculated for this reaction pathway (transition state structure **25**) are 15–45 kcal mol⁻¹ lower than the barriers to the [1,3]-shifts.^{90,93} According to the results of calculations, the Cope rearrangement ($X = \text{CH}_2$) and its hetero-analogue ($X = \text{NH}, \text{O}, \text{S}$) proceed in cyclopropene derivatives **23** as two-step reactions to give stable singlet biradical intermediates **26** (see Fig. 3). Unlike transition state structures **25**, biradical intermediates **26** have the symmetry C_s . The typical energy profile of the reaction pathway for [3,3]-sigmatropic shifts is shown in Fig. 2. Figure 3 presents the geometric parameters of the structures, *viz.*, the starting structure, the transition state structure and the structure of the biradical intermediate, generated through the [3,3]- and [1,3]-sigmatropic shifts in the course of the circumambulatory rearrangements of 1-(*N*-amidinyl)cyclopropene **23** ($X = \text{NH}, R^1 = R^2 = \text{H}$).

Calculations predicted that biradicals **26** should readily be transformed into more stable tricyclic structures **27**.

Actually, the investigation of thermolysis of 3-allylcyclopropene derivatives **19** (see Section III.8 and Refs 94 and 95) demonstrated⁸⁴ that the equilibrium mixture of products contained > 50% of the corresponding tricyclo[2.2.0.0]hexane derivative **27** ($X = \text{CH}_2$). The interconversion $\mathbf{26} \rightleftharpoons \mathbf{27}$ can be

considered as an example of isomerisation of the bond-stretching type.^{70, 96}

3. Rearrangements proceeding by a mechanism of [1,3]-sigmatropic shifts

The non-dissociative rearrangement pathway involving the forbidden suprafacial [1,3]-sigmatropic shift is untypical of cyclopropene derivatives, even of those containing organometallic groups, which exhibit very high ability to undergo circumbulatory migrations in the cyclopentadiene ring. For example, 3-(pentacarbonylrhenium)cyclopropene (**28a**), like its derivatives **28b,c**, is a structurally rigid compound. The transformations **28b** $\rightleftharpoons$ **28c** do not proceed in solution even at high temperature.⁷³

There is a high energy barrier (~ 32 kcal mol⁻¹) to the migration of the trimethylsilyl group in the 1,2-dimethyl-3-phenyl-3-trimethylsilylcyclopropene molecule.⁹⁷ By contrast, 3-phenylthio-1,2,3-triphenylcyclopropene **29a** (R = Ph) and di(1,2,3-triphenylcyclopropenyl) sulfide **29a** (R = C₃H₅) possess dynamic properties, and the ¹H and ¹³C NMR spectra of their solutions in C₂D₂Cl₄ are temperature-dependent (but are concentration-independent).⁴⁰

The energy barriers ($\Delta G_{25}^\ddagger$) to the migration of the phenylthio- and triphenylcyclopropenylthio groups calculated based on analysis of the line shapes of indicator signals in the ¹³C NMR spectra are 24.4 and 24.1 kcal mol⁻¹, respectively, which are 5–10 kcal mol⁻¹ higher than the barrier to migration of the phenylthio group in the cyclopentadiene system (see Section VI.4.b). This can be attributed to unfavourable conditions for delocalisation of the negative charge in the three-membered fragment of transition state structure **29c**.

R = Ph, C₃H₅.

The rearrangements of cyclopropene derivatives containing π bonds in the migrating groups M = X = Y are of interest. Semi-empirical (MINDO/3, MNDO/PM3 and AM1)⁹⁸ and *ab initio*⁹⁰ calculations demonstrated that the potential energy surfaces for C₃H₃NO and C₃H₃PO involve several alternative pathways of intramolecular rearrangements due to secondary orbital interactions between the migrating groups of this type and the ring; however, the relative energy of bicyclic structure **20b** (X = NO, R = H) corresponding to the transition state or intermediate for the 1,3-shift of the nitroso group around the cyclopropene ring is very high [35.3 kcal mol⁻¹; MP2(full)/6-31G**]. After the replacement of the nitrogen atom in the migrating group by the phosphorus atom, the local minimum of structure **20b** (X = PO, R = H) on PES calculated by the RHF/6-31G** method is only 5.1 kcal mol⁻¹ higher than the minimum of structure **20a** (X = PO, R = H). Interestingly, calculations^{90, 98} revealed local minima corresponding to rather stable pyramidal azatetrahedrane oxide **30a** [ΔE (RHF/6-31G**) = 89.0 kcal mol⁻¹] and pyramidal phosphatetrahedrane oxide **30b** [ΔE (RHF/6-31G**) = 55.4 kcal mol⁻¹]. However, these highly strained structures are not involved in the rearrangements of the η^1 isomers **20a** $\rightleftharpoons$ **20d**.

The possibility of the circumbulatory intramolecular migration for formylcyclopropene **31**, which is another isoelectronic analogue of nitrosocyclopropene, was considered theoretically at the MP2/6-31G** level⁹⁹ using the intrinsic reaction coordinate calculations¹⁰⁰ for the identification of reaction trajectories. It was found that η^2 structure **32** is a high-energy intermediate ($\Delta G_{25}^\ddagger > 42$ kcal mol⁻¹) for this rearrangement (Scheme 2).

It was expected that *exo* conformer **32** would undergo isomerisation into the *endo* form via ring inversion. However, it appeared that the transformation of structure **32** into the planar form involves the formation of two successive transition states **33a** and **33b**, and the local minimum corresponds not to *endo* conformer **32** but to the energetically more favourable isomers of Dewar furan **34**. It should be noted that conformer **33b** corresponds to the transition state structure for the circumbulatory $\eta^2 - \eta^3$ rearrangement of compound **34** involving the migration of the oxygen atom around the four-membered ring. An analogous rearrangement is also known for derivatives of Dewar thiophene (see Section III.5) but this rearrangement was not observed for derivatives of Dewar furan **34** (see Scheme 2). Therefore, the results of these calculations⁹⁹ led to the conclusion that the formyl group in the cyclopropene ring possesses low migration ability. Hence, it is beyond reason to expect that the rearrangement of compound **31** or its derivatives, unlike the rapid migration of the formyl group around the cyclopentadiene ring (see Section VI.2), is detectable by dynamic NMR spectroscopy.

4. Rearrangements of acylcyclopropenes catalysed by protonation

The intramolecular migration of acyl groups in cyclopropene derivatives is substantially accelerated under conditions of general or specific acid catalysis.^{5, 101} The complex formation with Lewis acids has the same or an even stronger effect (see Section VI.2).

According to MP2/6-31G** calculations,⁹⁹ protonation of formylcyclopropene **31** proceeds at the carbonyl oxygen atom to give four isomeric cations of which the *exo* conformer of 4-hydroxycyclobutenyl cation **35a** is most stable (Table 2, Fig. 4). The tetra-*tert*-butyl derivative of the 4-hydroxycyclobutenyl cation (**36**), which was prepared by oxidation of tetra-*tert*-butyltetrahedrane, has precisely this structure.¹⁰² It was demon-

Figure 4. Optimised (MP2/6-31G**) geometric parameters of the *exo* conformer of the 4-hydroxycyclobutenyl cation (35a), conformer 37a of the hydroxycyclopropenylcarbinyl cation and transition states 38a and 39a involved in the rearrangement. The charges on atoms (NBO scheme) are given in parentheses; the normal mode vectors of the imaginary frequency of vibration in TS are indicated by arrows.

Table 2. Relative energies (ΔE) of structures 35 and 37–39 (see Ref. 99) involved in the rearrangement of the 4-hydroxycyclobutenyl cation and the values of the only imaginary frequency (ν_{im}) of normal vibrations for structures of transition states (TS).

Structure	$\nu_{\text{im}}/\text{cm}^{-1}$	$\Delta E/\text{kcal mol}^{-1}$
35a	—	0
39a (TS)	272	10.1
37a	—	3.7
35b	—	8.1
39b (TS)	431	18.4
37b	—	4.9
38a (TS)	267	13.1
38b (TS)	266	20.1

Note. The energies were calculated by the *ab initio* MP2/6-31G** method.

strated that cation 36 undergoes a low-barrier rearrangement ($\Delta G^\ddagger \approx 15 \text{ kcal mol}^{-1}$) as a result of successive 1,2-shifts of the hydroxymethylene group around the cyclopropene ring. It was found that the chemical shift of the migrating sp^3 -hybridised carbon atom in the NMR spectrum of cation 36 remains unchanged over a broad temperature range. This is indirect evidence that only *exo* isomer 36 is involved in the reaction, and, consequently, the configuration of the migrating carbon centre undergoes inversion because the reaction pathway with retention of configuration would require the interconversion between the *exo* and *endo* conformers to occur in each step of the rearrangement.

This assumption was confirmed by *ab initio* calculations,⁹⁹ which demonstrated that the rearrangement of the 4-hydroxycyclobutenyl cation 35 proceeds in two steps through the intermediate formation of classical hydroxycyclopropenylcarbinyl cations 37. All main structures corresponding to local minima on PES of the $\text{C}_4\text{H}_5\text{O}^+$ cation, which are involved in degenerate

circumambulatory rearrangements of the conformers of the 4-hydroxycyclobutenyl cation, are shown in Scheme 3. The migrations of the protonated formyl group around the three-membered ring in the *exo* (35a) and *endo* conformers (35b) of the 4-hydroxycyclobutenyl cation proceed as non-concerted two-step reactions to give the *exo* (37a) and *endo* (37b) conformers of the hydroxycyclopropenylcarbinyl cation, respectively, as intermediates.

The calculated energy barriers to the 1,2-shifts of the hydroxymethylene groups (10.1 and 10.3 kcal mol^{-1} for conformers 35a and 35b, respectively) are in satisfactory agreement with the experimental activation free energy for the circumambulatory rearrangement of tetra-*tert*-butyl derivative 36 of cation 35a. The eclipsed conformer of hydroxycyclopropenylcarbinyl cation 38b, whose formation as an intermediate or transition state in the rearrangement would lead to retention of stereochemical configuration of the migrating carbon atom, lies on PES off this pathway. The intersection of the reaction pathways through the

ring inversion mechanism $35a \rightleftharpoons 38a \rightleftharpoons 35b$ requires that the higher energy barrier be overcome compared to that calculated for the rearrangement $35a \rightleftharpoons 39a \rightleftharpoons 37a$. Therefore, the two-step circumambulatory rearrangement of the *exo* isomer of 4-hydroxycyclobutenyl cation $35a$ accompanied by the inversion of configuration of the migrating carbon centre is the intramolecular rearrangement pathway corresponding to the minimum energy.

V. Circumambulatory rearrangements in a four-membered ring

High-level *ab initio* calculations^{99, 103, 104} and X-ray diffraction study¹⁰⁵ of cyclobutenyl cation **4** showed that this cation has a non-planar homoaromatic structure intermediate between the planar and bicyclo[1.1.0]butyl forms.

The migration of the group M in derivatives **4** can, in principle, proceed as a series of successive 1,2-shifts ([1,4]-sigmatropic shifts) of the migrating group around the four-membered ring (path *a*) or as [1,3]-sigmatropic shifts of the cyclopropyl fragment around the three-membered ring of the homoaromatic cyclobutenyl (homocyclopropenyl) cation (path *b*).

Koptug and co-workers¹⁰⁶ found that cation **40a** containing deuterated methyl groups at positions 1 and 3 underwent intramolecular exchange resulting in the distribution of the labelled groups between positions 1, 2 and 3, but not 4, of the ring. Hence, the mechanism associated with path *a* can be excluded.

The sigmatropic rearrangements of a series of other carbon-centred groups (alkyl, aryl and allyl) and the hydrogen atom around the cyclobutene ring, which are characterised by energy barriers higher than 15–25 kcal mol^{−1}, were reported.^{53, 107} By contrast, the migration of the anionic trichloroaluminium group in the permethylated σ complex of cyclobutadiene **4** (M = AlCl₃[−], R = Me) proceeded rather rapidly ($\Delta G_{25}^\ddagger < 25$ kcal mol^{−1}).¹⁰⁵ Unlike the rearrangements of the cyclobutenyl cations with the carbon-centred migrating groups, this dynamic process involves successive 1,2-shifts of the AlCl₃[−] group.

The formation of isomers of 2-azapyrylium salts in the reactions of σ complexes of dichloroethylene-, trichloroethylene- and tetraalkylcyclobutadienyldialuminium hexabromide with nitrosyl chloride¹⁰⁸ stimulated the examination of the possibility of the σ, π -mechanism for the rearrangement of nitrosocyclobutenyl cations **4** (M = NO, R = H). Semiempirical¹⁰⁹ and *ab initio*¹¹⁰ calculations demonstrated that the intermediate pyramidal cation with the η^4 -coordinated nitroso group corresponds to a local minimum on PES of the C₄H₄NO⁺ cation. However, alternative reaction pathways proceeding through the intermediate formation of structures such as N,O-substituted Dewar benzene and bullvalene are energetically more favourable.^{105, 109}

As demonstrated in Section III.5, circumambulatory rearrangements in neutral four-membered rings proceed by the η^2 – η^3 mechanism corresponding to the [1,3]-sigmatropic shift. The interconversion of isomers of bicyclopentene **41** is one of the first and most well-studied examples of this type of thermal rearrangement.¹¹¹ This rearrangement is highly stereoselective and proceeds according to the Woodward–Hoffmann rules with the inversion of stereochemical configuration of the migrating carbon atom in the cyclopropyl fragment.

$$\Delta G^\ddagger (41a \rightarrow 41b) = 21.7 \text{ kcal mol}^{-1}$$

Unlike the rearrangements of bicyclopentenes **41**, an analogous degenerate rearrangement of the *exo* conformer of the tetrakis(trifluoromethyl) oxide derivative of Dewar thiophene **42** (see Ref. 65) proceeds in solution very rapidly even at low temperatures: $\Delta G_{-124}^\ddagger = 6.8$ kcal mol^{−1}.

The possibility of the dynamic behaviour of the starting derivative of Dewar thiophene, which is the only known bicyclic isomer of aromatic five-membered heterocycles, was not examined. However, recent *ab initio* calculations (MP2/6-31 G**) and calculations at the B3LYP/6-31 G** level¹¹² demonstrated that 1,3-sigmatropic shifts of the oxygen and chalcogen atoms around the four-membered ring can occur in metastable Dewar isomers of furan, thiophene, selenophene and tellurophene **43** (X = O, S, Se, Te). The energy barriers estimated for these processes are no higher than 25 kcal mol^{−1}. The results of these calculations are given in Table 3 and Fig. 5.

Table 3. Relative energies (ΔE) (compared to the aromatic structure) and energy barriers ($\Delta E^\ddagger$) for the rearrangements of the Dewar isomers of five-membered heterocycles **43**.¹¹²

X in 43	$\Delta E^\ddagger$ /kcal mol ^{−1}		ΔE /kcal mol ^{−1}	
	MP2/6-31G**	B3LYP/6-31G**	MP2/6-31G**	B3LYP/6-31G**
O	66.6	67.8	23.2	16.1
S	57.2	57.2	26.4	16.0

Topology of PES for the 1,3-sigmatropic rearrangements of Dewar isomers of furan, thiophene, selenophene and tellurophene according to the results of *ab initio* calculations (MP2/6-31G**) ¹¹² and geometric parameters of the starting (at the top) and transition (at the bottom) structures.

VI. Circumambulatory rearrangements of element-centred migrating groups in the cyclopentadiene ring

Cyclopentadiene and its derivatives belong to the most important group of ligands in the chemistry of coordination compounds. That is the reason why their structures and dynamic behaviour associated with circumambulatory rearrangements were studied in close detail. Let us consider these rearrangements by classifying them according to the position of the central atom of the migrating group in the Periodic table.

1. Migrating substituents formed by Group 13 elements

Circumambulatory rearrangements of the migrating groups BR_2 , AlR_2 , GaR_2 and InR_2 ($\text{R} = \text{Alk}, \text{F}, \text{Cl}, \text{Br}, \text{I}$) in unsubstituted and transmethyated cyclopentadiene rings proceed rather rapidly ($\Delta G^\ddagger \leq 20 \text{ kcal mol}^{-1}$). Consequently, completely averaged ^1H or ^{13}C NMR spectra of compounds **44** were recorded at normal temperatures.^{16, 20, 26, 113} Although direct experimental evidence supporting the mechanism of these rearrangements is lacking, one can say with a fair degree of assurance that each step involves the 1,2-shift ([1,5]-sigmatropic shift) of the migrating group. This conclusion was confirmed by MNDO calculations.¹¹⁴

$\text{R}^2 = \text{H}, \text{Me}.$

In the presence of electron-releasing groups R in the migrating centre, the rate of rearrangements substantially decreases. As a result, the energy barriers to migration of the $\text{B}(\text{NMe}_2)_2$, $\text{B}(\text{OMe})_2$ and $\text{B}(\text{SEt})_2$ groups in the pentamethylcyclopentadienyl ring become measurable on the NMR time scale ($\Delta G_{25}^\ddagger = 17.2$, 14.4 and 10.2 kcal mol^{-1} , respectively).¹¹⁵ In pentamethylcyclopentadienylboranes in which the boron atom is coordinated by the pyridine molecule (lone electron pair on the nitrogen atom of the pyridine ring fills the unoccupied p orbital of the boron atom), the rearrangement is completely decelerated ($\Delta G_{25}^\ddagger > 25 \text{ kcal mol}^{-1}$).

An interesting rearrangement of a series of aluminium, gallium, and indium derivatives of 1-dimethylaminoethyl-2,3,4,5-tetramethylcyclopentadiene **45** was described.¹¹⁶ The ^1H and ^{13}C NMR spectra of compound **45** have two singlets in a ratio of 1 : 1 belonging to four Me groups at the carbon atoms of the cyclopentadiene ring, the spectral pattern being temperature-independent. The presence of the intramolecularly coordinated $\text{Me}_2\text{NCH}_2\text{CH}_2$ substituent restricts the shifts of the migrating substituents formed by Group 13 elements to only the adjacent carbon atoms. Hence, the dynamic behaviour is determined by

$\text{M} = \text{Al}, \text{R} = \text{H}, \text{Me}, \text{Et}, \text{Cl}, \text{Br}, \text{I}; \text{M} = \text{Ga}, \text{R} = \text{Cl}; \text{M} = \text{In}, \text{R} = \text{Cl}.$

rearrangements between isomers **45a–c**, which allowed the authors of the study¹¹⁶ to compare this mechanism with the movement of windscreen wipers.

2. Migrating substituents formed by Group 14 elements

1,2-Alkyl shifts in the cyclopentadiene ring can be observed at temperatures higher than 300 °C, which corresponds to activation free energies higher than 40 kcal mol^{−1}.¹⁸ According to more accurate data obtained for the rearrangement of hexamethylcyclopentadiene containing one trideuteriomethyl group, the activation barrier to migration of the CH₃ or CD₃ group is 43.1 kcal mol^{−1}.¹¹⁷ In 5-(*p*-nitrobenzyl)-1,2,3,4,5-pentamethoxycarbonylcyclopentadiene, the migration of the *p*-nitrobenzyl group requires that the energy barrier of 30 kcal mol^{−1} should be overcome,¹¹⁸ which is close to the condition of structural non-rigidity ($\Delta G_{25}^\ddagger \leq 25$ kcal mol^{−1}).

It was hypothesised¹¹⁹ that circumambulatory rearrangements of 5-R-1,2,3,4,5-pentamethoxycarbonylcyclopentadiene derivatives **46** in polar solvents can be controlled by the ionisation–recombination mechanism involving heterolysis of the C_{sp}³–C_{Cp} bond. Actually, compounds **46** dissociate in methanol to form solvated ion pairs **46a**. Apparently, the collapse of the ion pairs giving rise to topomers **46** (degenerate circumambulatory rearrangement) can compete with the irreversible reaction with the solvent.

R = CH₂OMe, CHPh₂, CH₂C₆H₄OMe-4, adamantan-1-yl.

C_{sp}²-Centred groups have higher ability to migrate around the five-membered ring as compared to C_{sp}³-centred groups. The energy barrier ($\Delta G_{25}^\ddagger$) to the 1,2-shift of the phenyl group in 5-deuteriomethyl-1,2,3,4-tetramethyl-5-phenylcyclopentadiene is 37.8 kcal mol^{−1}.¹²⁰ Thermal rearrangements of a series of 5-substituted pentamethoxycarbonylcyclopentadienes^{121, 122} proceed as successive 1,2-shifts of the substituent, the energy barrier to this migration is only slightly higher than 25 kcal mol^{−1}. At 25 °C, the migration of the formyl group in 5-formyl-1,2,3,4,5-pentamethylcyclopentadiene **47** (R = H) proceeds much more rapidly ($k = 90$ s^{−1}); its energy barrier is only 14.8 kcal mol^{−1}.¹²³ This rearrangement is favoured by a secondary orbital interaction involving π -HOMO of the cyclopentadiene fragment and π^* -LUMO of the carbonyl group in transition state structure **47c**. Semiempirical calculations by the MINDO/3 method¹²⁴ confirmed that the orbital interaction of this type makes a substantial contribution to stabilisation of transition state structure **47c**.

In compound **47** (R = H), the formyl group undergoes rapid circumambulatory rearrangements in the five-membered ring, whereas other 5-acyl derivatives of 1,2,3,4,5-pentamethylcyclopentadiene are structurally rigid. To decrease the energy barrier to migration of the above-mentioned groups, powerful electron-withdrawing substituents, such as the trifluoro- or trichloromethyl group, should be introduced into the acyl fragment. The energy barriers ($\Delta G_{25}^\ddagger$) to migration of these groups around the pentamethylcyclopentadiene ring are 20.6 (hexachlorobutadiene) and 25.4 kcal mol^{−1} (DMF-d₇), respectively.¹²⁵ The coordination of the acyl oxygen atom by Lewis acid provides an alternative and more efficient way of accelerating the migration of the acyl group.¹²⁶ Upon the formation of complexes with AlCl₃, compounds **47** form bicyclic zwitterions **48**, which undergo circumambulatory rearrangement involving a series of 1,3-shifts of the cyclopropane fragment (η^2 – η^3 mechanism). The energy barriers to this rearrangement depend on the ability of the substituent R in zwitterion **48** to stabilise the positive charge and their values vary from ~ 5 (R = C₆H₄CF₃) to 10.9 (R = Me) and then to 18.2 kcal mol^{−1} (R = C₆H₄OEt).¹²⁶

Annulation of the benzene ring onto cyclopentadiene leads to an increase in the energy barrier to 1,2-shifts of carbon-centred groups by 9–11 kcal mol^{−1}. Because of this, thermal rearrangements in indene derivatives cannot be detected on the NMR time scale. In studies,^{127–129} the migration abilities of various C_{sp}³-, C_{sp}²- and C_{sp}-centred groups were examined using optically active 1,3-dimethylindenes **49**.

If the migration of the groups R proceeds more slowly than the migration of the hydrogen atom in 2*H*-indene **49b** ($k_2 > k_{-1}$), the rate of formation of compound **49c** can serve as a measure of the migration ability. If the group R undergoes more rapid migration compared to the hydrogen atom in molecule **49b** ($k_{-1} > k_2$), as in the case of R = CHO or Ar, the constant k_1 can be estimated based on the racemisation rates of optically active indenenes. The migration ability of the groups R thus estimated decreases in the following series: CHO > Acyl > H > CH=CH₂ > CO₂Me > C≡N > C≡CH > Ph > 1-naphthyl > Alk.^{127–129}

The migration ability of groups increases with increasing atomic number of the element within the same group of the Periodic table, as evidenced by a substantial acceleration of the rearrangements of the SiR_3 , GeR_3 , SnR_3 and PbR_3 migrating groups as compared to alkyl groups. Even a qualitative analysis of the ^1H NMR spectra of 5-trimethylsilylcyclopentadiene⁴² revealed the pronounced fluxional behaviour of this compound. More recent studies demonstrated that the energy barriers to migration of the trimethylsilyl group around the cyclopentadiene ring are $\sim 15 \text{ kcal mol}^{-1}$. These energies are most convenient for studying the kinetics and permutation mechanisms by dynamic NMR spectroscopy. This is the reason why the migration processes in silylcyclopentadienes have attracted particular attention in early studies of circumambulatory rearrangements (see, for example, the reviews^{15–17, 19, 20}). Generally, the 1,2-shifts of tin and lead-containing migrating groups in the five-membered ring of various cyclopentadiene derivatives proceed at very high rates, which cannot be measured directly using standard techniques of ^1H or ^{13}C NMR spectroscopy.^{130–132} The energy barriers to 1,2-shifts of substituents formed by Group 14 elements are given in Table 4.

Table 4. Energy barriers ($\Delta G^\ddagger$) to the 1,2-shifts of Si-, Ge- and Sn-centred groups (M) in cyclopentadiene derivatives $\text{C}_5\text{R}_5\text{M}$.

^a The activation energy (E_a).

Unlike the rearrangements of cyclopentadiene derivatives in which the migrating fragments are formed by Group 13 elements, the barriers to rearrangements of cyclopentadienylsilanes, -germanes and -stannanes are only slightly affected by substituents at the central atom of the migrating fragment. This is attributed to the absence of the low-lying unoccupied p orbital in the sp^3 -hybridised central atoms of the SiR_3 and GeR_3 groups (transition state structure **10a**), which plays an important role in stabilisation of the transition state structures of the migrating fragments of Group 13 elements.

The mechanism of rearrangements of η^1 -indenyl derivatives of main-group elements was analysed in the review,¹³⁷ where the reactivities of these compounds and indenyl derivatives of transition metals were surveyed and their use as precursors of chiral metallocene catalysts was discussed. The conclusion that migrations of the Si-, Ge-, Sn- and Pb-centred groups around the ring proceed as [1,5]-sigmatropic shifts giving rise to short-lived isoindene intermediates was demonstrated to be of general character.

Rearrangements of cyclopentadiene derivatives containing two or three SiR_3 groups in the ring were studied in detail by Ustynyuk and co-workers⁴⁴ and other researchers.²⁶ The equilibrium mixtures of di- SiR_3 -substituted cyclopentadienes bearing no other substituents in the ring can contain up to seven isomers, which are generated as a result of a series of 1,2-shifts of hydrogen atoms and SiR_3 groups in the ring. However, only two isomers,

viz., **50a** and **50b**, are usually observed. These isomers are produced by successive 1,2-shifts of the SiR_3 groups, the first isomer being the major product. The high stability of compound **50a** results from the hyperconjugative π -aromaticity of 5,5-disubstituted cyclopentadienes containing electropositive groups, such as SiR_3 , GeR_3 or SnR_3 .¹³⁸

3. Migrating substituents formed by Group 15 elements

a. Nitrogen-centred migrating groups

Ionisation–recombination mechanism. Circumambulatory migrations of N-centred substituents around the five-membered ring were first studied for arylazocyclopentadienes **51** whose rearrangements proceed through the ionisation–recombination mechanism.^{38, 39}

$\text{E} = \text{CO}_2\text{Me}$; $\text{R}^2 = \text{CO}_2\text{Me}, \text{Me}$ (for notations of R^1 , see Table 5).

The design of these rearrangements is based on the strategy opposite to that used for cyclopropene derivatives (see Sections III.1 and IV.1). It was demonstrated that there is a rather fine balance between the relative stabilities of covalent (**51a**, **51b**) and ionic (**51c**) isomers of arylazocyclopentadienes. To stabilise intermediate ion pair **51c**, the negative charge of the aromatic cyclopentadienyl anion should be additionally delocalised by introducing π -acceptor substituents into the Cp ring. For example, heating of arylazopentamethylcyclopentadienes **51** ($\text{R}^1 = \text{NO}_2$, $\text{R}^2 = \text{E} = \text{Me}$) did not lead to the heterolysis of the $\text{C}_{\text{Cp}}-\text{N}$ bond; instead, the rearrangement involved the migration of the arylazo group to the adjacent carbon atom.¹³⁹ At the same time, electron-releasing substituents in the benzene ring stabilise excessively ion pair **51c**, which becomes the major form of existence of compounds **51** ($\text{E} = \text{CO}_2\text{Me}$). In the solid state, such isomers of arylazopentamethoxycarbonylcyclopentadienes prevail even in the case of $\text{R}^1 = 4'\text{-NO}_2$ (Fig. 6).

At low temperature, mono-, di- and trinitrophenylazo derivatives **51** exist in benzonitrile as covalent compounds, which readily dissociate to form ion pairs **51c** upon heating. The collapse of the latter leads to the randomisation of the position of the arylazo group in the ring and, consequently, to the circumambulatory migration around the cyclopentadiene ring. The rate constants and activation parameters for the rearrangements of compounds **51** proceeding according to the ionisation–recombination mechanism are given in Table 5. For solutions of arylazo derivatives **51** in acetonitrile, these parameters are concentration-independent in the range of $0.03\text{--}0.30 \text{ mol litre}^{-1}$, which is indicative of the intramolecular nature of these rearrangements.

Figure 6. Molecular structures of 5-(2,4-dinitrophenylazo)-1,2,3,4,5-pentamethoxycarbonylcyclopentadiene (**a**) and 5-(4-nitrophenylazo)-1,2,3,4,5-pentamethoxycarbonylcyclopentadiene **51** (**b**) according to the results of X-ray diffraction analysis.^{38,39}

Heating of solutions of arylazopentamethoxycarbonylcyclopentadienes led to elimination of molecular nitrogen followed by rearrangements of the resulting arylpentamethoxycarbonylcyclopentadienes caused by 1,2-shifts of the methoxycarbonyl group around the five-membered ring.^{121, 122, 140}

1,2-Shifts. The slow degenerate circumambulatory rearrangements of 1,2,3,4,5-pentamethyl-5-nitrocyclopentadiene ($\Delta G_{172}^\ddagger = 25.1$ kcal mol⁻¹ in DMSO)¹⁴¹ and 1,2,3,4,5-pentamethoxycarbonyl-5-nitrocyclopentadiene ($\Delta G_{25}^\ddagger = 24$ kcal mol⁻¹ in chlorobenzene) and non-degenerate rearrangements of 5-alkyl(benzyl)-5-nitro-1,2,3,4-tetramethoxycarbonylcyclopentadienes **52a**¹⁴² proceed as 1,2-shifts ([1,5]-sigmatropic shifts) around the periphery of the cyclopentadiene ring. Compounds **52a** were prepared as mixtures with their isomers **52b** (in a ratio of ~ 1 : 1) by nitration of the corresponding cyclopentadienes in acetic anhydride at 50 °C and were then separated by chromatography. The energy barriers to the 1,2-shifts of the nitro group ($\Delta G_{25}^\ddagger = 24.0$ –26.6 kcal mol⁻¹) were determined from the

kinetics of establishment of an equilibrium between these isomers, which involves two successive 1,2-shifts of the nitro group proceeding through the intermediate formation of isomer **52c** (which was not observed by ¹H NMR spectroscopy due to its low equilibrium concentration).

R = CO₂Me, Me, CHMe₂, CH₂Ph.

Table 5. Kinetic and activation parameters for the migration of the arylazo groups in 5-arylazo-1,2,3,4,5-pentamethoxycarbonylcyclopentadienes **51** (R² = CO₂Me) in benzonitrile.^{38,39}

^a $\Delta S^\ddagger$ are given in cal mol⁻¹ deg⁻¹.

All attempts to synthesise nitrosocyclopentadiene derivatives failed. The rearrangements of these compounds were theoretically simulated by the semiempirical MINDO/3 method.¹⁴³ These calculations revealed two energetically almost equivalent transition state structures corresponding to the 1,2- and 1,3-shifts of the nitroso group. The relatively high stability of the latter structure is attributed to the fact that it conforms to the rules of electron calculation for pyramidal structures of this type.^{30,31}

[3,3]-Sigmatropic shifts. *N,N'*-Diaryl-*N*-(1,2,3,4,5-pentamethoxycarbonylcyclopentadienyl)amidines **53** generated by the reactions of *N,N'*-diarylamidines with compounds **52** (R = CO₂Me) underwent rapid degenerate rearrangements involving successive [3,3]-sigmatropic shifts of the amidinyl groups.^{144,145}

The fact that the rearrangements proceed as successive 3,3-shifts rather than as 1,2-shifts of the amidinyl groups is confirmed by the simultaneous averaging of the signals of the methyl groups of the aryl and methoxy fragments in the ^1H NMR spectra of solutions of diarylamidines **53** in hexachlorobutadiene observed at high temperatures. The kinetic parameters (Table 6) of the rearrangements, which were calculated based on analysis of full line shapes of both groups of indicator signals, are identical to each other. Quantum-chemical calculations (see Section III.8) provide additional evidence supporting the [3,3]-sigmatropic shifts (hetero-Cope rearrangement) in the amidinylcyclopentadiene molecules.

^a $\Delta S^\ddagger$ are given in cal mol⁻¹ deg⁻¹.

The thermal rearrangement of 5-isoselenocyanato-1,2,3,4,5-pentaphenylcyclopentadiene (**54a,b**) is an example of non-degenerate circumambulatory rearrangements in the cyclopentadiene system proceeding as [3,3]-sigmatropic shifts.¹⁴⁶ In solutions, this compound is in equilibrium with isomeric selenocyanate **54c** (in ratios of 3 : 2 and 2 : 3 in CDCl_3 and toluene- d_8 , respectively). The isothiocyanate derivative of pentaphenylcyclopentadiene does not exhibit fluxional behaviour in solutions (as well as 5-isothiocyanato-1,2,3,4,5-pentamethylcyclopentadiene¹⁴⁷), whereas the ^1H and ^{13}C NMR spectra of an equilibrium mixture of selenium-containing analogues **54a–c** are temperature-dependent. This indicates that two different competitive circumambulatory rearrangements proceed simultaneously. The more rapid rearrangement involves 1,2-shifts of the selenocyanate group around the five-membered ring (see Section VI.4.3), whereas the slower rearrangement ($\Delta G_{135}^\ddagger = 22$ kcal mol⁻¹) is associated with interconversions of isomers as a series of successive [3,3]-sigmatropic shifts involving all carbon atoms of the ring.

b. Phosphorus-centred migrating groups

In the unsubstituted cyclopentadiene ring, migrations of phosphorus-centred groups and hydrogen atoms proceed at similar rates, although in most cases the rates of 1,2-shifts of the P-centred migrating groups are higher than those of the hydrogen atoms.^{26, 148} The ability of phosphorus-centred groups to migrate was estimated by studying the kinetics of circumambulatory rearrangements of compounds in which non-migrating substituents are bound to all carbon atoms of the cyclopentadiene ring. The energy barriers (E_a) to 1,2-shifts of selected phosphorus-centred groups M in the $\text{C}_5\text{Me}_5\text{M}$ molecules are given below.¹⁴⁹

M	E_a /kcal mol ⁻¹	M	E_a /kcal mol ⁻¹
P=C(SiMe ₃) ₂	< 8	PCl ₂	12.0 ± 1.6
PH ₂	31.3 ± 1.8	PBr ₂	5.2 ± 3.1
PMe ₂	23.0 ± 0.5	P(CN) ₂	16.4 ± 0.3
PMeCl	16.4 ± 1.1	P(OMe) ₂	21.2 ± 0.4
PBu ^t Cl	21.3 ± 1.5	P(SMe) ₂	17.5 ± 1.3
PPh ₂	24.3 ± 1.5	PMe ₃ ⁺	> 35
PF ₂	16.7 ± 0.7	PR ₂ Cr(CO) ₅	> 35

Compounds containing two-coordinate phosphorus atoms exhibit a pronounced fluxional behaviour, whereas compounds containing four-coordinate phosphorus atoms are structurally rigid. The migration ability of the P(III)-centred groups sharply increases with increasing electronegativities of the ligands bound to the phosphorus atom. This fact can be explained taking into account the stabilising interaction between the orbitals of the lone electron pair on the P(III) centre and LUMO of the cyclopentadiene fragment: the electronegative ligands decrease the energy level of the orbital of the lone pair, and the energy gap between the above orbitals is narrowed. According to the results of MNDO calculations,¹⁵⁰ the 1,2-shifts of P(III)-centred migrating groups can proceed either with retention or inversion of configuration at the phosphorus atom depending on the type of the ligands bound to this atom. Thus, electropositive ligands facilitate the inversion of configuration at the migrating centre, whereas electronegative ligands are favourable for the retention of configuration. The tendency to retention of configuration increases in the series P < As < Sb.

c. Arsenic- and antimony-centred migrating groups

It was found that ligands bound to Group 15 elements have an analogous effect on the ability of these elements to undergo migration in cyclopentadienyl compounds of arsenic and antimony. The 1,2-shifts of the AsMe₂ groups in $\text{C}_5\text{H}_5\text{AsMe}_2$ and the shifts of the AsCl₂ group in $\text{C}_5\text{H}_5\text{AsCl}_2$ are characterised by the energy barriers $E_a = 15.0$ kcal mol⁻¹ and $E_a < 7$ kcal mol⁻¹, respectively. There is a pronounced tendency for a substantial increase in the migration ability of the groups formed by heavier elements on going from P- to As- and Sb-centred migrating groups. The activation energies for the circumambulatory rearrangements of dimethyl(1,2,3,4,5-pentamethylcyclopenta-

dienyl)phosphane, -arsane and -stibane are 23.0, 17.1 and 11.3 kcal mol⁻¹, respectively.²⁶

1,2,3,4,5-Pentamethylcyclopentadienyldihaloarsanes C₅Me₅.AsHal₂ (Hal = F, Cl, Br, I) are characterised by pronounced structural non-rigidity. Even at -90 °C, the ¹H NMR spectra of these compounds have only narrow singlets for the protons of the Me groups. In the ¹³C NMR spectra, the sp³- and sp²-hybridised carbon atoms and the carbon atoms of the Me groups¹⁵¹ also give common singlets. Moreover, attempts to freeze the migration of the AsHal[N(SiMe₃)₂] group in monoamide-substituted arsanes on the NMR time scale failed.¹⁵²

High rate constants of 1,2-shifts of migrating heavy Group 15 elements are attributed to the fact that there are favourable conditions for interactions between the π orbitals of the central atom and the cyclopentadienyl fragment in these compounds.^{152, 153} A comparison of the structures¹⁵³ of three fluxional stibanes **55a–c**, for which an increase in non-rigidity would be expected on going from unsubstituted compound **55a** to dichloride **55c**, showed that the mode of binding gradually changes from η¹(σ) to η³(π). In molecule **55c**, the C–C bond lengths in the five-membered ring are equalised, which is indicative of an increase in the ionicity of the compound giving rise to the symmetrical cyclopentadienyl anion. The sequence of structures **55a–55c** reflects a part of the pathway of the 1,2-shift of heavy migrating substituents formed by Group 15 elements in cyclopentadiene systems.

The bulky substituents in the cyclopentadiene ring influence both the relative stabilities of isomers generated in the course of circumambulatory rearrangements and the energy barriers to 1,2-shifts of the migrating groups M = XR₂ (X = P, As, Sb). For example, di-*tert*-butylcyclopentadienyl derivatives of arsanes and stibanes **56** occur primarily as isomers containing the substituent M in the allyl position and two *tert*-butyl groups in vinyl positions. The rearrangements involve shifts of the migrating groups between two vicinal carbon atoms of the ring.¹⁵⁴

X = As, Sb.

5-M-(1,2,3,5-Tetraisopropyl)cyclopentadienes **57** (M = PCl₂, PBr₂, AsCl₂ and SbCl₂) have different dynamics.¹⁵⁵ Analysis of the ¹H NMR spectra showed that the rearrangements caused by migrations of the PCl₂ (*E*_a = 13.1 ± 0.3 kcal mol⁻¹) and PBr₂ (*E*_a = 13.2 ± 0.3 kcal mol⁻¹) groups proceed as 1,2-shifts of the phosphorus atoms in space limited only by the carbon atoms of the ring adjacent to the CH centre, whereas the C(1) and C(2) atoms remain intact.

4. Migrating substituents formed by Group 16 elements

a. Oxygen-centred migrating groups

1,2-Shifts of oxygen-centred migrating groups around the cyclopentadiene ring proceed too slowly to be detected by dynamic NMR spectroscopy. Investigation of the kinetics of migrations of aryloxy groups is based on measurements of the lifetimes of individual isomers of 1,2,3,4,5-pentaaryl-5-aryloxycyclopentadienes **58**. For this purpose, a weak disturbance of degeneration of the rearrangement is required, which can be achieved, for example, by replacing one of the phenyl groups in the ring by the *p*-tolyl group.¹⁵⁶

The energy barriers (averaged for the 1,2-OAr-shifts **58a** → **58b** and **58b** → **58c**) for the rearrangement of isomers of 5-aryloxy-1,2,3,4-tetraphenyl-5-*p*-tolylcyclopentadiene (180 °C, in diphenyl oxide) are given below.¹⁵⁶

R	NH ₂	OMe	Me	H	Cl	NO ₂
Δ <i>G</i> ₁₈₀ [‡] /kcal mol ⁻¹	23.8	24.6	24.8	25.5	26.3	31.6

It can be seen that the presence of electron-releasing substituents in the migrating groups facilitates this rearrangement, whereas electron-withdrawing substituents lead to its deceleration. These results provide evidence supporting polar transition state **10c**, which was proposed for [1,5]-sigmatropic shifts in cyclopentadiene molecules. Semiempirical quantum-chemical calculations¹⁴³ of the rearrangement of compound **58** also confirmed that the three-membered ring of the η²-transition state structure bears a positive charge. Semiempirical calculations showed the occurrence not only of the expected η² structure but also of the second η³-type transition state structure for the symmetry-forbidden 1,3-shift of the aryloxy group; the latter is energetically less favourable than the 1,2-OAr-shift (the energy difference is 8–10 kcal mol⁻¹).

The circumambulatory rearrangements caused by [3,3]-sigmatropic shifts of O-centred migrating groups are also characterised by high-energy barriers, which do not satisfy the conditions of structural non-rigidity.^{157, 158} The kinetic parameters for the rearrangements of acyloxycyclopentadienes **59** (R¹ = C₆H₄Me-4) were determined from the rate at which the equilibrium between isomers **59a**, **59b** and **59c** (which were prepared by treatment of a mixture of isomers of bromo-*p*-tolyltetraphenylcyclopentadiene with silver carbonates) was established in solution (Scheme 4). These parameters are given in Table 7.

The equilibrium ratios between isomers **59** correspond to the statistical distribution **59a**:**59b**:**59c** = 1:2:2. The rearrangement rate is concentration-independent. No paramagnetic intermediate species were detected in the temperature range of 25–160 °C, which is indicative of the concerted intramolecular mechanism of the reaction. The fact that the rearrangement proceeds *via* [3,3]-sigmatropic shifts, *i.e.*, as the sequence **59a** ⇌ **59b** ⇌ **59c** ⇌ **59c'** ⇌ **59b'** ⇌ **59a** (see Scheme 4), rather than *via* the alternative [1,5]-sigmatropic shift as the sequence **59a** ⇌ **59c'** ⇌ **59b** ⇌ **59b'** ⇌ **59c** ⇌ **59a** was proved in the study of the time dependence of the ¹H NMR spectra of 5-ben-

zyl-1,2,3,4-tetra-phenyl-5-trifluoroacetoxycyclopentadiene **59a** ($R^1 = \text{Bn}$, $R^2 = \text{CF}_3$) (Fig. 7).

Due to the presence of the stereogenic C_{sp^3} centre in the ring of isomers **59c,c'** ($R^1 = \text{Bn}$, $R^2 = \text{CF}_3$), the energetically favourable reaction pathway can be readily identified based on ^1H NMR spectra, which show diastereotopic splitting of the signals for the methylene protons of the benzyl substituent R^1 characteristic of the prochiral methylene group (AB spectrum, δ 2.88 and 3.97, $^2J = 14.5$ Hz). In the ^1H NMR spectrum of isomers **59b,b'** ($R^1 = \text{Bn}$, $R^2 = \text{CF}_3$) in which the stereogenic C_{sp^3} centre is most far removed from the prochiral group, this splitting is absent. The assignment of the singlets for the methylene protons at δ 3.48 and 3.62 to isomers **59a** (symmetry C_s) and **59b**, respectively, was made after their separation and was also based on the X-ray diffraction data for compound **59a** ($R^1 = \text{Bn}$, $R^2 = \text{CF}_3$).¹⁵⁷ In the course of storage of a solution of **59a** at 80 °C, a singlet (δ 3.62) assigned to the methylene protons of isomer **59b** appeared and gradually grew in its ^1H NMR spectrum. Further heating led to slow accumulation of isomer **59c** in the reaction mixture, which was detected from the appearance of the AB quartet of the methylene group. The equilibrium between interconvertible isomers of **59** (**59a** : **59b** : **59c** = 65 : 22 : 13) was established upon storage of a solution in *o*-dichlorobenzene at 80 °C for 2 h. This spectral behaviour is unambiguously indicative of a sequence of interconversions of isomers **59** corresponding to the mechanism of [3,3]-sigmatropic shifts (see Scheme 4). The activation free energies ($\Delta G_{80}^\ddagger$) of interconversions of different isomers **59** ($R^1 = \text{Bn}$, $R^2 = \text{CF}_3$) calculated from the time dependence of the intensities of the signals in the ^1H NMR spectra are in the range of 26.5–27.2 kcal mol⁻¹. The difference in the mechanisms of migrations of the aryloxy and acyloxy groups around the cyclopentadiene ring is manifested also in the difference in the influence of the substituents in the migrating group on the energy barrier for the rearrangement. As can be seen from Table 7, the

Table 7. Equilibrium ratios between the isomers at 130 °C, rate constants and activation parameters for the rearrangements of compounds **59** ($R^1 = \text{C}_6\text{H}_4\text{Me-4}$) in *o*-dichlorobenzene.¹⁵⁷

^a $\Delta H^\ddagger$ and $\Delta G_{25}^\ddagger$ are given in kcal mol⁻¹.

^b $\Delta S^\ddagger$ are given in cal mol⁻¹ deg⁻¹.

Figure 7. Time dependence of the ^1H NMR spectra of compounds **59** ($R^1 = \text{Bn}$, $R^2 = \text{CF}_3$) in *o*-dichlorobenzene in the region of signals for the protons of the benzyl group (δ 2.50–4.30) at 25 °C (a) and after heating at 80 °C for 0.5 (b), 1 (c) and 2 h (d).¹⁵⁷

rearrangements of compounds **59**, unlike the analogous rearrangements of aryloxypentaarylcyclopentadienes **58**, are accelerated upon the introduction of electron-withdrawing substituents R^2 into the migrating group.

Unlike the [3,3]-sigmatropic rearrangements of allyl acetates catalysed by mercury or palladium salts,¹⁵⁹ the circumambulatory rearrangements of their oxygen analogues **59** are rather weakly catalysed [$\Delta(\Delta G_{80}^\ddagger) = 1.3$ –2.9 kcal mol⁻¹] by $(\text{CF}_3\text{CO}_2)_2\text{Hg}$ and $[\text{PdCl}_2(\text{PhCN})_2]$. This can be attributed to steric hindrance to the formation of complexes of these salts with oxygen centres in tetra- and pentaaryl-substituted compounds **59**.

b. Sulfur-centred migrating groups

1,2-Shifts. The rearrangement of bis(pentamethylcyclopentadienyl) sulfide **60** was not observed on the NMR time scale.¹⁶⁰ However, the replacement of one pentamethylcyclopentadienyl fragment in molecule **60** by the aryl group gives rise to fluxional compounds **61a**; the energy barriers to migration of the arylthio

61: $R^1 = \text{Me}$ (a), CO_2Me (b) (for notations of R^2 , see Table 8).

group around the cyclopentadiene ring are in the range $\Delta G^\ddagger = 22\text{--}24.5\text{ kcal mol}^{-1}$.^{161, 162}

The replacement of the methyl groups in the cyclopentadienyl fragment of compound **61a** by the electron-withdrawing methoxycarbonyl groups leads to a substantial acceleration of the rearrangement.^{161, 163–166} As can be seen from Table 8, the energy barriers for degenerate rearrangements of compounds **61b** are 5–8 kcal mol^{−1} lower than the corresponding barriers for sulfides **61a** containing the same migrating groups. This observation and the fact that the electron-releasing substituents in the aryl rings of the migrating groups promote the rearrangement are consistent with polar transition state structure **10c** for 1,2-shifts in the cyclopentadiene system. Analysis of line shapes in the temperature-dependent ¹H and ¹³C NMR spectra of compounds **61a, b** and semiempirical (MINDO/3 and MNDO) calculations of the pathways of this rearrangement¹⁶⁷ demonstrated that 1,2-shifts are preferable for migrations of the arylthio groups.

Table 8. Energy barriers ($\Delta G^\ddagger_{25}$) to 1,2-shifts of the arylthio groups in the cyclopentadiene ring of compounds **61**.

Structure	R ² in compound 61	Solvent	$\Delta G^\ddagger_{25}$ /kcal mol ^{−1}	Ref.
61a	4-OMe	<i>o</i> -dichlorobenzene	24.5	161, 163

61b	4-OMe	chlorobenzene	16.1	161, 163
61b	H	"	17.4	161, 163
61b	3-NO ₂	"	17.6	161, 163
61b	2-NO ₂	"	18.5	161, 163
61b	4-NO ₂	"	17.8	161, 163
61b	2,4-(NO ₂) ₂	"	19.0	161, 163
61b	4-CF ₃	"	20.7	161, 163

An interesting feature of compounds **61** is their half-sandwich structures, *i.e.*, the *s-cis* conformation with respect to the C_{CP}–S bond. This conformation is favourable for sulfides **60**¹⁶⁰ and, according to the results of X-ray diffraction studies, for tetra- and pentamethoxycarbonyl derivatives **61b**.^{164, 165} For the migration of the phenylthio group, not only the usual η^2 -type transition state structure **6** for the 1,2-shift but also the alternative η^3 -type transition state structure **7** were found to be possible. The latter structure is energetically less favourable (by 10 kcal mol^{−1}) than transition state structure **6** for the 1,2-shift. The opposite situation is observed for the migration of the disulfide (SSR) group. In the latter case, the transition state corresponding to the 1,3-shift is energetically more favourable (by 7 kcal mol^{−1}). This can be attributed to orbital interactions between the migrating group and the cyclic moiety of the molecule.^{167, 168} Investigation of the rearrangement of bis(pentamethoxycarbonylcyclopentadienyl) disulfide in solution by ¹H and ¹³C NMR spectroscopy demonstrated that it is characterised by a rather low energy barrier (15–17 kcal mol^{−1}).¹⁶⁴ However, no evidence in favour of the mechanisms of either 1,2- or 1,3-shifts for the migration of the RSS group was reported.

[3,3]-Sigmatropic shifts. To decide between the mechanisms of 1,2-shift ([1,5]-sigmatropic shift) and [3,3]-sigmatropic shift as the migration pathway of the dithioacyl groups around the cyclopentadiene ring, the prochiral group was introduced into the ring. The same approach was applied to acyloxycyclopentadienes (see Section VI.4.a). The circumambulatory rearrangement of *S*-(5-benzyl-1,2,3,4-tetraphenylcyclopentadienyl) *O*-ethyl dithiocarbonate **62a** (R¹ = CH₂Ph, R² = OEt) gave rise to two isomers **62b, c**. Taking into account that diastereotopic splitting of the peaks for the methylene protons in the ¹H NMR spectrum of isomer **62b** should be larger than that in the spectrum of isomer

62c because the prochiral and stereogenic centres in molecule **62b** are in close proximity, the following sequence of rearrangement steps was revealed:¹⁶⁹

R¹ = CH₂Ph, Ph, C₆H₄Me-4; R² = OEt, Ph.

In nitrobenzene-d₅, the equilibrium was established at 60 °C within 25 min; the isomer ratio **62a**:**62b**:**62c** = 45:25:30. The kinetic parameters for individual steps of the migration of the *O*-ethyl dithiocarbonate group in isomers **62** (R¹ = CH₂Ph, R² = OEt) are given in Table 9. The average rate constants and activation parameters for the slower migration of the dithiobenzoate group in solution of compound **62** (R¹ = C₆H₄Me-4, R² = Ph) in deuterionitrobenzene are as follows: $k_{130} = 1.8 \times 10^{-4}\text{ s}^{-1}$, $\Delta G^\ddagger_{130} = 30.7\text{ kcal mol}^{-1}$, $\Delta H^\ddagger = 28.9 \pm 0.7\text{ kcal mol}^{-1}$, $\Delta S^\ddagger = -4.5 \pm 1.0\text{ cal mol}^{-1}\text{ deg}^{-1}$.

Table 9. Rate constants and activation free energies for the [3,3]-sigmatropic shifts of isomers of the *O*-ethyl dithiocarbonate group in isomers **62** (R¹ = CH₂Ph, R² = OEt) in nitrobenzene-d₅.¹⁶⁹

Rearrangement	k_{60}/s^{-1}	$\Delta G^\ddagger_{60}/\text{kcal mol}^{-1}$
62a → 62b	7.5	24.3
62b → 62a	13.2	23.9
62b → 62c	8.9	24.2
62c → 62b	7.2	24.3

It can be concluded that 1,3- or 3,3-shifts, but not 1,2-shifts characteristic of the migration of the arylthio groups (see Section VI.4.b), are energetically favourable for the migration of the dithioacyl group around the cyclopentadiene ring. Although it is necessary to introduce one labelled sulfur atom to make an unambiguous choice between the mechanisms involving 1,3- and 3,3-shifts, the latter mechanism seems to be most probable, as evidenced by the results of theoretical simulation.¹⁷⁰

The results of calculations of the relative energies of transition state and intermediate structures for different pathways of migrations of heteroallyl groups in the cyclopentadiene ring are presented in Table 10.

Table 10. Relative (compared to the ground state structures) energies (ΔE) of the transition state and intermediate structures in different pathways of circumambulatory rearrangements of heteroallylcyclopentadienes calculated by the MINDO/3 method.¹⁷⁰

^a A saddle point was not found.

^b A biradical intermediate was not detected.

In calculations (see Table 10), the effects of the substituents in the cyclopentadiene ring and the migrating groups in compounds **53**, **59** and **62** were ignored. Nevertheless, the results of these calculations indicate with a fair degree of consistency that the [2,3]-sigmatropic shifts (structure **63b**) of the heteroallyl groups in the cyclopentadiene ring are highly improbable. As in the case of hetero-Cope rearrangements in a series of cyclopropene derivatives (see Section IV.2), the reaction pathways assuming [3,3]-sigmatropic shifts involve the transition through symmetrical biradical structures (**63d**), which can undergo isomerisation into tricyclic structures (**63e**). The energy profile of these rearrangements is analogous to that shown in Fig. 2.

c. Selenium- and tellurium-centred migrating groups

As mentioned in Section VI.3.a, 1,2,3,4,5-pentaphenyl-5-selenocyanatocyclopentadiene (**54c**) in solution undergoes two interrelated rearrangements, *viz.*, a non-degenerate rearrangement to form isoselenocyanate isomer **54a** through [3,3]-sigmatropic shifts and a rapid degenerate circumambulatory rearrangement through 1,2-shifts of the selenocyanate group around the cyclopentadiene ring. The kinetic and activation parameters for this rearrangement and another degenerate circumambulatory rearrangement of organylselenocyclopentadienes **64** *via* 1,2-shifts of Se-centred migrating groups are given in Table 11. Migrations of selenium-centred groups around substituted cyclopentadiene rings proceed more rapidly [$\Delta(\Delta G^\ddagger) = 3\text{--}4\text{ kcal mol}^{-1}$] than migrations of analogous sulfur-centred groups (see Table 8). Both electron-releasing (R^1) and electron-withdrawing (R^2) substituents facilitate acceleration of the rearrangement.

Recently, bis(pentamethylcyclopentadienyl) selenide and bis(pentamethylcyclopentadienyl) polyselenides $Se_n(C_5Me_5)_2$ ($n = 2\text{--}4$) have been synthesised.¹⁷² Measurements of their high-temperature ^1H and ^{77}Se NMR spectra are made difficult because of thermal instability of these compounds. At room temperature, these polyselenides are structurally rigid on the NMR time scale.

High thermal sensitivity is also typical of substituted tellurocyclopentadienes. A few known representatives of this class of compounds contain intramolecular $Te \leftarrow O$ or $Te \leftarrow N$ coordination bonds, which provide substantial kinetic and thermodynamic stabilising effects in a series of organic compounds of low-oxidation-state tellurium.^{173–175} The fluxional behaviour of several tellurocyclopentadienes **65** was studied. Based on analysis of line shapes in the ^1H NMR and ^1H 2D EXSY NMR spectra recorded for solutions of compounds **65** in deuteriochloroform, their dynamic behaviour can unambiguously be assigned to rapid intramolecular rearrangements involving 1,2-shifts of the aryltellurenyl groups around the cyclopentadiene ring.^{166, 176} The migration proceeds rapidly on the ^1H and ^{13}C NMR time scale even at $-90^\circ C$, and the protons of all five methoxycarbonyl groups are manifested as the only weakly broadened peak.

$R = CO_2Me$.

X in compound 65	k_{25} /s $^{-1}$	$\Delta H^\ddagger$ /kcal mol $^{-1}$	$\Delta S^\ddagger$ /cal mol $^{-1}$ deg $^{-1}$	$\Delta G_{25}^\ddagger$ /kcal mol $^{-1}$

Therefore, the migration ability of substituents formed by Group 16 elements in the cyclopentadiene system increases in the series $O < S < Se < Te$.

5. Migrating substituents formed by Group 17 elements

The migration of the halogen atoms around the five-membered ring cannot proceed by the ionisation–recombination mechanism because heterolysis of the $C_{Cp}\text{--}Hal$ bond would give anti-aromatic cyclopentadienyl cations. Intramolecular migrations of the chlorine and bromine atoms in a series of 5-alkyl-5-chloro(bromo)-1,2,3,4-tetramethoxycarbonylcyclopentadienes^{177–179} and 5-bromo-1,2,3,4,5-pentaphenylcyclopentadienes¹⁷⁸ proceed *via* successive 1,2-halogen shifts around the cyclopentadiene ring.

Isomers **66a–c** ($Hal = Cl$) were isolated from a mixture prepared by the reaction of 5-alkyl-1,2,3,4-tetramethoxycarbonylcyclopentadienes with *N*-chlorosuccinimide in the presence of catalytic amounts of benzoyl peroxide. Upon storage of solutions of individual isomers **66a, b** in dichlorobenzene, the equilibrium $66a \rightleftharpoons 66b \rightleftharpoons 66c$ is established, which requires the energy barriers in the range of $25.7\text{--}27.3\text{ kcal mol}^{-1}$ to be overcome

Table 12. Equilibrium concentrations of isomers **66a** and **66b** (Hal = Cl) and the kinetic parameters of their interconversions in *o*-dichlorobenzene at 80 °C.¹⁷⁹

R in compound 66	66a : 66b	k_{25}/s^{-1}		$\Delta H^\ddagger/\text{kcal mol}^{-1}$		$\Delta S^\ddagger/\text{cal mol}^{-1} \text{ deg}^{-1}$		$\Delta G_{25}^\ddagger/\text{kcal mol}^{-1}$

(Table 12). Although isomers **66c** are present in equilibrium mixtures in benzene in concentrations comparable to those of compounds **66a,b**, they were not detected by NMR spectroscopy in *o*-dichlorobenzene.

R = Me, Prⁱ, Bn; Hal = Cl, Br.

In molecule **66** (Hal = Br), 1,2-migrations of the bromine atom proceed more rapidly. The energy barriers for these rearrangements are in the range of 16.2–23.0 kcal mol⁻¹. In 5-bromo-1,2,3,4,5-pentaphenylcyclopentadiene, the energy barrier to intramolecular 1,2-bromine shifts is 16.7 kcal mol⁻¹ (in 1,1,2,2-tetrachloroethane). The stable pentaphenylcyclopentadienyl radical, which could exist as an intermediate in the rearrangement proceeding by a homolytic mechanism, was not detected.¹⁷⁸ As in the case of migration of the thioaryl group (see Section VI.4.b), semiempirical quantum-chemical (AM1) calculations demonstrated that not only the low-energy reaction pathway corresponding to 1,2-halogen shifts in the ring but also alternative reaction pathways involving 1,3-shifts of migrating groups can take place. However, the transition state structures corresponding to these mechanisms are energetically much less favourable than the transition state structures corresponding to the mechanism of 1,2-shifts (the energy difference is 35–40 kcal mol⁻¹).

The rapid migration of the iodine atom around the cyclopentadiene ring proceeding, apparently, *via* 1,2-shifts was also observed.¹⁸⁰ It was found that in the isomers of deuterated iodocyclopentadiene, which was prepared in an ether–benzene mixture (2 : 1) at –15 °C, the deuterium atoms are distributed over all positions of the cyclopentadiene ring. This behaviour of the label indicates that the iodine atom rapidly migrates around the ring. This conclusion was supported by the data on magnetisation transfer at ~20 °C,¹⁸⁰ which demonstrated that substantial deceleration of the rearrangement was achieved only upon a decrease in the temperature of a solution of deuterated CpI to –40 °C.

VII. Circumambulatory rearrangements in a six-membered ring

1. Rearrangements *via* 1,2-shifts

Circumambulatory rearrangements in six-membered rings in cationic systems proceed *via* 1,2-shifts (η^1 – η^2 -shifts) or η^2 – η^3 -shifts as well as *via* σ,π -shifts (see Sections III.2 and III.6). Rearrangements of the first type in a series of derivatives of the

benzenium cation are among the first cationic rearrangements proceeding on the NMR time scale, which have received the most study. These rearrangements were comprehensively surveyed in the reviews.^{17,53,181} In the present review, we briefly consider only selected, most important, results.

The mechanism of rearrangements of cations **5** involving sequences of 1,2-shifts of the migrating group M around the six-membered ring was confirmed by analysis of the line shapes in temperature-dependent ¹H and ¹³C NMR spectra, spin-echo and magnetisation-transfer experiments and data from 2D NMR spectroscopy. The elucidation of the nature of the fluxional behaviour of heptamethylbenzenium cation **5a** (M = R = Me) as a result of a series of successive 1,2-shifts of the methyl group around the ring demonstrated that 2D NMR spectroscopy is a method of choice for elucidating permutation mechanisms of exchange reactions.¹⁸²

The migration ability of various groups M in hexamethylbenzenium cations **5** (R = Me) decreases in the following series:¹⁸¹ Br > H > CH₂Ph > NO₂ > Cl > SO₃H > Et > Ph > Me > CH₂Cl > CHCl₂.

The energy barriers to migrations of some of the above-mentioned groups in compounds **5** are given in Table 13.

Table 13. Energy barriers ($\Delta G_{25}^\ddagger$) for circumambulatory rearrangements in hexamethylbenzenium cations **5** (R = Me) *via* 1,2-shifts of the migrating groups M.^{53,181}

M in cation 5	Solvent	$\Delta G_{25}^\ddagger/\text{kcal mol}^{-1}$
Me	HSO ₃ Cl	17.9
Et	HSO ₃ Cl	16.0
SO ₃ H	HSO ₃ F	15.6
Cl	HSO ₃ F	14.7
OMe	HSO ₃ F	> 11.7
NO ₂	HSO ₃ F–SO ₂ Cl ₂	12.2
H	HSO ₃ Cl	10.3
Br	HSO ₃ F–SO ₂ ClF	9.2

To correlate the migration ability of various groups in carbocations, useful semiempirical equations were deduced.^{53,181} The main equation (1)

$$\Delta G^\ddagger = a + bE_1 + cE_2 \quad (1)$$

includes the following two parameters: E_1 is the energy required for the cleavage of the C(1)–M bond and deformation of the M–C(1)–C(2) bond angle and E_2 is the energy produced upon the formation of a new M–C(2) bond due to the shift of the migrating group M to the adjacent C(2) cationic centre. One approach to estimating the parameters E_1 and E_2 is to approx-

imate these parameters by the energies of the C–M bonds in the $\text{H}_3\text{C}-\text{M}$ molecule and by the affinity for the proton or methyl cation, respectively.

It was found that circumambulatory rearrangements of some cations **5** in the solid state are as rapid as in solutions. For example, the energy barrier for the rearrangement of heptamethylbenzenium cation **5** ($\text{M} = \text{R} = \text{Me}$, SbCl_6^- as the anion) in the crystal is $17.3 \text{ kcal mol}^{-1}$ (see Ref. 183), which is $0.6 \text{ kcal mol}^{-1}$ lower than that for its solution in dichloromethane. The energy barriers for the rearrangement of cation **5** in the solid state are very sensitive to the unit cell parameters. For example, the rearrangement of compound **5** ($\text{M} = \text{Ph}$, $\text{R} = \text{Me}$), which crystallises in lower-symmetry crystal lattice compared to its analogue with $\text{M} = \text{R} = \text{Me}$, is nonobservable in the solid state even at high temperature.

2. $\eta^2-\eta^3$ -Rearrangements

Migrations of the cyclopropane fragment around the six-membered ring were found by Berson,¹⁸⁴ who attributed the exchange between the deuterium positions in 2,6-dideuterio-3,7,7-trimethylcycloheptatriene at high temperatures (300°C) to the intermediate formation of norcaradiene derivatives, which undergo $[1,5]$ -sigmatropic ($\eta^2-\eta^3$) rearrangements. Migration of this type was directly observed at 77°C in the study of the rearrangement of the corresponding dicyano derivative for which norcaradiene valence tautomer **67** is energetically more favourable than the 7,7-dicyanocycloheptatriene form.^{185, 186}

Generally, such rearrangements are characterised by higher energy barriers compared to those corresponding to conditions of structural non-rigidity.^{17, 69, 186} It was found that the migration of the methylene group around the aromatic ring is accompanied by the inversion of configuration of the migrating carbon atom¹⁸⁷ (contrary to the Woodward–Hoffmann rules). This result was explained based on the results of density functional theory calculations (UB3LYP/3-21G and UB3LYP/6-31G* + ZPE) for the pathways of the rearrangement of 7-cyano-7-methylnorcaradiene.¹⁸⁸ The transition state structures for both pathways, *viz.*, both with inversion and retention of stereochemical configuration of the migrating centre, were localised, the first structure being energetically more favourable (by $\sim 1 \text{ kcal mol}^{-1}$). This difference corresponds to the 97:3 ratio between the processes occurring with inversion and retention of configuration, which is consistent with the experimental ratio of 92:8.

VIII. Circumambulatory rearrangements in a seven-membered ring

1. Rearrangements proceeding by the ionisation–recombination mechanism

Heterolysis of the C–M bond in 7-substituted cycloheptatriene **3** afforded the aromatic tropylium cation. This corresponds to rearrangements of compounds in which migrating groups M possess fairly high electron affinity, *i.e.*, form stable anions in the ionisation–recombination pathway. Hence, it is not surprising that circumambulatory rearrangements^{37, 189} of isothiocyanates and isoselenocyanates **68a–g** derived from cycloheptatriene proceed as random rearrangements involving preliminary ionisation of C–N bonds. The kinetic parameters of these rearrangements, which were calculated based on analysis of line shapes in temperature-dependent ^1H NMR spectra, are given in Table 14.

Table 14. Activation free energies for circumambulatory rearrangements of cycloheptatrienes **68**.

X in compound 68	R in compound 68	Solvent	$\Delta G_{25}^\ddagger$ /kcal mol $^{-1}$	Ref.
O	Ph	nitrobenzene- d_5	> 25	189
S	H	$\text{CDCl}_3-\text{CD}_3\text{CN}$ (1:3)	12.1	37
S	H	CDCl_3	14.3	37
S	H	$\text{CS}_2-\text{CDCl}_3$ (10:1)	14.8	37
S	Ph	nitrobenzene- d_5	24.3	189
Se	Ph	"	22.4	189

$\text{R} = \text{H}, \text{Ph}; \text{Y} = \text{NCX} (\text{X} = \text{S}, \text{Se}).$

An increase in the rate of the rearrangement of compound **68** ($\text{X} = \text{S}$, $\text{R} = \text{H}$) with increasing polarity of the solvent is indicative of the occurrence of the pre-equilibrium ionisation step. The migration of the isothiocyanate group in heptaphenylcycloheptatriene proceeds much more slowly than the analogous rearrangement in isothiocyanatocycloheptatriene, which may be associated with steric hindrance produced by the bulky phenyl groups in the recombination step. The energy barriers to hindered rotation of the phenyl groups in molecule **68** ($\text{R} = \text{Ph}$, $\text{X} = \text{O}, \text{S}, \text{Se}$) were estimated at $\sim 16 \text{ kcal mol}^{-1}$.¹⁸⁹ The migration rates of the isothiocyanate and isoselenocyanate groups are independent of the concentration of the solution, which indicates that this rearrangement proceeds through the intermediate formation of tight ion pairs **69**.

Thermally induced heterolysis of the C–N bond in *N*-(cyclohepta-1,3,5-trien-7-yl)phthalimide also led to the circumambulatory rearrangement of the phthalimide group, which migrates around the cycloheptatriene ring through the intermediate formation of the tropylium cation–phthalimide anion tight ion pair ($\text{C}_6\text{D}_5\text{NO}_2$, $\Delta G_{180}^\ddagger = 24.8 \text{ kcal mol}^{-1}$).¹⁹⁰

Examples of heterolytic dissociation of the $\text{C}_{\text{tropylium}}-\text{O}$, $\text{C}_{\text{tropylium}}-\text{C}$ and $\text{C}_{\text{tropylium}}-\text{N}$ bonds in compounds which are potentially prone to circumambulatory random rearrangements were offered.^{191–197} In these studies, the possibility of these rearrangements occurring was not discussed, but the equilibria $70\text{a} \rightleftharpoons 70\text{b} + 70\text{c}$,¹⁹¹ $71\text{a} \rightleftharpoons 70\text{b} + 71\text{b}$ (see Ref. 192) and $72\text{a} \rightleftharpoons 72\text{b} + 72\text{c}$ (see Ref. 193) were examined. The heats of

heterolysis (ΔH°) of 7-aryloxycycloheptatrienes **70a** depend substantially on the nature of substituents in the aryl ring. For example, the heat of heterolysis $\Delta H^\circ = 10.6 \text{ kcal mol}^{-1}$ for compound **70a** ($R = 4\text{-NO}_2$) is almost 10 kcal mol^{-1} lower than that for its methoxy-substituted analogue ($R = 4\text{-OMe}$). This difference is indicative of the importance of delocalisation of the negative charge in the anion favourable for ionisation of compounds **70a**. According to the dynamic ^{13}C NMR spectroscopic data, the activation free energies of heterolysis of fullerene derivatives **72a**, which dissociate into ions in dimethyl sulfoxide or the DMSO– SO_2 system, are rather low ($7.7\text{--}9.3 \text{ kcal mol}^{-1}$).

$R = \text{H, Bu}^t, \text{cyclo-C}_6\text{H}_{11}$.

Detropylation of *N,N*-dimethyltropylamine and *N*-tropylacetamide¹⁹⁸ and the dynamic equilibrium between 1-, 2- and 3-chloro-substituted 7-chlorocycloheptatrienes¹⁹⁹ are other examples of equilibria of this type involving, apparently, steps of ion recombination at an arbitrary position of the ring.

2. Homolytic reaction pathway

Thermal dissociation of C–C σ bonds in hydrocarbon molecules generally involves their homolytic cleavage. For instance, sterically overcrowded 1,3,5-tri-*tert*-butyl-7-(9-fluorenyl-9-phenyl)-cyclohepta-1,3,5-triene (**73a**) dissociates upon heating in *m*-xylene or cyclohexane to form the 1,3,5-tri-*tert*-butylpropyl (**73b**) and 9-phenylfluorenyl (**73c**) radicals ($\Delta H^\ddagger = 23 \text{ kcal mol}^{-1}$, $\Delta S^\ddagger = 22.0 \text{ cal mol}^{-1} \text{ deg}^{-1}$)²⁰⁰ detected by EPR spectroscopy. Evidently, the recombination step proceeds randomly. This reaction is a first example of cycloheptatriene rearrangements proceeding by a radical mechanism.

The formation of radical pairs whose subsequent recombination leads to shifts of the substituents in the ring can also be initiated photochemically, like in the rearrangements of 1-indenylcyclopropene derivatives.⁹⁵

3. Rearrangements via 1,2(2,3)-shifts

As demonstrated in Section III.2, 1,2-shifts ([1,7]-sigmatropic shifts) of the dialkylboryl group lead to the rapid rearrangement of [1-4- η^4 -*exo*-7-(dipropylboryl)cycloheptatriene]tricarbonyliron (**11**).⁵⁰ The question arises as to whether rearrangements of this type can proceed without coordination of the cycloheptatriene ring, for example, in compound **74** ($M = \text{BPr}_2$).⁶² Studies of 7-dipropylborylcycloheptatriene by ^1H 2D EXSY NMR spectroscopy demonstrated that in solutions, an equilibrium between this compound and its 7-*exo*-(dipropylboryl)norcaradiene isomer is rapidly established, and migration of the dipropylboryl group occurs, the latter process being observed at temperatures higher than 293 K. According to the results of density functional theory calculations (B3LYP/6-311+G**//B3LYP/6-31G*) for a model system, the energetically most favourable migration mechanism involves 1,2-shifts of the dipropylboryl group in the cycloheptatriene ring ($\Delta H^\ddagger = 18.4 \text{ kcal mol}^{-1}$). The calculated energy barriers for the possible 1,5- and 1,3-shifts (Scheme 5) are 27.4 and 25.7 kcal mol^{-1} , respectively.

Scheme 5

The fact that the migration of the dialkylboryl group around the cycloheptatriene ring proceeds primarily *via* 1,2-shifts was attributed⁶² to the characteristic features of the electronic structure of the transition state, which corresponds to a Möbius-type aromatic system containing eight electrons on eight active orbitals.²⁰¹ From this viewpoint, the 1,2-shift should be unfavourable for the migration of groups containing two additional electrons on active orbitals compared to boron-centred groups. However, this assumption was not confirmed in the case of rearrangements of sulfur-centred migrating groups. 7-Phenylthiocycloheptatriene **74** ($M = \text{SPh}$)^{40, 202} and cycloheptatrien-7-yl ethyl dithiocarbonate **74** [$M = \text{SC(OEt)=S}$]²⁰³ undergo circumambulatory rearrangements at rates comparable to those found for the migrations of boron-centred groups in compound **74** with $M = \text{BPr}_2$. According to the data from ^1H and ^{13}C 2D EXSY NMR spectroscopy, the phenylthio- and, probably, ethyldithiocarbonate groups migrate around the cycloheptatriene ring *via* successive 1,2-shifts ([1,7]-sigmatropic shifts). The kinetics of both rearrangements is independent of the concentrations of solutions, which is indicative of their intramolecular character. The kinetic parameters of these rearrangements are summarised in Table 15.

Since studies of the mechanisms by dynamic NMR elucidated only the type of the permutation mechanism, an alternative mechanism involving [2,3]-sigmatropic shifts for the rearrangement of compound **74** [$M = \text{SC(OEt)=S}$] cannot be excluded.

The theoretical simulation of the mechanism of rearrangement of model system **74** [$R = \text{H, M} = \text{SCH(=S)}$], which is an analogue of compound **3**, was carried out by *ab initio* calculations at the MP2/6-31G** level.⁹³ The optimised geometric parameters and energies of the transition state structures relative to the ground state of thioformylthionecycloheptatriene **74** are shown in Fig. 8. Calculations provided evidence that the 2,3-shift is the energetically most favourable channel of the rearrangement. The larger size of the cycloheptatriene ring as compared to that in lower cyclopolyenes allows more diverse pathways of circum-

Table 15. Kinetic and activation parameters for the circumambulatory rearrangements of 7-phenylthiocycloheptatriene **74** ($M = \text{SPh}$)^{40, 202} and cycloheptatrien-7-yl ethyl dithiocarbonate **74** [$M = \text{SC(OEt)=S}$]²⁰³ calculated from the data of dynamic ¹H and ¹³C NMR spectroscopy.

ambulatory rearrangements, including the formation of transition states **74a–f**, to proceed.

4. Rearrangements via 1,3-shifts

The presence of the $\text{Fe}(\text{CO})_3$ group in molecule **11** facilitates the 1,3-migration of the dipropylboryl group observed by dynamic NMR spectroscopy. This migration along with the main reaction channel (1,2-shift) contributes to the mechanism of the circumambulatory rearrangement.⁵⁰ In uncoordinated compound **74** ($M = \text{BPr}_2$), the 1,3-migration proceeds much more slowly and

is experimentally undetectable, although it is known that the boryl groups in polyunsaturated dialkylboranes can undergo rapid [1,3]-sigmatropic shifts.^{204, 205}

5. Rearrangements via 1,4-shifts

Unlike the cyclopentadiene system for which the energetically most favourable mechanism of circumambulatory rearrangements involves thermally allowed suprafacial [1,5]-sigmatropic shifts of the migrating group (1,4-shifts) (see Section VI), the rearrangements of this type in cycloheptatrienes are characterised by high energy barriers. For example, the migrations of silicon- or germanium-centred groups in compounds **74** [$M = \text{SiPh}_3$ (see Ref. 206) and GePh_3 (see Ref. 207)] are unobservable. At temperatures higher than 130 °C, [1,5]-sigmatropic hydrogen shifts take place in these cycloheptatriene derivatives. At 150 °C, the methoxy group in 7,7-dimethoxycycloheptatriene undergoes [1,5]-sigmatropic shifts characterised by fairly high activation barriers.²⁰⁸ In cycloheptatrienes, rather rapid rearrangements *via* [1,5]-shifts were observed only for migrating substituents formed by Group 14 elements of a lower period of the Periodic table, *viz.*, SnPh_3 , SnMe_3 and SnMe_2Cl (see Section III.4). This is attributed to the fact that [1,5]-sigmatropic shifts in the cyclopentadiene system proceed as 1,2-shifts along the pathways of the smallest motions of the migrating groups, whereas these shifts in the cycloheptatriene system do not correspond to this pathway (1,4-shifts). Additional arguments in favour of the 1,2-shift were obtained in calculations of the geometry of the transition state structures for various reaction pathways associated with the migration of the dimethylboryl group in compound **74** ($M = \text{BMe}_2$)⁶⁰ and the dithioformate group in its analogue with $M = \text{SCH}(\text{S})$ (see Fig. 8). If the rearrangement proceeds *via* 1,2-shifts ([1,7]-sigmatropic shift), the seven-membered ring in the transition state remains virtually planar, while the C–B and C–S bond lengths moderately increase. By contrast, the ring is forced to adopt a distorted conformation with substantially elongated C–B (1.859 Å) and C–S (2.363 Å) contacts if the rearrangement proceeds *via* 1,4-shifts ([1,5]-sigmatropic shifts). Therefore, it can be assumed that steric rather than electronic factors are predominantly responsible for fairly high energy barriers to [1,5]-sigmatropic shifts in the cycloheptatriene system. This accounts for the fact that the migration ability of various carbon-centred groups in benzocycloheptatrienes **75** depends to a much lesser extent on the nature of the migrating group compared to those in indene system **49**. The rearrangements $\text{75a} \rightleftharpoons \text{75b}$ proceed upon heating of solutions of compounds **75** in benzene in sealed tubes.²⁰⁹

The migration ability of carbon-centred groups decreases in the following series: $\text{CHO} > \text{CN} > \text{C}\equiv\text{CH} > \text{C}(\text{O})\text{Me} > \text{CO}_2\text{Me} > \text{Alk}$.

6. Rearrangements via [3,3]-sigmatropic shifts

The shifts of the isothiocyanate groups in tropyli isothiocyanate **69** belong to random processes, *i.e.*, the positions of the migrating group after ionisation of the starting molecule is randomly chosen (see Scheme 5), whereas the energetically favourable mechanism of the rearrangement of tropyli azide **76** involves the selective 1,3-migration of the azide group.⁸⁷ Dynamic ¹⁵N NMR spectroscopic studies confirmed that this migration is associated also with the exchange between the positions of the terminal nitrogen atoms in the azide group. Since the rate of this process is equal to the rate of circumambulatory migrations of the azide group around the seven-membered ring, 1,3-migrations should correspond to [3,3]-sigmatropic shifts.

Along with the [3,3]-sigmatropic shift, the following alternative reaction pathways take place: ionisation – recombination and [1,5]-sigmatropic shift. The contribution of the ionic mechanism increases as the polarity of the solvent increases (26% and 34% in THF and CD₃CN, respectively). The activation free energy barriers for various mechanisms of circumambulatory rearrangements of compound **76**, which were estimated based on analysis of line shapes in NMR spectra, are given in Table 16.

Table 16. Activation free energies ($\Delta G_{-48}^\ddagger$) for the circumambulatory rearrangements of tropyl azide **76**.^{87, 88}

Solvent	$\Delta G_{-48}^\ddagger$ /kcal mol ⁻¹		
	random shift	[3,3]-shift	[1,5]-shift
CD ₃ CN	14.8 ± 0.2	14.0 ± 0.2	16.0 ± 0.5
CDCl ₃	15.2 ± 0.5	14.9 ± 0.6	17.0
THF	16.5 ± 0.4	15.9 ± 0.4	17 ± 1

Although direct evidence of [3,3]-sigmatropic shifts of the isoselenocyanate groups in 7-isoselenocyanatocycloheptatriene **68** (Y = NCS_e) is lacking, the presence of small amounts of selenocyanate isomer **68** (Y = SeCN), which was observed in the mass spectrum of the starting isoselenocyanate,¹⁸⁹ is indicative of the possibility of this rearrangement occurring in the gas phase.

IX. Circumambulatory rearrangements in multimembered rings

Circumambulatory migrations in the eight- and nine-membered cyclopolyene rings are virtually unknown. Rearrangements in neutral eight-membered systems can proceed only in bis-hapto compounds (see Section III.5). The only known example is interconversions of the isomers of 9-cyano-4,9-dimethylbicyclo[8.1.0]nonatriene (**77**) occurring as migrations of the cyclopropyl group.²¹⁰

Compound 77	a	b	c	d
Yield at 102 °C (%)	35	33	21	11

Heating of a solution of cyclopolyene **77a** afforded a mixture of all four isomers. The activation free energy of the rearrangement **77a** → **77b** is 29 kcal mol⁻¹. Each step of the circumambu-

latory rearrangement involves the inversion of stereochemical configuration at the C(9) centre. The thermal rearrangement of isomer **77a** attended by the exchange between the positions of the cyano and methyl groups proceeds analogously.

The rapid circumambulatory rearrangement of cyclononatrienyl(dipropyl)borane **78** was studied by Bubnov and co-workers.⁵⁶ The dynamic process associated with 1,3-shifts of the dipropylboryl group in molecule **78** (R = Pr) is detected by ¹H NMR spectroscopy even at –100 °C. The activation free energy barrier for migrations of the dipropylboryl group, which was calculated based on analysis of line shapes in the ¹³C NMR spectra in the temperature range from –100 to –40 °C, is low ($\Delta G_{-78}^\ddagger$ = 8.8 kcal mol⁻¹). This value is well reproduced by calculations of model compounds **78** and **79** (R = Me) using the density functional method²¹¹ by relating this barrier to the interconversions of the most stable *cis-endo* isomers **78a** ⇌ **78b** ⇌ ... According to the results of calculations, the dialkylboryl group in the energetically less favourable *cis-exo* isomer of **79** undergoes the 1,2-shift to form *mono-trans* conformer **79a**, which, in turn, can undergo 1,3-boron shifts. These rearrangements are shown in Scheme 6.

Scheme 6

The fluxional behaviour of cyclononatrienyl(trimethyl)tin was studied in detail in the temperature range from –100 to –78 °C by ¹³C–¹³C EXSY NMR spectroscopy. The results of these studies demonstrated that the Me₃Sn group in the *exo* conformer undergoes 1,2-shifts ([1,9]-sigmatropic shifts) around the nine-membered ring.²¹² The activation energy of this process (6.0 ± 0.6 kcal mol⁻¹) agrees well with the calculated (B3LYP/3-21G*) value.

X. Fluxional compounds as efficient carriers of groups and precursors of structurally rigid chiral ligands

Compounds whose fluxional behaviour is determined by the ionisation–recombination mechanism involving dissociation into ions can serve as soft carriers of functional groups. This takes place when the rearrangement proceeds in solutions containing another substrate, which possesses a fairly high affinity for the migrating group, thus competing with the starting counterion in the recombination step. For example, arylazo derivatives of 1,2,3,4,5-pentamethoxycarbonylcyclopentadiene **51** (see Section VI.3.a) serve as efficient carriers of arylazo groups facilitating their migration to the nucleophilic carbon and nitrogen centres in various acidophobic compounds.^{38, 39, 213–216} The reactions proceed smoothly at room temperature in benzene to give various arylazo compounds in ~90% yields. The most important transformations of this type are shown in Scheme 7.

Not only ionisable arylazo compounds **51** but also 5-arythio-1,2,3,4,5-pentamethoxycarbonylcyclopentadienes **61**, which are characterised by low energy barriers to circumambulatory migrations of the arylthio groups (see Section VI.4.b), behave as

Scheme 7

$\text{E} = \text{CO}_2\text{Me}$; $\text{Ar}^1 = \text{C}_6\text{H}_4\text{NO}_2\text{-4}, \text{C}_6\text{H}_4\text{NO}_2\text{-2}, \text{C}_6\text{H}_4\text{SO}_2\text{CF}_3\text{-4}$; $\text{Ar}^2 = \text{C}_6\text{H}_4\text{Me-4}, \text{C}_6\text{H}_4\text{OMe-4}$.

efficient carriers of these groups.^{217–220} Intermolecular migrations of the arylthio groups are illustrated in Scheme 8.

Scheme 8

$\text{E} = \text{CO}_2\text{Me}$; $\text{Ar}^1 = \text{C}_6\text{H}_4\text{NO}_2\text{-4}, \text{C}_6\text{H}_4\text{NO}_2\text{-2}$;
 $\text{Ar}^2 = \text{C}_6\text{H}_4\text{Me-4}, \text{C}_6\text{H}_4\text{OMe-4}$.

Potentially fluxional hexabromocyclopentadiene **1** ($\text{R} = \text{M} = \text{Br}$) is also able to undergo the intermolecular transfer of the bromine atom to the nucleophilic carbon centres.^{221, 222} This reagent brominates smoothly aromatic amines and alcohols, furans, thiophenes and ketones activated at the α -carbon atoms, the electrophilic substitution of aromatic compounds proceeding selectively at the *para* position due to formation of intermediate π complexes.

$\text{X} = \text{NMe}_2, \text{NMeCOMe}, \text{OH}, \text{OMe}$.

The cyclopentadienyl ligand exhibits properties of a readily leaving group in the exchange reactions of fluxional P-, Ga-, Si-, Sn- and Ge-centred pentamethylcyclopentadiene derivatives with nucleophiles.²²³

The migrations of groups analogous to those shown in Schemes 7 and 8 can also be carried out as intramolecular reactions, provided that the cyclopentadiene ring contains an additional nucleophilic centre, which can compete with the carbon atoms of the ring for the mobile migrating group bound to this ring. The correct choice of functional groups in the molecule of a fluxional compound allows one to perform the rational design of structures which are difficult to prepare according to conventional synthetic procedures. This approach can be exemplified by the new rearrangement of *N*-1,2,3,4,5-pentamethoxycarbonylcyclopentadienyl-*N,N'*-diarylamidines **53** observed in solutions at high temperatures.²²⁴ This rearrangement afforded previously unknown *N*-methoxycarbonyl-*N,N'*- α -triarylamidinium *N*-cyclopentadienides **80a**, which readily eliminated the *N*-methoxycarbonyl group upon treatment with a methanolic solution of NaOH to give (after neutralisation of the solution) amidinium *N*-cyclopentadienyl ylides **80b**. The zwitterionic structures of the ylides were confirmed by X-ray diffraction analysis of a series of derivatives **80**.^{224–226}

The rearrangement **53** → **80a** can proceed either *via* the direct 1,4-shift of the methoxycarbonyl group or as a two-step process involving an additional 1,2-shift to the carbon atom of the ring **53** → **81** followed by the 1,5-shift of this group. The possibility of the second mechanism is evidenced by rather low energy barriers to the 1,2-shifts ($E_a \approx 25 \text{ kcal mol}^{-1}$) of the methoxycarbonyl group in 5-R-1,2,3,4,5-pentamethoxycarbonylcyclopentadienes.^{119, 122} However, simulation of the mechanisms of migration of the methoxycarbonyl group for a series of amidinyl-cyclopentadiene derivatives taking into account the methoxycarbonyl and aryl substituents in the cyclopentadiene and amidine fragments, respectively, by the MNDO quantum-chemical method provided theoretical evidence for the occurrence of the 1,4-shift of the methoxycarbonyl group.²²⁷

The presence of electron-releasing groups in the C-aryl ring facilitates the shift of the equilibrium **53** ⇌ **80a** toward N-ylide (Table 17).

The non-planar molecules of N-ylides **80b** are chiral, and the presence of both the amidine and cyclopentadiene residues in these molecules provides their bifunctional character. Hence, compounds **80b** hold promise as chiral N-functionalised cyclopentadienyl ligands in the synthesis of metal complexes serving as potential catalysts for asymmetric reactions.^{228–233} In such complexes, the cyclopentadiene fragment and the nitrogen atom of the side chain coordinate the metal centre in a bidentate fashion giving rise to the rigidly coordinated chiral centre at the metal atom. Complexes of this type with N-centred functional groups, such as

the aminoethyl and pyridyl groups, were studied.^{234–237} Compounds **80b**, which contain the bulky 1-naphthyl group in the α position of the amidine triad and retain a stable chiral structure both in the crystals and solutions even upon heating to 180°C (the energy barrier to rotation about the $\text{C}_\alpha\text{--C}_{\text{Ar}}$ bond $\Delta G_{180}^\ddagger > 26 \text{ kcal mol}^{-1}$), are of particular interest. In gold(I) complexes with 1-naphthamidine N-cyclopentadienides prepared recently, the rigidity of a chiral structure is provided by additional coordination of the gold atom by the π system of the cyclopentadiene ring.²³⁸ Analogous thallium complexes retain stable chiral structures through coordination of the thallium atom both by the nitrogen atom of the side chain (N–Tl) and the π system of the cyclopentadiene ring (Tl–Cp, η^5 -binding).²³⁹

XI. Conclusion

Circumambulatory rearrangements can serve as models of many important chemical processes associated with migrations of functional groups, which allow one to prepare compounds with various structures. The elucidation of the mechanisms of such rearrangements, their driving forces and factors responsible for the energy barriers to shifts of the migrating groups around the ring helps in understanding the mechanisms and stereoelectronic requirements of a series of more complex reactions. The results surveyed in the present review demonstrate that circumambulatory rearrangements are not limited to shifts of mobile organometallic groups around the ring but involve also various migrating substituents of Group 13–17 elements. In particular cases, such Group 13–17 element-centred migrating substituents exhibit high ability to undergo intramolecular shifts comparable to the mobility of organometallic groups.

The circumambulatory rearrangements of cyclopentadiene derivatives were studied in sufficient detail. In most cases, these rearrangements proceed *via* successive 1,2-shifts ([1,5]-sigmatropic shifts) of the migrating group around the five-membered ring. The energy barriers to migrations of the substituents M whose central atoms belong to one and the same group of the Periodic table decrease with increasing atomic number of the element due primarily to a gradual decrease in the energy of the $\text{C}_{\text{sp}^3}\text{--M}$ bonds with increasing ordinal number of the period. In the presence of electron-withdrawing substituents in the five-membered ring, the migration rate increases. In the case that a migrating group can form a stable cation and the five-membered ring contains electron-withdrawing substituents, which facilitate delocalisation of the negative charge in the cyclopentadienide anion, the $\text{C}_{\text{sp}^3}\text{--M}$ bond readily undergoes ionisation and the rearrangement proceeds through the ionisation–recombination mechanism within the tight ion pair that formed. In the presence of nucleophiles possessing a higher affinity for a migrating group compared to the starting cyclopentadiene residue, the cationic migrating group can be shifted to the foreign nucleophilic centre. Such compounds serve as efficient soft carriers of functional groups.

The electronic requirements for circumambulatory rearrangements of derivatives of three- and seven-membered cyclopolyenes characterised by low energy barriers are opposite to those considered above for cyclopentadienes. Aromatic stabilisation of these cyclopolyene rings is achieved in their cationic forms and increases upon the replacement of the hydrogen atoms in the ring by electron-releasing groups. As a consequence, circumambulatory rearrangements of cyclopropene and cycloheptatriene derivatives containing electronegative migrating groups and electropositive substituents in the rings proceed by the ionisation–recombination mechanism. By contrast, the differences in the stereoelectronic requirements for migrations of heteroallyl groups in various cyclopolyenes are dictated primarily by steric factors.

The rate constants of circumambulatory rearrangements vary over a wide range characteristic of intramolecular migrations, *viz.*, from 10^6 to 10^{-8} s^{-1} at room temperature, which corresponds to energy barriers of $5\text{--}40 \text{ kcal mol}^{-1}$. Depending on the ring size,

Table 17. Equilibrium and rate constants of the rearrangement **53** ⇌ **80a** (*o*-dichlorobenzene, 120°C).²²⁴

the nature of the migrating group, substituents in the ring and the medium, compounds **1–5** and their higher homologues can exhibit very high structural non-rigidity or, on the contrary, substantial rigidity, *i.e.*, according to the classification proposed in the study,²⁴⁰ these compounds can be assigned to both fluxional structures and structures which undergo slow rearrangements. An interesting feature of circumambulatory rearrangements is a diversity of mechanisms responsible for simple intramolecular shifts of migrating groups around the cyclopolyene ring. Among these are various sigmatropic shifts of migrating groups, haptotropic rearrangements and ionisation pathways. Very fine variations in the structure can switch the reaction between possible pathways resulting in topomerisation or isomerisation of cyclopolyene derivatives. In this respect, circumambulatory rearrangements of substituted cyclopolyenes provide a good example of the limitations of the so-called ‘principle of Ockham’s razor’,²⁴¹ which is often used as a qualitative criterion for analysis of reaction mechanisms. The Woodward–Hoffmann rules of the conservation of orbital symmetry are also non-universal for the prediction of mechanisms and stereochemistry of circumambulatory rearrangements of cyclopolyene compounds although these rearrangements belong to typical pericyclic processes. To account adequately for the electronic and steric factors, critical regions of potential energy surfaces should be calculated by quantum-chemical methods at a high level of theory.

III. Synthesis of polymers based on 2,4,6-trinitrotoluene derivatives	903
IV. Conclusion	909

Abstract. The feasibility of conversion of 2,4,6-trinitrotoluene into condensation monomers (nitro compounds, diamines, *etc.*) and their applications in the synthesis of aromatic polymers has been analysed within the framework of a general problem of 2,4,6-trinitrotoluene conversion. The use of aromatic dinitro compounds and diamines for the preparation of oligomeric polyethers and polyamides (or polyimides), respectively, is considered. The possibility of the synthesis of polyamides and polyimides containing side aliphatic and aromatic groups and possessing better (in comparison with the corresponding unsubstituted polymers) characteristics is demonstrated. The bibliography includes 157 references.

I. Introduction

Aromatic condensation polymers belong to the most important class of thermostable high-molecular-mass compounds^{1–8} that have found wide application in the most advanced fields of science and technology.⁹ In this connection, a search for sources of raw materials for the synthesis of such polymers is the key problem, which determines further progress in this branch of chemistry.¹⁰ Of special interest is the development of methods for the synthesis of monomers from cheap and available raw materials, especially those based on compounds subject to utilisation, *e.g.*, the use of phosgene for the preparation of polycarbonates¹¹ or of dichlorodiphenyltrichloroethane (DDT) for the synthesis of a broad range of condensation polymers.^{12–16}

Large-scale investigations^{17–22} carried out in Russia over the past decade were aimed at the preparation of monomers and aromatic condensation polymers based on 2,4,6-trinitrotoluene

(trotyl, TNT),²³ a regnant, cheap and available product contained in large amounts in out-of-date ammunition liable to liquidation.

The simplest TNT derivatives used as monomers in the synthesis of condensation polymers include aromatic dinitro compounds (monomers for aromatic oligo- and poly-ethers^{24,25}) and aromatic di- and triamines (monomers for aromatic polyamides and polyimides^{10,26–30}). Some transformations of TNT into condensation monomers are depicted in Scheme 1.

II. Synthesis of condensation monomers based on 2,4,6-trinitrotoluene and its derivatives

Complete or partial reduction of TNT is the simplest reaction in the series of TNT transformations (Scheme 1, route *a*). Monoaminodinitrotoluenes, diaminonitrotoluenes and 2,4,6-triaminotoluene (TAT) can be obtained depending on the method and conditions for TNT reduction.

Thus reduction of TNT with sulfides of monovalent metals affords 4-amino-2,6-dinitrotoluene.³¹ Depending on the reaction conditions, the reduction of TNT with hydrazine hydrate in the presence of Raney nickel or iron chloride on activated charcoal yields either 2-amino-4,6-dinitrotoluene or 2,6-diamino-4-nitrotoluene.³² However, complete reduction of TNT resulting in TAT presents the greatest interest. Complete reduction of TNT to TAT is achieved by catalytic hydrogenation (Scheme 2, route *a*).³³ Electrochemical reduction of TNT in dilute HCl in the presence of TiCl₃ (Scheme 2, route *b*) leads to TAT · 3 HCl (yield 95%),¹⁸ which is much more resistant to oxidation than the free base.

Scheme 1

Scheme 2

(a) catalytic hydrogenation, (b) electrochemical reduction, HCl (dilute), TiCl_3 .

2,4,6-Triaminotoluene can be used for the synthesis of both polymers, *e.g.*, polyimides (PI) and a series of condensation monomers, substituted diamines in particular.^{34,35}

Thus partial hydrolysis of $\text{TAT} \cdot 3 \text{HCl}$ gave 2,6-diamino-4-hydroxytoluene,³⁵ whereas the reaction of TAT with a threefold molar excess of phthalic anhydride resulted in 2,4,6-tripthalimidotoluene, which was further converted into 2,4-diamino-6-phthalimidotoluene.³⁶ Since this procedure yields an isomer of 2,4-diamino-6-phthalimidotoluene (5%–10%) along with the main product, the pure monomer is prepared using the following reaction sequence (Scheme 3):³⁶

Yet another pathway for TNT conversion into condensation monomers (Scheme 1, route *b*) is based on the replacement of the nitro groups of TNT by nucleophiles under conditions of aromatic nucleophilic substitution.^{37–39} It is of note that reactions of TNT with bases are usually accompanied by the formation of an anionic 1,3- σ -complex **A**, which is further converted into a more stable 2,4,6-trinitrobenzyl anion **B** rather than the nitro groups being replaced.^{40,41} This anion can undergo further chemical transformations.

Scheme 3

These processes can only be prevented if 'soft' nucleophiles, *e.g.*, benzenethiols and their heterocyclic analogues are used or if the reactions are carried out in dipolar aprotic solvents of the amide type.^{42, 43} Thus reaction of TNT with benzenethiol in the presence of K_2CO_3 in *N*-methylpyrrolidone (*N*-MP) (50 °C, 2 h) leads to 2-methyl-3,5-dinitrodiphenyl sulfide (yield 72%); the reduction of the latter with hydrazine hydrate results in 3,5-diamino-2-methyldiphenyl sulfide (yield 86%).

A broad range of condensation monomers was obtained following the route *c* (Scheme 1), which is based on the demethylation of TNT; this reaction yields 1,3,5-trinitrobenzene (TNB).

There are different ways to demethylate TNT; the most important includes the oxidation of the methyl group to the carboxy group and subsequent decarboxylation.^{44, 45}

Aromatic nucleophilic substitution^{37–39} was used for the replacement of the nitro group in TNB by alkoxy-^{46–48} or perfluoroalkoxy groups.^{49–55}

$\text{R} = \text{H, Alk, (CF}_2)_n\text{X (X = F: } n = 1; \text{X = H: } n = 2, 4, 6).$

The monosubstituted dinitro compounds thus obtained were reduced to the corresponding diamines.^{46, 51–53}

Considerable attention has been given to the replacement of the nitro groups in TNB by aryloxy groups.^{56–58} One, two or three nitro groups in TNB can be replaced using aromatic nucleophiles.

$\text{Ar} = \text{Ph, 2-MeC}_6\text{H}_4, 3\text{-MeC}_6\text{H}_4, 4\text{-XC}_6\text{H}_4$ ($\text{X} = \text{F, Br, I, OH, EtO, NH}_2, \text{CH}_3\text{C(O), COOH, NO}_2, 3\text{-ClC}_6\text{H}_4$ etc.

The replacement of the first nitro group in TNB occurs under mild conditions (80 °C) and gives high (60%–95%) yields of 3,5-dinitrodiaryl ethers^{56, 57} which are easily converted into the corresponding aryloxy-substituted diamines. The replacement of the nitro group in 3,5-dinitroaryl ethers requires more drastic conditions, *viz.*, heating to 150 °C. The yield of 3,5-diaryloxy-substituted nitrobenzenes is 50%–70%. The formation of 1,3,5-triaryloxybenzenes as a result of replacement of the nitro group in 3,5-diaryloxy-substituted nitrobenzenes is possible only at 200 °C (yield 25%–30%).

The nitro group in 3,5-dinitrodiaryl ethers can easily be replaced by a mono- or bisphenolic residue. Thus 3,5-dinitrodiphenyl ether reacts with 4-amino- or 4-acetamidophenol to give 3-nitro-5-[4-amino(amido)phenoxy]diphenyl ether. Hydrolysis of 3-nitro-5-(4-acetamidophenoxy)diphenyl ether leads to 3-nitro-5-(4-aminophenoxy)diphenyl ether; subsequent reduction of the latter gives 3-amino-5-(4-aminophenoxy)diphenyl ether.⁵⁹

R = H, COCH₃.

It is noteworthy that 3-amino-5-(4-aminophenoxy)diphenyl ether contains an ether bond which can be incorporated into the main polymeric chain by polycondensation.

The replacement of the nitro group in dinitrophenyl ethers by bisphenolic residues yields dinitro compounds and diamines which contain no less than two ether groups; these can potentially be incorporated into the main polymeric chain.^{60, 61}

An alternative approach to the synthesis of such diamines includes the reaction of bisphenols with a twofold molar excess of TNB,⁵⁷ subsequent treatment of the tetranitro compounds formed with phenol and reduction of dinitro compounds to diamines.

It is of note that the reduction of intermediate tetranitro compounds allows preparation of a novel type of aromatic tetraamines, viz., bis(3,5-diaminophenoxy)arylenes.

Monosubstitution of TNB is also employed in the synthesis of 3,5-dinitrodiphenyl sulfide;^{42, 62} its reduction gives the corresponding diamine. Oxidation of the sulfide group in 3,5-dinitrodiphenyl sulfide to the sulfonyl group and subsequent reduction of 3,5-dinitrodiphenylsulfone yield 3,5-diaminodiphenyl sulfone.⁶²

3,5-Diaminophenyl benzothiazol-2-yl sulfide was synthesised from TNB in addition to monomers containing a phenylthio group.⁶³ The former is prepared by treatment of TNB with 2-mercaptobenzothiazole (which is less expensive than benzene-thiol) and subsequent reduction of the benzothiazol-2-yl 3,5-dinitrophenyl sulfide formed.

Monomers with functionalised aryl groups were synthesised besides dinitro compounds and diamines containing non-reactive aryl substituents.⁶⁴ Among the former, aromatic diamines containing free hydroxy and carboxy groups, e.g., 3,5-diamino-4'-hydroxy- and 3,5-diamino-4'-carboxydiphenyl ethers, present special interest.^{57, 64, 65}

Yet another fairly interesting route of TNT conversion into condensation monomers includes reactions involving the methyl group (Scheme 1, route *d*). The methyl group of TNT, which is effectively activated by nitro groups, reacts easily with aldehydes to give trinitrophenyl-substituted alkenes.⁶⁶

$\text{R} = \text{H}, \text{Ph}.$

Such monomers can be converted into aromatic amines containing alkene substituents.

The reaction product of isophthalic aldehyde with a twofold molar excess of TNT⁶⁶ is a promising starting monomer for polycycloaddition reactions (*e.g.*, the Diels–Alder reaction^{67–70}).

III. Synthesis of polymers based on 2,4,6-trinitrotoluene derivatives

1. Polyamides and polyimides

TAT presents the greatest interest among partial or complete reduction products of TNT. TAT-based phthalimido-substituted PI⁷⁵ were prepared by a selective polyacylation procedure.^{71–74}

The synthesis of phthalimido-substituted aromatic PI includes treatment of TAT with an equimolar amount of phthalic anhydride; this results in a mixture of mono-, bis- and tris(*o*-carboxybenzoyl)-substituted TAT derivatives with the predominance of the monoderivative **1**, which is due to a decrease in the activity of the free amino groups following monoacylation.⁷⁶

It is of note that the reaction of a free amino group in TAT with the carbonyl group of the substituent of the acylated amino group, due to their mutual *meta*-arrangement, is impeded in comparison with that in the reaction product of *o*-phenylenediamine with phthalic anhydride.⁷³

In order to obtain isomeric poly-*o*-carboxyamides **3a–c** (PCA) containing side *o*-carboxybenzamide groups, the acylation product of TAT with phthalic anhydride (a mixture of isomers) was treated with an equimolar amount of aromatic tetracarboxylic dianhydrides **2a–c** {3,3',4,4'-diphenyl oxide tetracarboxylic dianhydride (**2a**), 3,3',4,4'-benzophenonetetracarboxylic dianhydride (**2b**) and 2,2-bis[(3,4-dicarboxyphenyl)phenoxy]propane dianhydride (**2c**)} in *N*-MP at room temperature. The polyacylation process can be complicated due to the chemical heterogeneity of the TAT monoacylation products. Thus bis(*o*-carboxybenzoyl)triaminotoluene effects the polymeric chain termination, whereas non-acylated TAT favours the formation of branched and even cross-linked structures. Notwithstanding, homogeneous reaction solutions are formed in the synthesis of PCA **3a–c** with side *o*-carboxybenzamide substituents (Scheme 4).

Phthalimido-substituted polyimides **4a–c** are obtained from the corresponding PCA **3a–c** upon treatment with a fourfold excess of the pyridine–acetic anhydride mixture (1 : 1).⁷⁷ This is added to a solution of polycarboxyamide in *N*-MP at room temperature. The temperature is then increased to 100–110 °C and the reaction mass is kept at this temperature for 4 h. This reaction proceeds under homogeneous conditions and yields PI **4a–c** with a reduced viscosity (η_{red}) $\sim 0.3 \text{ dl g}^{-1}$ and molecular mass $\sim (22–105) \times 10^3$.

Scheme 4

The imide structure of the products formed (the absorption maxima are around 720, 1370, 1720 and 1780 cm^{-1}) and the absence of non-cyclised units (within the limits of experimental error) were confirmed by the IR spectroscopic data.

All the PI synthesised are readily soluble in *N*-MP, DMF and a tetrachloroethane : phenol mixture (3 : 1). Good solubility of PI is due to the presence of methyl and phthalimide substituents and the isomeric character of the units in the polymer.

The softening temperatures (T_{soft}) of PI **4a–c** established by the thermomechanical method and the temperatures at which a 10% loss of the sample mass occurred ($T_{10\%}$) were determined by the dynamic thermogravimetric analysis (TGA) and found to be equal to 270–360 and 400–450 $^{\circ}\text{C}$, respectively.

The stable monomer TAT · 3 HCl is used for the synthesis of aromatic PI along with the easily oxidisable free base TAT. In the case of the former, it is first converted into a free base. To this end, a TAT · 3 HCl suspension is treated with pyridine whereupon solubilisation of the starting material occurs, which is followed by subsequent processing according to the procedure of PI synthesis from the free base (TAT) (see Scheme 4).

The polyimides **5a,c,d** having similar but more ordered structures were prepared by the reaction of 2,4-diamino-6-phthalimidotoluene (**6**) with aromatic tetracarboxylic dianhydrides **2a,c,d**.³⁶

X = O (**a**), $\text{OC}_6\text{H}_4\text{C}(\text{CH}_3)_2\text{C}_6\text{H}_4\text{O}$ (**c**), $\text{C}(\text{CF}_3)_2$ (**d**).

Polyimides **5** are synthesised by high-temperature polycyclocondensation in *m*-cresol using quinoline as a catalyst. This reaction proceeds under homogeneous conditions; the reaction products contain no non-cyclised fragments (IR spectroscopic data). All the PI synthesised are soluble in *N*-MP, *m*-cresol and butyrolactone. Polyimide **5c** is soluble in both the aforementioned solvents and THF, chloroform and cyclohexanone, and PI **5d** is also soluble in acetone. This is due to the presence in PI **5c,d** of phthalimide and methyl substituents, *m*-phenylene fragments and 'hinged' hexafluoroisopropylidene groups.

According to the data from thermomechanical analysis, T_{soft} of the polymers **5a,c,d** are 275–350 $^{\circ}\text{C}$, and $T_{10\%} = 415\text{--}465$ $^{\circ}\text{C}$ (data from TGA in air at a heating rate of 4.5 $^{\circ}\text{C min}^{-1}$). A comparison of PI synthesised from diamine **6** in accordance with Schemes 2 and 3 demonstrated that their thermal characteristics and solubilities differ slightly from one another, presumably due to the difference in their isomeric compositions.

The reaction of 3,5-diamino-2-methyldiphenyl sulfide (**7**) with aromatic tetracarboxylic dianhydrides **2a–d** is carried out in accordance with the following scheme (Scheme 5):

R = O (**a**), CO (**b**), $\text{OC}_6\text{H}_4\text{C}(\text{CH}_3)_2\text{C}_6\text{H}_4\text{O}$ (**c**), $\text{C}(\text{CF}_3)_2$ (**d**).

Two approaches were used in the synthesis of PI **8a–d**: (1) the reaction of the diamine **7** with aromatic tetracarboxylic dianhydrides in *N*-MP at room temperature, which yields PCA **9a–d**, with subsequent imidisation of these polymers using the pyridine–acetic anhydride mixture (1 : 1); (2) high-temperature (160 $^{\circ}\text{C}$) polycyclocondensation of the starting monomers in *m*-cresol catalysed by quinoline.

In virtually all cases, the PI **8a–d** prepared in *m*-cresol were characterised by higher values of η_{red} in comparison with the polymers of the same structures prepared in *N*-MP. For example, the η_{red} values for PI **8c** prepared in *m*-cresol and *N*-MP are equal to 0.80 and 0.30 dl g^{-1} , respectively.

High solubility in *N*-MP, DMF and *m*-cresol is a distinguishing feature of the PI under study. The polyimide **8d** is also soluble in THF, cyclohexanone, chloroform, dichloromethane and even in acetone. The presence of phenylthio substituents is one of the factors which determine high solubility of PI **8**, which is in keeping with the published data.^{78–80}

Studies of the effects of methyl substituents on the properties of PI by comparing characteristics of polymers based on 3,5-diamino-2-methyldiphenyl (**7**) and 3,5-diaminodiphenyl sulfide have shown that methyl-substituted PI possess higher solubilities. The softening temperatures of the methyl-substituted PI are 250–285 $^{\circ}\text{C}$, i.e., somewhat higher than those of the corresponding PI devoid of methyl groups. On the contrary, the decomposition temperatures of methyl-substituted PI are lower (310–370 $^{\circ}\text{C}$) than those of PI containing no methyl groups.¹⁴

Considerable attention has been given to the synthesis of heterochain polymers containing no methyl groups, especially to the synthesis of polymers based on aromatic diamines containing a phenoxy substituent, which affects favourably the solubility of aromatic condensation polymers.^{78–85} For example, polyamides **11a,b** (PA) were prepared on the basis of 3,5-diaminodiphenyl ether (**10**). (Some aromatic PA are widely known owing to their excellent thermal and mechanical properties.^{86–88}) These PA were

synthesised using terephthalic (**12a**) and isophthalic (**12b**) acid dichlorides.^{89,90}

The synthesis of PA **11a,b** was carried out using two different approaches: (1) low-temperature polycondensation in *N*-MP^{86,90} and (2) low-temperature polycondensation in chloroform in the presence of triethylamine as an HCl acceptor.^{86–90}

The polyamides **11a,b** are readily soluble in organic solvents [*N*-MP, dimethylacetamide (DMAA), DMF, *m*-cresol, etc.]; their decomposition temperatures are 350–400 °C. These characteristics are in good agreement with those obtained in earlier studies on aromatic PA containing phenoxy substituents.^{80,83} Glass-transition temperatures of the PA synthesised (236–275 °C) are lower than those of unsubstituted PA with similar structures.^{86,87} This suggests that phenoxy substituents exert a plastifying effect.

Considerable attention has been given to the synthesis of PI containing aromatic substituents. The interest in substituted PI is due to the poor processability of unsubstituted PI.^{26–30,91,92} Among PI containing aromatic substituents, phenoxy-substituted polymers are especially popular. Such PI were prepared^{58–61,90,93,94} by treatment of phenoxy-substituted amines **10, 13–16** with tetracarboxylic dianhydrides (Scheme 6).

The PI **17–21** can be prepared by three routes:⁹⁵ (1) low-temperature polycondensation in *N*-MP with subsequent catalytic imidisation of the PCA formed in the reaction solution in the presence of pyridine–acetic anhydride (1 : 1); (2) high-temperature polycondensation in *N*-MP in the presence of azeotrope-forming compounds; (3) high-temperature polycondensation in *m*-cresol catalysed by isoquinoline.

A comparison of PI prepared by three different methods has demonstrated that high-molecular-mass polymers are formed in nearly all cases.

Polyimides **17** and **18** except for those PI based on pyromellitic dianhydride are soluble in *N*-MP, *m*-cresol and a tetrachloroethane–phenol mixture, which suggests a favourable influence of the phenoxy substituents on the solubility of the polymers. The values of η_{red} for these polymers in *N*-MP are equal to 0.30–0.83 dl g^{−1} ($M_w \leq 48\,000$). Some PI demonstrate good film-forming properties. The softening temperatures (T_{soft}) (180–380 °C) and $T_{10\%}$ (500–550 °C) of the polymers **17** and **18** differ significantly from one another.

Polymers **17** based on 3,5-diaminodiphenyl ether (**10**) may be considered as PI analogues based on *m*-phenylenediamine. A comparison of properties of these two groups of polymers suggests that the introduction of phenoxy substituents leads to an increase in the solubility of the polymers and a decrease in their glass-transition temperatures, indicating that phenoxy groups behave as chemical plasticisers. This finding is in good agreement with the literature data.^{78–84,96–101}

Polyimides **19–21** have $\eta_{\text{red}} = 0.22–1.00$ dl g^{−1} (*N*-MP) and M_w up to 77 000 (*N*-MP, sedimentation data). With the exception of polypyromellitimide, these polymers are soluble in organic solvents. Some of them form films. The polymers **19–21** prepared

in accordance with Scheme 6 have low softening temperatures (165–213 °C) and high decomposition temperatures ($T_{10\%} = 470–550$ °C), which determines their processability into articles using solvent-free methods.

A comparison of various characteristics of these PI has shown that polymers **19** based on bis(3-amino-5-phenoxy)diphenyl bisphenol ethers manifest the best solubility; some of them are soluble even in cyclohexanone. They also have the lowest T_{soft} .

In addition to PI containing five-membered imide rings, PI with six-membered imide rings, viz., polynaphthylimides and polypyrrolenimides, have been synthesised; the latter are known to be more hydrolytically stable and thermostable than polynaphthylimides.^{102–105}

The synthesis of phenoxy-substituted polynaphthylimides and polypyrrolenimides^{90,106} was carried out as follows:

Y = bond (**10**), $-\text{O}-\text{C}_6\text{H}_4-\text{O}-\text{C}_6\text{H}_3(\text{OPh})-$ (**14**);

All these reactions were carried out in phenolic solvents (*m*-cresol, *m*- or *p*-chlorophenols) under high-temperature polycondensation conditions using benzoimidazole and/or benzoic acid as a catalyst. The polymerisation process is homogeneous in all cases and yields deeply coloured polymers.

Some of the polymers synthesised are well soluble in organic solvents and possess good thermal characteristics. Thus the polynaphthylimide

is soluble not only in *N*-MP and the tetrachloroethane–phenol mixture (3 : 1), but also in DMF, chloroform and, partially, in

Y = S (**22**, **24**), SO₂ (**23**, **25**);

X = O (**a**), CO (**b**), OC₆H₄C(CH₃)₂C₆H₄O (**c**), C(CF₃)₂ (**d**).

DMA. Enhanced solubility of this polynaphthylimide in comparison with the polymers prepared from the same dianhydrides and aromatic diamines containing no phenoxy substituents^{105, 107} demonstrates a positive influence of the hydroquinone bis(3-amino-5-phenoxy)diphenyl ether structure on the solubility of the polymers.

Polyimides containing phenylthio- and phenylsulfonyl side groups^{62, 94} were prepared from the diamines **22** and **23** in accordance with Scheme 7.

The polyimides **25a–d** based on 3,5-diaminodiphenyl sulfone (**23**) are characterised by lower η_{red} values (0.25 dl g^{−1}) than PI **24a–d** based on 3,5-diaminodiphenyl sulfide (**22**) (0.79–1.20 dl g^{−1}). This difference may be due to the negative effect of the electron-withdrawing phenylsulfonyl group on the reactivity of the amino groups.

The solubility of the PI **24a–d** in organic solvents strongly depends on the nature of the dianhydride used. The values of η_{red} of the polymers in *N*-MP are fairly high (0.79–1.20 dl g^{−1}), while moderate softening temperatures (210–250 °C) combine with high decomposition temperatures (400–460 °C).

The polyimides **26a,c,d** containing benzothiazol-2-ylthio groups were prepared by high-temperature polycyclocondensation of the diamine **27** with the dianhydrides **2a,c,d** in *m*-cresol.¹⁰⁸

X = O (**a**), OC₆H₄C(CH₃)₂C₆H₄O (**c**), C(CF₃)₂ (**d**).

All the PI **26** were synthesised under homogeneous conditions. These polymers have $\eta_{\text{red}} = 0.29\text{--}0.42$ dl g^{−1}, $T_{\text{soft}} = 215\text{--}265$ °C and $T_{10\%} = 325\text{--}400$ °C. The polymer **26a** is soluble in *N*-MP, the PI **26c**, in *N*-MP and THF and the PI **26d** is soluble in *N*-MP, THF and chloroform. The positive influence of benzothiazol-2-yl side groups on the solubility of the polymers has been observed previously.^{109, 110}

PI containing functional side groups, first of all, hydroxy groups, were synthesised along with PI prepared from TNT derivatives devoid of reactive substituents.^{65, 111}

Recently,^{112–119} PI containing free hydroxy groups have attracted the keen attention of investigators because of the possibility of forming hydrogen bonds, which increases the glass-transition temperatures of the polymers, favours their solubilities in amide solvents and enhances moisture absorption.¹¹⁶

It is noteworthy that hydroxy groups can be used as the reaction centres for the introduction of other side groups, *e.g.*,

unsaturated substituents able to form crosslinked structures;¹¹⁷ chromophores imparting nonlinear optical properties to the PI^{120–122} and thermally unstable side groups prone to thermal decomposition with the formation of low-permittivity nanofoams.^{123–125}

Polyimides based on 3,5-diamino-4'-hydroxydiphenyl ether (**28**), 2,6-diamino-4-hydroxytoluene (**29**) and the tetracarboxylic dianhydrides **2a–d** were prepared in two steps.

28, **30**, **32**: R = H, Y = $-\text{O}-\text{C}_6\text{H}_4-$; **29**, **31**, **33**: R = CH₃, Y = bond;
X = O (**a**), CO (**b**), OC₆H₄C(CH₃)₂C₆H₄O (**c**), C(CF₃)₂ (**d**).

The first step includes the preparation of PCA **30a–d** and **31a–d** in *N*-MP under mild conditions (25 °C). The second step, *viz.*, polycyclisation of PCA, is carried out in the absence of the pyridine–acetic anhydride mixture to prevent acylation of the hydroxy groups. After addition of toluene to the reaction mixture (for azeotropic distillation of water), the reaction temperature is raised to 180 ± 10 °C and the solution is kept at this temperature for 6 ± 1 h. This method has recently found wide acceptance in PI synthesis.^{95, 126} Cyclisation of PCA **30a–d** and **31a–d** from all the aromatic tetracarboxylic dianhydrides **2a–d** occurs under homogeneous conditions and yields PI **32a–d** and **33a–d** with moderate viscosities ($\eta_{\text{red}} = 0.28\text{--}0.80 \text{ dl g}^{-1}$) and high degrees of cyclisation.

All the PI synthesised represent amorphous polymers with glass-transition temperatures of 223–369 °C typical of flexible-chain PI and decomposition temperatures of 378–439 °C. They are well soluble in organic solvents; the PI based on the dianhydride **2d** manifest the best solubility.

The introduction of alkoxy substituents into the PI macromolecules enhances their solubilities. It is known that the presence of methoxy substituents in PI macromolecules increases their solubilities in organic solvents.⁹⁶ The methoxy-substituted PI are prepared starting from 3,5-diaminoanisole.⁴⁶

The PI **34a–c** were synthesised by the reaction of 3,5-diaminoanisole with dianhydrides **2a,b** and pyromellitic dianhydride (**35**) using three different procedures:^{90–92} low-temperature condensation of 3,5-diaminoanisole with tetracarboxylic dianhydrides in amide solvents followed by thermal (route 1) or catalytic (route 2) imidisation of the PCA formed in the presence of the pyridine–acetic anhydride mixture (1 : 1) and high-temperature (150–180 °C) condensation in *m*-cresol in the presence of a catalyst (quinoline, isoquinoline or benzoic acid) (route 3).

The reaction of 3,5-diaminoanisole with tetracarboxylic dianhydrides in amide solvents (*e.g.*, *N*-MP) is carried out at room temperature. This reaction proceeds in a homogeneous system and yields PCA with relatively high η_{red} ($0.47\text{--}1.12 \text{ dl g}^{-1}$).

Catalytic imidisation affords PI more soluble in comparison with polymers synthesised by solid-phase methods;⁹⁶ therefore, this approach presents the greatest interest. Catalytic imidisation is performed by adding the pyridine–acetic anhydride mixture to a prepolymer solution and stirring the boiling reaction mixture for several hours. In all cases studied, the imidisation was accompanied by precipitation of the polymer from the reaction mass in the form of a swollen gel. It is noteworthy that this does not prevent the cyclisation of the *o*-carboxamide fragments into imide fragments with a high degree of conversion.

Polypyromellitimide **34c** does not soften unless the decomposition temperature is reached. The softening temperatures of polyimides **34a,b** are 300 and 310 °C, respectively.

Depending on the structure of the central fragment of the dianhydride, the thermal stabilities of the PI synthesised decrease in the following order: **34c** > **34b** > **34a**. This is consistent with the generally accepted viewpoint on the correlation between the structures of the polymers and their thermal stabilities.^{127, 128}

Dynamic TGA studies of thermal stabilities of PI prepared (air, heating rate 4.5 °C min^{-1}) have shown that $T_{10\%}$ depends only insignificantly on the polymer structure: $T_{10\%}$ is ~ 400 °C for all the PI studied. The relatively low thermal stabilities of the polymers **34a–c** can be attributed to the presence of the methoxy groups.

The polyimides **34b,c** are insoluble in amide-type (including *N*-MP) or any other solvents; only the PI **34a** is soluble in *m*-cresol and the tetrachloroethane–phenol mixture (3 : 1). Presumably, the ‘hinged’ groups have a more pronounced effect on the solubility of the polymers than methoxy substituents.

The high solubility of the polymer **34a** in phenolic solvents has made it possible to obtain virtually colourless films with a tensile strength of 114 MPa (at 25 °C) and elongation at rupture of 9%.

An attempt to synthesise the PI **34a** by high-temperature condensation in *m*-cresol was less successful, although this was performed in a homogeneous medium. The η_{red} value of the polymer **34a** thus prepared is much lower than that of the corresponding polymer obtained by catalytic cyclisation of PCA.

Polymers containing perfluoroalkyl side groups also present substantial interest.^{49–51} Such polymers have found wide application in aerospace and electronic engineering owing to their high thermal stabilities, mechanical strengths and good insulating characteristics.^{129–133} These technological fields have a continuing demand for transparent PI (coating of solar batteries) and low-permittivity PI (reduction of delay periods in electric circuits). The optoelectronic industry requires PI transparent at the wavelengths exceeding that of the visible light and possessing controllable refraction indices. Introduction of fluorine into polyimide materials is one of the most efficient approaches to the synthesis of such PI.^{134–136} The introduction of side fluoroalkoxy groups into the starting monomers is also widely used.

The synthesis of fluorinated PI based on diamines of the general formula

X = F: $n = 3, 6, 7$; X = H: $n = 10$.

has been described.¹³⁷

However, the values of η_{red} of the polymers thus prepared were relatively low and decreased with an increase in the length of the fluoroalkoxy group. This may be due to two reasons, viz.: (1) a decrease in the reactivities of fluorinated diamines as nucleophiles due to the presence of electron-withdrawing fluoroalkoxy groups; (2) the steric hindrance of the amino group in the *ortho*-position relative to the bulky fluoroalkoxy group. This circumstance has stimulated the search for new ways to synthesise fluorinated PI.

Some novel representatives of such PI were synthesised from perfluoroalkoxy-substituted *m*-phenylenediamines **36** based on TNT and various aromatic tetracarboxylic dianhydrides.^{51–54}

Y = F: $n = 1$; Y = H: $n = 2, 4, 6$;
X = O (**a**), $\text{OC}_6\text{H}_4\text{C}(\text{CH}_3)_2\text{C}_6\text{H}_4\text{O}$ (**c**), $\text{C}(\text{CF}_3)_2$ (**d**).

This reaction is carried out in *m*-cresol in the presence of isoquinoline (160 °C, 5 h). The homogeneous reaction conditions favour the preparation of PI completely soluble in *N*-MP. Depending on their structures, such PI are also soluble in other organic solvents. Thus the polymers **37c** are soluble in chlorinated solvents but are insoluble in acetone, whereas the PI **37d** are soluble in acetone, but not in chlorinated hydrocarbons. High solubility of the PI **37** may be due to the presence of side perfluoroalkoxy and bridging groups^{96,136} as well as to the amorphous structure of these compounds (X-ray diffraction data).

Virtually all PI **37** are high-molecular-mass compounds with $T_{soft} = 155–265$ °C (thermomechanical analysis data) and

$T_{10\%} = 400–430$ °C, which exceed those of the methoxy-substituted PI **35**. It should be noted that T_{soft} of the polymers **37** decreases with an increase in the length of the fluoroalkoxy group. Colourless strong elastic films were cast from solutions of the PI **37** in THF. Pressing of these PI at temperatures exceeding T_{soft} by 100 °C at 10 MPa produced transparent yellowish articles. The polymers **37** possess relatively low refraction indices and dielectric constants (ϵ), which is in good agreement with the known data.^{124,137}

2. Aromatic oligo- and polyethers

Aromatic nucleophilic substitution of nitro groups can be employed for the preparation of aromatic polyethers,^{24,25,138} although there are few examples of such reactions.¹³⁸ A serious problem in the synthesis of polyethers from mononuclear dinitro compounds is passivation of the second nitro group following replacement of the first nitro group by a nucleophile. What is also essential is that nitro group activators usually occupy the *ortho*- and *para*-positions. Therefore, the possibility of using 3,5-dinitrodiphenyl sulfone, a TNT-based mononuclear compound containing an electron-withdrawing activating group in the *meta*-position with respect to the nitro groups, in the synthesis of aromatic polyethers is of interest for investigators.⁹⁰

The model reaction of 3,5-dinitrodiphenyl sulfone with phenol was carried out in *N*-MP (150 °C, 6 h).

The synthesis of the polyether **38** based on 3,5-dinitrodiphenyl sulfone and bisphenol A was carried out under identical conditions.

38

Although the polyether formed has low molecular mass ($n = 5$, $M_n = 1900$, $M_w = 2600$), this reaction has demonstrated the feasibility of polyether synthesis from mononuclear dinitro compounds containing an activating group in the *meta*-position with respect to the nitro groups, which is in agreement with the earlier data.¹³⁹ It seems therefore expedient to use the dinitro-compound,

which represents the reaction product of 4,4'-dimercaptodiphenyl sulfide with a twofold molar excess of 3,5-dinitrodiphenyl sulfone and subsequent oxidation of the sulfide groups to the sulfonyl groups, as a starting monomer for the synthesis of high-molecular-mass polyethers.

IV. Conclusion

The development of condensation monomers and polymers based on TNT and its derivatives offers a solution for two different problems, *viz.*, utilisation of TNT and design of cheap and accessible PI with enhanced processability into articles.

Taking into account the increasing interest in dendritic polymers in the past two decades,^{140–151} it may be expected that the progress in the chemistry of monomers and polymers based on TNT will be associated with the synthesis of such polymers. It should be noted that TAT is an ideal trifunctional core for the synthesis of novel representatives of dendritic PA and PI, while 1,4-bis(3,5-diaminophenoxy)benzene can serve as a tetrafunctional core for the preparation of dendritic PA and PI.

The A₂B-type monomers derived from TNT^{152, 153} can find application in the synthesis of superbranched polymers.^{154–157} In particular, 3,5-diamino-4'-carboxydiphenyl ether can be used for the preparation of superbranched aromatic PA containing peripheral amino groups, whereas 3,5-dinitro-4'-hydroxydiphenyl ether is a promising starting material for the synthesis of superbranched aromatic polyethers based on aromatic nucleophilic nitrosubstitution.

The novel architecture of these polymers determines their novel properties which in turn opens up new areas for their application.

This review has been written with financial support of the International Science and Technology Center (Grant No. 419).

Abstract. Experimental methods of determination of the fractal dimensions of fractal aggregates are described. The results of studies on aggregation of colloidal particles in different regimes are discussed. Data on the hydrodynamics of colloid dispersions containing fractal aggregates and on the rheology of fractal gels are presented. Capillary phenomena in fractal systems as well as the structural and mechanical properties of aerogels and peculiar features of the optical properties of fractal aggregates are described. The bibliography includes 395 references.

I. Introduction

Disperse systems are of frequent occurrence in nature. The solid component of such systems represents aggregates of colloidal particles, which were among the first physicochemical objects described in the framework of fractal geometry approach. Currently, most studies on fractals are also carried out using fractal aggregates as examples. This is due to the fact that these objects can form a variety of structures, which can be identified with ease in model experiments. It was also found that fractal aggregation provides a way of simulation of many processes which at first glance have nothing to do with particle aggregation.

Fractal aggregates are constituents of a vast variety of systems. Their properties to a great extent predetermine the physicochemical characteristics of the entire systems. In this review the emphasis is placed on the physical properties of aggregates. We will discuss the experimental methods of determining the structure of aggregates and the laws of aggregation, which are based on these properties. Both widely used experimental methods and some promising original techniques for determination of the fractal dimension of aggregates are considered.

In the review we will show how the fractal parameters[†] of surfaces and the properties of aerogels (systems comprised of aggregates of the primary particles) can be determined. The properties of aerogels thus implicitly reflect those of fractal aggregates. Of great importance for both aerogels and fractal surfaces are the capillary phenomena. On the one hand, they form the basis for some methods of determination of the fractal dimension of porous media. On the other hand, they affect the evolution of the structure of aerogels, especially at high temperatures.

A large part of the review is concerned with the hydrodynamic characteristics of fractal aggregates. Undoubtedly, these characteristics are of great practical value, because they are responsible for many properties of colloidal dispersions. A wide range of conditions suitable for studying the hydrodynamic behaviour of fractal aggregates is due to frequent occurrence of colloidal dispersions.

Recently, considerable progress has been achieved in studies of the optical properties of fractal aggregates. Researchers perceived that it is the fractal structure of aggregates that strongly affects the electromagnetic field distribution inside them. The fractal structure causes localisation of the electromagnetic field and a dramatic increase in its strength in some local domains. The effects revealed are of interest for all researchers who study highly dispersed metallic systems.

II. Experimental studies of the properties of fractal aggregates

1. Methods of determination of the fractal dimension

The most widely used methods of determination of the fractal dimension of aggregates include (i) sedimentation technique, (ii) electron and optical microscopy and (iii) light, X-ray and neutron scattering. The highest efficiency is provided by the third group of methods, while both microscopy techniques are most easy in use.

The methods based on optical and electron microscopy involve the determination of the dependence of the masses of aggregates on their sizes or construction of the plot of the density correlation function for an image of an aggregate.^{2–6} They can be used to study the aggregates whose fractal dimension (d_f) is at

Received February 2003

Uspekhi Khimii 72 (11) 1027–1054 (2003); translated by A M Raevsky

[†] For the definitions of the most important fractal parameters, see Ref. 1.

most two, because at $d_f > 2$ the images of a large proportion of the primary particles will overlap. Strictly speaking, some corrections⁷ for the overlap of the particle images should be included even if one deals with fractal aggregates characterised by $d_f < 2$.

Two main approaches are employed in the microscopy studies. One of them involves plotting the density correlation function determined using the image of the aggregate *vs.* the distance from the centre of the aggregate in the double logarithmic coordinates. For fractal aggregates, the plot obtained must be linear. In this case, the fractal dimension can be determined from the slope of the plot using the known relationship for the density distribution function, $\rho(r)$, in the aggregate (see Ref. 1)

$$\rho(r) \propto r^{d_f-d}, \quad (1)$$

where r is the distance from the centre of the aggregate and d is the space dimension.

Following the other approach, one should plot the dependence of the number of particles contained in a square covering the aggregate on the length of the square side (the so-called sand-box technique). This method employs the dependence of the number, N , of particles in an aggregate on the size, R , of the aggregate (see Ref. 1)

$$N = k_0 \left(\frac{R}{a} \right)^{d_f}, \quad (2)$$

(k_0 is the prefactor and a is the size of the primary particles), because the square side acts as the size of the aggregate. For a fractal aggregate, the experimental points fall on a straight line plotted in the double logarithmic coordinates ($\log N - \log R$) and the slope gives the fractal dimension.

The main advantage of the microscopy techniques is the possibility of determination of many fractal parameters, which provide versatile characterisation of aggregates (*e.g.*, a two-dimensional image of a fractal aggregate can be characterised by seven different fractal dimensions⁸). At the same time, these methods are applicable only to rather loose fractal aggregates with $d_f < 2$ (see above).

Yet another procedure for the determination of d_f of aggregates is based on the estimation of the fractal dimension of their sections. This is a useful method of studying opaque composites. It was substantiated by Miyazima and Stanley⁹ who derived an equation for the fractal dimension of the structure (d_{fs}) formed upon intersection of two fractal objects

$$d_{fs} = d_{f1} + d_{f2} - d,$$

where d_{f1} and d_{f2} are the fractal dimensions of the overlapping aggregates.

A section of a fractal object is obtained by intersecting a fractal with a plane. Therefore, the fractal dimensions of a three-dimensional object and its section are related by a simple relationship

$$d_{fs} = d_f - 1.$$

Practical evaluation showed¹⁰ that the fractal dimension of flocs determined using this technique coincided with that found from the three-dimensional structure reconstructed using electron microscopy.

In fact, similar considerations also form the basis for confocal scanning laser microscopy, which recently has been used for the determination of characteristics of fractal aggregates.¹¹ This method involves the determination of the particle distribution in the focal plane of an optical microscope, which is then used to determine the fractal dimension of aggregates. To obtain more reliable results, the fractal object is scanned in different planes.

However, the most widely used methods are small-angle X-ray^{12–15} and neutron^{16–18} scattering. The most popular technique is static light scattering,^{19–24} which involves the determination of the fractal dimension from the dependence of the

scattered intensity on the scattering vector. In the case of dynamic light scattering,^{3, 23, 25–27} the fractal dimension is found from the temporal dependence of the average size of the aggregate. Lin and co-workers²⁸ first showed that this is a power dependence with the exponent $1/d_f$.

A great body of experimental information on the determination of fractal dimensions has been accumulated to date. Therefore, the fractal dimension measurements themselves are no longer topical. Attention now focusses on the studies of the laws of structural transformations experienced by those systems whose evolution is accompanied by the growth of fractal aggregates in some stage. These investigations are mainly based on the studies of light scattering from aggregates.^{29–33}

If a system comprises N particles of the same size, the scattered intensity is given by

$$I(q) = N^2 P(q) S(q), \quad (3)$$

where q is the magnitude of the scattering vector and $P(q)$ is the form factor, which for spherical particles has the form

$$P(q) = \left[24 \frac{\sin(q/2) - (q/2) \cos(q/2)}{q^3} \right]^2, \quad (4)$$

where $S(q)$ is the structure factor

$$S(q) = \frac{1}{N^2} \sum_{j=1}^N \sum_{i=1}^N \exp[i\mathbf{q} \cdot (\mathbf{r}_i - \mathbf{r}_j)], \quad (5)$$

where $\mathbf{q}$ is the scattering vector and $\mathbf{r}_i$ and $\mathbf{r}_j$ are the particle coordinates. The structure factor can be expressed through the density correlation function, $C(r)$, of the aggregate

$$S(q) = \frac{1}{N} \left[1 + 4\pi \int_0^\infty C(r) r^2 \frac{\sin(qr)}{qr} dr \right]. \quad (6)$$

The normalising factor $1/N$ is introduced to provide $S(q=0) = 1$.

From Eqn (6) it follows that the structure factor strongly depends on the density distribution in the system under study. Suppose that the pair correlation function of fractal aggregates in the three-dimensional space is given by

$$C(r) \propto r^{d_f-3} h\left(\frac{r}{R_g}\right)$$

and that the cutoff function has a Gaussian shape

$$h(x) = e^{-x^2},$$

where

$$x = \frac{r\sqrt{d_f}}{2R_g},$$

R_g is the radius of gyration of the aggregate. Then, the structure factor can be calculated using an exact analytical expression

$$S(q) = e^{-(qR_g)^2/d_f} F_1 \left[\frac{3-d_f}{2}, \frac{3}{2}, \frac{(qR_g)^2}{d_f} \right], \quad (7)$$

where F_1 is the hypergeometric function.

The shape of the cutoff function has a rather strong effect on the structure factor. Using the exponential cutoff function

$$h(x) = e^{-\kappa_1 x}, \quad x = \frac{r}{R_g},$$

one gets

$$S(qR_g) = \left(1 + \frac{q^2 R_g^2}{\kappa_1^2} \right)^{(1-d_f)/2} \frac{\sin[(d_f-1) \arctg(qR_g/\kappa_1)]}{(d_f-1)(qR_g/\kappa_1)}. \quad (8)$$

The set of cutoff functions also includes the functions employed in the model of overlapping spheres, where

$$h(x) = 1 - \frac{3}{4}\kappa_2 x + \frac{\kappa_2^3}{16}x^3 \quad \text{at } x < \frac{2}{\kappa_2}$$

and

$$h(x) = 0 \quad \text{at } x > \frac{2}{\kappa_2},$$

and the stretched exponent

$$h(x) = e^{-\kappa_3 x^{\kappa_4}}.$$

Using these cutoff functions makes the expressions for the structure factor of a fractal aggregate more cumbersome.

Experimental studies of the effect of finite aggregate size on the small-angle light scattering intensity were reported.^{34,35} The possibility of reconstructing the cutoff function from the structure factor $S(q)$ was pointed out,^{36,37} which can also be done for polydisperse aggregates provided that the structure factor is measured for a broader interval of q values.

Fractal aggregates of complex structure and the corresponding structure factors were studied by Zhu and White³⁸ assuming an oscillating radial density distribution in the aggregate. Using such an exotic density distribution, it was found that the model correctly reproduces the experimental scattering pattern obtained for aggregates in a polydimethylsiloxane/paraffin liquid mixture.

Expressions (7) and (8) describe individual aggregates. Colloidal dispersions are always characterised by some aggregate size distribution, or particle number (s) distribution. This complicates the expressions for the structure factor³⁵ and, hence, comparison of the theoretical and experimental dependences. In particular, calculations³⁹ of various parameters, which can be determined in the static light scattering experiments, were carried out with the following aggregate size distribution

$$N_s = s^{-\tau} \exp\left[-\left(\frac{s}{\langle s \rangle}\right)^{\beta_s}\right],$$

where τ and β_s are numerical parameters and $\langle s \rangle$ is the average number of particles, and with the stretched exponential cutoff function. The expressions derived are too cumbersome and therefore not presented here.

Usually, static light scattering experiments involve intensity measurements in some range of scattering angles, $a \ll q^{-1} \ll R_g$, corresponding to the so-called small-angle scattering rather than in the whole available interval of scattering angles. In this case, the scattered intensity is given by

$$I(q) \propto (qR_g)^{-d_f}. \quad (9)$$

This relationship permits both the fractal dimension and the radius of gyration of aggregates to be determined.

In dynamic or quasi-elastic light scattering experiments information on the size of an object is obtained by analysing the relaxation times of translational, rotational and 'configuration' diffusion. The theory of dynamic light scattering has been well developed.⁴⁰ This method involves measurements of the correlation function of scattered light

$$g^{(2)}(t) = \frac{\langle I(0)I(t) \rangle}{\langle I(0) \rangle^2}, \quad (10)$$

i.e., the time-averaged product of the scattered intensities measured at instants separated by an interval t .

The second-order correlation function (10) is related to the first-order correlation function $g^{(1)}(t)$ as follows

$$g^{(2)}(t) = 1 + G|g^{(1)}(t)|^2, \quad (11)$$

where G is some function determined by the experimental conditions. The dynamical structure factor for dilute dispersion of particles of the same size is given by

$$S(q, t) = S(q)g^{(1)}(t) = S(q)\left(-Dq^2 t\right), \quad (12)$$

where $S(q)$ is the static structure factor and D is the particle diffusion coefficient. In the Stokes approximation the diffusion coefficient has the form

$$D = \frac{kT}{6\pi\eta R_h},$$

where η is the viscosity of the medium and R_h is the hydrodynamic radius of the particle.

Dependence (12) has a clear physical interpretation, namely, the relaxation time $1/(q^2 D)$ is the time taken for a spherical particle to travel the distance $1/q$. In the case of non-spherical (e.g., rod-like) objects rotation can affect the scattered intensity at $qR \gg 1$. This also holds for flexible objects (e.g., polymer chains) where conformational relaxation can contribute to the dynamical structure factor at $qR \gg 1$. For most colloidal objects (in the absence of depolarising scattering) only translational motion contributes to the dynamical structure factor at $qR \ll 1$. Usually, the experimental data allow the initial rate of change in the correlation function or the first cumulant to be found

$$\Gamma_1 = -\left.\frac{d \ln S(q, t)}{dt}\right|_{t=0} = q^2 D. \quad (13)$$

Monodispersed systems are rare in occurrence; therefore, the contribution of polydispersity to the system's dynamics should be included. Experiments with polydisperse systems permit the averaged dynamical structure factor to be determined

$$S(q, t) = \sum_{s=1}^{\infty} s^2 N_s S_s(q, t), \quad (14)$$

In this case, the averaged first cumulant is given by

$$\frac{\Gamma_1}{q^2} = \left[\sum_{s=1}^{\infty} D_s s^2 N_s S_s(q) \right] / \left[\sum_{s=1}^{\infty} s^2 N_s S_s(q) \right] \quad (15)$$

(it will be recalled that the subscript s denotes the corresponding characteristics of the aggregates composed of s particles).

Thus, the measured diffusion coefficient values are averaged over $s^2 N_s$. This complicates processing of experimental data. A more detailed consideration of the problem can be found in, e.g., a review.²⁶

Improved dynamic light scattering methods were developed. Recently,⁴¹ it was shown that the so-called time-resolved dynamic light scattering technique allows not only the gel point of the dispersion to be determined but also the critical behaviour of the system during the sol–gel transition to be studied and the mechanism of gel formation and the architecture of gel-forming clusters to be predicted. The scattering spectrum exhibits some characteristic features suitable for identification of the sol–gel transition and obtaining information on the system under study.

In conclusion of this chapter, mention may be made that both static and dynamic light scattering techniques employed in studies of fractal aggregates can be significantly improved. This can be achieved by comparing the results of model light scattering calculations with the experimental data. For this reason, numerical simulation of aggregation of colloidal particles is carried out simultaneously with calculations of light scattering by the growing aggregates. Recently,⁴² the temporal evolution of the intensity of small-angle light scattering by the system of aggregating colloidal

particles was numerically simulated. Both irreversible and reversible coagulation of primary particles and aggregates were considered. The probability for the diffusing particles and aggregates to coagulate by collisions was varied over a wide range. It was shown that irreversible aggregation can lead to growth of clusters with the fractal dimension varied from 1.78 (diffusion-limited cluster–cluster aggregation, or DLA) to 2.1 (reaction-limited cluster–cluster aggregation, or RLA). At $qR_g \gg 1$, the scattered intensity depends on the scattering vector as follows

$$I(q) \propto q^{-d_f}.$$

The plot $I(q)$ exhibits a peak which becomes higher as the particle coagulation probability decreases. This points to densification of the particles. In the case of reversible aggregation, the peak appeared in early stages is shifted towards small q values as the time passes. This is accompanied by an increase in the scattered intensity and in the fractal dimension of the aggregates present in the system. Finally, the peak disappears. The theoretical relationships derived in Ref. 42 correctly reproduce the experimental data obtained for aggregates of polystyrene latex particles reported by Giglio *et al.*^{43,44} It was pointed out that phenomenological dependences of the type⁴⁵

$$S(q) = S(0) \left(1 + \frac{2}{3d_f} R_g^2 q^2 \right)^{-d_f/2}, \quad (16)$$

which have no extrema, were obtained for the conditions characterised by the significant role of thermally induced restructuring of clusters.

2. Experimental studies of the growth of fractal aggregates

Aggregation processes are studied to solve various problems. We will consider some most important avenues of research into the kinetics of particle aggregation accompanied by growth of fractal objects.

One investigation line is to obtain complete information on the coagulating system and to compare the experimental data with the predictions made using the Smoluchowski kinetic equation. Research in this field has long been carried out. A typical example is provided by the study⁴⁶ concerned with the growth dynamics of fractal aggregates composed of 10-nm gold particles. Aggregation occurred upon adding hydrochloric acid to a hydrosol. The rate of particle coagulation was controlled by varying the amount of acid. The temporal dependence of the aggregate size was determined using dynamic light scattering. The fractal dimension of aggregates, d_f , was estimated at 1.9 rather than exactly determined. The aggregate size was found to be time dependent as follows

$$R \propto t^{z/d_f},$$

where $z = 1/(1-\mu)$ and μ is the homogeneity parameter of the coagulation kernel. At high acid concentrations, μ was equal to -0.6 . As the concentration of the acid added decreased, the μ value gradually increased to 1. It was pointed out that the limiting value of the parameter μ obtained at high acid concentrations differs from zero ($\mu = 0$ corresponds to the DLA regime). A tendency of μ to unity at low acid concentrations corresponds to the RLA regime characterised by exponential increase in the aggregate size. Hence, the study⁴⁶ demonstrated that the experimental kinetics of particle aggregation is in agreement with the predictions of the Smoluchowski theory.

‘Workability’ of the Smoluchowski equation was confirmed in a number of light scattering studies, in particular, in the experiments on aggregation of 3-nm silica nanoparticles in aqueous solutions at different pH values and temperature (d_f varied from 1.75 to 2.01)⁴⁷ and polystyrene latex particles of size 60 and 140 nm dispersed in aqueous solutions in a wide range of changes in the salt concentration in the solution.⁴⁸ Both studies revealed

good agreement between the theoretical and experimental temporal dependences of the aggregate sizes.

Yet another research avenue is to study colloidal dispersions of more complex composition and the kinetics of aggregation accompanied by growth of fractal aggregates under conditions that differ from both DLA and RLA regimes. This can be illustrated taking the results of studies^{49–52} as examples. For instance, easily restructurable aggregates characterised by low fractal dimension were grown in the experimental studies on coagulation of oppositely charged particles of different size and shape.^{49,50} Deviations from the DLA and RLA laws were found^{51,52} in those experiments where particles coagulated upon adding non-indifferent electrolytes capable of changing the surface charge of the particles. These deviations were ascribed⁵² to the short-range repulsive forces that operate in such systems (see Refs 53–55).

The growth dynamics and the fractal dimension of aggregates also depend on the presence of stabilisers (surfactants or polymers) on the particle surfaces. Surfactant modifiers can serve not only as regulators of the rate of coagulation but also initiators of the process. For such systems the laws of aggregation can be significantly different.^{56–58} Nevertheless, it should be noted that modification of the particle surface not necessarily affects the fractal dimension of aggregates.⁵⁹

Quite unexpected results were obtained⁶⁰ in studies of aggregation of polystyrene latex particles stabilised by poly(*N*-isopropyl)acrylamide. The rate of particle aggregation was controlled by varying the temperature of the system and by adding salt. It was found that the fractal dimension of aggregates increases from 1.8 to 2.7 with increasing the salt concentration and, hence, the rate of coagulation. This change could not be obtained by combining the DLA and RLA regimes. What is more, the experimentally determined laws of changes in the fractal dimension could not be explained by the restructuring of aggregates (DLA-grown aggregates were characterised by a fractal dimension of 1.7 before and of 2.1 after restructuring).

To establish the mechanism of such an unusual aggregation process, the laws of the growth of fractal aggregates of polystyrene latex particles stabilised by sodium dodecylsulfate were studied comprehensively.⁶¹ The experiments involved variation of the particle sizes and the degree of coverage by the surfactant layer. Coagulation of particles was initiated by adding salt. The fractal dimension of aggregates and the temporal dependence of the mass of aggregates were determined using static and dynamic light scattering, respectively. It was established that salt additives affect both the mechanism of aggregation and the structure of aggregates, whereas the adsorption layer of the surfactant affects only the structure of aggregates (more exactly, it mainly affects restructuring of aggregates after completion of aggregation process). Changes in the kinetics of particle aggregation and in the fractal dimension of aggregates were compared with the changes in the potential of interparticle interaction determined in the Derjaguin–Landau–Verwey–Overbeek approximation with inclusion of the adsorption layer of surfactant. It was found that the unusual mechanism of the formation of the fractal structure is governed by a rather complex procedure of particle aggregation. Namely, the primary act of aggregation corresponds to the case where particles come within a distance which is nearly equal to twice the thickness of the adsorption layer. This allows particles to retain lateral mobility, which is responsible for restructuring of aggregates. Only after some time do the particles begin to contact one another, thus losing mobility in the aggregate.

Apparently, the unexpected results obtained in Ref. 60 can be explained by the fact that the authors of this study assumed a linear dependence of the mass of aggregates on time. However, it was found that this not necessarily holds in the case of the complex mechanism of aggregation. In particular, power dependences of the mass of aggregates on time with different exponents were obtained⁶¹ and some deviations from them at certain salt concentration values were pointed out.

Aggregation of 50-nm hematite particles in the presence of adsorbing polymer (polyacrylic acid) was studied.⁶² The fractal dimension of aggregates was determined using static light scattering with different cutoff functions. The polymers used had different molecular masses (1.36×10^6 and 3.69×10^4). Three regimes of particle aggregation, *viz.*, pre-DLA, DLA and post-DLA were practically implemented. The fractal dimension determined with the exponential cutoff function was 0.1 to 0.2 larger than that found using the Gaussian cutoff function. The fractal dimensions were independent of the molecular mass of the polymer. The fractal dimension of the DLA grown aggregates was 1.84 with the exponential cutoff function or 1.73 with the Gaussian cutoff function. At low polymer content, no DLA regime was attained and the aggregation was reaction limited (growth of more compact aggregates with a fractal dimension of 2.0). Aggregation in the post-DLA regime (excess of polymer) was slow, but the structure of aggregates ($d_f = 1.8$) was similar to the structure formed in the DLA regime.

The studies carried out before Zhang's communication⁶² were concerned only with aggregation of polymer-stabilised particles initiated by salt additives^{60,63} or with flocculation using a polymer whose radius of gyration was much smaller than the hydrodynamic radius of the colloidal particles.⁶⁴ The fractal dimension greater than 3 [the exponent in the expression for $S(q)$ changed from 2.83 to 3.42] was obtained at a low content of the polymer (fulvic acids).⁶³ At a large content of fulvic acids, the fractal dimension varied from 2.03 to 2.27. Growth of looser structures was explained by the formation of polymer links despite the low molecular mass of the polymer (~ 1000).

Zhang and co-workers⁶² also studied^{65,66} aggregation of hematite particles initiated by adding polyacrylic acid using dynamic light scattering. It was found that aggregation occurs due to neutralisation of the charge on the surface of particles by the adsorbing macromolecules. The fractal dimension of aggregates (1.88) was independent of the molecular mass of the polymer.

3. Restructuring aggregates

In most systems the growth of fractal objects is almost without exception accompanied by their restructuring in different stages of aggregation. Usually, experiments are designed to allow for and to carry out a separate study of this process. Theoretical studies on restructuring of aggregates began immediately after performing the first numerical experiments on the growth of fractal aggregates. Initially, densification was treated formally, *i.e.*, assuming that particles and aggregates are free to rotate, be bent, twisted, *etc.*; more recent studies were carried out with inclusion of the relative motion of particles in aggregates.^{67–69}

Martin *et al.*²⁶ investigated the kinetics of aggregation of silica particles of radius 11 nm dispersed in aqueous solutions and reported a spontaneous increase in the fractal dimension of aggregates. In these experiments, particle coagulation was initiated by adding a salt. The temporal dependences of the radius and fractal dimension of aggregates were determined using dynamic light scattering. A power-law increase in the mean radius with time at different initial concentrations of particles and different regimes of coagulation was found, which corresponded to conventional kinetics of particle aggregation. The fractal dimension changed from 1.73 for fast (diffusion-limited) to 2.05 for slow (reaction-limited) aggregation. At the same time, it was pointed out that the fractal dimension of the system under study is determined not only by the regime of aggregation but also by some other parameters (*e.g.*, concentration and the chemical nature of the salt added). Long-term observations revealed a dramatic change in the fractal dimension of certain aggregates due to restructuring. An analogous restructuring of aggregates also occurred when the dispersion was in a shear flow.

Similar results were obtained in the experiment⁷⁰ with silica particles of size 5 and 9.4 nm (aggregation was also initiated by adding a salt). The kinetics of particle aggregation in the DLA and

RLA regimes corresponded to that predicted by the Smoluchowski equation with the relevant coagulation kernels. However, the fractal dimension of the DLA-grown aggregates increased to a value of 1.8 after passage of a long time. The change in the fractal dimension was also associated with restructuring of aggregates.

Restructuring of aggregates was also observed in studies of polymer-initiated aggregation^{71,72} (a polymer was added to the solution) and various aerosol systems.^{73,74}

4. Anisotropic aggregates

Most fractal aggregates are anisotropic.^{75,76} This opens up new prospects for studies of their structure and the kinetics of growth.

To characterise anisotropic aggregates, it is possible to introduce two fractal dimensions and the self-affinity exponent. To determine these parameters, one should obtain aggregates with pronounced anisotropy. A good example is provided by aggregates of soot particles and some other highly dispersed aerosols. Here, the prefactor and the fractal dimension can be determined with ease;⁷⁷ however, the prefactors obtained much exceeded those found for a conventional RLA model. To eliminate this problem, an extended characterisation of aggregates of soot particles was carried out.⁷⁸ The particles were found to be self-affine rather than self-similar objects. Fitting the experimental data for the entire population of aggregates gave conventional values of the fractal dimension ($d_f = 1.7$) and the self-affinity exponent¹ ($A = 0.91$).

In the case of anisotropic particles the static and dynamical structure factors can be expressed as multipole expansions⁷⁵

$$S(q) = \sum_l S_l(q), \quad (17)$$

$$S_l(q, t) = \sum_l S_l(q) \exp \left[-Dq^2 t - l(l+1)\Theta t \right],$$

where

$$S_l(q) = \sum_{m=-l}^l \left| \sum_{i=1}^N J_l(\mathbf{q} \cdot \mathbf{r}_i) Y_{lm}(\Omega_i) \right|^2 \quad (18)$$

and $J_l(\mathbf{q} \cdot \mathbf{r}_i)$ is the l th order Bessel spherical function, Y_{lm} is the lm th order spherical harmonic, Ω_i is the orientation of the vector $\mathbf{r}_i$ determining position of the i th particle with respect to the centre of mass of the aggregate; and Θ is the rotational diffusion coefficient given by

$$\Theta = \frac{kT}{8\pi\eta R_h^3}.$$

The scaling behaviour of terms of the multipole expansion (17) for the aggregates grown in the diffusion-limited and reaction-limited cluster–cluster aggregation regimes and in the diffusion-limited particle–cluster aggregation regime was studied in detail by Meakin *et al.*⁷⁵ For cluster–cluster aggregation, they found that the fractal dimension describes the q -dependence of not only the total structure factor but also the terms of the multipole expansion. By contrast, clusters formed by particle–cluster aggregation did not exhibit the same degree of scale invariance.

Relationship (15) for anisotropic aggregates is valid only in the small- q limit ($q \rightarrow 0$). However, the scaling behaviour of the second cumulant for anisotropic aggregates changes at $q \rightarrow 0$. It is an easy matter to find that the following relation holds for anisotropic aggregates at $q \rightarrow 0$

$$\frac{\Gamma_2}{\Gamma_1^2} = Q \left(\frac{\Theta}{D} \right)^2, \quad (19)$$

where Q is a constant; for spherically symmetric aggregates this ratio equals zero.

The optical method^{79,80} of investigation of fractal aggregates is based on their natural anisotropy. The essence of the technique is as follows. The scattered intensity is measured after switching on and off a constant electric field. Switching on the field causes the fractal aggregates to be oriented in space, thus changing the scattered intensity. Switching off the field is followed by disordering of aggregates and the scattered intensity changes again. By analysing the dynamics of changes in the scattered intensity and by comparing the steady-state scattered intensities in the presence and in the absence of external field it is possible to determine the diffusion coefficients of aggregates. Using a number of dispersion samples prepared by successive removal (by, *e.g.*, centrifugation) of aggregates of different sizes, it is possible to determine their fractal dimension. Experiments with silica particles gave a fractal dimension of 2.5.⁸⁰ Analysis of experimental data also revealed a linear dependence of the induced dipole moment of aggregates on their size.

Theoretical analysis^{81–83} of the laws of relaxation of orientational optical effects showed that the anisotropic structure of aggregates can make itself evident in the orientational turbidimetric effect, which is measured in unpolarized laser beam. The effect manifests itself as a difference between the optical densities of colloidal dispersions in which fractal aggregates are disordered and oriented by the external field. This effect is due to the dependence of the total extinction cross-section of anisotropic aggregates on their orientation. The theory of orientational turbidimetric effect was generalised⁸⁴ by inclusion of the interaction between dipoles in the fractal aggregate. The magnitude of the effect was calculated for fractal clusters of different size grown under specific conditions and then evaluated experimentally. Theoretical predictions (in particular, scale invariance of the structure of aggregates and turbidimetric effect) were confirmed by the experiments with 40-nm silica particles. Namely, the dependences of the magnitude of the effect on the aggregate size and on the emission wavelength specifically normalised fell on the same curve.

Yet another method⁸⁵ of studying the laws of growth of anisotropic aggregates involves the determination of the kinetics of development and relaxation of birefringence, which is observed in dispersions of fractal aggregates upon application of external electric field. The technique was evaluated taking dispersions of 9.5 nm polystyrene latex particles as examples (particle aggregation was initiated by adding a salt). The fractal dimension of aggregates and the growth rates were in agreement with the corresponding values found for these systems by dynamic light scattering.

5. Aggregation in transient regime

Particle aggregation is carried out in a particular regime. Diffusion-limited cluster–cluster aggregation causes clusters with a fractal dimension of 1.8 to grow; the fractal dimension of the RLA grown clusters can be as large as 2.1. Not only the fractal dimensions but also the functions $f(x)$ determining the cluster size distribution are different. In the case of diffusion-limited cluster–cluster aggregation one has

$$N_s(t)^2 \propto s^{-2} f\left(\frac{s}{\langle s \rangle(t)}\right),$$

and the function $f(x)$ has the form

$$f(x) \approx e^{-x}.$$

The mean aggregate size varies with time as follows

$$\langle s \rangle(t) \propto t.$$

In the case of reaction-limited cluster–cluster aggregation one has

$$f(x) \approx x^{-1.5} e^{-x}$$

and $\langle s \rangle$ exponentially increases with time. Usually, the results of theoretical studies of DLA are in good agreement with the experimental data and with the results of numerical simulation. As to RLA studies, agreement is observed only in the initial stages of the process. Deviations from the RLA regime were established in both model³³ and numerical^{86,87} experiments. Namely, the fractal dimension varied with time and the exponential growth of the aggregate size was changed by a power-law process.

Systematic studies of the transition region between diffusion- and reaction-limited cluster–cluster aggregation were carried out.^{88–92} Aggregation of polystyrene latex^{88–91} and silica⁹² particles was initiated by adding a salt. The salt concentration was chosen to deliberately perform experiments in the transient regime of aggregation. Dynamic and static light scattering studies reliably established that the transition does occur. Experimental data were confirmed by the results of calculations using the Smoluchowski coagulation equation with a time-dependent coagulation kernel (kernel parameters were chosen based on information on the interaction between latex particles in electrolyte solutions). The possibility of solving the inverse problem, namely, determination of parameters of the interaction between latex particles from the kinetics of coagulation (more rigorously, from the point of transition from one regime of aggregation to another) was also shown.

Experiments showed⁹⁰ that the aggregate size increases linearly with time and that the so-called stability factor, w_c , is related to the fractal dimension

$$d_f = 1.45 + 0.857 \ln w_c. \quad (20)$$

This dependence is valid if the stability factor varies within an order of magnitude.

Differences between the $I(q)$ dependences obtained for the DLA and RLA regimes were reported.⁹¹ Experiments on diffusion-limited cluster–cluster coagulation of polystyrene latex particles revealed that the $I(q)$ dependence passes through a maximum at a finite q value. As the process developed, the peak shifted towards small q , which corresponded to spinodal decomposition. Similarly to the results reported earlier for other systems,^{43,93} no peak was observed for the $I(q)$ dependence when the process was performed in the RLA regime. Transient aggregation studies revealed a gradual transition from the RLA to the DLA regime. The change in the regime of aggregation was accompanied by some delay in the appearance of the $I(q)$ peak; development of the coagulation process led to disappearance of the peak.

Studies of various systems using calculations with the Smoluchowski equation for transient regime of aggregation allowed one to choose the coagulation kernels, which best described the experimental kinetics of particle aggregation.^{89,94–97}

6. Anisotropic particles

Most theoretical and experimental studies are carried out using spherical particles. Aggregation of anisotropic particles also causes the formation of fractal structures.^{98,99} This process was studied¹⁰⁰ in detail by experimenting with iron(III) particles 20–30 nm long and 2–3 nm in diameter, which were electrostatically stabilised in the aqueous dispersion. Coagulation of particles was initiated by adding an electrolyte. The characteristics of aggregates were determined using dynamic light scattering, transmission electron microscopy and small-angle X-ray scattering. Experiments revealed the formation of fractal aggregates with $d_f = 1.95$. The temporal dependence of the aggregate size exhibited two linear portions; the growth rate changed after the aggregate size became as large as nearly 300 nm. A tendency to parallel orientation of particles in the aggregate was pointed out. Because of this, aggregates contain rather dense regions, the extent of densification being strongly affected by the rate of coagulation. It is the dense regions that serve as building blocks for the fractal structure of the whole aggregate.

The first theoretical study of diffusion-limited aggregation of anisotropic particles was reported by Meakin *et al.*¹⁰¹ who

analysed fast and slow rotation of particles in a two-dimensional system with substantially different coagulation probabilities for two different particle orientations. The structure of the growing aggregates was shown to be strongly dependent on the particle rotation rate. Namely, slow rotation of particles with a prescribed orientation causes needle-shaped aggregates to grow, whereas fast rotation or aggregation of disordered particles leads to branched aggregates.

The aggregation of rod-like and fibrous particles and corresponding gel formation was studied.¹⁰² Simple estimates gave expressions for the concentration of the disperse phase at the gel point, the coordinates of the maximum of the structure factor of the dispersion and for the gel density. The relationships obtained differed from the corresponding expressions for spherical particles only in that the cubic root of the particle volume was used instead of the particle radius. Experimental data on the volume fractions of the disperse phase were reported, which corresponded to transition of dispersions of iron(III) hydroxide, clay, rod-like particles imogolite (aluminosilicate fibres), boehmite and silica particles to the gel state. It was found that gel formation occurs at the volume fractions of the disperse phase that are nearly an order (sometimes, two orders) of magnitude smaller than those corresponding to random packing of rods. The fractal dimension of aggregates of rod-like particles depended on their nature and varied from 1.95 for hematite aggregates to 2.35 for boehmite ones.

The depolarised dynamic light scattering technique appeared to be convenient for studies of aggregation of optically anisotropic particles. For systems composed of such particles the depolarised component in the scattered light is independent of the extent of their aggregation. Besides, it was shown^{103, 104} that at sufficiently small q values the decay of the correlation function of photons is governed solely by the rotational diffusion coefficient. Experiments on the aggregation of crystals of a (tetrafluoroethylene-*co*-hexafluoropropene) copolymer showed that the correlation function has the form of a stretched exponent

$$g_d(t) = \exp \left[- \left(\frac{t}{\tau_d} \right)^{\beta_d} \right],$$

where τ_d is some characteristic time and the parameter β_d is related to the fractal dimension as follows

$$\beta_d = \frac{d_f}{3 + d_f}.$$

Crystals of the above-mentioned polymer (size 40 nm) were characterised by a fractal dimension of 2, which was in good agreement with the prediction based on the RLA model.

7. Polydispersed colloids

The effect of particle polydispersity on the structure of fractal aggregates was experimentally studied¹⁰⁵ taking mixtures of virtually monodispersed hematite particles of size 70 and 216 nm as examples. Mixing of two stable dispersions of particles of the same size was followed by their coagulation induced by addition of salt. At the same time, experiments on coagulation of monodispersed particles were carried out. The fractal dimension was determined using three methods based on static light scattering, namely, relationship (9) for the q dependence of the scattered intensity, the Guinier equation for very small scattering angles

$$I(q) = I(0) \left[1 - \frac{1}{3} (qR_g)^2 \right]. \quad (21)$$

and correlation of the average mass and the radius of gyration of aggregate at a given scattered intensity $I(0)$. The fractal dimensions obtained were very close (about 1.75) irrespective of whether the system was monodispersed or bidispersed.

Fractal structures are also formed in atmospheric aerosols, which can thus be treated as polydisperse colloidal systems. Atmospheric aerosols and their laboratory-born analogues were studied using various methods.¹⁰⁶ Interpretation of experimental data was complicated by the fact that atmospheric aerosols can undergo essential restructuring owing to absorption of atmospheric water. It was found that the fractal dimension of atmospheric aggregates can vary from 1.5 to 3; the structure factor (prefactor) of fractal aggregates also varied over a wide range. In some cases the fractal dimension increased as the number of particles in aggregates increased. Apparently, this was due to restructuring of aggregates.

8. Search for new systems and methods

Most recently reported experimental studies on fractal aggregates were devoted to searching for new systems suitable for aggregation. For instance, a light scattering study¹⁰⁷ showed that porphyrin molecules form fractal aggregates in aqueous solutions in the DLA regime. The fractal dimension of aggregates of humic acid particles is typical of RLA regime.¹⁰⁸ Aggregation of copper oxide particles initiated by addition of an exotic biopolymer produced by microorganisms was also investigated.⁶⁴ The results of studies on the effect of ferrocene additives on the density and fractal dimension of soot aggregates formed during combustion of methane in a laminar diffusion flame were reported.¹⁰⁹ Aggregation of fullerenes C_{60} and C_{70} in a mixed toluene–acetonitrile solution was studied.¹¹⁰ The aggregate sizes were determined using static and dynamic light scattering. The aggregation process was found to occur reversibly. Sedimentation of aggregates began after they grew to nearly 300 nm. The hydrodynamic radius and the radius of gyration of aggregates were determined. The fractal dimension was 2.1 for C_{70} and 2.9 for C_{60} clusters.

Growth of fractal aggregates from vesicles bound by a special agent (streptavidine) was studied.¹¹¹ A feature of the aggregation process was the use of a small amount of binder to provide finite sizes of the growing aggregates; the growth of aggregates ceased after consumption of the whole amount of binder introduced into the system. Static light scattering measurements of aggregates of different sizes gave the same value of the fractal dimension (2.9).

A somewhat different vesicular structure was also observed.¹¹² Vesicles 30–50 nm in diameter were formed from variously functionalised fullerene molecules. Aggregation of such vesicles led to formation of a foam-like structure with cavities of different size. Light scattering and transmission electron microscopy data showed that the growing structure was self-similar with a fractal dimension of 1.4.

A number of studies concerned the laws of the growth of fractal aggregates from particles immediately after formation of the latter in various physicochemical processes. Formation of fractal structures immediately after nucleation of hydrous ferric oxide from 10-nm particles was studied.¹¹³ It was established that the fractal dimension of aggregates of hydrous ferric oxide particles increases from 1.5 to 2 as time passes. A static light scattering study of aggregation of AgI particles formed by mixing of aqueous solutions of $AgNO_3$ and KI was reported.¹¹⁴ Depending on the salt concentration ratio (the higher the fraction of $AgNO_3$, the greater the d_f value), aggregates with fractal dimensions varied from 1.61 to 2.88 grew in solution. A rather smooth dependence of the fractal dimension on the salt concentration ratio was established. Apparently, changes in the component concentrations in the system under study were followed by changes in the particle aggregation regime from DLA to RLA. Restructuring of aggregates cannot also be ruled out. Growth of fractal aggregates from silver nanoparticles formed in γ -irradiated aqueous solutions was studied.¹¹⁵ Fractal aggregates of size 20 and 100 nm were obtained. Depending on the reaction conditions, the fractal dimension of aggregates changes from 1.7 to 1.8.

Surface-enhanced Raman scattering was proposed as a tool for studying the kinetics of aggregation of colloidal particles.¹¹⁶ Experiments were carried out with pyridine molecules adsorbed

on the silver bromide surface. Temporal dependences of the Raman scattering intensity were determined for different regimes of particle aggregation. According to the model proposed, the intensity decreases with time obeying a power law

$$I_R \propto t^{(d_f-3)/d_f} \quad (22)$$

The exponent depends on the mechanism of particle aggregation. Fitting the experimental data gave a fractal dimension of 1.81 and 2.16 for colloidal dispersions aggregated in the DLA and RLA regime, respectively.

III. Hydrodynamics of fractal aggregates and their dispersions

1. The hydrodynamic radius of a fractal aggregate

The hydrodynamic properties of fractal aggregates were studied.^{117–120} Using numerical simulation and experimental studies, it was established^{118, 121–123} that the hydrodynamic radius and the radius of gyration of an aggregate are related by a simple relation

$$R_h = \beta_h R_g. \quad (23)$$

For three-dimensional spherical aggregates, the parameter β_h can be expressed through the fractal dimension¹²¹

$$\beta_h = \left[\frac{2(2 + d_f)(d_f - 1)^2}{d_f^3} \right]^{1/2}. \quad (24)$$

For aggregates with $d_f = 2.1$, one gets $\beta_h = 1.04$. Other models (see, e.g., Ref. 124) included the dependence of β_h on the number of particles in the aggregate. However, this had little effect on the absolute values of β_h .

Some other values of the parameter β_h were also obtained. For instance, Wiltzius¹²³ reported β_h values of 1.03 and 0.62 found from calculations based on the Kirkwood–Riseman model (see Ref. 125) for rather large aggregates using a step and an exponential cutoff function, respectively. This indicates a high ‘sensitivity’ of the hydrodynamic radius to the structure of the aggregate perimeter. The experimental hydrodynamic radius of the RLA-grown fractal aggregates of 3.5-nm silica particles was found to be 0.72, thus lying between the limiting values predicted by theory. These results were considered¹²² underestimated because of ignoring possible polydispersity of aggregates in processing experimental data. The β_h value determined with inclusion of polydispersity varies in the range 0.82–0.98 depending on the type of the cutoff function.¹²² Numerical simulation¹²¹ (off-lattice RLA model) gave a β_h value of 0.97, which remained virtually constant as the aggregate size changed,¹²¹ whereas calculations¹²⁴ in the framework of Brinkman’s model assuming a uniform permeability of aggregates gave $\beta_h = 1.23$. Rogak and Flagan¹¹⁹ solved the hydrodynamic problem using the scattering method with different models of self-similar aggregates and obtained $\beta_h \approx 1$. This approach is applicable only to clusters composed of a small number of particles. The expression relating β_h to the number of particles in the aggregate was extrapolated to the case for large aggregates using a special procedure based on replacement of a group of particles in large aggregates by one spherical particle. Numerical calculations¹²⁰ in the framework of Brinkman’s model assuming a radially varying aggregate porosity allowed the dependence of the parameter β_h on the fractal dimension and aggregate size to be determined. The β_h values obtained were in agreement with the results of calculations carried out using other models and with the experimental data.

Based on dimension considerations,¹²⁶ a simple relation between the radius of gyration and the hydrodynamic radius of aggregate was established

$$\beta_h = k_0^{1/d_f} \sqrt{\frac{2 + d_f}{d_f}}.$$

The β_h values calculated using this equation correspond to the results obtained earlier. The dependence of the viscosity of dispersions containing fractal aggregates on the volume fraction of primary particles was also calculated. Viscosity calculations were performed using various models developed to determine the hydrodynamic permeability of porous media.

The hydrodynamic characteristics of a fractal aggregate were calculated numerically¹²⁷ and analytically¹²⁸ using the Brinkman model for the flow of a fluid inside the aggregate. It was shown¹²⁷ that if the fractal dimension of the aggregate is greater than two, structural inhomogeneity has no effect on the hydrodynamic characteristics and the aggregate can be treated as a particle characterised by uniform porosity.

Filippov¹²⁹ calculated the hydrodynamic radius of a fractal aggregate using the multipole expansion of the solution of the Stokes hydrodynamic equations. The expansion coefficients were found by numerically solving the corresponding system of algebraic equations. Calculations were carried out with inclusion of viscous fluid slip on the surface of spherical particles constituting the fractal aggregate. The calculated R_h values coincided with the radius of gyration of the aggregate to an accuracy of 5% to 10% for a wide range of change in the number of particles. As should be expected, taking into account the slip effect led to a decrease in R_h . The same approach was also employed for calculating the thermophoresis and electrophoresis velocities of fractal aggregates.¹³⁰ They decrease on increasing the number of particles in the aggregate, being for rather large aggregates nearly 10% lower than the corresponding velocities of a single spherical particle.

The problem of heat transfer between a fractal aggregate and its environment is related to the hydrodynamic problem.¹³¹ Calculations were carried out for free-molecular and continuum heat transfer regimes. It was shown that using the radius of gyration as the equivalent radius can introduce large errors, especially for aggregates characterised by small fractal dimension and in the case of free-molecular heat transfer.

The results of calculations of the hydrodynamic drag of fractal aggregates using different equations were compared¹³² with the experimental data on the settling velocities of aggregates of different size. The results obtained using the models with radially varying hydrodynamic permeability of aggregates were in agreement with the experimental data.

For aggregates in a gas, the hydrodynamic radius is determined by the Knudsen number

$$\text{Kn} = \frac{l}{d'},$$

where l is the mean free path of molecules and d' is the diameter of the primary particles.

Numerical calculations¹³³ showed that the collision frequency of gas molecules with a small DLA-grown aggregate is virtually independent of the Knudsen number. An increase in the aggregate size causes the effective diameter of collisions to increase in proportion to $N^{0.417}$ and $N^{0.446}$ (N is the number of particles in the aggregate) at $\text{Kn} = 2$ and $\text{Kn} = 200$, respectively.

Collisions of a point particle with fractal aggregates were studied in more detail¹³⁴ taking the DLA-, RLA- and ballistic-grown aggregates as examples (restructuring of aggregates was also considered). Scattering of a point particle by the monomer surface was described by the laws of elastic and diffuse scattering and by a cosine curve. Simulation showed that at $d_f < 2$, the collision cross-section, σ , is proportional to the number of particles in the aggregate, N . At $d_f > 2$, the following relation is valid

$$\sigma \propto N^{2/d_f}.$$

The number of collisions of a point particle with the aggregate is independent of the aggregate size at $d_f < 2$ and increases in proportion to N^{1-2/d_f} at $d_f > 2$. The momentum and the angular

momentum transferred from the point particle to the aggregate by collision were also calculated. It was shown that the drag in a rarefied gas is proportional to N at $d_f < 2$ and to N^{2/d_f} at $d_f > 2$. The angular momentum transferred to the uniformly moving aggregate is proportional to N^{1/d_f} .

A general consideration of the problem of the motion of a particle scattered by the fractal structure was reported.¹³⁵ According to calculations, the root-mean-square value of the multiple scattering angle increases with an increase in the free path of particles in proportion to l^{d_f} . This indicates that the angular distribution of particles scattered by the fractal medium is narrower than for the non-fractal medium characterised by the same mean free path of the particles. The possibility of determining the fractal dimension of the structure from the shape of the angular distribution of the scattered particles was pointed out.

2. Aggregation in shear flow

Sonntag and Russel^{136, 137} pioneered experiments on the growth of fractal aggregates in a shear flow. They experimented with polystyrene latex particles and varied the shear flow rate, particle concentration and the composition of the disperse medium, which determines the parameters of the particle–particle interaction. It was found that the fractal dimension of aggregates weakly depends on the shear rate and the particle concentration. The d_f values obtained (1.8 to 2.5) mainly depended on the particle–particle interaction. The average cluster size (R) was also shown to be related to the shear rate ($\dot{\gamma}$)

$$R \propto \dot{\gamma}^{-\kappa_R}, \quad (25)$$

where $\kappa_R = 0.35$. The aggregate size was independent of the particle concentration.

Relationship (25) can also be derived based on theoretical considerations. Let us represent an aggregate as a set of chains that transfer the mechanical stress from one end of the aggregate to the other end. The chains are characterised by the chemical dimension d_c and by the bending modulus (E)^{138–140}

$$E \approx E_1 \left(\frac{a}{r} \right)^{2+d_c}, \quad (26)$$

where E_1 is the elastic modulus of a monomer unit, r is the distance between the chain ends and a is the chain segment length (or the size of primary particles).

Numerical simulation^{141, 142} showed that the hydrodynamic stress is localised at the periphery of aggregates. This allows the limiting aggregate size corresponding to the beginning of restructuring induced by hydrodynamic forces to be determined with ease. For a flow with the shear rate $\dot{\gamma}$, the hydrodynamic force is

$$F_h \propto \eta \dot{\gamma} R^2, \quad (27)$$

and the limiting radius is given by

$$\frac{R_r}{a} \propto \left(\frac{\eta a \dot{\gamma}}{E_1} \right)^{-1/(3+d_c)}; \quad (28)$$

then one gets

$$\kappa_R = \frac{1}{3 + d_c}.$$

The parameter E_1 cannot be calculated using the known expressions for the interaction potential of colloidal particles, because this interaction depends on the interparticle distance only. Therefore, the E_1 value is usually chosen empirically as some fraction of the particle–particle interaction.

Expressions (27) and (28) were evaluated^{143–145} using numerical experiments with variation of the type of the interaction between particles in the fractal aggregates and the structural organisation of the aggregates ('rigid' and 'soft' aggregates were

studied). According to calculations, these relations are valid with a reasonable accuracy for aggregates of different nature. The parameters of the 'soft' and 'rigid' aggregates corresponded to the experimental values found for dispersions of polystyrene latex^{136, 146} and silica particles¹⁴⁶ (aggregates of these particles can be treated as the 'soft' and 'rigid' ones, respectively).

A number of theoretical studies^{147–156} (most of them involved numerical simulation) concerned the effects of the concentration^{147, 148} and Brownian motion¹⁵¹ of primary particles, walls,¹⁵⁰ hydrodynamic interaction¹⁵² and structure field flow^{153–155} on the laws of growth of fractal aggregates in non-uniform fluid flows. Particle–cluster and cluster–cluster aggregation regimes were considered.^{147–149, 153–155} The laminar flow and a weak turbulent flow with mixing of the fluid was also simulated.¹⁵⁵ The possibility of obtaining a self-similar size distribution of compact aggregates in shear flow was reported.¹⁵⁶ No self-similar size distribution was obtained for fractal clusters because of exponential growth of the average cluster size. Simulation using a model two-fraction colloidal dispersion with inclusion of shear-induced fragmentation led to steady-state distributions of fractal aggregates in shear flow.¹⁵⁷

The subject of experimental studies^{158–162} was the influence of mixing¹⁵⁸ and shear rate^{159–161} on the structure of aggregates growing under the fast and slow coagulation conditions and in the presence of intense Brownian diffusion (see Ref. 162). In the absence of Brownian motion the fractal dimension was independent of the shear rate,^{163–165} while in the presence of intense Brownian motion the aggregates exhibited¹⁶² two structural zones with different fractal dimensions, the greater fractal dimension corresponding to the longer length scale. This situation was also numerically simulated,¹⁶³ namely, particle aggregation in shear flow was studied assuming either a complete or partial restructuring of aggregates including aggregation in the absence of restructuring. Simultaneously, the intensity of small-angle light scattering by the grown aggregates was calculated in the Rayleigh–Gans–Debye approximation. The results obtained showed that the scattered intensity patterns corresponded to a fractal dimension of 1.8 on short and of 2.1 on long length scale, respectively. Therefore, the fractal dimension of aggregates in shear flow can be changed only on long length scales.

A large number of recent experimental studies were concerned with the laws of growth of fractal aggregates in turbulent flows.^{164–166} It was found that the fractal dimension increases with the stirring rate (turbulent flow intensity). This was confirmed by numerical simulation.¹⁶⁶

3. Sedimentation of fractal aggregates

The sedimentation velocity (v_s) of a dense aggregate composed of s particles is given by

$$v_s = \frac{2\Delta\rho g a^2}{9\eta} \frac{a}{R_h} s, \quad (29)$$

where $\Delta\rho$ is the density difference between the particle and the fluid, g is the free fall acceleration and η is the fluid viscosity. Since the number of particles in a fractal aggregate is related to the aggregate size by relation (2), the sedimentation velocity is

$$v_s = v_{s0} \left(\frac{R}{a} \right)^{d_f-1}, \quad (30)$$

where v_{s0} is the sedimentation velocity of a single particle.

From relationship (30) it follows that v_s increases as the aggregate size increases. Therefore, for rather small primary particles there is a critical aggregate size such that for any larger size sedimentation dominates Brownian motion in aggregation processes. The critical size, R_{cs} , can be determined with ease assuming that the times taken for the aggregate to travel the average inter-aggregate distance by sedimentation and by Brownian diffusion are equal. Simple estimation showed¹⁶⁷ that

$$R_s \propto a\varphi^{1/4d_f} \left(\frac{3kT}{4\pi\Delta\rho g a^4} \right)^{1/4d_f}, \quad (31)$$

where φ is the volume fraction of primary particles.

In the initial stage of growth, the settling aggregates are small and insensitive to hydrodynamic stress. However, after reaching a certain critical size they can undergo restructuring. There are two ways of determining the critical size. If sedimentation of already grown aggregates occurs, the critical size is found by analogy with the critical aggregate size in shear flow [see expression (28)]: in the case of sedimentation one has

$$F_h \approx 6\pi\eta R v_s$$

and the first critical radius is given by

$$R_r \propto a \left(\frac{3E_1}{4\Delta\rho g a^2} \right)^{1/(1+d_f+d_c)}. \quad (32)$$

The exponent in expression (32) equals ~ 0.25 and the critical radius weakly depends on the elastic modulus of the single unit. When comparing the calculated and experimental data, one should take into account the possibility of restructuring, which causes densification of aggregates and an increase in their fractal dimension. Restructuring of aggregates was both numerically simulated^{143, 144} and observed in model colloidal systems;^{24, 34, 136, 137, 146, 168} the fractal dimension usually varied from 1.8 to 2.4.

The second critical radius corresponds to the case where sedimentation is accompanied by growth of fractal aggregates. If attractive interparticle forces acting between two collision-coagulated aggregates are smaller than the hydrodynamic force, the resulting structure will be broken and the aggregates will move away from each other. In this case, the limiting aggregate size is determined assuming that the attractive force is equal to the hydrodynamic force. If the molecular attractive force dominates, the bonding force for two spheres (particles) separated by the distance h_s is given by

$$F_b = \frac{Ha}{12h_s^2},$$

where H is the Hamaker constant. In this case, the limiting radius of the settling aggregates is

$$R_b \propto a \left(\frac{1}{16\pi\Delta\rho a^2 h_s^2} \right)^{1/d_f}. \quad (33)$$

It can be determined from experimental data or estimated assuming that the molecular attraction force equals the steric repulsion force. The results obtained from size distribution calculations for the settling aggregates^{169, 170} and from model experiments^{171, 172} confirmed the existence of the limiting sizes defined by relationships (28) and (33).

A number of experimental procedures for determining the fractal dimension of aggregates using sedimentation analysis is based on the fact that the hydrodynamic radius differs only slightly from the radius of gyration. The deposit density

$$\varphi_s \propto R_h^{d_f-3} \quad (34)$$

was compared^{173, 174} with the viscosity of a dispersion of fractal aggregates

$$\eta_d = \frac{n}{(1 - b_v \varphi_a)^{c_v}}, \quad (35)$$

where b_v and c_v are some constants in the empirical dependence¹⁷⁵ of the dispersion viscosity on the volume fraction of the solid phase ($c_v \approx 5.2$ and $b_v \approx 0.4$) and $\varphi_a \propto R_h^3$ is the volume fraction

of aggregates in the dispersion. The radius of fractal aggregates was estimated from the data on the dispersion viscosity while the fractal dimension was evaluated from the sedimentation volume. The fractal dimension can also be determined using the aggregate viscosity and settling velocity data.^{176, 177}

The settling velocity, v_s , of a dispersion is related to the sedimentation volume, V_s as follows¹⁷⁸

$$v_s = A_0 \left(\frac{V_s}{V_0} \right)^{(d_f-1)/(3-d_f)} \left[1 - B_0 \frac{V_s}{V_0} \right]^{c_v}, \quad (36)$$

where A_0 and B_0 are some constants and V_0 is the sedimentation volume of non-aggregated particles.

Methods of determination of the fractal dimension only from the sedimentation velocity of aggregates of different size, characterised by the same d_f value were proposed.^{179, 180} They involve a special procedure for processing experimental data¹⁸⁰ followed by finding a correlation between the sedimentation velocities of two fractal aggregates and a third aggregate formed from the first two aggregates.¹⁷⁹ (It should be noted that modern methods allow the particle aggregation process to be monitored with ease and are therefore often used for practical purposes,¹⁸¹ in particular, for preparation of aerosols possessing high sedimentation stability.) Given a constant number of particles, from relationship (30) it follows that the sedimentation velocities of the three fractal aggregates must be related as follows

$$v_{s1}^{d_f/(d_f-1)} + v_{s2}^{d_f/(d_f-1)} = v_{s3}^{d_f/(d_f-1)}, \quad (37)$$

By measuring the settling velocities of the aggregates it is possible to unambiguously determine their fractal dimension. Experiments carried out following the design mentioned above gave $d_f = 1.97$ and 1.19 for aerosol particles of soot and magnesia, respectively. These values are in good agreement with those found for the same systems using electron microscopy.

It is possible to determine the fractal dimension by studying the sediment morphology.¹⁸² However, this approach can be practically implemented only when using non-destructive methods of investigation.

If aggregates are composed of small particles or if the density difference between the disperse phase and the disperse medium is small, sedimentation can slow down due to thermal motion of particles and aggregates. Since in the gravitational field the local concentration of monomers varies with height, the characteristic aggregate size will also change with height.¹⁸³ By measuring the density of the disperse phase and the aggregate sizes at different heights one can determine the fractal dimension and draw some conclusions about salient features of structural organisation of aggregates.

Sedimentation of colloidal dispersions is not completed by the formation of loose deposit. Usually, the height of the deposit layer slowly decreases with time due to densification of fractal aggregates. The consolidation dynamics were studied by Potanin and Russel¹⁸⁴ who preliminarily established that the bulk viscosity, η_v and the yield stress, P_c , of the deposit (fractal aggregates) are given by

$$\eta_v \propto \left(\frac{1 - \varphi}{\varphi_m} \right)^{-\kappa} \varphi^{\gamma_\eta}, \quad (38)$$

$$P_c \propto \left(\frac{1 - \varphi}{\varphi_m} \right)^{-\kappa} \varphi^{\gamma_p},$$

where $\varphi_m \approx 0.61$ is the limiting volume fraction of filling and κ_φ is a fitting parameter,

$$\gamma_\eta = \frac{3 + 2d_c}{1 - d_f},$$

$$\gamma_P = \frac{3}{3 - d_f}.$$

The results of calculations using relations (38) are in good agreement with the experimental data¹⁸⁵ for oleic acid stabilised by alumina particles. The best agreement with the experiment was achieved using a two-fraction model for the sedimenting dispersion, which deals with the deposit itself and the dispersion, which settles without formation of an elastic network.

4. Fractal gel rheology

Recently,¹⁸⁶ a typical example of a detailed rheological study of a gelling colloidal dispersion was reported. The subject of this investigation was a colloidal dispersion of 43-nm silica particles. Flocculation was initiated by adding a salt. The dispersion structure was determined using small-angle X-ray scattering while the storage and loss moduli were determined by oscillation shear rheometry. The scale range of surface fractality was found; however, the fractal dimension was not determined. It was shown that an elastic gel network is formed as time passes. It was established that a slow process proceeds in the system, which results in the change (namely, an increase) in the gel storage modulus but leaves the local structure of the gel virtually unchanged. Shear-induced breakdown of the gel network causes no significant changes in the local structure of the dispersion, whereas the storage and loss moduli decrease substantially. The kinetics of recovery of the moduli mentioned above, measured after shear relieving, differs from the kinetics of growth of the same moduli in the course of flocculation. The laws established are characteristic of fractal colloidal gels of different nature. In particular, the experimentally observed¹⁸⁷ rheological behaviour of a gel of protein molecules was explained only using the fractal approach.

Based on a model treating a gel as an ensemble of contacting fractal aggregates, a simple relation between the elastic modulus of gel and the volume fraction of particles was obtained¹⁴

$$E_e \propto \varphi^{(1+\zeta)/(3-d_f)}, \quad (39)$$

where ζ is the parameter responsible for the size dependence of the elastic constant of a fractal object (K_e)¹⁸⁸

$$K_e \propto \frac{K_0}{R^\zeta}. \quad (40)$$

Since then, the elastic and rheological characteristics of gels have been analysed with inclusion of the concept^{139,140} of elastic chains, which are responsible for elastic energy transfer in aggregates and characterised by the chemical dimension.

Considerable attention in theoretical studies has been paid to the so-called weak gels composed of nanoparticles. The formation of loose fractal aggregates in these systems causes gelation even at very low particle concentration (2 vol.% – 3 vol.%). Such systems possess unusual rheological properties. For instance, two regimes of Newtonian flow of dispersions of silica particles at low and high shear stress can differ in viscosity by nine orders of magnitude. At the same time, it is possible to analyse these systems theoretically. The rheological properties of such gels have been the subject of a large number of studies (see, e.g., Refs 138 and 189–195).

At low shear rates, the viscosity of a gel is determined by relaxation processes related to breakdown and nearly complete re-formation of interparticle bonds. As the shear rate increases, stress overshoot occurs. In this case the energy dissipation mechanism changes. The system goes to the state of a dispersion of hydrodynamically interacting fractal aggregates. In fact, the system seemingly goes from the 'solid-like' to the 'liquid-like' state.

Since in this case the interparticle interaction plays the determining role, the rheological characteristics depend not only on the gel structure but also on the parameters of the interparticle

interaction. The most important parameters are the bonding energy, U_c ; the bonding force, F_c ; and the force constant

$$k_{el} = \frac{d^2 U}{dh_s^2} = k_g \frac{F_c}{h_c} \approx k_g \frac{U_c}{h_c^2}, \quad (41)$$

where U is the potential of the interparticle interaction, h_s is the distance between the particle surfaces and h_c is the distance between the particle surfaces at the potential well minimum.

From the equations for the balance of forces and the energy balance one can derive¹⁹⁵ the dependences of the rheological characteristics of weak gels on the volume fraction of particles of the disperse phase.

In the case of oscillating small-amplitude perturbations, the storage modulus is given by

$$G' \propto c_g k_g^{1/2} c_1^{-1} \frac{F_c}{a^2} \varphi^{\gamma_G}, \quad (42)$$

where c_g is a constant of the order of unity,

$$c_1 = \frac{U_c}{kT} \exp\left(-\frac{z_c U_c}{kT}\right)$$

(z_c is the coordination number of the particles in the aggregate) and

$$\gamma_G = \frac{7 + 2d_c - 2d_f}{3 - d_f}.$$

At low shear rates, the dispersion viscosity is

$$\eta \propto c_\eta c_1^{-2} \tau_0 \frac{F_c h_c}{a^3} \varphi^{\gamma_\eta}, \quad (43)$$

where c_η is a constant,

$$\tau_0 = \frac{kT}{6\pi\eta_0 a^3}$$

is the characteristic time of particle diffusion in the disperse medium and η_0 is the viscosity of the disperse medium and

$$\gamma_\eta = \frac{7 + 3d_c - 2d_f}{3 - d_f}.$$

At high shear rates, the effective viscosity is given by

$$\eta = \eta_0 \left(1 - \frac{\varphi_a}{\varphi_m}\right)^{-2.5\varphi_m} + \frac{1}{\gamma} c_\eta \frac{F_c h_c}{a^3} \varphi_a^2 \left(\frac{\varphi}{\varphi_a}\right)^{(5-2d_f-d_c)/(3-d_f)}, \quad (44)$$

where $\varphi_a = \varphi/\varphi_i$ is the volume fraction of aggregates and $\varphi_i \approx (R_g/a)^{d_f-3}$ is the volume fraction of particles in the aggregate. The former parameter depends on the shear rate and aggregate strength and can be determined using the relationship

$$\frac{5\pi}{2} \eta \dot{\gamma} R_g^2 \approx F_c \left(\frac{\varphi}{\varphi_a}\right)^{1/(3-d_f)}, \quad (45)$$

corresponding to the case where the hydrodynamic stress applied to the aggregate equals the ultimate strength of the aggregate. The model correctly reproduces the experimental data. In particular, analysis of Eqn (44) revealed a Newtonian rheology of gel at high shear rates.

The hypothesised gel flow mechanism¹⁹⁵ was confirmed¹⁹⁶ by numerical simulation under constant shear. Gel was shown to have a yield point and three flow regimes corresponding to increasing stress were revealed. At low strain, no stress overshoot occurs and the system is in viscoelastic flow state. An increase in the strain applied causes fragmentation of the system into large

aggregates and transition to the viscoplastic flow state. This favours further fragmentation of aggregates and then the system goes to the pure viscous flow state.¹⁹⁷

The dependences obtained¹⁹⁸ for a two-dimensional system of colloidal particles in a complex potential with inclusion of bending elasticity of the interparticle bonds are similar to relations (42)–(44). The dynamics of gel in shear flow were simulated by the Monte Carlo method. The formation of a fractal gel in the system was followed by applying a shear strain. The temporal evolution of the stress developed in gel and the dependences of the stress on the relative deformation and on the steady-state shear rate were traced. Most dependences showed a power-law behaviour, which is typical of fractal structures. Analogous power-law dependences were obtained from similarity considerations, which also allowed the relations between the exponents and the fractal parameters of gel to be followed. Fragmentation studies of fractal aggregates in shear flow showed that this process is to a great extent determined by the bending elasticity of the interparticle bonds.

IV. Optical properties of fractal aggregates

In Section II, structure-dependent peculiar features of small-angle light scattering were considered assuming single scattering and small sizes of primary particles constituting fractal aggregates compared to the emission wavelength.

A study going beyond the scope of this approximation was reported.¹⁹⁹ To include the multiple scattering effects and the fact that the particle size is comparable with the emission wavelength, the light scattering intensity was calculated in the framework of the Mie theory. Each scattering particle in the aggregate was considered as being in some effective medium characterised by a refractive index corresponding to the average aggregate density. The approach was developed²⁰⁰ with allowance for the fact that the optical characteristics of the effective medium containing the scattering particles vary with the fractal aggregate density. As a result, the form-factor responsible for the scattering by a single particle appeared to be position-dependent, thus affecting the total scattered intensity. The method proposed allows additional information to be extracted (in particular, not only the fractal dimension but also the aggregates sizes were determined).

This approach was experimentally evaluated²⁰¹ taking light scattering by aggregates of 0.8- μm latex particles as an example. Experiments involved variation of the concentration and the extent of aggregation of primary particles. Using the Mie theory for the description of scattering by single particles, a greater body of information was obtained from both small-angle and large-angle light scattering data. This allowed not only the fractal dimension of aggregates but also the aggregate size distribution to be determined.

Interesting results were obtained in studies on the behaviour of electromagnetic radiation in fractal aggregates and on the spectrum of the scattered radiation, especially in the presence of nonlinear effects.

The optical properties of fractal aggregates were first studied by Shalaev and Stockman²⁰² who calculated some optical characteristics in the self-consistent approximation with inclusion of the dipole–dipole interaction between monomers. It was shown that fractal aggregates possess unique optical properties, which differ from the properties of single particles and continuous media. The formation of a fractal causes broadening and splitting of the characteristic lines of the primary particles in the absorption spectrum; however, these lines remain centred near their initial positions, which correspond to the minimum absorption of the fractal. Therefore, the lines can still be treated as resonance ones, which is associated with a fast decrease in the fractal density on going towards its periphery [see Eqn (1)].

Broadening of the lines of the metallic particles forming fractal aggregates was confirmed experimentally (see, *e.g.*, Ref. 203). It is used for monitoring the growth of aggregates in colloidal dis-

persions even under very fast aggregation conditions.^{204,205} The theoretical approach²⁰² was developed by Karpov *et al.*,²⁰⁶ who provided an explanation for all features in the spectra of aggregated colloidal silver particles. In particular, it was found that the second peak in the absorption spectrum of a colloidal dispersion is due to two predominant geometric parameters of aggregates (the size of primary particles and the distance between neighbouring particles) rather than specific resonances in the ensemble of particles. These parameters predetermine the increase in the spectral density of the surface plasmon resonances in a specific wavelength range, which manifests itself in the spectra of sols characterised by rather narrow size distribution of the primary particles (5 to 25 nm).

Yet another important property of fractals is production of surface-enhanced Raman scattering (SERS) by impurity sites.²⁰³ This provides an explanation²⁰⁷ for the experimental observation of the strongest SERS signal from aggregated metallic particles in colloidal solutions.

Studies on the nonlinear optical properties of fractal aggregates of metallic particles showed that aggregation causes a dramatic enhancement of the nonlinear optical response in the region of plasmon resonance characteristic of single metallic particles.^{202, 208–221} When the frequency of incident radiation is off resonance, the decay rate of the absorption of a fractal aggregate is lower compared to single particles while the absorption coefficient per particle increases. The imaginary part of the polarisability of a particle in the cluster is related to the detuning, Δ , by the following power-law dependence²¹⁰

$$\chi''(\Delta) \propto a_p^2(a_p\Delta)^{d_0-1}, \quad (46)$$

where a_p is the distance between primary particles and d_0 is the optical spectral dimension (this parameter lies between 0.3 and 0.6 for different types of fractals). From this relationship it follows that the frequency dependence of the particle's response in the aggregate dramatically differs from the resonance dependence for a single particle. Namely, absorption of the incident wave far from resonance is still high and slowly decreases obeying a power-law dependence as the frequency detuning increases. In some cases, the absorption cross-section increases so greatly that it is more appropriate to describe the situation in terms of the transparency–opacity transition in fractal aggregates.²²²

The results of calculations of the absorption coefficients of fractal and non-fractal aggregates of metallic particles were presented in a comprehensive study²²³ of clusters grown in different aggregation regimes. According to calculations, the absorption spectrum of fractal aggregates must have a complex pattern in contrast to the absorption spectrum of non-fractal aggregates, which exhibits a single sharp maximum. For fractal aggregates, the absorption maximum no longer corresponds to the resonance frequency and there is a system of absorption maxima whose positions and intensities are governed by the aggregate structure and by the number of particles in the aggregate.

Fractal aggregates can also sustain optical (dipolar) eigenmodes,²¹⁰ which can be localised in some range of wavelengths that are shorter than the emission wavelength.^{210,214} This favours concentration of the electromagnetic energy in the domains whose size is smaller than the diffraction limit of conventional optical devices.

The dispersion equation for the eigenmodes of a fractal aggregate has the form

$$\lambda \propto a_p(a_p^3\Delta)^{(d_0-1)/(3-d_f)}, \quad (47)$$

where λ is the emission wavelength.

Near the resonance frequency ($a_p^3\Delta \ll 1$), the dipolar eigenmode is delocalised. As the frequency detuning increases ($a_p^3\Delta \approx 1$), the eigenmode becomes well-localised at the wings of the absorption bands, *i.e.*, $\lambda \approx a_p$. Localisation of optical excitations favours creation of strong local fields, which leads to giant

enhancement of resonant Rayleigh and Raman scattering and nonlinear light scattering^{215–217, 224, 225} observed in colloidal dispersions of some metals. Photomodification of fractal aggregates of silver particles²²⁶ was also explained by localisation of optical excitations.

The results of calculations of dipolar modes localised on fractals are presented in Fig. 1. The local field intensity distributions (shown in Fig. 1 are the isolines corresponding to different electromagnetic field intensities) clearly indicate localisation of the electromagnetic field on the fractal object.

Figure 1. Electromagnetic field intensity distribution on a model fractal aggregate.²²³

The typical size of fractal aggregates composed of nearly 10-nm particles does not exceed the emission wavelength in the optical or IR spectral region. Therefore, such aggregates can be treated as elementary dipoles. Nevertheless, their nonlinear optical characteristics are to a great extent determined by fluctuations of the electromagnetic field inside the aggregates. The corresponding numerical calculations^{214, 227–233} showed that the zones of large fluctuations are localised in different small domains of fractals and their positions vary as the emission wavelength varies.

Estimation of the enhancement factor gave

$$G_e \approx \delta_r \left(1 + \frac{A^2}{\delta_r^2} \right) |\chi''(A)|, \quad (48)$$

where δ_r is the reciprocal Q-factor of resonance, which is determined by resonance amplitude and width. As can be seen, the enhancement factor can be very large at $A \gg \delta_r$.

The calculated dependences of the enhancement factor for different ensembles of particles (regular packs and fractal aggregates of metallic silver particles characterised by a fractal dimension of 1.78) are presented in Fig. 2. As can be seen, the enhancement factor increases to the greatest extent in the case of fractal aggregates. Local enhancement of electromagnetic waves can be explained as follows. In spite of a loose structure, fractal aggregates are characterised by a high probability of finding several particles near a given particle. This is due to the fact that the correlation function of a fractal structure decreases regardless of how the origin of coordinates is chosen.¹ Because of this, neighbouring particles in fractal structures are always strongly coupled. As a result, at any orientation and polarisation of the field there are resonant ensembles of particles, which causes excitation of localised optical modes far from resonance.

Thus, a broad spectrum of localised resonance modes of a fractal aggregate is due to the dipole–dipole interaction between constituent particles. Localisation of modes in different randomly

Figure 2. Enhancement factor as a function of the wavelength for fractal aggregates (1), randomly distributed metal particles with the same packing density (2) and close-packed metal particles (3).²²³ The total number of particles in systems is 500. Calculated using the parameters for silver.

located cluster domains causes large local fluctuations of the field and the appearance of ‘strong-field’ and ‘weak-field’ domains. In the case of fractal colloidal aggregates of nearly 10-nm silver particles the localisation length varies with the emission wavelength and equals ≈ 100 nm in the blue spectral region and 20 nm in the near IR region.

Shalaev²²³ reported the results of calculations of the enhancement factors of other nonlinear optical effects in fractal aggregates (four-photon scattering, second optical harmonic generation and Raman scattering). The enhancement mechanism of nonlinear optical effects is analogous to the mechanisms of localisation of optical radiation and enhancement of local fields (see above).

Predictions of giant enhancement of the nonlinear optical properties of single particles^{202, 206–221} aggregated into fractal structures were experimentally tested in the studies of four-photon scattering and nonlinear refraction and absorption.^{234, 235} Aggregation of initially isolated particles into fractal aggregates led to an increase in the conversion factor of four-photon scattering by a factor of 10^6 and to enhancement of nonlinear refraction and absorption by a factor of 10^3 . Localisation and large fluctuations of local fields in fractals were observed using near-field scanning optical microscopy.^{214, 231–233} Experiments²³¹ were carried out with fractal aggregates ($d_f = 1.78$) of 10-nm silver particles. The aggregates were excited by laser radiation at 488 and 514.5 nm. It was established that the field localisation length is 60 to 140 nm, which is in good agreement with the results of calculations.

The list of the nonlinear optical properties of fractal aggregates considered above is far short from being complete. Experimental evidence of nonlinear gyrotropy of fractal silver clusters due to non-local interaction and its enhancement upon aggregation of silver nanoparticles in a colloidal solution was also reported.²³⁶ Using a specially developed procedure, the contributions of the local and non-local effects to gyrotropy were distinguished. Measurements showed that aggregation of particles into fractal aggregates with $d_f = 1.7$ causes a substantial increase (by about two orders of magnitude) in the contribution of nonlinear gyrotropy.

Localisation of dynamic excitations on disordered structures (in particular, fractals) is a universal property and plays a significant role in many physical processes.^{237–241} In addition to localisation of light-induced dipolar excitations, the fractal structure also favours ‘trapping’ of electromagnetic radiation (light).²¹⁷ The light ‘trapping’ mechanism is similar to the mechanism of localisation of electromagnetic field (see above). At the same time, a somewhat different mechanism of light trapping in a fractal aggregate was reported.²⁴² This mechanism ‘works’ in the case of

rather large aggregates and is associated with the predicted²⁴³ strong localisation of light in close-packed granulated media due to the motion of photons along loop trajectories. This light localisation mechanism requires that the aggregate be composed of weakly absorbing particles, the photon wavelength be comparable with the aggregate size and the positions of particles in the cluster be strongly correlated. In this case, at low fractal dimensions of aggregates (a critical d_f value of 2 was obtained²⁴²) this trapping mechanism also leads to high concentration of the electromagnetic field in fractal aggregates, thus providing an explanation for high reactivity of nanoparticles in fractal aggregates.²⁴²

The fractal structure of aggregates is also responsible for enhancement of the Rayleigh resonant scattering of electromagnetic radiation. The corresponding numerical and analytical calculations were reported by Shalaev, Botet and Jullien.²¹⁵ The enhancement factor of the Rayleigh scattering

$$F_R = \frac{\sigma_s}{N\sigma_{s1}}$$

(σ_s is the scattering cross-section for a fractal aggregate composed of N particles and σ_{s1} is the scattering cross-section for a single particle) depends on the fractal dimension and the aggregate size.

For small aggregates one has

$$F_R \propto \frac{N}{a_p^3 \delta_r} (a_p^3 \Delta)^{d_o+1}. \quad (49)$$

For large aggregates

at $d_f < 2$ one has

$$F_R \propto \frac{(a_p/\lambda)^{-d_f}}{a_p^3 \delta_r} (a_p^3 \Delta)^{d_o+1},$$

at $d_f = 2$ one has

$$F_R \propto \frac{(a_p/\lambda)^{-2}}{a_p^3 \delta_r} \ln[(ka_p)^2 N] (a_p^3 \Delta)^{d_o+1},$$

and at $d_f > 2$ one has

$$F_R \propto \frac{(a_p/\lambda)^{-2}}{a_p^3 \delta_r} N^{1-2/d_f} (a_p^3 \Delta)^{d_o+1}, \quad (50)$$

In conclusion, it should be recalled that aggregates of conducting particles in composition materials near the percolation threshold also have a fractal structure. Therefore, percolation systems are also characterised by fluctuations of electromagnetic field and possess nonlinear optical properties.²²³ The nature of the magnetic field fluctuations in and nonlinear optical properties of percolation systems has much in common with the corresponding features of fractal aggregates. Because of this, we leave the percolation systems out of our consideration.[‡]

V. Capillary phenomena in fractal systems

1. Wetting of fractal surfaces

The contact angle on a fractal surface greatly differs from the contact angle on a smooth surface. Theoretically, the contact angle on the fractal surface was determined by Hazlett²⁴⁵ who studied the case where the droplet size exceeded the length scales on which the scaling relations are valid. This situation is typical of macroscopic systems. The expressions derived for the contact angle on the fractal surface were confirmed experimentally.^{246–249} Here, we will present the relationship for the contact angle, which

corresponds to a more general case²⁵⁰ where the droplet size is comparable with the scale range of surface fractality of the substrate. In this case, the contact angle depends on the effective radius, R_d , of the droplet and is given by[§]

$$\cos \theta_f = \cos \theta_0 \left\{ \left[\frac{1 - (\gamma_{02}/\gamma_{01})(d_2/d_1)^{2-d_f}}{1 - (\gamma_{02}/\gamma_{01})} \right] \left(\frac{d_1}{R_d} \right)^{2-d_f} \right\}, \quad (51)$$

where d_1 is the size of the molecules of the liquid; d_2 is the size of the molecules of the gas (or equivalent phase); $\cos \theta_0 = (\gamma_{02} - \gamma_{01})/\gamma_{12}$, θ_0 is the contact angle on the smooth surface and γ_{01} , γ_{02} and γ_{12} are the energies of the liquid/solid, gas/solid and gas/liquid interfaces, respectively. If the droplet size exceeds the longest length scale from the scale range of surface fractality, R_d should be read as denoting the latter parameter.

From relationship (51) it follows that an increase in the droplet size causes the cosine of the contact angle to increase in absolute value. This means that the droplets increasingly better (or worse) wet the surface as the droplet size increases. Deterioration of wetting of fractal surfaces was confirmed experimentally.^{246, 247}

Fractal surfaces possessing very high water- and oil-repellent abilities were reported.²⁴⁸ The results obtained in a large series of experiments on the water- and oil-repellent properties of fractal surfaces were discussed.²⁴⁹ To impart these properties to the surface of anodised aluminium with $d_f = 2.19$, it was treated with perfluoroalkyltrichlorosilanes and perfluorinated monoalkyl phosphates, respectively. The dependences of the contact angle of a water/ethanol mixture on the smooth and fractal surfaces of anodised aluminium treated with various modifiers are shown in Fig. 3. As can be seen, the contact angle on the smooth surface gradually increases as the surface tension increases, while in the case of the fractal surface the regions of slow change in the contact angle are separated by a discontinuity region. Figure 4 presents a correlation between the contact angle on the fractal surface and the contact angle on the smooth surface. The experimental data are well fitted by the equation

$$\cos \theta_f = \cos \theta_0 \left(\frac{d_1}{R_d} \right)^{2-d_f}, \quad (52)$$

which is a particular case of relationship (51).

The fractal nature of the substrate affects not only the contact angle. Investigations of capillary phenomena on fractal surfaces require some relationships to be revised. In particular, the

Figure 3. Contact angle of a water/ethanol mixture on a smooth (1) and fractal (2) anodised aluminium surface treated with various modifiers as a function of the surface tension of the mixture.²⁴⁹

[‡] Readers who are interested in this problem are addressed to a review,²⁴⁴ which presents a comprehensive treatment of these effects.

[§] The fractal dimensions of surfaces will be also be denoted as d_f . We believe this should not cause any misunderstanding.

Figure 4. Correlation between the contact angle on the fractal surface and the contact angle on the smooth surface for water/ethanol mixture.²⁴⁹

possibility of significant changes in the kinetics of heterogeneous nucleation on fractal surfaces was pointed out.²⁵⁰ In addition to the classical chemical mechanism of manifestation of the Rebinder effect, yet another mechanism becomes possible^{251, 252} in the case of wetting of a metal surface with an eutectic mixture of metals or with some other liquid metal. It is believed^{251, 252} that high roughness and the fractal structure of the interface can favour creation of a high concentration of photons in the region of metal/metal or metal/eutectic mixture contact. The high photon concentration may cause a mechanical disruption of the surface of solids.

Wetting studies of fractal surfaces are closely related to the problem of determination of the characteristics of porous bodies. To solve this problem, two approaches were developed. One of them is based on capillary condensation on fractal surfaces (wetting of a porous body), while the other is based on a mercury porosimetry technique (intrusion of a nonwetting fluid into a porous medium).

At first, consider the problem of intrusion of a nonwetting fluid into a porous body, because it is somewhat simpler.[†] As mercury intrudes a nonwetting porous body, the first to be filled are those pores whose radius of curvature, r_h , meets the condition

$$r_h \geq \frac{2\gamma_h |\cos \theta_0|}{p}, \quad (53)$$

where p is the pressure of mercury, γ_h is the surface tension of mercury and θ_0 is the contact angle on the smooth surface. This relationship has a simple physical meaning, *viz.*, for a pore to be filled with mercury, the external pressure must exceed the capillary pressure. Here, the radius of curvature determined by the sign of equality in relation (53) acts as the length scale in measuring the fractal surface area. The surface area, Σ , of the mercury/porous body interface is determined from the work W_h done in intruding mercury, which is fully spent for an increase in the interface area,

$$W_h = -\Sigma\gamma_h \cos \theta_0 = - \int_0^V p dV, \quad (54)$$

where V is the volume of mercury intruded in the porous body.

The fractal dimension of the surface of the porous body is determined from experimental data using the equation

$$d_f = 2 - \frac{d \ln \Sigma(r_h)}{d \ln r_h}. \quad (55)$$

This approach was proposed by Neimark.²⁵⁵ A somewhat different method of determination of the fractal dimension of a model porous body was developed earlier,²⁵⁶ but it is applicable to particular cases only. The necessity of refinement of relation (55) was pointed out,²⁵⁷ because a part of the mercury surface does not contact the solid phase. More accurate relationships allowed one to attain agreement between the data on the fractal dimensions of porous bodies obtained using mercury porosimetry and adsorption techniques.

It should be noted that such a refinement is not always necessary. The need for refinement is most probably due to poorly pronounced fractal structures of the porous bodies under study. One should employ a specific procedure (see Ref. 258) for choosing those portions in the $\Sigma(p)$ plot that correspond to the fractal structure. Correct choice of such portions allows the fractal dimensions of various objects (soot, aerogels) determined from mercury porosimetry data²⁵⁸ to be in agreement with the values found using small-angle X-ray scattering and adsorption methods.

A capillary condensation based version of the adsorption technique was also proposed.²⁵⁵ The method assumes that a sufficiently thick adsorption film covers the whole surface of a porous body. The surface area of the film/vapour interface is governed by the vapour pressure; the radius of curvature of the meniscus acts as a 'probe' size and is given by

$$r_1 = \frac{2\gamma_l V_m}{kT \ln(p_s/p_v)}, \quad (56)$$

where γ_l is the surface tension of the liquid, V_m is the volume of the molecule, p_s is the saturated vapour pressure and p_v is the current vapour pressure. The expression for the pressure dependence of the surface area, Σ_1 , of the liquid/vapour interface can be found from the work done in forming the interface and has the form

$$\Sigma_1 = \frac{RT}{\gamma_l} \int_{\Gamma}^{\Gamma_{\max}} \ln\left(\frac{p_s}{p}\right) d\Gamma, \quad (57)$$

where Γ is the adsorption (in moles) and $\Gamma_{\max}$ is the maximum adsorption. The fractal dimension is then determined from Eqn (55) using the radius r_1 instead of r .

A modified capillary condensation method was reported.^{259, 260} However, it cannot be considered rigorously substantiated.

2. Restructuring of aggregates

Capillary phenomena play a significant role in the evolution of fractal aggregates. There are two types of capillary phenomena. The first type includes condensation of liquids on aerosol fractal aggregates. Capillary forces acting at the liquid/vapour interface can cause changes in the aggregate structure provided low strength of fractal aggregates. The second type of capillary phenomena is responsible for the evolution of aggregates due to 'sintering' of particles.

Experiments^{261, 262} revealed changes in the structure of aggregates^{261, 262} exposed to cyclic variation of the relative humidity of the atmosphere. At first, experiments were carried out to obtain qualitative information. Detailed studies²⁶³ involved (i) variation of the composition of aerosol soot particles and of the duration of condensation–evaporation cycles and (ii) measurements of the fractal dimension of aggregates at different instants. Based on the results obtained, it was concluded that capillary forces play the determining role in the evolution of aggregates and a linear correlation between the fractal dimensions of aggregates before and after condensation cycle was established. It was shown that the coefficient of proportionality is to a great extent determined by the degree of particle hygroscopicity. A mechanism of change in

[†]We will not dwell on specific features of the mercury porosimetry technique. Detailed information on the subject can be found in, *e.g.*, Refs 253 and 254.

the structure of aggregates was proposed²⁶⁴ and applied to aggregates of carbon black particles in water and benzene vapours. To change the extent of hydrophobicity, the aggregates were exposed to polyethylene glycol vapours. The extent of particle hydrophobicity was monitored by the adsorption isotherms of water vapours. Experiments showed that the change in the aggregate structure strongly depends on the size of condensate droplets. If the droplets were rather large, densification of the entire aggregate occurred to give a dense globule. At small droplet sizes, densification of a small (mainly central) region of the aggregate occurred. A simple model was also proposed in this study, which qualitatively reproduced the experimental dependences.

As mentioned above, capillary forces also change the structure of aggregates in the absence of condensate. Densification of carbon black aggregates on short-term heating to 300 °C^{265,266} and of silica aggregates on prolonged storage²⁶⁷ was observed. However, in the latter case the mechanism of densification is still to be clarified (formally, the Ostwald ageing and sintering of particles were assumed). The change in the fractal dimension of carbon black particles on heating was also reported.²⁶⁸ A detailed experimental study on the effect of heating on the fractal characteristics of silver particles was carried out.²⁶⁹ Aggregates of particles were heated in an inert gas stream over different periods of time at temperatures between 25 and 520 °C. A good correlation between the heating time, temperature and the fractal dimension of aggregates was established (Fig. 5). Based on the results obtained, the possibility of targeted change in the fractal dimension of aggregates of silver particles by varying the temperature and heating time was suggested. The experimental data were in good agreement with the results of Monte Carlo simulation of the sintering of fractal aggregates.²⁷⁰

It should be noted that sintering of fractal aggregates is not necessarily accompanied by an increase in their fractal dimension. For instance, it was shown²⁷¹ that sintering of rather large fractal aggregates affects the lower and upper cutoff lengths only, whereas the fractal dimension of aggregates remains virtually unchanged. Experiments²⁷² with silica aerogels confirmed these theoretical results. More detailed models for sintering of aerogels, which predict a constant fractal dimension, were also proposed.^{273–275} A detailed study on the laws of changes in the fractal dimension of sintered aggregates was carried out.²⁷⁶ Using numerical experiments, the relation between the aggregate size and the evolution of its fractal dimension was followed. At small sizes, sintering is unavoidably accompanied by an increase in the

fractal dimension. As the aggregate size increases, changes in the fractal dimension become progressively less pronounced in spite of essential changes in the aggregate morphologies.

A thermodynamic analysis²⁷⁷ of sintering of fractal aggregates involved establishment of conditions under which densification of the aggregate structure begins. The possibility of fragmentation of aggregates was also revealed. The calculated temperature dependences of the fractal dimension of gold aggregates coincided with the experimental data.

Numerical simulation of sintering of two-dimensional fractal aggregates due to particle diffusion along the perimeter was carried out²⁷⁸ using the known aggregation procedure²⁷⁹ that allows structures with prescribed fractal dimension to be grown. Fragmentation of fractal aggregates was also simulated. The number of fragments was shown to be proportional to the initial surface area of the aggregate. The coefficient of proportionality was a complex function of the fractal dimension of the aggregate (it is only known that this coefficient decreases as d_f increases).

VI. The fractal surface

Many materials, from classical adsorbents to ore particles, have fractal surfaces.²⁸⁰ In this Section, we will consider the fractal surfaces of porous bodies except for aerogels because of specific morphological features of their surfaces.

The fractal dimension of a surface can be determined using different methods. These are measurements of the surface area using molecules of different size, the micrographs of the cross-sections of porous bodies, the dependence of the surface area of porous particles on their sizes, the time taken to transfer the excitation energy from donor molecules to the adsorbed acceptor molecules, the small-angle X-ray scattering and adsorption measurements, the hydrodynamic permeability of porous bodies, the rates of surface chemical reactions, the kinetics of adsorption, *etc.*^{281–283} Many of these methods are based on the description of the kinetics of processes proceeding on fractal surfaces, which requires introduction of new concepts and dimensions. Because of this, we will restrict ourselves to analysis of the classical methods of determination of the fractal dimension of the surface and point out some new approaches. There are a few studies concerned with the development of various models of porous bodies (see, *e.g.*, Refs 284 and 285) and they have much in common with the models employed for the description of growth of fractal aggregates.

The fractal dimension of porous bodies can be determined in a different manner; however, we will not dwell on all of them. Here, mention may be made that the procedure recommended²⁸⁶ by the IUPAC involves the determination of the fractal dimension of a porous body from the pore size distribution

$$\frac{dV_p}{dr_p} \propto r_p^{2-d_f}, \quad (58)$$

where V_p and r_p are the pore volume and pore size, respectively.

1. Small-angle X-ray scattering

Small-angle X-ray and neutron scattering have long been used for the determination of the structure of porous bodies. These methods are suitable for studies on the length scales from atomic sizes to those observed using conventional optical microscopy. This scale range covers virtually all known porous media, being a prerequisite for a wide use of these experimental techniques. The dependence of the scattered intensity, $I(q)$, on the scattering angle (vector), q , is determined by the structure of the porous body.

X-Ray scattering occurs by collisions with electrons while neutron scattering occurs by collisions with atomic nuclei. The scattering by atomic nuclei is governed by the isotope composition of the nuclei. Using various combinations of isotopes, it is possible to enhance or mask certain properties intrinsic in the structure of

Figure 5. Fractal dimension of silver aggregates plotted vs. heating temperature.²⁶⁹ Heating time/s: 1.6 (1), 3.2 (2) and 4.8 (3).

the porous body. No significant differences between the results obtained by neutron and X-ray scattering were established.

Peculiar features of the atomic structure do not manifest themselves in the case of small-angle scattering. Because of this, the scattering curves are usually analysed using the two-phase model of a porous body, which assumes that the porous body comprises two phases of constant density, a solid and a void. The intensity of scattering by the fractal surface is given by²⁸⁷

$$I(q) = \pi c(\Delta\rho)^2 I_e \Gamma(5 - d_f) \sin \left[\frac{\pi(d_f - 1)}{2} \right]^{- (6 - d_f)}, \quad (59)$$

where c is a constant, $\Delta\rho$ is the electron density difference (or the neutron scattering length difference) between two phases, I_e is the intensity of scattering by single electron (or by one scatterer) and $\Gamma(x)$ is the gamma function.

At small q , the fractal dimension is determined from the slope of logarithm of the scattered intensity plotted vs. logarithm of the scattering angle.

At $d_f = 2$, expression (59) represents the well-known Porod law for X-ray scattering by smooth surfaces,^{288,289} according to which

$$I(q) \propto q^{-4}. \quad (60)$$

This relationship was extended²⁹⁰ to the case for emission wavelengths comparable with the radius of curvature of smooth surfaces and the corresponding corrections to the Porod law were derived. Yet another expression for the scattered intensity with inclusion of the surface curvature corrections has the form²⁹¹

$$I(q) \propto q^{d_f-6} + q^{d_f-8} \frac{(6 - d_f)(5 - d_f)}{12} \times \left[\frac{1}{R_1 R_2} + \frac{3}{8} \left(\frac{1}{R_1} - \frac{1}{R_2} \right)^2 \right], \quad (61)$$

where R_1 and R_2 are the principal radii of curvature averaged over the inner (fractal) surface. This relationship was used to determine the fractal dimension of typical adsorbents and the necessity of allowance for the surface curvature corrections in the case of porous bodies was confirmed.

2. Adsorption technique

On length scales shorter than 1 nm the fractal dimension of a surface can be determined by measuring the adsorption capacities of monolayers of molecules of different size δ , and comparing them with the dependence of the surface area on δ

$$\Sigma(\delta) \propto \left(\frac{1}{\delta} \right)^{d_f-2}. \quad (62)$$

The method of determination of the fractal dimension based on evaluation of the surface area according to Brunauer–Emmett–Teller using molecules of different size is often objectionable.²⁹² This is due to the fact that the surface sites of particular molecules are not known with certainty. As a result, different authors report contradictory data on the fractal dimensions of the same materials, including the values exceeding the limiting d_f value ($d_f = 3$). It should be noted that in some cases one fractal dimension can appear to be insufficient for complete characterisation of the fractal structure of the surface of adsorbents with a complex structure of the pore space. Therefore, one should introduce a hierarchy of fractal dimensions for a given porous body,²⁹³ which can be treated as a particular characteristic of inhomogeneity of the porous body. Introduction of the hierarchy of fractal dimensions corresponds to the so-called multifractal approach (see Section IV in Ref. 1).

On length scales from 1 to 100 nm the fractal dimension is determined from polymolecular adsorption data using two methods. The first is based on the dependence reported by Pfeifer et

al.²⁹⁴ (the number of molecules necessary to cover the free surface of the adsorption layer decreases as the layer thickness increases). In the case of adsorption on fractal surfaces, a modified Frenkel–Halsey–Hill equation is used

$$\ln \left(\frac{p}{p_0} \right) = - \frac{A_F}{k T T^n}, \quad (63)$$

where p is the pressure of the adsorbing gas, p_0 is the saturation pressure, A_F is the parameter determining the adsorbate–adsorbent molecular interaction and T is the number of moles of the adsorbed gas. Ignoring the surface tension effects, one gets

$$n = \frac{3}{3 - d_f}.$$

If the contribution of surface tension predominates,^{295,296} then

$$n = \frac{1}{3 - d_f}.$$

These relationships are valid for self-similar surfaces. In the case of self-affine surfaces, of great importance is the roughness index (α) determining the relation between the surface ‘width,’ w , and the lateral size, L , of the surface

$$w \propto L^\alpha.$$

If the surface tension effects are weak, $n = 3$; if they predominate, $n = 2/\alpha - 1$ at $\alpha > 0.5$ and $n = 3$ at $\alpha < 0.5$ (see Ref. 297).

The Frenkel–Halsey–Hill equation was used by different authors to estimate the fractal dimensions of various porous bodies.^{298–300} Recently, the fractal dimension of the surface of adsorbents has been determined using the Dubinin–Astakhov equation generalised to the case for fractal surfaces.^{301–303} The Neimark method^{304–306} (see above) is also often used to this end.

The fractal dimensions determined using the methods mentioned above were compared in the framework of model calculations.³⁰⁷ The emphasis was placed on the inclusion of the effect of finite scale range of surface fractality. According to calculations, the fractal dimensions determined using different methods are equal to one another if the range of scales covers two orders of magnitude and can differ by more than 10% if it does not exceed an order of magnitude. This conclusion was confirmed³⁰⁸ by measuring the fractal dimensions of titania aerogels prepared under different conditions. It was shown that the monolayer and polymolecular adsorption techniques give similar results, though the corresponding fractal dimensions can differ by nearly 0.1. An analogous conclusion was drawn³⁰⁹ from comparison of the results obtained using different methods in the experiments with silica particles prepared by hydrolysis of tetraethoxysilane in microemulsions. Even the fractal dimensions determined using different methodologies^{255,260} appeared to be similar, though the earlier studies sometimes revealed distinctions between the results obtained by these methods.

Yet another method of determination of the fractal dimensions of porous bodies from the adsorption data was developed by Olivier and co-workers.^{310–312} The approach involves construction of the so-called composite adsorption isotherm assuming independent adsorption in pores of each size. For pores of a particular size, the adsorption isotherm is calculated by employing density functional theory.³¹¹ On these assumptions and on imposing the fractal structure of the surface it is possible to construct a composite isotherm whose shape is determined by the fractal dimension of the surface. Comparison of the experimental and model isotherms allows the fractal dimension of the porous medium to be determined. The fractal dimensions of some objects determined using the composite adsorption isotherm were compared³¹² with the fractal dimensions estimated using the Frenkel–Halsey–Hill and Neimark equations. It was shown that the fractal dimensions determined using different methods are related by a linear dependences with different slopes (they are determined

by the pore size scales on which the surface exhibits fractal properties).

Yet another reason for significantly different results obtained for different adsorbents using different methods is that porous bodies are characterised by some hierarchy of fractal dimensions rather than a single fractal dimension value (see above). The distribution of fractal dimensions can be rather broad and usually covers the values determined in single experiments.³⁰³

Two important features should be pointed out. The lower limit of the scale range of surface fractality can be found³⁰⁴ by comparing the adsorption isotherm for a given sample and the standard adsorption isotherm for the smooth surface. (Strictly speaking, Neimark and Unger³⁰⁴ reported the upper limit of the scale range of surface fractality.) At the same time, the method proposed provides no possibility for the surface fractality to be established unambiguously and requires additional studies.

The fractal structure of the surface governs the shape of the adsorption isotherms. This is due to the fact that the fractal nature of the substrate affects the properties of the adsorption layer.^{313, 314} In particular, it was shown³¹⁵ that the inclusion of adsorbent surface fractality allows the Temkin adsorption isotherm to be obtained in the case of non-interacting adsorbate molecules. It was also assumed that wide use of the Temkin isotherm can be explained by frequent occurrence of adsorbents with fractal surfaces.

3. Surface profiles

The adsorption technique is usually employed in studies of the closed fractal surfaces. The fractal dimension of an open surface can be determined by measuring the surface profiles (a single profile for isotropic surface). In the case of anisotropic surfaces, one cross-section is insufficient. There are several methods of processing the surface profile. In particular, it is possible to obtain the height (h_f) correlation function using the relationship

$$R_s(y) = \langle h_f(x)h_f(x+y) \rangle, \quad (64)$$

or to determine the structure function

$$S_s(y) = \langle [h_f(x) - h_f(x+y)]^2 \rangle, \quad (65)$$

where x and $x+y$ are the coordinates in the xy plane.

For fractal surfaces, both the height correlation function and the structural function are related to y by a power-law dependence

$$S_s(y) \propto R_s(y) \propto y^{6-2d_f}.$$

The possibilities of determining the dimensions of the open fractal surfaces using scanning probe microscopy data and surface profile measurements were analysed in detail.³¹⁶ It was shown that the shape of the correlation or structural function permits not only the fractal dimension to be determined but also the characteristic length scale of surface fractality to be revealed in the case of self-affine surfaces.

Going to longer length scales exceeding the upper limit of surface fractality does not mean³¹⁷ a constant surface area measured by probes of different size. Even on long length scales, the surface area measured depends on the probe size because it becomes rough due to fluctuations. In this case, the surface area measured decreases obeying a power law as the probe size increases,³¹⁷ the exponent being dependent on the fractal dimension in a much more complex manner compared to relation (62).

Peculiarities of the behaviour of the structure and correlation functions as well as problems that arise in determining the fractal dimension of anisotropic surfaces were considered in detail by Wu.^{318, 319} In particular, it was shown that the fractal dimensions of model surfaces can depend on the type of the function (S_s or R_s) employed in the computational procedure. The fractal dimension can also be a function of other physicochemical parameters of solids.³²⁰

4. Other methods

An original method³²¹ of determination of the fractal dimension of metallic surfaces involves scattering studies of surface plasmon polaritons (SPP) by rough surfaces. In the case of well-developed fractal surface, localisation of the SPP is possible. The scheme of calculations of the fractal dimension using the laws of SPP scattering was evaluated taking films grown by evaporation – condensation in different regimes suitable for preparation of smooth and rough surfaces. The fractal dimensions determined are in good agreement with those found using the film surface profiles.

The fractal dimensions of the surfaces of conducting solids can be determined using electrochemical methods. Comparison of the fractal dimensions determined using atomic force microscopy and cyclic voltammograms appeared to be similar.³²²

The method proposed³²³ for semiconductor films involves measurements of the photocurrent from their surface. It was assumed that the photocurrent (I_f) is proportional to the absorbed energy and, correspondingly, to the surface area of the specimen. In this case

$$I_f \sim L^{d_f}, \quad (66)$$

where L is the linear dimension of the specimen.

Experiments³²³ carried out using films of different linear size gave the fractal dimensions which coincided with those determined for the same films using atomic force microscopy.

Yet another method of determination of the fractal dimensions of the open surfaces was proposed in a study³²⁴ on the laws of scattering of helium atoms by silver submonolayers of different structure on Pt (111). According to calculations, the scattered intensity is related to the difference between the tangential components of the wave vectors of the incident and scattered atomic beams (Δk)

$$I_a(\Delta k) \sim (\Delta k)^{d_f-4}. \quad (67)$$

This relation was confirmed experimentally. The technique seems to be promising because experimental methods of studies on scattering of atoms and molecules by solid surfaces are well developed.

VII. Aerogels

Aerogels are used as heat insulators, catalyst supports,³²⁵ reservoirs for flammable fluids and elements of acoustical and optical devices,³²⁶ in Cherenkov counters³²⁷ and solar cells,³²⁸ for the growth of photoluminescent silicon crystals³²⁹ (in this case, aerogels themselves can possess photoluminescent properties³³⁰). Aerogels are highly porous, low density materials characterised by small pore sizes. They are produced by drying hydrogels prepared by a sol–gel process under supercritical conditions. In particular, the most widely used silica aerogels are prepared by hydrolysis of tetraethoxysilane or tetramethoxysilane in aqueous alcoholic solutions. Aerogels of other metal oxides are prepared from corresponding alkoxides.³²⁶

The sol–gel process involves hydrolysis of precursors followed by polycondensation of hydrolysis products. Particles formed during polycondensation (sol) aggregate and then form a continuous network (gel). Preparation of gel is followed by its drying. Depending on the drying regime, a glass, ceramic or aerogel can be obtained. The density of aerogels can be varied within two orders of magnitude from several hundredth to 1 g cm^{-3} .

Studies of aerogels face some difficulties³³¹ because of strong perturbations introduced into the structure of aerogels when using conventional methods such as mercury porosimetry, thermoporosimetry and adsorption technique. Therefore, these objects are often studied using contact-free methods, *viz.*, small-angle neutron, light and X-ray scattering as well as optical, acoustical and thermomechanical methods.

It has long been established using small-angle X-ray^{332, 333} and neutron^{334, 335} scattering that aerogels have a fractal structure on the length scales from several to 1000 Å and that their mass fractal dimensions lie between 2.1 and 2.4. The pore surface of aerogels is also fractal; the parameter d_f can approach the limiting value (≈ 3).

The longest length scale, ξ , of aerogel fractality is usually called the correlation length (by analogy with the correlation length in percolation theory). The size of fractal domains is, as a rule, from several tens to a hundred of nanometres. The density of aerogels equals that of the gel-forming fractal clusters and is determined by the correlation length

$$\rho(\xi) = \rho_0 \left(\frac{\xi}{a} \right)^{d_f-3}, \quad (68)$$

where ρ_0 is the density of the substance the primary particles of radius a are made of. The pore size distribution for aerogels also obeys a power-law dependence.³³⁶

Consider the results of several recent investigations on the structure of aerogels. Reidy *et al.*³³⁷ reported a small-angle neutron scattering study of the structures of three aerogels prepared by hydrolysis of tetraethoxysilane (TEOS), triethoxysilane (TES) and trimethoxysilane (TMS). Three gel models were employed, the interference, fractal and maximum entropy ones. The first model assumes that aerogel is composed of homogeneous spheroidal granules with a prescribed aspect ratio and lognormal size distribution.³³⁸ According to the second model, gel comprises fractal fragments of size ξ . The third model treats gel as a system of homogeneous particles and derives a particle size distribution consistent with the maximum configuration entropy.³³⁹ Analysis of scattering patterns showed that the TEOS aerogels were best described by the maximum entropy model, while the TES and TMS aerogels were best described by the fractal model (a version with fractal primary particles for TES aerogels and with fractal surface of the pore space for TMS aerogels).

The structures of aerogels can be modified in a different manner. The most efficient way is to introduce an aerosil into the disperse medium. This can result in aerogels which either have no fractal structure³⁴⁰ or have a binary fractal structure.³⁴¹ When aerogels were prepared from sodium silicate solutions, the gel structure was strongly dependent³⁴² on the pH value of the medium, which can be attributed to the change in the surface charge of the primary particles, which governs the rate of coagulation and the fractal dimension of aggregates. The addition of hydrogen peroxide to aerogels prepared by hydrolysis of methyl silicate led to somewhat unexpected results.³⁴³ Namely, the fractal dimension of certain systems remained unchanged and even increased as their density decreased.

The mechanical properties of aerogels are of great practical value and therefore attract particular attention. The power-law dependence of the Young's modulus, E , of aerogels on their density ρ (ρ_0 is the density of the framework-forming material)

$$E = E_0 \left(\frac{\rho}{\rho_0} \right)^m \quad (69)$$

was confirmed in numerous studies. The exponent m is not a universal scaling factor; even for the silica-based gels it varies from 2.5 to 3.8 depending on the substances used for the preparation of aerogels and on the regimes of subsequent drying and heat treatment. Apparently, this exponent is related to the fractal dimension of aerogel; however, this was not rigorously substantiated. A possible relation is as follows:³⁴⁴

$$m = \frac{5 - d_f}{3 - d_f}. \quad (70)$$

The mechanical properties of aerogels are often described using the bulk modulus K_b , which relates the change, Δp , in the

pressure applied to a sample to the relative change in the sample volume

$$\Delta p = -K_b \left(\frac{\Delta V}{V} \right). \quad (71)$$

The moduli E and K_b are related by

$$K_b = \frac{E}{3(1 - 2\nu)},$$

where ν is the Poisson ratio.

The modulus K_b is also related to the density by a power-law dependence

$$K_b = \rho^{\kappa_b}, \quad (72)$$

where the exponent κ_b for silica aerogel varies from 3.08 to 3.38 (the mean values are ≈ 3.2 and 3.6 in the regions of plastic and elastic deformation, respectively).³⁴⁵ Analysis of a large array of experimental data on the elastic moduli of aerogels revealed³⁴⁶ an unambiguous relation between the parameter κ_b and the pore size distribution and a hierarchy of pore size distributions over a broad range of length scales provided that relationship (72) is valid.

At temperatures below 1 K, the specific heat of aerogels obeys the law

$$C_p \sim T^{\alpha_c},$$

where the exponent α_c ($\alpha_c \approx 1.4$) is virtually independent of the density of ultralight aerogels ($\rho < 0.4$).³⁴⁷ The thermal conductivity of aerogels is a constant at low temperatures and increases in proportion to T^{α_t} ($\alpha_t \approx 1.2$) at higher temperatures. At low temperatures, the specific heat of aerogels is determined by the phonon density of states. Brillouin scattering studies revealed that the frequency dependence, $N_v(\omega)$, of the density of phonon states at the wavelengths comparable with the length scales of domains of the fractal structure of aerogels deviates from the dependence typical of the phonon spectrum. Namely, this dependence still obeys a power law but the exponent changes from $(d-1)$ to $(d_{fr}-1)$

$$N_v(\omega) \sim \omega^{d_{fr}-1}.$$

The new exponent is called a fracton or the spectral dimension. For silica aerogels, $d_{fr} \approx 1.3$. The fracton dimension characterises specific features of the oscillations of those aerogel fragments which have a fractal structure. Peculiarities of the vibrational spectra of fractal structures and aerogels have been analysed in detail (see Refs 189 and 348, respectively); therefore, we will not dwell on them. Mention may be made that the fracton concept was first proposed by Alexander and Orbach.²³⁷

Fractons are natural oscillations of a fractal. If aerogel is treated as a set of fractal clusters, fractons characterise peculiar features of their vibrational dynamics. Strictly speaking, the fracton dimension of clusters 'grown' in numerical experiments can be determined only in analogous numerical simulation (see, e.g., Ref. 349). According to calculations, the fracton dimension weakly depends on the fractal dimension. At the same time, an analytical relation between these dimensions was derived in the framework of a certain model. A simple equation was proposed,³⁵⁰

$$d_{fr} = \frac{d_f}{1 + b(3 - d_f)}, \quad (73)$$

in which the parameter b determines the dependence of the velocity of sound, v_s , on the aerogel density

$$v_s(\rho) \propto \rho^b.$$

Relation (73) was reported³⁵¹ as a particular case of general relations derived for elastic and thermal characteristics of hierarchic structures. Some other relationships are as follows:

$$b = \frac{m-1}{2}, \quad (74)$$

$$\alpha_t = d_{fr} + \frac{1-2d_{fr}}{d_f},$$

$$\alpha_c = d_{fr}.$$

In addition to Brillouin scattering, the Raman light scattering also plays a significant role in studies of aerogels. It was shown³⁵² that the response of the Raman scattering by aerogels depends on the frequency of electromagnetic radiation (ω) and is described by a universal law

$$\chi_R(\omega) \sim \omega^{-\phi}, \quad (75)$$

where the exponent ϕ is determined by three dimensions, viz., the mass fractal dimension, d_f ; the fracton dimension, d_{fr} , which characterises the density of vibrational states; and the dimension d_σ characterising the deformation of particles by fractons. The dependence of the exponent ϕ on these dimensions is determined by the mechanism of Raman scattering. If the mechanism involves the interaction between permanent and induced dipoles, then

$$\phi_{dd} = 2 \left[\frac{d_{fr}}{d_f} (d_f - 3 - d_\sigma) \right] + 1. \quad (76)$$

If the mechanism involves modulation of the polarisability by atomic oscillations, one has

$$\phi_p = 2 \left(1 - \frac{d_{fr} d_\sigma}{d_f} \right). \quad (77)$$

Relationships (75)–(77) were verified taking silica aerogels of different density as examples.³⁵³ Gels were heat treated and exposed to hydrostatic load and uniaxial compression. Experiments with all samples showed that the parameter ϕ is independent of the density of gel and remains unchanged during heat treatment of aerogels resulting in their densification. However, mechanical deformation favoured a decrease in ϕ due to a change in the fracton dimension of the loaded samples.

Changes in other mechanical and fractal characteristics of aerogels due to their densification were also studied.^{354–356} Structural changes were mainly detected using small-angle X-ray scattering. Densification of aerogels caused the correlation length to decrease, while the fractal dimension slightly increased (Fig. 6). As a rule, the corresponding parameters of the densified aerogels and of the initially more dense aerogels coincided. In some cases the fractal dimension of the mechanically compressed aerogels remained unchanged.³⁵⁶

More significant were the changes in the fractal dimension upon densification by sintering.^{357–359} Analysis showed^{271, 274, 360, 361} that, in spite of an increase in the fractal dimension of aerogels on sintering, a great body of information on the initial structure is retained. The difference between mechanical compression and sintering consists in that sintering causes densification of the network of bonds while mechanical compression causes restructuring of aggregates without formation of new bonds. Noteworthy is that the changes in the structure of aerogels on compression or sintering implicitly affect their physicochemical properties. For instance, it was shown both theoretically³⁶² and experimentally³⁶³ that the gas permeability of aerogels depends solely on their density which can vary over a wide range.

Aerogels have a fractal pore surface.^{308, 330, 364–370} The fractal dimension can be determined by various methods and usually lies between 2.5 and 2.8, though in some cases can reach the limiting values 2.92–2.98 (see Refs 308 and 364). The fractal dimension of

Figure 6. The size of primary particles (1), the fractal dimension (2) and the correlation length (3) plotted vs. the bulk density for mechanical densification (a) and sintering (b) of aerogels.³⁵⁶

the surface of aerogels strongly depends on the procedure employed for the preparation of gel (more exactly, on the regimes of drying,^{365–368} ageing³⁶⁹ and mechanical treatment.³⁷⁰) Heat treatment of aerogels usually causes the fractal dimensions of their surfaces to decrease, while mechanical treatment can cause both a decrease and an increase in d_f .³⁷⁰

No rigorous correlation between the bulk fractal dimension of aerogels and the fractal dimension of their surfaces was established as yet. Even an increase in the bulk fractal dimension was observed³⁶⁹ in the experiments on ageing of aerogels accompanied by a dramatic decrease in the fractal dimension of the surface from 2.75 down to a value of 2, which is typical of a non-fractal surface.

VIII. Conclusion

The methods of fractal geometry are widely used in natural science. As shown by the material presented in this review and in Ref. 1, intensive research on the fractal structures is being carried out. Because of the extensive literature on the subject, many aspects of physical chemistry of the surface phenomena and colloidal systems are left out of consideration. We can only give a short list of the most important research avenues. The fractal approach is employed in the studies on the properties of foams^{371, 372} and on the kinetics of binding of bioactive molecules with surface-immobilised receptors.^{373–378} The fractal analysis is used to describe replacement of nucleotides in DNA molecules³⁷⁹ and to analyse spontaneous aggregation of multilayered lipid vesicles.³⁸⁰ Recently, considerable attention has been paid to fractal aggregates growing in sea water.^{381, 382} Sedimentary rocks also have fractal surfaces.^{383–385} The fractal structure of cracks developing in brittle materials and polymers^{386–388} is described using not only the conventional fractal approach but also multifractal methodology.^{389, 390} The behaviour of grain boundaries in polycrystalline materials³⁹¹ and their transformations on exposure to various external factors³⁹² is considered in the framework of fractal formalism. Reversal of the magnetisation of thin polycrystalline layers is treated³⁹³ as a development of fractal clusters composed of magnetic domains. Fractal concepts are used in studies on capillary electrophoresis³⁹⁴ and simulation of growth of gallstones.³⁹⁵ This list of research avenues that successfully employ the concepts of growth of fractal structures is far short from being complete.

In spite of extensive literature concerning the fractal structures in various colloidal systems, many problems are still to be solved. The totality of experience accumulated during the last two decades shows that often solving new applied problems requires revision of the foundations of theory of fractal objects. Therefore, the development of fractal concepts is inevitable.

Abstract. The results of investigations on the kinetics and mechanisms of thermolysis of the main classes of organic peroxides in solution are generalised. The relationship between the kinetics and mechanism of thermolysis and the peroxide structure is analysed. The main attention is given to the decomposition reactions of peroxides that are not confined to mere homolysis of the O–O bond and the factors responsible for the abnormalities in the thermolysis mechanism. The thermolysis mechanisms of trioxides, dioxiranes and peroxides are considered in detail. The bibliography includes 210 references.

I. Introduction

Organic peroxides are the main sources of free radicals in chemical practice. They are widely used for initiating radical (including chain) processes and crosslinking of polymers.^{1,2}

The low thermal stability of peroxides due to the presence of a weak O–O bond and the strong dependence of the decomposition time on their structures allow their wide use as initiators in a broad range of temperatures, from ~ 40 to ~ 200 °C. Redox systems of the type 'hydroperoxide–metal ion' and 'diacyl peroxide–amine' enable initiation even at 0 °C.

The present review is the first attempt to generalise the published data on the thermolysis of virtually all classes of organic peroxides in solution. Some previous publications were intentionally included in the review in order to present the problem in a complete and comprehensive way.

Thermal decomposition of peroxides in solution follows both homolytic (with cleavage of one or two bonds simultaneously) and

non-radical routes. The kinetics and mechanism of thermolysis depend on the structures of peroxides and the modes of their interactions with the solvent. The latter is especially important for hydroperoxides, which easily form hydrogen bonds.

The kinetics and mechanisms of reactions occurring in solutions were discussed in several monographs and reviews.^{1–3} Special attention was given to motion and collisions of the reacting species in liquid media and effects of their direct interactions with solvent molecules. As a result of such interactions, the original species and the transition states become surrounded by a structured shell consisting of solvent molecules, which changes their electronic structures and, as a consequence, their reactivities.

There are few papers devoted to the analysis of a relationship between the structure of peroxides and the mechanism of their thermolysis in the gas phase (see Ref. 4 and references cited therein), whereas thermolysis in solution has been studied for virtually all synthesised organic peroxides. This circumstance permits one to compare structural features of these compounds and to establish differences between them.

It is noteworthy that the mechanism of homolysis is not always sensitive to specific characteristics of the medium, since this process is not accompanied by any significant redistribution of charges in the molecules of the starting peroxides. However, if there is a competition between ordinary homolysis and other thermolysis routes, including non-radical rearrangements and, especially, heterolytic transformations, changes in solvent properties may have a crucial effect on the mechanism of the thermolysis.

Intermolecular contacts and reactions occurring in the solvent cage affect essentially the kinetics, mechanism and, as a consequence, composition of reaction products.^{1,2} Thermal decomposition of organic peroxides has previously been considered in several monographs.^{5–10} The effect of pressure on the kinetics and mechanisms of thermolysis (including $\Delta V^\ddagger$) depends on the mode of the interaction of the reactants with the solvent, the viscosity of the solvent and the processes occurring in the solvent cage.¹¹

The idea of N N Semenov on the competition between bimolecular homolytic reactions and monomolecular reactions simultaneously generating a highly stable product was confirmed by the calculations of Denisov^{12,13} based on the use of a semi-empirical parabolic model. Such a decomposition route also takes place in the thermolysis of peroxides.

Received 4 February 2003

Uspekhi Khimii 72 (11) 1055–1080 (2003); translated by R L Birnova

In the limiting step, thermolysis of peroxides usually involves initial cleavage of the weakest O—O bond. However, depending on the structures of the reactants and the reaction conditions, there may be some deviations from the 'simple' mechanism. The main attention in this review is given to the abnormalities of the mechanisms of thermal decomposition of peroxides, particularly of non-trivial mechanisms with complex rearrangement of the bonds.

II. Alkyl and aralkyl peroxides

As a rule, the passage from gas-phase decomposition to thermolysis in solution does not result in any changes in the reaction mechanism. Thus rate constants for high-pressure decomposition of di-*tert*-butyl peroxide in cyclopropane¹⁴ in vapour (124–160 °C) and in the liquid phase (100–124 °C) represent a common straight line with a preexponential parameter $\log A = 15.52 \pm 0.23$ (s⁻¹) and $E = 156.9 \pm 0.4$ kJ mol⁻¹ in the $\log k_1 - 1/T$ coordinates. The values around the critical point of cyclopropane phase transition also fall on this straight line.

The decomposition kinetics of a series of alkyl and aralkyl peroxides in the gas phase and in hydrocarbon solvents were compared.¹⁵ The correlation dependence for these compounds [$\log A = 1.883E - 1.0$ (A in s⁻¹, E in kJ mol⁻¹)] was shown to correspond to the isokinetic temperature of 483 K. The activation energies for the decomposition of the symmetrical peroxides ROOR increase in the following order: Et < PhMe₂C < Me ≈ Prⁿ < Bu^t ≈ EtMe₂C.

The main decomposition route for the peroxides R¹OOR² includes homolysis of the O—O bond:

The oxy radicals thus formed undergo either further recombination in the solvent cage with subsequent regeneration of the original peroxide, or reaction with the surrounding solvent molecules (HSol):

or monomolecular decomposition to form a ketone and a radical of lower molecular mass (β -decomposition):

The radicals thus generated are eventually replaced by the radicals derived from the solvent

which are then recombined into dimers

or undergo disproportionation to give an alkene and a stable saturated molecule.

As a rule, electronic effects of substituents only slightly affect the rate of thermal decomposition of alkyl peroxides. Thus the coefficient ρ^* in the Taft equation for the electron-withdrawing groups of tertiary peroxides is -0.13 (150 °C, chlorobenzene),¹⁶ whereas that for *tert*-butyl peroxybenzoates is 0.38 (120 °C, CCl₄).¹⁷ A very strong effect of electron-donor groups ($\rho^* = -11.0$) and a small effect of electron-withdrawing groups ($\rho^* = -0.13$) were observed in the decomposition of dialkyl peroxides.^{18,19} However, such a discrepancy in the ρ^* values can be attributed to the fact that steric effects have not been taken into consideration.²⁰

The thermolysis of allyl *tert*-butyl peroxide in toluene,²¹ in addition to ordinary homolysis of the O—O bond, is accompanied by two types of induced decomposition:

(1) abstraction of H[•]

(2) addition

The presence of an allyl group in a peroxide offers diverse possibilities for their synthetic use in the thermolysis in solution. Thus the thermolysis of allyl *tert*-butyl peroxide in the presence of carboxylic acids (R¹R²CHCOOH) gives rise to lactones (yield 20%–50%)

which represent recyclisation products of the expected epoxy acids.²²

The presence of α -C—H bonds in peroxides brings about a competition between homolysis of the O—O bond and concerted cyclic formation of molecular hydrogen:

These reactions were studied in detail;^{21,23,24} the yields of H₂ for different peroxides are listed in Table 1.

Table 1. The formation of H₂ in the thermolysis of the peroxides ROOR in solution.

R	Solvent	Yield of H ₂ (%) ^a	10 ⁵ k_H /s ⁻¹ (see b)	E_H /kJ mol ⁻¹
Temperature 130 °C				
EtMeCH	toluene	22	1.35	134
Ph ₂ CH	"	95	19.3	117
Temperature 140 °C				
Me ₂ CH	toluene	7.5	5.0 (62.6)	134
	propan-2-ol	8.4	28.5 (310.5)	—
	methanol	30.5	67.2 (152.6)	72
	water	41.5	296.0 (419.0)	—

^a Upon complete decomposition of the peroxide; ^b the rate constant for the homolysis is given in parentheses (10⁵ k_r /s⁻¹).

With an increase in the solvent polarity, the rate constant for hydrogen formation increases much faster than the homolysis rate constant. The yield of H₂ in the pyrolysis of diisopropyl peroxide in the gas phase is insignificant, which confirms the polarity of the transition state of the concerted cyclic reaction.

The presence of a double bond and other substituents favouring stabilisation of a carbon-centred radical formed in the α -position with respect to the peroxy group favours decomposition of peroxides at the C—O bond instead of the O—O bond.

tert-Butyl diphenylcyanomethyl peroxide undergoes decomposition in boiling cumene²⁵ to give acetone and *tert*-butyl alcohol in low yields (5% and 16%, respectively); tetraphenylsuccinonitrile is formed as the main product.

Endoperoxides of anthracene and its derivatives are readily decomposed into the original aromatic compounds and oxygen. Thus the thermolysis of 9,10- (**1**) and 1,4-anthracene endoperoxides (**2**) and 1,4-naphthalene endoperoxides **3** affords the original arenes and oxygen in yields exceeding 95%.^{26, 27}

Part of the oxygen is formed in the singlet state (¹O₂) (Table 2). As can be seen, the yield of ¹O₂ decreases with an increase in the preexponential factor *A* (positive activation entropy Δ*S*[‡]); for low values of *A*, the yield of ¹O₂ is virtually quantitative. It is of note that the biradical mechanism of oxygen formation provides low yields of ¹O₂ due to S,T conversion, whereas the concerted mechanism with simultaneous bond cleavage ensures a quantitative yield of ¹O₂:

Table 2. Activation parameters and the yield of ¹O₂ in the thermolysis of endoperoxides.

Peroxide	<i>T</i> / °C	10 ⁶ <i>k</i> / s ^{−1}	<i>E</i> _a / kJ mol ^{−1}	log <i>A</i>	Yield of ¹ O ₂ (%)
1a	60.2 ^a	0.45	138	15.4	32
	66.2 ^b	1.70	133	14.9	35
1b	60.2 ^a	0.44	135	14.9	52
	66.2 ^b	1.74	126	13.7	73
2a	73.2 ^a	0.43	127	13.0	92
	15.1 ^b	2.09	103	13.0	95
3a	12 ^b	5.30	103	13.7	76
3b	24.8 ^b	2.10	110	13.8	69

^a In 1,4-dioxane; ^b in chlorobenzene.

The high exothermicity of O₂ formation and the drop in ¹O₂ yields with an increase in temperature point to the predominance of the biradical mechanism. The enrichment of triplet oxygen generated from endoperoxide **1a** with the isotope ¹⁷O was observed in a strong magnetic field,²⁷ which is the result of ultrafine interactions within the biradical and provides additional evidence in favour of the biradical mechanism.

Studies of the thermolysis of β-hydroxyperoxides^{28–30} characterised by relatively high solubility in water revealed that their decomposition, similar to the decomposition of other peroxides R¹OOR², begins with the cleavage of the O—O bond. In the case of acyl derivatives and in the presence of water, thermolysis is accompanied by simultaneous hydrolysis of the ester bond.

III. Hydroperoxides

Thermolysis of hydroperoxides, which form homo- and hetero-associates in solution, is more complex than in the gas phase.^{31, 32}

According to Denisov,³¹ bimolecular decomposition of the type

occurs much faster than monomolecular decomposition, since the stability of the newly formed H—OH bond (483 kJ mol^{−1}) usually exceeds that of the H—X bond cleaved. The role of HX can be played by saturated hydrocarbons, alkenes, amines, alcohols and other compounds.³³

In the case of thermolysis involving association of two hydroperoxides

the activation energies of their decomposition in the complexes formed are the lower the higher is the enthalpy of the hydrogen bond.

According to X-ray diffraction data,³⁴ the hydroperoxide homoassociates R—O⁽¹⁾—O⁽²⁾—H can have different structures depending on the structure of the radical R. Thus *tert*-butyl hydroperoxide molecules form a hydrogen bond including the O⁽¹⁾ atom, whereas 1,1-diphenyl hydroperoxides form a hydrogen bond including the O⁽²⁾ atom. Because of steric hindrance, triphenylmethyl hydroperoxide forms a hydrogen bond with the π-electrons of the benzene ring of the second hydroperoxide molecule rather than with oxygen atoms. Obviously, the difference in the structures of the associates determines the mechanism of their thermolysis.

The dependence of specific rates of the decomposition of 1-methylcyclohexyl hydroperoxide and the consumption of the inhibitor on the initial concentration of the starting compound³⁵ suggests that homoassociation of hydroperoxides increases their reactivities up to a certain threshold level. Further aggregation of the hydroperoxide into a polymolecular associate does not lead to any further decrease in its thermal stability.

The addition of compounds that form stable associates with hydroperoxides results in dissociation of homoassociates with subsequent monomolecular decomposition (with respect to the hydroperoxide). Thus the addition of dioxane decreases the rate of

initiation of hydroperoxide decomposition in comparison with the initial solution.³⁶

The formation of hydroperoxide associates with electrophiles in solution favours the homolysis of the O—O bond: the stronger the electron shift in this bond, the more intense the homolysis.

At low concentrations of hydroperoxides in solution, their decomposition occurs predominantly by a monomolecular mechanism; with an increase in the hydroperoxide concentration, the bimolecular mechanism becomes predominant. The effect of addition of alcohols on the rate of hydroperoxide thermolysis is concentration-dependent. For example, the addition of cyclohexanol to a solution of cyclohexyl hydroperoxide in chlorobenzene^{5,37} results in the increase in the reaction rate to a maximum at a definite concentration of the alcohol and then to its decrease. The inhibition observed at higher concentrations of the alcohol is attributed to the formation of ternary complexes $\text{ROOH} \cdot 2 \text{ROH}$ which dissociate into radicals more slowly. The presence of carbonyl compounds along with associates in the reaction mixture results in the formation of 1-hydroperoxides

which are less thermostable than the original hydroperoxides³⁸ and undergo decomposition by the reaction:

The kinetic and thermodynamic parameters of reactions of cycloalkyl hydroperoxides with cyclohexanone in cyclohexane (the initial concentrations of the hydroperoxide and the ketone are equal to 0.02–0.05 mol litre⁻¹) (see Ref. 39) are listed in Table 3. Special mention should be made of the inertness of higher cyclic ketones in this reaction. Similar inactivity of higher cyclic ketones due to steric hindrance in the transition from the planar sp²-configuration to the sp³-configuration is observed in the addition of HCN to the corresponding ketones. The reversible formation of 1-hydroxyperoxides is catalysed by carboxylic acids. The data listed in Table 4 point to an increase in the rates of thermal decomposition of hydroperoxides upon addition of a ketone.

Of special note are reactions of hydroperoxides with the radicals formed upon thermolysis; these are accompanied by induced decomposition of hydroperoxides and their chain decomposition. This occurs in parallel with a series of secondary reactions:

The reaction of secondary hydroperoxides with the radicals $\text{ROO}^\bullet$ is accompanied by further destruction of hydroperoxides:

Table 3. Kinetic parameters of the reactions of hydroperoxides ROOH with cyclohexanone at 25 °C.

R	$10^3 k_2$ /litre mol ⁻¹ s ⁻¹	$K = k_2/k_1$ /litre mol ⁻¹	E_a /kJ mol ⁻¹	$Q = E_1 - E_2$ /kJ mol ⁻¹
Cyclohexyl ^a	1.0	8.0	21.2	39.4
Cyclooctyl	1.0	7.0	25.5	41.9

^a The reaction with cyclooctanone and cyclododecanone does not take place.

Table 4. Increase in the rate of the thermal decomposition of octyl hydroperoxide at 110 °C upon addition of cyclohexanone.

Reaction time /h	Decomposition (%)	
	without additives	with cyclohexanone
2	1.5	14.2
4	5.9	30.0
6	11.1	40.1

Note. For octyl hydroperoxide, $c_0 = 0.06$ mol litre⁻¹, for cyclohexanone $c_0 = 0.33$ mol litre⁻¹

The introduction of free radical scavengers suppresses induced decomposition of peroxides and permits one to estimate the contribution of the peroxide thermolysis proper (see also Refs 5 and 31). The kinetic characteristics of the reactions of the radicals $\text{RO}^\bullet$ and $\text{ROO}^\bullet$ with hydroperoxides are listed in Table 5 (data from Refs 40–47).

In biological objects, hydroperoxides exist in an aqueous medium. It is noteworthy that the transition from a hydrocarbon to an aqueous medium is accompanied by a significant decrease in the activation energy and an increase in the rate of hydroperoxide thermolysis. The corresponding parameters for *tert*-butyl hydroperoxide are as follows:⁶

Solvent	Initial concentration /mol litre ⁻¹	Decomposition rate constant /s ⁻¹ (T /°C)	E_a /kJ mol ⁻¹
n-Hydrocarbon	0.17	0.9×10^{-5} (150)	163
Water	0.05	0.14×10^{-5} (130)	126

The effect of pH on the decomposition kinetics of this hydroperoxide in water was studied.⁴⁸

Hydroperoxides are formed upon free-radical oxidation of DNA, which plays a crucial role in mutagenesis induced by ionising radiation. Thus the oxidation of 2'-deoxythymidine yields eight diastereomers of 5(6)-hydroxy-6(5)-hydroperoxy-5,6-dihydro-2'-deoxythymidine (**4a–d**, **5a–d**) and 5-(hydroperoxymethyl)-2'-deoxyuridine (**6**). The thermolysis of thymidine hydroperoxides in aqueous solutions was studied by Wagner *et al.*⁴⁹

Table 5. Kinetic parameters ($\log k$) of the reactions of peroxy and alkoxy radicals $\text{ROO}^\bullet$ and $\text{RO}^\bullet$ with hydroperoxides.

R in $\text{ROO}^\bullet$	Hydroperoxide	$T/^\circ\text{C}$	$\log k$	R in $\text{ROO}^\bullet$	Hydroperoxide	$T/^\circ\text{C}$	$\log k$

		21	0.20	EtMe_2C	EtMe_2COOH	30	7.95
cyclo- C_6H_{11}	cyclo- $\text{C}_6\text{H}_{11}\text{OOH}$	75	1.08	1-Me-cyclo- C_6H_{10}	1-Me-cyclo- $\text{C}_6\text{H}_{10}\text{OOH}$	30	7.60
$\text{Bu}^\dagger$	Et(Me)CHOOH	21	2.68	$\text{Bu}^\dagger$	cyclo- $\text{C}_6\text{H}_{11}\text{OOH}$	30	8.45
$\text{Bu}^\dagger$	see ^a	30	2.75	$\text{Bu}^\dagger$	1-Me-cyclo- $\text{C}_6\text{H}_{10}\text{OOH}$	30	8.18
		75	3.17	$\text{Bu}^\dagger$	$\text{Bu}^\dagger\text{OOH}$	30	8.40
PhMe_2C	see ^a	30	2.78	$\text{Pr}^\dagger$	$\text{Pr}^\dagger\text{OOH}$	30	7.70
See ^b	PhMe_2COOH	30	3.40				

Note. The reactions of cyclo- $\text{C}_6\text{H}_{11}\text{OO}^\bullet$ with hydroperoxides are related to the $\text{S}_{\text{N}}2(\text{C}-\text{H})$ type; the reactions of other radicals are of the type $\text{S}_{\text{N}}2(\text{OO}-\text{H})$.

trans-(5*R*,6*R*) (**a**), *trans*-(5*S*,6*S*) (**b**), *cis*-(5*S*,6*R*) (**c**), *cis*-(5*R*,6*S*) (**d**).

The thermolysis of thymidine hydroperoxides in highly purified water occurs in accordance with the following schemes (see Table 6):

**Table 6.** Kinetic parameters of the thermal decomposition of thymidine hydroperoxides in aqueous solutions.

Hydroperoxide	$10^5 k_1/\text{s}^{-1}$ (37 °C)	$\Delta H^\ddagger$ /kJ mol ⁻¹	$\Delta S^\ddagger$ /J mol ⁻¹ K ⁻¹
4a	19	103	9.6
4b	12	105	15.4
4c	1.9	96	-31
4d	1.9	96	-31
5a	2.3	121	52
5b	2.0	125	64
5c	1.2	119	41
5d	0.56	147	125

As can be seen, the decomposition of the hydroperoxides **4a-d** involves dehydration of secondary hydroperoxide groups and subsequent hydrolysis, whereas the thermolysis of compounds **5a-d** involves tautomeric conversion of the hydroperoxide into an aldehyde and recyclisation.

IV. Dioxiranes

A series of novel oxidants, *viz.*, dioxiranes, possessing a unique combination of properties (high regio- and stereoselectivity of oxidation, high reactivity and mild reaction conditions) have been introduced into laboratory practice since the mid-1980's. The majority of investigations into the chemical properties of dioxiranes were carried out with dimethyldioxirane (**7b**, DMDO) and methyl(trifluoromethyl)dioxirane (**7c**) as examples.

$\text{R}^1 = \text{R}^2 = \text{H}$ (**a**), Me (**b**); $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{CF}_3$ (**c**).

Thermal stability studies have shown that highly reactive dioxiranes react simultaneously by several routes. This accounts for discrepancies in results obtained by different authors. According to some authors,^{50, 51} the half-life ($\tau_{1/2}$) of dioxirane **7b** at room temperature is 7 h or 26 days, respectively. According to other authors,^{50, 52, 53} the decomposition of dioxiranes **7b** and **7c** cannot be described by first- or second-order kinetic equations, since the corresponding kinetic curves display a distinct induction period. However, at low concentrations of the dioxirane **7b** ($< 3 \times 10^{-2}$ mol litre⁻¹, see Refs 51 and 53) the rate of its thermolysis obeys the first-order kinetic law. Oxygen, which suppresses the decomposition of DMDO, has a pronounced effect on the composition of the reaction products.⁵³

The thermolysis of the dioxirane **7b** in acetone^{54, 55} occurs by three main routes, *viz.*, isomerisation (i), radical (r) and molecular (m) routes (Scheme 1).

The composition of the thermolysis products of DMDO depends on the presence of oxygen in the solution as well as on the presence and number of C-H bonds in the solvent molecule. The ratio of the main reaction products also depends on temperature (Table 7). If the decomposition is carried out in the presence of oxygen at 10 °C, methyl acetate is virtually the only reaction product. Its proportion in the total yield of the reaction products diminishes to 59%, if the reaction is carried out at 50 °C. Under these conditions, acetol (1-hydroxypropan-2-one) (39%) and acetic acid (2%) are formed in addition to methyl acetate. Quite a different situation is observed in the decomposition of DMDO in the absence of oxygen (the latter is removed by purging the

Scheme 1

**Table 7.** Yields of the thermal decomposition products of dimethyldioxirane.

Atmo- sphere	$T/^{\circ}\text{C}$	MeCOMe 	MeCCH_2OH 	$\text{MeCOCH}_2\text{CMe}$ 	MeCOH
O_2	10	0.98	0.02	—	—
O_2	50	0.59	0.39	—	0.02
O_2^a	50	1.00	—	—	—
Ar	41	traces	traces	1	traces

^a CCl_4 was used as a solvent; in other cases, acetone was used.

solution of DMDO with argon). Acetol acetate $\text{MeC(O)OCH}_2\text{C(O)Me}$ is the main thermolysis product at 41°C ; methyl acetate and acetol were found in insignificant amounts. The decomposition rate of dimethyldioxirane decreases in CCl_4 . The reason is the absence of C—H bonds in the solvent molecule; therefore, the isomerisation of DMDO into methyl acetate is the main pathway of its consumption.

The presence of dissolved oxygen is critical for the stability of dioxirane solutions. When oxygen is present in the solution, the rate of DMDO thermolysis is relatively small and obeys the first-order kinetic law with respect to dioxirane (Fig. 1). Removal of oxygen by purging the solution with argon or by chemical binding sharply increases the rate of DMDO consumption (see Fig. 1, curve 3); the reaction order is intermediate between the first and the second with respect to dioxirane. The reason for the sharp increase in the reaction rate is intense radical-chain induced

**Figure 1.** Typical kinetic curves for the consumption of dimethyldioxirane. Conditions: acetone, 50°C , preliminary purging of the solution with oxygen (a) or argon (b). The solid lines designate the results of treatment of the kinetic curves using a first-order (curves 1 and 2) or a mixed (first + second)-order equation (curve 3).

decomposition of the peroxide in the absence of O_2 . The thermolysis of DMDO proceeds in accordance with the following scheme (C is a complex):^{54,55}

Further transformations of radical intermediates are apparent: the alkyl radicals react with oxygen and induce the decomposition of dioxirane **7b** in the absence of oxygen [reactions (10)–(13)] and undergo decay in the recombination [reactions (16)–(18)]. Oxygen-centred radicals undergo β -cleavage [reactions (8), (11), (14)] or abstract the hydrogen atom from the acetone molecule [reactions (9), (12), (15)].

The induced decomposition of dioxirane under the action of the methyl radical [reaction (13), $k_{13} \approx 10^5 - 10^6 \text{ litre mol}^{-1} \text{ s}^{-1}$] ⁵⁶⁻⁵⁸ competes with the abstraction of hydrogen from the acetone molecule with the rate constant of $2.7 \times 10^3 \text{ litre mol}^{-1} \text{ s}^{-1}$ (see Ref. 59)

In the absence of oxygen, the chain decomposition of dioxirane **7b** occurs with the involvement of $\text{Me}\cdot$ and $\text{MeC(O)CH}_2\cdot$ radicals. In the presence of oxygen, the induced decomposition of compound **7b** is suppressed, while the chain termination involves the peroxy radicals.

Under these conditions, the thermolysis of DMDO is described by equations (1)–(9), (20), (21). A kinetic analysis of the decomposition reaction gave the following expression for the reaction rate:

$$W_{7b} = \{(\alpha_m + \alpha_r)k_1[\text{MeC(O)Me}] + \beta_i k_4\} [7b] = k_{\text{eff}}[7b], \quad (22)$$

where α_m and α_r are the contributions of the molecular and radical routes during the conversion of the complex C: $\alpha_m = k_2/A$, $\alpha_r = k_3/A$, where $A = k_{-1} + k_2 + k_3$; $\beta_i = k_5/(k_{-4} + k_5)$. Indeed, thermal decomposition of DMDO in acetone solutions saturated with oxygen obeys the kinetic law for first-order reactions with respect to dioxirane. The effective thermal decomposition rate constant, k_{eff} , does not depend on the concentration of dioxirane. At 50 °C:

$$k_{\text{eff}} = 1.8 \times 10^{-5} + 1.5 \times 10^{-6} [\text{MeC(O)Me}] \text{ s}^{-1}.$$

The activation parameters, *i.e.*, the preexponential factor $\log A$ and the energy of activation E_a , for the overall decomposition of DMDO in acetone are described by the expression:

$$\log k_{\text{eff}} = (10.2 \pm 0.6) - \frac{(90.4 \pm 3.8)}{\theta},$$

where $\theta = 2.3 RT \text{ kJ mol}^{-1}$. As mentioned above, the thermolysis of DMDO in carbon tetrachloride occurs at a slower rate, since in this case the thermal decomposition occurs by only one route, *viz.*, isomerisation of dioxirane into methyl acetate. The temperature dependence of the rate constant $k_i = \beta_i k_4$ in CCl_4 appears as:

$$\log k_{\text{eff}} = \log k_i = (7.1 \pm 0.3) - \frac{(75.3 \pm 2.1)}{\theta}.$$

The activation parameters of the isomerisation of the dioxirane **7b** into methyl acetate are consistent with the results of quantum-chemical calculations of a high basis set.⁶⁰ The energy diagram for the isomerisation of DMDO and the simplest dioxirane **7a** on a standard enthalpy of formation scale is shown

Figure 2. The energy diagram of isomerisation of dioxirane **7a** ($R = \text{H}$, $\Delta H_f^\circ = -1.3 \text{ kJ mol}^{-1}$) and dimethyldioxirane **7b** ($R = \text{Me}$, $\Delta H_f^\circ = -105.9 \text{ kJ mol}^{-1}$) into formic acid and methyl acetate, respectively. (The corresponding values for compounds **7b** and **7a** (in kJ mol^{-1}) are given in the numerator and the denominator, respectively). The sign $\neq$ designates the transition state.

in Fig. 2. The difference between experimental and calculated values of E_a seems to be related to the effect of the solvent. The limiting step of isomerisation, *viz.*, the formation of a biradical, requires the opening of the dioxirane ring in order to minimise the repulsion of lone electron pairs coplanar with the ring. The opening of the ring associated with the reduction of the bond angle between the substituents at the carbon atom is more difficult for substituents with larger size, which explains the increase in E_a in the homolysis of the dioxirane **7b** in comparison with compound **7a**. Indeed, the dioxirane **7a** is thermally much less stable than **7b**. Contrariwise, sterically hindered bis(mesityl)dioxirane forms stable crystals even at room temperature.⁶¹

The O–O bond homolysis product (biradical) decomposes through migration of H or Me resulting in the formation of the corresponding acid or its ester. This process is characterised by low activation energy, *e.g.*, for the biradical $\cdot\text{OCMe}_2\text{O}\cdot$ it is 13.4 kJ mol^{-1} . The decomposition of the biradical (or DMDO) into CO_2 and ethane requires much energy; therefore, this reaction cannot compete with the rearrangement into an ester.⁶⁰ Indeed, vacuum flash-pyrolysis of the dioxirane **7c** gives quantitative yields of methyl trifluoroacetate ($> 98\%$).⁶² The photolysis and thermolysis of dioxiranes in solutions are complicated by the decomposition of the peroxide induced by free radicals.

While analysing the ratio of the radical (r) and molecular (m) routes of dioxirane decomposition, one should bear in mind that dioxiranes react with many organic compounds at a very fast rate ($k_m \gg k_r$). In this case, we deal with a manifestation of a high oxidative activity of dioxirane with respect to the other reactant rather than with its thermolysis. The problems related to the products, kinetics and mechanisms of oxidation of various organic compounds by dioxiranes are documented.⁶³⁻⁶⁸ In the presence of compounds with non-activated C–H bonds, the radical route of dioxirane oxidation becomes more pronounced.

As mentioned above, complete removal (purging or chemical binding) of O_2 shifts the reaction towards radical-chain decom-

position of DMDO. This includes chain initiation [reactions (1)–(9)], propagation [reactions (10)–(15), (19)] and termination [reactions (16)–(18)]. It was found⁵⁵ that cross recombination is the most plausible step in the chain termination (17). In this case, the kinetic analysis of DMDO decomposition gives the following expression for the rate of consumption of the dioxirane **7b**:

$$W_{7b} = k^{(1)}[7b] + k^{(2)}[7b]^2, \quad (23)$$

where $k^{(1)}$ and $k^{(2)}$ are complex combinations of kinetic constants and acetone concentration. The first component of Eqn (23) reflects the consumption of compound **7b** in the reaction with the acetonoyl radical, while the second one describes the contribution of reaction (13) to the total rate of DMDO decomposition. This differential equation is readily transformed into an analytical expression which appears as:^{57, 66}

$$\ln \frac{(k^{(1)} + k^{(2)}[7b])[7b]_0}{(k^{(1)} + k^{(2)}[7b])} = k^{(1)}t. \quad (24)$$

Equation (24) effectively describes the kinetic curves of consumption of the dioxirane **7b** under conditions of induced decomposition.

Thus the role of oxygen in the thermolysis of DMDO consists of the inhibition of free-radical induced decomposition of the peroxide by route r. The calculation of the ratio of the amount of dissolved oxygen to the dioxirane **7b** decomposed in the induction step can be used for determining the contribution of the radical route of thermal decomposition of DMDO to the overall process. The ratio of decomposition reactions by routes r and m was studied⁵⁵ in the reactions of DMDO with acetone and some aliphatic hydrocarbons (Table 8). These data suggest that the reaction of DMDO with aliphatic hydrocarbons is indeed a radical reaction; it is not excluded that it proceeds exclusively by a homolytic mechanism ($k_3 \gg k_2$), whereas the efficiency of initiation is decreased due to intracage recombination [reaction (6)].

The known contribution of the radical route of the reaction of dioxirane **7b** containing a C–H bond and the kinetic parameters of the overall reaction allow one to determine the rate constants k_r and k_m as well as the corresponding activation parameters. The data for the reactions of DMDO with acetone and 2,2,4-trimethylpentane are given below.

Reagent	Reaction route	
	radical	molecular
Acetone	$\log k_r = 11.9 - 112.1/\theta$	$\log k_m = 9.5 - 96.2/\theta$
2,2,4-Trimethylpentane	$\log k_r = 11.1 - 91.2/\theta$	$\log k_m = 4.0 - 51.5/\theta$

The preexponential factors of the rate constants for the radical reaction of the dioxirane **7b** with acetone and 2,2,4-trimethylpentane are similar (with allowance for the statistic correction for six C–H bonds of acetone). The difference in the activation energies for these reactions (21 kJ mol^{−1}) reflects the difference in the strengths of the C–H bonds of acetone and 2,2,4-trimethylpentane subjected to the attack.

The values of partial rate constants for the reaction of DMDO with RH were calculated from the effective rate constant for the consumption of dioxirane in the oxidation of hydrocarbons (RH) and acetone:^{55, 57, 58, 69}

$$k^H = \frac{k_{\text{eff}}}{n[\text{RH}]} = \frac{(\alpha_r + \alpha_m)k_1}{n},$$

where n is the number of equivalent C–H bonds attacked by dioxirane. The results of calculations of k^H are listed in Table 9. Although the ratio of reaction routes for the reaction **7b** + RH changes in the series of compounds under study, the calculated

Table 8. Ratio of the molecular and radical routes in the reactions of dimethyldioxirane with organic compounds.

^a Temperature dependence of a bimolecular rate constant.

values of partial rate constants can be used to determine the relative reactivities of the substrates RH. The changes in k^H demonstrate the following regularities (Table 9):

1. Dioxirane is a pronounced regioselective oxidant. The primary C–H bond is attacked 10⁴ times less actively than the tertiary bond. Probably, the true value of the $k_{\text{tert}}/k_{\text{pri}}$ ratio is somewhat smaller, since the reactivity of acetone is decreased due to deactivation of the α-C–H bonds by the carbonyl group.

2. The activity of tertiary C–H bonds changes in the following order: aliphatic (1.0) < 'aromatic' (H–CAlk₂Ar) (2.0) < cage (4.0). Weakening of the C–H bond strength and retention of the radical reaction mechanism result in an increase in k^H on going from 2-methylbutane to cumene. The presence of carbocation-stabilising fragments in the molecule RH increases the contribution of the molecular route and the reactivity of the C–H bond (2-methylbutane and adamantane).

The ratio of radical and molecular routes is quantitatively characterised by the [O₂]/Δ[7b] ratio. The conditions influencing the ratio of these two routes are as follows:

— the contribution of the radical mechanism increases with temperature (see Table 8);

— the energy of homolytic dissociation of the C–H bond depends on the nature of the substrate to be oxidised: an increase in energy diminishes the contribution of the radical route. The energy of homolytic dissociation of tertiary C–H bonds is lower than that of secondary bonds.

The ratio of molecular and radical routes of reactions of peroxide oxidants with substrates to be oxidised has been repeatedly discussed in the literature. It is well known that the more pronounced the electrophilic properties of the peroxide (the affinity of the oxidant for the electron can be used as a measure of activity) and the electron-donor properties of the compound to be oxidised, the lower the temperature and the more polar the

solvent, the higher the probability of the molecular route of the oxidation. A similar situation is observed in the chemistry of dioxiranes. From a synthetic point of view, it is more reasonable to select conditions favouring the nonradical mechanism, *viz.*, low temperature, the use of dioxiranes possessing stronger oxidising properties (*e.g.*, **7c**) and compounds to be oxidised with activated C–H bonds that can effectively stabilise the positive charge on the C atom generated upon partial transfer of the electron density to dioxirane.

V. 1,2-Dioxetanes

Luminescence appearing upon formation of an electron-excited product is the main characteristic feature of the thermolysis of 1,2-dioxetanes (**A**) and their keto derivatives (α -peroxy lactones, **B**) (see Refs 70–74 and the references cited therein).

The excitation of the product is due to the fact that the difference between the enthalpy of activation $\Delta H^\ddagger$ of thermolysis and the standard enthalpy of the same reaction ΔH° exceeds the energy of the electron-excited state E^* , *i.e.*, $\Delta H^\ddagger - \Delta H^\circ \geq E^*$. The main routes of the thermolysis of 1,2-dioxetanes (**A**) and α -peroxy lactones (**B**) are as follows:

The schemes illustrating the ratios of energies in the individual steps of the thermolysis of some typical representatives of dioxetanes and α -peroxy lactones are shown in Fig. 3.⁷²

Figure 3. Diagram of the enthalpies of formation of reaction products (ΔH_f° /kJ mol^{−1}) in the thermolysis of tetramethyl-1,2-dioxetane and dimethyl-1,2-dioxetanone.

Product states: singlet S_K , triplet T_K , excited K^* and ground K_0 . The figures designate the energy of the transition from one state to another.

The values of ΔH° for different compounds lie in the range from -250 to -380 kJ mol^{−1}, while $\Delta H^\ddagger$ varies from 85 to 140 kJ mol^{−1}, which enables the occupation of triplet ($E_T^* = 250-330$ kJ mol^{−1}) and singlet [$E_S^* = E_T^* + (20-63)$ kJ mol^{−1}] states. A comparison of 1,2-dioxetanes and α -peroxy lactones has shown that the decomposition of the latter is much more exothermic. This is not surprising, however, since the incorporation of an sp^2 -hybridised carbon atom into a strained four-membered 1,2-dioxetane ring increases the exothermic character of the ring opening. The decomposition of α -peroxy lactones yields electron-excited CO_2 molecules; the energies of their excited triplet and singlet states are very high. The kinetic characteristics of the

thermolysis of some dioxetanes in solution are listed in Table 10.^{75–78}

The kinetic parameters of the thermolysis of tetramethyldioxetane in various solvents are very similar. The conservation of the activation energy in the decomposition of tetramethyldioxetane in benzene solutions and solid benzene templates at low temperatures is of note.⁷⁵ The activation energy of the thermolysis of unsubstituted dioxetane in the gas phase is equal to $91 \pm 5 \text{ kJ mol}^{-1}$, *i.e.*, it is 4 kJ mol^{-1} less than that for toluene. Thus, the energy of molecular thermolysis does not virtually depend on the phase state of the medium in the absence of a direct interaction with the solvent molecules. The stability of dioxetanes of the diadamantylidene series with respect to decomposition is especially high: E_a reaches 153 kJ mol^{-1} . The data listed in Table 10 and other published data suggest that the yields of excited singlet states are many times smaller than those of triplet states, *i.e.*, spin-forbidden processes occur much more intensely than spin-allowed ones. The yields of excited triplets usually increase with an increase in the stability of the starting peroxide.

Two main mechanisms for the thermal decomposition of dioxetanes have been proposed: formation of a biradical and concerted redistribution of the bonds.

The effect of substituents on the chemical kinetics of thermolysis and thermochemical and quantum-chemical calculations confirm the biradical mechanism of thermolysis.^{73, 74, 77} The enthalpies of formation, the geometry of the central fragment, the torsion angle $\text{O}-\text{C}-\text{C}-\text{O}$ and the strain energies in the ring were calculated for a large series of substituted dioxetanes and intermediate biradicals on the basis of a biradical model using the molecular mechanics method (MM2).⁷⁹ Together with the thermochemical calculations the use of the Benson additive group contribution method has made it possible to obtain efficient correlation equations relating the Arrhenius and free activation energies with the values of angle strain energies in the starting dioxetane and in the biradical. A relatively high predictive capacity of these correlation equations provides additional evidence in favour of the biradical mechanism.

VI. Trioxides

Compounds containing three or more neighbouring oxygen atoms are considerably less thermostable than peroxides ($\text{RO}-\text{OR}$).⁸⁰

Thermal decomposition, which proceeds exclusively by a homolytic mechanism, is the most typical reaction of dialkyl trioxides. Their decomposition yields alkoxy ($\text{RO}^\bullet$) and peroxy ($\text{ROO}^\bullet$) radicals which determine all subsequent reactions and reaction products. Direct evidence for the formation of peroxy radicals in the decomposition of di-*tert*-butyl trioxide was obtained by ESR (see, *e.g.*, Ref. 81). The *tert*-butoxy radical was identified from the signal of its adduct with a spin trap (2-methyl-2-nitrosopropane).⁸² Indirect evidence for the generation of $\text{Bu}^\bullet\text{O}^\bullet$ radicals also follows from a significant increase in the concentration of the radical $\text{Bu}^\bullet\text{OO}^\bullet$ after addition of *tert*-butyl hydroperoxide to a solution of $\text{Bu}^\bullet\text{OOOBu}^\bullet$ in CH_2Cl_2 :

The decomposition of $\text{Bu}^\bullet\text{OOOBu}^\bullet$ in the presence of free radical scavengers (sterically hindered phenols) occurs without evolution of oxygen, but is accompanied by yellow colouration of the solution due to the formation of quinolide peroxide.^{81, 83}

$\text{X} = \text{Me}, \text{Bu}^\bullet.$

The kinetics of radical decomposition of di-*tert*-butyl trioxide in CFCl_3 and CH_2Cl_2 (-20 to 7°C) was followed⁸⁴ by monitoring ionol (2,6-di-*tert*-butyl-4-methylphenol) consumption. The following activation parameters were established:

The probability (e) of the exit of radicals into the solution in the decomposition of di-*tert*-butyl trioxide does not virtually depend on temperature and constitutes $(90 \pm 10)\%$.⁸⁴

Under certain conditions, the decomposition of ROOOR is accompanied by chemiluminescence (CL) in the visible (350–650 nm) and IR (1000–1300 nm) regions of the spectrum.⁸⁵ Excited carbonyl compounds (*e.g.*, singlet-excited phosphene in the case of CH_2Cl_2) emit in the visible region, while singlet oxygen $^1\Delta_g\text{O}_2$ emits in the IR region. CL emitters are formed upon recombination of peroxy radicals generated in the decomposition of di-*tert*-butyl trioxide with subsequent involvement of the solvent in the radical-chain reaction.⁸⁶

The energy of the last reaction ($\sim 375 \text{ kJ mol}^{-1}$) is sufficient to generate phosphene or oxygen in the excited states (the excitation energies are equal to ~ 290 and 94 kJ mol^{-1} , respectively).⁸⁷ The chemiluminescence method was used to determine the excitation yields of singlet oxygen upon decomposition of di-*tert*-butyl trioxide in CH_2Cl_2 .⁸⁷ At -5.5°C , this yield is 22% (as calculated per original trioxide) and diminishes slightly with an increase in temperature (18% at 5.0°C). The termination of the kinetic chains in the decomposition of di-*tert*-butyl trioxide in CH_2Cl_2 occurs predominantly as cross recombination of peroxy radicals.⁸⁶

The quenching of the chemiluminescence in both visible and IR regions of the spectrum obeys first-order kinetics and is characterised by similar rate constants. The activation parameters of the thermal decomposition of dialkyl trioxides obtained in the temperature range from -20 to 18°C using the CL method are listed in Table 11.

The rate constants for the decomposition of di-*tert*-butyl trioxide (at 0°C) in carbon tetrachloride ($\epsilon = 2.23$) and nitromethane ($\epsilon = 38.6$) are 0.6×10^{-3} and $9.7 \times 10^{-3} \text{ s}^{-1}$, respectively (see Ref. 88), *i.e.*, they increase with the medium polarity. The same is true of di-*tert*-butyl peroxide; however, in the latter case this effect is less pronounced. For example, at 125°C the

Table 11. Activation parameters of the decomposition of dialkyl trioxides ROOOR in CH₂Cl₂ inferred from the chemiluminescence data.

R	Method ^a	log <i>A</i> (s ⁻¹)	<i>E</i> _a /kJ mol ⁻¹	Ref.

	Vis	15.0 ± 1.6	89.5 ± 8.2	87

^a Designations: IR, infrared spectroscopy; Vis, spectroscopy in the visible region of the spectrum.

decomposition rate constants of Bu^tOOBu^t in cumene ($\epsilon = 2.37$) and acetonitrile ($\epsilon = 37.5$) are equal to 16.0×10^{-6} and 34.7×10^{-6} s⁻¹, respectively. A symmetrical transition state of the peroxide RO...OR is stabilised by the solvent to a lesser degree than the non-symmetrical transition state of the trioxide RO...OOR. Therefore, the dependence of the activation energy on the medium polarity is expressed to a greater degree for the latter.

Di-*tert*-butyl trioxide is an effective initiator of the chain decomposition of ozone in CFCl₃ (−23 °C).⁸⁹ The consumption of O₃ occurs in accordance with the first-order kinetic law; the value of the effective rate constant k_{eff} depends linearly on [Bu^tOOOBu^t]^{1/2}. This process is described by the following scheme:

where RH = Bu^tOOOBu^t and its decomposition products.

The termination of the kinetic chains takes place as a result of cross-recombination of the radicals Bu^tO[•] and Bu^tOO[•] into the original trioxide; the contributions of irreversible consumption of the *tert*-butoxyl radical and the quadratic decay of the peroxy radicals are negligibly small. For this reason, the concentration of the trioxide does not change throughout the experiment ($\sim 10^4$ s), which simplifies the reaction scheme and yields the following expression for the effective rate constant for this reaction:

$$k_{\text{eff}} = 2(Kk_2k_3[\text{Bu}^t\text{OOOBu}^t])^{1/2},$$

where $K = k_1/k_{-1}$. The product of the rate constants for the reactions of O₃ with alkoxy and peroxy radicals was calculated from the linear dependence of k_{eff} on [Bu^tOOOBu^t]^{1/2}; k_3 was found to be equal to $\sim 1.7 \times 10^7$ litre mol⁻¹ s⁻¹ at −23 °C.

Transannular ozonides (cyclic analogues of dialkyl trioxides) are formed upon addition of ozone to anthracene and its 9,10-substituted derivative.^{90–94}

R¹ = H: R² = H (**a**), Me (**b**), Bu^t (**c**); R¹ = Me: R² = Me (**d**), Et (**e**), Bu^t (**f**), OMe (**g**), Ph (**h**), CH₂Ph (**i**); R¹ = R² = OMe (**j**).

The stability of transannular ozonides strongly depends on the nature of the substituents R¹ and R². The preparation of 9-(*tert*-butyl)-10-methylantracene ozonide (**8f**) stable at room temperature has been described.⁹³ The latter was isolated in a crystalline state and studied by X-ray diffraction analysis. The decomposition of the ozonide **8f** obeys the first-order kinetic law and is characterised by the following activation parameters: log *A* = 14.6 ± 0.3 (s⁻¹); *E*_a = 119.7 ± 2.1 kJ mol⁻¹. The activation energy of the decomposition of this compound exceeds those of the ozonides **8b** (*E*_a = 105 kJ mol⁻¹)⁹² and **8c** (*E*_a = 100 kJ mol⁻¹),⁹⁵ which points to stabilisation of transannular ozonides by bulky alkyl substituents. Interestingly, in the case of *cis*-1,2,3-trioxolanes their structures are destabilised by bulky substituents.

Heating of the ozonides **8b**, **8d** and **8f** results in their isomerisation into 10-methyl-10-(alkylperoxy)-9-anthrone (**9**) in nearly quantitative yields.^{90, 91, 93}

The decomposition of the ozonide **8h** is accompanied by evolution of molecular oxygen and a shift of the phenyl substituent to the oxygen atom; this affords 9-methyl-10-phenoxyanthracene (**10**). Endoperoxide **11** is formed in a small amount upon decomposition of the ozonide **8h**.

The radical decomposition of transannular ozonides was confirmed in the studies carried out in the presence of the free radical scavenger 2,4,6-tri-*tert*-butylphenol.⁹⁴ Selective homolysis of one of the O–O bonds is the first step in the decomposition of transannular ozonides and dialkyl trioxides.

Attempts to detect the formation of singlet oxygen in the decomposition of the ozonide **8g** in the presence of the ¹O₂ scavengers cyclohexene and 1,2-dimethylcyclohexene were unsuccessful.⁹⁴

Table 12. Activation parameters of the thermal decomposition of 1,2,3-trioxolanes.

	—	33.5	96
	9	29.3	98

^a $\tau_{1/2}$ = 0.06 s at -92 °C; ^b $\tau_{1/2}$ = 0.74 s at -92 °C.

Data on the kinetic regularities of the thermolysis of 1,2,3-trioxolanes (**12**) (primary ozonides) are relatively scarce (Table 12).

**12a–f**

$R^1 = R^3 = H$; $R^2 = R^4 = Et$ (**a**), Pr^i (**b**), Bu^t (**c**), Me (**d**);

$R^1 = R^2 = R^3 = R^4 = Me$ (**e**); $R^1 = Bu^n$, $R^2 = R^3 = R^4 = H$ (**f**).

Their decomposition was studied by IR⁹⁶ and ¹H NMR spectroscopy⁹⁷ by following the changes in the ozonide concentration and the accumulation of the ozonide transformation products.⁹⁸ In all cases studied, the thermolysis of 1,2,3-trioxolanes obeyed the first-order kinetic law.^{96–98}

The decomposition of primary ozonides yields a carbonyl compound $R^1R^2C=O$ and a carbonyl oxide R^3R^4COO ; the existence of the latter in the liquid phase was confirmed by spectroscopic data.⁹⁹ The final decomposition products (1,2,4-trioxolanes, peroxides and polymeric peroxides) are formed in subsequent reactions of carbonyl oxide molecules with one another, with carbonyl compounds and with the solvent or special additives.

The homolytic cleavage of the O–O bond is the most typical reaction of all trioxides under consideration. Thermal stability of

peroxides is the main feature which makes them different from trioxides. For example, the same rates of decomposition of di-*tert*-butyl trioxide and di-*tert*-butyl peroxide ($k = 1 \times 10^{-5}$ s⁻¹) are observed at -40 and 120 °C, respectively.

VII. Hydrotrioxides

Thermolysis of hydrotrioxides ROOOH was considered in detail in a recently published review;¹⁰⁰ therefore, here we shall confine ourselves to the description of the main characteristic features of this process.

The decomposition of ROOOH occurs in accordance with the first-order kinetic law.^{101–110} The activation parameters for the decomposition of some hydrotrioxides are listed in Table 13. High proneness of hydrotrioxides to homoassociation and complexation with a solvent determines a broad range of activation energies and preexponential factors which are interrelated in a compensation law. The thermal decomposition rate constant of ROOOH increases with the enhancement of the electron-withdrawing properties^{101–104} and polarity¹⁰⁵ of the substituent R.

In the thermal decomposition of hydrotrioxides, part of O₂ is evolved in a singlet excited state. In addition, the decomposition of some hydrotrioxides is accompanied by chemiluminescence in the visible region of the spectrum, which suggests the formation of free radicals during the thermolysis.

The thermal decomposition of hydrotrioxides may occur by different pathways:

where X[·] is any radical leaving the solvent cage and inducing the decomposition of ROOOH.

The first reaction (route *a*) takes place in the case of silyl hydrotrioxides. The decomposition mechanism of these compounds was studied in detail in the example of dimethylphenylsilyl hydrotrioxide.¹⁰⁴ The kinetic and activation parameters of this decomposition (high negative values of entropy of activation), considerable effects of substituents, dependence of the decomposition rate on the solvent polarity and the absence of the effect of the radical inhibitor (ionol) on the decomposition kinetics correlate with the predominantly molecular (> 90%) decomposition mechanism of silyl hydrotrioxides.

Table 13. Kinetic parameters of the thermal decomposition of hydrotrioxides.

HOOOH	(CD ₃) ₂ CO	-50 to 10	6.1	46.0	110

Note. RH is a starting compound used for the preparation of the corresponding hydrotrioxide.

B is a base.

The decomposition of ROOOH induced by free radicals (route *b*) is especially well pronounced in the case of cumyl hydrotrioxide.^{111,112} The thermal decomposition of this compound in acetone ($E_a = 66.9 \pm 0.4 \text{ kJ mol}^{-1}$; $\log A = 10.4 \pm 0.1$) is significantly retarded in the presence of ionol. The activation parameters of the reaction ($E_a = 100.0 \pm 0.4 \text{ kJ mol}^{-1}$; $\log A = 16.4 \pm 0.1$) change under these conditions. In the absence of the inhibitor, the reaction products are dimethylphenylmethanol (the main product), acetophenone and isopropylphenyl hydroperoxide. The decomposition occurs in accordance with the following scheme:

In the presence of ionol (ArOH), the induced decomposition is suppressed and dimethylphenylmethanol is formed as the only organic reaction product.^{111,112}

R = PhMe₂C.

Intramolecular hydrogen bonds can be formed in hydrotrioxides that are derivatives of alcohols, esters and acetals containing an additional oxygen atom at the α -C atom. For these compounds, the molecular mechanism for the decomposition [reaction (25)] is feasible.¹¹³ However, the experimental data altogether are more consistent with the radical mechanism of ROOOH decomposition; its first step includes the homolysis of the RO—OOH bond [reaction (26)] (the cleavage of ROOOH was demonstrated for α -hydrotrioxyethanol).

Self-association of ROOOH and the formation of intermolecular hydrogen bonds are responsible for the low exit of the radicals from the solvent cage.^{114,115} The main factors determining the direction of decomposition of ROOOH are as follows:¹⁰⁰

1. The nature of the atom bound to the hydrotrioxide group. The polarity of the X—O bond in the hydrotrioxide R¹R²R³XOOOH is the higher, the greater is the difference between the electronegativities of X and O atoms. It may therefore be expected that in the case of silyl hydrotrioxides (X = Si) the contribution of the molecular route will be greater than in the case of C-hydrotrioxides.

2. Temperature. Hydrotrioxides are typical peroxide compounds. An increase in temperature determines the relative increase in the proportion of radical processes characterised by higher values of activation energies and preexponential factors. At low temperatures, polar rearrangements without formation of radical intermediates are more probable.

3. Solvent. Polar solvents accelerate molecular decomposition of ROOOH, whereas the homolysis of the O—O bond is less dependent on the nature of the solvent.

4. Presence of an oxygen atom in the α -position with respect to the hydrotrioxide group. Such hydrotrioxides are characterised by the formation of an intramolecular hydrogen bond. Their decomposition occurs by a non-chain radical route.

VIII. Acyl peroxides

1. Peroxy acids

Peroxy carboxylic acids RC(O)OOH possess high oxidative properties and low thermal stabilities.^{6,116} Diverse reactions involving peroxy acids occur in solution and thus complicate the thermolysis itself. For example, hydrolysis in aqueous solutions is catalysed by mineral acids:

The non-catalytic decomposition of aliphatic and aromatic peroxy acids in aqueous solutions is second order with respect to the peroxy acid:^{117,118}

$$\frac{d[\text{RC(O)OOH}]}{dt} = k_{\text{eff}}[\text{RC(O)OOH}]^2.$$

The dependence of k_{eff} on the pH of the medium is described by a curve with a maximum at $\text{pH} \approx \text{pK}_a$ of the peroxy acid.⁶

Reactions of alkenes with peroxy acids yield epoxides.^{119,120}

In addition to the cyclic concerted epoxidation mechanism, the following scheme for the 1,3-dipolar cycloaddition has been proposed:¹²¹

The reversible reaction of peroxy acids with aldehydes yields 1-hydroxyperoxides:

The kinetic regularities of the thermolysis of peroxy acids depend on the reaction conditions. According to the published data,^{122, 123} the thermolysis of peroxy acids in solutions occurs by a radical mechanism:

A significant contribution to the thermolysis of peroxy acids is made by induced decomposition steps:

Oxygen-containing electrophilic radicals $\text{R}_e^\bullet$ attack the hydrogen atom, but do not react with the O—O bond. This reaction yields acylperoxy radicals. Nucleophilic radicals $\text{R}_n^\bullet$ (mainly, alkyl radicals) attack the peroxide group to give alcohols R_nOH . The presence or the absence of oxygen in the solution is the crucial factor which determines the route of radical decomposition of peroxy acids. In the presence of O_2 , nucleophilic radicals $\text{R}_n^\bullet$ are converted into electrophilic radicals $\text{R}_n\text{OO}^\bullet$. In the absence of oxygen, nucleophilic radicals $\text{R}_n^\bullet$ react with the solvent (provided that the latter acts as a donor of hydrogen atoms) to give radicals $\text{Sol}^\bullet$ or with a peroxy acid to give an alcohol R_nOH :

Radicals $\text{Sol}^\bullet$ react in a similar way.

Table 14. Thermolysis of the aliphatic peroxy acids RC(O)OOH in methanol at 25 °C.¹²⁴

R	$10^5 k_1 / \text{s}^{-1}$	R	$10^5 k_1 / \text{s}^{-1}$
n-C ₇ H ₁₅	1.75	n-C ₁₁ H ₂₃	2.35
n-C ₈ H ₁₇	2.23	n-C ₁₂ H ₂₅	1.75
n-C ₉ H ₁₉	2.93	n-C ₁₃ H ₂₇	1.75
n-C ₁₀ H ₂₁	1.60		

The thermal stabilities of peroxy acids also depend on the nature of the acid. The data illustrating the dependence of decomposition rate constants of peroxy acids on the length of the aliphatic chain are listed in Table 14.¹²⁴

2. Peroxy esters and peroxy carbonates

Thermolysis of peroxy esters has been discussed in several reviews.^{125–130} The main peculiarities of their decomposition mechanisms are related to asymmetry and the presence of an acyl group, which favour competition between the homolytic and heterolytic decomposition routes and their rearrangements.

Depending on the structure of peroxy esters, their thermolysis involves the homolysis of one or two bonds simultaneously. Peroxy esters can also undergo rearrangements.

The presence of α -hydrogen atoms favours the formation of a ketone and a carboxylic acid as a result of cyclic redistribution of the bonds.

Bartlett¹³⁰ proposed the classification of the peroxy esters $\text{R}^1\text{C(O)OOR}^2$ into two groups according to the mechanism of their thermal decomposition. In peroxy esters of the first group, the radical R^1 cannot exist in the form of a relatively stable free radical, whereas in peroxy esters of the second group the radicals R^1 can be stabilised due to delocalisation of the unpaired electron.

To the first type one may assign such peroxy esters as *tert*-butyl peroxyacetate and peroxybenzoate. The second group includes, in particular, *tert*-butyl peroxyphenyl acetate and its derivatives along with fairly unstable peroxy esters with $\text{R}^1 = \text{Ph}_3\text{C}$. Peroxy esters of the second group decompose much faster than their first-group analogues; their thermolysis is usually accompanied by simultaneous cleavage of two bonds, *viz.*, O—O and R—C. The decomposition rate of peroxy esters is usually the lower, the stronger is the starting carboxylic acid.

Denisov^{131, 132} and Pokidova¹³³ used the semi-empirical parabolic model of a bimolecular reaction modified for the calculation of kinetic and thermodynamic parameters of decomposition of molecules into radicals with simultaneous cleavage of several bonds for the determination of the corresponding parameters for a series of peroxy esters that dissociate presumably with simultaneous cleavage of R—C and O—O bonds. It was found also that with regard to the structure of the reaction centre, concerted decomposition is similar to addition reactions of carbon-centred radicals to the carbonyl group and of oxygen-centred radicals to alkenes.

A comparison of decomposition rates of dialkyl peroxides, peroxy esters and diacyl peroxides revealed that the presence of a carbonyl group at the α -carbon atom favours the cleavage of the O—O bond due to the conjugation of the free valence formed with the C=O group. On the whole, the effects of the substituents in the starting peroxide are rather diverse. The introduction of vinyl, phenyl and alkyl groups into the acyl fragment sharply increases the decomposition rate. Besides the inductive effect of substituents, this entails changes in the decomposition mechanism: fragmentation with simultaneous cleavage of two bonds caused by the weakening of the R—C(O) bond even in the transition state and stabilisation of the radical R^1 due to mesomeric and hyperconjugation effects of the substituents takes place instead of the cleavage of one O—O bond. The dependence of the homolytic decomposition of the peroxy esters $\text{R}^1\text{R}^2\text{R}^3\text{CC(O)OOBu}^1$ on the size of the alkyl substituents can be illustrated by the data

Table 15. Kinetic parameters of the thermolysis of $R^1R^2R^3CC(O)OObu^t$ in ethylbenzene at 60 °C.¹³⁴

R^1	R^2	R^3	k_1 (relative)
Me	Me	Me	1.0
Me	Me	Et	1.29
Me	Me	n-C ₈ H ₁₇	1.73
Me	Me	Bu ⁱ	2.30
Et	Et	Et	3.19

Me	Me	Bu ^t	3.40
Me	Me	Bu ^t CH ₂	2.60
Pr ⁱ	Pr ⁱ	Pr ⁱ	32

presented in Table 15.¹³⁴ Here, both the steric strain created in a peroxy ester by the substituents R^1 – R^3 and the inductive effects must be taken into consideration.

The introduction of *ortho*-substituents into the phenyl group of peroxybenzoates **13** leads to destabilisation of the ground state due to rotation of the carboxy group and its exit from the conjugation with the aromatic ring. As a result, the decomposition rates of peroxides **13c,d** are increased dramatically (Table 16).¹³⁵

$R^1 = R^2 = H$ (a); $R^1 = Me$; $R^2 = H$ (b), Me (c); $R^1 = R^2 = Bu^t$ (d).

Table 16. Kinetic and thermodynamic parameters of the thermal decomposition of peroxybenzoates **13a–d**.¹³⁵

Peroxy 13	R^1	R^2	k_1/s^{-1} (at 100 °C in cumene)	$\Delta H^\ddagger$ /kJ mol ⁻¹
a	H	H	9.7×10^{-6}	142.3
b	Me	H	1.2×10^{-5}	134.7
c	Me	Me	1.1×10^{-4}	133.5
d	Bu ^t	Bu ^t	2.8×10^{-4}	137.7

It is of note that the decomposition of peroxyacetate occurs several times more slowly than that of peroxybenzoates. The thermolysis of *tert*-alkyl peroxy-pivalates in the solvent cage^{136–138} affords equimolar amounts of *tert*-butyl and *tert*-alkoxyl radicals as a result of concerted cleavage of two bonds.

$R = Me, Et, Pr, Pr^i, Bu^i, PhCH_2$.

The reaction products correspond to nearly quantitative β -dissociation into alkyl and alkoxy radicals and CO₂.

The transition from the simple cleavage of the O–O bond to the decomposition with simultaneous cleavage of the O–O bond and decarboxylation results in a simultaneous decrease in the enthalpy and entropy of activation.

In the case of thermolysis of peroxy esters containing an ¹⁸O-labelled carbonyl group, the reverse recombination of the RC(O)O· radical in the solvent cage leads to the averaging of the distribution of the label between the carbonyl and peroxide oxygen atoms. An increase in the solvent viscosity favours reverse recombination and increases the degree of averaging of the label content. The secondary isotope effect (k^H/k^D) observed in the thermal decomposition of *tert*-butyl peroxyacetate is equal to unity,¹³⁹ which points to a non-synchronous cleavage of the bonds in its decomposition. At the same time, the magnitude of the isotope effect for *tert*-butyl *p*-methylphenylperoxyacetate and its derivatives markedly exceeds unity [1.03–1.06 per one H(D) atom], which unequivocally testifies to a synchronous mechanism of their decomposition.^{139–142}

The effects of substituents able to interact directly with the peroxide group and thus accelerate the homolysis of the peroxide bond are presented in Table 17.¹⁴³ As can be seen from these data, the presence of an unshared electron pair in the groups X in the *ortho*-position of the benzene rings of *tert*-butyl peroxybenzoates favours the formation of relatively stable radicals due to the cleavage of the O–O bond.

This effect of the substituent was termed by Martin¹⁴³ as ‘anchimeric acceleration’. Presumably, such substituents have a similar effect on the decomposition of diacyl peroxides.

Table 17. Kinetic and thermodynamic parameters of the decomposition of *tert*-butyl *o*-X-peroxybenzoates in chlorobenzene.¹⁴³

The presence of a C–H bond at the α -carbon atom enables the decomposition of peroxy esters according to a scheme acceptable for various classes of peroxides.¹⁴⁴

$R = H, Alk, Ar$.

In solution, the decomposition of peroxy esters by this concerted mechanism yields carboxylic acids and aldehydes or ketones.

The thermolysis of dicyclohexyl peroxydicarbonate in a pressure range from 0.1 to 500 MPa^{147, 148} revealed that its first step includes the cleavage of the O—O bond and the formation of oxycarboxy radicals. The volume effects of activation in benzene, toluene and acetonitrile are equally high ($11 \pm 0.5 \text{ cm}^3 \text{ mol}^{-1}$), which is attributed to the changes in the ratios of diffusion and recombination reactions occurring in the solvent cage and is regarded as evidence in favour of the cleavage of one O—O bond in the first decomposition step.

For a detailed description of peroxycarbonate thermolysis see Refs 10 and 149.

3. Diacyl peroxides

Decomposition of diacyl peroxides upon heating in solution was the subject of extensive studies which allowed identification of reaction products and elucidation of mechanisms and kinetic regularities of this process. The thermolysis of such peroxides occurs by two main competing routes with radical and non-radical mechanisms.

The homolytic decomposition begins with the cleavage of the O—O bond:

The solvent cage retains the radicals in the form of a radical pair and thus favours their recombination. Therefore, in the case of incomplete decomposition of a peroxide containing an isotopically labelled carbonyl oxygen the distribution of the latter will be averaged as a result of intraradical exchange:

This is followed by decarboxylation

and further reactions of the radicals with themselves and the solvent.

The averaging of the ^{18}O label over the carbonyl oxygen atom of the starting diacyl peroxide upon its partial thermolysis provides direct evidence for the initial formation of a contact radical pair. This is confirmed by the following facts:^{150, 151}

1. The thermolysis rate of cyclopropanecarbonyl peroxide decreases with an increase in the solvent viscosity, whereas the averaging rate of ^{18}O diminishes to a much lesser degree.

2. The enthalpy of activation of the decomposition of this peroxide exceeds the enthalpy of activation of the averaging of the ^{18}O content in CCl_4 by 8.4–11.7 kJ mol⁻¹. The entropy of activation of the averaging of ^{18}O is characterised by a small, although positive value in contrast to high negative values of entropies of activation of ordinary concerted sigmatropic rearrangements.

3. Substitution of the phenyl group for the cyclopropyl group leads to a decrease in the averaging rate of the label.

Hence, the mechanism of averaging of the isotopic label fits into the following scheme:

It is interesting to note that in the cyclic phthaloyl peroxide

the averaging of the isotopic label in solution at 80 °C occurs 40 times faster than its decomposition.¹⁵¹

Quantum-chemical studies (B3LYP calculations) of formyl peroxide¹⁵² confirmed the averaging mechanism involving the formation of a σ -acyloxy radical pair.

A high contribution of induced decomposition of acyl peroxides to the overall rate of their thermolysis in solution is yet another characteristic feature.^{153–155} For example, induced decomposition of benzoyl peroxide includes the following steps:

The corresponding expression for the reaction rate appears as:

$$W = k_d[\text{PhC}(\text{O})\text{OOC}(\text{O})\text{Ph}] + k_{\text{ind}}[\text{PhC}(\text{O})\text{OOC}(\text{O})\text{Ph}]^{3/2},$$

where $k_{\text{ind}} = k k_i^{1/2} (2k_t)^{-1/2}$ and $k_i = 2ek_d$, e is the proportion of radicals that exit the cage into the bulk.

The kinetic parameters of reactions of the radicals $\text{Me}^\bullet$, $(\text{Bu}^\bullet)$ and $\text{PhCH}_2^\bullet$ with various peroxides were calculated¹⁵⁴ using a parabolic model for bimolecular reactions (Table 20).

The rate of chain decomposition of benzoyl peroxide in the alcohols $\text{R}^1\text{R}^2\text{CHOH}$ is increased by an order of magnitude due to the reaction of the radicals $\text{R}^1\text{R}^2\text{C}^\bullet\text{OH}$ with the peroxide. This reaction was also studied using the aforementioned model.^{155, 156}

The ester $\text{RC}(\text{O})\text{OR}$ is formed from acetyl and benzoyl peroxides as a result of recombination of $\text{R}^\bullet$ and $\text{RC}(\text{O})\text{O}^\bullet$.

The volume of activation $\Delta V^\ddagger$, i.e., the change in the volume of a molecule upon the formation of an activated complex, in the cleavage of one bond approximates to 10 cm³ mol⁻¹, whereas that in the concerted cleavage of two bonds is 2–5 cm³ mol⁻¹ (see Ref. 11). The $\Delta V^\ddagger$ values for the thermolysis of diacyl peroxides without rearrangement vary from 2 to 5 cm³ mol⁻¹. The volumes of activation for the thermolysis of the following compounds are listed in the table below:^{157, 158}

Peroxide	$\Delta V^\ddagger / \text{cm}^3 \text{ mol}^{-1}$
Bis(3,5,5-trimethylhexanoyl) peroxide	2–3
Diocanoyl peroxide	2–3
Dibenzoyl peroxide	1–2

Asymmetric structures of diacyl peroxides and the use of polar solvents favour their decomposition into esters by non-radical routes involving both ionic and concerted mechanisms.

The formation of an ester $\text{ArC}(\text{O})\text{OC}(\text{O})\text{OAlk}$ in the thermolysis of $\text{ArC}(\text{O})\text{OOC}(\text{O})\text{Alk}$ as a result of a concerted rearrangement concomitant with a carboxy inversion was first reported by Leffler.^{159, 160} Here, the alkyl group migrates to the electron-deficient oxygen atom resulting in a nearly complete inversion of the configuration of the migrating group.

Table 20. Kinetic parameters of the bimolecular reactions of the radicals $\text{Me}^\bullet$, $(\text{Bu}^\text{t})^\bullet$ and $\text{PhCH}_2^\bullet$ with some peroxides at 80 °C.

Peroxide	$E_a/\text{kJ mol}^{-1}$			$k_1/\text{litre mol}^{-1} \text{s}^{-1}$		
	$\text{Me}^\bullet$	$(\text{Bu}^\text{t})^\bullet$	$\text{PhCH}_2^\bullet$	$\text{Me}^\bullet$	$(\text{Bu}^\text{t})^\bullet$	$\text{PhCH}_2^\bullet$
H_2O_2	36.7	33.6	48.6	1.51×10^4	1.31×10^4	3.14×10^2
$\text{Bu}^\text{t}\text{OOH}$	27.5	24.8	37.9	7.76×10^4	1.96×10^5	2.17×10^3
$[\text{MeC}(\text{O})\text{O}]_2$	37.3	39.8	48.0	5.40×10^3	2.40×10^3	1.40×10^2
$[\text{PhC}(\text{O})\text{O}]_2$	38.7	41.1	49.6	3.30×10^3	1.50×10^3	78.0
$\text{Bu}^\text{t}\text{OOBu}^\text{t}$	50	56	—	68	8.6	—

In this case, the redistribution of the ^{18}O label between the carbonyl and the peroxide oxygen atoms is either insignificant or altogether absent.^{161–170} The carboxy inversion is enhanced in the presence of Brønsted and Lewis acids.

Carboxy inversion is characterised by higher negative volume of activation and lower energy and entropy of activation than an ordinary radical decay.¹⁶⁷ The ionic type of this reaction was confirmed by a strong dependence of the decomposition rate on the changes in the electron-donor or electron-withdrawing properties of the aryl and alkyl groups.

The formation of compound RSol in the reaction of the radicals with the solvent and the formation of the recombination and disproportionation products ArR , RH and $\text{ArC}(\text{O})\text{OR}$ is yet another characteristic feature of the decomposition route of diacyl peroxides. An analysis of kinetics and compositions of decomposition products led Walling to suggest^{165–167} that both the radical and ionic pathways are realised through the same rate-limiting step in accordance with the following scheme:

This scheme includes the interaction and disproportionation of radicals. Supporting evidence for this mechanism was obtained in the studies of chemically induced dynamic nuclear polarisation (CIDNP) in the rearrangement products formed upon decomposition of *tert*-butylacetyl-*m*-chlorobenzoyl peroxide.

The formation of an ester from diacyl peroxide ($\text{PhMe}_2\text{CCH}_2\cdot\text{COO}$)₂ as a result of rearrangement on silica gel was also attributed to the electron transfer in the neophylcarbonyloxy radical pair $\{\text{PhMe}_2\text{CCH}_2\text{C}(\text{O})\text{O}^\bullet \cdot^\bullet\text{OC}(\text{O})\text{CH}_2\text{CMe}_2\text{Ph}\}$.¹⁷¹ If

the reaction is carried out on silica gel, the reaction rate increases considerably in comparison with the reaction carried out in solution. The decomposition products of $(\text{PhMe}_2\text{CCH}_2\text{COO})_2$ obtained in solution and on the surface of silica gel are also different. In the latter case, alkanes are not formed.

According to Taylor,¹⁶³ the electron transfer mechanism cannot be used for interpreting the results of thermal decomposition of cyclopropylacetyl cyclobutanecarbonyl peroxide and 4-pentanoyl *m*-chlorobenzoyl peroxide. Evidence in favour of the formation of an ion pair-like intermediate in the decomposition of a peroxide containing an R group able to form a stable cation was obtained.¹⁶⁴ An argument against the formation of a radical pair is the low value of CIDNP or its complete absence from the systems under study. However, some authors¹⁶² made reference to the difficulty in detecting polarised signals in complex samples and the strong dependence of experimental values of CIDNP on the relative rate of the reaction and on spin relaxation.

The following structures have been proposed for the intermediate species formed in the first step by different groups of investigators:

Special mention should be made of the studies^{172–174} of chemical polarisation of nuclei in the decomposition products formed in the thermolysis of cycloalkanoyl and cycloalkylacetyl peroxides in benzene and a benzene- CHBr_3 mixture; the data obtained testify to a radical mechanism of their formation. However, chemical polarisation of nuclei takes place only in those cases where relatively long-living radicals (methyl, cyclopropyl) or radicals stabilised by the π -bond are formed. No CIDNP was observed in other peroxy esters, which points either to a non-radical decomposition mechanism or the exclusive formation of short-living (less than 10^{-10} s) radicals in the solvent cage. The thermolysis of cyclobutyl and cyclopentylacetyl peroxides yields esters **16** and **17**, respectively. ^{13}C labelling studies have shown that in this case we deal with a skeletal rearrangement in the absence of hydride transitions.

The absence of hydride transitions points to the formation of an ion-radical pair in the transition state where the carbocation-like species undergo skeletal rearrangement:

R = cyclo-C₄H₇CH₂, cyclo-C₅H₉CH₂.

However, the energies and lifetimes of these species are not high enough for hydride transitions to occur.

Studies of a series of asymmetrical diacyl peroxides^{175–177} have shown that in the case of electron-donor and/or polar substituents thermolysis in nonpolar solvents proceeds by a radical route and yields acyl alkyl carbonates, alkenes, carboxylic acids and/or esters.

The proportion of heterolytic processes increases with stabilisation of the negative charge formed in the transition state.

The contribution of the homolytic process to the thermal decomposition of diacyl peroxides shows a good correlation with the energy of dissociation of the R–H bond, which characterises the stability of the radical R.

Studies on chemical polarisation of nuclei ¹H and ¹³C in the thermolysis products of these peroxides in CCl₄ revealed¹⁷⁸ that the contribution of secondary processes occurring outside the solvent cage diminishes with an increase in temperature.

IX. Sulfonyl peroxides

1. Alkanesulfonylperoxy acids

The thermal decomposition of the decanesulfonylperoxy acid C₁₀H₂₁SO₂OOH (R¹SO₂OOH) in *n*-decane (R²H) in an atmosphere of argon results in quantitative yields of C₁₀H₂₁SO₂OH (R¹SO₂OH) and a relatively high yield of the alcohols C₁₀H₂₁OH (R²OH) (ketones and H₂O are formed in trace amounts).¹⁷⁹

According to data from gas chromatography/mass spectrometry, the decomposition of decanesulfonylperoxy acid yields a mixture of primary and secondary alcohols. *n*-Decanol is not formed in noticeable amounts, whereas the ratio of decan-2-, -3-, -4- and -5-ols formed is close to the statistical value (1.2 : 1.0 : 1.2 : 1.15). With an increase in the initial concentration (*c*₀) of the peroxy acid, the total yield of *sec*-decanols with respect to the peroxy acid decreases (Table 21). The yield of the alcohols does not virtually depend on the nature of the bubbling gas (O₂ or Ar). This suggests that sulfonylperoxy acids are effective reagents for oxidative functionalisation of even non-activated C–H bonds of organic compounds.¹⁸⁰

Table 21. Yields of the secondary alcohols in the decomposition of decanesulfonylperoxy acid in oxygen-saturated *n*-decane at 50 °C.

10 ² <i>c</i> ₀ /mol litre ^{−1}	10 ² Δ <i>c</i> /mol litre ^{−1}	10 ² [sec-C ₁₀ H ₂₁ OH] /mol litre ^{−1}	[sec-C ₁₀ H ₂₁ OH]/Δ <i>c</i> (%)
0.82	0.77	0.58	75
2.6	2.6	1.5	57
6.5	6.5	2.3	35
7.6	7.5	2.0	27
11.0	11.0	2.4	22

Ketones are accumulated in much smaller amounts in comparison with alcohols (~0.6%–0.7% of the alcohol yield) owing to their ability to react fast with the peroxy acid. For example, the effective rate constant for the reaction of decanesulfonylperoxy acid with ethyl methyl ketone in *n*-decane at 50 °C is 0.5 litre mol^{−1} s^{−1} (see Ref. 181). Indeed, decanesulfonylperoxy

acid is an extremely potent oxidant of ketones in the Baeyer–Villiger reaction.^{182–184}

The thermolysis of decanesulfonylperoxy acid is complicated by its reaction with the solvent and homoassociation. As a consequence, the rate of this thermal decomposition depends on reaction conditions, in the first place, on the concentration of the sulfonylperoxy acid used. For this very reason, the kinetics of thermal decomposition of the sulfonylperoxy acid was formally characterised by an effective first-order rate constant.¹⁷⁹ The value of *k*_{eff} increases with an increase in the temperature and initial concentration of the peroxy acid (*c*₀).

Substitution of CCl₄ for *n*-decane leads to a significant decrease in the decomposition rate. Thus at 70 °C and *c*₀ = 0.07 mol litre^{−1} the half-lives of decanesulfonylperoxy acid in *n*-decane and CCl₄ are 4 and 33 min, respectively.

Some experimental results suggest the formation of free radicals in the thermolysis of sulfonylperoxy acids.

1. The thermal decomposition of an R¹SO₂OOH–R²H–O₂ system is accompanied by consumption of oxygen.

2. The decomposition of R¹SO₂OOH in an atmosphere of argon proceeds much faster than that in the presence of oxygen. For example, at *c*₀ = 9 × 10^{−3} mol litre^{−1} the initial decomposition rates of sulfonylperoxy acid in an atmosphere of O₂ and Ar are 1.3 × 10^{−5} and 4 × 10^{−6} s^{−1}, respectively. In an atmosphere of argon, the reaction rate decreases with time; for the 60% conversion of R¹SO₂OOH in Ar and O₂, the decomposition rates are levelled off.

3. The decomposition rate of peroxy acid in an R¹SO₂OOH–R²H–Ar system in the presence of the free radical scavenger 2,2,6,6-tetramethyl-4-hydroxypiperidin-*N*-oxyl is essentially the same as that in the R¹SO₂OOH–R²H–O₂ system.

Based on the data obtained, the following mechanism has been proposed for the thermal decomposition of the alkanesulfonylperoxy acids R¹SO₂OOH in R²H in an atmosphere of O₂:^{179, 181}

where C is a complex comprising two sulfonylperoxy acid molecules.

With regard to their oxidative capacities, alkanesulfonylperoxy acids are in no way inferior to such a potent oxidant as trifluoroperoxyacetic acid, but even surpass it in many aspects.

2. Acetyl cyclohexylsulfonyl peroxide

Of prime interest among other representatives of sulfonylperoxy acid derivatives is acetyl cyclohexylsulfonyl peroxide [cyclo-C₆H₁₁SO₂OOC(O)Me (ACSP)] which has found wide industrial application.

A significant contribution of radical processes to the thermolysis of ACSP can be illustrated by the chemiluminescence (CL)

observed during its decomposition.¹⁸⁵ However, whereas in the presence of O₂ the spectral pattern of CL (*i.e.*, the maxima at 400–440 and 500–540 nm) indicates the formation of excited triplet carbonyl groups as CL emitters, in an inert atmosphere the situation is less apparent. The intensity of CL decreases with ACSP consumption. In addition to a distinct maximum at 580–600 nm, the CL spectrum contains two signals of lower intensities with maxima around 650 and 690 nm. The intensity of CL decreases after addition of alkyl radical traps to ACSP. Presumably, the radiation emitter is formed in reactions involving alkyl radicals.

The kinetics of thermal decomposition of ACSP in an atmosphere of O₂ obeys the first-order kinetic law.¹⁸⁶ The activation parameters of the thermal decomposition of ACSP in various solvents are listed in Table 22.

Table 22. Effect of the solvent on the activation parameters of the decomposition of acetyl cyclohexylsulfonyl peroxide.¹⁸⁶

Solvent	log <i>A</i> (s ⁻¹)	<i>E_a</i> /kJ mol ⁻¹
n-C ₁₀ H ₂₂	16.2	123
cyclo-C ₆ H ₁₂	14.0	101
CCl ₄	16.5	127
PhH	14.5	114
PhMe	13.8	108
PhEt	13.1	104
PhPr ⁱ	14.7	115
MeCN	15.8	126
EtOH	12.5	103
Pr ⁱ OH	14.0	113

In argon, the kinetics of ACSP thermolysis is different. The kinetic order of this reaction with respect to peroxide increases to 1.5. Thus in n-decane:

$$\log k_{\text{ind}} = (13.2 \pm 0.5) - (93 \pm 3)/2.3 RT \text{ (litre}^{1/2} \text{ mol}^{-1/2} \text{ s}^{-1}\text{)}.$$

An analysis of the whole body of experimental data has made it possible to propose the following mechanism for ACSP decomposition:¹⁸⁷

where RH is n-decane.

Reaction (28) is the limiting step in the chain process. Oxygen inhibits induced chain decomposition of ACSP due to rapid oxidation of alkyl radicals to ROO[•]. Peroxy radicals are inactive with respect to ACSP and undergo recombination resulting in chain termination. The following expression was proposed for the rate constant of induced decomposition of ACSP in n-decane [reaction (28)]: $\log k = 10.8 - 36/2.3 RT$ (litre mol⁻¹ s⁻¹). For the rate constant for the monomolecular decomposition of ACSP in C₆H₄Cl₂ [reaction (27)], $\log k = 14.5 - 115.4/2.3 RT$ s⁻¹ (the activation energy is expressed in kJ mol⁻¹).

X. Peroxide derivatives of carbonyl compounds

Upon heating in neutral media, hydroxyperoxides formed in the reaction of hydrogen peroxide and hydroperoxides with carbonyl compounds easily dissociate into the original compounds.¹⁸⁸

The rate constants for the forward (*k*₂) and reverse (*k*₁) reactions are listed in Tables 23 and 24 (see Refs 39 and 188).

Different peroxy acetals and peroxy ketals including

and cyclic polyperoxides are formed in acidic media as a result of condensation of aldehydes or ketones with 1-hydroxyperoxides.^{188, 189}

The thermolysis of monoperoxy ketals¹⁹⁰ is characterised by the parameters listed in Table 25. Despite the large distance between the peroxide group and the substituent, the structure of the latter has a strong effect on the kinetic parameters of the thermolysis. In particular, non-valent interactions of the oxygen atoms of the substituent with the peroxide group are possible.

In the presence of an allyl substituent, the thermolysis of monoperoxy ketal occurs in accordance with the following scheme:¹⁹¹

Z = cyclo-C₆H₁₁; Y = H, Me, Ph; R¹ = H, Me; R² = Me, Et,

Table 23. Kinetic parameters of the decomposition of 1-hydroxyperoxides and their formation from hydroperoxides and aldehydes at 20 °C.

which includes the well-established reactions of induced decomposition of allyl peroxides:

The decomposition of diperoxyacetals is accompanied by the transient formation of peroxy esters¹⁹²

The decomposition of aromatic peroxy acetals occurs in accordance with the same scheme, *i.e.*, with the formation of peroxybenzoates as intermediates:¹⁹³

Under these conditions, the contribution of other parallel conversions of the initially formed radical increases.

The thermolysis of 2,2-bis(*tert*-butylperoxy)alkanes^{194–197} proceeds through selective cleavage of the O–O bonds rather than by a concerted mechanism. This confirms the similarity of the activation parameters of 2,2-bis(*tert*-butylperoxy)propane ($\Delta H^\ddagger = 145.6 \text{ kJ mol}^{-1}$, $\Delta S^\ddagger = 47.3 \text{ J mol}^{-1} \text{ K}^{-1}$) and di-

tert-butyl peroxide ($\Delta H^\ddagger = 153.6 \text{ kJ mol}^{-1}$, $\Delta S^\ddagger = 48.1 \text{ J mol}^{-1} \text{ K}^{-1}$) at 90–120 °C in the absence of induced decomposition (in cumene). The products formed are consistent with the following decomposition scheme:

A high volume of activation ($\Delta V^\ddagger = 22.3 \text{ ml mol}^{-1}$ at 200 °C)¹⁹⁸ is an argument in favour of a concerted decomposition mechanism. However, at relatively high temperatures this mechanism can be different.

A method for the introduction of Bu^tOO groups into organic molecules by the thermolysis of 2,2-bis(*tert*-butylperoxy)propane has been proposed.¹⁹⁷ Diperoxy ketals that simultaneously generate the radical Bu^tO·, causing the abstraction of the active hydrogen atom from the substrate, and the radical Bu^tOO·, which undergoes recombination with the radical Sol·,

were used as sources of Bu^tOO· radicals.

The thermolysis of 1,1-bis(*tert*-butylperoxy)cycloalkanes^{18, 199–201} in solution occurs with homolytic cleavage of one O–O bond which occurs at a much faster rate than the thermolysis of the corresponding alkyl *tert*-butyl peroxides

Table 26. Rate constants (at 110 °C) and activation parameters of the thermolysis of peroxides in cumene.²⁰¹

(Table 26). For cycloalkanes, the decomposition rate decreases in the following order: cyclopentane > 3,3,5-trimethylcyclohexane > cyclohexane > cyclooctane > cyclodecane. The dependence of the decomposition rate on the ring size suggests that stabilisation of the transition state due to the electron-donor effect of the cycloalkyl substituent and repulsion of free electron pairs of the oxygen atoms of the O—O group is a critical factor which determines the decomposition kinetics of geminal diperoxides.

The decomposition of cyclic diperoxides of the type

$\text{R}^{1-4} = \text{Alk, Ar}$

occurs with primary homolysis of one O—O bond with subsequent destruction of the biradical and cleavage of a C—O or a C—C bond.^{199, 202–206}

The choice of a decomposition route (*a* is the formation of ketones, *b* is the formation of hydrocarbon radicals) depends on the structure of the substituents: for $\text{R} = \text{Ar}$, the yields of ketones are 90%, whereas for $\text{R} = \text{Alk}$ they are as low as 10%–20% (in benzene) and even smaller. The higher the stability of the radical $\text{R}^\bullet$ the higher the yield of the ketone.

Cyclic diperoxides prepared from cyclohexanone undergo decomposition to give cyclohexanone and O_2 , lactone **18** and CO_2 , or cyclodecane and CO_2 .²⁰⁷

On the whole, cyclic diperoxides are more stable than their non-cyclic analogues.^{199, 207}

The generation of a biradical in the first step of the thermolysis of a cyclic diperoxide prepared from an indene derivative was confirmed by analysis of polarisation of nuclei in the decomposition products (the thermolysis of acyl peroxides, peroxy carbonates and other peroxy derivatives (see above) was studied using a similar approach).²⁰⁸

The thermolysis of cyclic triperoxides, like the thermolysis of cyclic diperoxides, begins with the formation of a radical pair which undergoes further destructive rearrangements. As a result, the kinetics of decomposition of cyclic triperoxides characterised by high degrees of conversion is first order. The kinetic data on the thermolysis of cyclic di- and triperoxides in solution are generalised in Table 27.²⁰⁹ The contribution of induced decomposition is insignificant, thus the activation parameters listed in the Table refer exclusively to the monomolecular decomposition.

Table 27. Kinetic parameters of the thermolysis of cyclic di- and triperoxides.

Peroxide	Solvent	$\Delta H^\ddagger / \text{kJ mol}^{-1}$	$\Delta S^\ddagger / \text{J mol}^{-1} \text{K}^{-1}$	$10^5 k / \text{s}^{-1} (145^\circ \text{C})$

XI. Conclusion

Depending on the structure of the compounds undergoing decomposition and the nature of the solvent, the thermolysis of organic peroxides in solution proceeds by both a homolytic mechanism with the cleavage of the O—O or OO—X bond and non-radical routes, through concerted rearrangement, in particular. Radical and non-radical decomposition reactions of peroxides normally occur in parallel. The formation of complexes and associates can increase the rates of both thermolysis routes.

Induced decomposition and recombination of radicals in the solvent cage diminish the proportion of radicals (*e*) released into the solvent. Kinetic estimates²¹⁰ show that the values of *e* for the peroxides R¹OOOR² are the closest to unity. In the case of symmetrical diacyl peroxides, *e* does not usually exceed 0.3–0.6 (*cf.* 0.3–0.7 for diaryl peroxides; 0.2–0.4 for dialkylperoxy ketals; and 0.5–0.9 for aromatic acids of *tert*-butyl peroxyesters).

This multivariant mechanism of thermolysis must be taken into consideration in those cases where organic peroxides are used as radical initiators of chemical reactions.

Abstract. The key approaches to the preparation of catalysts based on porphyrins and porphyrin metal complexes immobilised on polymeric supports are analysed. The factors determining the catalytic activity of porphyrin-containing polymer systems are outlined. Processes catalysed by such systems are considered. The bibliography includes 99 references.

I. Introduction

The design of metal complex systems immobilised on various supports has been vigorously progressing in recent decades. The main principles of immobilisation of metal complexes (MC) have now been formulated and routes for the development of this line of research have been outlined.¹ It should be noted that the reactions of transition metal compounds with the support restrict their mobility, which affects the rates and, in some cases, also the mechanisms of catalysed reactions. This should be taken into account when preparing supported metal complex catalysts.

The design of immobilised catalysts with active sites having a known structure and environment contributes to better understanding of the mechanisms of catalytic transformations and allows theoretically substantiated choice of the catalysts and prediction of the catalytic effect. The immobilised catalysts should be stable and show reproducibility of functional properties; it is also required that they be readily separable from the reaction products.²

When homogeneous metal complexes are used as catalysts, the catalytic transformation occurs in the coordination sphere of the transition metal under 'steric participation' of ligands in electron density redistribution and formation of intermediate active com-

plexes. It is generally considered that in this case, all metal complexes are identical and equally accessible to reactants. Meanwhile, the MC immobilised on supports (inorganic, polymeric, *etc.*) possess, generally speaking, different activities and some of the complexes can be inactive or even catalyse side reactions.^{1,2} However, immobilised systems have obvious advantages because they are more easily separated from products and recycled, which is especially important when dealing with fairly expensive metal porphyrins.

The problem of separation of catalysts from the reaction mixture is so acute that chemical processes based on homogeneous catalysts are seldom implemented in industry. Exceptions include the Ziegler–Natta catalysts (olefin polymerisation) and catalysts of the Wacker (ethylene oxidation to acetaldehyde) and Monsanto processes (methanol carbonylation to acetic acid).³ Therefore, it can be understood why specialists have always looked for ways of developing catalysts of a new type that would combine the advantages of homogeneous and heterogeneous systems.

A new impetus for research along these lines was given by the discovery of unique catalytic properties for the systems prepared by grafting transition metal complexes to polymer supports. The knowledge coming from studies of the functional activity of MC in natural systems prompted the search for efficient heterogeneous catalyst systems to be focused on imparting certain mobility to the 'attached' catalytic sites. This is attained by immobilisation of functionalised MC on polymeric supports, which are most mobile. In what follows we restrict ourselves to considering this particular type of 'attachment'. This review discusses the set of problems associated with the development of catalyst systems based on immobilised porphyrins and metalloporphyrins (MP).

II. Immobilised metal complexes as fragments of natural systems

Fastening of low-molecular-weight compounds including MC to mineral or polymeric substrates and participation of these immobilised compounds in various processes are frequently encountered in animate and abiotic nature. The presence of ions in the inorganic natural sorbents occurring as parts of soils and natural sedimentary deposits dictates the dynamics of element redistribution in nature, ore-formation processes, the formation of carbon mineral products, and so on. The transport and assimilation of metal ions in animate

nature determine almost all functions of native systems including enzymic, muscle, photosynthetic and other properties.^{1,2}

In particular, porphyrin metal complexes catalyse biochemical processes that provide for the vital activity of organisms. The specific activity of natural hemoproteins containing a protoporphyrin complex of trivalent iron (oxidase, monooxygenase, haemoglobin, myoglobin) is determined first of all by the spatial arrangement of the side functional groups of the polypeptide chain in the vicinity of the active site. In the best-studied monooxygenases, namely, cytochromes P-450, which oxidise xenobiotics such as steroids and cholesterol, within the microsomal system of the liver, the central Fe(III) ion of the haem is coordinated to the imidazole group of histidine and the thiol group of cysteine. The removal of these amino acid residues from the cytochrome active site results in enzyme deactivation. However, it is believed that in the haemoglobin molecule, iron protoporphyrin responsible for oxygen binding and oxygen transport to all organs and tissues of living creatures is coordinated to the imidazole groups of two histidine molecules. It should be noted that oxygen does not react with iron if iron is not coordinated to imidazole groups. In addition, strong binding between the haem and a protein is due to acid–base interaction of the carboxy groups of porphyrin with the side groups of the polypeptide chain.^{4,5}

As an example illustrating the possible conformational changes in the protein molecule in the vicinity of the metalloporphyrin active site, one can cite classical results of an X-ray diffraction study of ferro- and ferricytochrome *c* carried out by Dickerson and co-workers⁶ with a resolution of 0.245 (ferrocyclochrome) and 0.28 nm (ferricytochrome). Cytochrome *c* in mitochondrial membranes participates in the electron transport along the 'respiratory chain' and in oxidative phosphorylation of food, resulting in the synthesis of a versatile energy storage in the cell, namely, adenosine triphosphate (ATP), hydrolysis of which releases an energy of ~ 7 kcal mol⁻¹. The cytochrome *c* itself is a protein with a molecular mass of $\sim 123\,000$ containing 104 amino acid residues. Figure 1 sketches a stereoprojection of ferricytochrome *c*, indicating what types of rearrangement take

place in this system during the reduction of the central ion of the haem.⁷

It can be seen from Fig. 1 that the haem is linked to cysteines-14 and -17 of the protein by covalent sulfide bonds and to the imidazole nitrogen atom of histidine-18 and the sulfur atom of methionine-80 by coordination bonds *via* iron. The nitrogen atom of the imidazole ring of histidine-18 is involved in the hydrogen bond with the carboxy group of proline-30. On reduction of ferricytochrome *c*, the globule undergoes severe conformational changes (Fig. 1 *b*), only 21 amino acid residues of 104 remaining unaffected. Thus, the coordination properties of MP toward covalent binding to the fragments of biological systems are realised under dynamic variability of the 'environment' of the central ion and the porphyrin ring plane. The nature controls the catalytic or other properties of small molecules by 'attaching' them to supports, which formally do not participate in the process but indirectly influence it through the formation of non-covalent (coordination and hydrogen) bonds. This often changes the process direction and efficiency.

One more example of conformational rearrangements in biological macromolecules upon metal binding refers to the antibiotic valinomycin, first synthesised by M M Shemyakin in 1963. Valinomycin belonging to the class of cyclic depsipeptides can bind alkali metal ions (in particular, potassium ions) to give positively charged lipophilic complexes and perform the catalytic transport of these ions through hydrophobic zones of biological membranes. During this process, the valinomycin molecule undergoes complex conformational rearrangements, as shown in Fig. 2.⁸

It should be emphasised that the knowledge of dynamic aspects of the functioning of complex systems *in vivo* is not only of purely scientific but also of practical interest (we have in view the practical line of studies on metal complex catalysis, in particular, catalysis involving MP). Apparently, for efficient use of metalloporphyrins for practical purposes, it is necessary to follow nature's example, that is, to put them on various macromolecular supports.

Figure 1. A stereoprojection of the schematically depicted molecule of ferricytochrome *c* (a) and main structural changes (shown by arrows) taking place upon reduction of ferricytochrome *c* (b).⁷

Figure 2. Conformational changes in the valinomycin molecule upon complex formation with the potassium ion.⁸

III. Immobilised metal complexes in catalysis

Apparently, the first attempts at using MC attached to a polymer support as catalysts date back to the late 1960s. By as soon as 1975, British Petroleum and Mobil Oil Corporation had received about 2000 patents for the use of such catalysts. The first publications devoted to the use of immobilised MP and metallophthalocyanines (MPc) in catalysis appeared 10 years later.¹

Immobilisation may both decrease and increase the specific (per active site) efficiency of metal complexes as catalysts. In particular, poor solubility of transition metal complexes is often responsible for their low catalytic activity in homogeneous catalysis, while immobilisation of MC on polymer supports soluble in the given reaction medium can markedly increase the MC concentration in the solution and, hence, the efficiency in catalysis. The change in the catalytic activity upon immobilisation can be due to specific rearrangements of the polymer chain, the change in the stereochemical environment of the metal ion, *etc.*, which take place in the reaction medium.

In the general case, immobilisation of metal complexes on a polymer support can redound to the combination of advantages and elimination of disadvantages of homogeneous and heterogeneous catalysts. Development of such catalyst systems is a fairly complicated task. In order to take advantage of the whole potential of the catalyst systems based on MC coupled with polymer supports, it is necessary to accumulate experience in selecting polymer supports and methods for grafting the MC. Moreover, in every stage of development of immobilised catalysts, one should take into account specific features of the interaction of MC with the macromolecular material.

Metalloenzymes are known to be polymers whose active sites incorporate transition metal complexes with porphyrins or other ligands. High catalytic activity of enzymes is due to the existence of a whole series of interrelated factors, first of all, to the enzyme–substrate structural compliance caused by enhanced affinity of some biopolymer fragments to the substrate. These fragments of protein macromolecules form a three-dimensional network around the active site, the shape and dimensions of the network being consistent with the substrate size. This promotes accumulation of the substrate near the active site (so-called substrate enrichment) and creates favourable orientation of the reactant molecules. In addition, enzymatic catalysis often involves so-called multicentre coordination, which arises upon additional activation of the substrate by functional groups of the biopolymer.⁹

In the most general form, a polymer support suitable for chemical immobilisation of MC should meet the following requirements: (i) give a sufficient number of reactive functional groups; (ii) have a high specific (per unit volume) microporosity (iii) possess appropriate physical and mechanical properties; (iv) be chemically stable under catalysis conditions; and (v) be inert with respect to the reaction products. Depending on the type of catalytic process, polymer supports can be manufactured in different forms, in particular, as powders, granules, fibres, films (including membranes) or swollen gels. In terms of the degree of cross-linking of polymer supports, the metallopolymer catalysts (including those based on metal porphyrins) are classified into three groups — highly cross-linked beaded polymers approaching in properties inorganic substrates; lightly cross-linked swelling gel-type polymers; and linear soluble polymers whose macromolecular chain influences most appreciably the activity of the MC.

IV. Types of binding of porphyrins immobilised on polymer supports

1. Physical binding of MP to a polymer support

The ‘MP–polymer support’ systems in which the components do not form chemical bonds are usually prepared either by dispersing a polycrystalline porphyrin in a solution of the polymer (in the case of insoluble porphyrins) or by co-dissolution of the polymer and porphyrin followed by casting on an appropriate surface and solvent evaporation to prepare a film, or by impregnating a finished polymer film by a solution of porphyrin.

For example, for the preparation of bactericide photoreactive systems that generate singlet oxygen, metal-free 5,10,15,20-tetrakis(*N*-methylpyridinium-4-yl)porphyrin (**1**) as the tosylate was impregnated into regenerated cellulose films.^{10, 11} The films were 50 μm thick, the process was carried out in water or aqueous methanol at 50 °C.

Films containing tetra(*tert*-butyl)phthalocyanine (**2**) were prepared by co-dissolution of phthalocyanine **2** and cellulose diacetate in wet acetone with subsequent casting on an appropriate surface.¹¹

Vankelecom *et al.*^{12–14} prepared porphyrin- and phthalocyanine-containing catalytically active membranes based on polydimethylsiloxanes (PDMS) by dispersing a porphyrin or phthalocyanine catalyst pre-deposited on an inorganic support (zeolites with different degrees of porosity) in a PDMS solution followed by casting a polymer film. The key prerequisite for uniform distribution of the catalyst in the matrix is the use of relatively dilute solutions of the polymer. The resulting polymer systems catalyse the selective epoxidation of hydrocarbons on treatment with *tert*-butyl hydroperoxide.

The same researchers^{15–17} proposed one more method for the preparation of porphyrin-containing membranes based on PDMS. To this end, a solution of the porphyrin complex of manganese or iron in dichloromethane was added to a mixture of prepolymer (RTV 615A) and a cross-linking agent (RTV 615B) in the same solvent. The mixture was stirred for 1 h at room temperature and left overnight. Polymerisation was carried out *in vacuo* at 150 °C. The catalyst systems prepared in this way proved to be efficient in epoxidation of enols and oxidation of alcohols to ketones.^{15–17} It was stressed that these composite catalyst systems containing iron porphyrins can be regarded as simple models of cytochrome P-450.^{18,19}

2. Covalently bound metalloporphyrins

Covalently bound metalloporphyrins are obtained most often by copolymerisation or polymerisation of porphyrin-containing monomers.^{20–31} In particular, the synthesis of THF-soluble copolymers of styrene with methyl methacrylate or acrylonitrile and vinyltetraphenylporphyrin has been reported.^{24–27} The scheme of preparation of copolymers **3** based on the vinylporphyrin complex of copper and styrene is shown below.

Neither vinylporphyrins themselves nor their metal complexes undergo homopolymerisation, which is due to either steric (bulky porphyrin substituents) or electronic factors (conjugation of the growing radical with the π -system of the porphyrin). The above procedure was used to obtain copolymers containing zinc and copper tetraphenylporphyrins. The content of MP in the polymer was 1 mol %–2 mol %, the molecular mass $M_w \approx 400\,000$. For increasing the content of porphyrin units in the copolymer, one should employ monomers in which the double bond is located far from the macrocycle.²⁸

The synthesis of copolymers **4** soluble in chloroform, based on mono-*N*-acryloylated [tetra(*p*-aminophenyl)porphyrinato]manganese (TAPPMn), vinylpyridine and methyl methacrylate, has been reported.²⁹

The content of TAPPMn in copolymer **4** was 3 mol %–7 mol %, $M_w \approx (2.5–4.0) \times 10^4$.

Benzene- and chloroform-soluble polyacrylates **5**, **6** with $M_w \approx (0.7–2.0) \times 10^4$ containing copper and vanadyl tetraphenylporphyrins (TPPCu and TPPVO) have been prepared by radical polymerisation of the corresponding monomers.³⁰ It was found that the molar extinction coefficient for the Soret band is lower for the polymer than for the monomer and a new absorption band appears at 630 nm. This may be due to electronic interaction of the porphyrin rings with fragments of the polymer chain.

5, 6

M = Cu²⁺ (TPPCu, 5), VO²⁺ (TPPVO, 6).

For the preparation of catalysts with controlled activity, one can use systems **7** and **8** formed upon polycondensation of pyrrole, sodium *o*-formylbenzenesulfonate and dipyrrolylethioporphyrim (Scheme 1).³¹ Using this reaction, it is possible to introduce a definite amount of porphyrin into the polymer to obtain a non-conjugated (**7**) or polyconjugated (**8**) porphyrin-containing polymer.

After metallation, such systems can be active in decomposition of hydrogen peroxide, oxidation of phenol and other processes that take place in aqueous media.

Mixed-type porphyrin-containing polymers (for example, **9**) have also been reported.³² In these polymers, MP are linked to the polymer support by covalent bonds through substituents present

in the pyrrole rings of the porphyrin ligand; the central metal ion in the MP is additionally coordinated by the functional groups of the polymer chain. Shown below is the structure of the polymer modified with hemin, which is bound to the polymer chain by both covalent and coordination bonds (compound **9**).³²

9

Polymers **10**, containing zinc tetraphenylporphyrin (TPPZn) and cholesterol, were prepared by copolymerisation of (5-methacroyloxyhexanoyloxyphenyl-10,15,20-triphenylporphyrinato)zinc with cholesteryl methacroyloxyhexanoate.³³

Scheme 1

(a) H⁺ (Cat.), DMF, room temperature, N₂, 24 or 50 h; (b) H⁺ (Cat.), DMF, room temperature, O₂, 6 days.

10

The content of TPPZn in polymers **10** was 0.1 mol %. It was suggested³³ that in this copolymer, the cholesterol residues are involved in electronic interactions, resulting in the formation of 'cavities' which accommodate the porphyrin fragments.

Polymer systems containing covalently bonded porphyrins can be obtained by treatment of polymers having functional groups (carboxy, amino, hydroxy) with porphyrins containing reactive substituents in the ring. Thus the reaction of low-molecular-mass poly(ethylene glycol) with mesoporphyrin IX containing carboxy groups afforded porphyrin-containing polymers efficient in the photogeneration of singlet oxygen.³⁴

Some studies discuss the problems of polymer modification by metalloporphyrins. In particular, Govorov and co-workers^{35–38} described the synthesis of polymeric catalysts based on poly(vinyl alcohol) (PVA) and a number of natural porphyrins, namely, pheophytin *b* (catalyst **11**), rhodin *g*₇, and their copper and cobalt complexes.

11

The resulting catalysts proved to be active in the decomposition of hydrogen peroxide in an aqueous medium.^{35,36}

A rather simple method for the preparation of porphyrin-containing insoluble polymers has been exemplified in tetra(aminophenyl)porphyrin (TAPP) modification of chloromethylated polystyrene³⁹ and polybenzaldehyde⁴⁰ cross-linked by divinylbenzene (Fig. 3). The subsequent metallation of these compounds by cobalt or aluminium salts resulted in the synthesis of polymeric MC used for reversible binding of molecular oxygen.

Figure 3. Structure of TAPP immobilised on chloromethylated polystyrene cross-linked by divinylbenzene.³⁹

A similar method has been used to prepare polymeric catalysts on the basis of chloromethylated polystyrene and TAPPMn.⁴¹ This catalyst proved to be active in the epoxidation of alkenes in the presence of imidazole or pyridine.

3. Metalloporphyrins bound to the polymer matrix by coordination bonds

The coordination of MP to polymers occurs most often through the central metal atom. Thus porphyrinatocobalt coordinated to the imidazole fragment of the octyl methacrylate–1-vinylimidazole copolymer (polymer **12**) has been used to prepare oxygen permselective membranes.⁴²

12

The membranes were prepared from a solution of these compounds in acetone. The same researchers obtained copolymers **13** of vinylidene dichloride, methyl methacrylate and vinylimidazole containing porphyrinatocobalt immobilised through coordination bonds.⁴³ Membranes composed of this material were also oxygen permeable (the oxygen molecules were transferred through the membrane by the hopping mechanism).

13

Development of water-soluble polymeric catalysts based on metalloporphyrins is the subject of one more study of the same groups of researchers,⁴⁴ which describes the synthesis of micellar systems from aminoporphyrins (for example, etioporphyrin **14** containing amino groups).

These micellar systems are stabilised by polyelectrolytes [polyallylamine or poly(vinyl sulfate)] through the formation of donor–acceptor bonds (Fig. 4).

Figure 4. Structure of the complex formed by MP **14** and polyallylamine.⁴⁴

4. Polymeric catalysts with an ionic bond between metalloporphyrins and the matrix

The ionic interactions of MP with the polymer support can be found in the polymeric catalysts based on perfluorinated sulfonated cation exchange polymers (Nafion type) in the morpholine form and manganese porphyrins.^{45–47} Manganese porphyrins are immobilised on a sulfonate cation exchange membrane of the Nafion type through a morpholine bridge.⁴⁵

These systems exhibit catalytic activities toward hydroxylation of steroid alkenes in the presence of morpholine or imidazole.

It is noteworthy that metal-free porphyrins can also be fixed on sulfonate cation exchange materials (due to the formation of ionic bonds). For example, immobilisation of 5-(*p*-aminophenyl)-10,15,20-triphenylporphyrin (ATPP) in the protonated form on a sulfonate cation exchange matrix has given polymeric catalyst **15**,⁴⁷ active in the photogeneration of singlet oxygen.⁴⁶

V. Catalyst systems with metalloporphyrins embedded in micelles

Owing to the low polarity and the presence of charged groups and bound water, the structurally organised micellar aggregates can be used as analogues of a protein globule.⁴⁸ For example, in oxidation of organic substrates by oxygen-containing compounds in the presence of metalloporphyrins, phospholipid vesicles have been used as structure-forming agents,⁴⁹ resulting in a pronounced increase in the degree of conversion and a change in the reaction regiospecificity. Metalloporphyrins embedded in micellar structures were found to exhibit monooxygenase activity,⁵⁰ typical of P-450 type enzymes. Borovkova *et al.*⁵⁰ studied the kinetics of catalytic oxidation of unsaturated hydrocarbons with a system MP–reducing agent (NaBH₄)–dioxygen in the presence of micelle-forming agents, namely, Surf I (cetyltrimethylammonium bromide in a heptane–chloroform–ethanol mixture) and Surf II [sodium bis(2-ethylhexyl)sulfosuccinate in a heptane–ethanol mixture]. These systems displayed an extremal dependence of the specific rate constant k_s for the non-chain oxidation of cholesterol, anthracene and substituted naphthalenes on the concentrations of Surf I and Surf II (Fig. 5 and 6), the k_s value increasing significantly upon variation of the Surf I and Surf II concentrations in the ranges 0.05–0.30 mol litre^{−1} and 0.1–1.0 mol litre^{−1}, respectively. In the absence of surfactants, a certain contribution to the k_s value is apparently made by

Figure 5. Dependences of k_s for oxidation of cholesterol (curves 1–3) and anthracene (curve 4) by the MP–NaBH₄–O₂ system on the concentration of Surf I in a chloroform–heptane mixture (1:1). MP = TPPMnCl (1, 2, 4) and TPPFeCl (3).⁵⁰ The concentrations of cholesterol, anthracene, TPPMnCl, TPPFeCl and NaBH₄ were 2.2×10^{-3} , 4.3×10^{-3} , 6×10^{-5} , 1.3×10^{-4} and 0.1 mol litre^{−1}, respectively.

Figure 6. Dependence of k_s for the oxidation of cholesterol with the TPPMnCl–NaBH₄–O₂ system on the concentration of Surf II.⁵⁰ The concentrations of cholesterol, TPPMnCl and NaBH₄ were 2.2×10^{-3} , 6×10^{-5} and 0.1 mol litre⁻¹, respectively, and the concentration of EtOH was 2.65 vol. %.

diffusion restrictions; the reaction proceeds either in the diffusion or in the mixed diffusion and kinetic region.

The specific rate constant k_s in question was determined from the rate of formation of the product (v_p) at initial time instants

$$k_s = \frac{v_p}{[S][Cat]},$$

where $v_p = dQ/dt$ (Q is the concentration of the product, t is time), $[S]$ and $[Cat]$ are the substrate and catalyst concentrations, respectively. The catalysts used were tetraphenylporphyrin complexes with manganese, iron and cobalt (TPPMnCl, TPPFeCl and TPPCo). The manganese complex TPPMnCl was the most active in the oxidation of any of the studied substrates both in the presence and in the absence of surfactants. The specific rate constant for the non-chain oxidation of cholesterol increased 8–10-fold in the presence of Surf I and 10–18-fold in the presence of Surf II. The k_s value for the oxidation of anthracene increased by a factor of 5–8 when the system contained Surf I.

The products formed upon oxidation of cholesterol and anthracene were the same (3 β ,5 α -cholestanediol and 9,10-anthraquinone, respectively) as those formed in the absence of surfactants in the reaction mixture,⁵¹ while the ratio of the oxidation products of 2,6-dimethylnaphthalene and 2-methylnaphthalene (epoxytetralins and dihydroxytetralins) changed from 1 : 1 (without a surfactant) to 2 : 3 (with a surfactant).

The concentrations of Surf I and Surf II corresponding to a sharp increase in k_s were substantially higher than the critical micelle concentrations (CMC's) for both surfactants. Reverse micelles were formed with the polar tails of the surfactant molecules directed inwards. The observed extremal pattern of dependences $k_s = k_s([surfactant])$ can be attributed to redistribution of the catalyst and substrate molecules between the organic and micellar phases.⁵² An increase in the surfactant concentration is accompanied by an increase in the concentration of micelles and efficient accumulation of the substrate and the catalyst in the micelle bulk, which entails an increase in k_s (see Figs 5 and 6). Upon further increase in the surfactant concentration to values an order of magnitude greater than the CMC, phase separation with destruction of the reverse micelles starts in the reaction mixture, and process kinetics returns to the initial regime (observed in the absence of a surfactant).

The validity of the qualitative conclusions concerning the extremal dependence of k_s on c is also supported by the observed extremal dependence of k_s for the oxidation of cholesterol on the concentration of MP for surfactant concentrations exceeding the CMC (Fig. 7, curves 1 and 2) and by the fact that k_s almost does not depend on the MP concentration when no surfactant is present (Fig. 7, curve 3).

Figure 7. Dependence of k_s for the oxidation of cholesterol with the TPPMnCl–NaBH₄–O₂ system on the concentration of TPPMnCl in the presence of Surf II (curve 1), Surf I (curve 2) and in the absence of surfactants (curve 3) (in heptane).⁵⁰

The concentrations of Surf I, Surf II and cholesterol were 0.05, 0.5 and 2.2×10^{-3} mol litre⁻¹, respectively, the concentration of EtOH was 2.65 (1) and 4.42 vol. % (2, 3).

It is also evident that some concentration limit should exist for embedding of substrate molecules into the micellar phase. This is indicated by the dependences of the observed rate of cholesterol oxidation v_p in the presence of micelle-forming agents of both types on the cholesterol concentration shown in Fig. 8. The fact that the kinetic curves reach a stationary level (unlike the linear dependence of v_p on the cholesterol concentration in the absence of a surfactant) demonstrates the saturation effect in substrate embedding into the micelles.

The dependence of k_s values for these oxidation processes on the content of an aliphatic alcohol (or water) in the reaction mixture also deserves attention (Fig. 9). The necessity of introducing an alcohol (polar component) into the reaction mixture is due to the fact that sodium tetrahydroborate is insoluble in nonpolar

Figure 8. Rate of cholesterol oxidation v_p with the TPPMnCl–NaBH₄–O₂ system vs. cholesterol concentration in the presence of Surf I (curve 1), Surf II (curve 2) and in the absence of surfactants (curve 3) in a chloroform–heptane mixture (1 : 1).⁵⁰

The concentrations of Surf I, Surf II and TPPMnCl were 0.05, 0.5 and 6×10^{-5} mol litre⁻¹, respectively; the concentration of EtOH was 2.65 vol. %.

Figure 9. Dependences of k_s for cholesterol oxidation with the TPPMnCl–NaBH₄–O₂ system on the alcohol (or water) concentration (c') in the presence of Surf II (curves 1–6) and in the absence of Surf II (curve 7). The introduced alcohol (or water) used: ethanol (1–3), propan-2-ol (4), water (5), n-butanol (6).⁵⁰ The concentrations of cholesterol and TPPMnCl were 2.2×10^{-3} and 6×10^{-5} mol litre⁻¹, respectively, the concentration of Surf II was 0.2 (1), 0.1 (2), 0.05 (3–6) and 0 (7, in heptane) mol litre⁻¹.

solvents or chloroform. Depending on the nature of the alcohol, its concentration in the reaction mixture was 2.5 vol.%–3.0 vol.%. An increase in the content of alcohol (water) in the system resulted in a lower stability and a smaller size of the reverse micelles.

It was found that the rate of oxidation of cholesterol in the presence of Surf II decreases in the following sequence of the polar components added to the system: ethanol > propan-2-ol > n-butanol > methanol > water. The low k_s values observed with water and methanol are due to fast destruction of the reducing agent and loss in its activity.

It was also shown that the introduction of Surf I into the reaction system increases k_s for the oxidation of anthracene and the degree of its conversion (k_s increases 5–6-fold and the degree of conversion increases to 100%). Studies on the oxidation of substituted naphthalenes showed that the presence of reverse micelles formed by Surf I increases the specific rate constant for the oxidation of 2-methylnaphthalene in the presence of TPPCo by a factor of 4–6, and for 2,6-dimethylnaphthalene, this factor is 6–8. Simultaneously, the degrees of conversion increase from 10% to 30% and from 30% to 80%, respectively. The ratio of the oxidation products somewhat changes due to an increase in the yield of dihydroxy derivatives of tetralins (with respect to epoxy alcohols).

A significant feature found for the oxidation of hydrocarbons in the presence of surfactants is the substantial increase in the stability of the active form of the catalyst, which is more pronounced in the presence of Surf I than Surf II. It has been shown⁵⁰ for the oxidation of cholesterol in the presence of TPPMnCl that the turnover number of TPPMnCl until its complete decomposition ('discoloration') increased from 20–25 to 240–250 in the presence of Surf II and from 35–40 to 860–870 in the presence of Surf I. These data attest to a decrease in the rate of catalyst destruction. Apparently, this is related to a decrease in the probability that the intermediate complex $[MP]^{2+} - O_2$ –substrate involved in the oxidation⁵¹ would react with the hydroperoxide adducts formed during the reaction.

The above data provide grounds for treating MP solubilised by reverse micelles as a new type of porphyrin-containing catalyst for non-chain oxidation of alkenes characterised by enhanced efficiency and stability compared to monomer analogues.

VI. Catalytic activity of soluble and insoluble polymeric systems with immobilised porphyrins and their metal complexes

The catalytic activity of non-immobilised MP in the chain oxidation of unsaturated hydrocarbons by dioxygen in the presence of reducing agents has been described.⁵¹ It was shown that the Mn³⁺ and Fe³⁺ porphyrin complexes in the presence of sodium tetrahydroborate are efficient catalysts of the following reactions:

- regioselective oxidation of mono-, di- and trisubstituted aliphatic and trisubstituted steroid alkenes to ketones and secondary (or tertiary) alcohols (in the case of Δ^5 -steroid alkenes, the reaction proceeds with 100% stereo- and regioselectivities);
- oxidation of anthracene, its alkylated and phenylated derivatives and phenanthrene to the corresponding quinones; and
- oxidation of alkyl- and phenyl-substituted naphthalenes to dihydroxy- and epoxy-derivatives of tetralin.

A mechanism for the catalytic action of MP has been proposed. The mechanism is underlain by the view which implies the formation of an intermediate ternary complex MP–O₂–substrate where dioxygen is activated to a singlet-like state. Within the framework of this mechanism, it became possible to describe the whole set of data obtained for reactions of this type. New methods for the oxidation of cholesterol to 3 β ,5 α -cholestanediol (a new reaction in the chemistry of steroids) and oxidation of C₄–C₆ alkenes to tertiary alcohols have been developed.

1. Porphyrin-containing polymeric systems in the catalytic oxidation of steroid alkenes by dioxygen in the presence of reducing agents

This Section considers the results of studies^{29, 45, 46} dealing with oxidation of steroid alkenes with MP catalysts immobilised on polymers in the presence of sodium tetrahydroborate. The oxidation of these substrates by dioxygen was carried out in ethanol or its mixture with chloroform. The effective rate constants k_{ef} were found from the kinetic curves for oxygen absorption by the reaction system at the initial instants.

a. Oxidation of cholesterol in the presence of soluble polymeric catalyst systems

Soluble polymeric catalysts (PC) containing PMn were prepared by copolymerisation of methacrylates with the *N*-acryloyl derivative based on [tetra(*p*-aminophenyl)porphyrinato]manganese (PMn-AA) (the product of reaction between acryloyl chloride and TAPPMnOAc). The copolymers obtained in this way proved to be active catalysts for the oxidation of steroid alkenes (cholesterol, androstene). However, aliphatic, dienic, and fused aromatic hydrocarbons (ethylene, propylene, hex-1-ene, hex-2-ene, isoprene, anthracene and its derivatives or substituted naphthalenes) were not oxidised in the presence of these soluble PC. It was shown that oxidation of cholesterol to 3 β ,5 α -cholestanediol in the presence of soluble PC and NaBH₄ proceeds *via* the formation of cholesterol hydroperoxide, like oxidation in the presence of non-immobilised PMn,⁵¹ *i.e.*, the oxidation mechanism can be considered to remain the same on passing to soluble PC.

The scheme of catalytic action of MP in the presence of a reducing agent proposed in a number of studies^{51, 53–55} assumes the formation of an intermediate complex containing, apart from the reduced MP and dioxygen, a substrate molecule. It is significant that dioxygen and the alkene are coordinated on one side of the plane of the porphyrin ring. The possibility of this coordination is determined by the ability of the central ion of the MP occurring in the high-spin state to emerge from the plane of the porphyrin macrocycle by a distance of up to 0.05 nm. Previously, the existence of intermediate ternary complexes of this type has been postulated in the discussion of the oxidation mechanism of substrates involving haem enzymes.

It was assumed that the first stage ($P_1 \rightarrow P_2$) of the catalytic process (Scheme 2) is the reduction of the central ion in the MP molecule. The possible scheme of hydroxylation of substituted alkenes with the $\text{PMn}-\text{O}_2$ system in the presence of sodium tetrahydroborate is presented below.⁵¹

Scheme 2

The reaction of the reduced form of the catalyst (P_2) with the alkene and dioxygen molecules ensures the regioselectivity of the process and results in the intermediate product P_3 . Subsequently, under the action of the reducing agent, complex P_3 is converted into final products (A–D), possibly, *via* intermediate compounds P'_3 and P_4 . Depending on the alkene structure and the oxidation conditions, this can give ketones and secondary or tertiary alcohols. In the case of trisubstituted alkenes, the intermediate adduct P_3 with the tertiary carbon atom can be converted under the action of sodium tetrahydroborate (in particular, *via* hydroperoxide P_4) directly into tertiary alcohol. If complex P_3 contains a secondary carbon atom, *i.e.*, the initial alkene is disubstituted ($R^2 = \text{H}$), the hydroperoxide P_4 can either disproportionate to give ketones or be reduced on treatment with NaBH_4 to give secondary alcohols. According to this scheme, epoxides can be produced by two routes, namely, by disproportionation of the intermediate complex P_3 (this process predominates in the absence of hydride reducing agents) and by the reaction of hydroperoxide P_4 with a second alkene molecule (epoxidation of alkenes with hydroperoxides is a well-known reaction). Table 1 presents the effective 'specific' rate constants k_s for the oxidation of cholesterol related to the concentration of PC (for soluble PC) and the low-molecular-mass analogue (TAPPMnOAc) (*i.e.*, per catalyst molecule): $k_s = v_p / ([\text{MP}] \times [\text{substrate}])$, where v_p is the rate of transformation of cholesterol during the initial instants.

It follows from Table 1 that immobilisation can result in a substantial increase in the 'specific' TAPPMnOAc activity. This increase in the rate constants can be related to an increase in the local concentration of cholesterol near the active site caused by the participation of the macromolecular chain of the polymer catalyst in the effective sorption of the substrate. Evidently, in this case, the PC macromolecules should be sufficiently flexible. Indeed, an increase in the chain rigidity caused by introduction of a large

Table 1. Kinetic parameters of oxidation of cholesterol by dioxygen in the presence of copolymers of various acrylates and vinylpyridine (VP) with PMn-AA in a chloroform–ethanol mixture (1 : 1) at room temperature.²⁷

Second monomer ^a	[PMn] (mass %)	$10^5 [\text{PMn}]$ /mol litre ⁻¹	$10^5 v_p$ /mol litre ⁻¹ s ⁻¹	k_s /litre mol ⁻¹ s ⁻¹

Note. The cholesterol and NaBH_4 concentrations were 1×10^{-2} and 5.5×10^{-2} mol litre⁻¹, respectively.

^a Designations: MMA is methyl methacrylate, BMA is butyl methacrylate, OMA is octyl methacrylate, 4-VP is 4-vinylpyridine; ^b non-immobilised complex.

amount of PMn into the polymer chain entails a decrease in the specific catalytic activity of copolymers based on MMA and PMn-AA, while the PC based on 4-vinylpyridine and PMn-AA, which exists in solution as a rigid solvated structure, is virtually inert in this process. However, the introduction of MMA fragments into this PC increases the catalytic activity of the resulting terpolymer. The copolymers of PMn-AA with BMA and OMA do not exhibit a catalytic activity, possibly due to the shielding of the MP active sites by bulky side groups of the polymer support.

The temperature dependence of the effective rate constant for the oxidation of cholesterol in the presence of PMn-AA copolymers with MMA and BMA passes through a maximum at about room temperature (Fig. 10, curves 1 and 2). It should be noted that upon a decrease in the molecular mass of the synthesised PC

Figure 10. Temperature dependences of the rate constant for the oxidation of cholesterol in the presence of NaBH_4 and copolymers of PMn-AA with MMA (curves 1, 3) and BMA (curve 2) and also in the presence of non-immobilised TAPPMnOAc (curve 4).

The concentrations of cholesterol and NaBH_4 were 1×10^{-2} and 5.4×10^{-2} mol litre⁻¹, respectively. The concentrations of copolymers in relation to PMn were 1.8×10^{-5} (MMA) and 3.1×10^{-5} mol litre⁻¹ (BMA).

The molecular mass of MMA-based copolymers was 29 000 (curve 1) and 7 000 (curve 3).

(transition to oligomers), the k_s decreases and the temperature dependence acquires the Arrhenius form (curve 3 in Fig. 10).

This non-monotonic behaviour of k_s implies the possibility of temperature-induced conformational transitions in the system. In particular, this may be the rearrangement of the secondary structure of the polymer caused by the formation of hydrogen bonds. These processes are completed over a certain temperature range. Usually, rearrangements of this type are described using a cooperativity parameter depending on temperature (in the above-indicated temperature range) according to an activation law and defined as the equilibrium constant of the formation of one rupture in the sequence of hydrogen bonds. In the same temperature range, the intrinsic viscosity of the system (η) should also change according to the equation

$$\eta = \eta_0 \exp \frac{E}{RT},$$

where E is the activation energy for viscous flow. Indeed, the $\eta(T)$ dependences observed experimentally for the MMA copolymer with PMn-AA (the content of PMn was 0.3%), like those for poly(methyl methacrylate), were 'rectified' in the appropriate coordinates.²⁹ It is noteworthy that the introduction of 0.3% of porphyrin-containing groups in the copolymer changes the activation energy for viscous flow from 25.2 (for PMMA) to 50.4 kJ mol⁻¹ (for the PMn-AA copolymer).

b. Catalytic oxidation of cholesterol, substituted anthracene hydrocarbons and phenanthrene in the presence of metalloporphyrins immobilised on a perfluorinated sulfonate cation exchange copolymer

The insoluble PC containing MP were prepared by copolymerisation of methyl methacrylate with PMn-AA in the presence of a cross-linking agent (divinylbenzene) and by immobilisation of a number of monomeric PMn [P = TPP, tetra(*p*-methoxyphenyl)-porphyrin (TMPP) and hematoporphyrin (HP)] on insoluble polymeric supports at room temperature from solutions in dioxane in the presence of heterocyclic nitrogenous bases. Table 2

presents the data on the chemical structures and activities of the catalysts.

The insoluble copolymers of MMA and PMn-AA containing 3 mass %–5 mass % of TAPPMnOAc proved to be inert toward oxidation of cholesterol. The introduced PMn were easily washed out from the polymer matrices based on butadiene–styrene (**21**, **22**) and divinylbenzene–styrene (**19**, **20**) copolymers (see Table 2) under reaction conditions in a chloroform–ethanol solution. The low catalytic activity of the copolymers obtained by copolymerisation of PMn-AA with MMA or DVB (PC **23**–**25** in Table 2) became somewhat higher for lower degrees of cross-linking. This fact can be attributed to low accessibility of active sites of the catalyst in the cross-linked copolymer because the corresponding soluble PC (MMA copolymers with PMn-AA) exhibited high catalytic activities.

Catalysts **17** prepared by immobilisation of PMn on insoluble perfluorinated (sulfonate) cation exchange polymer films MF-4SK in the morpholine form manufactured at the scientific-production association Plastpolymer (St-Petersburg) exhibited a high catalytic activity towards the oxidation of cholesterol and anthracene. However, aliphatic alkenes were not oxidised in the presence of these catalysts. Note that if the central ion of the MP was linked to ionogenic groups of copolymers as a counter-ion, immobilisation resulted in the loss of the catalytic activity of PMn. This loss of activity can be attributed to the 'rigid' localisation of the Mn³⁺ in the vicinity of the ionogenic groups of the copolymers, which can prevent the reduction of the central ion and activation of oxygen. The 'rigid' fixing can be avoided by performing coordination of PMn through a bifunctional bridge, *i.e.*, heterocyclic nitrogenous base (morpholine, imidazole, piperazine). This type of immobilisation took place in the transformation of the sulfonate cation exchange copolymer into the morpholinium form (this process was monitored by IR spectroscopy based on the appearance of an absorption band at 3060 cm⁻¹ corresponding to the protonated form of morpholine in the spectra of copolymers) with subsequent treatment of this copolymer with a solution of PMn in dioxane (the absorption

band of the morpholinium ion was retained in the IR spectra of the copolymers).

The ability of the MF-4SK copolymer to bind PMn without the loss of catalytic properties of porphyrin is apparently due to the presence of fluorine-containing fragments in the α -position with respect to the SO_3^- groups, which causes migration of the electron density to the α -carbon atoms and thus enhances the acid properties of the copolymer sulfonic groups. In addition, the hydrophobicity of the fluorocarbon framework prevents the penetration of the polar solvent molecules into the diffusion channels of the copolymer;⁵⁶ as a consequence, the solvation environment of the ionogenic groups of MF-4SK differs substantially from that of the sulfo groups in other copolymers. The MF-4SK copolymer, unlike butadiene–styrene and divinylbenzene–styrene rubbers, has a rather ordered structure of simply connected channels along which the diffusion transfer of partially solvated ions and molecules takes place. This may stipulate high efficiency of the transfer of the initial reactants and products in MF-4SK along this system of channels.

Experimental data related to the kinetics of oxidation of cholesterol by dioxygen in the presence of the MF-4SK polymeric catalyst and NaBH_4 are presented in Table 3.

It can be seen that the rate constants for the oxidation of cholesterol (k_s) in the presence of monomeric and immobilised PMn are of the same order of magnitude but for insoluble PC, the overall yield of the product per catalytic site markedly increases due to the increase in the turnover number (μ) of the catalyst. This parameter introduced during generalisation of the formal Michaelis–Menten kinetics⁵¹ characterises the number of product molecules formed per ‘catalyst molecule’ throughout the whole process until the catalyst has completely decomposed, which necessarily takes place due to oxidative destruction processes. As regards the data presented in Table 3, note that, whereas the rate constant for cholesterol oxidation in the presence of monomeric PMn is affected substantially by the nature of the substituents in the porphyrin macrocycle, in the case of immobilised HPMn and TPPMn, the k_s values are virtually the same. It has been shown above that the rate constants for the oxidation of substrates in the presence of soluble PC in a homogeneous catalytic process increase due to the ‘polymeric effect’, namely, due to the involvement of polymeric fragments in effective sorption of the substrate. However, a substantial increase in the turnover number of the insoluble PC (10–100-fold compared to that of monomeric HPMn) is apparently indicative of a substantially lower susceptibility of immobilised PMn to destruction.

The destruction processes that take place during the catalytic action of monomeric PMn and PFe and soluble PC containing them proceed apparently through bimolecular reaction of the reduced catalyst (P_2) with oxygen adducts (P_3 and P_3') or with the intermediate compound P_4 (see Scheme 2), resulting in cleavage of the conjugation chain of the porphyrin ring. With the above-described coordination of PMn near the sulfo groups of the

polymer matrix, these bimolecular destruction processes occur at a considerably lower rate, which is responsible for the longer service life of insoluble PC. It should be emphasised that the aggregative state of the catalyst may dictate the route of oxidation.⁵⁷ Indeed, cholesterol is oxidised to $3\beta,5\alpha$ -cholestanediol in the presence of both soluble monomeric PMn and insoluble PC, while anthracene is oxidised to anthraquinone in the presence of monomeric PMn, but only anthracene endoperoxide is formed in the presence of insoluble PC containing PMn. Alkyl-substituted anthracenes and phenanthrene are oxidised in a similar way (*i.e.*, to endoperoxides).

The whole set of results can be easily interpreted within the framework of the above Scheme 2 according to which oxygen reacts with reduced MP at initial stages of the process and then the ternary intermediate complex, $\text{MP}-\text{O}_2$ –substrate, is produced. According to Scheme 2, no noticeable transfer of charge or spin density to oxygen takes place in the adducts formed from PMn and PFe with O_2 , and oxygen passes into a reactive singlet-like state.⁵⁸ For the oxygen adducts PMn^{2+} and PFe^{2+} , two alternative structures were proposed, one with the terminal tilted attachment of the dioxygen molecule to the MP (structure **A**) where the Mn and Fe cations are linked to only one of the oxygen atoms and the $\text{M}-\text{O}-\text{O}$ angle is 120° and the other, with a symmetrical arrangement of oxygen (structure **B**) with the central cation coordinated to the oxygen double bond.

According to quantum-chemical calculations,⁵⁸ structure **A** is energetically favourable for isolated complexes. However, the complexes are stabilised in solutions due to solvation effects and the proportions of forms **A** and **B** do not necessarily correlate with the quantum-chemical estimates; therefore, in the general case, both structures should be taken into account.

When a catalytic reaction is carried out in a polar solvating solvent, the probability of interaction between the substrate and the catalyst in form **A** or **B** depends obviously on the nature of the substrate. The polar cholesterol molecules (dipole moment $\mu_C = 1.99$ D) should be coordinated preferably near complexes of type **A**. This type of interaction is responsible for the subsequent formation of 5α -hydroperoxycholesterol (**26**), which then reacts with sodium tetrahydroborate, being reduced to alcohol **27**.

Table 3. Kinetic parameters of cholesterol oxidation in the presence of PMn immobilised on perfluorinated sulfonate copolymer MF-4SK and monomeric PMn in ethanol at 20°C .⁴⁵

Catalyst system	$10^2 [\text{Cholesterol}]$ /mol litre $^{-1}$	k_s /litre mol $^{-1}$ s $^{-1}$	$10^{-2}\mu$	Degree of conversion (%)
TMPPMnOAc	4.0	9	2	96
Immobilised TMPPMnOAc *	8.0	26	400	95
TPPMnOAc	4.0	8	2	95
Immobilised TPPMnOAc *	8.0	26	400	96
HPMnOAc	2.5	0.5	1.2	80
Immobilised HPMnOAc *	8.0	30	400	96

Note. The concentrations of NaBH_4 and PMn were 5×10^{-2} and 2.5×10^{-3} mol litre $^{-1}$, respectively. In the case of insoluble polymeric catalysts (asterisked), the conventional concentration [PMn] corresponding to the amount of PMn contained in the polymer per ml of the reaction mixture was calculated.

For the symmetrical anthracene molecules, having an extensive system of π -conjugation, the coordination and the formation of the intermediate ternary complex with form **B** of the catalyst are apparently more energetically favourable, although the content of this form in the solution may be lower than that of form **A**. Anthraquinone is produced according to the following scheme

An activated transition of form **A** into form **B** upon coordination of anthracene near the $\text{MP}-\text{O}_2$ complex is also possible. It is clear that for cholesterol the formation of this product is completely ruled out. However, at high PMn concentrations where the proportion of form **A** markedly increases, anthracene can also react with the 'asymmetrical' form of the oxygen adduct PMnO_2 , which leads to the appearance of anthracene endoperoxide in the reaction system. This is also facilitated by the large

bulk of the PMnO_2 complex with a tilted orientation of oxygen (form **A**).

When PMn is immobilised on insoluble polymer supports, the symmetry of the molecular fields of the above-described complexes decreases, which would suppress even more strongly the formation of symmetrical oxygen adducts (**B**), *i.e.*, the probability of formation of the corresponding oxidation products would diminish. Indeed, it has been noted above that oxidation of anthracene on insoluble immobilised PMn gives only anthracene endoperoxide.

2. Immobilised porphyrins and their metal complexes in hydroxylation, decomposition of hydrogen peroxide, electrooxidation, reversible binding of substrates, epoxidation and photocatalysis

Examples of the title processes catalysed by immobilised porphyrins and metalloporphyrins are given in Table 4. This list of reactions should be considered as a supplement (with some refinement) to the information on these reactions considered in the previous review.⁵⁹

Let us discuss in more detail the processes included in Table 4.

It has been shown that immobilisation of phaeophytin *b* and its cobalt and copper derivatives on PVA yields active catalyst systems used for H_2O_2 decomposition.^{36, 37} The catalytic activities of phaeophytin and its metal complexes in aqueous solutions of H_2O_2 are nearly equal. In the absence of porphyrin, with cobalt chloride dispersed in PVA, the reaction does not proceed. Cobalt complexes of phaeophytin dispersed in water do not initiate the reaction either. The mechanisms of these processes have not yet been elucidated; however, it has been suggested^{36, 37} that the

Table 4. Examples of processes catalysed by immobilised porphyrins and their metal complexes.

Catalysed process	Catalyst system ^a	Type of binding	Ref.
Decomposition of hydrogen peroxide	phaeophytin <i>b</i> (11), rhodin <i>g</i> ₇ , their Co and Cu complexes immobilised on poly(vinyl alcohol)	covalent	36, 37
Epoxidation of alkenes	TAPPMn (4) immobilised on chloromethylated polystyrene cross-linked by divinylbenzene	"	41
Photooxidation of hydrocarbons	TPPFe ^{III} –Nafion	ionic	60
Hydroxylation of cholesterol and alkenes	copolymers of TAPPMn with methacrylates (methyl, butyl, octyl) and 4-vinylpyridine	covalent	29
	TPPMn (TMPPMn or HPMn)–morpholine–Nafion	ionic	45, 46
Hydroxylation of aniline and oxidation of alkenes	TPPFe ^{III} –poly(γ -methyl-L-glutamate)	covalent	61
Electrooxidation of NO	glassy carbon electrode–polymeric TMHPP–Nafion	physical adsorption	62
Reversible oxygen binding	PCo–vinylimidazole copolymer with octyl methacrylate (sensor system)	coordination	42
	H ₂ TPP(2-NHCOBu ^t) ₄ –copolymer of vinylidene chloride, vinylimidazole and methyl methacrylate	"	43
	TAPPCo immobilised on chloromethylated polystyrene cross-linked by divinylbenzene	covalent	39
Photogeneration of singlet oxygen	TMPP tosylate (1)–regenerated cellulose	physical adsorption	10
	TMPPPd ^{II} –TDCPPFe ^{III} –Nafion	ionic	60
	MATPP (15)–Nafion	"	47
	(tetrapyrrolylporphyrinato)tin–silica	physical adsorption	63
Photoinduced modelling of oxygenase activity	TPPFe–Nafion	ionic	64

^a Designations: TAPP is 5,10,15,20-tetra(*p*-aminophenyl)porphyrin; TMHPP is tetrakis(3-methoxy-4-hydroxyphenyl)porphyrin, TMPP is tetrakis(*N*-methylpyridinium-4-yl)porphyrin, TDCPP is tetrakis(2,6-dichlorophenyl)porphyrin, MATPP is 5-(*p*-aminophenyl)-10,15,20-triphenylporphyrin.

mechanisms of decomposition of H_2O_2 in the presence of phaeophytin and its metal complexes are different.

The epoxidation of alkenes⁴¹ takes place with the participation of sodium periodate in acetonitrile in the presence of imidazole or another nitrogenous base. Due to the high degree of matrix cross-linking, the immobilised TAPPMn behaves as a typical heterogeneous catalyst where only near-surface layers are active. Immobilisation increases markedly the catalyst stability against degradation in the presence of sodium periodate, which is a strong oxidant. The degree of conversion reaches 95%.

The oxidation of a mixture of cyclohexene and cyclohexane by dioxygen on exposure to sunlight at 20 °C under atmospheric pressure has been studied.⁶⁰ In addition to the $\text{TPPFe}^{\text{III}}$ –Nafion system, the researchers used also chlorinated or fluorinated analogues of porphyrinatoiron immobilised on Nafion. The porphyrins were added to the reaction mixture after swelling of the resin in a mixture of dichloromethane and ethanol. The immobilisation of $\text{TPPFe}^{\text{III}}$ was found to result in a growth of the photocatalytic activity and stability of the catalyst. The ratio of the products formed in the catalytic reaction differed somewhat (from that obtained in the oxidation in the presence of non-immobilised porphyrinatoiron).

The covalent binding of TPPFe to poly(γ -methyl L-glutamate) afforded polymeric catalysts active in hydroxylation of aniline on treatment with hydrogen peroxide and in the oxidation of alkenes.⁶¹ Immobilisation was carried out in aqueous methanol. The catalyst obtained in this way was much more active than non-immobilised analogues.

Cizewski *et al.*⁶² developed a sensor device for determination of nitrogen oxide based on its anodic oxidation. The catalyst was prepared by successive deposition *via* electropolymerisation of tetrakis(4-hydroxy-3-methoxyphenyl)porphyrin (or its nickel complex) and Nafion film layers onto the surface of a glassy carbon electrode. The oxidation proceeded throughout the whole bulk of the film. The limit of determination of nitrogen oxide by this method was 10^{-4} mol litre⁻¹.

It should be noted that metalloporphyrins and metallophthalocyanines deposited on graphite or carbon electrodes are often used in electrooxidation or electroreduction processes (for example, proton to hydrogen). The use of Nafion films containing metalloporphyrins, in particular TPPCo , for coating the electrodes increases the efficiency of this process.^{65–68}

Membrane systems selectively permeable for oxygen have been prepared using cobalt porphyrin complexes and polymer supports.^{39, 42, 43} The polymeric systems based on vinylimidazole copolymers proved to be most efficient. The introduction of Co into the polymer increased the membrane permeability by a factor of 25. The ratio of the oxygen and nitrogen permeability coefficients of the membranes reached several hundreds.

The photogeneration of singlet oxygen upon photoexcitation of regenerated cellulose films containing adsorption-bound porphyrins has been studied.¹⁰ The photogeneration of singlet oxygen to the gas phase has been studied in the presence of protonated MATPP immobilised on the Nafion film and on quartz⁴⁷ and in the presence of (tetrapyridylporphyrinato)tin supported on silica gel.⁶³ The process was more efficient with MATPP immobilised on a polymer support. The efficiency of generation of singlet oxygen was found to increase with an increase in the temperature of the support. The TPPFe immobilised on the Nafion film was used to model the oxygenase activity exhibited by the system on photoexcitation.⁶⁴

To summarise the data, it can be stated that immobilisation of MP on insoluble polymeric supports results most often in a higher stability of the catalyst. This may also change the selectivity and increase the efficiency of the catalysed processes compared to the processes taking place in the presence of free MP. If the substrate is a bulky molecule, as is the case for hydroxylation of cholesterol, the MP molecule should retain some mobility during the catalytic transformation. However, in other cases, there is no need for MP

mobility (the case of photogeneration of singlet oxygen on MATPP immobilised on Nafion).

Some publications deal with the redox reactions taking place in metalloporphyrin (Co, Zn, Mn, *etc.*) molecules immobilised on poly-4-vinylpyridine and Nafion. In this case, polymeric films with immobilised MP were applied on glass electrodes,^{69–73} which were immersed into an electrolyte solution. The electrochemical charge transfer to the polymeric film was studied in a three-electrode system.

VII. Photochemical processes involving deposited layers of porphyrins

In recent years, the possibilities of functional use of not only porphyrin-containing polymer systems but also molecular aggregates and supramolecular ensembles formed with participation of porphyrin molecules and metalloporphyrins have been found. Scanning probe microscopy (SPM) and its versions — scanning tunnelling (STM), atomic-force (AFM) and scanning magnetic (SMM) microscopies — allow one not only to examine the arising structures at the atomic and subatomic levels but also to transfer and isolate separate molecules on a solid surface.^{74–78} These techniques cover the scale from fractions of a nanometre to several micrometres. The appropriate instruments allow one to control the ‘assembly’ and the structural organisation of molecular and supramolecular ensembles. In particular, recently STM has been used to elucidate the supramolecular aggregation on the surface of gold of the molecules of substituted tetraphenylporphyrin containing cyanophenyl substituents, which initiate the aggregation. This aggregation gave di-, tri- and tetrameric (*cis* and *trans*) aggregates.⁷⁹ The STM technique was also used to visualise *in situ* the process of formation of highly ordered structures of tetramethylpyridiniumporphyrin (in the form of tosylate) on an iodine-modified gold surface.⁸⁰ The process was performed in 0.1 M solutions of perchloric acid.

The new potential of nanotechnology can be associated with the use of deposited molecular layers formed under self-assembly conditions where the structural organisation of the layers (for nanometre to fractions of micrometre levels) is dictated by the structure of the molecules and interactions between them. Porphyrins and related molecules can be used for deposition, as they are capable of aggregation upon both precipitation from solutions and sputtering onto various substrates. In this Section, we present the results of investigation of the structure of vacuum deposited layers of tetraphenylporphyrin and some of its derivatives over a broad range of surface concentrations N_{tot} ($N_{\text{tot}} \approx 10^{-11} - 10^{-9}$ mol cm⁻²) of deposited molecules.⁸¹ These layers proved to be functionally active for generation of the singlet oxygen $^1\text{O}_2$ to the gas phase upon the photosensitised excitation of the molecular oxygen $^3\text{O}_2$ adsorbed on the deposited TPP layer. The rate of generation of $^1\text{O}_2$ depended on the structure of deposited layers on scales of about fractions of a micrometre. The conclusions concerning the structure of porphyrin layers on different spatial scales were drawn from the micrographs obtained by transmission electron and atomic-force microscopy. The recent interest in the photogeneration of singlet oxygen to various media is related to the possibility of initiating the photosensitised oxidation of biologically active substrates and to the problem of photodynamic therapy in medicine.

Here, it is pertinent to note that SPM analysis of the surface structure is based on the processing of digitised ‘roughness profiles’ along the scans obtained from a surface section with characteristic dimensions ranging from tens of nanometres to tens of micrometres. As a rule, the results are represented as images of fragments of the surface structure (for example, molecular aggregates) or the general surface morphology under conditions of ‘model highlighting’;^{82, 83} the appearance of images can depend appreciably on the type of this highlighting and, at the operator’s option, pictures different in kind (from the Carpathians to the Himalayas) can be obtained from the same section of the surface.

No routine and generally accepted methods for the processing of digitised data in order to derive parameters generally characterising the key features and peculiarities of the surface under study have been developed as yet. The purely statistical processing methods giving the average roughness and the corresponding variances and semiinvariants are barely used now, because they do not provide information on a significant feature of the structures, namely, the correlations in the spatial organisation of fragments with different spatial scales. The Mandelbrot fractal dimension^{84,85} proved to be inadequate for correct representation of the differences between complex surface structures. New prospects for parametrisation have appeared due to flicker-noise spectroscopy (FNS),^{86–88} which is based on the views on the information significance of the irregularities in real structures ('spikes', 'jumps' and discontinuities of derivatives) on different spatial scales and the degree of correlation of these irregularities (connectivity) over the surface.

Photogeneration of singlet oxygen to the gas phase was studied in an all-soldered glass setup⁸¹ in the presence of tetraphenylporphyrin and other porphyrin photosensitisers. Porphyrins were sputtered onto quartz plates with an area of 20 cm². The surface concentration of porphyrin was determined from the intensity of the Soret band in the electronic spectra of solutions of TPP in chloroform recorded after washing the porphyrin off the surface of quartz plates. The lowest detectable surface concentration was 5×10^{-12} mol cm⁻². The ¹O₂ concentration was determined using semiconductor sensors.⁴⁷ The working pressure of dioxygen in the setup was maintained at 0.1 Torr. A DRSh-500 mercury lamp with a BS-8 light filter was used as the light source. The efficiency of photogeneration of singlet oxygen was estimated from the steady-state concentration c_S of singlet oxygen in the setup bulk under continuous photoexcitation of the system (in the absence of a photosensitiser deposited on quartz, no generation of singlet oxygen was detected upon photoexcitation). The data were presented as the reduced bulk concentrations $c_{S_0}^{\text{red}} = c_S/c_{S_0}$, the concentration of singlet oxygen formed in the setup at a temperature of 20 °C being taken as c_{S_0} . The c_{S_0} value was estimated using decomposition of 9,10-diphenylanthracene endoperoxide yielding a controlled amount of ¹O₂.⁸⁹ According to this estimate, $c_{S_0} \approx 10^{-13}$ mol cm⁻³ ($\sim 10^{11}$ particles cm⁻³).

Electron microscopy data were obtained using a JEM-2000 EX-II transmission electron microscope. The samples were prepared by depositing TPP on a NaCl single crystal and then carbon replicas were formed from the deposited surface. The generation of singlet oxygen was studied for samples prepared by depositing TPP onto quartz. The surface reliefs were analysed for TPP layers deposited onto mica plates. A Solver P47 atomic force microscope (NT-MDT, Zelenograd) was used. The studies were carried out in the semicontact mode, the surface concentration of porphyrin (N_{tot}) being varied in the range of 10^{-11} – 10^{-9} mol cm⁻². Electronic absorption spectra were recorded on a Specord UV-VIS spectrophotometer.

Figure 11 presents the dependence of the efficiency of generation of singlet oxygen on the overall surface concentration of TPP. It can be seen that this dependence has a broad maximum in the concentration range $N_{\text{tot}} \approx (4–12) \times 10^{-11}$ mol cm⁻². The photosensitised generation of singlet oxygen is known to start with excitation of the sensitizer molecules and includes several steps.⁹⁰ Under experimental conditions, the surface layer of the deposited porphyrin films exists in the stationary photoexcitation state in which electronic-vibrational transitions take place in the molecular-crystalline fragments of the porphyrin layer. The porphyrin molecules in the initial singlet state ¹Π pass into the excited ¹Π* states upon photon absorption. Under the conditions of electronic-vibrational transitions, intersystem crossing becomes possible in the molecular-crystalline fragments giving excited porphyrin molecules in the ³Π* triplet spin state. The photosensitisation of the triplet ³O₂ molecules, which are coordinated most probably near the porphyrin macrocycles, can be accomplished through these excited states. In this case, the oxygen

Figure 11. Efficiency of generation of singlet oxygen by deposited TPP layers at different average surface concentrations of porphyrin.

molecules ¹O₂ in the singlet excited state formed upon energy transfer are also coordinated at the porphyrin molecules. This means that the generation of singlet oxygen to the gas phase is possible only in the case where the characteristic time of desorption of the coordinated ¹O₂ molecules does not exceed their deactivation time in the coordinated state.

Within the framework of a formal kinetic scheme, from which some of the above-described intermediate steps have been eliminated, the process of ¹O₂ generation to the gas phase induced by a light quantum $h\nu$ can be represented as the following set of transitions:

Here k_1 , k_2 , k_3 and k_4 are the rate constants for processes (1)–(4), respectively, namely, the formation of porphyrin molecules in the triplet spin state ³Π*, generation of the ¹O₂ molecule to the gas phase, deactivation of the porphyrin molecule in the ³Π* state and deactivation of the ¹O₂ molecule on the surface sites, in the chamber bulk and on the chamber walls. It is evident *a priori* that chemical transformations (1)–(3) occur on the surface of the porphyrin film; therefore, the rate of these chemical processes should be determined by the surface concentrations of the reactants. However, to simplify the subsequent analysis and to obtain analysable final relations, we shall write the equations of formal kinetics for the concentrations of oxygen molecules in the singlet and triplet states (c_S and c_T) in the gas phase assuming that the necessary equilibrium between the adsorbed and free forms of oxygen is attained over a short period of time. Therefore, all constants appearing in the set of equations of formal kinetics should be taken as effective values. In the stationary case, this set assumes the form

$$\frac{dN^*}{dt} = k_1 w N - k_2 c_T N^* - k_3 N^* = 0, \quad (5)$$

$$\frac{dc_S}{dt} = k_2 c_T N^* - k_4 c_S = 0, \quad (6)$$

$$N_0 = N + N^*, \quad (7)$$

$$c_0 = c_T + c_S, \quad (8)$$

where w is the parameter characterising energy absorption by the deposited layer under photoexcitation conditions (determined by the product of the incident luminous flux, the extinction coefficient and the effective thickness of the absorbing layer); N and N^* are the surface concentrations of the porphyrin molecules in the ¹Π and ³Π* states, respectively, efficiently involved in the photo-

generation of singlet oxygen; N_0 is the overall surface concentration of the TPP molecules participating in the photosensitised generation of singlet oxygen; and c_0 is the total concentration of oxygen in the gas phase.

The solution of the set of equations (5)–(8) for the steady-state concentration c_S in the gas phase has the form

$$c_S = \frac{k_1 k_2 w N_0 c_0}{k_3 k_4 + k_1 w (k_4 + k_2 N_0) + k_2 k_4 c_0}. \quad (9)$$

It is worth noting that under the experimental conditions, $c_S/c_T \approx 10^{-4}$, which implies fulfilment of the inequality

$$\frac{k_1 k_2 w N_0}{k_3 k_4 + k_1 w (k_4 + k_2 N_0) + k_2 k_4 c_0} \ll 1. \quad (10)$$

When comparing the obtained expression (9) with the experimentally observed dependence $c_S = c_S(N_{\text{tot}})$, one should take into account the effective dependence of the rate constants k_1 , k_2 , k_3 and k_4 on N_0 . It is natural to suggest that $N_0 = \theta N_{\text{tot}}$, where θ is the fraction of porphyrin molecules participating in photosensitisation processes. Before discussing these dependences, we shall consider the experimental results of analysis of the structure of porphyrin polymolecular layers formed upon vapour deposition of porphyrin on a quartz substrate.

With low concentrations of the deposited TPP ($N_{\text{tot}} \ll 10^{-9} \text{ mol cm}^{-2}$), porphyrin islands are formed on the mica and quartz surfaces, the number and the dimensions of the islands being different for different N_{tot} . As follows from the transmission electron microscopy data, when $N_{\text{tot}} = 1.8 \times 10^{-11} \text{ mol cm}^{-2}$, TPP forms particles with linear dimensions 15–50 nm, the distances between them being greater than the particle size by a large factor. The increase in the surface concentration of TPP to $4.1 \times 10^{-11} \text{ mol cm}^{-2}$ results in the growth of both the dimensions of porphyrin particles (30–100 nm) and their number per unit area. Further increase in N_{tot} to $1.5 \times 10^{-10} \text{ mol cm}^{-2}$ induces mainly an increase in the linear dimensions of the islands to 100–150 nm. Figure 12 shows typical images of the porphyrin islands for $N_{\text{tot}} = 4.1 \times 10^{-11} \text{ mol cm}^{-2}$. These micrographs demonstrate that the particles formed are inhomogeneous as regards both their internal structure and the elevation above the support level. When $N_{\text{tot}} > 10^{-9} \text{ mol cm}^{-2}$, continuous porphyrin layers are formed.

The tentative inferences concerning the crystal structure of porphyrin ‘macroislands’ were drawn from analysis of the X-ray diffraction patterns obtained using an electron microscope in the microdiffraction mode.⁸¹

When N_{tot} is low and the deposited layer is mainly composed of small islands, these islands (the seeds for larger aggregates) are crystalline. As the island dimensions increase (with an increase in the surface concentration of porphyrin), the proportion of the amorphous component increases (the number of crystal reflections located on concentric circles diminishes and the amorphous halo grows). When the islands grow to their maximum size, the crystalline component becomes less pronounced. Presumably, the growth of the islands ceases when the crystalline seeds have been coated by an amorphous layer of porphyrin. Thus, upon an increase in the surface concentration N_{tot} , the overall degree of the layer crystallinity decreases and, hence, the degree of amorphisation increases.

The conclusions drawn about the morphology of the deposited TPP layers are confirmed by the data from atomic-force microscopy. The results are presented in Fig. 13 *a–c*, which show the typical surface reliefs of deposited TPP for different surface concentrations N_{tot} . The formation of a TPP layer on the support starts with the appearance of relatively small particles with a height of up to 5 nm. When the surface concentration of porphyrin increases to $N_{\text{tot}} = 2.0 \times 10^{-11} \text{ mol cm}^{-2}$, the height of some aggregates of porphyrin molecules reaches 80 nm, the diameter being 10–50 nm (Fig. 13 *a*), which is in line with the electron microscopy data. Further increase in N_{tot} induces mainly an increase in the number of new (small) seed islands formed on the defects of the mica surface, while the growth of particle height virtually ceases. As the surface concentration reaches $N_{\text{tot}} \approx 10^{-9} \text{ mol cm}^{-2}$, bridges between the separate aggregates of TPP molecules appear, which gives rise to a continuous layer (Fig. 13 *b*). Figure 13 *c* shows an enlarged image of a surface section obtained at $N_{\text{tot}} = 1.5 \times 10^{-12} \text{ mol cm}^{-2}$ with a separate large porphyrin particle. It can be clearly seen in the relief that the particle is non-uniform in height.

The atomic-force microscopy data were processed in terms of a special programme of flicker-noise parametrisation of chaotic surfaces.^{86,91,92} The parameters used for the quantitative description of the surface included the average roughness height of the surface h , the correlation length L_1 for the types of surface irregularities (jumps), and the dimensionless parameter n , which is a factor of Fourier spectra in the flicker-noise section describing the rate of loss of the correlation links in the sequence of spike-type irregularities. Table 5 presents the calculated flicker-noise parameters.

The structural features of the porphyrin (TPP) layers deposited on NaCl identified on the basis of electron-microscopy images of the layers recorded at different surface concentrations of TPP, including the high surface concentrations N_{tot} (the region of

Figure 12. Typical electron micrographs of samples of deposited TPP at a surface concentration of $4.1 \times 10^{-11} \text{ mol cm}^{-2}$. Magnification (a) $\times 50\,000$, (b) $\times 500\,000$.

Figure 13. Typical surface reliefs of deposited TPP (a, b) and a separate island of deposited TPP (c).

Dimensions of sections: $20 \times 20 \mu\text{m}$ (a, b) and $600 \times 1000 \text{ nm}$ (c). The surface concentrations of TPP were 2.0×10^{-11} (a), 1.3×10^{-9} (b), $1.5 \times 10^{-12} \text{ mol cm}^{-2}$ (c).

continuous layer) are in good agreement with the structural features of mica-deposited TPP layers determined using atomic-force microscopy data on scales of tens and hundreds of nanometres. In other words, the structure of deposited porphyrin layers on submicro- and microscopic scales is determined to a higher extent by the interaction of the porphyrin molecules with one another and, to a lower extent, by the effect of the support (quartz or mica). This conclusion is very significant for the subsequent analysis because the photosensitised generation of singlet oxygen to the gas phase was studied taking TPP layers deposited on quartz as an example. In view of the foregoing, we assume that the pattern of variation of the flicker-noise parameters following an increase in N_{tot} , revealed in analysis of the structure of mica-deposited porphyrin layers, is similar to the pattern of variation of the corresponding parameters of the layers deposited on quartz.

In the analysis, we shall proceed from the data presented in Table 5, which demonstrate how the parameters L_1 and n , which characterise, on the nanometre and submicrometre scales, the structural organisation of the molecular crystals of porphyrins formed upon sputtering onto the quartz support, depend on the surface concentration N_{tot} of porphyrin. In particular, the decrease in the correlation length L_1 and the increase in the

Table 5. Quantitative parameters of deposited TPP layers characterised by flicker-noise spectroscopy.

$N_{\text{tot}} / \text{mol cm}^{-2}$	$L_1 / \mu\text{m}$	n	$h / \mu\text{m}$
5.2×10^{-11}	0.332	2.85	0.0182
1.3×10^{-9}	0.190	2.86	0.0236
2.4×10^{-9}	0.0623	3.32	0.0316

parameter n with an increase in N_{tot} in the film continuity region attest to the loss of correlation relationships in the film structure following an increase in the surface concentration of porphyrin. This fact may be responsible for the experimentally observed (see Fig. 11) decrease in the rate of generation of singlet oxygen to the gas phase with an increase in N_{tot} in the region of high surface concentrations ($N_{\text{tot}} > 10^{-10} - 10^{-9} \text{ mol cm}^{-2}$).

It has been noted above that the formation and the subsequent desorption of $^1\text{O}_2$ occur under continuous excitation of the deposited crystalline porphyrin layers. The experimental data obtained in recent years, most often using scanning atomic-force and tunnelling microscopy, confirmed the earlier hypotheses^{93,94} concerning the substantial length of the solid-phase surface regions (from several nanometres to hundreds of nanometres) involved in structural rearrangements after chemisorption of simple gases (H_2 , O_2) and the relative retardation (to times of $\sim 10^{-11} \text{ s}$ or longer) of the relevant electronic and conformational rearrangements.^{95,96}

As applied to the problem we are considering, this means that the structural features of the molecular crystalline porphyrin layers identified on nanometre scales by FNS analysis of atomic-force microscopy data^{91,92} and determining the transfer of the electronic-vibrational excitation in the surface layers can affect the rate of $^1\text{O}_2$ generation to a vacuum upon photoactivation of the surface layers of porphyrin crystals. In particular, a decrease in the degree of correlation of fragments of the crystal structure of the surface layers determined by a decrease in L_1 and an increase in n may be expected to result in lower effective rate constants k_1 and k_2 , whereas the constants k_3 and k_4 may, on the contrary, increase [see reactions (1)–(4)]. These assumptions, which imply the introduction of effective dependences $k_i = k_i(N_0)$, because the parameters L_1 and n vary with N_{tot} according to a known pattern (see Table 5), provide a natural interpretation for the concentration dependences $c_s = c_s(N_{\text{tot}})$ for the steady-state $^1\text{O}_2$ concentration presented in Fig. 11 (linear increase in c_s at low N_{tot} , reaching a maximum and a decrease at high N_{tot}) and allow one to estimate the parameters appearing in Eqn (9).

The correlation of the flicker-noise parameters with the surface concentration, which reflects quantitatively the degree of chaotisation of the deposited layer, is in full conformity with the trend of the rate of generation of singlet oxygen to decrease. Attention is drawn first of all by the non-trivial character of the result obtained, in particular, under the conditions of photo-excitation of deposited TPP layers considered here, the rate of generation of singlet oxygen is determined by the structural features of such layers revealed on scales exceeding by two orders of magnitude the proper atomic scale (fractions of a nanometre). Thus, in the heterogeneous photogeneration of $^1\text{O}_2$, the crucial role is played by the dynamics of redistribution and accumulation of the excitation energy of polymolecular porphyrin layers with the formation of local dynamic fluctuations sufficient for the generation of singlet oxygen molecules followed by their injection to the gas medium.

In connection with this result, we would like to note the following. The problems associated with the role of heterogeneity of the surface structure at the atomic or molecular level in heterogeneous catalysis have long been debated in the literature. From Temkin's standpoint (cited from Ref. 97), the surface of a heterogeneous catalyst is inhomogeneous in the adsorption capacity. According to Ostrovskii,^{98,99} the surface involved in heterogeneous catalysis is effectively 'homogeneous' in reactivity

of the chemisorbed phase ('chemadphase'), which is largely due to the diffusion transfer of components over the surface. Both suggestions are hypothetical because they are based on analysis of the kinetics of heterogeneous catalytic transformations (in particular, for the synthesis of ammonia) rather than on direct experiments on the measurement of surface diffusion or identification of surface heterogeneity on the basis of reactivity on the atomic level. The more so, because the formal kinetics equations give in both cases the same or similar dependences (see Ref. 98). The concept we develop here concerning the role of dynamic rearrangements of the surface (upon photoexcitation under conditions of heterogeneous catalysis) in the formation of local excitations determining the kinetics of chemical reactions and the efficiency of sorption-desorption processes, actually 'reconciles' these opposite viewpoints. Indeed, the effects of structural rearrangements with reorganisation of metastable fragments of a real surface with external excitation actually 'homogenise' the surface with dimensions of tens or hundreds of nanometres with respect to the kinetics of chemical processes taking place on this surface even when the surface is initially heterogeneous on the atomic level.

In conclusion, it should be noted that photosensitised generation of $^1\text{O}_2$ upon photoexcitation of deposited layers proved to be dependent on the chemical structure of the porphyrin molecules. This is demonstrated in Fig. 14, which presents the data on the steady-state concentrations of the singlet oxygen in the gas phase under conditions of photoexcitation of deposited layers of different porphyrins with the surface concentrations $N_{\text{tot}} \approx 10^{-11} - 10^{-9} \text{ mol cm}^{-2}$ corresponding to the maximum $^1\text{O}_2$ generation upon photoexcitation of TPP.

The reduced values of the steady-state concentrations are related to the corresponding value of the concentration of singlet oxygen upon TPP photoexcitation. It follows from Fig. 14 that the efficiency of generation of $^1\text{O}_2$ on the photoexcitation of different porphyrins can differ by an order of magnitude: the lowest activity is found for deuterioporphyrin, while the highest one is found for dicarboranylporphyrins CP3 and CP2.⁸¹ The apparent paradox of this result lies in the fact that the dicarboranylporphyrins CP3 and CP2, which form the most active deposited layers, were obtained by introducing carborane substituents into deuterioporphyrin molecules, which not only form the 'least active' layers for the photogeneration of $^1\text{O}_2$ but also

Figure 14. Comparative chart of the efficiency of generation of singlet oxygen by various porphyrins.

The following abbreviations are used: TPP is tetraphenylporphyrin, TMPP is tetra(*p*-methoxyphenyl)porphyrin, MATPP is 5-(*p*-amino-phenyl)-10,15,20-triphenylporphyrin, TPP-St is 5-(*p*-stearoylamino-phenyl)-10,15,20-triphenylporphyrin, Deuterio is dimethyl ether of deuterioporphyrin, CP1 is 1,3,5,8-tetramethyl-2,4-divinyl-6(7)-[(2-benzoyloxycarbonyl)ethyl]-7(6)-[2-(*m*-carboran-9-yl)oxycarbonyl]porphyrin, CP2 is 1,3,5,8-tetramethyl-6,7-di[2-(*o*-carboran-3-yl)carbamoyl]porphyrin, CP3 is 1,3,5,8-tetramethyl-6,7-di[2-(*m*-carboran-9-yl)methoxycarbonyl]porphyrin.⁵¹

demonstrate the least photosensitising activity (of all the porphyrins we studied) in the generation of singlet oxygen in homogeneous processes.⁸¹

The resolution of this paradox can be attributed to the specific structural organisation of porphyrin layers on the nanometre and submicrometre levels produced by packing of the porphyrin molecules deposited on a support under slow deposition conditions. Here, it is pertinent to note that the change in the angle (to 45°) at which the flux of porphyrin molecules is directed on the support has virtually no influence on the efficiency of the resulting layers towards photosensitised generation of singlet oxygen. This means that with the deposition conditions used, one can speak about realisation of quasi-steady-state conditions for the formation of film structure on different spatial scales, where the critical role is played by steric factors and intermolecular interactions. Evidently, the relatively bulky carboranyl substituents in the porphyrin molecules (especially in CP2 and CP3, whose molecules contain two such substituents) favoured the formation of less dense and 'more organised' (less 'chaotised') structures of deposited films under conditions of slow quasi-equilibrium deposition where a great free space ensured the possibility of more equilibrated adjustment of the porphyrin molecules getting on the surface to the structure of the layer. It is noteworthy that elucidation of the features of generation of singlet oxygen to the gas phase upon photoexcitation of deposited layers of various porphyrins allows a targeted search for efficient porphyrin-containing sensitising systems for liquid-phase oxidation of organic compounds.

VIII. Conclusion

The development of efficient catalytic systems based on immobilised metal complexes of porphyrins for specified chemical processes is faced with two types of problem. First of all, it is necessary to know the dynamics of an elementary catalytic event with allowance for all the key factors that influence the process kinetics (here, we mean the influence of electronic and conformation structures of MP, including the type of the central ion and side groups, the environment, and the dynamics of its fragments). Evidently, homogeneous catalyst systems based on MP and the systems with MP immobilised on soluble polymer supports should serve as model systems for the kinetic studies. It is necessary to take into account the role of the solvent and the functional groups (for example, amino acids) of the polymer in the catalytic activity of these systems. Recall that an amino acid residue (histidine) localised in place of one of the haem axial ligands regulates the enzymic activity of cytochrome *c*. A solvent that solvates the MP molecules can also affect appreciably the specific (per MP molecule) catalytic activity due to specific 'heterogeneity' of the solvation shell formed.

The second type of problem encountered in the development of immobilised metalloporphyrin systems is associated with elucidation of the role of the polymeric surrounding of MP. Although immobilisation of MP on a polymeric support results in all cases in lower mobility of the environment fragments near the MP, the choice of the matrix for immobilisation (polymers with functional groups, gels) leaves a place for variation of the local mobility of such fragments. The main point is to understand what positive effects can be attained and what type of labile environment (polar groups, amino acid residues, *etc.*) should be created.

A decrease in the mobility of fragments of the environment in the vicinity of the porphyrin ligand can bring about positive effects, in particular, decrease the probability that destructive factors would occur in the vicinity of the porphyrin ring. Perhaps, this accounts for the substantial increase (compared to the homogeneous case) in the turnover number of PMn immobilised on Nafion film until its degradation during non-chain hydroxylation of cholesterol.

It can be suggested that the search for new efficient porphyrin-containing polymeric systems will also continue along other routes. In our opinion, the main avenue of this research should be development of a fairly controllable labile environment of the porphyrin ligand — in conformity with the key principles of functioning of natural systems.

This work was carried out with the financial support of the International Science and Engineering Centre (Grant 1592) and within the bounds of the project for the Support of Leading Scientific Schools (Grant NSh 00-15-97431).

Modern methods for the determination of physicochemical states of microelements in natural waters

E V Polyakov, Yu V Egorov

Contents

I. Introduction	985
II. Instrumental methods	986
III. Hyphenated methods	990

Abstract. The state-of-the-art in studies on the determination of ion – molecular and colloidal forms of microelements in aqueous solutions is analysed. Instrumental and hyphenated methods for the determination of such forms of microelements as aqua-ions, complexes, true and adsorption colloids are considered. The bibliography includes 153 references.

I. Introduction

The methods used to monitor the concentrations of microelements in aqueous media, determine the sources from which they enter the hydrosphere and predict the dynamics of migration of separate physicochemical forms of microelements in the hydrosphere are of importance for studies in environment protection.^{1–5} A survey of publications on this subject over the past 10–15 years revealed considerable changes in the instrumentation and theoretical generalisation of methods used to determine the physicochemical state of microelements in aqueous media. We intend to analyse these changes in the present review.

The role of microelements in environmental objects is estimated by determining their concentrations in samples. If the content is low, concentration and separation methods based on distribution of microelements between phases, *viz.*, ion exchange, sorption, extraction, precipitation and coprecipitation, flotation, electroprecipitation, filtration, distillation, sublimation, dialysis, *etc.* are used, depending on the analysis scheme. Each of the methods listed above involves trans-phase interaction of separate chemical forms of a microelement; therefore, knowledge of the physicochemical state of a microelement in a sample is required in order to maximise its concentration and/or separation from admixtures. In the laboratory, this is achieved by converting the existing form of a microelement to a chemical form convenient for concentrating. Under field conditions, correction of the state of a microelement is often impossible or inefficient; therefore, the selection of a chemical analytical method for the determination requires independent information about both the chemical and

phase compositions of all the forms of the extracted microelement in the medium of interest.⁵

This problem has been studied insufficiently, so difficulties of a methodological nature exist. First, the physicochemical processes involving microelements and occurring in industrial and natural aqueous systems are complex indeed. Second, the development of the interphase distribution-based theory of reactivity in interrelated systems of ionic, molecular, colloidal and suspended forms of microelements in solution is in its infancy. Third, for field conditions (unlike laboratory conditions), there is a lack of approved methods for the determination of the chemical and phase compositions of microelements in natural aqueous media; approved test procedures and standard samples of their separate chemical forms are also unavailable.^{6–10} Fourth, it is necessary to consider the factors affecting the violation of equilibrium and/or steady states of microelements in a sample when it is transferred from a natural medium to a laboratory.^{1–9, 11}

Not only analytical chemists, but also heads of enterprises and bodies involved in environmental monitoring, are interested in development and perfection of methods for analysis of the physicochemical state of microelements in the hydrosphere.¹² The most promising methods result from combinations of column chromatography with high-performance spectrometric detection of separate elements. Analyses can be made less expensive by using combined methods of selective oxidation – reduction, coprecipitation, membrane extraction, dialysis and stripping voltammetry.^{12–18}

The relationships between the transport properties of microelements in the aqueous phase and the content of specific organic and inorganic components of soils or bottom sediments are studied using selective dissolution of groups of compounds, anion-exchange and distribution chromatography and ultrafiltration.^{1, 7, 9, 19} A sample can contain coexisting microelements as suspensions and colloids along with truly dissolved forms, including molecular, cationic and anionic complexes with inorganic and organic ligands.^{1, 19} Colloidal forms of microelements can be detected by sequential filtration of a liquid sample through membranes with pore sizes from 0.5 μm to 1 nm. Ionic compositions are determined by electrophoresis and ion-exchange chromatography after separation of the suspended fraction.^{20, 21}

In the early 1990s, the interest of researchers in the forms in which inorganic compounds exist in solutions increased due to the aggravation of global environmental problems (Fig. 1). As a result, new instrumental and combined physicochemical methods appeared; these methods made it possible to monitor not only the analytical concentrations of microelements in aqueous solutions, but also their chemical and phase compositions.

II. Instrumental methods

1. Time resolved laser fluorescence spectroscopy

Time Resolved Laser Fluorescence Spectroscopy (TRLFS) is a popular modern instrumental method used to determine the state of microelements in solutions.^{22–26} Neodymium lasers with a pulse energy of 2.5–2.7 mJ and adjustable frequency are the main elements of setups that implement this method. For example, the wavelength of 266 nm was selected to excite the fluorescence of UO_2^{2+} ions; pulse excitation is followed by a decay of the fluorescence signal in the wavelength range from 407.0 to 634.0 nm. This is measured by scanning at discrete times in the range from 0.1 to 15 μs . Each spectrum in this time range is obtained by averaging the results from 100 laser-induced excitations.²² This method was used to determine the interaction between uranium(VI) ions and silicic acid in model solutions of sodium perchlorate. Analysis showed²² that the red shift in the fluorescence spectrum is caused by chemical reaction of UO_2^{2+} with $\text{Si}(\text{OH})_4$.

According to the theory of fluorescence signal formation, the overall amplitude (A_0) and the amplitudes of signals from various complexes (A_i) are related by the following expression:

$$A_0 = \sum_{i=1}^n A_i e^{-t/\tau_i}, \quad (1)$$

where t is the signal relaxation time and τ_i is the characteristic time of fluorescence decay. It was shown²² that uranyl silicate complexes comprise species of a single type with the ratio $\text{UO}_2:\text{UO}_2\text{Si}(\text{OH})_3^+ = 1:0.95$. By decomposing the fluorescence spectrum into components, one can determine the stability constants of complexes directly in solution (without concentrating). By combining TRLFS and thermodynamic simulation methods, it is possible to use characteristic fluorescence spectra and τ_i values in order to identify uranium complexes (Fig. 2), including $\text{Ca}_2\text{UO}_2(\text{CO}_3)_3(\text{aq})$ in mine waters,²³ and determine the compositions and stability of complexes of trivalent actinides with natural analogues of fulvic and humic acids in model solutions^{24,25} and in hot brines.²⁶ The theory and potential of the TRLFS method are described in detail elsewhere.²⁷

2. Laser induced breakdown spectroscopy

Laser Induced Breakdown Spectroscopy (LIBS)^{28–30} is among the most promising instrumental methods for the study of the state of inorganic compounds in solutions. The method is based on controlled excitation of characteristic emission spectra. Plasma

Figure 2. Results of TRLFS determination of the compositions of uranium complexes (a–c);²² (1) UO_2^{2+} , (2) $\text{UO}_2\text{OSi}(\text{OH})_3^+$, (3) $\text{UO}_2(\text{OH})_2(\text{aq})$, (4) $(\text{UO}_2)_2\text{CO}_3(\text{OH})_3^-$, (5) UO_2OH^+ , (6) $(\text{UO}_2)_3(\text{OH})_5^+$, (7) $(\text{UO}_2)_2\text{CO}_3^{2-}$, (8) $\text{UO}_2(\text{CO}_3)_3^{4-}$.

with a temperature of 2500–25 000 K is formed by focusing a pulsed laser beam on the solution studied; the beam has a power density of $10^{15} \text{ W cm}^{-2}$ and creates an electrostatic field of up to $10^{11} \text{ V cm}^{-1}$ in the focal plane.²⁸ As the plasma temperature is lowered and the intensity of the continuous spectrum from the microsample within the sample decreases, characteristic lines of elements appear in the emission spectrum; they are analysed using a special detector.

The LIBS method is used to perform elemental analyses of solid samples (alloys, soils, minerals, microelectronic devices), liquids (milk) and gases (air, aerosol particles). The application of this method to analysis of liquids opens up new prospects in chemical analytical studies.^{28,30} Transformation of an aqueous solution or droplet-sized samples to plasma by a laser beam with a wavelength of $\sim 500 \text{ nm}$ with beam focusing makes it possible to obtain signals from microelements that exist as colloidal phases or adsorption colloids (in this case, the intensity of emission lines is 10^3 times higher than that from ionic and molecular forms of the same element).

The use of the method under consideration in studies of uranium, americium and plutonium migration with ground waters makes it possible to determine the amounts of colloidal fractions of these elements in complex natural objects. By varying the power of the laser beam, it is possible to determine the phase compositions and sizes of colloid particles of hydroxycarbonates of certain transuranium elements [e.g., $\text{Am}(\text{OH})\text{CO}_3$] at their

solution concentrations of 10^{-5} – 10^{-6} mol litre $^{-1}$. The LIBS method is most sensitive to low concentrations of colloid particles typical of natural waters. In the case of high concentrations of such particles (*e.g.*, in aqueous carbonate solutions of uranium and plutonium), the intensity of emission lines of an element decreases due to secondary oxidation of metal atoms in hot plasma and due to multiple scattering effects. To determine the phase composition and size distribution of colloid particles, it is recommended that the LIBS method be combined with other colloid fractionation methods.^{28,29}

3. Laser photo-acoustic spectroscopy

The potential of a new highly sensitive method for the determination of the state of ionic and colloidal forms of microelements in solutions, *viz.*, laser photo-acoustic spectroscopy (LPAS), is based on the absorbing ability of species being studied and on the power of the available pulse laser with adjustable wavelength.³¹ The intensity of the photo-acoustic signal in this method is proportional to the power density absorbed by particles. The method is based on the determination of characteristic changes in the volume of molecules of a compound of interest (that are in contact with solvent molecules) caused by emission of thermal energy upon transition from an excited state to a ground state following selective absorption of laser irradiation quanta.

The selectivity of LPAS is determined, first, by the high conversion efficiency of absorbed energy of monochromatic irradiation into thermal energy; second, the possibility of recording (using high-precision piezoelectric sensors and detection circuits with high time resolution) a sound wave that appears due to changes in the volumes of molecules upon their deactivation.^{31–38} In addition to a laser, the main elements of a photo-acoustic registration system comprise a cell for the solution being studied, a transducer of ultrasonic waves to voltage pulses, and an electronic system for starting the registration scheme, digitising and storing of data that arrive from the ultrasonic transducer. The construction of miniaturised photo-acoustic cells allows one to study microsamples (down to 10^{-7} dm ^{3}) in real-time mode.^{32,33}

The LPAS method can be used to determine a microelement concentration down to 5×10^{-6} mol litre $^{-1}$ and to monitor its variations in time, both in homogeneous and heterogeneous samples. The LPAS method has the advantage that it allows one to determine the physicochemical state of elements in aqueous solutions simultaneously containing molecular forms as well as true and adsorption colloids of microelements.^{31,35–38} This method was used to study the state and sorption behaviour of Cr(VI) microquantities on hematite under competitive sorption of phosphate ions,^{35,39} to determine the concentration and sizes of Tc(IV) colloid particles^{36,38} and to reveal the physicochemical state and nature of Np(IV) colloids.³⁷

4. X-Ray absorption spectroscopy

X-Ray spectroscopic absorption methods with the use of synchrotron radiation are widely used to study the nearest environment of atoms of a microelement in aqueous and heterogeneous electrolyte–solid systems.^{40–67} Data on the structure and short-range order of microelement compounds in a suspended adsorbed state can be obtained by EXAFS (Extended X-Ray Absorption Fine Structure) and XANES (X-Ray Absorption Near Edge Structure) methods.⁴¹

The EXAFS method provides extended data on the local environment of an absorbing atom, namely, the type and number of its nearest neighbours, interatomic distances in a sphere with a radius of 5–6 Å; furthermore, information on bond angles can be obtained based on multiple diffusion of photoelectrons and on data for near-edge absorption of several different elements in a compound studied. The EXAFS oscillation structure originating from diffusion of photoelectrons on atoms of the local environment is usually observed in the range of 100–1000 eV above the absorption edge.

The XANES method is used to study the electronic structures of compounds. Using this method, one can obtain information, *e.g.*, about the oxidation state of the absorbing atom and on the symmetry of its coordination sphere. An XANES structure occupies the range from ~ 50 eV before the absorption edge to 100–150 eV after the edge. The resonance bands generated by electron transitions from the core level to vacant levels up to removal of the electron from the atom (photoionisation) are comparatively narrow; the bands after the absorption edge, which correspond to electron transitions to quasi-bound states, are broader.

Both methods are used to study the state of elements in bulk samples and in surface phases that are formed due to sorption processes involving microelements and surface sorbents, *i.e.*, soils and colloid particles.

If traditional instrumental methods are used to study the state of microelements in a liquid phase (*e.g.*, UV and IR spectroscopies), distinguishing individual signals corresponding to a compound of interest from those corresponding to the support without their chemical separation is the main difficulty.⁴¹ After chemical separation, it is incorrect to apply data on the composition of chemical forms of a microelement to the original natural solution or heterogeneous system.

The EXAFS method is devoid of such restrictions, because, as noted above, the spectra contain information about the chemical environment, interatomic distances and the number of the closest neighbours of a microelement atom.⁴¹ In fact, it was noted in an EXAFS study on the identification of the state of hardly soluble lead compounds in soil that it was possible to decrease the detection limit of chemical compounds (below 10^{-3} mass%) at a relative measurement error of 5%.⁴¹

By combining the EXAFS method with free boundary electrophoresis, it is possible to reach sensitivity of 10^{-5} – 10^{-8} mol litre $^{-1}$. It was shown using these methods that the sorption of uranium by hematite at pH 4.5 is caused by partial binding of carbonate (hydrogencarbonate) anions with uranyl cations in monomeric carbonate uranium complexes. However, it is dimeric complexes that are responsible for the sorption of uranium on the surface around pH 6.5. Based on this fact, it was concluded that the mobility of U(VI) tricarbonates complexes in ground water is low.⁴³

Studies on the state and sorption behaviour of actinides with different oxidation states showed that their mobilities were considerably affected by the redox potential of the solution. Foster *et al.*³⁵ and Antonio *et al.*⁴⁴ developed a procedure to determine the formal redox potentials of neptunium in soil and ground waters for the Np(IV)/Np(V) and Np(IV)/Np(III) pairs and formulated the objectives for subsequent EXAFS studies on the sorption behaviour of neptunium complexes in natural waters. This method was used to study the coordination environment of Cd(II) sorbed by goethite in the presence of sulfate, oxalate and citrate ions and anions of humic acids; it was shown that cadmium atoms are surrounded by six oxygen atoms in the first coordination sphere and by two iron atoms in the second sphere.⁴⁵ In oxalate and citrate solutions, precipitation of a sparingly soluble cadmium compound on goethite facets occurs. A drawback of the latter study⁴⁵ is that the results obtained for cadmium concentrations of 10^{-3} – 10^{-4} mol litre $^{-1}$ in solution were extrapolated to the region of microconcentrations typical of soil and ground waters.

The EXAFS method was used to obtain structural information on the composition of cadmium, zinc and copper complexes with organic ligands in non-aqueous solutions;⁴⁶ data on the composition and structure of chloride Cu(II) complexes at ordinary and elevated temperatures in solutions simulating sodium chloride thermal water by matrix elements are reported by Collings *et al.*⁴⁷ It was shown that copper chloride complexes are not formed in the temperature range of 25–75 °C at sodium chloride concentrations in the range of 0.2–2.2 mol litre $^{-1}$; under hydrothermal conditions, the CuCl^+ and CuCl_2^0 species

start to predominate as the temperature is increased from 125 to 175 °C; at chloride concentrations up to 5 mol litre⁻¹ in the temperature range of 25–75 °C, the CuCl₃⁻ and CuCl₄²⁻ species predominate, but the CuCl⁺ and CuCl₂⁰ species start to predominate again at 175 °C (due to the formation of Na–Cl ion pairs).

The EXAFS method was used to study the state of AuCl₃ in chloride solutions.⁴⁸ Sherman *et al.*⁴⁹ analysed the state of different-valent tin chloride complexes in 0.5–2.5 mol litre⁻¹ sodium chloride solutions in the temperature range of 25–250 °C. Data on the coordination of copper, zinc and arsenic ions in sodium hydrosulfide solutions were reported.^{50, 51} Seward *et al.*^{52–54} used EXAFS to determine the state of AgNO₃, CdCl₂, AgClO₄ and SrCl₂ in aqueous solutions. Mosselmans *et al.*⁵⁵ studied the coordination of molybdenum, cobalt and cadmium aqua-complexes; the state of antimony and yttrium in chloride solutions was studied in a number of works.^{47, 48, 56, 57} The compositions of metal complexes (in particular divalent and tetravalent tin complexes) found by EXAFS sometimes noticeably differ from the compositions obtained by thermodynamic simulation:⁴⁹ in the chloride concentration range 0.5–2.5 mol litre⁻¹ and the temperature range of 25–350 °C, an increase in chloride concentration increases the numerical value of factor *n* in the formula SnCl_n²⁻ⁿ from 3.4 to 3.9, which suggests that the SnCl₃⁻ and SnCl₄²⁻ complexes predominate. If the temperature has been increased from 250 to 350 °C, the SnCl₄²⁻ complexes are mainly present. The SnCl₆²⁻ complex predominates in oxidising media; this implies higher solubility of SnO₂ (in comparison with that obtained by thermodynamic calculation) in this medium and the possibility of efficient transport of di- and tetravalent tin in hydrothermal processes.

It is particularly efficient to use EXAFS spectroscopy in combination with molecular dynamics methods in studies on the polymerisation of aqua complexes in solutions, because it is possible to register changes in the inner coordination sphere (metal–ligand–metal) directly. In this way, the polymerisation of SrCl₂ in concentrated chloride solutions was confirmed directly.⁵²

This method is efficient in studies on ion–molecular and other forms of elements in solutions. However, its use in ecological studies of natural waters that have complex microelement compositions is presently limited by the low sensitivity and selectivity, as well as by the necessity of preliminary withdrawal and conservation of samples.

The XANES method, which is being intensely developed at present, is much more sensitive.^{58–67} Using this method, one can analyse the chemical bonds between atoms, oxidation states and chemical compositions of compounds formed by microelements at their solution concentrations of about 10⁻⁶ mol litre⁻¹. The theory of the method has been described in a number of publications.^{65–67} The XANES method was used to obtain data on the sorption behaviour of lead in soils,^{62, 63} the physicochemical state of arsenic in bottom sediments,^{59, 60} the mechanism of Cr(VI) reduction in natural solutions⁶¹ and also to study the state and sorption behaviour of separate valent forms of plutonium in the water–soil system.⁶⁴

5. Mass spectrometric methods

The Laser Microprobe Mass Spectrometry (LMMS) and especially the Static Secondary Ion Mass Spectrometry (SSIMS) methods are used as direct instrumental methods for determination of the physicochemical state of microelements that predominantly exist in the adsorbed state. The characteristic mass spectra of simple ions and ion clusters serve as the main source of data on the chemical composition of compounds being studied.⁶⁸

The use of LMMS mass spectrometers with Fourier transform of the signal provides a mass resolution of 10⁵ with a sensitivity of about 1 ppm for separate ions.⁶⁸

The instrumental potential of Secondary Ion Mass Spectrometry (SIMS) for chemical analysis of microquantities of inorganic compounds is more versatile, since the signal results from

bombardment of the surface of a sample of interest by a primary ion beam (*e.g.*, Ar⁺, O⁻) with an energy of several kiloelectronvolts. This increases considerably the intensity of the secondary beam of ions (both positive and negative) from the sample and the overall sensitivity of the method. The static version of this method, *viz.*, SSIMS, employs a low-intensity beam of primary particles, thus making it possible to study compositions of compounds with extremely high mass numbers. The sensitivity of the SSIMS method can range within 10²¹–10¹⁵ atoms cm⁻². Time of Flight Static Secondary Ion Mass Spectrometry (TOF SSIMS) makes it possible to identify the molecular composition of a compound of interest based on the set of secondary ion clusters, which is unique for each compound.^{68, 69} Therefore, when analysing biological and natural solid samples, compounds can be identified by matching the sample composition with the secondary ion spectrum.⁶⁸

Mass spectrometric methods are used in high-precision studies on the molecular composition of microcomponents with concentrations below 10⁻⁶ mol litre⁻¹. These methods are primarily used to assess the state of adsorbed compounds. A mass spectrum obtained by SSIMS is a superposition of spectra corresponding to original molecular states of microelements and to their reaction products with stable ions in the gas phase. In the LMMS method, the possibility of obtaining mass spectra of molecules of interest is based on the specific features of the signal formation. An advantage of the LMMS method is that it provides a relatively high spatial resolution on the sample surface (0.1–10 μm); the SSIMS method makes it possible to perform sequential in-depth analysis of a sample at molecular resolution. Owing to the high signal-to-noise ratio, the LMMS method provides direct (that is, without the use of composition standards) data on the molecular composition of samples. To obtain such data by SSIMS, one has to compare the mass spectra of a sample in question with the mass spectra of samples with standard compositions. Evidently, the two methods complement each other. They can be modified in order to study the chemical composition of microelements in solution, provided that the relationship between the composition of the solid sample being analysed and the composition of the original sample is established when the solution is being prepared for analysis.

The problem of sample preparation for mass spectrometric studies on the composition of complex compounds of microelements in solutions is solved, to a considerable extent, by using Electrospray Mass Spectrometry (ESMS).⁷⁰ It is used for quantitative determinations of metal ions in inorganic, organometallic and complex compounds and is based on a genuine way of generating ionic clusters.

The experimental value of the ESMS method is that electro-spraying of a sample transfers ions and molecules existing in the original solution to be studied to the gas phase. This occurs due to two main processes, *viz.*, creation of charged micro-droplets of the solution and transfer of ions of elements from the micro-droplets to the gas phase. The original information on the chemical composition and oxidation state of an element is preserved in these processes. Charged micro-droplets are formed on passing a solution of interest through a conductive capillary with an inner diameter of ~ 100 μm kept under a 2–4 kV voltage relative to the counter-electrode, as a rule, the mass spectrometer sampler (the tool for introducing a sample into the mass spectrometer). Under an electric field gradient, separation of charges occurs in the surface layer of electrolyte micro-droplets; as a result, it acquires an excess positive charge leading to intense carryover of positive ions from the surfaces of micro-droplets and evaporation of the surface layer of the liquid meniscus in the capillary (Taylor's cone).⁷¹ Owing to the electrophoretic motion of the liquid in the near-surface region, the charged surface layer stretches as a thin (1–10 μm) fibre towards the sampler of the mass spectrometer, breaks into positively charged micro-droplets and forms a cone in a stable electro-spraying mode.⁷²

The field of application of ESMS includes studies on molecular reactions in the gas phase and formation of bioorganic and organometallic complexes in non-aqueous solvents.⁷⁰ The drawbacks of the method include the complexity of sample preparation from natural objects and the necessity of maintaining reproducible instrumental conditions when mass spectra are recorded. An advantage of the method is that information on the oxidation states of metals (microelements) in aqueous solutions and on the presence of mono- and polyatomic anions (nitrates, thiocyanates, chromates, permanganates, oxohalides, various sulfur anions, *etc.*) and transition metal complexes with inorganic and organic ligands can be obtained. The limitations of the quantitative version of this method include the dependence of the reproducibility and sensitivity in the determination of clusters of microelements on the solution electrical conductivity and the narrow signal range (3–4 orders of concentration). These limitations can be eliminated by simultaneous spraying of an additional background electrolyte solution. This will make it possible to determine the chemical composition of microelements at concentrations $\sim 10^{-8}$ mol litre⁻¹ (see Ref. 70).

Determination of the state of microelements by ESMS in real natural solutions is complicated by the noise that appears in the mass spectra. Preliminary separation of elements and their chemical forms, *e.g.*, by high-performance liquid chromatography and other methods, is used to increase the signal-to-noise ratio.^{70, 73}

6. Voltammetry methods

Electrochemical methods are among the most convenient instrumental methods for the study and determination of the ion-molecular state of microelements in natural aqueous solutions; of these, Stripping Voltammetry (SV) is worth special attention.⁷⁴ The main advantage of this method in studies of natural waters is its selectivity with respect to separate chemical forms of microelements and low detection limits of microelements. The relatively low cost of analysis, the possibility of its automation and the small size of the instruments make it possible to use the stripping voltammetry under field conditions, in particular, in prolonged continuous analyses and when composing distribution maps of separate forms of microelements in seawater and fresh water as part of above-water and underwater experiments.⁷⁴ After preliminary concentration of a microelement from the aqueous phase, the SV method can be combined with subsequent cathodic or anodic dissolution of the analyte accumulated on the working electrode.

The multi-element version of the accumulation method makes it possible to reach detection limits of microelements in seawater as low as 10^{-10} – 10^{-12} mol litre⁻¹ (Ref. 74). Up-to-date polarographs are three-electrode systems (working electrode, auxiliary electrode and reference electrode); a dropping mercury electrode, a hanging mercury drop electrode or a thin rotating film mercury electrode is used as the working electrode. In the former case, measurements are carried out on a continuously renewed surface of the working electrode; this is advantageous as high analysis reproducibility is ensured. The second version is usually implemented by electrodeposition of mercury on surfaces of glassy carbon, graphite, metallic conductors (gold, iridium), graphite fibre; this enhances the sensitivity owing to high ratios of the working electrode surface to the solution volume.

In recent years, mercury (deposited on carbon fibre or iridium wire) and gold microelectrodes with sizes < 10 μ m have become more and more popular. They are characterised by a much weaker effect of capacitance current and an increased signal-to-noise ratio; these electrodes allow microelement concentrations $< 10^{-10}$ mol litre⁻¹ to be determined owing to an improved efficiency of deposition on the working electrode and the suppression of diffusion effects.

Stripping voltammetry with anodic polarisation (Anodic Stripping Voltammetry, ASV) is used successfully to analyse relatively high (due to adverse effects of overlapping of signals from interfering elements) concentrations of copper, cadmium, lead, zinc and thallium in seawater.⁷⁴ It is recommended to

increase the negative potential in the metal deposition stage so as to make it 0.3–0.4 V higher than the reduction potential. After accumulation of a microelement of interest as an amalgam in the reduction stage, subsequent anodic polarisation of the working microelectrode results in oxidation of the reduced form of the microelement, thus providing both quantitative and qualitative information (as the oxidation potential is a specific characteristic of an element) about the metal on the electrode. The method requires additional analytical operations, *viz.*, calibration and standardisation of measurements.

The SV version with cathodic polarisation and adsorption of the sample (Adsorptive Cathodic Stripping Voltammetry, AdCSV) is a more sensitive method used as an alternative to traditional inversion voltammetry. The sensitivity is increased by introducing a specific ligand into a solution. The role of the ligand is to form a relatively stable complex ion with the microelement being determined which can be adsorbed on the working electrode surface at constant potential and then be involved in the reduction process. The reduction is generally carried out with linear sweep of the signal amplitude; if the discharge electrochemical stage is reversible, a square high-frequency AC component is applied. This suppresses the interfering capacitance currents, slows down the competing step of adsorbed oxygen reduction and shortens the analysis duration. The techniques described above create conditions for reaching very low detection limits of metals (10^{-12} mol litre⁻¹ for cobalt, platinum, titanium) in seawater.⁷⁴

The high sensitivity for trace amounts of compounds makes SV a convenient method to study forms of existence of microelements in aqueous solutions. For example, the concentrations of many transition metals (cobalt, copper, iron, zinc) in natural water (river, lake, seawater) are generally extremely low but they can considerably affect biochemical processes involving hydrobionts.^{75–77} Simple aqua ions are the most bioactive and toxic forms as they easily penetrate cell membranes of phytoplankton and algae. Complexes with organic ligands (humic and fulvic acids, ethylenediaminetetraacetic acid, *etc.*) are devoid of this ability, and the susceptibility of micro-organisms to these metals decreases if such ligands are present in aqueous solutions.

In studies on exchange processes, the SV method is one of the few instrumental methods that make it possible to determine the valence of microelements in solutions, as well as the fractions of separate microelements in the free form and as organic complexes at concentrations around 10^{-9} mol litre⁻¹ in natural water (see Refs 78–92). For example, it was shown using the AdCSV method that the natural state of Cr(VI) in Mediterranean Sea water matches the data from thermodynamic calculations of the concentration of the most stable form of chromium, CrO_4^{2-} , in an oxygen-saturated solution. However, determination of the overall chromium content in seawater after decomposing its organic complexes by UV irradiation and sorption separation of Cr(III) showed that it contains tri- and hexavalent chromium ions (Fig. 3). The presence of trivalent chromium is explained by the photochemical reduction of the CrO_4^{2-} ions in the seawater surface layer.⁷⁹

The ratio of free metal forms to those bound in complexes can be found using the ASV and AdCSV methods. The equilibrium concentrations of an aqua ion and its labile complexes with inorganic and organic ligands are determined using the ASV method. The AdCSV method is used to establish the chemical nature of organic ligands. To do so, it is necessary to provide conditions for competitive complexation of an added ligand (with a known complexation scheme) and natural ligands in a solution of interest. Based on results of concentration measurements for the free and bound forms of a microelement, the concentration complexation constant with natural ligands is calculated. The true compositions of organic (primarily bioorganic) complexes of the majority of microelements in seawater and fresh water are unknown; algae and products of phytoplankton biodegradation are believed to be the main sources of organic ligands.⁷⁴ For example, it was found by means of SV that over 99% of dissolved

Figure 3. Concentration profiles of Cr(III) (1), Cr(VI) (2) and total chromium (3) at different depths of the western part of the Mediterranean Sea determined by AdCSV.⁵⁵

iron is bound with organic ligands and is characterised by an arbitrary complexation constant of $\sim 10^{18}$. Using SV combined with direct determination of microelement concentrations and preliminary filtration-based fractionation, it is possible to determine the ratio of ion–molecular and colloidal forms of a metal of interest.

III. Hyphenated methods

At present, studies on the physicochemical state of microelements in solutions combining techniques for separation of individual microelement forms with high-sensitivity instrumental methods for detection of separated microelements have become one of the leading directions.^{7,9,93–102} In favour of this is the appearance of high-sensitivity instruments for electrochemical, emission and mass spectrometric analyses.

1. Chromatographic methods

Numerous procedures have been developed based on chromatographic methods including a procedure for the determination of hexavalent chromium and tungsten by extractive isolation of their ternary complexes with rutin (quercetin-3 β -rutinoside) in the presence of cetyltrimethylammonium and procedures for determination of the valence and chemical composition of molecular and cationic complexes of tri- and pentavalent arsenic (mono- and dimethylarsonium, arsenobetaine and some other arsenic compounds), organic and inorganic derivatives of tetra- and hexavalent selenium, divalent lead and mercury, di- and tetravalent tin, tri- and hexavalent chromium.¹⁰³ The multistage separation and independent determination of the forms of state of these microelements in aqueous media are carried out by automated control of the chromatographic process, using standard samples of the states and compositions of microcomponents in the medium of interest or in some other similar medium. The sensitivity of hyphenated methods with respect to separate chemical forms can reach $10.0\text{--}0.01\text{ }\mu\text{g litre}^{-1}$ for media in which the chemical compositions of the complexes to be analysed are known beforehand.

In their review, Vanhaecke and Moens⁹⁴ analysed works published in the past decade and dealing with chromatographic methods with mass spectrometric detection for the determination of the chemical composition of microelements in natural objects. Of these, column separation with reversed phases, ion-exchange sorption, ion pair sorption and gel filtration are the most popular methods. The latter method can be used to determine simulta-

neously the behaviour and degree of complexation of metal ions in natural waters in the presence of dissolved organic compounds. This is achieved by combining gel filtration and mass spectrometry with simultaneous determination of the total carbon content (e.g., by UV spectroscopy) in the fractions eluted from a chromatographic column.⁹⁴

Today, the analytical instrumentation market offers transportable toolkits for the analysis of the chemical state of separate microelements. A toolkit comprises a microcolumn of specific type for high-performance liquid chromatography (HPLC) combined with a mass spectrometer; this allows one to determine the concentration of separate valence forms of such microelements as chromium, selenium and arsenic.

Hyphenated methods based on chromatography are beginning to compete with traditional radiochemical methods for the analysis of the isotopic and elemental composition conventionally used in technologies of processing and burial of spent nuclear fuel. Using the methods considered here, one can determine the forms of migration of both radionuclides corresponding to the middle of the Periodic System (s-, p-, d- and f-elements) and trans-actinide elements.^{104–110} The possibility of using inductively coupled plasma mass spectrometry and thermal-ionisation mass spectrometry was shown: preliminary HPLC separation of ionic complexes of uranium, americium, and curium is followed by determination of the $^{241}\text{Am}/^{238}\text{U}$ and $^{244}\text{Cm}/^{238}\text{U}$ isotope ratios in separate chemically pure fractions with the use of the double isotope dilution method.¹¹¹ The chemical separation of uranium and plutonium was performed in an anion-exchange column; that of americium and curium, by HPLC (stationary phase, Nucleosil SA; 0.14 M 2-hydroxy-2-methylbutyric acid, pH 4.1 as the eluent). The use of the hyphenated method provides a relative determination error of 2.5% in the isotope ratio range from 1 to 0.001.

Hyphenated methods are generally used with standard samples of states of the microelements studied (e.g., alkyl derivatives of tin, mercury and arsenic). Their kinetic inertness makes it possible to neglect the effects of foreign components, that is, potential ligands and competing complexing agents, when an aliquot of the standard is added to the solution under study.¹¹²

An example of the use of hyphenated methods for determining the states of labile organic and inorganic metal complexes is given by Pesavento *et al.*¹¹³ who studied the formation of manganese, nickel, cadmium, and copper complexes with ligands of unknown composition. The Chelex-100 chelating resin with iminodiacetate groups was used as a selective ion exchanger. The state of ions of these elements in seawater (samples from Ligurian Sea, Italy) was determined by ion-exchange titration of the solution with a selective ion-exchange resin under static conditions. Based on the results of titration, the content of the elements sorbed by the ion-exchange resin was determined from the ratio of the volumes of the solution and the resin. The total concentrations of an element in a system with standard composition and in a natural system being studied, as well as the coefficient of side reactions were found from experimental data using the Schubert method. The agreement between the results of measurements served as a criterion that the degree of complexing of a microelement with ligands of unknown nature in seawater was determined correctly. Seawater was initially purified from suspended matter and (partially) from colloidal particles. Therefore, one can characterise the ratios of simple and complex ions of manganese, nickel, cadmium and copper in seawater, but not the composition and nature of these complexes, based on information obtained. Pesavento *et al.*¹¹⁴ also studied the physicochemical state of aluminium in potable water by ion exchange titration and found that very stable aluminium complexes with complicated composition were present at pH 6–7 in addition to aquahydroxo complexes.

The application of chromatography-based hyphenated methods makes it possible to carry out detailed studies on the state of microelements, identify their oxidation states and determine their environment in both simulated and natural aqueous systems.^{114–117}

2. Electrophoresis

Methods for the determination of the state of stable and radioactive microelements based on the analysis of electrophoretic mobilities of ions and colloidal particles in a free electrolyte and in a porous medium have been used for a long time. Both theoretical and methodical approaches have been developed for these methods.^{7,9,95,96} The application of such methods has broadened considerably over the past decade. Instruments based on the principle of capillary electrophoresis are now commercially available.^{118–121} These instruments are successfully used in radiochemistry and in ecological and biochemical studies in order to determine the charges of individual ions, oxoanions, as well as inorganic and organic metal complexes.^{119–121}

Separation by capillary electrophoresis is based on differences in the migration of ions of microelements along a capillary filled with a solution of an electrolyte. The capillary diameter is close to the thickness of the dense part of the double electric layer at the capillary walls; therefore, the resulting mobility of ions in the capillary is concurrently affected by the electrophoretic and electroosmotic flows of the electrolyte.

Two versions of capillary electrophoresis are used, *viz.*, zone electrophoresis in free electrolyte and electrokinetic micellar chromatography. The first version is used to separate individual chemical forms of a microelement in ordinary solutions. In this case, separation depends primarily on the ratio of the charge of a solvated ion to the size of its solvate shell. The second variant is intended for separation of microelements in micellar (colloidal) solutions; its efficiency is mainly determined by the micelle charge and the mechanisms of distribution of the molecular forms of the microelement between the electrolyte and micelles.¹²⁰ Capillary electrophoresis is particularly efficient if the element being determined is present as both charged complexes and colloidal particles. As in the case of free boundary electrophoresis, the efficiency of separation of individual microelement forms is strongly affected by kinetic factors of the reaction of the complex-forming ion with the ligands.^{112, 119, 120}

A number of publications are available^{119–122} on the results of separations and determinations of metals in various oxidation states by combined methods based on capillary electrophoresis on quartz glass microcolumns. For example, the following elements were separated and determined: selenium, arsenic, tin, mercury, chromium, iron, platinum and vanadium; trivalent iridium, europium, cadmium and tetravalent rhodium, $\text{Al}^{3+} - \text{F}^-$ complexes, divalent zinc, di- and trivalent cobalt and a number of their alkyl derivatives, amino, cyano, chloro, and acetate complexes, both in artificial solutions and in river water, seawater and rainwater, as well as in soil extracts, liquid radioactive waste and biological environments. The following issues were noted: insufficient sensitivity of detecting instruments, necessity of using spectral detection methods, improvement of sampling methods and methods for preparation of media for sampling, improvement of procedures for checking the quality of analytical data obtained, and creating a base of standard samples of particular microelements and media in various states.

3. Filtration methods

In the past decade, there has been an increasing number of studies on the role of the colloid-dispersed state of microelements in their migration in water.^{123–153} The usual method of studying the colloidal state of microelements employs the principle of ultrafiltration. Chemically inert filtering materials with pore size from a few nanometres to tens of nanometres have been developed. Filtrating devices using both ordinary frontal filtration and cross-flow filtration (CFF) are now commercially available. Owing to the more favourable flow dynamics, the latter variant provides considerable advantages in studies on the size of colloidal particles, their charge and chemical nature.^{130–140}

The CFF principle involves the separation of colloidal particles with a volume concentration c_B on a membrane filter surface.¹³⁸ The movement of the incoming colloidal solution

occurs laterally with respect to the porous membrane surface, while the filtration occurs tangentially with respect to the wall due to the hydrostatic pressure gradient, which appears in the near-the-wall liquid film because of the concentration polarisation, and a change in the penetrating filtration flow (J). The J value depends on the concentration parameters of a colloid solution by the relationship

$$J = k \ln \left(\frac{c_w - c_p}{c_B - c_p} \right), \quad (2)$$

where k is the mass-transfer coefficient determined experimentally or from empirical hydrodynamic relationships; c_w is the concentration of colloidal particles near the wall; and c_p is the concentration in the flow that has passed through the membrane. The initial flow of a liquid being analysed is divided into two flows during cross-flow filtration: the penetrated and delayed flows. It is the ratio of concentrations in these flows that carries information about the content of the colloid fraction, for which the rejected particle size is equivalent to the membrane pore diameter, in the original flow.¹³⁸

A comparison of cellulose- (Millipore Pre-scale CFF) and polysulfone-based (Amicon CFF) commercial filters in the cross-flow filtration mode¹³⁹ showed their similar efficiencies: both filter types retain up to 91% of colloidal particles with rejected sizes shown in the filter passports. The major fraction of standard colloidal dextrin solution with a nominal molecular mass of 3000 is removed from water by filters with a rejecting mass of 1 kDa; up to 30% of colloidal dextrin particles are lost in the case of polysulfone-based membranes owing to the sorption in the filter material. Losses of protein colloids (in particular, lactalbumin) are considerable on both filters. The content of colloidal particles of organic carbon introduced in seawater as a standard is determined without a systematic error. However, when seawater is analysed using cross-flow filtration, 'breakthrough' of some fractions of both low- and high-molecular fractions is observed.^{140, 141}

For example, in a study of organo-inorganic colloids of ^{230}Th and ^{234}Th in seawater by ultrafiltration it was found that physical separation of the ionic and colloidal fractions of thorium on membrane filters with rejecting mass < 10 kDa is accompanied by adsorption of micro-quantities of thorium and mechanical interaction with the membrane material (polysulfone, polypropylene, *etc.*).¹⁴⁰ The adsorption losses increase with a decrease in the organic carbon concentration; they cannot be suppressed by acid treatment of the membranes. In total, the changes in the fraction of the colloidal fraction of ^{234}Th coincide with the changes in the concentration of the colloidal fraction of organic carbon with molecular masses > 10 kDa.

Using frontal or cross-ultrafiltration in combination with monitoring the sizes and charges of particles by dynamic light scattering methods (laser photon-correlation spectroscopy) and Doppler electrophoresis, it is possible to determine not only the usual characteristics of colloids but also their acid–base properties. These methods were employed¹³⁰ to show the possibility of transferring natural colloidal particles from an estuary (river–sea hydrochemical border) to an electrolyte solution followed by determination of the acid–base properties of the colloids that have been concentrated. Furthermore, a conclusion about the nature of an organic colloidal compound in river water was drawn, and the range of organic colloid sizes (2–3000 nm) in the electrolyte solution after filtration concentrating was determined. It was found that the particle size increases with time and decreases with an increase in pH of the electrolyte. The acid–base properties of freshly prepared concentrates of a natural organic colloid differ from the acid–base properties of humic acids. This fact was explained¹³⁰ by possible formation of organo-mineral colloids involving large particles of colloidal iron hydroxide.

Sorption of humic acids on the surface of boehmite ($\gamma\text{-AlOOH}$) particles involves a similar interaction mechanism of

colloidal particles: anion exchange of ligands occurs in the initial stage; after that, the organic acid undergoes condensation on the hydroxide surface as its concentration increases.¹⁴² The ion-exchange mechanism of interaction of organic and inorganic colloids is considered as a complex variety of the metal–ligand coordination interaction¹⁴³ characteristic of microcomponents with high hydrolysis constants (in particular, for high-charged ions of transition metals and actinides).^{131, 144, 145} In radiochemistry, such interaction occurs during the heteronucleation of colloids present in trace amounts.⁹

The real picture of stepwise colloidal interactions in natural aqueous systems is complicated by the fact that colloids of inorganic hydroxides of the majority of transition metals present in trace amounts are nano-sized particles,^{107–114} migration of which in natural waters increases considerably in the presence of humic acids. The migration of microelements mainly occurs by this mechanism.^{123, 124, 131, 146}

The discreteness of fractional analysis of the colloidal state of microelements in frontal and cross-ultrafiltration methods does not allow the size distribution of colloid particles to be estimated and hence prevents a comprehensive explanation of the effects of size on the physicochemical state and migration. The drawbacks of filtration methods also include poor resolution of particles according to size and frequent fouling of filter pores.

These drawbacks are eliminated in a hyphenated method uniting sedimentation separation of colloids in a centrifugal field with mass spectrometric detection of the elemental compositions of separate colloidal fractions in the stream (Sedimentation Field-Flow Fractionation, SdFFF).^{128, 147–153} According to this method, the capillary with the colloid solution of interest is simultaneously affected by a tangential centrifugal field and a longitudinal axisymmetrical pressure field. The effect of these fields on the flow results in separation of particles into fractions, which are successively eluted from the capillary. The concentration of colloidal particles in the eluate is determined by inductively coupled plasma mass spectrometry or by UV spectroscopy. The method makes it possible to concentrate colloidal fractions. The eluate fractions can be passed for a more thorough study of the composition of colloidal particles by scanning tunnelling microscopy, X-ray diffraction analysis and X-ray fluorescence spectroscopy.^{128, 148–153} Based on SdFFF data, one can plot a differential curve of distribution of colloidal particles against eluate fractions (volumes) or elution time, and then according to the diameters of spherically similar particles with concentrations $< 100 \mu\text{g litre}^{-1}$. By comparing distribution curves for organic carbon and separate elements, particles are identified as true colloids or pseudo-colloids (of organic or mineral nature). This method is particularly efficient in studies of the state of colloidal forms of microelements.

* * *

By now, studies of physicochemical states of microelements in aqueous media have become an independent scientific direction of interdisciplinary type that combines problems and methods of analytical and physical chemistry of ultra-dilute solutions, radiochemical and geochemical analysis of the ion–molecular and phase analysis of compounds. It is obvious that the instrumental base is growing rapidly, and ample new information is therefore appearing about the chemical, phase and dispersion composition and reactivity of separate forms of stable microelements both in natural systems and their geochemical combinations.

This study was financially supported by the Russian Foundation for Basic Research (Project No. 01-03-33177).

IV. Design of molecular magnets	1006
V. Conclusion	1008

Abstract. The review concerns the state-of-the-art in studies on the magnetic chemistry of exchange clusters (polynuclear transition-metal complexes in which the unpaired electrons of particular sites are involved in magnetic exchange due to both direct or indirect, *via* bridging ligands, interactions of their wave functions). Particular emphasis is placed on (i) theoretical models that can be used to interpret experimental data in terms of the effective Hamiltonians and chemical bonding theory and (ii) molecular nanomagnets (complexes containing a large number of magnetic atoms and possessing unusual properties). The bibliography includes 158 references.

I. Introduction

Magnetic chemistry studies the interrelations between the magnetic properties of chemical compounds and their molecular and electronic structures. Creation of a theoretical basis for magnetic chemistry is intimately associated with the development of quantum mechanics.^{1,2} Current progress in magnetic chemistry is due to improvement of its theoretical foundations and posing new problems of preparative chemistry.^{3–25}

The first advances in magnetic chemistry were due to the discovery of correlations between the magnetic properties and the type of chemical bonding in diamagnetic crystals and organic molecules.³ Studies on the splitting of transition-metal atomic orbitals (AOs) in mononuclear complexes^{4–7} became even more important, because prediction of these effects belongs to the key results obtained using the ligand field theory, which is the main model in the theory of electronic structure of transition-metal compounds.

In 1952, it was found that the interactions between paramagnetic metal atoms in polynuclear complexes can cause a

pronounced temperature dependence of the magnetic moment.⁸ This class of compounds is called ‘exchange clusters’. The spin–spin correlations in the exchange clusters are due to the same exchange interactions as in the magnetically ordered crystals; however, they occur within isolated molecules. Therefore, detailed interpretation of experimental data based on the conventional molecular orbital (MO) theory is an easy task in the case of clusters. In magnetically ordered crystals the microscopic nature of magnetic interactions is masked by a continuous spectrum of elementary excitations. Such continuum systems have been the subject of solid state physics,^{2,26} which uses methods based on consideration of translational symmetry of crystals rather than specific features of pair atom–atom interactions in them to interpret the properties.

At the same time, the border between the physics of magnetic phenomena and magnetic chemistry is rather conventional. In particular, complexes containing a large number of paramagnetic atoms exhibit a magnetic memory effect,^{22–25} which is characteristic of crystals. At the same time, computational methods based on division of crystals into small clusters proved their efficiency in the case of magnetism.²⁷

Usually, the magnetic properties of exchange clusters smoothly depend on temperature and the corresponding curves can hardly be used to assess particular characteristics of the electronic structure. Because of this, interpretation of experimental data in magnetic chemistry is based on two related but clearly distinct divisions of theory.

The object of a phenomenological theory is to determine the form of model Hamiltonians and to develop relevant methods of solution in order to find the parameters of such Hamiltonians by comparing the calculated and experimental characteristics. Phenomenological theories are usually based on some general considerations. Therefore, treatment of experimental data as a set of parameters of the model Hamiltonian can be considered correct. Calculations of the parameters of the Hamiltonian using particular versions of the theory of electronic structure is the object of microscopic theory.

In accord with the aforesaid, in this review we will briefly outline the theoretical methods of modern magnetic chemistry, which are employed to interpret the experimental data, and then dwell on some applications of these methods to molecular nanomagnets, the most complex and promising class of polynuclear complexes.

II. Phenomenological theory

1. Exchange effect and the exchange Hamiltonian

The simplest way of introducing the notion of exchange interaction is to consider the interaction between a pair of atoms containing one unpaired electron each. Using the spin functions of two electrons, $|\alpha\rangle$ and $|\beta\rangle$, it is possible to derive the following functions of the total spin S

$$|1\rangle = \left(\alpha\alpha, \frac{\alpha\beta + \beta\alpha}{\sqrt{2}}, \beta\beta \right)$$

and

$$|0\rangle = \frac{\alpha\beta - \beta\alpha}{\sqrt{2}}.$$

Then, the total wave functions can be written as

$$\begin{aligned} \psi(1) &= \varphi_- |1\rangle, \\ \psi(0) &= \varphi_+ |0\rangle, \end{aligned} \quad (1)$$

where φ_- and φ_+ are the corresponding radial components.

The spin functions $|1\rangle$ and $|0\rangle$ are of different symmetry. According to the Pauli principle, the functions φ_- and φ_+ should also be of different symmetry and, hence, describe the states characterised by different Coulombic energies (E). The exchange effect consists of the appearance of energy difference (splitting), which is usually denoted as

$$-2J = E(S=1) - E(S=0), \quad (2)$$

where J is the exchange parameter.

Depending on which has a lower energy, the magnetic triplet ($-2J < 0$) or the non-magnetic singlet ($-2J > 0$), one deals with ferromagnetic or antiferromagnetic exchange, respectively. As the temperature decreases, the magnetic moment increases in the former and decreases in the latter case. The rate of the change in the magnetic moment depends on the parameter $|-2J|$. This dependence serves as the basis for the determination of the parameters of exchange interactions in clusters.

Formally [see relation (2)], the exchange effect can be treated as some 'interaction', which causes orientation of the spins $\mathbf{S}_1$ and $\mathbf{S}_2$. The corresponding spin Hamiltonian has the form

$$\hat{H} = -2J \mathbf{S}_1 \mathbf{S}_2. \quad (3)$$

Since

$$-2J \mathbf{S}_1 \mathbf{S}_2 = (\mathbf{S}_1 + \mathbf{S}_2)^2 - \mathbf{S}_1^2 - \mathbf{S}_2^2 = \mathbf{S}^2 - \mathbf{S}_1^2 - \mathbf{S}_2^2, \quad (4)$$

passing from operators to their eigenvalues, we get

$$E(S) = -J[S(S+1) - S_1(S_1+1) - S_2(S_2+1)]. \quad (5)$$

From this it follows that

$$E(S=1) = -\frac{1}{2}J,$$

$$E(S=0) = \frac{3}{2}J,$$

$$E(S=1) - E(S=0) = -2J,$$

which coincides with relation (2).

Compared to the simple expression (2), relationship (3) for the spin Hamiltonian has advantage consisting of the possibility of generalisation to the multi-centre systems with arbitrary spins of the paramagnetic particles.

From general considerations^{14, 20, 28} it follows that in the absence of orbital degeneracy the interaction between localised spins can be described using the spin Hamiltonian

$$\begin{aligned} \hat{H} = & -2 \sum_{ij} J_{ij} \mathbf{S}_i \mathbf{S}_j + \sum_{ij} \mathbf{G}_{ij} [\mathbf{S}_i \times \mathbf{S}_j] + \sum_{k \geq 2} \sum_{\gamma} J_{\gamma}^{(k)} \mathbf{O}_{\gamma}^{(k)} + \\ & + \sum_{ij\alpha\beta} J_{ij}^{(d)} (\mathbf{S}_{\alpha i} \mathbf{S}_{\beta j} + \mathbf{S}_{\beta i} \mathbf{S}_{\alpha j}) + \sum_i \mu_B \mathbf{S}_i \mathbf{g}_i \mathbf{H}. \end{aligned} \quad (6)$$

Here, the subscripts i and j denote paramagnetic ions, α and β are the spin components; $-2J_{ij}$ are the Heisenberg isotropic exchange parameters; $\mathbf{S}_i$ and $\mathbf{S}_j$ are the spin operators of the magnetic atoms; $\mathbf{G}_{ij}$ are the vector parameters of antisymmetric exchange; and $J_{ij}^{(d)}$ are the anisotropic exchange parameters. All higher-order isotropic exchange operators $\mathbf{O}_{\gamma}^{(k)}$ can be derived by summing similar terms in the expressions $(\sum_{ij} \mathbf{S}_i \mathbf{S}_j)^k$. The last term in relationship (6) describes the Zeeman interaction with external magnetic field $\mathbf{H}$, $\mathbf{g}_i$ are the g -tensors and μ_B is the Bohr magneton. Usually, the Heisenberg term predominates.

2. General relations of theory of magnetism

In the approximation of isotropic g -factors the static magnetic susceptibility of orbitally non-degenerate exchange clusters is given by²⁰

$$\begin{aligned} \chi_m &= \chi'_m + N\alpha = \\ &= \frac{N_A \mu_B^2 \sum_{\gamma, S} g^2(\gamma, S) S(S+1)(2S+1) \exp[-E(\gamma, S)/kT]}{3kT \sum_{\gamma, S} (2S+1) \exp[-E(\gamma, S)/kT]}. \end{aligned} \quad (7)$$

Here χ'_m is the magnetic susceptibility per mole of paramagnetic molecules, $N\alpha$ is the correction for temperature-independent paramagnetism of the metal ions and for diamagnetism of ligands, N_A is the Avogadro constant and $\sum_{\gamma, S}$ denotes summation over all quantum numbers.^{4, 13, 20}

Often, construction of temperature dependences of the magnetic properties of real clusters requires the inclusion of corrections for the monomer impurity

$$\chi = (1-\eta)\chi_m + \eta\chi_{\text{mono}}, \quad (8)$$

(η is the monomer fraction and χ_{mono} is the magnetic susceptibility of the monomer) and for intermolecular exchange²⁹⁻³¹

$$\chi_{\text{cl}} = \frac{\chi'_m}{1 - 2z'J'\chi'_m/Ng^2\mu_B^2}, \quad (9)$$

where z' is the number of nearest neighbours and χ'_m and $2J'$ are the parameters of intermolecular exchange.

The magnetic susceptibilities of polyatomic clusters χ'_m can reach very high values, so that intermolecular exchange can strongly affect the magnetic properties even at rather small values of the intermolecular exchange parameters $-2z'J'$.

For mononuclear complexes characterised by the only spin state S and $E(\gamma, S) = \text{const}$, Eqn (7) takes the form

$$\chi'_{\text{mono}} = \frac{N_A g^2 \mu_B^2 S(S+1)}{3kT} \quad (10a)$$

or

$$\chi'_{\text{mono}} T = \frac{N_A g^2 \mu_B^2 S(S+1)}{3k}. \quad (10b)$$

Hence, for such systems the right side of this equation is temperature independent.

In the high-temperature limit $|E(\gamma, S)| \ll kT$, Eqn (7) is the sum of the contributions of n paramagnetic atoms in a molecule

$$\chi'_m = \sum_i^n \chi'_{\text{mono}}(i), \quad (11a)$$

or

$$\chi'_m T = \sum_i^n \chi'_{\text{mono}}(i) T. \quad (11b)$$

Relationships (10b) and (11b) show the advantages of using the parameters $\chi'_m T$ instead of χ'_m in the analysis of experimental data. The high-temperature values $\chi'_m T$ permit the spins of the metal ions to be determined by simple summation of n constant contributions (10b). If one knows the trend and rate of changes in $\chi'_m T$ on lowering the temperature, it is possible to determine the sign and estimate the magnitude of exchange interactions. If, at low temperatures, the parameter $\chi'_m T$ corrected for the monomer impurity and intermolecular exchange takes some nonzero value, relationship (10b) also allows the ground-state spin to be evaluated.

Often, the ratio

$$\chi'_a = \frac{\chi'_m}{n} \quad (12)$$

is used instead of χ'_m and $\chi'_m T$ (here, n is the number of atoms; usually, χ'_a is denoted as χ'_m !). Then, the effective magnetic moment is given by

$$\mu_{\text{ef}}^2 = \frac{3kT\chi'_a}{N_A\mu_B^2} \approx 7.991\chi'_a T. \quad (13)$$

For mononuclear complexes, the parameter

$$\mu_{\text{ef}} = g[S(S+1)]^{1/2} \quad (14)$$

is temperature independent and can be used in analysing the experimental data in nearly the same way as the parameter $\chi'_m T$. However, this is less convenient because μ_{ef} (in contrast to $\chi'_m T$) is a non-additive quantity.

The $\chi'_{\text{mono}} T$ and μ_{ef} values for all realistic S at $g = 2$ are as follows:

S_i	1/2	1	3/2	2	5/2	3	7/2
$\chi'_{\text{mono}} T / \text{cm}^3 \text{ K}$	0.375	1.000	1.875	3.001	4.377	6.002	7.898
μ_{ef} / μ_B	1.732	2.828	3.873	4.899	5.916	6.928	7.937

3. The energy level and magnetic susceptibility calculations

The shape of the curves $\chi(T)$ is highly 'sensitive' to the magnitude and sign of the parameters $-2J_{ij}$, which mainly depend on the energies of the levels $E(\gamma, S)$.³² Therefore, the parameters $-2J_{ij}$ can be determined using best-fit procedures for the experimental and calculated $\chi(T)$ values. Clearly, the reliability of a particular procedure depends on the correctness of the theoretical model employed. The formalism of deriving correct spin Hamiltonians has been well developed.¹⁴ Because of this, the most important problem is to calculate the eigenvalues (energies) of such spin Hamiltonians.

A method of finding the simplest analytical solutions to the spin Hamiltonians of a large number of types of cluster structure was reported.³³

a. Analytical solutions to the spin Hamiltonians

Theorem. Consider a system that can be divided into two subsystems, L and M , such that (1) the spin Hamiltonians of the subsystems L and M have the solutions $E_L(\gamma_L, S_L)$ and $E_M(\gamma_M, S_M)$, respectively; and (2) all particles of one subsystem interact with particles of the other subsystem in an identical manner. Then, the solution of the total spin Hamiltonian has the form

$$E = E_L + E_M - J_{LM}[S_{LM}(S_{LM} + 1) - S_L(S_L + 1) - S_M(S_M + 1)], \quad (15)$$

where S_L and S_M are the spins of the subsystems, $-2J_{LM}$ is the parameter of the exchange interaction between particles of the

subsystems and S is the total spin, which can take the following values

$$S = S_L + S_M, S_L + S_M - 1, \dots, |S_L - S_M|. \quad (16)$$

In the simplest case (binuclear complexes) from Eqns (15) and (16) one gets

$$E = -J_{12}[S_{12}(S_{12} + 1) - S_1(S_1 + 1) - S_2(S_2 + 1)], \quad (17)$$

$$S_{12} = S_1 + S_2, S_1 + S_2 - 1, |S_1 - S_2|. \quad (18)$$

Equation (5) is a particular case of Eqn (17).

The equilateral triangle (Fig. 1a) meets the conditions of the theorem mentioned above. According to Eqns (15) and (16), here one has

$$E = -J_{12}[S_{12}(S_{12} + 1) - 2S_1(S_1 + 1) - J_{123}[S_{123}(S_{123} + 1) - S_{12}(S_{12} + 1) - S_3(S_3 + 1)], \quad (19)$$

where

$$S_1 = S_2,$$

$$J_{123} = J_{13} = J_{23},$$

$$S_{123} = S_{12} + S_3, S_{12} + S_3 - 1, \dots, |S_{12} - S_3|. \quad (20)$$

Figure 1. Schematic view of the structures of triangular (a), trigonal (b) and nonanuclear (c) clusters for which analytical solutions of the spin Hamiltonian exist.

Among tetramers, the theorem is applicable to, *e.g.*, a trigonal pyramid (Fig. 1b), which can be represented as a combination of a regular triangle 123 and a mononuclear species 4. Therefore, taking into account Eqns (15) and (19), one has

$$E = -J_{123}[S_{123}(S_{123} + 1) - 3S_1(S_1 + 1)] - J_{1234}[S_{1234}(S_{1234} + 1) - S_{123}(S_{123} + 1) - S_4(S_4 + 1)], \quad (21)$$

where

$$S_1 = S_2 = S_3,$$

$$J_{1234} = J_{14} = J_{24} = J_{34},$$

$$S_{1234} = S_{123} + S_4, S_{123} + S_4 - 1, \dots, |S_{123} - S_4|.$$

Other solutions can be obtained using the next terms of the expansion. For instance, an analytical solution for the nonanuclear cluster shown in Fig. 1c can be found by simply representing the system as a combination of two square fragments 'linked' by the interaction parameters $J_{ij} = 0$. Then, the eight-particle subsystem interacts with the symmetrically arranged central species. Solving this simple problem using general methods requires considerable efforts.³⁴

To interpret the magnetic properties of various types of polynuclear complexes based on the theory outlined above, a software library was developed.²⁰

b. Method of irreducible tensor operators and consideration of spatial symmetry

If the system under study does not meet the conditions formulated in the theorem given in Chapter II.3.a, one should numerically solve the corresponding spin Hamiltonian. For small molecules, the solutions can be obtained by diagonalisation of the matrix of the operator (6), written in the complete basis set of the product functions:

$$|S_1 m_1\rangle |S_2 m_2\rangle \dots |S_n m_n\rangle. \quad (22)$$

However, the number of such functions,

$$N_f = \prod_{i=1}^n (2S_i + 1)$$

rapidly increases as the number and magnitude of the spins S_i increase. For instance, even for a relatively simple Fe(III) complex with $n = 8$ and $S_i = 5/2$ the order of the matrix in the basis set of the functions (22) is $N_f = 1\,679\,616$. Computer diagonalisation of matrices of so high an order is currently impossible.

The situation is significantly simplified if we take into account only the Heisenberg exchange, which usually predominates. Indeed, the first term in expression (6) can be represented as the sum of zero-rank irreducible tensor operators³⁵

$$\sum X_{ij} = -2 \sum J_{ij} S_i S_j = \quad (23)$$

$$= 2\sqrt{3} \sum J_{ij} \{ \dots [(S_1^{(k_1)} S_2^{(k_2)})^{(k_{12})} S_3^{(k_3)}]^{(k_{123})} \dots S_n^{(k_n)} \}^{(0)},$$

where, e.g., the contribution $-2J_{13} S_1 S_3$ corresponds to the tensor operator with $k_1 = k_{12} = k_3 = 1$ (all other $k_\alpha = 0$). Other 'multiplication' schemes that obey the quantum vector addition rule^{1,2} can also be applied to Eqn (23). Based on the Wigner–Eckart theorem,³⁶ in the basis set of the total spin functions one can write

$$\langle \dots SM | \sum X_{ij} | \dots S' M' \rangle = \delta(M, M') \delta(S, S') \times \quad (24)$$

$$\times 2\sqrt{3} (2S + 1)^{-1/2} \times \sum J_{ij} \langle \dots SM | X_{ij} | \dots SM \rangle,$$

where $\langle \dots SM | X_{ij} | \dots SM \rangle$ are the reduced matrix elements, which can be calculated with ease.^{35–37}

Thus, the method of irreducible tensor operators (ITO) involves division of the isotropic spin Hamiltonian matrices into blocks corresponding to particular S and M values. In particular, for the above-mentioned octanuclear complex of trivalent iron the maximum order of the matrix in the basis set of the functions $|\dots SM\rangle$ is only 16 576. This allowed the software library²⁰ to be extended by including some modules written to interpret the magnetic properties of rather large clusters ($n \leq 16$) possessing no particular symmetry.

More detailed analyses of applications of the ITO method to the phenomenological theory of magnetism are available.^{7, 14, 20, 38}

The inclusion of spatial symmetry of molecules allows the orders of the matrices to be significantly reduced even in the case of low symmetry. To this end, it is sufficient to go from the basis set of the functions $|\dots SM\rangle$ to the functions $|\dots I^{(\alpha)} q_\alpha SM\rangle$, which are transformed by rows q_α of irreducible representations of the $I^{(\alpha)}$ point group.³⁹ For instance, in the case of an octanuclear Fe(III) complex⁴⁰ of a rather low symmetry (D_2), this passage causes the maximum order of the matrix to reduce from 16 576 down to 4170. This means that the required computer memory and the diagonalisation time are reduced by a factor of nearly 16.⁴¹

c. Cyclic clusters and linear chains

There is a large family of n -nuclear cyclic clusters, for which the Heisenberg spin Hamiltonian has the form

$$\hat{H} = -2J \sum_i S_i S_{i+1}, n+1 \equiv 1 \quad (25)$$

The most thoroughly studied uniform chains ($n \rightarrow \infty$) have the same spin Hamiltonian.

The J - and S -alternating chains with the spin Hamiltonian

$$\hat{H} = -2J \sum_i S_{2i} (S_{2i-1} + \alpha S_{2i+1}) \quad (26a)$$

(α is the alternation constant) and

$$\hat{H} = -2J \sum_i S_{2i} (s_{2i-1} + s_{2i+1}), s \neq S, \quad (26b)$$

(S and s are the spins in the alternated chain), respectively, have also been studied.

There is an analogy between cyclic clusters and linear chains. In both cases, the spin Hamiltonians depend on the single parameter, $-2J$, so the theoretical curves once calculated can be then used for all chains of a given type. Besides, cyclic clusters and linear chains possess a translational symmetry, which corresponds to periodic boundary conditions $n+1 \equiv 1$.

It should be noted that the magnetic properties of chains and other infinite systems are described using the quantity χ'_a [see Eqn (12)], because χ'_m is not defined in these cases.

In spite of considerable interest in linear chains as candidates for molecular magnets^{19, 22–25} and models of superconducting cuprates,⁴² there are few calculations of the magnetic properties of linear chains.

Numerical calculations of uniform chains with $S_i = 1/2$ and $n \leq 11$ were reported.⁴³ The possibility of approximation of infinite chains using finite ones was first demonstrated, the quality of approximation being significantly improved when using periodic boundary conditions. The effect of the chain length on the energy spectrum was first reported by Tsukerblat *et al.*⁴⁴ and on the magnetic properties by Hatfield *et al.*³⁸ Studies^{45–48} in which exact numerical solutions of functions $\chi'_a(T)$ for antiferromagnetic and ferromagnetic chains with $S_i = 1/2$ were obtained deserve particular attention. The $\chi'_a(T)$ plots for uniform chains with $S_i = 1$ were reported.⁴⁹ Theoretical dependences $\chi'_a(T)$ were also obtained for all S_i values ranging from $1/2$ to $7/2$ obtained by the high-temperature expansion method⁵⁰ and in the classical spin approximation.⁵¹ A review⁵² provides a comprehensive consideration of theoretical results for uniform and J -alternated chains with $S_i = 1/2$. Based on these results, one can no longer use the popular theoretical Weng curves⁵³ the plotting of which is based on rather rough assumptions.⁵⁴

The results of numerical calculations^{17, 55–57} of J -alternated chains with $S_i = 1/2$ and 1 were presented in the form of fractional rational functions. For $S_i = 1$, the $\chi'_a = f(\alpha, J, T/J)$ plots were reported.⁵⁸ These calculations were performed for finite cycles; however, the results obtained must also correctly describe the magnetism of infinite chains, because the $\chi'_a(T, n)$ curves rapidly match the limiting $\chi'_a(T, n \rightarrow \infty)$ curves at $\alpha \neq 1$.⁵⁹

The results of magnetic susceptibility calculations for S -alternated chains with $s_{2i} = 1/2$ and $S_{2i+1} \leq 5/2$ were briefly outlined.^{60, 61} The case for $s_{2i} = 1/2$ and $S_{2i+1} = 5/2$ has been studied in more detail.⁶² Analytical solutions for the systems with $s_{2i} \ll S_{2i+1}$ and the parameters S_{2i+1} approximated by classical spins were also reported.^{18, 63}

The limited number of theoretical $\chi'_a(T)$ curves for cyclic and quasi-one-dimensional systems is to a great extent due to the little amount of attention paid to the possibilities of symmetrisation of the basis set. In particular, for a real cyclic cluster Fe₁₀ (see Ref. 64) on going from the complete basis set to the $|\dots SM\rangle$ -representation and then to the $|\dots I^{(\alpha)} q_\alpha SM\rangle$ functions symmetrised in the C_{10v} group, the maximum order of the secular equation is reduced from 60 466 176 to 484 155 and then down to 48 480, which seems to be quite acceptable for being solved with modern computers.

4. Non-Heisenberg exchange

Higher-order isotropic exchange operators in Eqn (6) cause insignificant modification of the intervals between the spin levels. They have little effect on the magnetic properties, the more so if the parameters $J_\gamma^{(k)}$ are small.^{14, 20} Because of this, we will not dwell on them.

a. Antisymmetric exchange

The notion of antisymmetric (AS) exchange, $\sum G_{ij}(\mathbf{S}_i \times \mathbf{S}_j)$, was phenomenologically introduced by Dzyaloshinskii.⁶⁵ The energy,

$$|G| \sim \frac{J(g-2)}{2}$$

of this interaction estimated by Moria⁶⁶ was found to be relatively low. However, if isotropic exchange favours alignment of spins or their antiparallel orientation, the AS exchange favours a perpendicular alignment of spins. In crystals, this leads to formation of non-collinear magnetic structures, which was called 'weak ferromagnetism',^{2,65} and in clusters, to manifestation of nontrivial magnetic and spectroscopic properties.¹⁴ Magnetic measurements⁶⁷ carried out using a specially synthesised trinuclear complex of divalent copper seem to remain the most reliable confirmation of the Moria estimate as yet.

b. Anisotropic exchange. Molecular magnetic memory effect

If Z is the molecular axis of light magnetisation, the major contribution to the operator of anisotropic exchange has the form DS_Z^2 (see Ref. 68). Because of this, in the magnetic field $H \parallel Z$ for any (in particular, for the lowest well separated level $|S\rangle$) the solution to the spin Hamiltonian has the form:

$$E = DM^2 - g\mu_B H M, \quad (27)$$

where $M = S, S-1, \dots, -S$; $g \sim -g_e > 0$.

Consider the behaviour of the lowest energy level $|S\rangle$ of such a system with $D < 0$ in the magnetic field (Fig. 2a). Application of an external $H > 0$ followed by slow reduction of temperature will make only the lowest level $M = -S$ populated. Let us reduce the field H down to zero. From Fig. 2a it can be seen that at $H \rightarrow 0$ the levels $M = -S$ and $M = S$ become degenerate. However, no instantaneous equalisation of the level populations will occur because the transition $| -M \rangle \rightarrow | M \rangle$ is forbidden for $H \parallel Z$.⁶⁸ Hence, at $H = 0$ the system under study will retain its magnetisation corresponding to $M = -S$. This is the essence of the molecular magnetic memory effect.

An increase in the ground-state spin S is accompanied by an increase in the energy difference, $\Delta M = 2S$, between the two

lowest-lying levels, a decrease in the transition probability between them and, hence, a slowing down of relaxation of the magnetisation.

Another mechanism of relaxation of the magnetisation involves successive thermal population of higher levels. The nearest of them, $|M = \pm(S-1)\rangle$, is separated from the ground-state energy level $|M = \pm S\rangle$ by an interval of $D(-2S+1)$. Therefore, slowing down relaxation of the magnetisation favours an increase in not only S but also $|D|$. Complete thermalisation of the system corresponds to the overcoming of the barrier between $M_{\max}$ and $M_{\min}$

$$\Delta E \approx |D|S^2,$$

which confirms the conclusion drawn.

At rather large S values, not only the level $M = -S$ but also the levels $M = -S+1, -S+2$ can have long lifetimes. The latter levels can be individually populated by selective excitation. Thus, multilevel molecular magnetic memory is possible.

If $D \geq 0$, different levels with close M values cross one another at $H \rightarrow 0$ (see Fig. 2b), which leads to unavoidable rapid thermalisation and the absence of magnetic memory effect. A similar situation is typical of systems with any D , if the ground state forms a group of spin levels: numerous crossings of the levels with close moments inevitably lead to fast relaxation of the magnetisation.

In all cases, acceleration of relaxation is also favoured by the anisotropic exchange operators of the type $E(\mathbf{S}_X^2 - \mathbf{S}_Y^2)$, which appear at symmetries lower than axial symmetry.⁶⁸

The anisotropic exchange parameters are combinations of dipole-dipole, pseudodipole and single-ion contributions;^{19,68} therefore, their estimates are usually based on experimental data.

III. Microscopic theory

Targeted synthesis of compounds with predictable magnetic properties (design of molecular magnets) is mainly based on the calculated and experimentally confirmed 'structure-magnetic property' correlations.^{15,19-21} Because of this, in this section the emphasis is placed on theoretical description of such correlations, the more so as this problem is somewhat simpler than calculations of numerical values of the exchange parameters.

Microscopic models in modern magnetic chemistry of exchange clusters are based on Anderson's theory of magnetism (see, e.g., Refs 9 and 69). In particular, most models use the magnetic orbital approximation.¹⁹ In essence, this approximation is the same as that used in the ligand field theory,^{7,20,21} namely, only those nonbonding and antibonding orbitals are considered, which mainly belong to the metal atoms and can contain unpaired electrons.

1. Natural orbital approximation

The natural orbital approximation is based on the assumption that a polynuclear complex can be represented as a system composed of mononuclear fragments. Quantitatively, the validity of the natural orbital approximation is determined by the possibility of division of the system under study into weakly interacting mononuclear fragments. However, this approximation is convenient for qualitative analysis of exchange effects, because it allows well-known concepts of the ligand field theory^{6,7,20,21} to be used.

a. Ferromagnetic and antiferromagnetic exchange

In Anderson's theory, the expression for the parameter of exchange interaction between the unpaired electrons localised in the natural orbitals, Φ_a and Φ_b , of two sites a and b has the form

$$-2J_{12} = -2\langle \Phi_a \Phi_b | \frac{e^2}{r_{12}} | \Phi_b \Phi_a \rangle - 4\delta \langle \Phi_a | V | \Phi_b \rangle. \quad (28)$$

Here $\langle \Phi_a \Phi_b | e^2/r_{12} | \Phi_b \Phi_a \rangle$ is the Coulombic energy of two-electron charge distribution (this energy is always positive; i.e., it corresponds to the ferromagnetic contribution $-2J^f < 0$). In the

Figure 2. Splitting of the spin level S due to the action of the anisotropic exchange operator DS_Z^2 and magnetic field at $D < 0$ (a) and $D > 0$ (b).

Figure 3. Schemes of direct and indirect electron–electron interactions favouring antiferromagnetism (*a*, *c*) and ferromagnetism (*b*, *d*).

second term δ is the overlap integral $\langle \Phi_a | \Phi_b \rangle$, and $\langle \Phi_a | V | \Phi_b \rangle < 0$ is the matrix element of effective one-electron Hamiltonian V . This term appears only in the case of non-orthogonal orbitals ($\delta \neq 0$). In the Heitler–London scheme, it is responsible for the formation of chemical bonds involving paired electrons. Therefore, $-2J_{12} < 0$ only at $\delta \sim 0$.

The aforesaid serves as the theoretical basis for the well-known Goodenough–Kanamori rules.⁹ They can be exemplified in the simplest way by considering a direct interaction between d-orbitals of two neighbouring metal atoms. Figure 3 *a* presents a scheme of the formation of the metal–metal bond involving paired electrons in the case of strong antiferromagnetism. If, from symmetry considerations, $\delta = 0$ (Fig. 3 *b*), the resulting effect is ferromagnetism. A more complicated situation is observed when direct interaction is absent but a bridging ligand *L* is available. However, this can be simplified by considering that the predominant contribution to the antiferromagnetic exchange is due to the interaction of unpaired electrons on the bridge.⁷⁰ Indeed, in this case the natural orbitals (with inclusion of the bridging ligand only) take the form

$$|\Phi\rangle \sim d + \alpha\varphi_L,$$

where α is the covalency. Figure 3 *c* illustrates the case where the orbital φ_L is common to both centres. Here, one has

$$\delta = \langle \Phi_a | \Phi_b \rangle \sim \langle \alpha\varphi_L | \alpha\varphi_L \rangle = \alpha^2 \neq 0,$$

which corresponds to indirect antiferromagnetic exchange. The case where

$$\delta \sim \langle \Phi_{La} | \Phi_{Lb} \rangle = 0$$

corresponds to indirect ferromagnetic exchange (Fig. 3 *d*).

b. The bond covalency and bond length effects

From the aforesaid it follows that an increase in the bond covalency (α) must cause an increase in the parameter $|-2J|$. Indeed, this holds for compounds with the F^- , O^{2-} , S^{2-} and Se^{2-} bridges.¹¹

At long metal–bridging ligand distances (R), the site–site interactions vanish; therefore, the fact that the dependence $|J(R)|$ has a decreasing character is not in doubt. This dependence was revealed^{71,72} by analysing experimental data for oxides and fluorides and a quantitative correlation was established

$$-2J \sim R^{-m}, m = 10-12. \quad (29)$$

c. Angular dependence of superexchange

Using the natural orbital approximation, it is an easy matter to derive an expression for the angular dependence of superexchange on a monatomic ligand.

Let the sites *a* and *b* (Fig. 4) contain one unpaired electron in the orbitals d_{z^2} , the lobes of which are directed at the bridging ligand *L* and overlapped with its valence orbitals *s* and *p*. Then,

Figure 4. Directions of the local axes in the fragment M–L–M.

the natural orbitals in the local system of coordinates have the form

$$\Phi_a \sim d_{z^2} + \alpha p_z - \beta s, \quad (30a)$$

$$\Phi_b \sim d_{(z')^2} + \alpha p_{z'} - \beta s, \quad (30b)$$

where α and β are the covalency parameters. By substituting relations (30a) and (30b) into (28), we get the expression for the antiferromagnetic contribution with inclusion of the interaction on the ligand only⁷⁰

$$-2J^{af} = -4\alpha^4 V_1 \cos^2 \theta - 4\alpha^2 \beta^2 (V_1 + V_2) \cos \theta - 4\beta^4 V_2. \quad (31)$$

Here

$$V_1 = \langle p_z | V | p_z \rangle < 0,$$

$$V_2 = \langle s | V | s \rangle < 0$$

and it is considered that

$$p_{z'} = p_z \cos \theta - p_x \sin \theta.$$

Since α^2 is nearly an order of magnitude greater than β^2 (see Ref. 73), the major contribution to Eqn (31) comes from the first term at all angles except for the range $\theta \approx 90^\circ$. The presence of the angle independent term causes the minimum of $-2J^{af}$ to be attained at $\theta \approx 95-100^\circ$ rather than $\theta = 90^\circ$.

As for the ferromagnetic contribution, after substituting expressions (30a) and (30b) into the relationship

$$-2J^f = -2 \langle \Phi_a \Phi_b | \frac{e^2}{r_{12}} | \Phi_b \Phi_a \rangle$$

one gets the sum of terms of the same order of magnitude, which only slightly depends on the angle θ . This conclusion was proved by direct numerical estimates (see, e.g., Ref. 74). In addition, usually $|-2J^f| \leq -100 \text{ cm}^{-1}$ (see Ref. 19), whereas $-2J^{af}(\theta)$ can take values ranging from 0 to $\sim 2000 \text{ cm}^{-1}$ (see Refs 20 and 75). Thus, to an accuracy of relatively small and nearly constant contribution, the expression (31) provides a correct explanation for the angular dependence of superexchange. Usually, Eqn (31) is used in the parametric form

$$-2J = -2J_1 \cos^2 \theta - 2J_2 \cos \theta - 2J_3, \quad (32)$$

where J_1 , J_2 and J_3 are determined from the experimental data, the parameters also including the ferromagnetic contribution. Expression (32) correctly describes the angular dependence of superexchange for a broad class of oxide crystals⁷⁶⁻⁷⁸ even without considering J_2 , though the explanation for subtle effects similar to exchange striction in NiO (see Ref. 79) also requires the inclusion of a linear term.

d. Double exchange and heteronuclear complexes

Compounds containing paramagnetic ions of the same metal in close oxidation states can exhibit the so-called double exchange.⁸⁰ Physically, it is due to the fact that the ‘extra’ electron (or hole) migrates between two equivalent centres and alternately interacts

with the localised spins S_i . This causes the formation of spin levels with energies

$$E(S) = \pm bS, \quad (33)$$

$$S = 2S_i + \frac{1}{2}, 2S_i - \frac{1}{2}, \dots, \frac{1}{2},$$

so that the order of the lowest $2S_i$ -levels corresponds to ferromagnetic non-Heisenberg exchange. Using the same notations as above, one gets

$$b \sim \alpha^2 V_1 \cos \theta + \beta^2 V_2.$$

Comparison of this expression with Eqn (31) shows that double exchange can result in strong ferromagnetism even in the case of a large antiferromagnetic contribution. This occurs in, e.g., tetra(μ -1,8-naphthyridine- N,N')bis(bromonickel)tetraphenyl borate.⁸¹ Double exchange in this mixed-valence Ni(II)/Ni(I)-complex with structure similar to that of copper acetate is so significant that only the lowest level ($S = 3/2$) is populated even at $T \approx 400$ K.

There are only a few systems exhibiting double exchange, because in most mixed-valence complexes the 'extra' electron is trapped by one centre and the centres become inequivalent.¹⁴ This is intrinsic in heteronuclear clusters in which the 'extra' electrons are localised on one centre. This causes the appearance of a ferromagnetic contribution due to transfer of the unpaired electron of one centre to the vacant orbital of the other centre and/or one of the electrons of the filled orbital of one centre to the half-filled orbital of the other centre due to direct or indirect interaction.^{10, 11}

An example of the aforesaid is provided by heterobinuclear complex $\text{CuVO}(\text{fsa})_2\text{en} \cdot \text{CH}_3\text{OH}$, where $\text{H}_4(\text{fsa})_2\text{en} = N,N'$ -bis-(2-hydroxy-3-carboxybenzylidene)-1,2-diaminoethane, in which the Cu^{2+} and VO^{2+} ions are linked via an oxygen bridge.⁸² The scheme of interaction between magnetic orbitals in this complex is shown in Fig. 5. The orbitals of the unpaired electrons of Cu(II) and vanadium monoxide ($|x^2 - y^2\rangle$ and $|xy\rangle$), respectively) are orthogonal from symmetry considerations; however, the metal atoms are separated by a monatomic oxygen bridge only. This should result in strong Anderson ferromagnetism. At the same time, the unpaired electron can be transferred from the $|x^2 - y^2\rangle$ orbital of Cu(II) to the vacant orbital $|x^2 - y^2\rangle$ of vanadium monoxide and from the filled orbital $|xy\rangle$ of Cu(II) to the half-filled orbital $|xy\rangle$ of vanadium monoxide. In this case, it is hard to determine which mechanism makes the predominant contribution to the experimental value $-2J = -118 \text{ cm}^{-1}$ (see Ref. 82). The exchange parameters in complexes with a linear magnetic fragment $\text{Cr(III)}-\text{O}-\text{Fe(III)}$ were analysed.⁸³ Such complexes are

Figure 5. Scheme of interaction between magnetic orbitals in the complex $\text{CuVO}(\text{fsa})_2\text{en} \cdot \text{CH}_3\text{OH}$ (a) and possible types of electron transfer mechanism (b).

characterised by shortened M—O bonds, which must favour the transfer mechanism. Nevertheless, no corresponding anomalies in the $-2J$ values were found.

2. The Hay–Thibault–Hoffmann model

Within the molecular orbital (MO) method, more consistent is the Hay–Thibault–Hoffmann (HTH) model.⁸⁴ According to this model, the parameter $-2J$ of homobinuclear complexes is given by

$$-2J = \frac{-2 \sum_{ij} J_{ij}^f - \sum_{\mu} \Delta^2(\mu)/2K_{ab}}{4S_a S_b}. \quad (34)$$

Here $-2J_{ij}^f$ are the ferromagnetic contributions due to the electrostatic interaction of the unpaired electrons occupying the orbitals $|i\rangle$ and $|j\rangle$ of two centres; the second term is the antiferromagnetic contribution $-2J^{af}$; $2K_{ab} = 5-10 \text{ eV}$ (see Ref. 84) is the metal–metal charge transfer energy, which is stable for the atoms of the same transition-metal row; and S_a and S_b are the spins of the metal ions.²⁰ The parameters $\Delta(\mu)$ are the energy differences between the symmetric (s) and antisymmetric (as) MOs composed of combinations of orbitals of the unpaired electrons of the magnetic sites a and b, $\sim (d_a^a \pm d_b^b)$, and of the ligand orbitals. In Fig. 6, these orbitals and the parameter $\Delta(\mu)$ are shown for the triatomic linear fragment containing three orbitals and four electrons (for simplicity, the non-bridging ligands are not shown).

Figure 6. Molecular orbital scheme of the triatomic four-electron fragment.

In the case of a heterobinuclear system, the $-2J^{af}$ values somewhat increase, but the corresponding corrections for the metals of the same row are small.⁸⁵

As shown above, the sign and trends of the changes in the parameter $-2J$ are mainly determined by the antiferromagnetic contribution, which, according to the HTH model, depends on the energy difference between the MOs $d_a^a \pm d_b^b$ (plus the ligand orbitals). This allows the powerful formalism of the MO method to be employed. For instance, it is convenient to calculate the $\Delta(\mu)$ values using the generalised angular overlap model^{21, 86–88} based on the variational perturbation theory.⁸⁹

In the approximation of weak metal–ligand bond covalency, the matrix elements of the effective Hamiltonian for the metal orbitals can be represented as the sum over all k ligands^{21, 86–88}

$$h_{ij} = \sum_k \sum_{mn} H_m H_n U_{mn}^k \langle i|m\rangle_k \langle j|n\rangle_k, \quad (35)$$

where the subscripts i and j label the orbitals of the metal atoms, the subscripts m and n label the ligand orbitals and $H_{m,n}$ are the ligand orbital energies. The matrices, U , of the intraligand interactions can be most conveniently expressed through the inverted matrices

$$U_{mn}^{-1} = \begin{cases} (H_d - H_m - H_n) \langle m|n \rangle, & m \neq n, \\ H_d - H_n, & m = n. \end{cases} \quad (36)$$

Here H_d are the energies of the atomic d-orbitals. No restrictions are imposed on the number of the metal atoms and on the energy of intraligand interactions. Because of this, expression (35) can be applied to mono- and polynuclear complexes with both monatomic and polyatomic ligands that can be either monodentate or polydentate.

a. Polynuclear compounds with OR (XX') bridges

An example of efficient use of the HTH model and the generalised model of angular overlap is provided by the theory of exchange interactions for binuclear copper(II) complexes with OR bridges (Fig. 7).

Often, the O–R bonds in complexes with such a geometry are ignored.¹⁹ In this case, one should expect that the angular dependence of superexchange in such complexes is described by relation-

Figure 7. Structure of the central fragment of binuclear complexes with OR bridges (L is any ligand; OR is a carboxylate or alcoholate group).

Figure 8. Experimental dependences $\varphi(\theta)$ (a) and $2J(\theta)$ (b) for binuclear Cu(II) complexes with OR bridges.

Compounds: bis[*N*-picolinoyl-3-aminopropoxidoaqua cuprate(II)] (1, see Ref. 90); bis(piperidinium)[di-μ-methoxobis(2,4-dinitrophenolato)-cuprate(II)] (2, see Ref. 91); tetrakisothiocyanatocuprate(I)-bis[μ-[2-(3-aminopropyl)aminoethanolato]-*N,N'*,μ-O]dicopper(II) thiocyanate (3, see Ref. 92); Cu₂(fsa)₂en · CH₃OH (4, see Ref. 93); (2-diethylaminoethanolato)copper(II) thiocyanate (5, see Ref. 94); di-μ-(benzyloxo)-bis[(2,2,6,6-tetramethylheptane-3,5-dionato)copper(II)] (6, see Ref. 95); di-μ-methoxo-bis[(2,4,6-trichlorophenolato)(quinoline)copper(II)] (7, see Ref. 96); bis[heptanetrionato(2)]bispyridinedicopper(II) (8, see Ref. 97); bis[*N,N*-bis(2-diethylaminoethyl)-2-hydroxyethylamino-O]dicopper(II) diperchlorate (9, see Ref. 98); bis[3-(*N,N*-dimethylamino)propyl-2-hydroxyethylamino-O]dimethanoldicopper(II) diperchlorate (10, see Ref. 99); bis[*N*-(3-hydroxypropyl)(pyrrol-2-yl)methylideneiminato]dicopper(II) (11, see Ref. 100); (2-dipropylaminoethanolato)copper(II) isocyanate (12, see Ref. 101); [2-hydroxy-*N*-(3-hydroxypropyl)-α-methylbenzylideneiminato]copper(II) (13, see Ref. 102); [2-hydroxy-*N*-(3-hydroxypropyl)-5-nitrobenzylideneiminato]copper(II) (14, see Ref. 102) and (5-methyl-7-oxo-4-azaoct-4-enolato)copper(II) (15, see Ref. 103).

ship (32). However, this is not the case, as shown by the experimental dependence $2J(\theta)$ presented in Fig. 8. As can be seen, this plot is a broken rather than smooth line and obeys the same pattern as the plot $\varphi(\theta)$, where φ is the angle OOC. Such a shape of the $2J(\theta)$ plot can be explained based on the generalised model of angular overlap.

The complexes in question are comprised of two nearly square mononuclear fragments with the unpaired electrons in the $|x^2 - y^2\rangle$ orbitals. Possible schemes of arrangement of the orbitals of the metal ions, the bridging atom and the substituent are shown in Fig. 9. For simplicity, we will restrict ourselves to analysis of the strongest σ -interactions between these orbitals and the p-orbitals of the bridging O atoms and the σ -bonds O–R.

Figure 9 c presents the projection of the geometry of exchange through one bridging ligand on the *XY* plane. The letters a and b denote the lobes of the $|x^2 - y^2\rangle$ orbitals, directed at the bridging ligand; p₁ and p₂ are the in-plane p-orbitals of the bridging O atom, p₃ (not shown) is the orbital p_z; and σ is the σ -orbital of the carbon atom. From symmetry considerations, for the matrix elements of the effective Hamiltonian (35) constructed in the basis set of the orbitals of copper atoms, |a⟩ and |b⟩, one gets $h_{aa} = h_{bb}$ and $\Delta = 2h_{ab}$. To include the second oxygen bridge, this value should be doubled. Finally, according to expression (34),

$$-2J^{af} = \frac{\Delta^2}{2K_{ab}}.$$

Thus, revealing trends of changes in the $-2J^{af}$ values requires only the parameter h_{ab} to be analysed.

Using relationships (35) and (36) and Figs 7, 9 c, one can easily show that

$$h_{ab} = A \cos \theta + A \frac{x}{1-x} \cos^2 \varphi \cos^2 \frac{\theta}{2}. \quad (37)$$

Here

$$A = \frac{H_p^2 (\langle d|p \rangle^*)^2}{H_d - H_p},$$

$$x = \frac{(H_d - H_p - H_\sigma)^2 (\langle p|\sigma \rangle^*)^2}{(H_d - H_p)(H_d - H_\sigma)};$$

$\langle d|p \rangle^*$ and $\langle p|\sigma \rangle^*$ are the radial components of the overlap integrals for the Cu–O and O–C bonds.

Since $|x| \gg 1$ in the case of interest (strong O–C interaction), one gets

$$h_{ab} \approx A (\cos \theta - \cos^2 \varphi \cos^2 \frac{\theta}{2}). \quad (38)$$

In addition, $\theta \approx 90^\circ$. Then

$$h_{ab} \approx A \cos^2 \varphi \cos^2 \frac{\theta}{2}$$

and

$$-2J^{af} \approx \cos^4 \varphi \cos^4 \frac{\theta}{2}. \quad (39)$$

Figure 9. Possible schemes of arrangement of the orbitals of the metal ions (a), bridging atom (b) and the substituent linked to the bridging atom (projection on the *XY* plane) (c).

These relationships point to strong dependence of exchange on the angles $M-O-M$ and $O-O-C$. In real complexes, variations of the angles θ are small (see Fig. 7) because of steric hindrances. Therefore, the $2J^{af}$ values and, hence, the values

$$-2J = -2J^f - 2J^{af},$$

must be primarily determined by the angles $O-O-C$, which can vary over a wide range (from 180° to 90°). A decrease in the angle between the $O-C$ and the Cu_2O_2 plane favours manifestation of the properties of a strong antiferromagnetic, because $\varphi \approx 180^\circ$ corresponds to the maximum $-J^{af}$ value. On the contrary, deviation of the $O-C$ bond from the Cu_2O_2 plane leads to a dramatic decrease in $-2J^{af}$ and, finally, to ferromagnetic properties. Correlations of the experimental dependences shown in Fig. 8 are in good agreement with these conclusions. The fact that $-2J < 0$ already at $\varphi \approx 140^\circ$ can be explained by a very strong dependence of $-2J^{af}$ on φ .

The results obtained have a clear physical meaning. Figure 9a illustrates a 90° exchange through the monatomic bridge while Fig. 9b differs from it only in that the orbitals p_x and p_y are transformed into the equivalent orbitals p_1 and p_2 , respectively (i.e., Fig. 9b corresponds to the same 90° ferromagnetic exchange). This can be understood with ease if one takes into account the fact that the orbital d_a-d_b interacts with the orbital p_1 in exactly the same manner as the orbital d_a+d_b interacts with the orbital p_2 . Because of this, $\Delta = 0$ and the system is ferromagnetic. Consider now Fig. 9c drawn with inclusion of the $O-C$ bond. Here, the orbitals $|p_2\rangle$ and $|\sigma\rangle$ form two combinations (a strongly bonding and a strongly antibonding one), which virtually do not interact with the orbitals of the metal atom. Thus, only the overlap between the d_a-d_b and p_1 orbitals remains, which is strong in the whole range of changes in the angle θ , except for the non-physical range $\theta \approx 0^\circ$. As a consequence, $\Delta \neq 0$, thus providing conditions for antiferromagnetism of all complexes with $\varphi \approx 180^\circ$. At $\varphi \approx 90^\circ$, the in-plane p-orbitals of the O atom are no longer overlapped with the carbon σ -orbital. In this case, the exchange geometry corresponds to the interaction through a monatomic bridge (at $\theta \sim 90^\circ$, this interaction is ferromagnetic; see Fig. 9a, b). Quantitative description of experimental data for some alcohols and related compounds (cubanes) was also reported.⁸⁶

According to Eqn (34), the antiferromagnetic contribution (39) is typical of not only Cu(II) complexes but also any other compounds which contain the unpaired electrons in the $|x^2-y^2\rangle$ orbitals and have appropriate structures (see Fig. 7). In addition, not only the OR bridges but also other $\mu_{1,1}$ -coordinated ligands XX' with strong $X-X'$ bonds can be involved. Therefore, in the case of similar Ni(II), Mn(II), Mn(III), Fe(II), Fe(III) and Co(II) complexes one should expect manifestation of antiferromagnetic properties at $\varphi \approx 180^\circ$ and ferromagnetic properties at $\varphi \approx 90^\circ$. Numerous examples substantiating the correctness of this conclusion have been reported.^{16,20}

General relationships (37) and (38) allow the limiting cases, viz., transition to monatomic ligands ($x = 0$) and to $\theta = 180^\circ$, to be reproduced correctly. In the latter case, the parameter $-2J$ is independent of the position and even the presence of a substituent. If $X-X'$ interactions are weak ($|x| \ll 1$), relations (37) and (38) predict a shift of the minimum $-2J^{af}$ value (strongest ferromagnetic properties) from that corresponding to $\theta \approx 90^\circ$. This can be qualitatively explained with ease using Figs. 9b, c. Indeed, the lobes of the orbitals p_1 and p_2 (Fig. 9b) have the same amplitudes, thus being responsible for $\Delta = 0$. Hence, $-J^{af} = 0$ at $\theta = 90^\circ$. The interaction $|p_2\rangle-|\sigma\rangle$ (Fig. 9c) changes the amplitude and energy of the orbital p_2 . Therefore, to obtain $-2J^{af} = 0$ again, one should change the angle θ . Of course, this can be done if the orbital p_2 is not completely suppressed in the case of strong $|p_2\rangle-|\sigma\rangle$ interaction. This is also in agreement with the experimental data.¹⁰⁴

Relations (37) and (38) also describe more subtle effects, e.g., a linear dependence $-2J(\theta)$ in dimeric hydroxo-bridged complexes

of Cu(II).¹⁰⁵ This required the inclusion of correlation between the angles θ and φ , which was observed experimentally. The reasons for qualitatively different character of the dependences $-2J(\theta)$ in dimeric fragments of oxo- and hydroxo-bridged chromium(III) complexes were established and corresponding quantitative description was obtained using a more complicated theory.¹⁰⁶ Finally, the simple physical nature of the phenomena in question favoured a better insight into the magnetic properties of complexes with more complex ligands.

b. Complexes with bridging ligands N_3^-

Similarly to, e.g., ligands of the OCH_3 type, the bonds in the linear ligands N_3^- are strong. However, high symmetry of the N_3^- ligand leads to quite different structure of energy levels.

The p_y orbitals of this anion are shown in Fig. 10a. As can be seen, the MO $\phi_y(s) \approx p_{y1} + p_{y3}$ is involved in strong π -interaction with the orbital p_{y2} , while the orbital $\phi_y(as) \sim p_{y1} - p_{y3}$ retains its nonbonding character and, hence, can be involved in the interaction with metal atoms. This orbital is schematically shown in Fig. 10b. Clearly, the orbital $\phi_z(as)$ has the same shape. The orbitals p_x are involved in interactions with one another and also with s-orbitals. Therefore, symmetry analysis is insufficient to obtain correct MOs. However, the results of simple calculations using extended Hückel theory⁸⁴ showed that, among all orbitals of this type, only the MO $\phi_x(s)$ shown in Fig. 10c has an energy similar to that of the $\phi_{y,z}(as)$ MO. In addition, the amplitudes of the outer lobes of all the three orbitals $\phi_x(as)$, $\phi_z(as)$ and $\phi_y(s)$ are similar.

Figure 10. Orbitals of the linear ligand N_3^- ; p_y -orbitals (a), nonbonding orbital $\phi_y(as)$ (b) and nearly nonbonding orbital $\phi_x(s)$ (c).

Let us proceed to interpretation of experimental data. The bridging ligands N_3^- can be coordinated in two fashions. One type of coordination, $\mu_{1,3}-N_3$, is shown in Fig. 11a. The overlap of the orbitals of the $\mu_{1,3}-N_3$ ligand with the lobes of the $|x^2-y^2\rangle$ orbitals of two Cu(II) atoms, a and b, is schematically presented in Fig. 11b. As can be seen, the combination d^a-d^b is involved in effective interaction with both the $\phi_y(as)$ and $\phi_x(s)$ orbitals, while the orbital d^a+d^b remains nonbonding. This must result in large splitting, $\Delta(x^2-y^2)$, between them and in strong antiferromagnetism [see Eqn (34)].

Indeed, all the known Cu(II) complexes with the structure in question possess nearly diamagnetic (or weakly paramagnetic) properties.^{19,107} Similar complexes of nickel(II) and manganese(II) also contain unpaired electrons in the orbitals $|x^2-y^2\rangle$; as a consequence, they also exhibit strong antiferromagnetic properties.¹⁰⁸

The structure of complexes with $\mu_{1,1}-N_3$ bridges is shown in Fig. 12a. The overlap of the orbitals of the $\mu_{1,1}-N_3$ ligand with the

Figure 11. Structure (a) and orbital overlap scheme (b) for binuclear Cu(II) complexes with $\mu_{1,3}$ -bridging ligands N_3^- .

lobes of the orbitals $|x^2 - y^2\rangle$ of two Cu(II) atoms (a and b) is illustrated in Fig 12 b. Visually, this scheme is similar to that of the overlap with orbitals of the monatomic ligand (see Fig. 9 b). They are also similar in essence, because we have shown that the energies and amplitudes of the orbitals $\phi_x(\text{as})$ and $\phi_y(\text{s})$ are also similar (see above). Hence, one should expect that at Cu–N–Cu angles $\approx 90^\circ$ copper(II) complexes with $\mu_{1,1}$ - N_3 bridges manifest strong ferromagnetic properties similarly to the complexes with monatomic ligands.

Figure 12. Structure (a) and orbital overlap scheme (b) for binuclear Cu(II) complexes with $\mu_{1,1}$ -bridging ligands N_3^- .

Indeed, all Cu(II) complexes of this type are ferromagnetic (provided there are no significant structural distortions) and the $-2J$ value can be as high as $\sim -200 \text{ cm}^{-1}$ (see Refs 74 and 109).

Similar nickel(II) complexes also possess ferromagnetic properties,¹⁰⁸ because they also contain the unpaired electrons in the $|x^2 - y^2\rangle$ orbitals. Besides, nickel(II) complexes also contain the unpaired electrons in the $|z^2\rangle$ orbitals, for which the conditions for the overlap with the in-plane orbitals of bridging ligands at $\approx 90^\circ$ are much like those for the $|x^2 - y^2\rangle$ orbitals. It should be emphasised that, in addition to the high ground-state spin, these nickel(II) complexes are characterised by large (in absolute value) parameters D (-10 to -20 cm^{-1} , see Refs 110–112). Therefore, such complexes are of particular interest for design of molecular magnets.

Potentially, the N_3^- ligand is a bisbidentate one (see Figs 11 and 12). Therefore, it is convenient for the synthesis of polynuclear complexes and even multidimensional structures. To date, some advances have been achieved in this field.²⁶

It is an easy matter to find out that a symmetric system with an odd number of ligand orbitals always contains a nonbonding orbital which can be involved in efficient interaction with the orbitals of the metal atoms. Because of this, such ligands are rather promising for creating a strong exchange at long metal–metal distances. Indeed, a Cu(II) complex characterised by an exchange parameter, $-2J$, of 26 cm^{-1} at a metal–metal separation of about $7.6 \text{ \AA}$ was synthesised.¹¹³ This is four to five orders of magnitude greater than the value predicted by expression (29). At the same time, it is not surprising because the shortest way of metal–metal exchange is a pentaatomic symmetric chain.¹¹³

c. ‘Parallel’ and ‘antiparallel’ coordination

According to Eqn (35), an increase in the number of identical, symmetrically coordinated bridging ligands must cause the splitting Δ to increase. In the case of heteroligand complexes, the

Figure 13. Parallel (a, b) and antiparallel (c) coordination of the bridging ligands.

situation can change. Consider a model system without writing expressions for particular cases.

Figure 13 a,b presents the schemes of the interaction between the bridging ligands through the s- and p-orbitals. In both cases, the ligands contribute to $\Delta(x^2 - y^2)$ in an identical manner (*i.e.*, their action is mutually strengthened):

$$\Delta_s \approx \Delta_{s1} + \Delta_{s2};$$

$$\Delta_p \approx \Delta_{p1} + \Delta_{p2}.$$

Due to different symmetry of the s- and p-orbitals, the high-lying combinations are symmetric (Fig. 13 a) and antisymmetric ones (Fig. 13 b). Both cases must lead to manifestation of strong antiferromagnetic properties, because Eqn (34) contains a term proportional to Δ^2 . However, for a heteroligand complex (Fig. 13 c) the different signs of Δ_s and Δ_p lead to

$$|\Delta_{sp}| \approx |\Delta_{s1}| - |\Delta_{p2}|.$$

Therefore, ‘antiparallelism’ of these contributions should lead to a decrease in Δ even with respect to Δ_{s1} and Δ_{p2} . It is ‘antiparallelism’ of the contributions that provides an explanation for unexpectedly weak antiferromagnetic properties of a large number of heteroligand complexes (see, *e.g.*, Ref. 114).

In principle, Δ_{sp} can be nearly equal to zero. This is the only reason for ferromagnetic properties of Ni(II) complexes of low symmetry, in which the metal atoms are linked through monatomic, triatomic (OH_2) and polyatomic (*e.g.*, OOCMe)^{115, 116} ligands with different node structure of the σ -orbitals.

d. Heterocyclic and other complex bridging ligands

Until now, we have considered complexes with relatively simple ligands that have a clear orbital structure. In complex ligands, the orbital lobes can be oriented in different ways and simple formulae for the angular dependence of superexchange are no longer valid.

Using EHT,⁸⁴ it was shown that in binuclear complexes of Cu(II) with imidazole (Fig. 14 a) the largest contribution to exchange comes from the symmetric and antisymmetric ligand orbitals (Fig. 14 b).¹¹⁷ The strongest ferromagnetic properties should be observed at a Cu–N–N angle of about 158° (see Ref. 117), which nearly corresponds to the bisectrix of the angles between the lobes of the symmetric and antisymmetric ligand orbitals. This is not surprising because of the similar amplitudes and energies of these orbitals.

Expression (35) permits the contributions of these and even more complex ligands to be included by simply inverting the matrices $\|U^{-1}\|$ [see relation (36)]. This allows one to obtain results in the analytical form, which is convenient for revealing various trends. However, in the case of polyatomic ligands of low symmetry, such an inversion will result in complicated multi-parameter expressions, which can hardly be analysed. Therefore, it is more appropriate to analyse complexes with such ligands using a compromise approach, which involves calculations of the electronic structures of the ligands using quantum chemistry methods followed by substitution of the results obtained into expression (35).

Figure 14. Structure of imidazole-bridged binuclear Cu(II) complexes (a) and the imidazole orbitals involved in effective interaction with the orbitals of unpaired electrons (b).

3. The model of exchange channels

In the case of multielectron metal atoms, the parameter $-2J$ is determined by the sum of the contributions over all pairs of half-filled orbitals [see Eqn (34)]. This strongly complicates analysis and/or the trends in manifestation of exchange interactions, especially if there is no predominant contribution. The model of exchange channels¹¹⁸ allows one to eliminate these problems.

Expression (34) can be re-written in more compact form:

$$-2J = \sum_{ij} \frac{-2J_{ij}}{4S_a S_b} = \frac{-2J_\Sigma}{4S_a S_b}. \quad (40)$$

From relation (34) it can be seen that the parameters $-2J_{ij}$ are independent of the degrees of orbital filling if the orbitals differ from $|i\rangle$ and $|j\rangle$. Therefore, pairs of one-electron orbitals of the sites a and b form specific channels of exchange interaction. The denominator, $4S_a S_b$, is the number of such interaction channels. Among the series of isostructural compounds containing paramagnetic ions of metals of the same row in similar oxidation states, variations of the number of electrons should not cause significant changes in the electronic structure parameters that appear in relationship (34). This suggests transferability of the contributions of the corresponding exchange channels in the series of isostructural systems. Transferability permits the parameters $-2J_{ij}$ to be 'calibrated' against the known experimental data and then used for predicting the magnetic properties of other systems belonging to the given isostructural series.

Let us re-write expression (40) as follows

$$-2J_\Sigma = \sum_{ij} (-2J_{ij}) = -2J 4S_a S_b. \quad (41)$$

The parameter $-2J_\Sigma$ is spin independent. It is determined only by the contributions of the exchange channels. Because of this, physically, this is the exchange energy, which is a convenient parameter for analysing the changes in the mechanisms of exchange interactions upon replacement of paramagnetic ions.¹¹⁹

Consider some binuclear carboxylates $[\text{LM}(\text{COOR})_2]_2$, where $\text{M} = \text{Ti}^{3+}$, V^{3+} , Mn^{2+} , Ni^{2+} and Cu^{2+} (for $\text{M} = \text{Ti}^{3+}$ and V^{3+} , $\text{L} = \text{Cp}^-$ only).^{120–123} These complexes have a rigid structure similar to that of copper acetate monohydrate (Fig. 15) and possess the properties of strong antiferromagnetics due to indirect exchange through OC(O) bridges.

Table 1 lists the half-filled orbitals, the $-2J$ values averaged over a large number of compounds with different R and L as well as the $-2J_\Sigma$ values.

Taking into account the maximum overlap, it is clear that the most effective interaction channels are due to superexchange between the σ -orbitals ($d_{x^2-y^2}$, $-2J_{vv}$) and π -orbitals (d_{xy} , $-2J_{\xi\xi}$) through the OC(O) bridges.

It is an easy matter to find out that pronounced variations of the parameter $-2J$ on going from one metal to another can be explained using the model of exchange channels.

Indeed, among four channels ($d_{xy} - d_{xy}$, $d_{xy} - d_{z^2}$, $d_{z^2} - d_{xy}$ and $d_{z^2} - d_{z^2}$) in the V^{3+} complexes, only the $d_{xy} - d_{xy}$ channel is effective. According to Eqn (41), in this case we get

Figure 15. Structure of Cu(II) acetate monohydrate.

Table 1. Magnetic parameters of binuclear carboxylates.

Ion	Half-filled orbitals	$-2J/\text{cm}^{-1}$	$-2J_\Sigma/\text{cm}^{-1}$
Ti^{3+}	d_{xy}	1000 ± 200	1000 ± 200
V^{3+}	d_{xy}, d_{z^2}	280 ± 40	1120 ± 150
Mn^{2+}	$d_{xy}, d_{z^2}, d_{x^2-y^2}, d_{xz}, d_{yz}$	30 ± 4	750 ± 100
Ni^{2+}	$d_{xy}, d_{x^2-y^2}$	300 ± 20	1200 ± 80
Cu^{2+}	$d_{x^2-y^2}$	340 ± 50	340 ± 50

$$-2J_\Sigma = -2J(\text{V}^{3+}) \times 4 \times 1 \times 1 \approx -2J_{\xi\xi} \approx -2J(\text{Ti}^{3+}) = 1000 \text{ cm}^{-1},$$

which is in good agreement with the experimental data. Similarly, for Ni^{2+} dimers one gets

$$-2J_\Sigma \approx -2J_{\xi\xi} - 2J_{vv} \approx -2J(\text{Ti}^{3+}) - 2J(\text{Cu}^{2+}) \approx 1300 \text{ cm}^{-1},$$

which coincides with the experimental value within the limits of experimental error. In the case of Mn(II) complexes, agreement is somewhat worse due to ignoring a total of twenty small ferromagnetic cross-contributions $-2J_{ij}^f$.

Many other examples are also available.^{124–127} Based on the model of interaction channels, the $-2J$ values for ten systems were estimated to a high accuracy using only a set of three calibration parameters.^{125–127}

4. Antiferromagnetics with metal–metal bonds

Until recently, it was accepted that compounds with metal–metal bonds can possess only trivial magnetic properties, viz., be diamagnetic or paramagnetic at an even or odd number of electrons, respectively (see Ref. 128 and references cited therein). However, chromium(III) cyclopentadienylchalcogenates (Fig. 16) have strained structures^{129–131} indicating the presence of metal–metal bonds but possess antiferromagnetic properties ($-2J \sim 400 \text{ cm}^{-1}$, which is typical of the systems with 'through-ligand' exchange).

Using the model of exchange channels, one can also determine the conditions for this class of magnetic materials to exist. Indeed, for the magnetic moment of an antiferromagnetic complex to be temperature dependent at not too high temperatures, at least the first excited state should be populated. This leads to the requirement

$$-2J = \frac{-2J_\Sigma}{4S_a S_b} < 1000 \text{ cm}^{-1}, \quad (42)$$

Figure 16. Structure of $(\pi\text{-C}_5\text{H}_5)_2\text{Cr}_2(\mu\text{-S})(\mu\text{-SCMe}_3)_2$.¹²⁹

i.e., $-2J < 1000 \times 4S_a S_b$. From this it follows that the large value of the parameter $-2J_\Sigma$, which is due to the presence of the metal–metal bond, does not necessarily cause diamagnetic properties to be possessed at rather large values of the product $4S_a S_b$. The chromium(III) complexes under consideration ($S_i = 3/2$) meet this condition.

This approach allowed compounds with metal–metal bonds to be found among double chlorides of composition AMCl_3 .¹³²

At the same time, there are strong grounds to believe that if the major contribution to the exchange is due to the formation of the metal–metal bond $d_\eta^a - d_\eta^b$, the largest contribution in expression (34) comes from the second term. Therefore, the energy difference, $\Delta(\eta)$, between the antibonding and bonding MOs is given by¹³³

$$\Delta(\eta) \approx \sqrt{-2J \cdot 4S_a S_b \cdot 2K_{ab}}. \quad (43)$$

This value is a natural measure of the binding energy, which can be estimated with ease, because relationship (43) contains some known or readily measurable parameters. It should be emphasised that attempts to reveal weak metal–metal bonds using other experimental or theoretical methods face great difficulties.

IV. Design of molecular magnets

The term ‘design of molecular magnets’ was introduced to denote targeted synthesis and studies of compounds built of molecular blocks and containing unpaired electrons involved in some interactions. This is a very broad field of research. In this review, molecular magnets mean polynuclear complexes which have high spins of the low levels and, hence, high magnetic moments. This bridges the gap between molecular magnets and conventional magnetic materials.

As mentioned above, high magnetic moments due to ferromagnetism can be expected in the case of specific geometry of the bridging groups, different symmetry of the magnetic orbitals and mixed valence of the complex-forming metal. However, the first two cases can hardly be implemented in practice in a predictable manner, while the mixed-valence systems (in addition) tend to be transformed into heterovalent weak ferromagnetic complexes. At the same time, the conditions for occurrence of strong antiferromagnetism are much simpler. This is often employed in various methods of attaining high magnetic moments.

1. Tetranuclear complexes

A typical example of tetranuclear complexes is provided by a trivalent iron complex (Fe_4^{III}), which was synthesised and studied recently.^{64, 134} The structure of this complex is shown in Fig. 1*b*. The interactions between the central and peripheral iron atoms occur through pairs of methoxo bridges and have an antiferro-

magnetic character ($-2J_{1234} = 21.1 \text{ cm}^{-1}$). However, this causes no diamagnetism and the ground-state spin, S , equals five. At first glance, this is a quite unexpected result, but this is not the case [it is sufficient to simply substitute $S_i = 5/2$ and $-2J_{1234} > 0$ ($-2J_{1234} \sim 0$) into relation (21)]. However, there is also a simple qualitative substantiation of this result. Indeed, antiferromagnetic interaction between the central and peripheral Fe atoms leads to antiparallel orientation of the spins of the latter with respect to the spin of the former atom and, hence, their alignment.

Thus, we get $S = 3 \times 5/2 - 5/2 = 5$. The cluster under study is characterised by a rather large D value (-0.2 cm^{-1}) and therefore exhibits a magnetic memory effect (see Section II.4.b), which, however, is observed only at $T \leq 1 \text{ K}$ due to the relatively small S and $|D|$ values.¹³⁴

The magnetic properties of a series of complexes with the $[\text{Mn}_4(\mu_3\text{-O})(\mu_3\text{-X})]^{6+}$ core and a structure similar to that of a distorted cubane, which resembles the structure shown in Fig. 1*b*, were studied.^{135–137} Since the atoms of the magnetic core, $\text{Mn}^{\text{IV}}\text{Mn}_3^{\text{III}}$, are in different oxidation states, antiferromagnetic exchange $\text{Mn}(\text{IV})\text{--Mn}(\text{III})$ results in $S = 9/2$ and a spin alignment similarly to the case of complex Fe_4^{III} . For all complexes of this type the parameter D is negative (more exactly, -0.3 to -0.5 cm^{-1}); therefore, they exhibit a magnetic memory effect at $T \leq 1 \text{ K}$ similarly to Fe_4^{III} .

In a ‘butterfly’-like $\text{Mn}_2^{\text{II}}\text{Mn}_2^{\text{III}}$ complex the central $\text{Mn}(\text{III})$ ions are linked through two O atoms of methanolic groups while their interaction with the terminal $\text{Mn}(\text{II})$ atoms occurs through the same oxygen and bidentate acetate bridges. All the $\text{Mn}\text{--Mn}$ exchange interactions have a ferromagnetic character;¹³⁸ as a consequence, $S = 9$. In combination with the value of the parameter D (-0.32 cm^{-1}) this leads to a relatively high activation energy for relaxation of the magnetisation ($\sim 12 \text{ cm}^{-1}$). In the dehydrated form of the complex $\text{Mn}_2^{\text{II}}\text{Mn}_2^{\text{III}}$, antiferromagnetic exchange through the solvent molecules leads to a decrease in S down to 8, the anisotropic exchange also weakens ($D \approx -0.25 \text{ cm}^{-1}$) and the activation barrier decreases.

A similar complex V_4^{III} is characterised by the $-2J_{12}$ and $-2J_{13}$ values of -31.2 and 27.5 cm^{-1} , respectively (see Ref. 139). The competition between ferromagnetic and antiferromagnetic exchange causes the total spin ($S = 3$) to become smaller than the sum of the spins $S_{\text{max}} = 4$. Because of this, the activation barrier is at most 1.5 cm^{-1} . Complexes of Cr_4^{III} , Mn_4^{III} and Fe_4^{III} (analogues of the vanadium complex in question) also have low ground-state spins.¹³⁹

2. Complex Fe_8

A $\text{Fe}(\text{III})$ complex with the central fragment $[\text{Fe}_8(\mu_3\text{-O})_2(\mu_2\text{-OH})_{12}]^{8+}$ (see Ref. 140) is usually denoted as Fe_8 . It has a D_2 symmetry (Fig. 17), which allows the full matrix of the secular determinant of dimension 1679 616 to be divided into blocks of dimension ≤ 4170 (see Section II.3.b). Exact numerical calculations of the magnetic susceptibility were carried out and the exchange parameters were estimated.⁴⁰ All interactions in the Fe_8 complex have antiferromagnetic character; nevertheless, the ground state has a spin S of 9. The anisotropic exchange parameter D equals -0.19 cm^{-1} (see Refs 141 and 142); therefore, at $T \leq 1 \text{ K}$ the complex exhibits a marked hysteresis of the magnetisation and the activation barrier to relaxation of the magnetisation is rather high ($\sim 17 \text{ cm}^{-1}$, see Ref. 40).

3. Complexes Mn_{12}

A typical representative of Mn_{12} complexes is $[\text{Mn}_{12}\text{O}_{12}(\text{O}_2\text{CR})_{16}(\text{H}_2\text{O})_4] \cdot 2 \text{ MeCOOH} \cdot 4 \text{ H}_2\text{O}$ ($\text{R} = \text{Me}$)¹⁴³

Figure 17. Structure of complex Fe_8 .

with a tetragonal structure (Fig. 18). Even full inclusion of symmetry considerations provides no possibility of division of a total of 10^8 basic states into blocks of admissible size for computer calculations. However, the exchange parameters were estimated by comparing the calculated positions of several low levels with experimental data (see the caption to Fig. 18).¹⁴⁴ This complex is characterised by $S = 10$ and $D = -0.4 \text{ cm}^{-1}$; therefore, the activation barrier to relaxation of the magnetisation reaches a value of 49 cm^{-1} (see Refs 145 and 146). Complex Mn_{12} has a higher symmetry (C_4) than complex Fe_8 so the anisotropic exchange parameters of the type $C(S_+^4 + S_-^4)$ make a much smaller contribution. It is these operators that make the $|S, M\rangle \rightarrow |S', M'\rangle$ transitions allowed; therefore, it is not surprising that at 2 K the Mn_{12} complexes retain their magnetisation for a period of several months.¹⁴⁷

Figure 18. Structure of Mn_{12} complexes.

Mn(III) atoms with a spin of 2 (I) and Mn(IV) atoms with a spin of $3/2$ (2). The exchange parameters are as follows: $-2J_1 = 150 \text{ cm}^{-1}$, $-2J_2 \approx -2J_3 = 60 \text{ cm}^{-1}$ and $-2J_4 = -45 \text{ cm}^{-1}$.

Generally, the outer-sphere ligands have little effect on the magnetic properties of Mn_{12} complexes. However, replacement of bidentate bridging ligands O_2CMe by O_2CEt results in a decrease in S down to 9, while the one-electron reduction of acetate is accompanied by the transformation of $\text{Mn}_8^{\text{III}}\text{Mn}_4^{\text{IV}}$ into $\text{Mn}^{\text{II}}\text{Mn}_7^{\text{III}}\text{Mn}_4^{\text{IV}}$ and by an increase in S to $19/2$.¹⁴⁸ These and a number of other substituted complexes are also characterised by slow relaxation of the magnetisation.¹⁴⁹

4. Complex Fe_{13}

The first thirteen-nuclear complex of trivalent iron is $(\text{C}_5\text{H}_6\text{N}^+)_5[\text{Fe}_{13}(\mu_4\text{-O})_4(\mu_2\text{-OMe})_{12}\text{F}_{24}]\text{MeOH} \cdot 4\text{H}_2\text{O}$.¹⁵⁰ Its structure comprises four triangular $[\text{Fe}_3(\mu_3\text{-O})(\mu_2\text{-OMe})_3]$ subunits linked to the central tetrahedral FeO_4 moiety via monatomic oxygen bridges. The structure of this complex is schematically shown in Fig. 19. Ignoring weak exchange through fluorine bridges, the four triangular subunits can be considered non-interacting. In this case, the theorem (see Section II.3.a) can be applied to this complex. This permits analytical calculations of the energies of all $\sim 1.3 \times 10^{10}$ spin levels of the system and plotting of the theoretical curves of the temperature dependence of the magnetic susceptibility. Interpretation of experimental data (obtained in the temperature range 2–300 K) in the framework

Figure 19. Structure of complex Fe_{13} .

of this theory showed that interactions within the triangular subunits and with the central iron atom are characterised by the exchange parameters $-2J_{12} = 30 \text{ cm}^{-1}$ and $-2J_{13} = 43 \text{ cm}^{-1}$, respectively.¹⁵¹ In spite of the antiferromagnetic character of all interactions, the ground state has a nonzero spin. The high ground-state spin is due to the interaction between the central and peripheral atoms, which tends to align the spins of the latter (see Fig. 19). Unlike the Fe_4 complex, in the compound Fe_{13} due to the competing interactions within the triangular subunits the highest possible spin $S_{\text{max}} = 12 \times 5/2 - 5/2 = 55/2$ is not reached. However, calculations showed that the ground-state spin can increase up to $31/2$ and even more with an increase in the J_{13}/J_{12} ratio from ~ 0.7 to ~ 1 . In practice, this can be attained by, e.g., replacing the $\mu_4\text{-O}$ bridging ligands by some ligands with enhanced electron-donor ability.

5. n -Nuclear complexes with $n > 13$

Currently, the problem of synthesis of polynuclear complexes containing a prescribed number of magnetic metal atoms is still far from being solved. However, methods of synthesis of such complexes are rapidly developing. In particular, crystals containing alternating complexes of trivalent iron $[\text{Fe}_{19}(\mu_3\text{-O})_6(\mu_3\text{-OH})_6 \cdot (\mu_2\text{-OH})_8\text{L}_{10}(\text{H}_2\text{O})_{12}]^+$ (Fe_{19}) and $[\text{Fe}_{17}(\mu_3\text{-O})_4(\mu_3\text{-OH})_6 \cdot (\mu_2\text{-OH})_{10}\text{L}_8(\text{H}_2\text{O})_{12}]^{3+}$ (Fe_{17}), where $\text{H}_3\text{L} = \text{N}(\text{CHRCOOH})_2 \cdot (\text{CH}_2\text{CH}_2\text{OH})$, $\text{R} = \text{H}$, were synthesised and studied.¹⁵² Both complexes have flattened compact structures (Fig. 20) and can be considered as a result of further complication of the structures of complexes Fe_8 and Mn_{12} . Experimental data showed that at least one of the two complexes has a ground-state spin, S , of $33/2$. Complexes of Fe_{19} with $\text{R} = \text{Et}$ and Me characterised by $S = 31/1 - 33/2$ and $S = 33/2$, respectively, were synthesised.¹⁵³ Currently, they have the highest ground-state spins. However, the magnetic memory effects in these complexes are weak because the parameter D of the complex with $\text{R} = \text{Me}$ equals only -0.035 cm^{-1} .

Attainment of large negative D values is likely a common problem to studies of the systems comprising only metal atoms in the S -states. Indeed, in this case the single-ion contribution to D is small⁶⁸ while the exchange is nearly isotropic. Only the dipole–dipole contribution can be large, provided that all the metal–metal bond axes are nearly parallel. Clearly, this is not probable for compact polynuclear molecules. For the same reason, strong magnetic memory effects are also not probable in the high-spin systems containing organic radicals.¹⁵⁴

Experimental data for a large number of other polynuclear complexes and their theoretical interpretation can be found in the literature.^{22–25, 154}

Figure 20. Structures of complexes $[\text{Fe}_{19}(\mu_3\text{-O})_6(\mu_3\text{-OH})_6(\mu_2\text{-OH})_8(\text{L})_{10}(\text{H}_2\text{O})_{12}]^+$ (a) and $[\text{Fe}_{17}(\mu_3\text{-O})_4(\mu_3\text{-OH})_6(\mu_2\text{-OH})_{10}(\text{L})_8(\text{H}_2\text{O})_{12}]^{3+}$ (b).

V. Conclusion

The last five decades have been characterised by rapid development of the chemistry, crystal chemistry and magnetic chemistry of exchange clusters. Analysis of experimental data for several thousands of relatively simple complexes allowed researchers to reveal and theoretically substantiate a variety of correlations between the exchange parameters and the characteristics of the electronic structure and the geometry of both molecular fragments and entire molecules. Taken together with the progress of preparative methods, this serves as a reliable basis for the development of a new research avenue in the field of coordination chemistry, namely, design of molecular magnets. In contrast to colloid chemistry,¹⁵⁵ coordination chemistry concerns polynuclear systems ($N \sim 10-20$) in the form of crystalline substances composed of 'building blocks' (molecules of a particular shape, size and orientation). Hence, such systems possess definite physical properties. At the same time, if magnetic inorganic crystals are usually grown from high-temperature melts, polynuclear complexes can be obtained from solutions at room temperature. This opens up considerable promise for the synthesis of magnets of various composition, structure and properties.¹⁵⁶⁻¹⁵⁸ In particular, the magnetic sites in crystals of polynuclear complexes can comprise molecular and submolecular units possessing nontrivial magnetic properties rather than simple metal ions.

This review has been written with financial support from the Basic Research Programmes of the Presidium of the Russian Academy of Sciences, Russian Foundation for Basic Research (Project Nos. 02-03-33075 and 03-03-32517) and from the CNR (Italy).

X-Ray spectra and electronic structure of boron compounds[†]

V D Yumatov, E A Il'inchik, V V Volkov

Contents

I. Introduction	1011
II. Characteristics of boron compounds, their structures and chemical bonds	1011
III. The physical bases of X-ray spectroscopy	1016
IV. X-Ray spectroscopy and electronic structure of boron compounds	1019
V. Conclusion	1031

Abstract. The state-of-the-art in boron chemistry, the characteristic features of boron compounds and crystalline phases based on them, the chemical bonds in these compounds and their electronic structures are considered. The physical principles of X-ray spectroscopy and the results it provided on the chemical structures of boron compounds and the nature of chemical bonds in them are discussed. Data for X-ray photoelectron and ultraviolet photoelectron spectroscopies for various elemental boron modifications, boron oxide phases, borides, nitrides, halides, derivatives of boron hydrides and carboranes, as well as metalloboranes are compared. The bibliography includes 247 references.

I. Introduction

The chemistry of elemental boron, its compounds and crystalline phases based on them is currently a vast and quite complicated scientific field at the boundary of inorganic and organoelement chemistry. Boron compounds are successfully used in various areas of materials science, in catalysis, inorganic and organic synthesis, biochemistry, agriculture, medicine, *etc.* The fundamental and applied aspects of boron chemistry are covered in sufficient detail in numerous papers, reviews and monographs and in patent literature. The publication of a festschrift on boron chemistry and special journal issues on the subject^{1–3} is evidence of the great scientific and practical value of this field of science.

The study of bond nature in compounds by both theoretical and experimental methods providing information about electronic structure is a task of current interest in modern chemistry. The results of such studies allow explanation of physicochemical properties of compounds and their reactivities and forecast ways for their synthesis. In this review, we generalise the main data of studies on the electronic structures and characteristics of chemical bonds in boron compounds by X-ray emission and X-ray absorption spectroscopies (XES and XAS, respectively). Special attention is focused on the use of these methods in combination with X-ray photoelectron spectroscopy (XPS) and ultraviolet photoelectron spectroscopy (UPS). The role of quantum-chemical calculations in interpreting the spectra is also considered. In

order to systematise data from numerous publications, we first discuss the state-of-the-art of boron chemistry and specific features of chemical bonding and coordination in the most typical classes of boron compounds and then briefly present the principles and experimental fundamentals of XPS, UPS, XES and XAS. The results of X-ray spectral studies are generalised for the main classes of boron compounds; emphasis is made on those classes that have been considered in lesser detail in previous reviews, particularly, on boron hydride compounds. Finally, we discuss the relationship between the discovered features of the electronic structures of boron compounds and their physicochemical characteristics.

II. Characteristics of boron compounds, their structures and chemical bonds

A boron atom ($z = 5$) has the $1s^2 2s^2 2p^1$ electronic configuration. When boron or boron compounds form solid phases, the valence electrons assume a more energetically favourable configuration, *viz.*, $1s^2 2s^1 2p^2$, where the boron atom has four valence atomic orbitals (AO) $2s$, $2p_x$, $2p_y$, $2p_z$ and only three valence electrons.^{4,5} A specific feature of this configuration is that, owing to the small covalent atomic radius of boron (0.80–1.01 Å) and ionic radius of B^{3+} [0.15 Å and 0.25 Å for coordination numbers (CN) 3 and 4, respectively], the electrons of a boron atom and the AOs are localised in the strong field of the nucleus with relatively weak shielding [the first ionisation potential (IP) of a B atom equals 8.3 eV].⁶ This feature imparts unusual chemical properties to boron, which allow this element with a simple electronic structure to form a very complex system of compounds and crystalline phases characterised by numerous types of chemical bonding. In particular, it is noteworthy that a boron atom can form σ -bonds involving AOs in the sp^2 configuration, *e.g.*, in such molecules as BX_3 (where X is a halogen), BR_3 , *etc.* The vacant $2p_z$ -AO predetermines the strong electron-acceptor properties of boron, which interacts with electron donors to give adducts and complexes of the $R_3N \cdot BH_3$, $BX_3 \cdot NH_3$, $Me_2O \cdot BF_3$, $[BF_4]^-$, and $[BPh_4]^-$ types. Multi-centred (mainly three-centred) bonds are formed in cluster-type boron hydrides and their derivatives, certain borides and elementary boron.^{3–5} Such compounds refer to electron-deficient systems. These compounds contain fewer valence electrons than is required to form electron pairs between neighbouring atoms that form chemical bonds. For example, a diborane(6) molecule (B_2H_6) contains 12 valence electrons (six

[†] Dedicated to the 100th anniversary of Academician Anatoly Vasil'evich Nikolaev, the author of many classical works in borate chemistry.

Figure 1. Trends in modern boron chemistry.

pairs), which enable the formation of seven bonds: six B–H bonds and one B–B bond. The electronic structures of this type of molecule are described using the multi-centred two-electron bond concept within the molecular orbital (MO) method. Study of the electronic structures of numerous boron compounds of various types by theoretical (quantum-chemical) and experimental methods is a topical problem.

Figure 1 shows schematically the directions of modern boron chemistry. This is not a comprehensive scheme, but we will use it to determine the order for presenting and discussing experimental data. We will focus the most attention on certain reviews concerning boron chemistry and on experimental methods.

The starting materials for the preparation of boron compounds, boron-containing products and materials based on them include oxide derivatives extracted from ores (boron oxide, boric acid, borates, peroxyborates).^{4, 7–11} The complexity of the crystal structures of B_2O_3 , various modifications of boric acid and structures of borate and polyborate anions in solutions and in crystalline phases has been noted.^{4, 10, 11} Figure 2 shows the structures of a number of oxide boron compounds and their typical fragments. In oxygen compounds, the coordination number of a boron atom can be equal to three (sp^2 -hybridisation and π -bonds) or four (sp^3 -hybridisation and only σ -bonds). The lamellar structure of orthoboric acid¹⁰ consists of triclinic cells, each containing four $B(OH)_3$ molecules, that are held by hydrogen bonds ($=B-O-H \cdots O-B=$) to a considerable extent (their lengths are 2.72 Å if the boron coordination number is equal to three). Each oxygen atom is involved in hydrogen bonds with two hydrogen atoms. Studies of this system are of interest for revealing the effect of hydrogen bonds on the electronic structures of the constituent atoms. The structures of polyborate anions are more complex:^{10, 11} ions containing from 1 to 6 or 9 boron atoms, such as $[B_5O_7(OH)_4]^{3-}$, $\{B_9O_{14}(OH)_4[OB(OH)_2]_2\}^{7-}$, etc., can be present in salts of these anions, both in solutions and in crystals. A six-membered heterocycle boroxol is the main structural fragment of polyborate anions; this can be part of monomeric,

polymeric and 'fused' polycyclic structures containing oxygen atoms with CN = 3.

Numerous publications deal with the preparation of pure boron, study of its structure and properties and technological and applied aspects of its usage (see, *e.g.*, the reviews and monographs^{4, 5, 8, 10, 12–14}). Elementary crystalline boron is an exceptionally 'difficult' subject. Studies of the structures of its crystalline phases and the respective physical properties are complicated by the fact that over ten polymorphic modifications of boron are known.^{5, 12} The three most stable polymorphic modifications of fused boron have been characterised reliably: the α -rhombohedral (B_{12}), α -tetragonal (B_{50}) and β -rhombohedral modifications (B_{105}). Figure 3 shows fragments of certain crystal structures of boron. The β -rhombohedral form is thermodynamically most favourable.^{10, 12, 14} Amorphous boron phases are also known; they are generally formed at relatively low temperatures. Difficulties in the preparation of chemically pure samples of individual boron phases are caused by its high melting point (2450 K), its considerable chemical reactivity (*i.e.*, high probability of contamination by admixtures from the gaseous environment and from the equipment) and the large number of crystal modifications with slow phase transitions between them. All these facts should be taken into consideration in studies and interpretation of the data on boron properties. An icosahedron with I_h symmetry is the structure-forming element of crystalline boron phases, 12 boron atoms with coordination numbers 5 occupy its vertices (B_{12}) (the coordination number is 6 in the formation of bonds between the B_{12} clusters), the B–B interatomic distances are equal to 1.73–1.79 Å (see Fig. 3*a*).^{2, 10} Owing to the electron deficiency and the relatively high ionisation energy of boron atoms (8.298 eV¹⁵), the B–B bond has substantially covalent rather than metallic character.¹⁰ Polymorphic modifications differ in the spatial arrangements of the B_{12}

Figure 3. Fragments of structures of elementary boron crystal modifications.^{4, 5, 8, 10, 12, 14}

(*a*) B_{12} icosahedron; (*b*) basis layer of B_{12} icosahedra in the structure of α -rhombohedral boron; the numbers 1 and 2 indicate that the triangles are located in different levels (1, upper, 2, lower); (*c*, *d*) structural fragments of β -rhombohedral boron based on a 'giant icosahedron' B_{84} (to provide a better picture, the B_{12} icosahedron existing in the structure is drawn in black circles).

icosahedra, the nature of bonds between them and the coordination numbers of boron atoms. Figure 3*b* shows an example of the mutual arrangement of the B_{12} icosahedra in crystalline structures. Furthermore, this polyhedron or its fragments are incorporated in many boron compounds belonging to various types. Amorphous boron can contain discrete groups containing from 2 to 6 bound B_{12} clusters together with structural units of about 100 atoms built of species involving more than 12 boron atoms (with a size of ~ 15 Å), as well as undeveloped icosahedra and sole atoms in pores.^{13, 16–18} Such structure variations affect boron properties, including electronic properties.

Borides, *i.e.*, compounds and phases in which boron atoms are bound with more electropositive elements (mainly with metals, M), represent a vast class of compounds with diverse compositions and structural types.^{4, 5, 8, 10, 12, 19–22} Many of them have a set of valuable physicochemical properties (including mechanical, thermal, corrosion, electrophysical and magnetic properties); a number of phases were found to be superconductors. The crystal-chemical aspects of boride chemistry are generalised in a monograph.²⁰ The compositions and structure types of binary borides M_mB_n are greatly diverse (Fig. 4). The existence of about 200 such borides were reported.¹⁰ Twenty-four boride compositions have been studied reliably, *viz.*, from M_5B (the metal-rich boride range) to MB_{100} (the boron-rich boride range); however, six variants of the following stoichiometric compositions, the M_2B , MB , MB_2 , MB_4 , MB_6 and MB_{12} are the most abundant. Moreover, numerous variable-composition phases and solid solutions are known. There are at least six possible configurations of boron atoms in boride structures^{10, 22} in which M–B, B–B and M–M bonds are combined in different ways, while boron can be present as single atoms or pairs of atoms, or form zigzag linear structures, branched chains, planar one-dimensional and two-dimensional hexagonal networks, and 3D cluster fragments (see Fig. 4). In a number of works,^{10, 20, 23} binary borides were classified according to the position of the metal in the Periodic table; however, no correlation of boride compositions and structures with the position of the metal could be revealed. For example, hexaborides MB_6 are typical of both alkaline-earth metals and lanthanides and actinides that are quite different from the former; however, these borides have similar structures. Diborides MB_2 are formed by metals of different groups, *viz.*, Mg, Al, Gd, Zr, V, U, *etc.*^{4, 10, 20} The nature of chemical bonding in borides is complex. Various combinations of covalent, ionic and metallic bonds exist. Numerous ternary and more complex borides and other compounds, including boron-containing fullerenes and nanostructures, have been obtained and studied.^{8, 10, 12, 20, 22, 24} The results of quantum-chemical studies on electronic structures and chemical bond nature in borides were generalised by Ivanovskii and Shveikin.^{12, 22}

At least 2500 publications (apart from patents) dealt with problems of chemistry and technology of boron nitride (BN), its crystalline modifications and most important applied properties; Refs 12 and 25–32 are the most interesting. Four crystal modifications of boron nitride are known: two graphite-like modifications, *viz.*, hexagonal (hBN) and rhombohedral (rBN), and two dense diamond-like ones, *viz.*, cubic, or sphalerite-like (cBN) and wurtzite-like (wBN), are present in the phase diagram.^{33–35} In lamellar graphite-like modifications, the B and N atoms form σ -bonds with each other; moreover, π -bonding also occurs in the layer planes due to interaction of vacant AOs of the boron atom with the lone electron pair of the nitrogen atom. Bonding between the layers in the hBN structure is also largely determined by the van der Waals and electrostatic interactions of oppositely charged boron and nitrogen atoms in layers located one above another (see Fig. 4*f*). The bonding of the boron and nitrogen atoms with the tetrahedral coordination in cBN occurs due to the interaction of sp^3 -hybrid states. The electronic structure of boron nitride was studied comprehensively; see, *e.g.*, Refs 12 and 36–39.

The fundamentals of the chemistry of boron halides are described in a number of reviews.^{10, 40, 41} Covalent trihalides

Figure 4. The main structural motives of certain metal borides and hexagonal boron nitride (hBN).

(a) shapes of ideal boron atom bonding in metal-rich borides;^{10,20,22} (b) the AlB₂ crystal structure characteristic of many other diborides;^{10,20} (c) hexagonal layers of B and M atoms in MB₂ structures; (d) cubic structure of metal hexaborides MB₆ containing octahedral clusters of boron atoms;^{4,10,22} (e) cuboctahedral B₁₂ clusters in the structures of dodecaborides MB₁₂;¹⁰ (f, g) lamellar structure of hBN and bonding of B and N atoms in layers.^{4,10}

BF₃, BCl₃, BBr₃ and BI₃ are the most typical. Their molecules are characterised by planar trigonal structures with *D*_{3h} symmetry; sp²-hybridisation of the 2s-, 2p_x- and 2p_y-AOs of the boron atom occurs in these molecules, whereas the 2p_z-AO remains vacant.^{10,40} Therefore, boron trihalides are strong Lewis acids (electron acceptors) that form adducts of the type L·BF₃ with Lewis bases (L) (see Refs 42–44). Higher boron halides are also of interest for scientists;^{45,46} these include, *e.g.*, B₂F₄ and B₃F₅, clusters such as B₈Cl₈ and B₈F₁₂ and the icosahedral *closo*-B₁₂F₁₂²⁻ anion.

The chemistry of boron hydrides and their derivatives is currently matter of intense development. Its fundamentals were established in 1912 in the classical studies by Stock, which he generalised in a monograph.⁴⁷ In 1920–1940s, boranes were considered as some kind of ‘chemical exotics’, as their stoichiometry and the nature of chemical bonds in them could not be rationalised in terms of the classical electronic valence theory. It is

of note that the chemistry of boranes and the principles of the valence theory (Lewis’ octet theory of bonding electron pairs) appeared almost simultaneously; however, the former turned out to be an opposite of the latter. A rapid development of boron hydride chemistry began in the 1950s. Of note are two types of structures and compositions of the borane systems. The first one includes the simplest systems, such as borane (BH₃), BH₃·L, the tetrahydroborate anion (BH₄⁻) and its derivatives, *e.g.*, diborane(6) (B₂H₆). The second type, which is extraordinarily abundant, includes higher boron hydrides and their cluster derivatives, *e.g.*, B₅H₉ and B₁₀H₁₄; substituted decaboranes B₁₀H₁₂L₂; *closo*-borate anions B₁₀H₁₀²⁻, B₁₂H₁₂²⁻ (of the B_nH_n²⁻ type); carboranes B_{n-2}C₂H_n, including *ortho*-, *meta*- and *para*-carboranes(12) (B₁₀C₂H₁₂) and their anionic derivatives B₉C₂H₁₂⁻; ‘sandwich’-like complexes of transition metals with the composition [M^{III}(η⁵-B₉C₂H₁₁)₂]⁻; metalloboranes and metallocarboranes, *e.g.*, Sn^{II}B₉C₂H₁₁; skeletal isomers of the heteroatomic cluster (C₅H₅)₂Co^{III}B₈C₂H₁₀; thia-*nido*-borane clusters B₉SH₁₁, B₉SH₁₂, B₉SH₁₁·L; borane polymers, and many other compounds.^{4,10,46–63} Figures 5 and 6 show schematically the main bond types and examples of structures typical of borane systems. The structures of such compounds (see Fig. 5) are mainly formed with involvement of such bonds as B–H (two-centred terminal σ-bond), B–B (two-centred bond, *e.g.*, in B₅H₈–B₅H₈), B–H–B (three-centred bridging bond in B₂H₆ and other boranes), B–B–B (three-centred triangular bond, deltahedron in clusters), BBB (three-centred central bond), M–H–B–H (three-centred bridging heteroatomic bond, *e.g.*, in Zr[BH₄]₄).

It is impossible to describe borane clusters in terms of two-centred bonds due to electron deficiency. The concept of a two-electron three-centred bond in boranes was introduced by Longuet-Higgins⁶⁴ and developed in the Lipscomb topological system,^{65–67} which resulted in the formulation of the Wade ‘2*n* + 2’ rule for the calculation of ‘skeletal’ electrons that perform bonding in a cluster polyhedron. If one knows the number of ‘skeletal’ electrons, it is possible to explain and predict the structures of cluster systems in terms of the topology of polyhedra and to systematise such systems.^{56,68–70} These concepts serve as a base for classifying cluster structures into *closo*, *nido*, *arachno* and *hypho* types; they are also taken into consideration in the prediction of ways for synthesising new compounds. Yet another, exceptionally important feature of deltahedral borane clusters is that many of them are three-dimensional aromatic systems. The concept of three-dimensional aromaticity and even superaromaticity was introduced by Hoffmann and Lipscomb back in 1962⁷¹ and was subsequently developed in a number of publications.^{4,46,52,57,72–75} Such properties of borane clusters as delocalisation of electrons over MOs,⁷⁶ chemical stability and specific reactivity⁷⁷ are related to aromaticity. Like benzenoid cyclic aromatic systems, different types of three-dimensional borane cluster structures are characterised by high exaltation values[‡] of diamagnetic susceptibility^{75,78,79} and polarisability. The nature of bonds formed by M atoms in metalloboranes is a matter of discussion, as electron density can be distributed between a metal and aromatic clusters in different ways.^{56,58,80} It is undoubtedly interesting to use experimental methods that reveal electronic structures in studies of the nature of bonds in boron hydrides. Until now, the available reviews have covered this subject insufficiently.

[‡] Exaltation of diamagnetic atomic susceptibility is the increase in the absolute diamagnetic susceptibility upon inclusion of the atom in an aromatic system.

Figure 5. Bond type characteristics of boranes and their derivatives.^{4, 10, 58, 64–67}

(a) Formation of a B–H–B three-centre bridging bond and schematic representation of the relative energies of three MOs; (b) same for central BBB bonds; (c) same for open B–B–B bonds; (d) types of bonds and structure fragments, including the heteroatomic M–H–B–H bridging bond and a triangular element of a BBB deltahedron; (e) structure of diborane(6) molecule incorporating B–H bonds and a B–H–B bridging bond; (f) structure of zirconium tetrahydroborate $[\text{Zr}(\text{BH}_4)_4]$ molecule with heteroatomic $\equiv\text{Zr}-\text{H}-\text{B}-\text{H}$ bridging bonds; (g, h) closed deltahedral clusters consisting of B and C atoms in *ortho*- and *meta*-carboranes(12), respectively.

The chemistry of heterocyclic boron compounds is vast. These compounds are characterised by heteroatomic structures containing mainly from 4 to 6 atoms in a ring, systems of fused boron heterocycles and polymers.^{10, 81–87} However, no molecular cyclic systems consisting exclusively of boron atoms (similar to cyclohexane, benzene and naphthalene molecules) are known. Along with B atoms, the rings can contain C, O, N, P, Si and S atoms in various combinations. A scheme of MOs upon interaction of B and N atoms in heterocycles is shown in Fig. 7.

Ligands at the ring-forming atoms mainly include organic substituents (alkyls, aryls) and halogens that also stabilise the system. Certain five-membered heterocycles, e.g.,

are aromatic and form mononuclear and polynuclear mono- and polymetallic ‘multi-decker’ ‘sandwich’-type complexes with transition metals (Fe, Co, Ni, Cr, Ru) in which planar B_2SC_2 , B_3C_2 and other rings serve as bidentate ligands.^{61, 86, 88}

M = Fe, Co, Ni.

The nature of chemical bonding in cyclic structures, especially in boron complexes, is rather complex. This involves vacant $2p_z$ -AOs of boron, which interact with lone electron pairs belonging to the AOs of other atoms in rings (N, P, S, etc.) with partial π -bonding.

By now, the chemistry of organoboron compounds has evolved into an extensive field of science that studies the laws of formation, reactivities, structures and properties of compounds and systems containing $=\text{B}-\text{CR}=$ bonds with consideration of modern concepts on the electronic nature of bonds.^{84, 85, 89, 90}

To a certain extent, the data considered above reflect the complex structure of boron compounds and the diversity of chemical bond types therein. Therefore, the use of experimental methods, such as X-ray emission spectroscopy, X-ray photoelectron spectroscopy and UV photoelectron spectroscopy, com-

Figure 7. Scheme of AO interaction and qualitative scheme of MOs for the interaction of boron and nitrogen atoms in heterocycles with partial π -bonding.⁸³

bined with modern quantum-chemical methods for calculation of electronic structures, allows a deeper insight into the nature of chemical bonds in boron compounds.

III. The physical bases of X-ray spectroscopy

The principles of the XPS, UPS, XES and XAS methods and their experimental bases have been covered in numerous publications, starting from the classical monographs by Blokhin⁹¹ and Siegbahn *et al.*⁹² These principles and the experimental techniques for their implementation have subsequently been developed in detail and used to study various compounds.^{42, 93-103} It should be noted

that the majority of works on this subject have been carried out in the 1970s and in the early 1980s, when these methods were being implemented intensely. The basic theoretical principles of these methods have not changed considerably since that time. Great advances in the hardware implementation of these research methods have been achieved in recent years due to the development of synchrotron radiation (SR) sources.

1. The bases of X-ray photoelectron spectroscopy and UV photoelectron spectroscopy

Let us start our consideration of the physical bases of X-ray spectroscopy from the XPS and UPS methods, since these methods are used to study the process of 'preparation' for a secondary electron transition in an atom, namely, electron photoemission upon impact of ultraviolet (UV) or X-ray photons and formation of a vacancy on one level of an atom or a molecule. The probability of vacancy formation as a function of the excitation irradiation energy is studied using X-ray absorption spectroscopy. In turn, X-ray emission spectroscopy is used to study the decay of such a vacancy; in particular, the latter can be located on an inner atomic shell.

The XPS and UPS methods are based on the Einstein equation for photoeffect:

$$h\nu = IP + E,$$

where $h\nu$ is the energy of a photon (excitation radiation) impacting an atom; IP is the ionisation energy (potential) or the binding energy (E_b) of a valence or an inner electron level of an atomic-molecular system, which is coordinated with the calculated orbital energy; E is the kinetic energy of a photoelectron, which can be measured by an electron speed analyser. UPS employs ultraviolet irradiation for the excitation, whereas XPS employs soft X-ray irradiation. The most common UV sources include the He(I), He(II) and Ne(I) resonance lines (21.2, 40.8 and 16.8 eV, respectively), which allows the energies of outer electrons of atomic-molecular systems to be determined.^{42, 94, 96, 98} The sources used in XPS mainly include the MgK_{α} - (1253.6 eV) and AlK_{α} -radiation (1486.6 eV).^{42, 93, 96, 97, 99, 100} A photoelectron spectrum is the dependence of the number of emitted photoelectrons per unit time, *i.e.*, the line intensity (I), on the ionisation potential (IP) or binding energy (E_b) (the magnitudes of IP and E_b are usually expressed in eV). The measured values of IP or E_b make it possible to reveal the order of energy levels in a molecule, their symmetry, the bonding or antibonding character of separate MOs, and the relative contributions of different AOs of adjacent atoms when a MO is formed (these data are important for understanding various physical and chemical properties of a compound). In order to interpret UPS and XPS spectra of various compounds, it was suggested (with a considerable degree of approximation) to allocate three spectral regions, depending on the electron binding energy.¹⁰³ The first region ($E_b \approx 0-15$ eV) characterises structures formed with involvement of electrons from outer valence MOs, which are mainly formed by incompletely filled electrons of valence AOs. The second region ($E_b \approx 15-50$ eV) covers the structures formed by electrons of inner valence MOs (IVMOs). Finally, the third region ($E_b \gtrsim 50$ eV) contains lines reflecting the positions of deep inner (core) AOs. At present, a concept is being developed that IVMOs are considerably involved in chemical bonding along with valence MOs.¹⁰³ X-Ray spectroscopy confirms some statements of this concept by shedding light on the very complex actual electronic nature of chemical bonds. It should also be noted that the UPS method is used to study valence shells, whereas XPS is often used to study inner (atomic) shells, though it is used rather extensively to study outer shells as well.

2. X-Ray emission and absorption spectroscopies and their specific features

X-Ray emission and absorption methods provide information about the energy, composition and symmetry of molecular

orbitals. The use of these methods for the study of chemical bonds is covered in a number of monographs.^{42, 96, 99, 101}

Let us consider the physical principles of the XES and XAS methods. X-Ray emission radiation appears to be due to transitions of electrons from outer occupied levels of a molecule to inner atom-like levels that contain vacancies, which, in turn, are formed due to interaction of the molecules with a beam of high-energy electrons or upon irradiation by X-ray photons. X-Ray absorption spectra reflect transitions of electrons from an inner level to outer vacant levels of a molecule caused by incidence X-ray radiation. The main distinctive feature of these processes is that these are involved in both emission and absorption electron transitions of an inner level; the electrons on this level contribute only slightly to the chemical bond and have an almost atomic character. On the other hand, outer MOs form a system of orbitals common to the entire molecule. One can find the ionisation potential of a valence MO (IP_i) by determining the energy of an X-ray photon, which is equal to the energy of electron transition between two levels, *viz.*, an outer valence level (i) and an inner level (k), $h\nu = E_{ik}$, and given the ionisation potential of the inner MO (IP_k) (which is obtained by XPS):

$$IP_i(\text{MO}) = IP_k(\text{AO}) - E_{ik}.$$

Experimental values of $IP_i(\text{MO})$ are also provided by UPS. Hence, using the above relationship as the base, one can compare the X-ray and photoelectron spectra in a single energy scale of ionisation potentials (this operation was called matching).⁹⁶ Such a combined use of XES, UPS and XPS allows much more precise identification of specific spectral lines. However, X-ray emission spectra of different elements of a chemical compound under study can provide not only the values of MO energies but also data on the contributions of separate AOs of these elements to these values. X-Ray absorption spectra provide similar data about vacant MOs. As noted above, XES and XAS spectra can be used not only to study the energy spectrum of a molecule but also to analyse the composition of molecular orbitals, namely, to determine the squares of the coefficients at the atomic wave functions constituting an MO. To illustrate this, Fig. 8 shows a qualitative scheme of X-ray transitions from two MOs, i and j , to inner 1s-levels of boron and carbon atoms (taken as examples) within a polyatomic molecule. (It should be remembered that the short notation of X-ray spectra includes the element symbol, the level to which the electron transition occurs, and — for emission spectra — a Greek letter indicating the particular transition. In the case of absorption spectra, no Greek letter is specified.) As one can see from Fig. 8, transitions from valence MOs i and j to the same inner level, *e.g.*, B1s, give X-ray BK_{α} -spectral lines whose intensity ratio is equal to the ratio of squares of the contributions of the 2p-AOs of boron ($I_i/I_j = c_{iB2p}^2/c_{jB2p}^2$). CK_{α} -Spectral lines can be analysed in

Figure 8. Scheme of X-ray transitions in the molecule and their identification. See the text for explanations.

a similar way; furthermore, more valence and inner levels can be taken as examples. A detailed analysis of this method for the determination of energy positions of MOs and their compositions is presented in a number of publications^{42,96,101} where its scope and limitations are discussed. It should be noted that the K_{α} -spectra of B, C, N, O and F atoms considered in this review allow one to determine the contributions of 2p-AOs of these atoms to MOs of chemical compounds; the K_{β} -spectra of P, S and Cl atoms allow the determination of the contributions of 3p-AOs to MOs, the $L_{2,3}$ -spectra of these atoms provide the contributions of 3s- and 3d-AOs, and finally, the L_{α} -, L_{β} -spectra of Fe, Co and Ni atoms provide the contributions of the 3d-AOs.

The instruments and procedures used to obtain X-ray emission and absorption spectra have been described in detail in a number of monographs.^{42,91,95,96,99,101,104} The scheme of an X-ray spectrometer is shown in Fig. 9. The X-ray emission radiation of a compound under study, that can be either in a solid or gaseous state, is excited by electrons or photons. The induced radiation passes through a number of diaphragms and falls on the dispersing element and, after reflection from the latter, on the detector. Expansion of the X-ray radiation from the compound into a spectrum by the dispersing element followed by recording of the spectrum can give the dependence of the radiation intensity on the wavelength or photon energy (in eV). X-Ray absorption spectra are obtained as follows. A sample to be studied is placed in the way of X-ray radiation and the attenuation/absorption factor (defined as the logarithm of the ratio of the beam intensity that has passed through the sample to the initial beam intensity) is determined as a function of the energy of the monochromatic exciting radiation. In the case of samples non-transparent to soft X-ray irradiation, X-ray absorption spectra are recorded in the electron yield mode (complete or partial yield, or yield of Auger electrons as a function of energy discrimination of detected electrons).¹⁰⁴ Synchrotron radiation, whose intensity is many orders of magnitude higher than that from X-ray tubes, is increasingly used at present to excite X-ray transitions in chemical systems.^{105–107}

Figure 9. Schematic diagram of an X-ray spectrometer.

(1) Electron gun or primary radiation (photon) source; (2) compound under study; (3) sample holder (secondary anode); (4) system of apertures; (5) dispersing element (analyser crystal or diffraction lattice); (6) detector.

The information provided by X-ray absorption spectra can also be obtained from electron energy loss spectra (EELS).¹⁰⁸ The essence of this spectral method is as follows: as a result of inelastic collision of monochromatic electrons with molecules under study, one of their inner electrons passes to one of the available vacant levels, whereas the loss of the energy of the incidence electron is equal to the energy of this transition. Having determined the electron energy before the collision and that after the collision using an energy analyser, one can plot the energy spectrum of transitions from different inner molecular levels to vacant orbitals.^{108,109} Inelastic scattering of hard X-ray irradiation (X-ray Raman scattering) can be used in a similar way.

A specific feature of chemical bonding in many boron-containing compounds is that it involves donor–acceptor interactions. The formation of a donor–acceptor bond between two molecules (e.g., $NX_3 \cdot BY_3$, where X, Y = H, Hal, Alk etc.) occurs

Figure 10. Scheme of donor–acceptor interaction in the two-level model approximation. See the text for explanations.

due to the electron density transfer from the highest-energy occupied orbital of the donor to the lowest-energy vacant orbital of the acceptor (for more details, see Refs 110–112).

Donor–acceptor interaction in the two-level model approximation is demonstrated in Fig. 10. A system under study contains two valence-saturated molecules, viz., a donor (D) and an acceptor (A). The highest occupied MO (HOMO) of the donor contains a lone electron pair localised on the ‘d’ atom (see Fig. 10). The wave function of this orbital, $\Psi(D)$, consists of one wave function of the ‘d’ atom, $\psi(d)$. The lowest unoccupied MO (LUMO) of the acceptor is localised on the ‘a’ atom. Its wave function $\Psi^*(A)$ (here and below, vacant orbitals are marked with asterisks) also consists of one wave function of the ‘a’ atom of the acceptor molecule, i.e., $\psi^*(a)$. It is sometimes called a lone hole pair. Thus, the HOMO of the ‘D’ molecule and the LUMO of the ‘A’ molecule are similar to the AOs of the ‘d’ and ‘a’ atoms, respectively. Interaction of the ‘D’ and ‘A’ molecules through the ‘d’ and ‘a’ atoms results in an occupied bonding orbital with the wave function $\Psi(DA)$ and a vacant antibonding orbital with the wave function $\Psi^*(DA)$:

$$\Psi(DA) = c_d \Psi(D) + c_a \Psi^*(A) = c_d \psi(d) + c_a \psi^*(a),$$

$$\Psi^*(DA) = c_d^* \Psi(D) - c_a^* \Psi^*(A) = c_d^* \psi(d) - c_a^* \psi^*(a),$$

where c_d , c_a , c_d^* and c_a^* are expansion coefficients of the MOs over the AOs. The degree of electron density transfer from the donor to the acceptor, in both the main and excited states, depends on the values of the squares of these coefficients.

Let us consider how the donor–acceptor interaction manifests itself in X-ray spectra. The HOMO of the donor molecule (lone electron pair) is described by the wave function of the highest occupied AO of the donor atom. The expansion coefficient of the AO in the MO is equal to unity ($c_{ij} = 1$). The donor molecule does not have any other orbital with such a high contribution of this AO. Naturally, inasmuch as $I \sim c_{ij}^2$ (see Fig. 8), the electron transfer from the HOMO gives the most intense line in the X-ray spectrum. In the two-level model approximation, the HOMO of the new compound DA resulting from the formation of a donor–acceptor bond is described by a wave function consisting of two AOs, viz., that of the ‘d’ atom of the ‘D’ molecule and that of the ‘a’ atom of the ‘A’ molecule. Accordingly, the participation coefficient of the AO of the ‘d’ atom of the donor molecule ‘B’ becomes less than unity. Hence, the relative intensity of the X-ray line originating from the electron transfer from the MO of the DA molecule to the inner level of the ‘d’ atom of the same molecule also decreases. It is assumed that deeper MOs of both the donor and acceptor do not change, that is, the bond formed between the molecules does not introduce considerable disturbance, and their electrons are not involved in the formation of the chemical bond. As a result, the structure and intensity of the rest of the X-ray spectrum change quite insignificantly. In such a case, filling of the LUMO under consideration changes the intensities in the X-ray absorption spectra of the acceptor molecule within the DA adduct. It should be noted that the approach described above is

rather approximate and that it is useful for illustration purposes only.

IV. X-Ray spectroscopy and electronic structure of boron compounds

Fundamental X-ray spectral studies of boron compounds were carried mostly in the 1960–1970s by a group of physicists from the Leningrad University.¹⁰⁴ The X-ray spectra recorded in the 1930–1940s when the ultra-mild X-ray spectroscopy was in its infancy were limited by the low resolution of equipment and were only descriptive (see the references in the monograph by Maisel *et al.*⁹⁹).

1. Oxide systems

X-Ray studies have been conducted for only a few oxygen-containing boron compounds. The majority of studies dealt with the electronic structure of boric anhydride (B_2O_3). The following spectra were recorded and discussed: emission BK_α -spectra,^{39, 93, 104, 113–127} OK_α -spectra^{116, 117} and absorption BK -spectra.^{39, 104, 115, 122, 123, 128–132}

Extensive application of synchrotron radiation as a source for the excitation of X-ray fluorescence in studies of the electronic structure of B_2O_3 began in the 1990s.^{121–125} It was used in a number of studies^{122, 123, 128–131} of X-ray absorption spectra of boron. O'Brien *et al.*¹²¹ and Muramatsu *et al.*^{122–124} studied the BK_α -emission spectra of boron (Fig. 11) using monochromatic synchrotron radiation. It was found that changes in the energy (or wavelength) of excitation radiation change both the energy positions of single lines and their intensities, and hence the shape of the entire spectrum. The behaviour of the highest-energy

structure (the region of ~ 190 – 210 eV in the transition energy scale) is characterised by the greatest differences. Having related the energies of emission lines to the values of the energy maxima in the X-ray absorption spectrum (see Fig. 11 *a*), one can say that vacant orbitals (excited state) specifically manifest themselves in the emission spectrum due to reemission transitions. Reemission transitions have first been studied by Fomichev *et al.*³⁹ The reemission process involves two steps, *viz.*, transition of an electron occurs in the first step, *e.g.*, from an occupied K -shell to a vacant orbital to form a line in the absorption spectrum and reverse transition of the electron to the original level K occurs in the second step, which results in a line in the emission spectrum. Generally, these lines have the same energies if both spectra are compared (see, *e.g.*, Ref. 104). Studies of the behaviour dynamics of reemission lines as a function of the exciting radiation energy revealed the existence of some kind of resonance: if the excitation energy coincides with the energy of electron transition from the K -shell of the boron atom to a vacant orbital, the intensity of the reemission line increases.^{123, 124} The theory of resonance excitation was considered in a series of fundamental studies (see, *e.g.*, the monograph by Mazalov *et al.*⁹⁶ and references cited therein). It should be noted that a version of X-ray emission spectroscopy which uses resonance excitation is called resonant inelastic X-ray scattering (RIXS) in current literature.

A combined analysis of the K_α -spectra of boron and oxygen and the XPS spectrum of B_2O_3 in the valence band was carried out.¹³³ All the spectra were reduced to a common energy scale using XPS data. The structure of a particular cluster was considered. Based on X-ray spectra, conclusions on the contributions of the 2p-AOs of oxygen and boron to different levels of the valence band were drawn.

One of the first interpretations concerning boron X-ray emission and absorption spectra was based on quantum-chemical calculations in the CNDO approximation.¹³⁴ It was assumed that the symmetry point group of the boron atom's nearest environment in the planar network is D_{3h} . The calculation was first performed for the BO_3^{3-} cluster, *i.e.*, only the first coordination sphere was taken into account; after that, for better fit with experimental X-ray emission and absorption spectra, the BO_3B_3 cluster was calculated, *i.e.*, the second coordination sphere was also taken into account. This is likely to be the only study where X-ray emission and absorption spectral lines of boric anhydride, B_2O_3 , are compared with the symmetry and energy parameters of levels calculated by quantum-chemical methods. The $X\alpha$ -DV (discrete variation) approximation was used to simulate the X-ray BK_α -emission spectrum,¹²⁴ though Muramatsu *et al.*¹²² reported only the overall spectrum shape but not the energies of the spectrum-forming MOs calculated by the quantum-chemical method. A more detailed approach was used by Kawai *et al.*¹³⁵ who reported the energies of the MOs forming the theoretical spectrum and their symmetries; in the case of boric anhydride B_2O_3 , they considered the $B_2O_5^{4-}$ cluster (point symmetry group D_{2d}) in which each boron atom is surrounded by three oxygen atoms. However, Kawai *et al.*¹³⁵ only studied the X-ray OK_α -emission spectrum.

The X-ray emission and absorption spectra of B_2O_3 reduced to a common energy scale using the binding energies of inner electrons¹⁰⁰ are presented in Fig. 12, which shows XPS spectra in the valence band. The zero of the binding energy scale corresponds to the Fermi level (E_F) of the X-ray photoelectron spectrometer (see Refs 92 and 133). Different spectra were compared using XPS data in the energy region corresponding to inner layers.¹⁰⁰ To identify the structures of these spectra, let us compare different spectra, as has been done by Nakhmanson and Baranovskii,¹³⁴ based on data on the electronic structure of the BO_3^{3-} cluster with D_{3h} symmetry. X-Ray OK_α - and BK_α -emission spectra provide data on the contributions of the 2p-AOs of oxygen and boron to the occupied MOs, while the corresponding absorption spectra reflect the structures of vacant orbitals. The low-energy (henceforth, the transition energy scale is implied) $e'(\sigma)$ -

Figure 11. X-Ray absorption spectrum of boron (*a*) and X-ray BK_α -emission spectra of boric anhydride B_2O_3 (*b*–*e*) obtained at different synchrotron excitation energies (E_{hv}).¹²³ $E_{hv} = 214.8$ (*b*), 203.1 (*c*), 196.8 (*d*), 193.0 eV (*e*).

Figure 12. X-Ray OK_{α} -emission spectrum (a),¹¹⁶ X-ray BK_{α} -emission spectrum (b, spectrum 1),¹¹⁵ X-ray spectrum near the radiation BK -absorption edge (b, spectrum 2)¹³¹ and X-ray photoelectron spectrum in the B_2O_3 valence band (c).¹³³

line of the X-ray BK_{α} -emission spectrum, which coincides with an intense line in the XPS spectrum (see Fig. 12), matches the MO with e' symmetry mainly formed from oxygen and boron 2s-AOs. In the X-ray BK_{α} -emission spectrum, this is manifested due to a small admixture of the $B2p$ -AO. Electrons of this orbital form σ -bonds between boron and oxygen atoms. They are followed by one orbital with a'' symmetry (π -bond) and two MOs with e' symmetry (σ -bond) mainly consisting of boron and oxygen 2p-AOs. They manifest themselves as a low-energy shoulder on the dominant line and as this line of its own in the X-ray OK_{α} -emission spectrum, and also as a broad intense band in the X-ray BK_{α} -emission spectrum (see Fig. 12). There is a corresponding broad band consisting of three lines in the X-ray photoelectron spectrum. The first line of the X-ray spectrum near the BK -absorption edge of boron, which is identified as a vacant $a''(\pi^*)$ -MO, matches the highest-energy maximum of the X-ray BK_{α} -emission spectrum. This provides reasons to assign the latter to a reemission transition line, *i.e.*, electron transition from the excited $a''(\pi^*)$ -level to a vacancy in the boron K -shell. Finally, the last broad line in the absorption spectrum is matched with the antibonding unoccupied $e'(\sigma^*)$ -MO.

The X-ray OK_{α} -emission spectrum of boron suboxide B_6O was studied.^{135, 136} Quantum-chemical calculations of the B_6O structure and of this spectrum were performed in the $X\alpha$ -DV approximation using a cluster of two triangles, which contained boron atoms in the vertices and oxygen atoms in the centres (B_6O_2). The electronic structures were calculated and the X-ray OK_{α} -emission spectra were constructed as a function of the distance between the oxygen atoms and hence between the planes in which these triangles are located. Kawai *et al.*^{135, 136} chose this distance in such a way that the theoretical and experimental spectra matched most closely and compared it with data on the B_6O structure. An experimental X-ray BK_{α} -emission spectrum was published earlier,¹³⁷ with the spectrum structure studied at different energies of the excitation SI.

The X-ray BK_{α} -emission spectrum^{113, 120} and X-ray OK_{α} -emission spectrum of H_3BO_3 were obtained.¹³⁸ The BK -absorption spectra of this compound were recorded in a number of studies,^{128, 129, 132, 139} the first of which employed SI. The X-ray absorption spectrum was also reported.¹³⁹ The spectra of H_3BO_3 and B_2O_3 are very much alike because the boron and oxygen atoms have the same nearest environment. The identification of maxima in the structures of X-ray BK_{α} -emission and BK -absorption spectra of H_3BO_3 was performed on the basis of calculation of these spectra in the CNDO approximation.¹³⁴

The electronic structures of other oxide compounds of boron were also studied.^{113, 120, 128} For example, X-ray emission spectra of boron were recorded and described for $Na_2B_4O_7$,¹¹³ $AlBO_3$, $Be_2(BO_3)OH$, $Mg[(OH)_3BOB(OH)_3]$, $CaB_2Si_2O_8$ and BPO_4 .¹²⁰ The X-ray absorption spectra of boron for $Na_2B_4O_7 \cdot 10H_2O$, $NaBO_3 \cdot 4H_2O$, $Zn[B_2O(OCOME)_5]_2$ and BPO_4 were obtained using SI.¹²⁸

2. Elementary boron, borides and boron carbide

Numerous studies deal with X-ray emission (Refs 93, 104, 113–117, 122, 126 and 140–145) and X-ray absorption spectra of elementary boron.^{104, 115, 122, 129, 130, 140, 143, 144} Although several modifications of crystalline and amorphous boron exist, their X-ray spectra differ insignificantly. The most considerable 'chemical' effects are observed in the BK_{α} -spectra on transition from elementary boron to its oxide and nitride (see Sections IV.1 and IV.3). The spectra of B, B_2O_3 and BN show noticeable differences: a considerable low-energy shift of the main band is observed for B_2O_3 and BN (by 2.72 and 2.45 eV, respectively, with respect to B); in addition, the spectra of B_2O_3 and BN contain new lines in comparison with the spectra of elementary boron. These include a low-energy line (165.4 eV in the spectrum of B_2O_3 and 169.0 eV in the spectrum of BN), which originate probably from electron transitions from the MO mainly containing the $B2s$ -AO (with a small contribution of the $B2p$ -state) to the K -shell of the boron atom containing a vacancy, as well as the maxima which appear due to reemission transitions (191.4 and 190.0 eV for B_2O_3 and BN, respectively).⁹³ These features may be related to changes in both the chemical environment of the boron atom and the character of binding (see, *e.g.*, Ref. 93). A comparison of X-ray emission and X-ray absorption spectra of amorphous boron allowed the band gap width to be evaluated.¹⁴⁰ Sobczak and Persy¹⁴⁴ reduced the BK_{α} -emission and BK -absorption spectra, as well as the photoelectron spectrum in the valence band, to a common energy scale using the energies of inner $B1s$ -electrons. They also presented an X-ray isochromate¹⁴⁴ of elementary boron whose structure compares with that of the XAS spectrum (the method to obtain isochromates was described, *e.g.*, by Maisel *et al.*,⁹⁹ who also gave references to early X-ray spectroscopic studies). Results of studies on the electronic structures of different modifications of elementary boron were generalised in the monograph by Ivanovskii and Shveikin.¹²

The monograph by Zhurakovskii¹⁴⁶ should be considered among the first works on the electronic structures of borides M_nB_m (where M is a metal) studied by X-ray spectroscopy. He presented a large number of X-ray spectra and related them to

parameters that characterise the electronic structures of compounds (the energies and relative intensities of spectral lines). The results of more recent studies on the electronic structures of metal borides were generalised in the monograph by Ivanovskii and Shveikin.¹²

Studies on medium-temperature superconductivity carried out in the past decade showed that this property is inherent in MgB_2 as well.¹⁴⁷ Its electronic structure was studied by various physical methods, including XES and XAS.¹⁴⁸

The X-ray BK_α -emission spectra,^{104, 113–116, 118, 120, 126, 149, 150} CK_α -emission spectra¹¹⁶ and X-ray absorption spectra^{104, 115, 130, 149, 150} of boron carbide B_4C were recorded and described. The X-ray BK_α -emission and BK -absorption spectra of B_{10}C and B_{11}C were studied,¹⁵⁰ and the X-ray BK_α -emission spectrum of B_{12}C_3 was published.¹¹⁷ Unfortunately, traditional analysis of these spectra based on calculation results was not carried out in these studies, hence identification of spectral lines was not performed either.

3. Boron nitrides and other binary compounds

The X-ray BK_α -emission spectra of boron nitrides (Refs 39, 93, 104, 113–118, 120, 121, 124–126, 133, 136, 140, 151–155) their X-ray BK -absorption spectra,^{39, 104, 115, 122, 130, 140, 151–153, 156, 157} NK_α -emission spectra^{93, 104, 116–118, 126, 133, 140, 151–154} and NK -absorption spectra were studied.^{104, 131, 151–153, 156} Considerable attention was given to the study of the structures of these spectra. For example, it was shown that admixtures of elementary boron or a boron oxide film affect the X-ray BK_α -emission spectrum of hBN.³⁹ Furthermore, the existence of several modifications of crystalline boron nitride gave grounds for studying the composition of a BN sample in order to find out whether it contained only one or several modifications.¹⁵⁴ The X-ray spectra of boron nitride modifications, cBN and hBN, differ markedly. Joyner and Hercules¹³³ studied X-ray emission spectra along with the photoelectron spectrum in the valence band of hBN.¹³³

As noted above (see Section III.2), SI is currently being used ever more often to obtain X-ray spectra. This irradiation source was also used to study the emission and absorption X-ray spectra of boron nitride.^{121, 122, 124, 125, 130, 131, 158–170} In a number of experiments, emission spectra of boron nitride were recorded with excitation of X-ray fluorescence by monochromatic (or quasi-monochromatic) SI. The X-ray fluorescence spectra obtained in this way differ in the energy positions of separate lines and their relative intensities depending on the wavelength of the excitation line. This effect was observed for X-ray lines of both BK_α - and NK_α -emission.^{121, 122, 124, 158–165} In some works,^{124, 159, 161} monochromatic radiation was used to study the high-energy structures of spectra or lines of reemission transitions (*cf.* Section IV.1, analysis of the X-ray spectra of B_2O_3). The intensity of a line corresponding to reemission transition increases abruptly at a certain energy of the excitation photon.

The polarisation character of X-ray emission spectra of hBN single crystals and changes in the bands of these spectra (their positions and intensities) for different directions of the radiation exit from single crystals with respect to particular crystallographic orientations were studied.^{171–174} Synchrotron radiation was used as the irradiation source in many studies.^{37, 158, 167, 175–180} The orientation emission effect was also used to determine the symmetry of vacant orbitals that manifest themselves in absorption spectra.^{167, 177–180} Electron energy loss spectroscopy was used to study the orientation effects in hBN crystals.^{181, 182} The dependence of the reflection factor of ultrasoft X-ray irradiation by hBN near the K -edge of boron absorption on the grazing incidence angle was studied.^{183, 184} In this study, reflections from two crystal faces cut in parallel and normally to its main symmetry axis were measured successively. These spectra agree satisfactorily with those obtained in the electron yield mode (see Section III.2).

One of the first calculations of boron nitride was carried out for hBN using the CNDO method with the first (the BN_3^{6-} cluster) and second (BN_3B_6) coordination spheres taken into account.¹³⁴

As expected, the results are similar to X-ray spectroscopic experimental data provided that the effect of the second coordination sphere is taken into account. The main specific features of X-ray emission and absorption spectra are related to the structure of the nearest environment of an excited atom, which explains the differences between the X-ray spectra of different BN modifications. Based on calculations of the electronic structure in the $X\alpha$ -DV approximation, a theoretical X-ray BK_α -emission spectrum of boron nitride was obtained.¹²² Data on calculations on the electronic structure of boron nitride were summarised and compared to experimental spectra in certain monographs.^{12, 185} The most recent achievements in this field are reported in Refs 186–192.

This was the general survey of X-ray studies on the electronic structure of boron nitride. Let us consider some of its aspects more specifically and see how chemical bond features manifest themselves in the X-ray spectra. Figure 13 *a, b* shows the X-ray spectra of the hexagonal and cubic modifications of boron nitride, respectively. The X-ray BK_α - and NK_α -emission spectra were taken from Refs 151 and 152, while the BK - and NK -absorption spectra were taken from Ref. 131. All the spectra refer to a common energy scale relative to the Fermi level, taking into account the binding energies of inner B1s- and N1s-electrons obtained by XPS;¹⁰⁰ they are compared with photoelectron spectra of boron nitride in the valence band.^{193, 194} The X-ray spectra of hexagonal boron nitride are interpreted on the basis of results of CNDO calculations¹³⁴ for the BN_3^{6-} cluster (symmetry point group D_{3h}) and MNDO calculations (MOPAC-60 software) for a hypothetical isolated BN molecule (symmetry group $C_{\infty v}$). The results of the latter are shown in Fig. 14. MNDO calculations for such a molecule give quite a moderate qualitative picture of the electronic structure of boron nitride as a polyatomic system that has different modifications, but maintains its main features. Passage from an isolated BN molecule to a polyatomic system results in dithering of the MO into a band whose description requires calculations within the zone theory of solids or quantum-chemical calculations of polyatomic clusters. If hBN is considered with the nearest environment taken into account, then the e' -MO is the orbital whose electrons form the σ -bond in the layer plane (hBN is considered as a lamellar structure). Molecular orbitals of this symmetry are built of $2p_x$ - and $2p_y$ -AOs of boron and nitrogen; the MOs with the a_2'' symmetry are built of $2p_z$ -AOs and are responsible for the π -type chemical bond in the layer normal to the network plane. The deepest valence level is comparable with the low-energy line of X-ray BK_α -emission spectrum of low intensity (see Fig. 13); no similar line was found in X-ray NK_α -emission spectra presented in Refs 151 and 152. Only Hayasi¹¹⁶ succeeded in obtaining a low-intensity maximum with a transition energy of ~ 377 eV. A comparison of both of these low-energy lines in the X-ray BK_α - and NK_α -emission spectra show that their energies match each other and the energy of the most intense line in the XPS spectrum.¹⁹³ According to quantum-chemical calculations, these lines can be related to the level corresponding to the σ -bond and mainly consisting of the $2s$ -AOs of boron and nitrogen. They appear in X-ray BK_α - and NK_α -emission spectra because the $e'(\sigma)$ -MOs contain an admixture of $2p$ -AOs of the same atoms (see Fig. 13). An increase in the transition energy produces intense maxima with fine structure in X-ray BK_α - and NK_α -emission spectra; these maxima coincide if the spectra are superimposed. It is suggested to match the intense BK_α -band with the a_2'' -MO and to match the high-energy shoulder successively with two orbitals with e' symmetry.¹³⁴ However, the results of MNDO calculation (see Fig. 14) and data of studies on polarisation effects in X-ray emission spectra³⁷ (see Fig. 13) suggest that a somewhat different order of these orbitals should be assumed: as the transition energy increases, two MOs with e' symmetry are followed by a MO with a_2'' symmetry (see Fig. 13). The fact that the maxima in X-ray BK_α - and NK_α -emission spectra and XPS spectra coincide in the valence band if a comparison is made using the energy positions of inner orbitals allows these

Figure 13. X-Ray NK_{α} - (a, b) and BK_{α} -emission spectra (c, d) (spectra 1)^{151, 152} and NK- (a, b) and BK-absorption spectra (c, d) (spectra 2)¹³¹ and photoelectron spectra (e, f)^{193, 194} in the valence band of hexagonal (a, c, e) and cubic (b, d, f) boron nitride.

X-ray spectra to be interpreted as well (see Fig. 13). According to CNDO calculations, the first vacant orbital¹³⁴ has a_2'' symmetry and corresponds to a narrow line in the X-ray BK-absorption spectrum (see Fig. 13) and to a distinct line in the X-ray NK-absorption spectrum.¹³¹ The same conclusion can be drawn based on the fact that the line positions coincide when the X-ray BK- and NK-spectra are superimposed. It is also evident from Fig. 13 that

the first low-energy line in X-ray absorption spectra coincides with the reemission line in the X-ray BK_{α} -emission spectrum, which thus can be related to the lowest vacant $a_2''(\pi^*)$ level. The two next vacant MOs with the e' symmetry manifest themselves in X-ray absorption spectra as two distinct lines¹³¹ (see Fig. 13).

As noted above, studies of orientation (polarisation) effects have played an important role in the interpretation of boron

Figure 14. Theoretical X-ray NK_{α} - (a) and BK_{α} -emission spectra (b) of boron nitride (MNDO calculation). The vertical bars show the contributions of atomic N2p (a) and B2p orbitals (b) to the MO.

nitride spectra (see Refs 37, 158, 167 and 171–180). In fact, for a one-dimensional layer of crystalline hBN (assuming weak interaction between the layers), band electron states can be subdivided according to σ - and π -symmetry corresponding to σ - and π -bonding between atoms. The electric-field vector of the electromagnetic wave (polarisation plane) appearing due to the transition, *e.g.*, from the π -state to a $1s$ -vacancy, is parallel to the $2p_z$ -orbital. If one varies the orientation of the analyser crystal (which expands the emission radiation into a spectrum) relative to the boron nitride single crystal, it is possible to record changes in the intensity of the band related to the π -state and even its disappearance.^{42, 171, 172} The use of SI for studying this effect provides yet another advantage. The point is that such radiation becomes plane-polarised. By changing the angle between the incidence radiation and the plane of the boron nitride crystal (grazing incidence angle), one can also observe changes in the intensity of the π -band in the spectrum. The emission spectra of hBN obtained with the use of SI at different grazing incidence angles³⁷ are presented in Fig. 15.

Figure 15. Orientation effects in X-ray BK_{α} - (a, c, e) and NK_{α} -emission spectra (b, d, f) of hexagonal boron. Dependence of the relative intensities of the lines corresponding to σ - and π -bonds on the angle between the incident polarised radiation and the crystal surface (grazing incidence angle θ).³⁷

$\theta = 10^\circ$ (a, b), 30° (c, d), 80° (e, f).

The X-ray spectra of boron phosphide were studied.^{104, 114, 117, 137, 151, 195–197} A comprehensive X-ray spectral study of this compound was carried out; its BK_{α} -, PK_{β} - and $PL_{2,3}$ -emission spectra, as well as BK_{α} -, PK_{β} - and $PL_{2,3}$ -absorption spectra were obtained.^{104, 151, 195, 196} The dependence of BK_{α} -spectrum on the excitation radiation length was studied.^{137, 197} Interpretation of boron phosphide spectra was carried out.¹⁹⁸ Studies reporting X-ray emission spectra of boron and phosphorus in $B_{13}P_2$ and $B_{13}As_2$ are also of note.^{117, 136}

4. Boron halides and their derivatives

X-Ray BK_{α} - and FK_{α} -emission spectra of boron trifluoride (D_{3h} symmetry group) in solid¹³⁸ and gaseous¹⁹⁹ states were published. Studies of X-ray absorption by BF_3 are more numerous. For example, X-ray BK_{α} -absorption spectra^{104, 115, 129, 200–205} and FK_{α} -absorption spectra^{204–206} were described. In some studies,^{201–203, 206} SI was used to obtain X-ray spectra of boron

Figure 16. Experimental X-ray and photoelectron [He(I)] spectra of NH_3 and BF_3 (a–c) and X-ray emission spectra of $NH_3 \cdot BF_3$ (d–f).

See the text for the designations of the lines.)

trifluoride. Electron energy loss spectra were recorded for BF_3 ;²⁰⁷ moreover, vibration excitation upon inelastic scattering of electrons on this molecule was studied.²⁰⁸ The spectra of boron trifluoride were also discussed elsewhere.^{209–218} Experimental emission spectra were compared with theoretical spectra obtained by *ab initio* calculations on the electronic structure of BF_3 .¹⁹⁹ The X-ray BK_{α} -emission spectrum of BF_3 was calculated by the $X\alpha$ -DV method.¹²² X-Ray absorption spectra of the BF_3 molecule were analysed by quantum-chemical methods.^{219–222} The X-ray emission BK_{α} - and FK_{α} -spectra of boron trifluoride¹⁹⁹ are presented in Fig. 16a. It also shows the X-ray BK_{α} - and FK_{α} -absorption spectra^{115, 204} and the photoelectron spectrum of boron trifluoride.²²³ (XPS data for BF_3 were taken from Ref. 224.) Figure 17 presents theoretical X-ray emission spectra.¹⁹⁹ In the boron trifluoride molecule, the $2a_2''$ π -type orbital acts as the LUMO. This vacant (acceptor) orbital interacts with the orbital of the lone electron pair of the donor molecule resulting in the formation of a donor–acceptor bond. This orbital manifests itself as rather distinct lines A and D in X-ray BK_{α} - and FK_{α} -absorption spectra (see Fig. 16a,b). The interpretation of other lines in BK_{α} - and FK_{α} -spectra (B, C, E, F, G and H) and the dissension that appeared in this connection were discussed.^{207, 208} The assignment of lines in the X-ray emission spectra of boron trifluoride (occupied orbitals) is demonstrated in Fig. 16. Studies showed that the MOs whose electron density is located on fluorine atoms are the highest occupied orbitals. They are followed by MOs with predominant population on the boron atom. The S , S_1 and S_2

Figure 17. Theoretical X-ray emission spectra of NH_3 and BF_3 (a–c) and $\text{NH}_3 \cdot \text{BF}_3$ (d–f) obtained by *ab initio* calculations.¹⁹⁹

(a, d) $\text{FK}\alpha$ -spectra; (b, e) $\text{BK}\alpha$ -spectra; (c, f) $\text{NK}\alpha$ -spectra (ϵ is orbital energy). The vertical bars show the contributions of atomic orbitals to the MOs.

maxima are caused by electron transitions in double-ionised molecules; they are generally not considered in interpretations of X-ray spectra in the context of chemical bond studies (see, e.g., Ref. 99).

Boron trichloride has only been studied by X-ray absorption spectroscopy. The X-ray BK- and $\text{ClL}_{2,3}$ -absorption spectra of BCl_3 ^{104, 200, 202, 218, 225, 226} almost coincide. The spectra were interpreted based on *ab initio*²⁰² and CNDO/2²¹⁹ calculations. Identification of separate lines in the X-ray absorption spectrum of boron trichloride was reported.^{225, 226} It was noted²⁰⁰ that the BK-absorption spectrum of BCl_3 is less shifted towards high energies than the similar spectrum of BF_3 . This results from the fact that the effective positive charge on the B atom in boron trichloride is lower. The X-ray BK-absorption spectrum of BBr_3 was obtained and its interpretation based on *ab initio* calculations was carried out.²⁰²

Let us consider in more detail the $\text{NH}_3 \cdot \text{BF}_3$ complex (symmetry group C_{3v}), which is formed upon donor–acceptor inter-

action of NH_3 and BF_3 molecules. This complex was studied by X-ray spectral methods.¹⁹⁹ The ammonia and boron trifluoride molecules were first considered separately, then changes observed in the spectra during complexing were noted. The experimental and theoretical X-ray spectra¹⁹⁹ and the photoelectron spectra of ammonia²²⁷ and boron trifluoride²²³ are shown in Figs 16 and 17. The spectra were compared using the energy positions of inner-shell electrons.²²⁴ The absorption spectrum of $\text{NH}_3 \cdot \text{BF}_3$ was obtained by Akimov *et al.*²²⁸ The spectrum structure was identified using calculations in the *ab initio* and MNDO approximations.¹⁹⁹

The scheme of MOs of ammonia, boron trifluoride and the $\text{NH}_3 \cdot \text{BF}_3$ complex composed using the results of MNDO calculations¹⁹⁹ is shown in Fig. 18. It also presents results of fragment analysis (expansion of a molecule's MOs into the constituent fragment orbitals).²²⁹ It should be expected within the framework of donor–acceptor bonding that the main interacting orbitals include the $3a_1$ HOMO of ammonia and the $2a_2^{**}$ LUMO of boron trifluoride (or $6a_1^*$ in pyramidal configuration, symmetry group C_{3v} , for BF_3 in the complex with ammonia). It is evident from Figs 16–18 that these are orbitals ($3a_1$ and $2a_2^{**}$) with high contributions of the 2p-AOs of nitrogen and boron, respectively. It follows from calculations (see Fig. 18) that the nitrogen–boron bond in $\text{NH}_3 \cdot \text{BF}_3$ mainly involves electrons of three MOs, *viz.*, $8a_1$, $7a_1$ and $6a_1$; the properties of the wave functions of remaining occupied MOs are similar to those of the original molecules (NH_3 and BF_3). Orbitals with a_1 symmetry are bonding and appear due to interaction of the $3a_1$ -MO of ammonia with $6a_1^*$, $5a_1$ - and $4a_1$ -MOs of boron trifluoride. It should be noted that only the formation of the $8a_1$ orbital predominantly involves the vacant $6a_1^*$ -MO of boron trifluoride (see Fig. 18). Hence, the $8a_1$ -MO can be related (to a certain approximation) to the bonding orbital of

Figure 18. Correlation diagram of MOs for the $\text{NH}_3 \cdot \text{BF}_3$ complex and its fragments, NH_3 and BF_3 . Results of MNDO calculation.¹⁹⁹

The calculation was carried out for the pyramidal BF_3 molecule (C_{3v} symmetry); designations of the corresponding MO of the planar BF_3 molecule (D_{3h} symmetry) are given in parentheses. The numbers near the connecting lines correspond to the contributions (in percent) of the orbitals of the NH_3 and BF_3 fragments to the MOs of the $\text{NH}_3 \cdot \text{BF}_3$ molecule. Dashed lines indicate contributions smaller than 10%.

the two-level donor–acceptor bond model (see Section III.2), though it involves rather a large contribution ($\sim 47\%$) of the occupied $5a_1$ orbital of the acceptor. The changes in the electronic structure on passage from isolated NH_3 and BF_3 molecules to the $\text{NH}_3 \cdot \text{BF}_3$ complex are reflected in X-ray NK_α -emission spectra (see Figs 16 and 17). The intensity ratio of lines $I(8a_1)/I(3e)$ in the spectrum of the complex is much lower than the $I(3a_1)/I(1e)$ ratio in the spectrum of pure NH_3 . Since it follows from calculations that the $1e$ -MO of ammonia and the $3e$ -MO of the $\text{NH}_3 \cdot \text{BF}_3$ complex are similar, the relative intensities of their corresponding X-ray lines almost do not change, hence one can state that the contribution of the $\text{N}2p$ -AO to the $8a_1$ HOMO of the complex is smaller than that of the similar $3a_1$ -MO of ammonia. This can serve as a confirmation of electron density transfer from the ammonia molecule to the boron trifluoride molecule, which mainly involves the highest valence MOs. The complex in question contains two vacant orbitals, *viz.*, $9a_1^*$ and $10a_1^*$ (see Fig. 18), which can be matched with the vacant MO in the two-level model (see Section III.2). Data of experimental and theoretical studies¹⁹⁹ of the $\text{NH}_3 \cdot \text{BF}_3$ complex (see Figs 16–18) allow the character of electron density distribution in it to be understood. For example, the highest occupied orbitals are mainly populated by $\text{F}2p$ electrons. At higher binding energies, predominant contribution to the orbitals is made by boron $2p$ -AOs. The deepest valence MOs are mostly composed of nitrogen $2p$ -AOs. It should also be noted that the overlapping of bands in the NK_α - and BK_α -spectra evident when they are compared can suggest that the nature of the $\text{B} - \text{N}$ bond is largely covalent.

Figure 19. X-Ray emission FK_α - (a) and BK_α -spectra (b, spectrum 1),²³¹ BK -absorption spectrum (b, spectrum 2)¹²⁸ and X-ray photoelectron spectrum in the valence band of BF_4^- (c).²³¹

X-Ray emission spectra of boron and fluorine were obtained for $\text{BF}_3 \cdot \text{C}_6\text{H}_5\text{CH}=\text{NC}_6\text{H}_4\text{Me-}p$.¹³⁸

Compounds KBF_4 and NH_4BF_4 (the point symmetry group of the BF_4^- anion is T_d) were studied by X-ray emission spectroscopy, and K_α -emission spectra of boron^{230, 231} and fluorine²³¹ were obtained. X-Ray BK -absorption spectra were studied^{128, 129} using SI as the excitation source. Figure 19 presents X-ray emission spectra and X-ray photoelectron spectra in the valence band for the BF_4^- anion²³¹ and its X-ray absorption spectra.¹²⁸ Identification of spectral lines was carried out elsewhere.²³¹

5. Boron hydrides and their derivatives

a. Simplest systems

Experimental X-ray spectral data for borane (BH_3) are unavailable. This results from the fact that BH_3 molecules do not exist as monomers under ordinary conditions; they occur as B_2H_6 bridge dimers (see Fig. 5e). The X-ray absorption spectrum of diborane was obtained by Zimkina and Vinogradov.²⁰⁴

Analysis of the electronic structure of $\text{Me}_3\text{N} \cdot \text{BH}_3$ based on X-ray emission spectroscopy data was carried out.²³⁰ X-Ray BK_α - and NK_α -emission spectra were obtained. A comparison of X-ray NK_α -emission spectra of Me_3N and its adduct with BH_3 showed that the relative intensity of the line in the X-ray emission spectrum of trimethylamine associated with the lone electron pair decreases abruptly in the $\text{Me}_3\text{N} \cdot \text{BH}_3$ spectrum.^{230, 232} As with the $\text{NH}_3 \cdot \text{BF}_3$ complex discussed above (see Section IV.4), this results from electron density transfer from the trimethylamine nitrogen atom to the vacant orbital of the borane molecule with formation of a donor–acceptor bond.

The anions BH_4^- with tetrahedral symmetry in the KBH_4 and NaBH_4 molecules were studied;²³⁰ X-ray emission²³⁰ and absorption¹²⁸ spectra were obtained.

b. $\text{B}_n\text{H}_n^{2-}$ anions and boron clusters

The *closo*-borane anions $\text{B}_{10}\text{H}_{10}^{2-}$ and $\text{B}_{12}\text{H}_{12}^{2-}$ (symmetry groups D_{4d} and I_h , respectively, see Fig. 6a), the electronic structures of which were studied by X-ray spectroscopy,^{230, 233} are characterised by considerable electron density delocalisation over the entire cluster, which determines their aromatic properties and unusually high resistance to decomposition in different chemical reactions (see the references in Ref. 230). The geometric structure of the $\text{B}_{10}\text{H}_{10}^{2-}$ anion is such (see Fig. 6a) that two groups of equivalent boron atoms exist, *viz.*, vertex atoms $\text{B}(1)$ and $\text{B}(10)$ and equatorial atoms (all the rest). Their coordination numbers are 5 and 6, respectively; a greater negative charge is localised on atoms with the smaller coordination number, *i.e.*, $\text{B}(1)$ and $\text{B}(10)$, in the cluster.^{230, 233}

Figure 20 demonstrates the X-ray BK_α - and $\text{CuL}_{\alpha 1,2}$ -emission spectra of $\text{Cu}_2\text{B}_{10}\text{H}_{10}$ and the X-ray BK_α -emission spectrum of $\text{Cs}_2\text{B}_{10}\text{H}_{10}$. These spectra show that the distribution maximum of copper $3d$ -electron density is located in the upper part of the valence band (~ 3.3 eV below the Fermi level), whereas the distribution maximum of boron $2p$ -electron density corresponds to its lower part (~ 6.7 eV below the Fermi level). The observed overlapping of the BK_α - and $\text{CuL}_{\alpha 1,2}$ -bands allows one to assume that the interaction of the copper $3d$ -orbitals with the hydroborate anion is of covalent nature.^{230, 233}

The shape of the BK_α -emission spectrum of ionic $\text{Cs}_2\text{B}_{10}\text{H}_{10}$ and the energy positions of lines in it (Fig. 20) remain almost unchanged, which results most likely from delocalisation of valence electrons in the $\text{B}_{10}\text{H}_{10}^{2-}$ anion stabilising the system of its valence MOs.

X-Ray emission BK_α - and CK_α -spectra of *ortho*- and *meta*-carboranes(12) 1,2- and 1,7- $\text{C}_2\text{B}_{10}\text{H}_{12}$ were studied²³⁴ (see Fig. 5g,h); the electronic structures of these compounds were calculated by the *ab initio* method in the 6-31G* basis set and the corresponding simulated spectra were obtained (Fig. 21). Correlation and fragment analysis of the MOs of these compounds and the $\text{B}_{12}\text{H}_{12}^{2-}$ boron cluster were carried out (Fig. 22).

Figure 20. X-Ray emission BK_{α} -spectra (solid lines) of $\text{Cu}_2\text{B}_{10}\text{H}_{10}$ (a) and $\text{Cs}_2\text{B}_{10}\text{H}_{10}$ (b).²³⁰ The dashed line shows the X-ray $\text{CuL}_{\alpha 1,2}$ emission spectrum.

Figure 21. Experimental (solid lines, upper scales of transition energies) and theoretical (dashed lines, lower scales) X-ray emission spectra of 1,2- $\text{C}_2\text{B}_{10}\text{H}_{12}$ (a, b) and 1,7- $\text{C}_2\text{B}_{10}\text{H}_{12}$ (c, d).²³⁴ (a, c) BK_{α} -spectra; (b, d) CK_{α} -spectra.

Electron energy loss spectra (see Section III.2) were obtained for a series of boranes and carboranes, viz., *nido*-pentaborane(9) (B_5H_9), *nido*-2,3-diethyl-2,3-dicarbaheptaborane(8) ($\text{Et}_2\text{C}_2\text{B}_4\text{H}_6$), *nido*-decaborane(14) ($\text{B}_{10}\text{H}_{14}$), *closo-o*-carborane ($\text{C}_2\text{B}_{10}\text{H}_{12}$), and 1,2-dicarbaundecaborane(11) ($\text{C}_2\text{B}_9\text{H}_{11}$).^{235, 236} Quantum-chemical calculations of the electronic structures of these compounds

Figure 22. Correlation diagram (MNDO calculation) of energy levels in the $\text{B}_{12}\text{H}_{12}^{2-}$ anion, 1,2- $\text{C}_2\text{B}_{10}\text{H}_{12}$ and 1,7- $\text{C}_2\text{B}_{10}\text{H}_{12}$.²³⁴ The capital letters A, B and C designate the MOs which appear as the corresponding maxima in the X-ray spectra; the numbers in parentheses indicate the total contributions of the carbon 2p-AOs to the MOs.

were carried out in the MNDO and EHMO approximations (extended Hückel method); this served as a basis for composing theoretical spectra and interpreting experimental spectra.^{235, 236}

c. Borane clusters with Lewis bases ($\text{B}_{10}\text{H}_{12}\text{L}_2$)

The electronic structure of borane clusters $\text{B}_{10}\text{H}_{12}\text{L}_2$ (where L is a Lewis base) was considered in terms of X-ray emission transitions for three compounds, viz., $\text{B}_{10}\text{H}_{12}(\text{NH}_3)_2$, $\text{B}_{10}\text{H}_{12}(\text{SMe}_2)_2$ and $\text{B}_{10}\text{H}_{12}(\text{PPh}_3)_2$.

X-Ray studies of 6,9-bis(ammonia)-*arachno*-decaborane(12) [$\text{B}_{10}\text{H}_{12}(\text{NH}_3)_2$] have been carried out.^{230, 237, 238} The structure of this cluster (point symmetry group C_{2v}) and the atom numbering in it are shown in Fig. 6d. When considering the electronic structure of $\text{B}_{10}\text{H}_{12}(\text{NH}_3)_2$ it was assumed that its molecule consists of two fragments, viz., the borane cluster ($\text{B}_{10}\text{H}_{12}$) and the ammonia molecule.^{237, 238} The chemical bond between these fragments is assumed to be of donor–acceptor nature; the NH_3 molecule acts as a donor, while the borane fragment is an acceptor. Quantum-chemical calculations of the electronic structure of the $\text{B}_{10}\text{H}_{12}(\text{NH}_3)_2$ cluster and its fragments, i.e., $\text{B}_{10}\text{H}_{12}$ and NH_3 , were carried out using the MNDO method.^{238, 239} Figure 23a shows the correlation diagram built on this basis and the results of fragment analysis of the composition of the $\text{B}_{10}\text{H}_{12}(\text{NH}_3)_2$ molecular orbitals formed by the MOs of the fragments, i.e., the $\text{B}_{10}\text{H}_{12}$ borane cluster and the NH_3 molecule. Among the highest occupied orbitals of the $\text{B}_{10}\text{H}_{12}$ cluster, one can note a group of MOs, e.g., $3a_2$, $8a_1$ and $5b_1$, which become orbitals of the complex and almost do not change their symmetry upon coordination of ammonia. In this case, they are shifted upwards in parallel with a decrease in the binding energy (see Fig. 23a). Similar behaviour is observed for deeper MOs. For example, the $5b_2$ orbital of the $\text{B}_{10}\text{H}_{12}$ cluster contributes noticeably to the $8b_2$ -MO of the complex. The electrons of this orbital are localised in the cluster and are not involved in the formation of the chemical bond with ammonia. The formation of the orbitals of the complex responsible for the interaction of ammonia with the borane fragment involves not only the vacant MOs of the $\text{B}_{10}\text{H}_{12}$ cluster as an acceptor but also its occupied orbitals, which play an important role in the process. While only electrons of the $3a_1$

Figure 25. Scheme of MOs of the $B_{10}H_{12}(SMe_2)_2$ cluster and its fragments (a), experimental X-ray and UV [He(I)] photoelectron spectra of Me_2S (b–e) and experimental X-ray spectra of $B_{10}H_{12}(SMe_2)_2$ (f–i).²⁴⁰ (b, f) SK_{β} -spectra; (c, g) $SL_{1,2}$ -spectra; (d, h) CK_{α} -spectra, (e) UPS spectrum; (i) BK_{α} -spectrum. Dashed lines indicate the contributions of vacant orbitals.

diagram of MOs of the $B_{10}H_{12}(SMe_2)_2$ cluster and of its fragments ($B_{10}H_{12}$ and Me_2S); the results of fragment analysis of this cluster (MNDO calculation); the X-ray and UV [He(I)]²²⁷ photoelectron spectra of Me_2S reduced to a common energy scale (with the use of XPS data²²⁴); and X-ray spectra of $B_{10}H_{12}(SMe_2)_2$. The point symmetry group of both compounds is C_{2v} . As one can see from Fig. 25 b, f, the most noticeable changes on transition from dimethyl sulfide to its adduct with borane are observed in the X-ray SK_{β} -emission spectrum. They are similar to the changes observed in X-ray spectra upon coordination of the ammonia molecule to the borane cluster. The maxima in all emission spectra of free dimethyl sulfide are also identified in this figure.^{96, 241} For example, the $2b_1$ HOMO is formed by a lone electron pair or, more accurately, it is an orbital with high S3p-population. Interaction of the $2b_1$ HOMO of Me_2S with the $5b_2$, $6a_1$ and $4b_2$ orbitals of $B_{10}H_{12}$ upon coordination of a dimethyl sulfide molecule to the borane cluster (see Fig. 25 a) results in a series of new MOs, viz., $11b_2$, $12a_1$, $10b_2$ and $11b_2$ (see Fig. 25 a); the contribution of the 3p-AO of the sulfur atom to these orbitals is much lower than the contribution to the $2b_1$ HOMO of the free dimethyl sulfide molecule. Hence, the X-ray SK_{β} -emission spectrum will contain a low intensity line instead of the intense line corresponding to the lone electron pair (see Fig. 25 b, f). On the other hand, the structure of deeper MOs changes insignificantly. Thus, it can be concluded that the chemical bond between dimethyl sulfide and the borane cluster is of donor–acceptor nature and that it is formed by the lone electron pair of Me_2S and the 2p-orbitals of boron. The correlation diagram shows that the structure of the wave functions of the three occupied MOs, viz., $7a_2$, $14a_1$ and $9b_1$, of the $B_{10}H_{12}(SMe_2)_2$ cluster almost coincides with the structure of the three orbitals of the borane cluster in a

free state (see Fig. 25 a). The only difference is that the bond energy in the $B_{10}H_{12}(SMe_2)_2$ cluster is lower. The electron densities of the MOs of the above adduct are localised on boron atoms (and are absent from the ligands). This electron density distribution is clearly seen in the X-ray spectra. In fact, as one can see in Fig. 25 f–i, as the binding energy increases, the boron line with a maximum at ~ 5 eV with respect to the Fermi level (transition energy ~ 184 eV) characterising the contributions of the boron 2p-AO to the MO is the first line to appear; it is followed by lines characterising the contributions from the AOs of the ligands starting from the first line of the $SL_{2,3}$ -spectrum with a maximum of ~ 7 eV with respect to the Fermi level. It can be concluded from a comparison of spectra arranged in this way that the electron density of the highest MOs is predominantly localised on borane cluster atoms. In the dimethyl sulfide molecule, lone electron pairs ($2b_1$ -MO) are involved actively in the chemical bond with the borane cluster, including the B(6) and B(9) atoms (see Fig. 6 c). It was shown²⁴⁰ that in this case one can speak of preferential formation of an S–B donor–acceptor σ -bond. Finally, deeper MOs of the borane– Me_2S adduct are mainly composed of dimethyl sulfide's MOs. The formation of the chemical bond between the borane cluster and dimethyl sulfide molecules with involvement of vacant orbitals has certain specific features. Their contribution is spread along the series of the $B_{10}H_{12}(SMe_2)_2$ MOs and does not exceed 8% for any single orbital, although the total contribution of the vacant boron 2p-AOs amounts to 30%. The same situation is observed for the $B_{10}H_{12}(NH_3)_2$ cluster. It follows from quantum-chemical studies (MNDO calculations)²³⁹ that a bond of predominantly σ -type is formed between the B(6), B(9) and L atoms (see Fig. 6 d). However, a contribution of the π -component is also possible in

some cases, *e.g.*, with $L = \text{MeCN}$ and $\text{C}_2\text{H}_5\text{N}$. This interaction is very weak in the $\text{B}_{10}\text{H}_{12}(\text{NH}_3)_2$ cluster.

Changes in the valence of a sulfur atom with different coordinations on transition from such non-cluster compounds as H_2S and Me_2S (with a coordination number of 2) to $\text{B}_{10}\text{H}_{12}(\text{SMe}_2)_2$ and, finally, to the $\text{B}_9\text{SH}_{12}^-$ anion, in which the sulfur atom is directly introduced in the borane cluster,²⁴⁰ with a coordination number of 3, were studied. The changes in the chemical bond nature between the sulfur and boron atoms on passing from the $\text{B}_{10}\text{H}_{12}(\text{SMe}_2)_2$ cluster to the $\text{B}_9\text{SH}_{12}^-$ anion are no less interesting. The geometric structure of this anion and its X-ray SK_β -emission spectrum obtained by Yumatov *et al.*²⁴⁰ are presented in Fig. 26. The sulfur atom in the H_2S molecule forms two σ -bonds with hydrogen atoms, whereas the dimethyl sulfide molecule contains two similar $\text{S}-\text{C}$ σ -bonds along with a weak π -bond resulting from interaction of a lone electron pair of the sulfur atom with the 2p-electrons of the carbon atoms. This interaction does not affect considerably the structure of the X-ray SK_β -emission spectrum on transition from H_2S to Me_2S (see Figs 25 and 26): just a small decrease of the relative intensity of the line corresponding to the lone electron pair of the sulfur atom (b_1 -MO) is observed. As noted previously, the sulfur atom in the $\text{B}_{10}\text{H}_{12}(\text{SMe}_2)_2$ molecule forms a σ -type chemical bond (donor-acceptor bond) with a boron atom and two σ -bonds with carbon atoms of the methyl groups. In the $\text{B}_9\text{SH}_{12}^-$ thiaborane cluster (see Fig. 26), the sulfur atom forms two σ -bonds with the B(5) and B(7) atoms. By analogy with the dimethyl sulfide molecule, one can assume that there is weak π -interaction between these sulfur and boron atoms. The conjugation of the S atom with the B(2) cluster atom possibly involves a lone electron pair of the sulfur atom. Similar interaction manifests itself in X-ray SK_β -emission spectra on transition from the Me_2S molecule to the $\text{B}_{10}\text{H}_{12}(\text{SMe}_2)_2$ cluster. The line in the X-ray SK_β -emission spectrum of $\text{CsB}_9\text{SH}_{12}$, which was associated with a lone electron pair on the sulfur atoms in the spectra of H_2S and Me_2S (see Fig. 26), has very low intensity. The identity of X-ray SK_β -emission spectra of $\text{B}_{10}\text{H}_{12}(\text{SMe}_2)_2$ and $\text{CsB}_9\text{SH}_{12}$ confirms the assumption that the electronic states of the sulfur atom coordinated by three boron atoms in these clusters are similar. Hence, it can be assumed that noticeable conjugation of the lone electron pair of the sulfur atom with the 2p-electrons of the boron atoms occurs in the $\text{CsB}_9\text{SH}_{12}$ cluster, but it appears impossible to determine the type of the

$\text{S}-\text{B}(2)$ interaction based on X-ray spectral data only. Most likely, mixing of σ - and π -bonding occurs in this case, and it is the reason for the strong decrease in the electron-donor properties of the sulfur atom incorporated in the borane cluster.

Thus, the $\text{S}-\text{B}$ chemical bond in $\text{B}_{10}\text{H}_{12}(\text{SMe}_2)_2$ results from σ -interaction of the HOMO of dimethyl sulfide, which predominantly consists of the 3p-AO of the sulfur atom (lone electron pair), with orbitals of the borane cluster. The interaction of similar orbitals of B and S atoms probably occurs in the $\text{CsB}_9\text{SH}_{12}$ molecule as well. The results considered above reflect the substantial differences in the electronic state of sulfur atoms in non-cluster systems and in borane clusters with various coordination numbers. These differences can manifest themselves as differences in the reactivity of the systems in question.

Interaction of a ligand with the borane cluster in the molecule $\text{B}_{10}\text{H}_{12}(\text{PPh}_3)_2$ is no less complex.²⁴² The point is that the lone electron pair of the phosphorus atom in the free triphenylphosphine molecule interacts with electrons of the phenyl groups.^{110, 241} This affects markedly the structure of the X-ray PK_β -emission spectrum (Fig. 27). In fact, transition from triethylphosphine, in which this kind of interaction is absent, to triphenylphosphine is accompanied by a decrease in the relative intensity of the high-energy line caused by the lone electron pair of the phosphorus atom. One would think that the addition of a Ph_3P molecule to the $\text{B}_{10}\text{H}_{12}$ borane cluster would decrease the relative intensity of this line even more, as it was observed in the X-ray NK_α -emission spectrum on transition from NH_3 to $\text{B}_{10}\text{H}_{12}(\text{NH}_3)_2$ and in the SK_β -spectrum on transition from Me_2S to $\text{B}_{10}\text{H}_{12}(\text{SMe}_2)_2$. However, such an effect is not observed in this case. Possibly, the AO of the lone electron pair of the phosphorus atom in the complex is strongly bound to the MO of the borane cluster and cannot participate in π -conjugation with benzene rings.²⁴²

In this review, XPS results are considered only in combination with data from X-ray spectroscopy, although the former method is of great value on its own. In particular, this allows one to determine the charge characteristics of atoms in a molecule.^{92, 100} Let us provide a few examples. As noted above in the discussion of the X-ray absorption spectra of BF_3 and BCl_3 , the electron density on the boron atom is higher in the boron trichloride molecule than

Figure 26. X-Ray SK_β emission spectra of H_2S (a) and $\text{B}_9\text{SH}_{12}^-$ (b) and geometric structure of X_2S (a) and $\text{B}_9\text{SH}_{12}^-$ molecules (b).²⁴⁰ X = H, Me; S is a satellite peak.

Figure 27. X-Ray PK_β emission spectra of Et_3P (a), Ph_3P (b) and $\text{B}_{10}\text{H}_{12}(\text{PPh}_3)_2$ (c).²⁴² Matching spectral lines are designated by the same letters ('n' indicates a lone electron pair).

in the boron trifluoride molecule. According to XPS data, the energy of the B1s level decreases from 202.8 to 200.5 eV on transition from BF_3 to BCl_3 (mean values out of the values available in the database).²²⁴ This also suggests that the electron density on the boron atom is higher in the BCl_3 molecule than in BF_3 .⁹² The donor–acceptor interaction in $\text{NH}_3 \cdot \text{BF}_3$ and $\text{B}_{10}\text{H}_{12}\text{L}_2$ ($\text{L} = \text{NH}_3, \text{Me}_2\text{S}$) is accompanied by electron density transfer from the donor molecule to the acceptor molecule. Naturally, this decreases the electron density on the donor atom involved in the coordination. For example, transition from NH_3 to $\text{NH}_3 \cdot \text{BF}_3$ changes the energy of the N1s level from 398.8 to 402.1 eV,¹⁰⁰ suggesting an increase in the positive charge on the nitrogen atom.⁹² Similar behaviour is observed on passage from NH_3 to $\text{B}_{10}\text{H}_{12}(\text{NH}_3)_2$: the energy of the N1s level increases from 398.8 (see Ref. 100) to 402.4 eV,²³⁰ while transition from Me_2S to $\text{B}_{10}\text{H}_{12}(\text{SMe}_2)_2$ changes the energy of the S2p_{3/2}-level from 163.0 (see Ref. 100) to 164.4 eV.²⁴³ In these cases, a positive charge also appears on the donor atom involved in the coordination upon the formation of $\text{B}_{10}\text{H}_{12}(\text{SMe}_2)_2$. More detailed XPS studies of boron-containing compounds are covered by reviews.^{244, 245}

d. Metalloborane and metallocarborane derivatives

X-Ray spectral studies of Fe^{III} , Co^{III} , Ni^{III} and Ni^{IV} dicarbollyl ‘sandwich’ complexes were carried out.^{230, 246} These compounds include anionic complexes $[\text{M}(\text{B}_9\text{C}_2\text{H}_{11})_2]^-$ ($\text{M} = \text{Fe}^{\text{III}}, \text{Co}^{\text{III}}, \text{Ni}^{\text{III}}$) and a molecular complex $[\text{Ni}^{\text{IV}}(\text{B}_9\text{C}_2\text{H}_{11})_2]^0$. Their ligands include cluster anionic derivatives of *ortho*-carborane(12), $(\text{B}_9\text{C}_2\text{H}_{11})^{2-}$ (see Fig. 6*j–l*). The M atom in such compounds is located between pentagonal planes $-\text{B}-\text{C}-\text{C}-\text{B}-\text{B}-$ formed by two $(\text{B}_9\text{C}_2\text{H}_{11})^{2-}$ anions; a ‘sandwich’ structure is formed as a result. In $[\text{M}(\text{B}_9\text{C}_2\text{H}_{11})_2]^{2-}$ complexes, the $-\text{C}-\text{C}-$ atom pairs in conjugated π -ligands $(\text{B}_9\text{C}_2\text{H}_{11})^{2-}$ can be located *trans* to the M^{III} atom for $\text{M} = \text{Ni}, \text{Fe}$, etc. (see Fig. 6*j*) or *cis* for $\text{M} = \text{Co}^{\text{III}}$, as in the $[\text{Ni}^{\text{IV}}(\text{B}_9\text{C}_2\text{H}_{11})_2]^0$ structure (see Fig. 6*k*, rotational isomerism). The configuration of ligands affects intermolecular interactions. The nature of the $(\text{B}_9\text{C}_2\text{H}_{11})-\text{M}-(\text{B}_9\text{C}_2\text{H}_{11})$ ‘sandwich’ bond is a matter of discussion. In early studies, this bond was considered as an analogue of the $\text{M}-\text{C}_5\text{H}_5$ π -bond in $\text{M}(\pi-\text{C}_5\text{H}_5)_2$

metallocenes. This assumption was based on the similarity of the geometric structure of $\text{M}-(\text{B}_9\text{C}_2\text{H}_{11})^-$ with the ‘sandwich’-type structure formed by the M atom and the cyclopentadienyl anion. Later, the concept regarding the nature of the $\text{M}-(\text{B}_9\text{C}_2\text{H}_{11})^{2-}$ bond changed: it is now believed that more considerable σ -bonding (σ -delocalisation) occurs in these complexes in comparison with the interaction of the delocalised π -electronic system of C_5H_5^- with the metal atom in $\text{M}(\pi-\text{C}_5\text{H}_5)_2$ (see Refs 230 and 246 and references therein). Therefore, dicarbollyl complexes are ‘sandwich’ cluster systems to a considerable extent. In most cases, charge transfer from the ligand to the metal atom occurs in these compounds.

X-Ray BK_α -emission spectra of dicarbollyl complexes²³⁰ are presented in Fig. 28 along with L_α -spectra of the central atoms. It was shown that an increase in the number of electrons in a metal 3d-shell results in a decrease in the energy band occupied by the HOMOs mainly formed with participation of electrons of that shell. In fact, the half-width of the $\text{Fe}L_\alpha$ -line is ~ 6.0 eV, that of $\text{Co}L_\alpha$ is ~ 4.0 eV and that of $\text{Ni}L_\alpha$ is ~ 3.0 eV. On the other hand, the binding energy of electrons of this group of orbitals increases in the same order. In fact, the energy of ML_α -lines for metals in dicarbollyl complexes relative to the Fermi level is ~ 2.5 eV for $\text{Fe}L_\alpha$, ~ 3.2 eV for $\text{Co}L_\alpha$ and ~ 4.2 eV for $\text{Ni}L_\alpha$. Thus, metal 3d-AOs make the main contribution to the HOMOs, whereas the MOs composed with participation of the boron 2p-AO lie deeper. Their energy is ~ 6.5 eV relative to the Fermi level. The strong overlapping of the BK_α - and L_α -bands may be evidence of efficient interaction of ligands with the central metal atom. Transition from the Ni^{III} complex to the Ni^{IV} complex stabilises the MOs composed with involvement of 3d-AOs even more and enhances the B2p–Ni3d interaction. Let us note the high stability of the energy position of the MO with a considerable contribution of the 2p-AO of the boron atom, which is probably caused by the aromatic character of closed three-dimensional systems.

6. Heterocyclic boron compounds

To our knowledge, heterocyclic boron compounds have only been studied by Doering *et al.*²⁴⁷ They studied the electron energy loss spectra of borazine (point symmetry group D_{3h}) (Fig. 29), which were noted (see Section III.2) to be similar to X-ray absorption spectra. According to the results of these studies, the π -system orbital (ϵ'') is the LUMO in the $\text{B}_3\text{N}_3\text{H}_6$ molecule; it manifests itself as an intense low-energy maximum in the spectra. It should

Figure 28. X-Ray BK_α and ML_α emission spectra (dashed and solid lines, respectively) of $\text{Cs}[(1,2-\text{B}_9\text{C}_2\text{H}_{11})_2\text{M}]$ dicarbollyl complexes.²³⁰ $\text{M} = \text{Fe}$ (a), Co (b), Ni (c), $(1,2-\text{B}_9\text{C}_2\text{H}_{11})_2\text{Ni}$ (d).

be added that certain details of electronic structures of a number of five- and six-membered boron-containing heterocycles were studied rather thoroughly by UPS and NMR spectroscopies.⁸³ Figure 7 shows a scheme of interaction of nitrogen and boron AOs and a qualitative scheme of MOs in some heterocyclic boron compounds. These systems involve π -bonding.^{83, 87}

V. Conclusion

In this review, it was shown for boron-containing systems as an example that X-ray spectral studies provide vast information about the electronic structures of chemical compounds. A specific feature of X-ray spectroscopy is that it provides information on the energy positions and structures of MOs which is comparable with results of quantum-chemical calculations. Although detailed information about the properties of occupied and vacant orbitals can be extracted from X-ray emission and absorption spectra, it seems most efficient to use these methods in combination with UV and X-ray photoelectron spectra reduced to a common energy scale. The use of absorption spectra, quantum yield spectra and energy loss spectra is especially beneficial for studies of boron compounds that possess acceptor properties. However, because of problems associated with the methods and instruments used, comprehensive X-ray spectral studies with involvement of UPS and XPS have as yet been carried out for a rather limited number of compounds.

A distinctive feature of studies on the electronic structures of chemical compounds of boron is associated with donor–acceptor interactions. In fact, clear detection of a lone electron pair of a donor molecule (HOMO) in X-ray emission spectra and a lone hole pair of an acceptor molecule (LUMO) (with a boron compound as an acceptor) in the absorption spectra, as well as changes in the electronic structures of these molecules upon adduct formation that are observable in X-ray spectra, made this a promising method for studies on the nature of donor–acceptor interaction. Studies of this interaction are based on the two-level model, according to which the formation of a bond only involves the HOMO of the donor and the LUMO of the acceptor; however, this is only an approximate model. The formation of this type of chemical bonds also involves deeper valence MOs of the donor and the acceptor. It is possible that this mechanism can be expanded for the donor–acceptor ligand–metal interaction in complex compounds; the results of its X-ray spectral studies are generalised in the monograph by Mazalov and Yumatov.²⁴¹

Abstract. The review surveys data on the use of cyclodextrins as chiral selectors in high-performance liquid chromatography and capillary electrophoresis. The mechanisms of enantiomer separation and the factors influencing the selectivity and efficiency of separation in various methods of chromatography and capillary electrophoresis are considered. Numerous examples of the practical application of cyclodextrins in separation of optical isomers are given. The bibliography includes 325 references.

I. Introduction

The necessity of separating stereoisomers (in particular, enantiomers) is, to a large extent, associated with their various biological activities.^{1–4} This problem arises in different fields of chemistry, biochemistry, pharmacology and agrochemical industry. The enantiomeric compositions of chiral compounds are generally determined by chromatographic methods and capillary electrophoresis (CE).

Enantiomers can be separated only with the use of systems containing a chiral selector, which should recognise the three-dimensional configurations of two isomers identical in chemical and physical properties.⁵ Two modes of separation are possible. In one mode, a chiral stationary phase (SP) and an achiral mobile phase (MP) are used. By contrast, another mode employs achiral stationary and chiral mobile phases. Chromatography more often employs the former mode of separation, whereas the latter mode is more commonly used in capillary electrophoresis.

Enantioselectivity of a chiral selector is based on the difference in its interactions with a pair of enantiomers. Two types of enantioselectivity, *viz.*, kinetic and thermodynamic, are considered. Kinetic enantioselectivity reflects the difference in the rate of interaction of a chiral selector with two enantiomers, whereas thermodynamic enantioselectivity reflects the difference in stabil-

ity of two possible diastereomeric adducts formed in the course of interaction. The mechanisms of separation of optical isomers are explained using models of chiral recognition, which are often based on a model of a 'three-point interaction' proposed by Dalgliesh.^{6,7} Interactions between a chiral selector and enantiomers are determined by a combination of various attractive and repulsive forces. Repulsive interactions occur generally due to steric hindrance and, more rarely, to dipole–dipole repulsions, whereas attractive interactions may be of diversified nature and include hydrogen bonds, Coulombic or dipole–dipole attractions, the formation of charge-transfer complexes (CTC), hydrophobic interactions (in aqueous systems), *etc.*

The formation of charge-transfer and inclusion complexes is of most importance in enantioselective sorption. The presence of π -electron systems in interacting compounds is necessary for the formation of CTC. Aromatic systems acting as both donating and withdrawing components often form stable CTC. Such π – π interactions together with Coulombic interactions and hydrogen bonds provide high activity of chiral selectors. Inclusion complexes are formed by compounds with specific structural features (the presence of a cavity), due to which their molecules can trap and hold suitable guest molecules. Rigid requirements providing the possibility of the formation of host–guest complexes assume stereoselectivity of this process, *i.e.*, enantiomeric guest molecules can be completely separated with the use of chiral host molecules. Cyclodextrins and crown ethers belong to a class of chiral selectors whose action is based on the inclusion effect.

Finally, in some cases chiral recognition can be performed based only on steric compatibility. The idea of 'molecular fingerprints' consists of creating a rigid chiral cavity in a polymer network such that it is suitable only for one of two enantiomers.²

Of a large number of known chiral selectors, polysaccharides⁸ and cyclodextrins (CD)^{9–12} find extensive application in chromatography and capillary electrophoresis. Cyclodextrins are particularly versatile because their modifications allow one to prepare selectors possessing new properties. Cyclodextrins modified with polar groups have not been adequately explored as selectors in HPLC. Aminated β -CD remains virtually unstudied. The use of this chiral selector in HPLC was first described by us.^{13,14}

The wide application of CD in liquid chromatography is favoured by the preparation of CD-based stable chiral sorbents by chemical modifications of silica gels. A sorbent of this type was first prepared by Fujimura *et al.*¹⁵ by the reaction of tosylated CD with aminopropylated silica gel, but this sorbent was readily subjected to hydrolysis. Armstrong and Mond¹⁶ used spacers containing from 2 to 20 carbon atoms and prepared cyclodextrin-modified silica gels possessing high hydrolytic stability by remov-

Uspekhi Khimii 72 (12) 1167–1189 (2003); translated by T N Safonova

ing non-selective polar adsorption centres. This gave impetus to the rapid development of chiral liquid chromatography. Recently, Crini *et al.*¹⁷ synthesised chiral phases by treating silica gel with cyclodextrin-containing polymers. However, sorbents of this type are insufficiently selective and their further improvement is required.

Cyclodextrins find application as chiral selectors in gas^{18–20} and liquid chromatography and capillary electrophoresis. The use of CD in enantiomer separation was examined in a large number of studies and surveyed in a number of reviews^{10, 12, 21–35} devoted to the discussion of both the principal theoretical problems and practical application of chiral separations on CD. However, Russian publications on chiral separations are scarce (many of these studies were carried out by Davankov and co-workers and were devoted to chiral ligand-exchange chromatography^{21, 36–38}). Reviews of cyclodextrin chiral selectors are lacking.

The aim of the present review is to close this gap. We consider the mechanisms of enantiomer separation and factors responsible for enantioselectivity of cyclodextrins with different structures. A large number of examples of the practical application of CD in separation of optical isomers are given. Taking into account a huge number of studies in this field, we focus our attention on the results of studies by high-performance liquid chromatography, capillary electrophoresis and electrocapillary chromatography published in 2000–2001. In the review, chiral separations on CD by gas and liquid chromatography and capillary electrophoresis are compared.

II. Cyclodextrins and their derivatives

Cyclodextrins are cyclic oligosaccharides similar in shape to crown ethers. Cyclodextrins are produced under the action of *Bacillus macerans* amylase on starch and consist of 6–12 D-glucose residues linked to each other by α -(1,4) bonds. Cyclodextrins containing 6–8 glucose residues are called α -, β - and γ -CD, respectively (Fig. 1).

The physical and chemical characteristics of CD are given in Table 1. As can be seen from this table, solubility of β -CD in water is very low compared to that of other oligosaccharides. However, its solubility increases substantially in aqueous organic solutions (methanol or ethanol, < 30%), at high pH, with the use of a supporting electrolyte and also on going to various β -CD derivatives.

The hydroxy groups of CD can be rather readily modified by chemical reactions giving rise to CD derivatives with various degrees of substitution. The chemical compositions of the products are determined by a number of factors, such as reaction conditions, properties of the reagents used, their ratio, *etc.*

Table 1. Selected chemical and physical characteristics of cyclodextrins.^{10, 39}

Parameter	Cyclodextrin		
	α	β	γ
Number of glucose residues	6	7	8
Molecular mass	972	1135	1297
Inner diameter /nm	0.57	0.78	0.95
Depth of the cavity /nm	0.78	0.78	0.78
Specific rotation (25 °C) /deg	150.5	162.5	177.4
Solubility (25 °C) /g/100 ml of H ₂ O	14.5	1.85	23.2
pK _a	12.33	12.20	12.08

Depending on the substituents introduced into CD, either uncharged or charged modified CD are produced. Methylated, acylated, hydroxyethylated and hydroxypropylated cyclodextrins belong to the former group, whereas aminated, methylaminated, carboxymethylated, sulfated, phosphorylated, *etc.* cyclodextrins belong to the latter group.^{10, 13, 14, 23, 39}

It should be noted that the preparation of cyclodextrin derivatives is a rather complicated process in the course of which either all hydroxy groups or only some of them are replaced. In some cases, the structures of the selectors thus formed were not studied in detail. In original publications, the names of selectors were often not detailed and only the types of substituents were reported. As a result, a large number of trivial names exist, which hinders a comparison of the results of investigations and their interpretation. In the present review, we give names of selectors which were used by authors of the cited studies.

The properties of modified CD differ from those of non-modified CD. The selectivity of enantiomer separation can be improved by increasing solubility, using the ability of CD derivatives to form secondary bonds or controlling the degree of hydrophobicity of the CD cavity.¹⁰ For example, dimethyl- β -CD (DM- β -CD) has a higher solubility and possesses a larger interaction surface compared to β -CD. The hydroxy groups of a substituent in β -CD, which are either charged or can be charged, may be very useful for optimisation of separation by HPLC and CE.

β -Cyclodextrin bearing hydroxypropyl substituents is of interest for separation of enantiomers containing one aromatic or heterocyclic ring and a two–four-membered carbon chain with substituents, which can form hydrogen bonds or serve as proton acceptors.²³ The presence of hydroxy groups in substituents modifying CD provides additional centres for hydrogen bonding. It should be noted that acylated β -CD and β -CD containing hydroxypropyl groups act both in reversed-phase and ‘polar

Figure 1. Molecular structures of cyclodextrins: α -cyclodextrin (a); β -cyclodextrin (b); γ -cyclodextrin (c).

organic' HPLC as well as CE, whereas methylated β -CD is used only in reversed-phase HPLC.

β -Cyclodextrins with bulky substituents, for example, (*S*)- and (*R*)-naphthylethylcarbamates and 3,5-dimethylphenylcarbamates, are commonly used for separation of enantiomers by HPLC.¹⁰

III. Cyclodextrins as chiral selectors in high-performance liquid chromatography

Enantiomer separation is most often carried out by high-performance liquid chromatography. In the last decade, this method has been extensively developed. Considerable progress in this area was made due to thorough investigations of the processes of chiral recognition of enantiomers and factors influencing this process. The use of cyclodextrins in HPLC provided a deeper insight into the characteristic features of enantiomeric recognition and extended the field of its application.

1. Mechanisms of separation on cyclodextrin chiral phases

In aqueous media, cyclodextrins adopt a toroidal conformation with a hydrophobic inner surface, because all hydroxy groups are located outside the cavity of the molecule. For this reason, hydrocarbon fragments of many organic compounds readily occupy the inner cavity to form inclusion compounds with CD. Cyclodextrins can be involved in both hydrophobic and polar interactions as well as in hydrogen bonding with sorbed molecules due to which this chiral selector has a broad spectrum of action. The main prerequisite for enantioselectivity of separation on CD is a particular size of the sorbate molecule, because the formation of an inclusion complex of the sorbate with CD plays a decisive role.

Stability of an inclusion complex depends substantially on the degree of hydrophobicity and steric compatibility between the guest and host (CD) molecules. Evidently, an inclusion complex cannot be formed if the diameter of the molecule is larger than the size of the CD cavity. If the diameter of the molecule is smaller than the size of the CD cavity, the complex can be formed, but the constant of its formation is much smaller than that for a molecule, which can be rigidly fixed in the cavity. It was experimentally found that compounds bearing one aromatic ring (for example, benzene) have a size suitable for α -CD, compounds with two aromatic rings (for example, naphthalene) are suited to the separation on β -CD, and compounds such as substituted pyrenes are suitable for the separation on γ -CD. The presence of one or several polar groups in the sorbate molecule is favourable for hydrogen bonding with the hydroxy groups of CD.

The selectivity of complex formation is determined by the energy difference between inclusion complexes of CD with enantiomers. In most cases, enantiomers contain an aromatic ring (often more than one ring). It was found^{40,41} that separation depends on the position of the chiral centre and its environment. The enantiomeric resolution is higher if a chiral centre is involved in the ring and is bound to two or three sp^2 -hybridised carbon atoms. Complexes with a chiral centre enclosed in a sandwich consisting of two π systems, one of which is an aromatic ring and the other one is either a carbonyl group or the second aromatic ring, are best suited to the enantiomer separation. Successful separation is associated with the high rigidity of the molecule, the chiral centre serving as a point about which fragments of the molecule can rotate.

Most of the published experimental data demonstrate that the size of the β -CD cavity is optimum for the separation of a broad spectrum of optically active compounds, including those used in the pharmaceutical industry.²³ It should be emphasised that the sorbate molecule does not need to be completely located inside the CD cavity. Numerous examples of separation on β -CD of enantiomers containing three or four aromatic rings have been given.¹⁰ It appeared that it is quite sufficient if the sorbate

molecule is only partially located in the cavity and forms an inclusion complex.

The overwhelming majority of enantiomer separations were carried out with the use of β -CD and its various derivatives.¹⁰ To reveal the reasons for this advantage in separation of various compounds, let us consider the structure of the CD molecule (Fig. 2). Hydrophobic molecules analogous to benzene can enter into and leave the CD cavity and are reversibly sorbed on this surface. However, in the absence of hydrophobic sorbates, any other particles, including ions, can penetrate into the cavity. In addition, sorbate molecules can form hydrogen bonds with the hydroxy groups of the CD surface and/or interact with substituents located outside the cavity (in modified CD) and the residual silanol groups of silica gel.

Figure 2. Shape of the β -cyclodextrin molecule in aqueous solutions.²³

To extend the field of application and enhance the selectivity of chiral stationary CD phases, substituted CD with various functional groups are used.^{10,23} The presence of such groups provides additional interactions between the sorbate and the surface, which allows one to extend substantially the spectrum of racemates separated. Extensive investigations in this area are being continued. We proposed a new chiral selector, viz., aminated β -CD. Silica gel modified with aminated β -CD serves as an efficient sorbent for separation of amino acid derivatives and its application made it possible to extend substantially the spectrum of amino acid derivatives which can be separated. For example, separations of *N-tert*-butoxycarbonyl derivatives of amino acids were carried out. Earlier, the latter derivatives had been separated only with the use of hydroxypropyl derivatives of β -cyclodextrin.^{13,14}

In the case of modified β -CD with hydrophobic substituents, for example, with (*S*)-naphthylethylcarbamate or 3,5-dimethylphenylcarbamate, interactions on the surface occur through another mechanism. Depending on the type of the mobile phase, the following interactions between the sorbate and the surface prevail on these chiral stationary phases: the formation of π complexes in a normal phase, hydrogen bonding in a polar organic phase, and the formation of inclusion complexes in a reversed phase.¹⁰

The above-described chiral selectors are multimodal, because they are successfully used for separation of a large amount of various enantiomers and interact with the latter according to different mechanisms. The choice of a mobile phase is governed by the structure of the compound analysed, its stability and solubility in the mobile phase. The normal-phase method is most preferable, the 'polar organic' method ranks next, and the reversed-phase method occupies the last place because of its low resolution, relatively short lifetime of such chromatographic columns and small capacity factors.

Cyclodextrins find wide application as chiral additives to a mobile phase in enantiomer separations. In this case, recognition of enantiomers occurs due to the distribution of the sorbate between the stationary phase and the inclusion complex in the mobile phase. The resolution and selectivity in these systems depend on the type and concentration of the CD, the nature of the mobile and stationary phases and temperature. In some cases,

CD can be sorbed on the surface of a mobile phase and form a pseudostationary phase.⁴²

2. Separation of enantiomers in reversed-phase high-performance liquid chromatography

Most separations on CD-based chiral stationary phases are carried out by reversed-phase liquid chromatography, because inclusion complexes can be formed only in aqueous or aqueous–organic solutions. The stability constants of complexes are generally larger in water and decrease as the fraction of an organic solvent increases. It is known that the addition of various organic solvents to an eluent can change the selectivity of enantiomer separation. This effect is observed also for CD-based stationary phases.¹⁰

a. Choice of a mobile phase

Methanol and acetonitrile are used as organic additives to mobile phases. Ethanol, propanol, dioxane, dimethylformamide and tetrahydrofuran are used much more rarely. Water has the smallest eluting ability. For alcohols, the polarity increases in the series methanol < ethanol < propanol. Tetrahydrofuran and acetonitrile are similar in polarity to propanol. Solvents which are less polar than water and whose molecular sizes correspond to the sizes of the CD cavities are prone to be retained on stationary CD phases. Therefore, the capacity factors of sorbates depend on how rapidly the solvent molecules displace the compound to be determined from the CD cavity. For example, it is necessary to use a larger percentage of methanol than that of propanol to obtain comparable retention times in both cases.

Different ways of optimising the concentration of an organic solvent in a mobile phase are available. There are three possible types of chromatographic behaviour of compounds on the surface of the stationary CD phase. The corresponding dependences of the retention on the concentration of an organic solvent in a mobile phase are shown in Fig. 3.⁴³ The most general dependence is represented by curve 1, which shows that the retention decreases as the concentration of an organic component in the mobile phase increases. The curve reaches a minimum, *i.e.*, the 'dead time', and the further addition of the organic solvent has no effect on retention. This chromatographic behaviour is typical of compounds soluble in organic solvents (phenols, anilines and other aromatic and heterocyclic compounds).

Curve 2 illustrates the unique properties of stationary CD phases, which enable one to extend substantially the range of the compounds separated due to the application of 'polar organic' liquid chromatography. A decrease in the buffer/organic solvent ratio in the mobile phase leads to a decrease in retention (and

resolution). The retention minimum is achieved in the range of 50%–80% of an organic solvent in the mobile phase.⁴³ A further increase in the percentage of an organic solvent increases retention. Therefore, it can be assumed that the mechanism of recognition on stationary CD phases in elution of sorbates with mobile phases with a dominant concentration of an organic solvent differs substantially from that taking place in reversed-phase chromatography.

The third type of chromatographic behaviour is described by curve 3, which can also have a minimum. However, in this case the curve shape is not associated with the unique properties of stationary CD phases; instead, this is a consequence of insolubility or low solubility of sorbates in organic solvents. This behaviour is shown by many amino acids. Analogous dependences for amino acids were obtained also on traditional reversed-phase columns.⁴³

The curve is shifted to the right or left by changing from one organic solvent to another, the character of the dependence remaining unchanged.

b. Salt effect and influence of pH of a mobile phase

In some cases, the nature of the organic solvent is of less importance than pH and the ionic strength of the mobile phase. The effect of the concentration of the salt additive on the retention and enantioselectivity was studied for 5-dimethylaminonaphthalene-1-sulfonyl derivatives of amino acids (dansyl amino acids). As can be seen from Table 2, the addition of small amounts of a salt to the mobile phase leads to substantial changes in retention (k') and peak resolution (R_s) of enantiomers, whereas it has virtually no effect on the selectivity coefficient (α). The resolution is improved due to a decrease in the chromatographic band broadening. In some cases, the column performance is increased by a factor of 4.¹⁰

A comparison of the experimental data obtained with the use of additives of various salts to a mobile phase shows that the presence of the salt always leads to a decrease in the capacity factor of the column and an increase in resolution (Table 3). The effect of a decrease in retention of sorbates upon the addition of a salt to the mobile phase can be compensated by varying pH and concentration of the salt.

From the published data, it is known that triethylamine acetate is recommended as an additive to a mobile phase, because this reagent allows one to vary pH using buffer solutions. The effect of pH on the retention of dansyl-L-valine is shown in Fig. 4. Curve 2 characterises the dependence of the retention on the concentration of an organic solvent in the mobile phase (a mixture of methanol and water) in the absence of the salt additive. It should be noted that curve 2 has a minimum, which is absent in curves 1 and 3. It should also be emphasised that the behaviour of sorbates in acidic media differs from that in alkaline media (curves

Figure 3. Influence of the composition of a mobile phase on the retention of various compounds.⁴³ The description of curves (1–3) is given in the text.

Table 2. Effect of the ionic strength of a mobile phase on the separation of enantiomers of dansyl amino acids.⁴³

Note. Methanol–water (40 : 60) as the mobile phase, the flow rate was 1 ml min⁻¹. ^a The concentration of the salt was 0.02 mol litre⁻¹; ^b the capacity factor of the first enantiomer.

**Figure 4.** Influence of pH and concentration of an organic solvent on the retention of dansyl-DL-valine.

A 0.1% buffer solution of triethylamine acetate [pH 4.1, curve (1); pH 8.0, curve (3)] and pure water [curve (2)] were used as an aqueous component of the mobile phase.⁴³

1 and 3, respectively). High enantioselectivity of stationary CD phases in separation of compounds of an acidic or neutral nature is most often observed at pH ~ 4.0. This is associated with the ionic state of sorbates and depends on their pK_a . For instance, pH ~ 4 is optimum for most amino acid derivatives separated on β -CD, because compounds exist predominantly in the molecular form under these conditions.

c. Temperature effect

It is known that the constants of interactions between sorbates and the cyclodextrin surface depend on the temperature.¹⁰ As can be seen from Table 4, the selectivity coefficient and resolution increase as the retention temperature decreases. However, an increase in the resolution ability is not always achieved, because at low temperatures the mass transfer rate on the surface decreases and the chromatographic band is broadened. Therefore, an increase in selectivity has no positive effect because of an increase in the peak width at low temperatures. The use of low temperatures becomes favourable if there is a possibility of narrowing the chromatographic band by changing from one organic solvent to another or introducing various additives into the mobile phase.

In the temperature range of 60–90 °C, most inclusion complexes decompose on stationary CD phases. This fact is exploited in elution of sorbates when their retention on the surface is very strong. It should be noted that the influence of the temperature on

Table 4. Effect of the temperature on the separation of enantiomers of dansyl amino acids.⁴³

Compound	T / °C	k'_1 (see ^a)	α	R_s
Dansyl-DL-valine	23	2.4	1.16	1.5
	4	3.7	1.23	1.7
Dansyl-DL-phenylalanine	23	5.3	1.19	1.5
	4	8.8	1.3	1.8

the retention of sorbates on stationary CD phases is more pronounced than that on traditional reversed-phase sorbents.

d. Effect of the rate of a mobile phase

The standard flow rate which is used in commercial 250 × 4.6-mm CD columns packed with a sorbent with a grain size of 5–10 μ m varies from 0.5 to 2 ml min⁻¹. For some compounds, the chromatographic band is substantially broadened at a flow rate of 1–2 ml min⁻¹ in the absence of a buffer or salt additives to a mobile phase. This broadening occurs due to the characteristic features of the kinetics of formation of an inclusion complex, for which the mass transfer rate on the surface of a stationary phase is low. A decrease in the rate of the mobile phase from 1–2 ml min⁻¹ to 0.4–0.5 ml min⁻¹ can improve the column performance by a factor of 1.5–3.¹⁰

3. Enantiomer separation at high concentrations of an organic solvent in a mobile phase ('polar organic' method)

The characteristic features of separation by chromatography with mobile phases containing from 90% to 100% of acetonitrile or methanol differ substantially from those of separation by reversed-phase chromatography. If an organic solvent is dominant in a mobile phase, no inclusion complexes are formed because the CD cavities are occupied by solvent molecules (Fig. 5). Armstrong and co-workers^{22,44} hypothesised that this is a new modification of chromatography, which was called a 'polar organic mode of liquid chromatography'.

**Figure 5.** Scheme of the enantioselective mechanism of retention on β -cyclodextrins in the 'polar organic' mode (a) and normal-phase (b) chromatography.¹⁰

a. Structural characteristics of chiral recognition

In elution with mobile phases in which an organic solvent prevails, the retention and enantioselectivity of separation on CD are determined by hydrogen bonding and dipole–dipole interactions between the sorbate molecules and hydroxy groups of CD rather than by hydrophobic interactions (formation of inclusion complexes).^{10,22} In addition, steric factors can be of considerable importance in chiral recognition, which is typical of stationary phases based on CD derivatives.

Compounds separated in the 'polar organic' mode should be able to form hydrogen bonds. For instance, the replacement of

hydrogen at the secondary nitrogen atom adjacent to the chiral centre by the methyl group leads to a decrease or loss of enantioselectivity. This example suggests that the presence of the acidic hydrogen atom, *i.e.*, the proton donor, is of importance for recognition of enantiomers.⁴⁴

To separate enantiomers on nonmodified CD, it is necessary that the sorbate molecules contain at least two groups capable of hydrogen bonding.¹⁰ The retention and separation on cyclodextrin derivatives occur due to the formation of $\pi-\pi$ complexes or hydrogen bonding. Groups grafted to the CD surface also contribute to chiral recognition as a result of the appearance of steric interactions.

Mobile phases with a high content of an organic solvent offer advantages over the reversed-phase and normal-phase modes of liquid chromatography and allow one to extend substantially the range of racemates which can be separated. For example, separation of compounds such as β -blockers (propranolol, atenolol, timolol, *etc.*) can be carried out on β -CD only in the 'polar organic' mode.¹⁰

b. Influence of the mobile-phase composition

The retention and enantioselectivity of sorbates in the 'polar organic' mode of chromatography depend on the nature and concentration of an organic solvent. Acetonitrile is most commonly used in enantiomer separations.

Since molecules of acetonitrile serving as the major component of a mobile phase, unlike sorbate molecules, do not form hydrogen bonds with cyclodextrin, the retention of the compounds analysed may be very high. The presence of small additives of methanol, which can form hydrogen bonds with cyclodextrin and sorbate molecules, in a mobile phase leads to a decrease in retention to a reasonable time. However, a high excess of methanol can cause a loss of enantioselectivity. To improve recognition and efficiency of separation, small amounts of triethylamine and acetic acid ($\leq 1\%$) are recommended to be added to a mobile phase.^{10,44} The ratio between these additives in a mobile phase is determined primarily by selectivity of separation and depends on the nature of the sorbates.

One of the advantages of the 'polar organic' mode of chromatography is that it allows one to separate a series of water-insoluble organic salts. This problem cannot be solved by normal-phase chromatography in which sorbates should be electro-neutral.²³

4. Enantiomer separation by normal-phase high-performance liquid chromatography

Cyclodextrin-based stationary phases are used for separation of some compounds by normal-phase chromatography.^{10,23} Hexane-isopropanol mixtures in different ratios are used as mobile phases. In this case, components of a nonpolar mobile phase tend to occupy cyclodextrin cavities and, hence, the retention and separation occur through hydrogen bonding between the sorbate and hydroxy groups of cyclodextrin and also due to $\pi-\pi$ interactions. Satisfactory results were obtained in separations of various structural isomers (substituted benzoic acids, phenols, anilines, *etc.*) by normal-phase chromatography.²³

Studies of enantiomer separations on CD-based stationary phases by normal-phase liquid chromatography are few in number. All these studies were devoted to β -CD derivatives. In most cases, their enantioselectivity is higher than that of traditional chiral polysaccharide phases for normal-phase chromatography.

5. Practical application of enantiomer separation

Molecules of most compounds which are of interest from the viewpoint of pharmacology and biochemistry contain one or several asymmetric centres. Since optical isomers differ generally in pharmacological and biological activities, the enantiomer separation has attracted growing interest. High-performance liquid chromatography has gained wide acceptance, because it

provides high efficiency and selectivity of enantiomer separation, analyses being relatively inexpensive and time-saving.

The differences in the physiological activity of enantiomers of β -adrenoblockers (so-called β -blockers) gave impetus to investigations of chromatographic separation of enantiomers of such compounds. It is known that (*S*) enantiomers of such compounds are often 50–100 times more efficient than (*R*) enantiomers. The latter can even be toxic. These compounds are too polar to be separated by gas chromatography without preliminary derivatisation. Therefore, HPLC is the method of choice. Data on the use of β -CD and its derivatives for the determination and separation of enantiomers of β -blockers have been published in the literature. The recognition ability of the following cyclodextrins was examined: β -CD,^{9,45} perphenylcarbamate (PPC) β -CD,⁴⁶ carboxymethyl- β -CD (CM- β -CD),⁴⁷ heptakis(2,3-di-*O*-methyl)- β -CD,⁹ phenylcarbamate (PC) β -CD⁴⁸ and mono-6-azido-6-deoxy-PPC- β -CD.⁴⁹ In addition, the determination of β -blockers is of great interest in studies of the composition of human blood and urine. For example, propranolol enantiomers were quantified in human urine and plasma; the sensitivity of analysis was 1.5 ng ml^{-1} for each enantiomer. It was experimentally found that the concentration of the (*S*) enantiomer is always higher than that of the (*R*) enantiomer.⁵⁰

Enantiomer separations of hydantoin and its derivatives exhibiting anticonvulsive activity were carried out with the use of chiral additives of β -CD;^{51,52} β -CD, charged β -CD and CM- β -CD;⁵³ α -CD, β -CD and their permethylated (PM) derivatives;⁵⁴ and chiral stationary phases based on β -CD and trimethyl- β -CD (TM- β -CD).⁵⁵ Charged β -CD was also used as a stationary phase for separation of antiinflammatory drugs.⁵⁶

The chromatographic behaviour of the following compounds was investigated: antidepressants and their metabolites on acylated β -CD;⁵⁷ drugs used in cancer treatment⁵⁸ and anticonvulsive drugs and their metabolites on β -CD;⁵⁹ antiepileptics and their metabolites,⁶⁰ drugs used for treatment of allergic rhinitis⁶¹ and imidazole derivatives^{62,63} with the use of an additive of β -CD to a mobile phase and imidazole derivatives on β -CD;⁶⁴ the local anaesthetic procaine⁶⁵ and the antiinflammatory drug naproxen^{66,67} using various β -CD derivatives both as chiral additives to a mobile phase and as a stationary phase; profens on β -CD.⁶⁸ A procedure was developed for the detection of the anti-anxiety agent lorazepam in human plasma on a β -CD derivative.⁶⁹

Pentostatin was detected and separated with the use of a mobile phase in the presence of an additive of sulfated β -CD;⁷⁰ methylsalsolinol and its derivatives were detected and separated with the use of an additive of β -CD to a mobile phase. The biological and toxic properties of these compounds were studied.⁷¹ The behaviour of substituted decalins on various chiral stationary CD phases was investigated.⁷² The detection of the following pharmaceuticals and biologically active compounds was examined in a series of studies: methadone and its metabolites in main human biological liquids on β -CD and its derivatives,⁷³ 7-desmethylormeloxifene (metabolite of levormeloxifene)⁷⁴ with an additive of sulfated β -CD to a mobile phase, pirlindole on β -CD,⁷⁵ tropicamide on 2-hydroxypropyl- β -CD (HP- β -CD),⁷⁶ doxazosin on CM- β -CD,⁷⁷ trimipramine with the use of an additive of β -CD to a mobile phase;⁷⁸ carbisocaine on β -CD,⁷⁹ simendan and levosimendan on β -CD,⁸⁰ salsolinol and methylsalsolinol,^{81,82} terfenadine,⁸³ thalomid⁸⁴ using an additive of β -CD to a mobile phase; zopiclone and its metabolites on β -CD,⁸⁵ *etc.*^{9,47}

Cyclodextrins as chiral additives to a mobile phase (α -CD,⁸⁶ β -CD⁸⁷ and α -CD together with β -CD⁸⁸) are used also for separation of terpenes [($\pm$)- α -pinene, ($\pm$)- β -pinene, ($\pm$)-camphene and ($\pm$)-limonene]. The enantiomeric purities of these hydrocarbons were, generally, determined by polarimetry, because separation of these nonpolar compounds devoid of functional groups which can undergo derivatisation or interact with a selector presents difficulties. Consequently, a chromatographic method for the enantioselective separation of racemates of satu-

rated hydrocarbons should be based on the formation of inclusion complexes, because in this case steric effects play a decisive role. That is the reason why enantiomer separations are carried out with the use of cyclodextrins.

The separation of amino acid derivatives on chiral cyclodextrin stationary phases was extensively studied in the early 1990s. Amino acid derivatives containing the following modifying substituents were investigated in most detail: 4-dimethylaminoazobenzene-4'-sulfonyl (dabsyl), dansyl, 9-fluorenylmethoxycarbonyl (Fmoc), 2,4-dinitrophenyl (DNP), 3,5-dinitropyridyl (DNPY), phthalyl, benzyloxycarbonyl (Z), benzoyl, *tert*-butoxycarbonyl (BOC) and derivatives of *o*-phthalic anhydride (OPA).^{10,23} The mechanism of retention and separation of enantiomers was studied for the following compounds: dansyl amino acids on PM- β -CD,⁸⁹ dansyl- and 3,5-dinitrobenzoylamino acids on methyl- β -CD (M- β -CD),⁹⁰ DNP-amino acids on 3-*O*-methyl- β -CD,⁹¹ dansyl and dabsyl amino acids on β -CD,⁹² Fmoc amino acids and selected peptides on β -CD and γ -CD,⁹³ Fmoc and dansyl derivatives of DL-serine on γ -CD,⁹⁴ dansyl amino acids on β -CD, heptakis(2,3-di-*O*-methyl)- β -CD⁹ and γ -CD, which was modified with azobenzene derivatives,⁹⁵ 3,5-dinitrobenzoyl and dansyl amino acids on naphthylethylcarbamate (NEC) β -CD,⁹⁶ 1-fluoro-2,4-dinitrophenyl-5-L-alanineamido derivatives of amino acids on β -CD,⁹⁷ Z, benzoyl, dansyl, DNP, DNPY, OPA, BOC, Fmoc and phthalyl derivatives of amino acids on heptakis(6-amino-6-deoxy)- β -CD.¹³ The chiral ability of this aminated β -CD was compared with that of nonmodified β -CD¹⁴ for various derivatives of amino acids.

Interesting experimental chromatographic data were obtained in the separation of dansyl derivatives of amino acids on a chiral stationary phase based on β -CD modified with L-tyrosine.⁹⁸ Separations of nonmodified amino acids, *viz.*, enantiomers of DL-selenomethionine⁹⁹ and various amino acids from tobacco,¹⁰⁰ were carried out on β -CD.

As can be seen from the above-considered data, most separations were carried out on CD as chiral stationary phases. However, in some cases chiral additives of CD to a mobile phase were used. As an example we refer to the separation of naphthalene-sulfo derivatives of amino acids.¹⁰¹

Enantiomer separations of the following compounds were carried out: bicyclic 1,3-amino alcohols on NEC- β -CD,¹⁰² analogues of crown ethers on β -CD and heptakis(2,3-di-*O*-methyl)- β -CD,⁹ polychlorobiphenyls and certain pesticides on heptakis(tri-*O*-methyl)- β -CD (HTM- β -CD),¹⁰³ enantiomers of warfarin on β -CD,¹⁰⁴ phenoxypropionates on permethylated β -CD,¹⁰⁵ a number of carboranes on β -CD and acylated β -CD,¹⁰⁶ compounds analogous to isoflavone on β -CD,¹⁰⁷ fluoxetine and norfluoxetine with the use of CD both as chiral additives to a mobile phase and as a stationary phase.^{108, 109}

A number of studies were devoted to the quantification and separation of biologically active compounds, in particular, of amino alcohols belonging to one of the most important classes of chiral compounds. These compounds play an important role in metabolic processes in organisms and find extensive application in medicine and pharmacology. The optical purity of adrenaline was determined using 2,6-DM- β -CD as the stationary phase.¹¹⁰ Adrenaline and its analogues were quantified in biological liquids using additives of TM- β -CD to a mobile phase.¹¹¹ Quantification of adrenaline and noradrenaline was carried out on β -CD.¹¹² Ephedrine and methylamphetamine were quantified on β -CD.¹¹³ Methylenedioxymphetamines were detected on β -CD and HP- β -CD,¹¹⁴ and methamphetamine was quantified on phenyl- β -CD.¹¹⁵

IV. Enantiomer separation by capillary electrophoresis

Capillary electrophoresis is a modern method which allows one to perform rapid and highly efficient separations of compounds. Since enantiomers possess identical physicochemical properties, it

is necessary to change selectively their effective, *i.e.*, intrinsic, electrophoretic mobilities with the aim of carrying out their successful separation by CE. This is achieved upon the formation of stereoselective complexes through hydrophobic, π - π , dipole-dipole and van der Waals interactions and hydrogen bonds. To separate enantiomers by capillary electrophoresis, a chiral selector is either added to a supporting electrolyte (SE) or chemically grafted to a capillary wall or a stationary phase. In separations with the use of cyclodextrins as chiral selectors, the compounds are either completely or partially included into the CD cavity to form inclusion complexes stabilised by secondary bonds between polar groups of the chiral selector and the compounds that are separated.

1. Selected aspects of the mechanism of chiral separations by capillary electrophoresis

The model of separation of an enantiomer pair by CE was first proposed in 1992.¹¹⁶ It is assumed that chiral separation takes place if enantiomers have different affinities for a chiral selector, *i.e.*, different binding constants K_1 and K_2 , and if the electrophoretic mobility of the free enantiomer differs from that of the enantiomer involved in a complex. The difference in the electrophoretic mobilities is expressed by the following equation:¹¹⁶

$$\Delta\mu = \frac{[C](\mu_1 - \mu_2)(K_2 - K_1)}{1 + [C](K_1 + K_2) + K_1K_2[C]^2}, \quad (1)$$

where μ_1 and μ_2 are the electrophoretic mobilities of the free enantiomer and the enantiomer involved in a complex, respectively (it is assumed that these parameters are identical for both enantiomers) and $[C]$ is the concentration of the chiral selector. The optimum concentration of the chiral selector can be determined by solving the equation $d\Delta\mu/d[C] = 0$. In this model, the concentration depends only on the binding constants K_1 and K_2 :

$$[C]_{\text{opt}} = \frac{1}{\sqrt{K_1K_2}}. \quad (2)$$

From Eqn (1), it follows that the difference in electrophoretic mobilities is larger if the enantiomer-chiral selector complex migrates in a direction opposite to the direction of migration of the free enantiomer. This is confirmed by experimental results obtained with the use of charged CD, when the compounds that are separated and the chiral selector migrate in different directions.

The influence of the following two factors providing enantioselective separation of dansyl amino acids by CE was examined:¹¹⁷ the difference in the binding constants of enantiomers with the chiral selector (HP- β -CD) and the enantioselective change in pK_a upon complex formation in the pH range $pK_a \pm 2$ resulting in different charges of enantiomer-chiral selector complexes and, consequently, in different effective mobilities of the complexes. Intra- and intermolecular interactions often have a strong effect on acid-base equilibria and lead to changes in pK_a of acidic and basic groups in the molecule. Enantiomers are included into the CD cavity in different fashions to form hydrogen bonds which differ in strength and direction. Enantiomers also differ in the involvement in dipole-dipole interactions, which leads to different changes in pK_a of the amino and carboxy groups for two enantiomers. An enantioselective change in pK_a upon complex formation can lead to a difference in pK_a for two enantiomers up to 0.4 (for the carboxy group of dansyl tryptophan). In the pH range $pK_a \pm 2$, a change in the concentration of a chiral selector leads to the reversal of the enantiomer migration order. This phenomenon is observed if a more stable enantiomer-chiral selector complex possesses a higher effective mobility and the mobility of the complexes is lower than that of the free enantiomers.

The pH-dependent reversal of the migration order of di- and tripeptide enantiomers with the use of β -CD and its derivatives

was investigated.¹¹⁸ The possibility of this reversal depends on the structure of cyclodextrin, the amino acid composition and amino acid sequence in peptides. Phenylalanine containing the carboxy group at one end of the amino-acid chain is favourable for the reversal of the migration order. It was noted that the pH-dependent reversal of the migration order in the case of di- and tripeptides is observed at $\text{pH} \approx \text{p}K_a$ for carboxy groups.

2. Factors influencing enantiomer separation in capillary electrophoresis

The efficiency of enantiomer separation by CE is influenced by the following factors: the type and concentration of a chiral selector, pH and the composition of SE, organic and inorganic agents modifying SE and the capillary temperature. The effects of all the above-mentioned factors are briefly discussed below.

a. Type and concentration of a chiral selector

α -, β - and γ -Cyclodextrins contain different numbers of glucose residues and, consequently, their cavities differ in the inner diameter. Since the mechanism of enantiomer separation is based on the possibility of inclusion of a substrate into the CD cavity, both the sizes and shapes of the guest and host molecules are of great importance in chiral separation. These effects were examined in the studies.^{119–129} The importance of the choice of the type of CD as a chiral agent was demonstrated in different CE methods (capillary gel electrophoresis, isotachopheresis, capillary zone electrophoresis).^{119–121}

Various methylated β -CD as applied to the enantiomer separation of dansyl derivatives of amino acids were examined.¹³⁰ Methylation of CD at position 6 has no effect on the stereoselectivity of separation compared to the starting (native) CD, whereas the modification of position 2 renders chiral separation impossible. These data are indicative of the key role of the hydroxy groups of CD in the chiral recognition of dansyl amino acids. The importance of the type of CD in the chiral separation of several herbicides using selectively modified α -, β - and γ -CD was demonstrated in the study.¹³¹

The influence of the concentration of new positively charged CD, *viz.*, heptakis(6-deoxy-6-methoxyethylamino)- β -CD, on separation of enantiomers of profens and herbicides (chlorophenoxypropionic acids) was studied.¹³² The order of the decrease in the degree of complex formation of profen enantiomers with a chiral selector was revealed (from the difference in the migration times in the presence and absence of the selector). It was noted that the peak resolution decreases in the reverse order independently of the concentration of the CD derivative. The best resolution of enantiomer peaks was achieved for indoprofen and fenoprofen (R_s are 11 and 14, respectively). For chlorophenoxypropionic acids, the formation of more stable complexes with the chiral selector improves the peak resolution. A mixture of enantiomers of six different herbicides was successfully separated.

Various cyclodextrins were extensively investigated.^{133–136} For example, racemates of 42 of 86 drugs under study were separated with the use of HP- β -CD.

The review¹³⁷ surveyed data on the study of enantiomer separation using TM- β -CD. Of 86 pharmaceuticals, 47 compounds were successfully separated. The influence of the structures of the compounds analysed and chiral selectors (TM- α -CD, TM- β -CD, TM- γ -CD) on enantiomer separation was examined. Based on abundant data, it was found that the so-called 'substructure 4H',

where $A = C, N, \text{etc.}$, influences substantially the electrophoretic separation. Compounds containing this substructure not only

have high affinity for cyclodextrins but also can be separated with a high probability into enantiomers using the above-mentioned chiral selectors.

Interesting results were obtained with the use of various CD¹²³ (α -, β -, γ -, DM- α -, DM- β -, TM- α -, TM- β -CD) for separation of enantiomers of dansyl amino acids.

The advantage of charged CD in the chiral separation was demonstrated in the study¹²² devoted to separation of enantiomers of dansyl amino acids on charged mono-(6-amino-6-deoxy)- β -CD.

Sulfobutyl ether of β -CD (SBE- β -CD) is an important chiral selector, which finds wide application in CE. The advantages of this CD derivative for separation of a large number of racemates of chiral compounds were demonstrated in many investigations.^{138–146} It should be noted that peaks observed in capillary electrophoresis with the use of charged CD are often smeared, particularly at low pH in analysis of basic compounds.¹⁴⁷ A mixture of sulfated cyclodextrins, which differ in the degree of substitution, was used¹⁴⁸ for separation of enantiomers of 56 drugs.

The separation of dansyl amino acids with the use of new CD derivatives, *viz.*, 6-deoxy-6-*N*-histamino- β -CD and 6-deoxy-6-[4-(2-aminoethyl)imidazolyl]- β -CD, was investigated.¹⁴⁹ The former chiral selector is a monosubstituted positively charged β -CD in which the histamine moiety is bound to the C(6) atom of the monosaccharide fragment of the CD ring through the amino group. In the latter chiral selector, the histamine moiety is bound to the C(6) atom through the imidazolyl group. The number of positive charges in the molecules of these chiral selectors can be varied depending on pH, because the amino and imidazolyl groups have different $\text{p}K_a$. The best separation of dansyl amino acids was achieved with the use of the latter chiral selector. The same CD derivatives were used in the separation of enantiomers of α -hydroxy and carboxylic acids.¹⁵⁰ Separation with the use of the former chiral selector was attained at a concentration of 1 mmol litre⁻¹, whereas separation with the use of the latter chiral selector did not occur, which indicates that a short distance between the positive charge and the CD cavity is of importance for chiral separation.

New CD derivatives were proposed^{151–153} for separation of enantiomers of neutral and charged compounds. Heptakis(2,3-dimethyl-6-sulfo)- β -CD forms less stable complexes with the compounds analysed compared to two other derivatives, *viz.*, heptakis(2,3-di-*O*-acetyl-6-sulfo)- β -CD (HDAS- β -CD) and heptakis(6-sulfo)- β -CD, and exhibits the highest stereoselectivity of these three derivatives. An increase in the concentration of the chiral selector leads to a change in the elution order of enantiomers of neutral compounds. Enantiomers of weak bases and acids were separated at pH lower and higher than 7, respectively.¹⁵¹

Cyanoethylated β -CD was proposed for separation of basic and acidic racemic compounds.¹⁵⁴ The advantage of this chiral selector is that its solubility in water and organic solvents is relatively high.

Mono(6-glutamylamino-6-deoxy)- β -CD is a zwitterionic CD suited to the separation of uncharged compounds.¹⁵⁵ The charge of the chiral selector can be varied by changing the pH of SE: the chiral selector is positively charged at pH 2.3 and negatively charged at pH 10.3–11.2.

Enantiomers of herbicides, dansyl amino acids and profens were separated on heptakis(6-hydroxyethylamino-6-deoxy)- β -CD.¹⁵⁶ The stereoselectivity of enantiomer separation depends on the pH of SE. Chiral separations were obtained in the pH range 4–7.

Soluble polymers, which were prepared by the reactions of β -CD or carboxymethyl- β -CD with epichlorohydrin, were successfully used in chiral CE.^{157–161}

The concentration of CD in the supporting electrolyte is of primary importance in CE. Chiral separations very often do not take place, although the addition of CD causes a decrease in effective mobilities of enantiomers. One of the reasons is an

improper choice of the CD concentration. The existence of the optimum CD concentration (Eqn 2), at which the maximum enantiomer separation would be expected, was theoretically described in the study.¹¹⁶ In some cases, the maximum peak resolution is not attained (R_s increases as the concentration of CD is increased), because the optimum concentration of cyclodextrin cannot be achieved due to its low solubility in water.

Based on the data published in the literature, it can be concluded that the β -CD cavity (unlike the α - and γ -CD cavities) is most suitable for the chiral separation of a large number of compounds, particularly those involved in modern drugs. Most commercially available cyclodextrin derivatives were synthesised based on β -CD. As mentioned above, modified cyclodextrins differ substantially in their properties from native β -CD (they are readily soluble, can form secondary bonds and their cavities have different hydrophobicities), which can be used for improving the selectivity of enantiomer separation. The experimental difficulties in using charged cyclodextrins are associated with the fact that most commercially available selectors are complex mixtures containing a large number of isomers. A change in the concentration of charged cyclodextrins in SE leads to substantial changes in the ionic strength. In the presence of cyclodextrins, it is difficult to determine the precise rate of electroosmotic flow (EOF).

Charged β -CD derivatives find application in separations of enantiomers of neutral and charged compounds. In the case of the latter, the use of charged chiral selectors leads to larger R_s compared to neutral selectors. As mentioned above, the migration of a chiral selector in a direction opposite to the direction of migration of the compounds analysed facilitates enantiomer separation, because it increases the difference in the electrophoretic mobilities of the free enantiomer and the enantiomer involved in a complex.¹¹⁶

b. Concentration and pH of a supporting electrolyte

The choice of an appropriate supporting electrolyte (the type and concentration of a buffer solution, ionic strength, pH) is of great importance for achieving the optimum experimental conditions for enantiomer separation. The electroosmotic flow can be controlled and the ionic state of both the compounds separated and a chiral selector can be changed by varying the pH. The influence of the pH of a supporting electrolyte on the enantioselectivity was examined in virtually all the above-mentioned studies. The ionic strength influences both EOF and migration times of the compounds separated. Electromigration dispersion can be decreased by increasing the ionic strength of the buffer, which is, however, accompanied by an increase in the current in the system. The effect of the ionic strength on separation of enantiomers of warfarin was studied;¹⁶² *N*-tris(hydroxymethyl)methyl-3-aminopropanesulfonate containing CD as a chiral additive was used as the buffer; the ionic strength was increased by adding sodium chloride. An increase in the ionic strength of the buffer led to a decrease in the rate of EOF, an increase in the migration time and an improvement of peak resolution of warfarin enantiomers. In the study,¹⁶³ the optimum separation of isoproterenol enantiomers was achieved at relatively high SE concentrations (250 mM sodium acetate) with maximum efficiency, selectivity and peak resolution.

c. Capillary temperature

The capillary temperature is a very important parameter, which is necessary to control in chiral analyses by electromigration methods. The temperature influences the mobility of the compounds analysed, the kinetics and thermodynamics of complex formation with cyclodextrins, etc. The influence of the capillary temperature on the chiral separation was examined in the studies.^{164–171} It was found that the migration time and the peak resolution decrease as the temperature increases. In some cases, a reverse dependence was observed.^{172, 173}

d. Organic and inorganic modifying agents of supporting electrolytes

The addition of achiral compounds to SE changes the electroosmotic flow, viscosity, solubility of the compounds analysed and/or the chiral selector with a resulting change in electrophoretic mobilities giving rise to enantiomer separation. Enantiomers of *threo*-chloramphenicol and ketotifen were separated using heptakis(2,6-di-*O*-methyl)- β -CD with the addition of hydrophilic cellulose derivatives to SE.¹⁷⁴ In the cited study, an improvement of separation was attributed to a decrease in both EOF and adsorption of the compounds analysed on capillary walls. An analogous effect was observed in the study of the influence of polyvinyl alcohol on the chiral separation of several tocainides.¹⁷⁵ The introduction of short-chain alkyl ammonium cations into SE has a strong effect on the chiral separation of some pharmaceuticals. Separations of enantiomers of 22 drugs using β -CD, DM- β -CD, TM- β -CD, HP- β -CD with additives of tetramethyl- or tetrabutylammonium bromide were investigated.¹⁷⁶ The use of ammonium salts causes the reversal of EOF, an increase in the migration time and improvement of resolution of enantiomer peaks. The separation of enantiomers of several anaesthetics was also improved with the use of the tetrapropyl- and tetrabutylammonium cations in DM- β -CD-containing SE.¹⁷⁷ The influence of small organic cations on the chiral separation of compounds possessing basic properties was examined in the study.¹⁷⁸ Optical isomers of alprenolol, amphetamine, anisodamine, isoprenaline, pinacidil, synephrine and verapamil were separated with the use of HP- β -CD in the presence of tris(hydroxymethyl)methylamine (Tris), diethanolamine, triethanolamine, diethylamine or triethylamine. Of the additives used, triethanolamine proved to be most efficient for improving the selectivity.

Enantiomers of nonpolar primary amines are difficult to separate by CE with the use of only CD. To perform or improve the chiral separation of amines, DM- β -CD, hydroxyethyl- β -CD (HE- β -CD) and γ -CD in combination with 18-crown-6 were used.¹⁷⁹ The compounds analysed form inclusion complexes both with the chiral selector, which recognises amine enantiomers, and 18-crown-6. The mechanism of enantiomer separation with the use of CD and 18-crown-6 was elucidated in the study.¹⁸⁰ Compounds containing the amino group were separated on β -CD or its derivatives in the presence of an achiral crown ether (30 mmol litre⁻¹). A combination of a chiral selector (β -CD or succinyl- β -CD) and an achiral complex-forming agent (a borate buffer) made it possible to separate enantiomers of phenylethane-1,2-diol, 3-benzoyloxypropane-1,2-diol, hydroxybenzoin and 3-(*N*-benzyl-*N*-methylamino)propane-1,2-diol.¹⁸¹ The borate anion serves as a complex-forming agent for vicinal diols. The cationic ion-pair reagent quinine has a strong effect on separation of enantiomers of acidic and basic compounds on cyclodextrins.¹⁸²

The introduction of organic modifying agents into SE can change parameters, such as the binding constants of the chiral selector and enantiomers, the rate of EOF, conductivity of SE, solubility of the chiral selector and/or compounds analysed with a resulting change in the time required for analysis. The introduction of organic modifying agents into SE can either improve or impair the enantiomer separation. Chiral separations of several amino acids were performed in a capillary filled with polyacrylamide gel with the addition of 10% of methanol to CD-containing SE.¹¹⁹ Propranolol was separated into enantiomers only in the presence of methanol (10%–30%) in SE (phosphate buffer–urea– β -CD).¹⁸³ An improvement of chiral separation upon the addition of methanol was observed for mandelic acid,¹⁷⁰ warfarin¹⁶² and imidazole derivatives.¹⁸⁴ The influence of the organic modifying agents on the chiral separation was theoretically examined in the study.¹⁸⁵ In some cases, the addition of this agent impairs the chiral separation because the binding constants and the difference between the effective mobilities of enantiomers decrease when the optimum CD concentration is attained. Examples are separations of clenbuterol,¹⁸⁶ denopamine and trimetoprim,¹⁸⁷ deprenyl,¹⁸⁸ dioxypromethazine,¹⁸⁹ verapamil and

propafenone,¹⁹⁰ dansyl derivatives of phenylalanine, leucine and propranolol with the use of β -CD and in the presence of additives of alcohols containing from one to six carbon atoms in SE.¹⁹¹

3. Methods for optimisation of separation using cyclodextrins

The use of a large number of commercially available cyclodextrins in CE makes it difficult to formulate general rules for choosing conditions of enantiomer separation. The present knowledge of the processes of enantiomer separation does not allow one to choose *a priori* the best chiral selector for a particular racemate. The charged resolving agent migration (CHARM) model proposed by Williams and Vigh¹⁹² can be used for a rational choice of conditions for separation. This model enables one to estimate rapidly the ability of various charged cyclodextrins to perform chiral separation of any racemate.

Successful enantiomer separation depends on many parameters. Instrumental factors (separation potential, temperature) are rather well and predictably controlled in most modern instruments. The selectivity of separation in CE is determined by the ratio between the effective mobilities of the compounds separated and can be optimised based on the dependence of the effective mobility on the composition of the supporting electrolyte. However, the effect is predictable only for some of the compositional variables of SE (pH, the concentration and charge of the chiral selector used, the effective charge of the enantiomer, the rate of EOF). Such factors as the structure of a chiral selector and the addition of organic or inorganic modifying agents can cause essential but unpredictable changes. The CHARM model is based on the consideration of equilibria between protonation and complex formation of enantiomers with a charged chiral selector (the assumed enantiomer:selector ratio is 1:1) and the influence of these equilibria on the effective charges of enantiomers, their effective mobilities and selectivity of separation. Analytical expressions for calculations of the above-mentioned parameters of compounds of differing nature (non-electrolytes, strong and weak electrolytes) were reported in the study.¹⁹² It was demonstrated that the calculated values depend on the ionic mobilities of enantiomers involved in a complex and the free protonated and non-protonated forms of enantiomers, the protonation constants, the formation constants of enantiomer-selector complexes for protonated and non-protonated forms, pH and the concentration of the selector in SE. The theoretical resolution can be calculated if the binding constants, ionic charges and ion mobilities of different forms of enantiomers are known.

The CHARM model helps one in making a rational choice of the composition of the supporting electrolyte. For selectors which are strong multicharged electrolytes, the separation of neutral and charged analytes is independent of pH in the absence of EOF. For weak electrolytes, R_s is high at low pH for separation of weak acids in a non-dissociated form and for separation of weak bases as ions. At high pH, R_s is high for separation of weak acids as ions and for separation of weak bases in a non-dissociated form. Consequently, in the absence of EOF (*i.e.*, in a capillary with a neutral coating), it is necessary to perform only two series of measurements to find the best conditions for separation: at low pH of the supporting electrolyte (for example, at pH 2.2) and at high pH (for example, pH 9.5). At each pH, the type and concentration of CD are varied to find the maximum R_s . If the optimum chiral selector is known, the rate of EOF can be varied by changing the properties of capillary walls (anionic or cationic coating, uncoated walls) to improve the peak resolution, accelerate separation or change the enantiomer migration order. Finally, to carry out or improve separation, one can try to use organic modifying agents, surfactants or systems consisting of two chiral selectors. However, this does not necessarily improve the results.

Electromigration dispersion caused by the difference in mobilities of the ions of the sample and buffer often leads to broadening of the peaks (frontal peaks or peaks with 'tails'). This phenom-

enon can be reduced by increasing the ionic strength of SE or with the use of a buffer whose conductivity is equal to that of the band of the sample.

4. Micellar electrokinetic chromatography

Micellar electrokinetic chromatography (MEKC) allows one to separate uncharged components of a sample due to the difference in the probability of their presence in an aqueous mobile and pseudostationary phases. Sodium dodecylsulfate (SDS) is the surfactant most generally used in capillary electrophoresis for separation of enantiomers in the presence of cyclodextrins (CD-MEKC method). Micelles of SDS bear a negative charge and, consequently, possess electrophoretic mobility toward the anode. A scheme of electrophoretic separation of uncharged compounds by CD-MEKC with the use of SDS is shown in Fig. 6; the electroosmotic flow is directed toward the cathode. If the contribution of electrophoretic mobility of micelles is smaller than the contribution of electroosmotic mobility, micelles move toward the cathode, *i.e.*, the detector. Uncharged enantiomers form inclusion complexes with CD in an aqueous phase or are included into micelles and move at the rate of the latter. The separation of neutral enantiomers is based on the difference in their distribution between a CD-containing buffer solution and the interior of micelles. Since molecules of a sample interact with a pseudostationary phase, the metrological characteristics of CD-MEKC correspond to the characteristics of chromatography. It should be emphasised that MEKC on CD allows one to separate both uncharged and charged enantiomers if they are included into micelles.

Figure 6. Scheme of electrophoretic separation of an uncharged compound by CD-MEKC;³⁹ u_e is the rate of electrophoretic migration, N is an enantiomer.

In the first study devoted to separation of enantiomers by CD-MEKC,¹⁹³ the influence of the nature of a chiral selector on the chiral separation of thiopental, pentobarbital, phenobarbital and barbital was examined using α -, β -, γ -, DM- β - and TM- β -CD in a buffer containing 50 mM SDS and 4 M urea (pH 9.0) as examples. γ -Cyclodextrin containing a cavity with the largest diameter proved to be the most efficient chiral agent. The addition of other chiral compounds together with CD (for example, with D-camphor-10-sulfonate) improved the chiral separation of the compounds under study.

The MEKC method was employed in chiral separations of various compounds: amino acid derivatives,^{194–197} aromatase and barbiturate inhibitors,¹⁶⁵ β -blockers,¹⁹⁸ triazole derivatives,^{199,200} dihydropyridine derivatives,²⁰¹ cicletanine,²⁰² mephénytoin, phenýtoin and their 4-hydroxy derivatives,²⁰³ peptide derivatives,^{204,205} pesticides,²⁰⁶ *etc.* In CD-MEKC, bile acids belonging to chiral surfactants and their salts are also used for separating enantiomers of dansyl amino acids,^{207–209} baclofen and its analogues, mephénytoin and fenoldopam and their derivatives,²⁰⁷ amino acid derivatives, such as *N*-substituted 1-cyano-benzo[*f*]isoindoles (CBI amino acids),²⁰⁸ OPA amino acids,²¹⁰

phenylethylamines (diclofenac, ephedrine, methamphetamine, β -blockers)²¹¹ and binaphthyl derivatives.²¹² Mixed micellar mixtures of SDDS and taurodeoxycholic acid with β -CD are used to separate CBI-selenomethionine and selenoethionine enantiomers.²¹³ Enantiomers of dansyl amino acids were separated²¹⁴ with the use of an achiral polymeric surfactant (sodium salt of butyl acrylate–butyl methacrylate–methacrylic acid copolymer) in combination with β -CD; the peak resolution obtained in the cited study was better than that attained with the use of the β -CD–SDDS system.

5. Non-aqueous chiral capillary electrophoresis

The review³¹ surveyed data on enantiomer separations by non-aqueous CE. The effects of the concentration and the nature of the chiral selector used, apparent pH, the ionic strength, temperature and the nature of organic solvents on the mobility of enantiomers, selectivity and efficiency of enantiomer separation were discussed.

One of the most important advantages of non-aqueous CE is that it enables one to study compounds insoluble or poorly soluble in water. Solubility of cyclodextrins in many solvents is much higher than that in water. For example, the solubility of β -CD in *N*-methylformamide is higher than 700 mmol litre⁻¹, whereas its solubility in water is 18 mmol litre⁻¹.²¹⁵ Therefore, the chiral separation can be improved at higher cyclodextrin concentrations in organic media.^{215–223} The chiral separation of basic tricyclic drugs was investigated²¹⁶ with the use of β -CD, M- β -CD, HP- β -CD and γ -CD in formamide, *N*-methylformamide and *N,N*-dimethylformamide. In this case, the character of interactions between enantiomers and the chiral selector changes. It is assumed that hydrophobic interactions between enantiomers and the chiral selector are virtually absent and the formation of inclusion complexes proceeds to a very low extent. Apparently, the planes of the compounds separated lie on the cyclodextrin ‘cone’, and the compounds interact with the hydroxy groups of CD. This assumption is consistent with the binding constants of trimipramine, mianserin and thioridazine, which decrease from $\sim 10^4$ in water to $\sim 10^{-2}$ in *N,N*-dimethylformamide. The formation of inclusion complexes proceeds more readily in a polar solvent, for example, in formamide, than in less polar *N*-methylformamide because the difference in polarity of the solvent and the CD cavity is larger in the former case. The best results of chiral separations of tricyclic compounds were obtained with the use of β -CD and its derivatives, but not with γ -CD, although the diameter of the cavity in the latter is larger and is closer to the size of the molecules separated.

The drawback of the above-mentioned solvents is their intense absorption at 214 nm and at lower field. Ultraviolet-transparent supporting electrolytes can be prepared from methanol or mixtures based on this solvent. Enantiomers of 40 basic compounds in the H₃PO₄–NaOH–CH₃OH supporting electrolyte were separated with the use of heptakis(2,3-dimethyl-6-sulfo)- β -CD.²²⁴ The dependences of the effective mobilities, selectivity coefficients and peak resolution on the concentration of a chiral selector were studied in the range of 0–40 mmol litre⁻¹ and it was found that these dependences obey the theoretical predictions of the CHARM model with the use of a charged chiral selector.¹⁹²

6. Electrochromatography

Capillary electrochromatography (CEC) is a modern method which combines the advantages of HPLC and CE. Chiral CEC employs the principles of molecular recognition of enantiomers by a chiral stationary phase (CSP) and the electric field as the driving force for the transfer of enantiomers. The main advantage of CEC over HPLC is a higher column performance, which is a result of a planar plug-like profile of the mobile phase flow.

The main principles of chiral CEC were discussed in the review.²²⁵ The transfer of enantiomers through a capillary column occurs primarily due to EOF caused by the electric double layer in the vicinity of the charged surface of a stationary phase. The linear

rate of osmotic flow u_{eo} is proportional to the ζ potential, which characterises the electric double layer and depends also on the properties of a mobile phase (dielectric permeability ϵ , viscosity η , ionic strength) and the electric field strength E . In addition to the transfer caused by EOF, charged compounds have inherent electrophoretic migration in a direction determined by the ion charge. The linear migration rate of compounds can be increased by applying pressure to a column. The apparent linear migration rate of a compound u_{app} is the sum of the linear rate of EOF u_{eo} , the rate of electrophoretic migration u_{ep} and an increase in the rate due to the applied pressure u_{press} :

$$u_{app} = u_{eo} + u_{ep} + u_{press} \quad (3)$$

The chiral separation is always based on enantioselective molecular interactions between the compound and CSP or pseudo-SP (chiral additives), whereas the electrophoretic migration makes a contribution only to the total transfer of compounds, because enantiomers possess identical electrophoretic mobilities. The elution time t_e depends on the column length L , the chromatographic retention factor k and the linear migration rate of the compound u_{app} .²²⁶

$$t_e = \frac{L(1+k)}{u_{app}} \quad (4)$$

Two varying approaches are used for the direct separation of enantiomers in CEC: a chiral selector can be added to a mobile phase or immobilised on a solid support or a capillary wall (CSP).

Commercial reversed-phase achiral columns are generally used for the enantiomer separation in the presence of chiral additives in a mobile phase. In this version of CEC, the mechanism of separation is rather complex because it includes electrophoretic (for charged enantiomers) and chromatographic components. The enantioselectivity of separation is achieved due to the difference in the formation constants of enantiomer–chiral selector complexes, the difference in effective mobilities of the free enantiomer and the enantiomer involved in a complex and separation of diastereomeric complexes on SP.²²⁶ If EOF and electrophoretic migration of charged compounds occur in different directions, the elution order of enantiomers can be reversed by changing the mobile phase (this effect is well known in CE).¹¹⁷ It should be noted that α -, β -, γ -CD and their derivatives are most commonly used as additives to a mobile phase. Chlorthalidone enantiomers were separated on a column packed with octadecyl silica gel (ODS) (3 μ m) with HP- β -CD as a chiral selector.²²⁷ Enantiomers of phenylephrine and synephrine were separated on a silica gel column using HP- β -CD as a chiral selector.²²⁸ In the study,²²⁶ salsolinol enantiomers were separated by CEC on a column based on ODS in the presence of β -CD as a chiral additive and sodium heptanesulfonate as an achiral ion-pair reagent. The mechanism of separation in CEC in the presence of an additive of a chiral selector in MP was discussed in detail, and a theoretical model of enantioselectivity in such systems applicable to both neutral and charged compounds was proposed. Capillary electrochromatography with the use of a chiral selector in a mobile phase has no advantages over enantioselective CE.

A chiral stationary phase holds the most promise for separating enantiomers by CEC. There are three different approaches to CSP-based capillary columns.²²⁹

1. Open tubular columns, whose walls are chemically or physically modified with a chiral selector. Tubular columns with an inner diameter of ~ 50 μ m, which is optimum simultaneously for high column performance and UV detection (standard detection in most apparatus for CE) are required for enantiomer separation. The electroosmotic flow is created by residual silanol groups on a silica gel surface (for neutral chiral selectors). The only drawback of this approach is a small surface area accessible for the modification with a chiral selector. As a consequence, columns can be easily overloaded, which is manifested in peak

asymmetry and deterioration of the efficiency. The efficiency of separation is influenced by the thickness of the SP layer. Larger theoretical plate (t.p.) numbers are obtained on thinner films.

Enantiomer separation on an open tubular column using a 0.2- μm thick film of polydimethylsiloxane with permethylated β -CD (16%) (Chirasil-Dex) covalently grafted through the octamethylene spacer was first carried out for 1-phenylethanol and other compounds.²³⁰ In another study,²³¹ a capillary modified with permethylated γ -CD (Chirasil- γ -Dex) was used for the chiral separation of ibuprofen, flurbiprofen, cicloprofen and 1-phenylethanol. The effects of the pH of the buffer, the applied stress and the thickness of the SP layer were studied. An increase in the film thickness from 0.2 to 0.4 and 0.8 μm led to a substantial loss of efficiency: from 30 500 (300 000 t.p. m^{-1}) to 24 000 and 9500 t.p. per column, the selectivity of separation remaining virtually unchanged (1.17, 1.19 and 1.12, respectively). Enantiomer separations with the use of Chirasil-Dex films in open tubular columns were discussed in the review.²³²

2. Packed columns with CSP using standard chromatographic supports (silica gel or polymers) chemically modified with a chiral selector. For such chiral stationary phases, quartz capillaries with an inner diameter of 75 or 100 μm are used. Columns of this type are analogous to standard chromatographic columns but allow one to obtain a larger theoretical plate number. For CSP, smaller particles and/or longer columns can be used, because there are no such strong limitations on the pressure in CEC compared to HPLC. It should be noted that external pressure applied to a capillary can decrease the time of analysis but simultaneously leads to distortion of the planar profile of the flow typical of electromigration systems to give a parabolic profile of the flow resulting in a decrease in the column performance. As mentioned above, enantiomer separation can be performed using normal-phase, reversed-phase and 'polar organic' modes of HPLC. The latter two modes are predominantly used for CEC; the conditions of separations by HPLC can often be directly extended to CEC without loss of enantioselectivity. The mechanism of separation of enantiomers by CEC is identical to that by HPLC and was discussed above. The strength of interactions between an enantiomer and a chiral selector can be controlled by varying the composition of a mobile phase. This is more difficult to perform in CEC than in HPLC, because control over the retention and/or selectivity of separation in CEC always influences the rate of EOF and, in the case of charged compounds, the electrophoretic migration. In most cases, mobile phases include acetonitrile-based mixtures, which produce large EOF, and buffers with a low ionic strength. Acetonitrile as an organic modifying agent is best suited to attain a high rate of EOF and is, generally, preferred over methanol. A high rate and stability of EOF are important conditions in CEC. The ζ potential of the operating conditions as well as the rate and direction of electroosmotic flow are determined by the properties of mobile and chiral stationary phases. The choice of the corresponding support for the preparation of CSP is of more importance in CEC than in HPLC. Silica gels can differ substantially in the number of silanol groups resulting in differences in the rate of EOF for CSP prepared based on these silica gels. Examples of the use of this type of column are given below. Enantiomers of benzoin, hexobarbital, dansyl and 3,5-DNP amino acids were separated on capillary columns packed with CSP containing β -CD (5 μm , Cyclobond I).²³³ The use of a solution of triethylammonium acetate instead of a phosphate buffer led to the reversal of EOF and improved the separation of acidic compounds. This reversal of EOF observed for mobile phases containing small amounts of methanol (no more than 15%) cannot be attributed to adsorption of the triethylammonium ions on the SP surface and the formation of a dynamic anion exchanger. Chlorthalidone and mianserin enantiomers on CSP based on HP- β -CD (5- μm commercial column Cyclobond I 2000 RSP) were separated in the study.²²⁷ In the investigation,²³⁴ CSP

based on permethylated β -CD (pore size was 300 Å, 5 μm) was used for the enantiomer separation of several barbiturates, benzoin, glutethimide, methylthiohydantoin proline and methyl mandelate (the efficiency varied from 20 000 to 40 000 t.p. m^{-1}). A comparison of the separation of mephobarbital enantiomers by micro-HPLC and CEC on this capillary column demonstrated that the use of CEC led to a threefold increase in the efficiency of separation and improved the peak resolution from 2.08 to 3.39 without loss of enantioselectivity. Separations of enantiomers of the same compounds and esters of aryloxy-carboxylic acids performed on permethylated β -CD covalently bound through a spacer (octamethylene) to polydimethylsiloxane on silica gel (pore size was 300 Å, Chirasil-Dex) led to a further improvement of the column performance to 70 000 t.p. m^{-1} .²³⁵ The hydrophobic microenvironment and protection of polar silanol groups with a polysiloxane film improve the enantioselectivity. For example, 1-(2-naphthyl)ethanol was separated only on Chirasil-Dex rather than on covalently grafted permethylated β -CD as a chiral stationary phase.

3. Specially designed monolithic CSP prepared by *in situ* polymerisation in a capillary; such CSP have chiral selectors or chiral cavities introduced into a continuous polymeric matrix. Positively and negatively charged polyacrylamide gels (which give cathodic and anodic EOF, respectively) physically or chemically modified with β -cyclodextrin were prepared in capillaries, which already contained methacrylate groups.^{236–238} The advantage of these monolithic CSP is that there is no need to introduce an organic modifying agent, which can decrease enantioselectivity, into a mobile phase with the aim of performing enantiomer separation. Separations of terbutaline, propranolol and benzoin enantiomers were carried out using negatively charged gel.^{236, 237} Dansyl amino acids and some other acidic compounds were separated on positively charged polyacrylamide gel with covalently grafted allylcarbamoyle- β -CD.²³⁸ The column performance was as high as 150 000 t.p. m^{-1} .

7. Practical application of enantiomer separation

Data on enantiomer separations by CE with the use of cyclodextrins as chiral selectors were generalised in the reviews.^{29, 39, 239–244} Examples of chiral separations carried out in 2000–2002 (which were grouped according to the type of CD) are given in Table 5.

In spite of abundant data on the application of cyclodextrins in chiral separations by CE, studies devoted to quantification of enantiomers in real samples are few in number. Enantiomers in real samples are quantified in pharmaceuticals, medicine, biology and investigations of environmental objects. It should be emphasised that when performing stereoselective analyses of drugs, it is necessary to quantify an undesirable enantiomer at a concentration lower than 1%. The precise determination of the enantiomer ratio of 99.9:0.1 is often a more complicated problem than the 'simple' separation of racemates. Examples of quantification of enantiomers in real samples were given in the reviews.^{29, 39} The results obtained in 2000–2002 are presented in Table 6.

The principles and most important aspects of chiral analysis of pharmaceuticals were discussed and the data on quantification of enantiomers of drugs and their metabolites in biological liquids were surveyed in the reviews.^{245, 246} These reviews also gave examples of the practical application of the determination of enantiomers for an explanation of the possible mechanisms of pharmacokinetics and stereoselectivity of drug metabolism.

The review²⁴⁷ was devoted to chiral separations of amino acids and peptides. A large number of examples which illustrate the state-of-the-art separation of enantiomers and diastereoisomers of amino acids and peptides were offered. Ways of improving the selectivity and methods for optimisation of the parameters of chiral separation using the mathematical design of experiments were discussed.

Table 5. Examples of enantioselective separations by CE using various types of cyclodextrins.

Compound	CD	Supporting electrolyte, method of detection ^a	Ref.
Aromatic derivatives of aminophosphorous and aminohypophosphorous acids	α -CD	100 mM phosphate buffer, pH 7.5, and 40 mM CS ^b	248
5,11-Dihydro-11-[2-[2-[(<i>N,N</i> -dipropylaminomethyl)-piperidin-1-yl]ethylamino]carbonyl]-6 <i>H</i> -pyrido[2,3- <i>b</i>][1,4]benzodiazepin-6-one	sulfo- α -CD	25 mM triethylammonium phosphate, pH 2.5 and 5% CS	249
Lobeline, benzhexol	β -CD	50 mM Tris – phosphoric acid, pH 2.5 and 14% of a mixture: β -CD, P ₂ O ₅ , L-glutamic acid	250
Brompheniramine	β -CD	100 mM phosphoric acid – triethanolamine, pH 3.0 and 18 mg ml ⁻¹ CS	251
OPA amino acids	β -CD	40 mM borate buffer, pH 9.0, 60 mM sodium taurocholate, 15% propan-2-ol and 30 mM β -CD	210
Promethazine	β -CD	30 mM Na ₂ HPO ₄ , 15 mM citric acid, pH 2.5 and 1 mM CS; amperometric detection	252
Ibuprofen	β -CD	200 mM MES, ^c pH 4.4, 0.3% hydroxyethylcellulose and 15 mM CS	253
Thioureas (products of the reaction of fluorescein-5-isothiocyanate with amino acids)	β -CD	80 mM borate buffer, pH 9.3, 30 mM sodium taurocholate and 20 mM β -CD; FD ^d	254
Dextromoramide	HP- β -CD	100 mM phosphoric acid – triethanolamine, pH 3.0 and 15 mM CS	255
2-(4,5-Dihydro-1 <i>H</i> -imidazol-2-yl)-5-fluoro-2-methoxybenzo[1,4]dioxane	HP- β -CD	50 mM ammonium formate, pH 4 and 10 mM CS; CE-MS ^e	256
Cizolirtine and its dehydration products	HP- β -CD	50 mM borate buffer, pH 9.2, 150 mM SDDS, 5% n-butanol and 60 mM CS	257
3,4-Methylenedioxyamphetamine and two of its metabolites	HP- β -CD	50 mM phosphoric acid, pH 2.5 and 50 mM CS	258
Bis(phenethyl)amines, their cyclic analogues	HDAS- β -CD	50, 100 mM phosphate buffer, pH 3.0, 6.0, 7.5 and 0.5–9 mM CS	259
Synthetic analogue of wasp poison	HDM- β -CD ^f	50 mM 6-aminocaproic acid, pH 4.0 and 30 mM CS	260
1-(1-Naphthyl)ethylamine, 1-aminoindan, 1,2,3,4-tetrahydro-1-naphthylamine	HDM- β -CD ^f	200 mM Tris – 300 mM borate buffer, pH 7.0, 10 mM 18-crown-6 and 10 mM CS	261
Mianserin, cyclopentolate, fluoxetine, nisoxetine, verapamil, aminoglutethimide, dimethindene, doxapram, hydroxyzine, meclozine, ketoprofen	HDMC- β -CD ^g	50 mM phosphate buffer, pH 7.0 and 18–72 mM CS	262
[5-(4-Hydroxybutyl)-5'-methyl-2,2'-bipyridyl]-bis(2,2'-bipyridyl)Ru(II) bis(hexafluoroantimonate)	CM- β -CD	40 mM borate buffer, pH 9.5 and 7.5 mg ml ⁻¹ CS	263
4-(3-Isobutylamino-2-hydroxypropoxy)-3-alkoxymethylacetophenone derivatives	CM- β -CD	80 mM Tris-acetate buffer, pH 4.7 and 10 mM CS	264
Chlorpheniramine, methadone	CM- β -CD	100 mM phosphoric acid – triethanolamine, pH 4.0; 3.5 and 5 mM CS	265
Adrenaline, noradrenaline (1), ephedrine, pseudoephedrine (2)	CM- β -CD	(1) 20 mM phosphate buffer, pH 2.5, 12 mM 18-crown-6 and 5.2 mg ml ⁻¹ CS; (2) 100 mM NaOH, pH 12.9 and 16; 3.9 mg ml ⁻¹ CS; amperometric detection	266
Selenomethionine, selenocysteine, selenoethionine	sulfo- β -CD	35 mM citrate buffer, pH 7 and 1% CS	267
Fungicides	sulfo- β -CD	phosphate buffer, pH 3.0 or phosphate buffer, 2 M urea, pH 3.0 and 2% CS	268
Ormeloxifene and its derivatives	sulfo- β -CD	10 mM NaH ₂ PO ₄ , pH 3.0 and 2% CS	269
Spiro(2 <i>H</i> -benzofuro[2,3- <i>a</i>]quinolizine-2,4'-(1' <i>H</i>)-pyrimidine)-2'-(3' <i>H</i>)-one derivative, <i>cis</i> -aminoindanol	sulfo- β -CD	25 mM Na ₃ PO ₄ , pH 2.5 and 1.5% CS, PVA-coated capillary; 25 mM Na ₃ PO ₄ , pH 6.5 and 0.3% CS	270
Clenbuterol, salbutamol, tulobuterol	sulfo- β -CD	50 mM phosphate buffer, pH 2.24 and 25% CS	271
Nicardipine	sulfo- β -CD	20 mM triethanolammonium phosphate, pH 3 and 5% CS	272

Table 5 (continued).

Compound	CD	Supporting electrolyte, method of detection ^a	Ref.
Voriconazole	SBE- β -CD	50 mM NaH ₂ PO ₄ , pH 7.0 and 1 mM CS	273
Flobufen	HTM- β -CD	87.5 mM acetate buffer, pH 5.5, 10% methanol and 30 mM CS	274
Dimethindene	HTM- β -CD	100 mM phosphoric acid – triethanolamine, pH = 3.0 and 150 mg ml ⁻¹ CS	275
Naproxen	HTM- β -CD	25 mM H ₃ PO ₄ – 25 mM CH ₃ COOH – 25 mM H ₃ BO ₃ – NaOH, pH 5.0 and 3 mM CS, polyacrylamide-coated capillary	276
Propranolol, mexiletine, lobeline, propafenone, isoprenaline, bupivacaine, verapamil, ketamine	MPC- β -CD ^h	40 mM borate buffer, pH 9.18 and 2.5 mM CS	190
Methyl 4-(3,4-difluorophenyl)-6-methoxymethyl-2-oxo-1,2,3,4-tetrahydropyrimidine-5-carboxylate, hydrolysis products	QA- β -CD ⁱ	25 mM Tris-acetate buffer, pH 8.3 and 2.5% CS	277
2-(2,4-Dichlorophenoxy)-, 2-(4-chloro-2-methylphenoxy)propionic acids	EC- β -CD ^j	45 mM NaH ₂ PO ₄ , pH 5 and 12 mM CS	278
Di- and tripeptides	β -CD, PM- β -CD, HDM- β -CD, HTM- β -CD, HP- β -CD	50 mM phosphate buffer, pH 2.5 – 3.5 and 20 mg ml ⁻¹ CS	118
3-(3,4-Dihydroxyphenyl)alanine, 3-(3,4-dihydroxyphenyl)-2-hydrazino-2-methylpropionic acid	HDAS- β -CD, CM- β -CD	20 mM phosphate buffer, pH 2.5 and 20 mM CS	279
1,3,4-Thio-, 1,3,4-selenodiazine derivatives	HE- β -CD, HP- β -CD, M- β -CD	25 mM CH ₃ COONH ₄ – 1 M CH ₃ COOH or 25 mM citric acid – 12 mM Tris in methanol, formamide or a formamide : acetonitrile mixture (1 : 2) and 200 mM CS	280
Alkyl esters of amino acids, BOC and Z amino acids	HP- β -CD, CM- β -CD, SBE- β -CD	100 mM phosphoric acid – triethanolamine, pH 2.5; 4.0; 5.5; 0% – 30% methanol and 5 – 30 mM CS	281
Propranolol, hydrobenzoin, atenolol, nefopam, chlorcyclizine, 1,1'-binaphthyl-2,2'-diyl phosphate, trimipramine, primaxin, canadine, piperoxan	sulfo- β -CD, phosphated β -CD	50 mM phosphate buffer, pH 5.0 and 2% CS	282
Synthetic arginine-containing peptide and its derivatives	SBE- β -CD + β -CD	50 mM citrate buffer, pH 2.5 and 20 mM CS ₁ + 5 mM CS ₂ , PVA-coated capillary	283
Sertraline	sulfo- β -CD + HP- β -CD	20 mM borate buffer, pH 9.0, 50 mM sodium cholate, 15 mM CS ₁ + 5 mM CS ₂	284
Fenoprofen, flurbiprofen, ibuprofen, ketoprofen	sulfo- β -CD + HTM- β -CD	100 mM phosphoric acid – triethanolamine, pH 2.5 and 2 – 3 mM CS ₁ + 10 – 20 mM CS ₂	285
Aminogluthethimide	α -CD + HDM- β -CD; α -CD + HTM- β -CD	100 mM phosphate buffer, pH 2.5 and 10% – 95% CS ₁ + 90% – 5% CS ₂ , total concentration of CD was 15 mM	286
DNP derivatives of aspartic acid, alanine, glutamine, homoserine, proline, norvaline and glutamic acid	copolymer of allylamine and '2-hydroxy-3-methacryloyl- β -CD'	50 mM acetate buffer, pH 4.0 and 4 – 20 mM CS	287
2-Phenoxy-, 2-(4-chlorophenoxy)-, 2-(3-chlorophenoxy)propionic acids	trehalose cysteine-HSD ^k	22 mM Na ₃ PO ₄ , pH 6.0 and 2.5 mM CS	288
	trehalose cysteine-HSD, trehalose ammonium-HSD, trehalose β -alanine-amide-HSD	22 mM phosphate buffer, pH 6.0 and 1.50 – 5.00 mM CS; 22 mM borate buffer, pH 9.5 and 5.00 mM CS	289
Reaction product of homocysteine with 4-aminosulfonyl-7-fluoro-2,1,3-benzoxadiazole	γ -CD	50 mM Na ₃ PO ₄ , pH 2.25 and 50 mM CS	290
1-Methyl-3-phenylpropylamine, 1,2,3,4-tetrahydro-1-naphthylamine	γ -CD	50 mM phosphate buffer, pH 2.0, 10 mM 18-crown-6 and 40 mM CS	291

Table 5 (continued).

Compound	CD	Supporting electrolyte, method of detection ^a	Ref.
Thioureas (reaction products of isothiocyanates with amino acids)	γ -CD	100 mM borate buffer, pH 9.4, 30 mM SDDS and 10 mM CS; FD	292
1-Aminoindan, β -blockers, bupivacaine, bupropion, chlophedianol, 4-chloroamphetamine, chlorpheniramine, epinephrine, isoproterenol, ketamine, metaproterenol, methoxyphenamine, 1-(1-naphthyl)ethylamine, oxyphenyclimine, phenylpropanolamine, piperoxan, propafenone, terbutaline, tetrahydropapaveroline, tetrahydrozoline, tolperisone, trihexyphenidyl	ODAS- γ -CD ¹	25 mM H ₃ PO ₄ , 12.5 mM NaOH, CH ₃ OH and 2.5–30 mM CS	293
Alkyl aryl phosphates	ODAS- γ -CD ¹	25 mM MES, 12.5 mM NaOH, 0%–10% methanol and 5–20 mM CS	294
Uniconazole, diniconazole	CM- γ -CD	50 mM phosphate buffer, pH 6.5 and 5 mM CS	295
Ephedrine and amphetamine derivatised by 4-fluoro-7-nitrobenzofurazan	sulfo- γ -CD	50 mM phosphate buffer, pH 7.35, 1.5 mM SDDS and 10 mM CS; FD	296
Promethazine, ethopropazine, trimeprazine, thioridazine	β -CD, HP- β -CD, γ -CD	40 mM phosphate buffer, pH 3.0 and 0.02–3.0 mM CS ₁ or 0.4–6.0 mM CS ₂ or 2.5–6.0 mM CS ₃	297
Acebutolol, bepridil, cloperastine, diperodon, disopyramide, doxylamine, homochlorcyclizine, hydroxyzine, ketamine, oxyphenonium bromide, pheniramine, propiomazine	CM- β -CD, CM- γ -CD	100 mM phosphate or borate buffer, pH 6, 7, 8 and 2.5% CS	298
Polychlorobiphenyls	CM- γ -CD, β -CD, PM- β -CD	50 mM MES, pH 6.5, 2 M urea and 20 mM CS ₁ + 10 mM CS ₂ or 20 mM CS ₁ + 20 mM CS ₃	299
26 Drugs and their synthetic intermediates	SBE- β -CD + γ -CD + HDM- β -CD	50 mM NaH ₂ PO ₄ , pH 2.5 and 5% CS ₁ + 25 mM CS ₂ + 25 mM CS ₃	300

^a The method is not given if a UV detector was used; ^b CS is a chiral selector; ^c MES is 2-morpholinoethanesulfonic acid; ^d FD is fluorescence detection; ^e MS is mass spectrometry; ^f HDM is heptakis(2,6-di-*O*-methyl); ^g HDMC is heptakis(2-*N,N*-dimethylcarbamoyl); ^h MPC is mono-3-*O*-phenylcarbamoyl; ⁱ QA is quaternary ammonium salt; ^j EC is ethyl carbonate; ^k HSD is hemispherodextrin; ^l ODAS is octakis(2,3-diacetyl-6-sulfo).

Table 6. Enantioselective separations using cyclodextrins in analysis of real samples by CE.

Compound	Sample	CD	Supporting electrolyte, method of detection ^a	Ref.
Epimers of amygdalin	Chinese herbal remedies	α -CD	20 mM Tris–HCl, pH 9.0, 80 mM sodium deoxycholate and 25 mM α -CD	301
CBI baclofen	plasma	α -CD	50 mM borate buffer, pH 9.5 and 7 mM CS; FD	302
Rogletimide	serum	α -CD	10 mM NaH ₂ PO ₄ –5 mM Na ₂ B ₄ O ₇ , pH 2.5, 0.03 mM HTAB ^b and 60 mM CS	303
CBI aspartic acid	rat brain	β -CD	50 mM borate buffer, pH 9.0, 50 mM SDDS, 15% methanol and 20 mM CS; FD	304
CBI derivatives of seleno-methionine and selenoethionine	commercial L-SeMet	β -CD	30 mM NaH ₂ PO ₄ –10 mM H ₃ BO ₃ , pH 7, 50 mM SDDS, 50 mM taurodeoxycholic acid and 20 mM β -CD	213
Methadone, cocaine, amphetamine and its 3,4-methylene-dioxy derivatives	heroin	β -CD	100 mM K ₃ PO ₄ , pH 3.23 and 20 mM CS	305
Lactic acid	food products	HP- β -CD	90 mM phosphate buffer, pH 6.0 and 240 mM CS	306
	biological liquids	HP- β -CD	200 mM phosphate buffer, pH 6.0 and 413 mM CS, polyacrylamide-coated capillary	307
Terbutaline	the same	HP- β -CD	50 mM phosphate buffer, pH 2.5 and 10 mM CS	308
Methylphenidate	commercial samples	HDM- β -CD	100 mM H ₃ PO ₄ –triethanolamine, pH 3.0 and 15 mM CS	255

Table 6 (continued).

Compound	Sample	CD	Supporting electrolyte, method of detection ^a	Ref.
Ephedrine, propranolol, adrenaline, phenylalanine	spinal puncture, pharmaceuticals Gripex and Nurofen	CM- β -CD	20 mM Na ₂ B ₄ O ₇ , pH 7.5 and 20 mM CS	309
Amphetamine, methamphetamine	biological liquids	CM- β -CD	100 mM phosphate buffer, pH 2.5 and 10 mM CS	310
Metoprolol, its metabolite, <i>O</i> -desmethyl metoprolol	the same	CM- β -CD	100 mM acetate buffer, pH 4.0, 5% propan-2-ol and 10 mM CS	311
Albendazole sulfoxide	spinal puncture	sulfo- β -CD	20 mM Tris, pH 7.0 and 3% CS	312
Atropine	ophthalmological solution	sulfo- β -CD	55 mM phosphate buffer, pH 7 and 2.9 mM CS	313
Ofloxacin	biological liquids	sulfo- β -CD	50 mM phosphate buffer, pH 2.5 and 0.35 mM CS	314
Praziquantel, <i>trans</i> -4-hydroxy-praziquantel	plasma	sulfo- β -CD	20 mM borate buffer, pH 10, 20 mM sodium deoxycholate and 2% CS	315
Disopyramide, mono- <i>N</i> -des-alkyl disopyramide	"	sulfo- β -CD	20 mM acetate buffer, pH 5.0 and 0.2% CS	316
Eticlopride, sulpiride	serum	sulfo- β -CD	20 mM citrate buffer, pH 2.90 and 2% CS	317
Ofloxacin, desmethyl ofloxacin, ofloxacin <i>N</i> -oxide	biological liquids	SBE- β -CD	100 mM phosphate buffer – triethylamine, pH 2.0 and 0.65 mg ml ⁻¹ CS; FD	318
Tramadol, its metabolites	plasma	SBE- β -CD	40 mM ammonium acetate, pH 4.0 and 2.5 mg ml ⁻¹ CS; PVA-coated capillary; CE-MS	319
Venlafaxine, its metabolite	clinical samples	phosphated γ -CD	50 mM phosphate buffer, pH 2.5 and 20 mg ml ⁻¹ CS	320
Tramadol	biological liquids	CM- β -CD + M- β -CD	50 mM borate buffer, pH 10.0 and 40 mg ml ⁻¹ CS ₁ + 22.5 mg ml ⁻¹ CS ₂ ; FD	321
Carvedilol	plasma	succinyl- β -CD + M- α -CD	150 mM phosphate buffer, pH 3.0 and 7.5 mg ml ⁻¹ CS ₁ + 15 mg ml ⁻¹ CS ₂ ; FD	322
Amphetamine, methamphetamine, ephedrine, nor-ephedrine, their derivatives (simultaneous detection)	biological liquids	β -CD + HDM- β -CD	75 mM Tris – H ₃ PO ₄ , pH 2.5 and 3 mM CS ₁ + 10 mM CS ₂	323
Diastereomers of flavanone-7- <i>O</i> -glucosides	citron juice	γ -CD	200 mM borate buffer, pH 10.0 and 5 mM CS	324
Vestitone, medicarpin (simultaneous detection)	extracts from transgenic plants	HP- β -CD + HP- γ -CD	25 mM borate buffer, pH 10.0, 10% methanol and 2 mM CS ₁ + 20 mM CS ₂	325

^a The method is not given if a UV detector was used; ^b HTAB is hexadecyltrimethylammonium bromide.

V. Conclusion

A huge amount of the published data on the application of cyclodextrins in enantiomer separations demonstrates the important role of these chiral selectors in various methods of chromatography and capillary electrophoresis. Each method has advantages and limitations. Hence, it is useful to compare the possibilities of chiral separations by capillary gas chromatography, high-performance liquid chromatography, capillary electrochromatography and capillary electrophoresis and to discuss the prospects of the use of CD-based chiral phases.

High-performance liquid chromatography finds the most extensive application. Enantiomers are separated with the use of various CD and their derivatives (both polar and hydrophobic). The advantages of HPLC are associated with the availability of commercial columns, their high selectivity and rather high performance, diversity and high sensitivity of detectors, good reproducibility of the results and a large amount of published data on separations of enantiomers of differing nature.

Capillary gas chromatography with cyclodextrin phases is employed more rarely because of technological difficulties in the column manufacture. However, the number of CD used in capillary gas chromatography is rather large (like in liquid chromatography). This method enables one to separate enantiomers with a boiling point of no higher than 260 °C. Unlike HPLC, gas chromatography allows one to separate compounds devoid of an aromatic ring. The development of capillary gas chromatography with CD phases provided a deeper insight into processes responsible for separation of optical isomers. Depending on the type of CD, either the formation of inclusion complexes (β -CD and its polar derivatives) or surface interactions, *viz.*, hydrogen bonding and π – π interactions with substituents in the ring of CD (γ -CD and hydrophobic derivatives of β -CD), can play a decisive role. A predominance of hydrogen bonding and π – π interactions with substituents in the ring of CD provides an increase in the efficiency of chiral separations, because the rates of these processes are substantially higher than the rate of formation of inclusion complexes. Such selectors make it possible

to separate enantiomers possessing similar thermodynamic characteristics.

The advantages of capillary electrophoresis are a higher efficiency of separation and the ease of variation in the nature of a selector by adding various CD to a supporting electrolyte. The choice of chiral selectors in CE is limited by their solubility in aqueous solutions serving as SE. In some cases, aqueous–organic mixtures (with acetonitrile, methanol or dimethyl sulfoxide) can be used. This is the main limitation on the application of CE to separation of optical isomers. This difficulty is partially compensated by the ease of variation in the composition of a supporting electrolyte. Thus, a selector, its concentration and the pH of an electrolyte can be varied, mixed chiral selectors can be used and specific achiral additives can be introduced.

An essential problem in capillary electrophoresis is associated with the reproducibility of the results. To solve this problem, each subsequent separation must be performed using a fresh solution of the supporting electrolyte and the capillary must be washed with this solution between separations. This leads to a high consumption of a chiral selector and an increase in the time of analysis.

Yet another problem is the detection of enantiomers. A UV detector is most commonly used. Sorbates are detected as diastereomeric complexes with a chiral selector. Due to adsorption of the selector involved in SE, the sensitivity of determination of sorbates decreases. The sensitivity can be substantially different for various enantiomers that form diastereomeric complexes with different stability.

The experimental technique used in capillary electrochromatography approaches that employed in HPLC. Therefore, the nature of a selector can be varied over a wider range, which increases the sensitivity of determination and improves the reproducibility of the results. The retention of sorbates increases substantially (the capacity of a stationary phase increases), which improves the selectivity of separation, the efficiency of separation remaining comparable with that in CE.

All the aforesaid provides evidence that CEC holds considerable promise. In the future, CEC may displace both CE and HPLC as applied to chiral separations. However, the necessary condition is the development of technology for the production of columns for CEC, an increase in the stability of their characteristics and availability of various types of commercial columns.

Abstract. The approaches to the design of artificial ion channels are systematised and the data on their structure, stability and electrical conduction are summarised. The bibliography includes 104 references.

I. Introduction

The transport of ions through phospholipid membranes is among the most important requisites of functioning of living organisms.^{1–4} The key function of the phospholipid bilayer is to create a barrier preventing the hydrophilic molecules and ions present in the aqueous phases near the cell from penetrating inside the cell. This function is performed by the hydrophobic internal layer of the phospholipid membrane. Nevertheless, some polar compounds and ions are able to penetrate the membrane at a high rate. This selective permeability of natural membranes for certain particles is needed for many biological processes to occur.

The transport of ions through a membrane can be accomplished by carrier molecules (transporters) or through transmembrane channels. In biological systems, the ion transfer (biological transport) takes place mainly through ion channels formed most often by appropriate proteins (channel proteins), which produce channel structures in phospholipid membranes; the sites of binding of the transported substances in such proteins are accessible simultaneously from both sides of the membrane. In this case, the ion transport occurs very rapidly (10^6 – 10^8 ion s^{−1} per channel protein).^{4–7}

The rate of ion transport through a membrane by carrier molecules is lower by several orders of magnitude. This difference

between the rates is due to several reasons. An important reason is the fact that channel proteins do not undergo serious conformational changes upon the transport of ions from one side of the membrane to the other, whereas carrier molecules do undergo conformational changes when they bind the ions to be transported on one side of the membrane and liberate them on the other side. In addition, the binding sites for molecules being transported in the carrier molecules are accessible only on one side of the membrane.

The carrier molecules are used more often for artificial transport of ions than transmembrane channels. This is due to the fact that artificial transmembrane channels are compounds with complex organisation. The synthesis and elucidation of the three-dimensional structure of such compounds are faced with substantial difficulties. Nevertheless, artificial transport systems are very important because study of these systems is favourable for deeper understanding of the properties of channel proteins at the molecular level and forms the basis for the development of new pharmaceuticals and drug delivery systems.^{1,8} Transmembrane channels perform the ion transport through membranes by a flow or jumping mechanism.^{1–4}

The last decade has seen intensive research into biomimetic tubular structures mimicking natural ion channels^{9–17} which can be inserted into 3–5-nm thick bilayer membranes. Depending on the type of molecule that forms the channel and general features of its structure and also on the nature and mutual arrangement of the ion binding sites, synthetic ion channels are classified into different types. Some of them are sketched in Fig. 1.

The natural channel proteins consist of two key functional units, namely, the 'gate' and the 'pore'.⁸ The 'pore' implies the way of ion penetration through the membrane, while the 'gate' means the mechanism of switching on and off the ion flow. The ions that pass through the channel are considered as an ion flux. The ion flux through the membrane depends on the difference between the electrochemical potentials on the two sides of the membrane. The conductance, *i.e.*, the reciprocal of the resistance, serves as the measure of the efficiency of the ion flux.

Let us consider three main characteristics of ion channels:^{2,8} (i) the time it takes for the channel to attain a constant conductance (*i.e.*, the time of maintenance of an invariable geometric structure of the channel, for example, the critical length and pore diameter); (ii) ion selectivity caused by the energetic and geometric complementarity of the ions and the channel pores; and

Figure 1. Types of structures of ion channels.

(iii) the type of gate mechanism (gate opening–closing) acting in the channel.

The conductance of an ion channel depends on the pore size and length and on the dielectric constant. The ion selectivity also depends on many factors such as the size of the pores, the energy of ion dehydration, the electrostatic interaction between the ions and the amino acid residues that form the pore. (The channel activity of synthetic peptides is often measured using the method of planar bilayers.⁸)

Depending on the type of gate mechanism, ion channels are classified into sensing, ligand and mechanical ones. In the sensing

(voltage-controlled or electrically excitable) channels, the channel opening is induced by an electric signal. Examples of such channels are fast Na^+ -channels² or voltage-gated K^+ -channels, which respond to the change in the potential of nerve cells (Fig. 2 *a*).⁸ In the ligand (ligand-gated or chemically excitable) channels, opening or closing of the channel is induced by the chemical changes that take place under the action of an appropriate ligand. These channels can be exemplified by nicotinic cholinergic receptor (Fig. 2 *b*). In mechanical (mechanosensitive) channels, opening of the channel is due to expansion of the cell membrane. Channels of this type participate in muscle contraction and in the control of the osmotic pressure and cell volume.

A number of approaches to the design of ion channels and ion-sensitive membrane systems distinguished by high sensitivity and selectivity have now been proposed.¹⁸ The increase in interest in detecting biologically active substances *in vitro* and *in vivo* (for example, in individual cells and in tissue sections and organs) and in the development of nano-sized drugs and ion–molecular devices is stimulating studies aimed at the design of synthetic ion channels.

II. Compounds used as models of natural channels

A lot of data on the structure and properties of channel proteins which perform biological transport has been collected.^{1–4} The amino acid sequences in many channel proteins have been decoded. However, in investigations of the structure and the mechanism of channel operation, it was necessary to resort to model systems, due to the complexity of X-ray diffraction studies of transport proteins. Considerable capabilities for this modelling are provided by the use of oligo- and polypeptides [for example, some toxins^{19,20} and polyene (nystatin, amphotericin B) and peptide (gramicidin A, alamethicin and mellitin)^{21–23} antibiotics] capable of forming channel-like associates in bilayer phospholipid membranes.

1. Nystatin and amphotericin B

The polyene antibiotics — amphotericin B,^{24–26} filipin²⁵ and nystatin²⁷ — are membrane-active antimycotic agents.

Figure 2. Schematic view of ion voltage-gated (*a*) and ligand-gated (*b*) channels.

Designations in (*b*): (1) membrane, (2) pore, (3) ligand-gated fragment; (4) ligand; (5) ions.

Apparently, the lytic activity[†] and the ability of this type of antibiotic to induce the removal of low-molecular-weight compounds from cells with low selectivity are due to the association of

[†] Lytic activity is the ability of a compound to cause rupture of the cell wall.

these agents with steroid membranes to form pores. The formation of these complexes has been detected by NMR.^{21,26}

The molecules of polyene antibiotics 8 to 10 in number form a tubular structure (pore) with the hydroxy groups directed inwards in the membrane bilayer.^{22,28} The diameter of this pore is about 8 Å and water molecules are loosely accommodated inside. For the formation of a channel in the phospholipid bilayer, two cylindrical structures arranged according to the tail-to-tail pattern are required. This channel would be nonpolar from the outside but hydrophilic from the inside and would end with polar fragments of amino sugars. The association and dissociation of the tubular ensemble of polyene molecules result in opening and closing of the channel, respectively.^{22–28}

2. Gramicidin A and alamethicin

The best known ion channel is that formed by gramicidin A,^{2,29,30} which is a hydrophobic peptide composed of alternating L- and D-amino acids³¹ (HCO–L-Val–Gly–L-Ala–D-Leu–L-Ala–D-Val–L-Val–D-Val–L-Trp–D-Leu–L-Trp–D-Leu–L-Trp–D-Leu–L-Trp–NHCH₂CH₂OH). This ion channel is formed by two gramicidin A molecules arranged in the head-to-head mode by their N-end fragments to form a β (LD)-helical configuration³² (Fig. 3 a). In this helical structure, all the side chains are located outside, while the carbonyl groups are inside the channel. The total length of the gramicidin channel is equal to ~ 30 Å; the external and internal diameters are 15 and 5 Å, respectively. Owing to the small internal diameter of the channel, the transport through the channel can be performed only by a single molecule. The gramicidin channel is cation selective,³³ although gramicidin A itself is extremely hydrophobic and contains no polar amino acid. The conductance of a single channel formed by gramicidin is rather high. When the concentration of RbCl in the solution surrounding the membrane is 100 mmol litre⁻¹, the cationic conductance of the channel (for Rb) amounts to $30 \times 10^{-12} \Omega^{-1}$ per channel,² whereas the permeability for chloride anions is zero.³⁰ This selectivity is related to the electrostatic repulsion of the anions by the carbonyl group dipoles at the gate of the channel. The permeability of the gramicidin channel for single-charged cations changes in the following sequence: Cs⁺ > Rb⁺ > K⁺ > Na⁺ > Li⁺. The selectivity exhibited by the gramicidin channel with respect to these cations is not very high: it corresponds to a fivefold change in the permeability coefficients. The gramicidin channel is opened due to association of monomers to form a dimer and closed upon dissociation of the dimer (Fig. 3 a). The lifetime of the dimer is $\sim 10^{-3}$ to 10 s, depending on the lipid composition of the membrane and other factors.^{2,29,30} It is noteworthy that the gramicidin channel is not voltage-dependent.

Alamethicin (Alm) is a peptide antibiotic consisting of 20 amino acid residues, which forms transmembrane channels with a variable number of associated subunits in artificial^{34–37} and biological³⁸ membranes. The mechanism of ion transport by alamethicin has been studied rather comprehensively. The peptide

forms α -helices in the bilayer, which are associated with each other forming a channel which consists of several interconnected α -helices^{39–43} (Fig. 3 b). The conductance of this channel, unlike that of the gramicidin channel, depends on the potential applied to the surface of the bilayer membrane. Alamethicin channels start conducting ions (Na⁺, K⁺) only at a positive transmembrane potential (> 60 mV). Thus, they represent nano-sized ionic diodes which can conduct current only in one direction, like macroscopic diodes. The voltammetric characteristics of the alamethicin channel formed in a planar bilayer on the basis of a mixed lipid (egg phosphatidylcholine–egg phosphatidic acid–cholesterol in a molar ratio of 8 : 2 : 1) are shown in Fig. 4.

Figure 4. Average macroscopic current–voltage relationships for alamethicin channel (130 pmol of alamethicin, 1 M KCl, egg phosphatidylcholine–egg phosphatidic acid–cholesterol, 10 cycles from –100 to 100 mV at 5.7 mV s⁻¹).

3. Ion channels based on modified peptides and antibiotics

Futaki *et al.*³⁴ have prepared the channel peptide Alm–LeuZ by covalent linking of a leucine-enriched oligopeptide (LeuZ) to an ionophore, namely, alamethicin (Alm). As a result of this linking, it is possible to perform the extramembrane control of the association of the channel peptides Alm–LeuZ (Fig. 5) and thus to change the channel conductance. Here Alm–LeuZ = Ac–Alm–Gly–Gly–Gly–Gly–LeuZ–CONH₂, Alm = UP.
.UAUAQUVUGLUPVUUEQF, LeuZ = RXKQLEDKVEEL.

Figure 3. Schematic view of the ion channels formed in phospholipid membranes by peptide antibiotics, gramicidin A (a) and alamethicin (b) under the action of osmotic pressure.

Figure 5. Schematic view of a single channel formed in a lipid bilayer by an association of modified alamethicin subunits Alm–LeuZ (50 nmol Alm–LeuZ) (a) and current through this single channel at 100 mV (b).³⁴ Open 1 and Open 2 are the current levels observed for two different conformations of the channel.

R = Bu^tPh₂Si (**1**), H (**2**).

.LSKNYHLENEVARLKKLVGE, where U is (*R*)-aminoisobutyric acid (Aib), X is norleucine (Nle), A is Ala, D is Asp, E is Glu, F is Phe, G is Gly, H is His, K is Lys, L is Leu, N is Asn, P is Pro, Q is Gln, R is Arg, S is Ser, V is Val, and Y is Tyr.

The conductance of this single ion channel in 1 M KCl is $120 \times 10^{-12} \Omega^{-1}$. The channel behaviour is voltage dependent. The conformational transitions from the helical to the disordered structure which take place in extramembrane segments regulate the ionic conduction of the channel. Thus, it is possible to control the functioning of the channel by varying the conformation of the attached synthetic extramembrane fragment.

In 1977, Bamberg and Janko⁴⁴ connected two gramicidin A molecules by a malonic acid bridge and thus obtained malonylbis(deformyl)gramicidin. It was shown that this covalent dimer forms a channel in the bilayer lipid membrane, the conductance and the ion selectivity of this channel being the same as those of the gramicidin channel, while the time the channel remains open significantly increases. Whereas the open lifetime is 1–2 s for the single gramicidin channel, in the case of a single malonylbis(deformyl)gramicidin channel, it is several minutes.

Arndt *et al.*⁴⁵ also used gramicidin A molecules as building blocks for the design of artificial ion channels with a long-lived active conformation (unlike the natural short-lived gramicidin dimers). For this purpose, two gramicidin molecules were cross-linked by C₄-linkers based on succinic acid. To study the phenomenon of the active conformation of the channel protein, a series of gramicidin-based synthetic channels with a long open duration in solution has been developed. The compounds synthesised for this purpose contained gramicidin molecules connected by various C₄-linkers. The influence of the linkers on the channel behaviour was studied.⁴⁵

In the last decade, ion channels based on gramicidin and other antibiotics and on modified peptides have been used as sensing elements. These channels incorporated in a bilayer lipid membrane are highly sensitive and selective.¹⁸ Sensors making use of chemically modified gramicidin and alamethicin have been reported.^{46,47} Gramicidin ion channels bound to antibodies by covalent bonds were used to design biosensors for determination of proteins, viruses, antibodies, DNA, electrolytes, drugs, and pesticides. The ionic conductance of these channels is regulated by the interaction of substrates with the antibodies connected to gramicidin molecules through biotin bridges.

It is well known that tetrahydrofuran can efficiently solvate metal cations. Therefore, in the development of cation-conductive synthetic peptide channels, it has been proposed to use oligotetrahydrofurans and THF-substituted amino acids. On the basis of THF-containing amino acids, cation channels with biomimetic entrance and exit have been synthesised.⁴⁸

The biomimetic fragment present in the obtained structures **1** and **2** is gramicidin A. The entrance and the exit of the channels **1**

and **2** contain four tryptophan residues. Apparently, the indole side groups of tryptophan contribute to stabilisation of the structures of channels **1** and **2** through hydrogen bonding to the polar groups of the lipid membrane and electrostatic dipole–dipole interaction with the surface charge of the membrane. The compounds **1** and **2** contain a heptapeptide (L-Trp–D-Leu)₃–L-Trp, a tetra-THF-peptide fragment, a linker based on tartaric acid[‡] and a pentadecapeptide, namely, gramicidin A.

In the compound **1**, the terminal fragments of ethanolamine are protected by lipophilic *tert*-butyldiphenylsilyl groups, while in the compound **2**, they are free. Upon incorporation in the lipid bilayer, the compound **1** forms a channel with different levels of conductance, indicating the existence of several active conformations of the channel. The first conformation with a conductance of $15.4 \times 10^{-12} \Omega^{-1}$ and an average open-state duration of 500 ms is responsible for passage of ~30% of the cations through the channel. The second conformation ($19.7 \times 10^{-12} \Omega^{-1}$) is more rarely encountered; however, its contribution to the total cation flux is greater, as its lifetime in the open state is ~15 s. Channel **1** demonstrated selectivity with respect to single-charged cations (NH₄⁺ > Cs⁺ > K⁺ > Na⁺). Since the cations lose their hydration shells, at least partially, when passing through the channel, this selectivity is due to the difference in the dehydration energies of the cations.

The electrochemical experiments with gramicidin D carried out by Wang's group⁵⁰ have dealt with the effect of the gramicidin concentration in the bilayer lipid membrane on the properties of the channels formed by gramicidin. When the concentration of gramicidin D is high, its structure in the bilayer lipid membrane is represented only by dimers.

Futaki⁸ reported a new approach to the design of sodium ion channels on the basis of the peptide template H–Cys(Acm)–Lys–Cys(SH)–Pro–Gly–Cys(MBzl)–Glu–Cys(Ad)–Gly–OH (Fig. 6). He synthesised a compound containing four different α-peptides ([NaI]–[NaIV]) attached to the given peptide template.

The assembly of such a peptide ion channel is shown in Fig. 7. Chloroacetyl-γ-aminobutyric acid was attached as a spacer to the N-end fragments of the amino acid sequences of the [NaI]–[NaIV] peptides. All the [NaI]–[NaIV] α-peptides were linked to the template through the interaction of chloroacetyl fragments with the free SH groups of the template after selective removal of the S-protective groups. The protein thus produced showed an ion-channel activity in lipid bilayers, dependent on the conformational changes in the channel induced by the change in the voltage applied to the membrane.

[‡] (*S,S*)-Tartaric acid has already been successfully used as the bridge for the head-to-head covalent attachment for the gramicidin dimer.⁴⁹

Figure 6. Nonapeptide template and artificial ion channel assembled from it.

Designations: C is Cys, K is Lys, P is Pro, G is Gly, E is Glu, AcM is acetamidomethyl, MBzl is *p*-methoxybenzyl, Ad is 1-adamantyl.

4. Toxins

Toxins capable of forming channels in a bilayer membrane are often used to model ion channels. The problem of spontaneous

incorporation of these water-soluble hydrophilic proteins in the membrane bilayer appears to be most interesting. This problem has been studied using thionins and ϵ -toxin.^{4,19} Thionins are small cysteine-containing amphipathic plant proteins. Many of them are toxic for microorganisms and mammal cells. Hughes *et al.*¹⁹ have shown that β -purothionin isolated from wheat flour can form cation-selective ion channels in artificial and biological bilayer lipid membranes (plasma membrane of neurons of the rat hippocamp); this apparently is responsible for the toxicity of β -purothionin and other thionins with respect to cells.

Petit *et al.*²⁰ demonstrated that the ϵ -toxin produced by the *Clostridium perfringens* microbe forms in lipid membranes wide channels capable of carrying substances with a molecular mass of up to 1 kDa, for example, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide. The ionic conductance of this toxin in a synthetic bilayer membrane amounts to $50 \times 10^{-12} \Omega^{-1}$ at a KCl concentration of $100 \mu\text{mol litre}^{-1}$.

The method of template assembling of synthetic peptides has also been used to prepare a branched peptide containing a δ -toxin fragment.⁵¹ This peptide was used as a model to study the structure and the transport properties of the δ -toxin.

Figure 7. Synthesis of four-helical bundle-type peptide sodium channel [NaI]–[NaIV] containing peptide potential-sensitive segments (S4). For designations of amino acid residues, see the text, I is isoleucine, T is threonine.

III. Artificial transmembrane ion channels based on cyclic peptides

1. Cyclic peptides consisting of alternating natural and abiotic amino acids

Usually, cyclic peptides form hydrophilic ion channels shaped like stacks in bilayer membranes. These channels are formed as a result of specific intermolecular interactions either between the peptide fragments of the macrocycle or between the amino acid residues of the side chains. The possibility of formation of this type of associate by cyclic peptides (see Fig. 1) was predicted back in 1972 by Hassal *et al.*⁵² Later, it was shown by X-ray diffraction¹¹ that cyclic tetrapeptides composed of alternating α - and β -amino acid residues are packed into stacks through hydrogen bonding of the cyclic fragments thus forming hollow cylindrical structures.

Japanese researchers⁵³ have synthesised cyclic peptides **A–C** containing 3 to 5 dipeptide units on the basis of one abiotic [5-(*n*-alkanoylamino)-3-aminobenzoic acid] and one natural (L-alanine, L-aspartic acid, L-lysine and L-serine) amino acids (Fig. 8). The unnatural amino acid makes the cyclic peptides structurally rigid.

Analysis of the structure of the possible associates formed by such peptides and the data on the voltage-dependent blockade of the channels based on them by Ca^{2+} ions allowed the researchers⁵³ to conclude that ion channels consist of two peptide rings packed according to the tail-to-tail pattern. The peptide parts of the rings form the entrance and the exit of the channel, while the long alkanoyl chains penetrate the membrane. It was also shown that variation of the natural amino acid incorporated in the cyclopeptide, *e.g.*, replacement of the neutral L-alanine by either positively charged L-lysine or negatively charged L-aspartic acid, does not influence the channel selectivity.

Figure 8. Models of peptides containing 3 (**A**), 4 (**B**) and 5 (**C**) dipeptide units (vertical view).⁵³
 $R^1 = \text{Me}$; for clarity, the alkanoyl chains $\text{R}^2\text{C(O)}$ are not shown.

The ion channels formed by cyclic peptides **A–C** with systematically varied pore size, shape and lipophilicity had a conductance of $\sim 9 \times 10^{-12} \Omega^{-1}$ in a 500 μM aqueous solution of KCl. The selectivity of transport of the potassium cation with respect to the chloride anion ($P_{\text{K}^+}/P_{\text{Cl}^-}$) was 5.9, while that with respect to the sodium cation ($P_{\text{K}^+}/P_{\text{Na}^+}$) was ~ 12.5 .

Under conditions that mimic the biological conditions (addition of equal amounts of solutions of sodium and potassium gluconates), the sodium/potassium selectivity ($P_{\text{Na}^+}/P_{\text{K}^+}$) for the tetrapeptide $n = 4$ (Fig. 8, structure **B**) is equal to 0.40. The Li^+ cation cannot pass through this channel, despite the substantially smaller size (1.56 Å) compared to the K^+ cation (2.66 Å), because of the great energy expenditure required for dehydration (it has been noted above that dehydration is a necessary stage involved in the transport of cations through the channel²).

2. β^3 -Peptides

β^3 -Peptides represent a class of biopolymers of abiotic origin, which tend to form unusual types of secondary structures.^{11, 54–57} Gellman and co-workers^{54, 56} have shown that homooligomers of *trans*-2-aminocyclohexane- and -cyclopentanecarboxylic acids form helical structures. The cyclic oligomers formed by α -unsubstituted β -amino acids with the β -chiral carbon atom can adopt planar ring conformations; in the solid state, these can be combined through hydrogen bonding to form hollow tubular ensembles (cyclic β^3 -peptide nanotubes).⁵⁷ These ensembles are structurally similar to self-assembling associates of cyclic peptides consisting of alternating D- and L- α -amino acids (cyclic DL- α -peptide nanotubes).^{58–62} These two classes of nanotubes supplement each other in the structure and functions.¹¹

Ghadiri and co-workers¹¹ have shown that β^3 -peptides **3–5** with appropriately selected hydrophobic side chains can be self-assembled in the lipid bilayer membranes to form highly efficient transmembrane ion channels (Fig. 9).

Owing to their unusual structure, cyclic β^3 -peptide nanotubes of abiotic origin exhibit unique properties (selectivity, solubility). In particular, due to the unidirectional arrangement of the polar amide groups in space, the nanotubes based on cyclic β^3 -tetrapeptide subunits possess a macrodipole moment (Fig. 10 *a*), whereas the nanotubes based on cyclic DL- α -octapeptides (Fig. 10 *b*) are not dipoles. The dipole moment of the amide groups (macro-dipole) enhanced by the parallel arrangement of the macrocycles

Figure 9. Presumptive structure of self-assembling transmembrane channels formed by β^3 -peptides **3–5**.¹¹

Figure 10. Cyclic peptide nanotubes consisting of cyclic abiotic β^3 -tetrapeptides (a) and cyclic DL- α -octapeptides (b).¹¹

increases the selectivity of the ion channel formed by β^3 -tetrapeptides. The β^3 -tetrapeptide **3**, containing indole groups in side fragments, is readily soluble in polar solvents such as DMSO and DMF.

Cyclic β^3 -tetrapeptides possess a higher conformational rigidity and a higher degree of pre-organisation for self-assembly than larger β^3 -penta- and β^3 -hexapeptides. Powder X-ray diffraction and molecular modelling have shown that the β^3 -tetrapeptide molecule can exist as both C_2 - and C_4 -symmetrical conformations (Fig. 11).

The results of calculations of the diameters of macrocycles suggest that in the lipid membrane, β^3 -tetrapeptides occur in the C_4 -symmetrical conformation, because in this case, the ring diameter equals 2.6–2.7 Å, which allows water molecules and

Figure 11. Cyclic β^3 -tetrapeptides in C_2 - and C_4 -symmetrical conformations.¹¹ For clarity, the side groups are shown as methyl groups.

relatively small ions to pass through the central pore of the transmembrane channel.

A synthetic transmembrane channel based on the cyclic β^3 -tetrapeptide **3** has demonstrated a K^+ -conductance of $56 \times 10^{-12} \Omega^{-1}$ (Fig. 12), which is higher than the K^+ -conductance of the channel based on gramicidin A under the same conditions. The peptides **3** and **5** ensure a proton conductance through a liposome membrane.

Figure 12. Conductance of the K^+ ions at 60 mV (peptide **3**, the probability of channel opening is 0.14).¹¹

Experiments confirmed the possibility of using cyclic peptides as channels for water molecules and small ions. The jumps of the measured current (see Fig. 12) point to opening or closure of the channel caused by fast conformational transitions (see Fig. 11) or changes in the channel structure.

IV. Supramolecular ion channels based on extended linear molecules

1. β -Barrels based on functionalised oligo(*p*-phenylene)

Matile and co-workers^{14–17} have reported the development of giant transmembrane channels (β -barrels) (see Fig. 1), which consist of rigid bars of octa-*p*-phenylenes **6** and **7** connected by short antiparallel β -sheet structures (Fig. 13). The rigidity of the channel structure is based on the electronic repulsion of the phenylene groups which form the internal surface of the β -barrel. Recording of the current in a single channel at -50 mV revealed a fluctuation-induced appearance of fluxes amounting to 178 pA.

The channel **6** incorporated into monolamellar vesicles can convey an anionic fluorophore, 5(6)-carboxyfluorescein, by means of the cationic NH_3^+ groups of lysine, which line the internal surface of the hexamer of the compound **6** (see Fig. 13). For estimating the internal diameter of the β -barrel self-assembled in the membrane, the transport of carboxyfluorescein was studied (Fig. 14). Since a carboxyfluorescein molecule has a diameter of more than 9 Å, it can be carried through channels with a diameter of at least 20 Å. This nanopore is comparable in size with the natural β -barrel formed by the polypeptide α -hemolysin containing 293 amino acids.

2. Biomimetic oligo(oxyethylene) esters of carboxylic acids

Not only peptides but also various non-peptide structures can be used to construct artificial ion channels. In 1990, Menger *et al.*⁶³ synthesised a number of compounds with the general formula $R^1O(CH_2CH_2O)_nR^2$ (**8**), which facilitated the transport of ions through bilayer membranes.

The highest activity was found for compound **8a** [$R^1 = n-C_{11}H_{23}C(O)$; $R^2 = PhCH_2$, $n = 5$], whose molecules are

6: $\text{NH}_2\text{--Leu--Lys--Leu--COCH}_2\text{O--OCH}_2\text{CO--Leu--Lys--Leu--NH}_2$.

8a: $R^1 = n-C_{11}H_{23}C(O)$; $R^2 = PhCH_2$, $n = 5$;
8b: $R^1 = n-C_{13}H_{27}C(O)$; $R^2 = PhCH_2$, $n = 4$;
8c: $R^1 = n-C_{11}H_{23}C(O)$; $R^2 = PhCH_2$, $n = 4$;
8d: $R^1 = n-C_9H_{19}C(O)$; $R^2 = PhCH_2$, $n = 5$;
8e: $R^1 = n-C_7H_{15}C(O)$; $R^2 = PhCH_2$, $n = 5$.

stretched throughout the whole thickness of the lipid membrane thus forming channels. The spontaneous inclusion of compound **8a** in the lipid membrane is due to both the hydrophobic section of the fatty acid and the interaction of the π -electron system of the benzyl substituent with the quaternary ammonium group of the membrane lipids. The ion flux through the vesicle membrane was determined by time-resolved fluorescence spectroscopy using a fluorescent dye (pyranine) as the pH indicator. It was found that for a concentration of **8a** equal to 75 molecules per vesicle 30 ± 5 nm in diameter, the equilibrium between the exterior and interior ions is established almost instantaneously. Comparison of the efficiency of the transport of protons by compound **8a**, gramicidin D and 18-crown-6 ether has shown that compound **8a** surpasses gramicidin, while 18-crown-6 does not influence at all the ion flux through the bilayer lipid membrane. The last-mentioned fact deserves particular attention, because experiments with bulky liquid chloroform membranes (in this case, the ion transport is accomplished by ion carriers) give the opposite result, namely, 18-crown-6 transports the K^+ cations through a chloroform liquid membrane, whereas compound **8a** is completely inert. This is due to the fact that crown ethers are potent ligands, able to carry cations through a chloroform membrane,⁶⁴ while compound **8a** is a weak ligand for K^+ . This finding supports the assumption that compound **8a** carries the cations due to the formation of channels in the bilayer membrane. Some other facts also attest to the formation of an ion channel in the membrane. Indeed, ether **8a** is active even when present in nanomolar concentrations; in addition, the efficiency of cation transport is structurally specific, in particular, analogues of compound **8a** having either higher ($n > 5$) or lower ($n < 5$) hydrophilicity do not change the membrane permeability.

In order to elucidate the influence of the length of the fatty acid residue and the length of the oligo(oxyethylene) fragment on the efficiency of cation transport by compounds **8**, Schafer and co-workers⁶⁵ have synthesised and studied derivatives **8b–e**. Study of the transport of the Li^+ , K^+ and Cs^+ cations through the phospholipid membrane showed that only compounds **8b–d** form single channels (determined on the basis of the current). The highest efficiency was found for compound **8d**, which is probably due to the most favourable ratio of the total chain length and the number of ethylene glycol fragments. The increase in the conductance of this channel in the series $Li^+ < K^+ < Cs^+$ is correlated with the increase in the ion radius of the cation (Li^+ , 78; K^+ , 133; and Cs^+ , 169 pm) and also with the decrease in the radius of the hydrated cation (Li^+ , 382; K^+ , 331; Cs^+ , 329 pm). Apparently, in this case, the pore diameter varies from 340 to 660 pm.

When comparing the compound **8d** and gramicidin D regarding their ability to carry cations, it should be noted that in the case of gramicidin D, the highest ionic conductance of vesicles is observed when its concentration is as low as $1 \mu\text{mol litre}^{-1}$ (further increase in the gramicidin D concentration to $5 \mu\text{mol litre}^{-1}$ does not increase the ionic conductance). Conversely, an increase in the concentration of compound **8d** up to $20 \mu\text{mol litre}^{-1}$ still induces an increase in the conductance of the vesicle. This implies that the formation of the ion channel involves more than two molecules of **8d**, unlike gramicidin D. It was assumed⁶⁵ that the molecules of **8** are associated according to the 'head-to-tail' pattern, because only in this case can the hydrophilic part of the channel-forming compound extend throughout the whole membrane.

3. Biomimetic oligo-(*R*)-3-hydroxybutyrate

The low-molecular-mass polyhydroxybutyrates composed of 50–150 residues of (*R*)-3-hydroxybutyrate and oligohydroxybutyrates composed of less than 50 residues are common in prokaryotic and eukaryotic cells, where they form numerous coordination bonds with cations. They are able to transport ions through a phospholipid membrane in model planar bilayer systems and in liposomes. However, these channels have low selectivity and low sensitivity to the change in the transmembrane potential.⁶⁶ In

addition, for ion transport, it is necessary to build-in large amounts of these substances ($> 0.1\%$) in the membrane.⁴ Das *et al.*⁶⁶ have gained a higher efficiency from this transport system. They prepared complexes of oligo-(*R*)-3-hydroxybutyrates **9** ($n = 18–22$) with inorganic polyphosphates, which demonstrate a higher cationic conductance ($275 \times 10^{-12} \Omega^{-1}$) compared to that of the complexes formed by poly-(*R*)-3-hydroxybutyrates ($n = 120–140$) with polyphosphates ($100 \times 10^{-12} \Omega^{-1}$).

$n = 18–22$.

However, the selectivity of the transport of Ca^{2+} cations with respect to Na^+ cations by means of these oligomers is much lower than the selectivity of transport by polymers: 4:1 and $> 90:1$, respectively. These results confirm the hypothesis that polyphosphate fragments play the crucial role in the cation selectivity, while oligo- and poly-(*R*)-3-hydroxybutyrates are solvating agents (Fig. 15). Thus, the monodisperse biomimetic oligo-(*R*)-3-hydroxybutyrate/polyphosphate system can be efficiently used for the development of voltage-activated synthetic ion channels with a limited cationic selectivity (Fig. 16).

Figure 15. Structure of the channel formed by oligo-(*R*)-3-hydroxybutyrates with inorganic polyphosphates (vertical view).⁶⁸

The formation of ion-selective voltage-activated channels by poly-(*R*)-3-hydroxybutyrate/polyphosphate complexes has been considered in detail.⁶⁷ Complexes of these two polymers isolated from the plasmatic membranes of bacteria or obtained from synthetic polymers form voltage-dependent Ca^{2+} -selective channels in a planar bilayer membrane. The key factor in the solvation of calcium polyphosphates by polyhydroxybutyrates is the flexible core of the polymer and the optimal distance between the carbonyl groups of the ester fragments. In the models of channel complexes proposed by Reusch⁶⁸ and Seebach,⁶⁹ the highly polar poly-anionic polyphosphates are shielded from the hydrophobic region of the bilayer by amphiphilic polyhydroxybutyrates. As a result, numerous sites of cation binding are formed between the two polymers, *i.e.*, irregular binding cavities formed by the phosphoryl oxygen atoms belonging to the polyphosphate and the oxygen

Figure 16. Current–applied voltage dependence for the channel complexes of oligo-(*R*)-3-hydroxybutyrate with polyphosphates. Different designations of experimental points correspond to values obtained in parallel experiments.

atoms of the ester groups of poly-(*R*)-3-hydroxybutyrate, which bind more readily the Ca^{2+} cation than the Mg^{2+} cation.

4. Voltage-dependent channels based on cholic acid derivatives

The natural transport proteins are characterised by a high degree of controllability. Transition from the closed to the open (or conductive) state is usually induced by a particular process: phosphorylation, binding of small molecules (acetylcholine, Ca^{2+} and so on) or a change in the transmembrane potential. Conversely, most synthetic ion channels cannot be controlled: they switch from the closed to the open state as a result of random aggregation processes in the lipid bilayer.

The regulation of the permeability of bilayer membranes by applying a voltage is one of the fundamental approaches to the control of the overall conductance of ion channels and to the design of new supramolecular ionic devices (selective filters, conductors and so on) and pharmaceuticals. Voltage-dependent channels are opened or closed upon application of a voltage higher or lower than a certain critical value. Only a few studies dealing

with the preparation of synthetic voltage-dependent ion channels have been published to date.

The design of voltage-dependent ion channels **10–13** on the basis of cholic acid and its derivatives has been reported.^{70, 71} Compounds **10–13** are formed upon cross-linking of two fragments of cholic acid or its derivatives by a *m*-xylylenedicarbamate bridge.

$\text{R}^1 = \text{R}^2 = \text{CO}_2\text{H}$ (**10**), $\text{CH}_2\text{OC(O)CH}_2\text{N}^+(\text{CH}_3)_3\text{Cl}^-$ (**11**);

$\text{R}^1 = \text{OP(O)(OH)}_2$, $\text{R}^2 = \text{CO}_2\text{H}$ (**12**); $\text{R}^1 = \text{CO}_2\text{H}$, $\text{R}^2 = \text{OH}$ (**13**).

The length of channels formed by these compounds approximately corresponds to the thickness of the bilayer membrane (~ 40 Å). The rigid amphiphilic steroidal frameworks of compounds **10–13** have a favourable effect on the stability of the resulting channels. In order to elucidate the effect of the electric asymmetry of the ion channel on the possibility of controlling the channel by means of an applied transmembrane potential, two types of compounds have been prepared, those with identical (compounds **10**, **11**) and different (compounds **12**, **13**) terminal hydrophilic groups. The electric asymmetry of the structures of compounds **12** and **13** was attained by introducing different terminal hydrophilic groups, namely, a carboxy group and a phosphoric acid fragment and a hydroxy and carboxy groups, respectively.

In a bilayer membrane, compounds **10–13** formed stable single ion channels having long open durations (200 ms to 4.7 s); in addition, with a positive potential applied, higher ion currents were observed than on application of a negative potential, *i.e.*, an essential non-linearity of voltammetric characteristics was observed. Taking into account the cation selectivity of the channels formed by compounds **12** and **13** (for example, for channel **12**, the $P_{\text{K}^+}/P_{\text{Cl}^-}$ ratio is equal to 11), the researchers suggested that in a channel formed by compound **12**, the potassium cations move from the phosphoryl end of the molecule to the carboxylate one. The functioning of the channel based on compound **12** is schematically illustrated in Fig. 17.

Figure 17. Movement of the potassium cation in channel **12**.⁷¹

5. Voltage-dependent ion channels based on bismacrocylic amphiphiles

Fyles *et al.*¹² described the synthesis of bismacrocylic amphiphilic compounds **14** and **15**, where groups able to carry different charges are located on the opposite ends of the molecule, in particular, a mercaptoacetate (1−) and a thioglucose (neutral) group in compound **14** and a mercaptoacetate (1−) and a mercaptosuccinate (2−) group in compound **15**. The presence of such groups imparts a substantial dipole moment to compounds **14** and **15** and favours fixing of these molecules on the surface of a bilayer membrane.

It was found that the presence of a negatively charged (1−) and neutral end groups in compound **14** gives rise to an ion channel, characterised by regular changes in the ionic conductance. However, the voltammetric characteristics of such a channel proved to be almost linear, *i.e.*, opening of the channel did not depend on the voltage applied. This was attributed to a random orientation of the channel-forming molecules **14** in the membrane. Meanwhile, compound **15** forms a channel due to asymmetric orientation in the diphtanoyl phosphatidylcholine bilayer membrane such that the succinate group is located predominantly on the *cis*-face of the bilayer. As a result, a non-linear voltammetric characteristic of the channel is observed (similar to that typical of the alamethicin channel) with an opening threshold of about −30 mV (Fig. 18, curve 1). The drawbacks of this channel include the unstable behaviour of its opening and functioning. The non-linear voltammetric characteristic is observed only for the first cycles and disappears after 10–15 min of channel operation (Fig. 18, curve 2). The time the channel remains in the open state is exceptionally short, being equal to 0.5–10 ms. The current amplitude is variable and can change by an order of magnitude (1–10 pA). Thus, the qualitative characteristics of these channels, namely, the ‘explosive’ opening, variable flux values per opening, and low cationic selectivity, are indicative of a relatively low degree of structuring of the resulting channels.

Figure 18. Voltammetric characteristics of the ion channel based on compound **15** (118 nmol of **15**, 1 M LiCl, diphtanoyl phosphatidylcholine) with 1–7 (1) and 8–20 (2) cycles.

The presumptive mechanism of the functioning of voltage-dependent channel **15** is shown in Fig. 19.

Apart from the non-specific pre-association of compound **15** with the bilayer (structure **A**), the researchers also considered

Figure 19. Presumptive mechanism of operation of the voltage-dependent channel formed by **15**.

other types of association of this compound with the bilayer giving intermediate U-shaped (**B**) and transmembrane (**C** and **D**) structures. Since the processes involving penetration of the succinate dianion terminal group through the lipophilic membrane (transition from structure **B** to structure **C** and from structure **D** to structure **C**) occur more slowly than the processes of penetration of the acetate monoanion group (transition from **B** to **D**), it can be suggested that structure **D** with the succinate terminal group located on the *cis*-face of the bilayer is the first to be formed (see Fig. 18). In this case, opening or closure of the channel is due to parallel or antiparallel arrangement of the molecular dipole moment and external field vectors. Since the electrostatic repulsion of the succinate groups should be substantial, the degree of aggregation would depend appreciably on the stabilisation of the resulting supramolecular system due to the external electric field. In the case of antiparallel orientation of the dipole moment and external field vectors, ion-conductive aggregates are formed at negative potentials on the bilayer surface and the system proves to be more stable. The parallel orientation results in destabilisation, predominance of the electrostatic repulsion of likely charged terminal groups and destruction of ion-conductive aggregates.

6. The formation of supramolecular ion channels by amphiphilic ion pairs

Kobuke *et al.*^{72–74} have designed amphiphilic compounds able to be incorporated into bilayer membranes by combining a hydrophilic oligoether and a hydrophobic alkyl chain in an ion pair formed by an ammonium cation and carboxylate or phosphate anions. The researchers synthesised two types of amphiphilic ion pairs with the hydrophilic component represented by either an anion (compounds **16** and **17**) or a cation (compounds **18–21**).

Figure 20. Schematic view of the structure of supramolecular ion half channel formed by an amphiphilic ion pair. The black and white columns designate the hydrophilic and hydrophobic parts of the ion pair, respectively.

The presence of the hydrophilic oligoether moiety in the ion pair results in supramolecular aggregation of ion pairs. The hydrophilic parts of ion pairs in the aggregates are 'expelled' from the hydrophobic lipid membrane to give a half ion channel (Fig. 20). Further tail-to-tail dimerisation of these half channels forms a full single channel. It is evident that the stability of these supramolecular ensembles would depend on the hydrophilic–lipophilic balance within the amphiphilic ion pairs. The most stable channels were found to appear when the hydrophobic parts of the ion pairs contain two alkyl chains (compounds **17**, **19**, and **20**). The ion pairs containing one alkyl chain (compounds **16** and **18**) form channels with low stability. The ion pair **21** does not form channels at all. Probably, in this case, the four hydrophobic chains of cardiolipin mask the oligoether chain of the cation, thus hampering the formation of a supramolecular ensemble in the lipid membrane.

All the ion channels studied showed a cation selectivity (cations are transferred more efficiently than anions). For example, for channels **19** and **20**, the P_{K^+}/P_{Cl^-} values are equal to 4.9 and 16.8, respectively. Moreover, this is observed despite the

different characters of the anionic terminal groups in the hydrophobic component of the ion pair. Thus, the pattern of selectivity is determined by the nature of the intramembrane walls of the channel rather than by the type of terminal groups which form the entrance of the channel.

The discovery of voltage-dependent ion channels represented one more important result of this study. The probability of opening and closure of the channels formed from ion pairs of the monoammonium cation and the alkyl phosphate dianion (compounds **17** and **19**) depends on the voltage applied. Meanwhile, the ion pairs consisting of the monoammonium cation and the carboxylate (compounds **16**, **18**) or dialkyl phosphate (compound **20**) monoanions do not form voltage-dependent ion channels.

As noted previously, the presence of different charges (dipole moment) on the opposite ends of the channel is a necessary condition for the functioning of voltage-dependent ion channels. It is clear that the degree of aggregation of amphiphilic ion pairs in the half channel depends on many factors, and aggregates of diverse compositions are formed in the membrane. As a result, a single channel assembled from two such half channels has different negative charges on the opposite ends; in other words, it has a dipole moment. However, the dipole moments for different single channels assembled from two half channels in a random way are dissimilar and cannot be controlled. Therefore, the voltammetric characteristics of the resulting channels vary from one experiment to another.

7. Photochemical control of the ion transport using compounds containing an azobenzene fragment

The photochemical method for controlling ion channels based on modified gramicidin peptides has been reported in several publications.^{75–77} Schreiber and coworkers⁷⁵ have found that the gramicidin dimer containing an azobenzene bridging fragment in the *cis*-form acts as an ion channel. Higuchi *et al.*⁷⁶ have shown that in the case of azobenzenes linked to the α -helix of bispolyglutamate, the overall ion flux is controlled by photoisomerisation. Woolley and co-workers⁷⁷ have observed the variation of a single ion flux induced by isomerisation of the azobenzene fragments attached to the channel gate of gramicidin. On exposure to

laser radiation with a wavelength of 337 nm, the channels pass from the *trans*-state characterised by the highest flux levels of 14.9 ± 0.4 pA and lower current levels of 0.6 ± 0.1 pA to the *cis*-state with a flux level of 12.8 ± 0.4 pA and three current levels, 1.1 ± 0.1 pA (first level), 2.6 ± 0.1 pA (second level) and 3.5 ± 0.2 pA (third level). The subsequent illumination of the *cis*-channels by a 100-W table lamp for 10 min resulted in the transition into the *trans*-form.

Kobuke and Ohgoshi⁷⁸ have synthesised and studied a supramolecular synthetic ion channel based on *N,N*-dimethyl-*N*-octadecyl-*N*-[4-(4-butoxy)-*trans*-azophenoxy]butylammonium 3,8,13,18,23-pentaoxaheptacosanoate (**22**). The channel is an amphiphilic ion pair which isomerises on exposure to photo-radiation.

After this ion pair (single channel) had been incorporated into a planar phospholipid membrane, an ion flux was passed through it (Fig. 21). An important characteristic of this channel is that the period when the channel is open is longer than the period when the channel is closed. The channel based on compound **22** has shown different values of electrical conductivity, most of all, in the range of $(2-13) \times 10^{-12} \Omega^{-1}$. The channel was found to be selective for the potassium cation with respect to both the chloride anion and the sodium cation: the permeability ratios are as follows: $P_{K^+}/P_{Cl^-} = P_{K^+}/P_{Na^+} = 6.1$.

Figure 21. Current created by *trans*-azobenzene ion pair **22** at a voltage of 96.9 mV in a 500 mM solution of KCl and 5 mM Tris – HEPES buffer (pH 7.2) [Tris is tris(hydroxymethyl)aminomethane, HEPES is *N*-2-hydroxyethylpiperazine-*N'*-ethanesulfonic acid]. The dashed line corresponds to a closed channel. The short-lived opening and closure of the channel were observed at the points marked by one and two asterisks, respectively.

Upon photoirradiation at 367 nm, the *trans*-azobenzene fragment passes to the *cis*-form (Fig. 22). This isomerisation results in channel closure and the current does not pass through it. The subsequent transition of the *cis*-azobenzene fragment to the *trans*-form resumes the ion flux through single channels. Thus, the photocontrol of the channel throughput capacity was attained.⁷⁸

Figure 22. Possible mechanism of the photochemical control of the ion flux with the use of ion pair **22**.

V. Ion channels based on crown ethers

1. Tris- and tetrakis(diazacrown ether) channel-forming structures

Crown ether derivatives are convenient models for investigating the mechanism of functioning of ion channels in bilayer phospholipid membranes. In artificial channel-forming systems, crown ethers are used as either head groups or binding sites for the corresponding ion.

It has been shown^{79,80} that *N,N'*-bisalkylated and *N,N'*-bisbenzylated diaza-18-crown-6 ethers are self-aggregated in the solid phase to form channel-like ensembles. The length of the supramolecular structures thus formed determined by laser light scattering was 2000–3000 Å; the aggregates of alkylated diaza-18-crown-6 derivatives proved to be more stable than the aggregates of benzylated derivatives.

Meadows *et al.*⁸¹ reported that complexes of propargyl-substituted diaza-18-crown-6 with KBF_4 form a channel-like extended structure whose supramolecular organisation indicates that the diaza-18-crown-6 molecule within synthetic channels can play the same role as water that forms the hydration shell in natural proteins. This structure formed by cations and donor groups can mimic the natural cationic channels located in the lipid bilayer.

The amphiphilic nature of crown ethers allows one to use them as the channel gate. A substantial contribution to the understanding of the principles of design and functioning of artificial ion channels based on crown ethers was made by Gokel and co-workers.^{10,13,82,83} In particular, they synthesised a series of tris(diaza-18-crown-6) compounds **23–29**,⁸² which demonstrated the ability to be incorporated into lipid membranes to form ion channels.

Y = O (**23**), NH (**24**), $N(CH_2)_{11}CH_3$ (**25**),

For estimating the efficiency of the ion transport, two methods have been used most often, namely, determination of the exchange rate of the sodium cation in the vesicles by ^{23}Na NMR dynamic spectroscopy using shift reagents and determination of the conductance of planar bilayer membranes.

To establish the mechanism of action of synthetic channels based on tris(macrocyclic) systems, one should answer three main questions. The first one concerns the possibility of explaining the differences in the fluxes of the Na^+ cation through a bilayer membrane by different solubilities of ionophores in the membrane. For this purpose, the distribution coefficients of tris(crown ethers) **23–29** in the octanol–water system were calculated. The calculation showed that all the compounds studied occur preferably in the lipid bilayer: the ratio of the distribution coefficients is $10^{10}:1$ (i.e., the crown ethers occur entirely in the membrane phase).⁶⁰

The second question concerns the ion transport, because the ability of crown ethers to function as cation carriers is well known.⁸⁴ In order to answer this question, it was necessary to determine the mode of functioning of the systems of interest, whether they are ion carriers or ion channels. Therefore, experiments were carried out on Na^+ transport through lipid and bulky chloroform membranes by means of crown ethers **23–29**. It is evident that the transport through a chloroform membrane cannot occur by the channel mechanism, because in this case, the distance between the source and receiving aqueous phases is too great, unlike that in a bilayer lipid membrane. Figure 23 presents the measured rate constants for the transport of the Na^+ cations by crown ethers **23–29** in the lipid bilayer and chloroform membranes. For comparison, similar experiments were carried out with gramicidin (the natural channel-forming peptide) and valinomycin (a natural receptor of Na^+ ions).

Figure 23. Comparison of the efficiency of Na^+ transport by compounds **23–29**, gramicidin (G) and valinomycin (V) through chloroform and lipid bilayer membranes.

It can be seen from Fig. 23 that most of the compounds **23–29** studied are less active ion carriers than natural compounds. As expected, valinomycin proved to be the most efficient carrier, while gramicidin was the most effective channel-forming compound. The lack of correlation between the rates of transport of Na^+ ions through phospholipid and chloroform membranes by tris(crown ethers) **23–29** confirmed that they function in a bilayer membrane as channel-forming agents rather than mere ion carriers.

Finally, the last question concerns the role of the terminal residues of the crown ethers, whether they are the head groups through which the cations pass when they enter or leave the membrane? If the terminal crown-ether fragments function as the input elements of the channel, the transport efficiency should depend on the electron density on the macrocycle and on the nature of the substituents at nitrogen. Experiments with com-

pounds **26–28**, which differ only in substituents (H, OCH_3 and NO_2) in the benzene ring, showed a positive effect of electron-donating substituents on the ion flux. This influence is quite understandable, as an increase in the electron density at the entrance of the channel is expected to accelerate the transport of cations through the channel. On that ground, Murillo *et al.*⁸² suggested that the terminal residues of crown ethers are the head groups of the ion channel through which the cations pass.

Further investigation of tris(diaza-18-crown-6 ethers) as channel-forming structures in bilayer phospholipid membranes allowed researchers to propose a structure for the ion channel formed (Fig. 24).⁸³ They suggested that water molecules fill the channel and assist in the cation transport. This suggestion was based on the known fact that a chloroform membrane containing some tris(macrocyclic) compounds becomes rapidly saturated with water.

Figure 24. Structure of the ion channel formed by tris(diaza-18-crown-6 ether) **25**.¹³

Subsequently, Gokel and co-workers¹³ proposed using heterocyclic compounds as the terminal fragments of tris(macrocyclic) structures based on diazacrown ethers. It is known that side groups of some amino acid residues in transmembrane proteins serve to fix the protein helices relative to each other and relative to the bilayer membrane.⁴ This role is often performed by the indole fragment of tryptophan. It was shown by NMR spectroscopy that numerous tryptophan residues present in the gramicidin channel are directed toward the water–bilayer membrane interface. Therefore, Gokel chose indole as the terminal heterocyclic fragment. He prepared a series of compounds with the general formulae **30–32**, which were used to create ion channels in phospholipid vesicles. It was demonstrated experimentally that *N*-alkylindoles are able to form stable vesicles with neutral head groups represented by crown-ether fragments which control the cation transport (channel gate). The C_{12} hydrophobic bridge in tris(diazacrown ethers) **30–32** can be oriented in the membrane parallel to the lipid chains. Generally, the length of these tris(macrocyclic) channels proved to be sufficient to bridge the hydrocarbon region of the membrane and to form a channel.

Compounds **31** and **32** are able to transfer the sodium cation in the bilayer membrane, unlike compound **30**. This can be attributed to the fact that compound **30** forms in the membrane a hydrophilic globular conformation due to strong intramolecular hydrogen bonding between the NH groups of the indole substituent and heteroatoms of the macrocycle.

The synthesis of tetrakis(diazacrown ether) **33** has been described.⁸⁵ The researchers linked two macrocyclic fragments connected by long aliphatic chains to the central ferrocene fragment capable of functioning as a cationic 'filter'.

The length of the resulting channel was ~ 30 Å, which corresponded to the thickness of a typical biological membrane. It was assumed that variation of the head groups would create the basis for controlling the cationic selectivity.

Cyclic voltammetry studies of compound **33** showed that the strength of the coordination interaction of the Na^+ ion with the amide group of the ferrocene fragment decreases as the channel becomes filled with cations, which can be explained by charge repulsion. This does not occur for Ca^{2+} ions, apparently, due to their stronger coordination to the amide groups.

The transport of ions through such channels has been studied using biological membranes (fragments of hamster brain cells). The change in the membrane potential from -60 to $+60$ mV decreased the transmembrane cation flux following the accumulation of positive charge on the inner side of the cell. At -80 mV, the amplitude of the mean K^+ flux through a single channel was -4.0 pA, which corresponded to a conductance of $50 \times 10^{-12} \Omega^{-1}$. For a potential of 80 mV, this value was 2.4 pA ($30 \times 10^{-12} \Omega^{-1}$). These results indicate that the activity of these channels can be controlled to some extent by varying the applied voltage.

2. Artificial ion channels based on peptides containing crown-ether fragments

Voyer and co-workers^{86,87} proposed that crown ether fragments **34–36** be used for the creation of ion channels with a new architecture on the basis of synthetic peptides.

They synthesised a series of peptides **37–41** consisting of 21 amino acid residues carrying six crown ether fragments:

N-BOC-(Leu-**34**-Leu₃-**34**-Leu)₃-OMe (**37**),
N-BOC-(Leu-**35**-Leu₃-**35**-Leu)₃-OMe (**38**);
N-BOC-(Leu-**36**-Leu₃-**36**-Leu)₃-OMe (**39**);
N-BOC-(Leu-**36**-Leu₃-**36**-Leu)₃-OH (**40**);
H₂N-(Leu-**36**-Leu₃-**36**-Leu)₃-OH (**41**).

Since peptide **37** contains 15 L-leucine residues of the total 21 amino acid residues, it is sufficiently hydrophobic to be incorporated in a lipid membrane. Therefore, the channel is formed most likely due to stacking of crown ether rings (Fig. 25).

Figure 25. Axial projection of the α -helix of the hexacrown peptides **37–41** (a, the circles mark the sites of attachment of the crown ethers) and scheme of the channel formed by these peptides in the bilayer membrane (b).

Studies of the conformations of hexacrown peptide **37** and its analogues **38–41** by polarimetry and FT IR spectroscopy have shown that they exist as two forms, **A** and **B** (Fig. 26), which occur in equilibrium. Peptides existing in the inactive form **A** are adsorbed on the bilayer surface, while peptides in the active form **B** are arranged parallel to the aliphatic tails of lipids.

Aggregated crown peptide is adsorbed from a solution on the surface of a bilayer membrane. The adsorbed inactive form **A** of the peptide, partially immersed in the membrane, is reorganised to the active form **B** (see Fig. 26). It is noteworthy that in both the membrane and the solution, peptides occur in the stable α -helical conformation.

Figure 26. Model of the formation of the channel from peptides **37–41**. **A** is the inactive form, $\theta = 90^\circ$; **B** is the active form, $\theta = 30^\circ$.

VI. The use of 'bouquet' structures for the design of synthetic ion channels

1. 'Bouquets' based on 18-crown-6 and β -cyclodextrin

Lehn and co-workers^{88–91} used polyfunctional macrocycles, β -cyclodextrin and 18-crown-6 as the 'platform' for the design of artificial ion channels. It is common knowledge that crown ethers form labile complexes with alkali metal cations and that cyclodextrins have rigid cavities which are sufficiently large for hydrated alkali metal cations to pass through them. To make these channels amphiphilic, polyoxyethylene or polymethylene chains with polar terminal groups were linked to the macrocyclic 18-crown-6 and β -cyclodextrins.^{88,89} Four compounds differing in the type of central structure and the type of podand chains have been prepared in this way (the structures of two such compounds **42** and **43** are presented below). These compounds have been called 'bouquets'.

The ability of compounds **42** and **43** to be incorporated into phosphatidylcholine bilayers of the vesicles was studied by a number of methods (circular dichroism, UV/Vis spectroscopy, differential scanning calorimetry and so on).^{88,89}

It was found that the 'bouquets' are incorporated in the bilayers in two modes: in the U-mode (both hydrophilic ends are arranged on one side of the membrane) and in the transmembrane mode.

The transport of metal cations (Li^+ and Na^+) induced by the 'bouquet' compounds incorporated in liposomes⁹⁰ has been studied by NMR on alkali metal nuclei with a shift reagent (a 3:1 mixture of tetramethylammonium tripolyphosphate and dysprosium chloride), which allows one to distinguish between the signals from intraliposome metal cations (no shift) and those from extraliposome metal cations (a shift is observed). Upon creation of opposite gradients for the concentrations of Li^+ and Na^+ cations, the 'bouquets' induced the cation transport according to the antiport mechanism. The rate constants for ion transport calculated for the 'bouquets' based on 18-crown-6 with

polyoxyethylene and polymethylene chains were, on average, 6×10^{-3} and $10 \times 10^{-3} \text{ min}^{-1}$, respectively. While studying the cation transport along channels based on 18-crown-6, the researchers found out that an increase in the concentration of a compound in a membrane enhanced the transport only for the channel with polymethylene chains.

In order to distinguish between two transport mechanisms (an ion channel or an ion carrier), the transport rate through the membrane under usual conditions was compared with the transport rate through a frozen membrane. Switching to the gel state is expected to cause a substantial decrease in the rate of the ion flux for a carrier, which executes shuttle movements in the membrane, but to have almost no influence on the rate of the transport induced by a static channel structure. It was shown that the liquid crystal–gel phase transition did not result in a decrease in the transport rate only for two of the four 'bouquets', those based on cyclodextrin with polyoxyethylene chains and 18-crown-6 with hydrocarbon chains. The behaviour demonstrated by the compounds derived from 18-crown-6 with polyoxyethylene chains and from β -cyclodextrin with hydrocarbon chains does not allow one to classify them as channel structures; however, the results obtained do not indicate that they are ion carriers either.⁹¹

2. 'Bouquet' structures based on calixarenes

A few examples of using calixarenes for constructing artificial ion channels have been reported. A cyclic resorcinol tetramer with long alkyl chains has been synthesised and studied as an ion channel.⁹² It was found that this compound functions as a half channel with K^+ -selectivity. This channel is of interest as a model of natural ion-channel proteins having hydrophobic fragments. The uncharged and highly hydrophobic M2-segment of the nicotine acetylcholine receptor ...MTLSISVLLSLTVFLLVIV... can serve as an example.⁹³

The synthesis of two compounds based on calix[4]arene in the 1,3-alternate conformation (**44a,b**) has been described. In compounds **44a,b**, each phenol group of calixarene is connected

R = H (a), Bu^t (b).

through an oxygen atom to one dodecyl chain which ends with a 10-benzyl-1,10-diaza-18-crown-6 fragment.

The side chains in compounds **44a,b** are arranged on both sides of the central fragment, two chains on each side. The diazacrown fragments acting as head groups stabilise the distribution of side chains within the membrane. The total length of the channel is 34–60 Å, which is sufficient for bridging the lipid part of a typical bilayer membrane, whose average thickness is ~30 Å.⁹

The incorporation of compounds **44a,b** (1 mmol) in a bilayer membrane increases the membrane permeability for alkali metal cations [with smaller amounts of these compounds (1 nmol), the membranes show unstable permeability] (Fig. 27). The repeated introduction of solutions of compounds **44a,b** in the membrane increases the intensity and the frequency of the observed transitions (up to $300 \times 10^{-12} \Omega^{-1}$).

The probability for Na⁺ and K⁺ cations to flow through a calixarene platform has been estimated. In the solid state, the average distance between the centres of the aryl fragments in the 1,3-*alternate* calixarene conformation is 5.9 Å. This distance is sufficient for penetration of Na⁺ and K⁺ cations, because according to theoretical calculations, the benzene–M⁺–benzene distance in an ideal sandwich structure is 4.96 Å (for M = Na) or

5.84 Å (for M = K). Thus, it was shown that Na⁺ and K⁺ cations can flow through calix[4]arenes in the 1,3-*alternate* conformation.^{94,95}

However, in the case of tetra-*tert*-butylcalix[4]arene **44b**, the calixarene platform is completely blocked from both sides by bulky *tert*-butyl groups. To enable the flowing of cations through calixarene **44b**, the conformation must undergo a definite sequence of modifications: two aryl fragments should pass into the open state, to let the cation through, while the other two fragments are closed. Similar changes should take place at the other end of the molecule to let the cations out. However, at room temperature, calix[4]arene is unable to change its conformation. The results obtained by measuring the channel conductance for compounds **44a,b** did not allow the researchers to decide how the ions flow in such a channel, either through the macrocyclic ring of calixarene or outside the ring.

Compounds **44a,b** represent a new class of cation-conductive channels with a high level of conductance for the sodium and potassium cations. In these compounds, calixarenes in the 1,3-*alternate* conformation were used as the basic compounds for the design of ion channels.

VII. The use of the calixarene platform for the design of ion channels

1. The artificial ion channel based on a macrocyclic calix[4]resorcinarene with amphiphilic ester groups of cholic acid

As a result of further development of approaches to the preparation of nonpeptide ion channels — supramolecular and molecular half channels — Kobuke and co-workers⁹⁶ synthesised calix[4]resorcinarene **45** with four alkyl substituents. This compound forms a single ion channel with one conductance level. They also obtained a supramolecular ion channel on the basis of an amphiphilic derivative of rigid methyl cholate **46**. The channel

Figure 27. Conductance of compounds **44a** (a) and **44b** (b) (1 pmol each in THF, a 0.5 M solution of NaCl) in a planar bilayer membrane at 100 mV. For each compound, two different time sections are shown. The different patterns of these sections point to an unstable permeability regime.

Figure 28. Ion channel formed from two calix[4]resorcinarene **47** molecules connected in the tail-to-tail mode (one methyl cholate residue is omitted for clarity).

Figure 29. Time profiles of single channels **47** (a) and **45** (b). (a) 0.5 mol of KCl, pH 7.2, 70 mV; (b) 0.5 mol of KCl, pH 7.2, -74.4 mV.

formed by compound **46** in the bilayer membrane has a long open duration.

To prepare a molecular ion channel having one conductance level and a long open-state duration, calix[4]resorcinarene **47**, combining calixarene and methylcholine fragments, was synthesised. A study by ^{13}C NMR spectroscopy showed that compound **47** exists in a C_4 -symmetric conformation. The presence of hydrophilic head groups and amphiphilic steroidal fragments in calix[4]resorcinarene **47** allows the molecules in a bilayer membrane to form a tail-to-tail pair, which gives rise to a transmembrane channel (Fig. 28). The hydrophilic parts of the steroid groups form a hydrophilic pore around the central axis, whereas the hydrophobic parts are directed toward the lipid alkyl groups surrounding the channel. The ion channel formed by the molecules of compound **47** exists in the open state for a long time (Fig. 29).

On passing from compound **45** to compound **47**, the electrical conductance increases by 60%, but the cation/anion selectivity decreases simultaneously by 60%: the $P_{\text{K}^+}/P_{\text{Cl}^-}$ ratio decreases from 20 to 8. These changes attest to the formation of a more hydrophilic medium at the centre of the pore when steroidal fragments are used as side groups. The Na^+ and K^+ selectivities found for the channels based on calix[4]resorcinarenes **45** and **47** do not differ much, $P_{\text{K}^+}/P_{\text{Na}^+} = 3$ (for channel **45**) and 2.8 (for channel **47**).

The ion channels constructed from calix[4]resorcinarenes proved to be appropriate models for investigating the structure–function relationship in ion channels, as they exhibit one conductance level and the tail section can be varied. It should be noted that compound **47** has certain advantages over compound **45**, because the steroidal tail stabilises the open state of the channel

and promotes modification of the hydrophilic pore of the channel without a change in the general structure, which is confirmed by the values of conductance and selectivity of this channel with respect to cations.

A new approach to the design of ion channels on the basis of nanotubular structures has been developed by chemists from Kazan.^{97–100} It is based on self-stacking of functionalised calix[4]arenes through specific interactions (mainly, hydrogen bonding) between groups appropriately oriented in space. A series of amphiphilic organophosphorus calix[4]resorcinarenes self-assembled due to the presence of groups, linked to each other by strong hydrogen bonds, on the lower and upper rims of the macrocycle have been synthesised. An original method for the synthesis of calix[4]resorcinarenes **48a–e**, containing dialkoxy-

R = Et (a), Pr^n (b), Pr^i (c), Bu^n (d), Bu^i (e).

phosphoryl groups on the lower rim has been proposed.⁹⁹ Partial hydrolysis of these compounds yielded phosphonic monoesters **49a–e**.

Studies of self-aggregation of compounds **49a–e** in deuteriochloroform performed by 2D ¹H NMR techniques (NOESY and ROESY) confirmed the formation of tubular aggregates due to head-to-tail association of molecules in solution. This is also indicated by the presence of cross-peaks between the hydrogen atoms of the alkyl groups of the phosphorus fragments located on the lower rim of the macrocycle and the aromatic hydrogen atom located between two hydroxy groups on the upper rim (marked by arrows).

2. Calix[4]arene tubes as a new class of selective potassium ionophores

Determination of the structure of the potassium channel from *Streptomyces lividans* encouraged researchers to study the structural features of ion channels by using synthetic mimetics. Although the known synthetic receptors for K⁺ cations are rather good, they still do not demonstrate sufficient selectivity. High selectivity was attained by Beer and co-workers.¹⁰¹ They synthesised a new class of cryptand-like ionophores **50–58** derived from the biscalix[4]arene structure. Compounds **50–58** are composed of two calixarene fragments connected by four ethylene groups located on the lower rim. The ion channels based on these compounds show high selectivity for K⁺ cations over other Group I metal cations and Ba²⁺ cations.

50: R¹ = R² = R³ = Bu^t; **51:** R¹ = R² = R³ = Oct^t;
52: R¹ = R² = R³ = H; **53:** R¹ = R² = H, R³ = Bu^t;
54: R¹ = R² = Oct^t, R³ = Bu^t; **55:** R¹ = R² = Prⁱ, R³ = Bu^t;
56: R¹ = R² = Ph, R³ = Bu^t; **57:** R¹ = R² = Oct^t, R³ = H;
58: R¹ = Bu^t, R² = R³ = H.

Two calixarene fragments connected by four ethylene spacers provide a rigid ensemble of eight electron-donating oxygen atoms for complexation with the metal. The calixarene fragments endow the structure with a filter restricting the size of the incoming cations, similar to the tyrosine filter which exists in the cell potassium channels.

Variation of substituents on the upper rim ensures fine adjustment of the rate of K⁺ capture by the calixarene fragment; this was evaluated using NMR data on the conformational changes during binding. The selectivity of complex formation by compounds **50–58** with K⁺ was demonstrated by NMR and electro-spray mass spectrometry. According to X-ray diffraction data (Fig. 30), the potassium ion in compound **50** is localised at the centre of a partially flattened cube formed by oxygen atoms, the K–O distances varying from 2.759(6) to 2.809(6) Å. The cone cavities contain two methanol molecules.

For elucidating the influence of the nature of the counter-ion on binding of the K⁺ cation, complexation of compound **50** with a number of potassium salts has been studied. Substantial differ-

Figure 30. Structure of the crystalline complex of calix[4]arene **50** with K⁺.

ences in binding of the K⁺ cation were found. In particular, the complexation was most efficient with the iodide, hexafluorophosphate, benzoate and triflate anions present as counter-ions. The least pronounced or even zero binding was found for the nitrate, perchlorate and picrate anions. A competitive experiment for binding of the potassium cations by compound **50** and by [2.2.2]cryptand showed that the complex with the calix[4]arene tube **50** is exceptionally stable, whereas in the case of cryptand, 28% of potassium ions remain free after 15 h.

The selectivity of complexation of calix[4]arene tubes **50–58** with the potassium cation over other alkali metal cations and Ba²⁺ in a chloroform–methanol mixture (4 : 1) was determined at a 20-fold excess of Na⁺, Rb⁺, K⁺, Cs⁺, and Ba²⁺ iodides. Only K⁺ cations are bound by any of compounds **52–58**. Nanotube **50** binds less than 5% of Rb⁺, and tube **51** showed a 10% binding of Na⁺ cations after 48 h; over the same period of time, these compounds bind 100% of potassium. Thus, calix[4]arene tubes are highly selective for potassium cation and surpass in selectivity ionophores based on calix[4]crowns, which, despite the Na⁺/K⁺ selectivity, still capture substantial amounts of Rb⁺ cations.

Competitive complexation has also been studied by electro-spray mass spectrometry. All spectra of equimolar mixtures of compounds exhibited peaks only for the potassium complexes [M + K⁺] and [M + K⁺ + 2 H₂O]. Even in the case where the concentration of K⁺ decreased to 2.5 μmol litre^{−1} and the concentrations of competing ions were below 10 μmol litre^{−1}, the mass spectrum displayed the presence of only potassium-containing complexes, which proves substantial K⁺ selectivity of all of the calix[4]arene tubes.

In order to clarify how the K⁺ cation enters the calix[4]arene tube, molecular modelling of this process was performed. Two routes are possible for the potassium cations to flow through the tube, namely (i) the axial route where the cation passes the calixarene filter toward the polyether binding sites and (ii) the equatorial route where the cation is coordinated directly to groups of the cryptand-like binding sites. First, the influence of substituents occurring on the upper rim of the macrocycle (H, Bu^t, Oct^t, OH) was studied. It was found that the *tert*-butyl groups play an important role in the complexation through a change in the conformation of calix[4]arene tubes, which does not take place in the presence of sterically crowded *tert*-octyl groups, which block the *gggg*-conformation of the cone. The lack of alkyl groups on the upper rim (**52**, R¹ = R² = H) also deprives the cavity of any incentive to change the conformation.

Figure 31. Passage of a potassium cation through the macrocyclic ring of compound **59** in the 1,3-*alternate* conformation.

Data about the route travelled by the cation were obtained by molecular mechanics calculation of the energy of the cationic complex depending on the position of the potassium ion relative to the axis (along and across) of the calix[4]arene tube with a step of 0.5 Å. The flow of the cation through the *tert*-butyl groups of calix[4]arene with further movement along the axis toward the centre of the nanotube was found to be most favourable from the energy standpoint. Thus, the molecular modelling on the basis of crystallographic data confirmed that the potassium cation approaches the oxygen atoms along the axial plane of the calixarene dimer, passing through one of its lipophilic molecular cavities.

The possibility of passage of K^+ through the macrocyclic ring of thiacalix[4]arene has been confirmed experimentally by Solovieva *et al.*,¹⁰² who studied the 1:1 potassium complex (with chloride as the counter-ion) of the tetraamide derivative **59** in the 1,3-*alternate* conformation by 1D and 2D ^1H NMR spectroscopy in $CDCl_3$. They demonstrated the presence of chemical exchange between the amide fragments located on different sides of the macrocyclic plane, which are magnetically inequivalent in pairs (due to complexation with K^+). It is evident that such exchange is possible only in two cases: in the case of intramolecular migration of K^+ between the amide fragments located on different sides of the macrocyclic plane of 1,3-*alternate* **59** (Fig. 31) and upon dissociation of the complex formed on one side of the macrocycle and subsequent complexation on the other side of the macrocycle. The second route appears unlikely in nonpolar solvents ($CDCl_3$) due to the very low concentration of free ions in these solutions. Moreover, on heating in a nonpolar medium, this complex is destroyed and KCl precipitates.

3. Self-assembling nanotubes from combined calix[4]arene and guanosine fragments

It has been shown¹⁰³ that in the presence of sodium cations, calix[4]arene **60** containing guanosine fragments in the 1,3-*alternate* conformation forms self-assembling nanotubes.

It has been shown previously that telomeric DNA forms G-complexes with channels filled by the cations. The G-wires that reach 1000 nm in length can be visualised using atomic force

microscopy. This approach is based on the template self-assembly of guanosine on metal cations, in particular, in the presence of metal cations, guanosine forms a quartet with hydrogen bonds (Fig. 32 a). The cyclic G-quartet stabilised by the Na^+ or K^+ cation is capable of further self-assembly through stacking.

The Na^+ cations initiate one-dimensional association of G_4 -calix[4]arene **60** (Fig. 32 b). Calix[4]arene **60** in the 1,3-*alternate* conformation orients two orthogonal pairs of self-complementary G-nucleosides in such a way that they become capable of efficient intermolecular hydrogen bonding with neighbouring macrocycles. The process of assembling is fully reversible. The cation-template aggregation of calix[4]arene **60** can be controlled by varying the pH value and the temperature.

In the micrographs of compound **60** obtained by electron transmission microscopy, one can see extended structures about 1 μm long, which are arranged either as separate tubes or as 3 to 50 nm thick bundles of tubes. These structures are relatively straight and have no sharp turns. The thickness of separate tubes is close to the resolving power of the microscope, *i.e.*, it is about 3 nm.

Figure 32. Template self-organisation of guanosine on metal cations (a) and cation-template self-assembly of calix[4]arene **60** to form a nanotube (b).

The squares stand for the calix[4]arene in the 1,3-*alternate* conformation, ellipses are the guanosine fragments and circles show the Na^+ cation.

4. The anionic channel based on aminocalix[4]arene

Sidorov *et al.*¹⁰⁴ have studied the transport activity of the tetrabutylamide derivative of calix[4]arene in the 1,3-*alternate* conformation (compound **61**) with respect to Cl^- and HSO_4^- anions in liposomes, planar bilayer lipid membranes and cells of the HEK-293 line.

The results of ionic conductance measurements, together with ^1H NMR and X-ray diffraction data indicate that compound **61**, first, forms ion channels in bilayer membranes; second, performs ion transport through a cell membrane with a positive holding potential; third, inverts the pH inside liposomes at a concentration gradient of chloride anions; fourth, demonstrates a substantial Cl^-/SO_4^{2-} selectivity. Calix[4]arene **61**, which binds HCl and forms an ion channel in a bilayer lipid membrane, is a rare example of a synthetic nonpeptide ion channel demonstrating anion selectivity. The ability to bind HCl and the transporting activity of this compound can be explained by the three-dimensional structure and hydrophobicity of calixarene and the presence of amide side chains in the molecule. The change of any of these parameters either shifts the selectivity from the anion to the cation or deprives the molecule of the transport activity. The transport of anions by compound **61** takes place through the H^+/Cl^- symport or Cl^-/OH^- antiport. Some crystal data indicate that calix[4]arene **61** forms self-assembling channels able to transmit Cl^- anions and water molecules. In addition, compound **61** performs the voltage-dependent selective transport of Cl^- anions through the membranes of the HEK-293 cells. This opens up broad prospects for investigating compound **61** as an antibiotic capable of selective interaction with the bacterial cell.

VIII. Conclusion

It is known that cell membranes have a common structural organisation. They are constructed as phospholipid bilayers with associated membrane proteins responsible for specific functions. Some proteins function as receptors responding to an external signal by activation of a number of intracellular signal cascades, some

others are involved in the transport of ions and molecules through the cell membrane. The design of models that mimic the ion transport in biological systems is needed for the understanding of very complex membrane processes that regulate the relationship of living organisms with the environment. The research into transmembrane ion channels is among the most vigorously progressing routes of modern biochemistry, nanotechnology and supramolecular chemistry. The design of ion-molecular devices that mimic the principles of transmembrane signal transfer opens up absolutely new opportunities for the development of natural science and technology. The use of simple artificial channel-like systems representing an alternative to natural peptides and proteins would result in the development of new nano-sized structures (nanotubes, ionic wires, *etc.*) with the properties of abiotic transmembrane channels ensuring the ionic permeability in natural systems (cells). The use of such systems in biosensors is a new engineering approach to the design of sensors for detection of various substrates both *in vitro* and *in vivo*.

During the last decade, significant progress has been attained in the study of properties of artificial ion channels and the key requirements of the design have been developed rather thoroughly. Any transmembrane ion channel has contacts with both the hydrophobic core of the lipid bilayer and aqueous solutions. In this connection, the channel-forming structures should be amphiphilic. The sites of a compound or an associate that are in contact with the aqueous medium surrounding the membrane should be enriched with polar and readily ionisable functional groups and the residues in contact with the lipid chains should contain long non-polar segments whose length must be sufficient to bridge the bilayer. Thus, when designing channel-forming structures, one should bear in mind that molecules incorporated in the lipid membrane should consist of a hydrophilic head in contact with the polar environment and the non-polar tail, which is incorporated in the membrane due to hydrophobic interactions. This follows from energy principles. In addition, for binding and transport of ions, charged or polar groups must be present inside the bilayer, *i.e.*, ion channels should be polar from the inside and hydrophobic from the outside.

Two key approaches to the design of channel-forming structures can be distinguished. One approach is the creation of molecules or various ion pairs that are able to form channel-like associates upon incorporation into a phospholipid membrane. The degree of aggregation of chemical species to form a half channel or a channel depends on a large number of factors; therefore aggregates of a variety of compositions can appear in the membrane.

Most artificial ion channels switch from the closed state to the open state as a result of random aggregation processes in the lipid bilayer. Self-assembling oligomeric associates immobilised on an electrode surface and mimicking the properties of biomolecules represent the first step in the creation of new ion-molecular devices used as sensors for various types of chemical species. This equipment is needed first of all for the diagnostics and analysis of the state of the environment.

The second approach is the design of a single pore-forming molecular structure, most often, containing a macrocyclic system which can be spontaneously incorporated into the membrane. However, in the case of these structures, two mechanisms of ion transport may compete (an ion channel or an ion carrier). The molecular structures whose length is sufficient to bridge the phospholipid membranes are nano-sized. This opens up broad prospects for using such structures for miniaturisation of electronic devices.
