Abstract. Theoretical studies of the dynamics and kinetics of proton and hydrogen atom transfer processes occupy a special place in the kinetics of chemical reactions. The transition state theory is often inapplicable to these processes due to substantial quantum effects. Different approaches to the description of these reactions are discussed and compared. Calculations for a number of particular condensed-phase reactions involving proton or hydrogen atom transfer are analysed. Data of calculations of potential energy surfaces for the considered systems and the results of experimental kinetic and spectroscopic studies are presented. The bibliography includes 469 references.

I. Introduction

Proton transfer (PT) and hydrogen atom transfer (HAT) deserve special consideration in the study of chemical reactions. Due to substantial quantum effects, the transition state (TS) theory — which today forms the basis for investigations of reaction kinetics and mechanisms — is often inapplicable in these cases. The existing numerous theories of PT and HAT are complicated and diverse. This review is an attempt to consider and compare, from a unified standpoint, various approaches to the theoretical description of PT and HAT and to identify the common points and the scopes of applicability of these approaches. Without pretending to an exhaustive consideration, we endeavoured to provide a concerned reader with the main ideas and trends in the development of the research in this field. More comprehensive formulation of the outlined approaches can be found in the key references.

It should be noted that the difference between PT and HAT is largely conventional. In the limiting case, PT is an ionic heterolytic process in which the influence of the medium is crucial, whereas HAT is a radical homolytic process depending only slightly on the medium. In reality, all types of intermediate situations are encountered and it is difficult to adhere to a consistent terminology. In some cases, the use of a particular term can be contested;

however, in our opinion, this discussion does not deserve much attention.

Two factors, namely, tunnelling and effect of the medium, restrict the applicability of the TS theory and account for the exceptional position of the PT and HAT processes in the theory of chemical reactions. For consistent treatment of tunnelling, one should consider (or, more precisely, calculate) the quantum-dynamic evolution of the reaction subsystem on a multidimensional potential energy surface (PES). The reaction rate constant is obtained by statistical averaging of the results of this calculation. An adequate allowance for the medium implies that a very large number (hundreds or even thousands) of degrees of freedom for particles surrounding the reaction subsystem should be included in this dynamic investigation. Taking into account simultaneously both factors mentioned above constitutes the essence of the dynamic theory of chemical reactions in the condensed phase as a modern line of research in theoretical chemical physics.

In practice, the stringent requirements outlined above can be markedly released, in particular, by using simplified models for tunnelling transitions and by decreasing the number of additional degrees of freedom interacting with the tunnelling coordinate to tens or even less. Nevertheless, in recent years, record-breaking computations have been carried out (they are described in this review) which attempted to minimise the simplifying assumptions and their consequences. However, real objects (*e.g.*, reactions in enzymes) are so complicated that even these calculations are simplified models.

In any case, the major requirement of explicit inclusion of the tunnelling dynamics into the mechanism of the elementary process remains valid. This feature distinguishes the studies discussed in this review from the numerous studies whose authors attempted to consider the PT and HAT reactions on the basis of the traditional TS theory, *i.e.*, using a quasi-equilibrium statistical rate constant. As the premise, we accepted the statement that interpretation of the kinetics and the mechanism of these reactions based only on the language of the energetic and topographic characteristics of PES such as the height of the potential barrier and the reaction coordinate is inadequate and recedes to the background.

The material presented here is arranged in the following way. First, the main concepts of the PT and HAT dynamics in the condensed phase are considered. They were formulated in the 1970s–1980s and they are still being developed and refined. This is followed by applications of the theory to calculations of particular systems carried out during the last 10–15 years. Many of the publications cited present also original theoretical

developments; therefore, the subdivision into ‘theory’ and ‘applications’ is not fully consistent.

Simpler gas-phase reactions have been investigated much more extensively than reactions in the condensed phase. The relevant studies are not covered systematically but references to earlier reviews and monographs are given. However, since the understanding of the tunnelling dynamics of gas-phase reactions should precede any discussion of tunnelling in the liquid or solid phase or in biological objects, the key studies dealing with the theory of gas-phase PT and HAT are considered as examples.

Since we selected studies focused on the dynamics of an elementary process, the quantum-chemical calculations of PES (even the highest-level ones) are not of interest by themselves in this context. A summary of such calculations (the most significant in our opinion) is included as reference data together with experimental results. The experimental works presented in brief represent mainly investigations of the kinetics and mechanisms of PT and HAT by spectroscopy (NMR, UV, IR, radiospectroscopy, *etc.*). These studies provide the factual information necessary for the development and testing of the theoretical models discussed in the review.

II. Methods for the theoretical description of proton and hydrogen atom transfer

1. Potential energy surfaces

a. Reaction centre

Let us consider the reaction centre for PT or HAT in a simple two-mode linear model.

Here A_1 and A_2 are ‘heavy’ molecular fragments; their internal structure is not specified in detail now. The centres of gravity of particles A_1 , A_2 and H lie on the same straight line; this type of reaction is called collinear.

The dynamic behaviour of system (1) is fully described by variations of two coordinates, namely, the proton coordinate (s) measured from the centre of gravity of the whole complex (1) and the distance (R) between the heavy fragments. Figure 1 presents a typical PES $V(s, R)$ in these coordinates and cross-sections $V(s|R)$ of this surface along the coordinate s , which parametrically depend on R . For a symmetrical system ($\text{A}_1 = \text{A}_2$), the cross-sections are symmetrical. As R decreases, the double-well profiles become more gently sloping, which is accompanied by equalisation of the proton (hydrogen atom) bonds with fragments A_1 and A_2 . At the critical point R_c , the double-well potential profile turns into a single-well one. This PES topography determines the key characteristics of a PT or HAT reaction. Since one of the two equilibrium configurations of complex (1) is the initial state, either a PES with potential barriers with different heights (if $R_e > R_c$) or a barrierless PES (if $R_e < R_c$) appear, depending on the equilibrium distance R_e . In the former case, the initial equilibrium configuration is markedly asymmetrical ($\text{A}_1 - \text{H} \cdots \text{A}_2$), while in the latter case, it is nearly symmetrical ($\text{A}_1 \cdots \text{H} \cdots \text{A}_2$), even when the fragments A_1 and A_2 are different. In symmetrical systems, a combination of asymmetrical configurations of the reactants and products gives rise to a symmetrical double-well profile. The position of the top of the barrier, *i.e.*, TS (designated by $R^\ddagger$ in the axis R) cannot be smaller than R_c ($R^\ddagger \geq R_c$). The R_e and R_c values substantially depend on the nature of fragments A_1 and A_2 , most of all, their terminal atoms, which are linked to the proton or hydrogen atom that is transferred.¹ The distance between the terminal atoms (rather than between the centres of gravity of fragments A_1 and A_2) is usually taken as the coordinate R . For bimolecular reactions of non-polar reactants in the gas phase (for example, $\text{C} \cdots \text{H} \cdots \text{C}$), the R_e distance is great, $R_e \gg R_c$ (which corresponds to a van der Waals complex) and the barrier is usually

Figure 1. Typical symmetrical PES for PT or HAT reaction in the simplest two-mode collinear model;

(a) general view of the PES with isoenergy contour lines; closed loops (1–4) are isoenergy contour lines in arbitrary units; (b) PES cross-sections along the coordinate s for different R values; $R = R_e$ (reactants and products), $R = R^\ddagger$ (transition state) and $R = R_c$ (critical point). In the given case, $R_e < R^\ddagger$. The projections of the cross-sections on the R, s plane are shown by a dashed line in Fig. 1a.

rather high. Conversely, in the case of systems which tend to form strong and medium-strength hydrogen bonds (for example, the $\text{O} \cdots \text{H} \cdots \text{O}$ bonds in the condensed phase), the inequality $R_e < R_c$ usually holds, and the PES is often a single two-dimensional potential well. In this case, one cannot speak about a PT or HAT reaction. Particular examples of different possible situations are presented in Table 1. They mainly refer to electrically neutral systems; charged systems (FHF^- , H_3O_2^+ , *etc.*) with hydrogen bonds normally tend to form single-well PES.¹¹

In unimolecular processes, the reaction centre (1) is a fragment of an integrated, more or less rigid molecular structure. The equilibrium distance R_e stipulated by the structure is usually shorter than the R_e value between the reaction centres of the same type in bimolecular reactions. This is due to the fact that the $\text{A}_1 \cdots \text{H} \cdots \text{A}_2$ fragment in systems with intramolecular hydrogen bonds is non-linear. A typical example of the latter type is a *cis*-enol form of a β -dicarbonyl compound, for example, malonaldehyde or acetylacetone,^{12,13} which are six-membered chelate rings with an intramolecular hydrogen bond. The R_e values for these

Note. Systems with intramolecular PT or HAT were not considered because in this case, the triatomic $A_1-H\cdots A_2$ fragment is essentially non-linear. ^a No direct estimate for the R_c value is known; therefore, the corresponding $R^\ddagger$ values are given, which are close to R_c . ^b The R_c value was taken from the first reference and R_e is from the second reference.

systems are much shorter than the corresponding value for the O—H $\cdots$ O fragment presented in Table 1. The rigid structure of the environment ('cage effect') is probably responsible for acceleration of enzymic PT reactions.^{14,15} In this case, the structure of the reaction centre is dictated by the architecture of the protein globule of the enzyme, while R_e is sufficiently small to lower the reaction barrier to a plausible value.

Thus, the potential relief depends appreciably on the distance between the chemically non-bonded heavy atoms, which accounts for stringent requirements to the accuracy of quantum-chemical methods used to calculate the PES. Slight errors in the estimation of R_e can change the calculated height of the potential barrier (defined as the difference between the energies of the saddle point and the reactant minimum on the PES) and can appreciably distort the potential relief that controls the reaction event.¹⁶ On the other hand, in constructing semiempirical PES, it is expedient to consider the R_e value as a control parameter whose variation allows one to reproduce a required potential relief.¹⁷

b. Rearrangement of the medium and classification of modes

Intramolecular and intermolecular relaxation. In most cases, the simplest two-mode model (1) does not provide an adequate description of PT. As an example, we consider the PT in acetylacetone molecule.

Here $R_e = 2.535 \text{ \AA}$ (see Ref. 18). According to the above simplest model, this geometry is expected to produce a single-well symmetrical equilibrium configuration of the O $\cdots$ H $\cdots$ O hydrogen bond. In reality, acetylacetone is an example of a system having a potential barrier, although it is relatively low: $\Delta V^\ddagger = 2.5 \text{ kcal mol}^{-1}$ (see Ref. 19). This 'classical' barrier disappears when the quantum zero-point vibrations of the H atom are taken into account.¹⁹ The tendency for the formation of an asymmetrical structure by the molecule is enhanced by rearrangement of its bond lengths and bond angles around the reaction centre caused by the variation of the proton coordinate s (Table 2). In the literature, this effect is often referred to as 'environment reorgan-

Table 2. Bond lengths (Å) and O $\cdots$ H—O angles (deg) for a fragment of the cyclic acetylacetone structure and the structure corresponding to the TS of the intramolecular PT reaction found by the Möller–Plesset *ab initio* calculations¹⁹ (MP2/D95 + + **).

Parameter	Cyclic enol form ^a	TS

O $\cdots$ H—O	150.6 (137.0)	159.1

^a The values in parentheses are experimental data.¹⁸

isation'; this term has been borrowed from electron transfer theory. In this particular case, an intramolecular reorganisation is involved.

When the PT process is accompanied by a substantial change in the charge distribution and takes place in a polar solvent, there exists an alternative mechanism for stabilisation of asymmetrical structures due to solvent reorganisation: the solvation shell is adjusted to the charge distributions, which are different for the reactants and the reaction products. This situation is referred to as the 'medium reorganisation'. Proton transfer in electrically neutral systems, for example, in a conjugate acid–base system usually does not occur in the gas phase,²⁰ but readily proceeds in polar solvents,²¹ which is due to medium reorganisation.

It can be seen from the above examples that reorganisation of the surrounding of the reaction centre (both intramolecular reorganisation and that of the environment) includes simultaneous change of many degrees of freedom, *i.e.*, it is a multimodal process.

Harmonic double-well potential energy surface. The simplest pattern of multimode reorganisation corresponds to the model harmonic PES formed by two multi-dimensional paraboloids shifted relative to each other. The two-dimensional analogue of this PES is shown in Fig. 2. The reorganising modes Q are

Figure 2. Two-dimensional scheme of the reaction transition between two paraboloids; (a) two-dimensional analogue of the model harmonic PES; the paraboloid minima are located at points Q_i and Q_f ; (b) energy profile of the reactive transition (shown by a dashed line in the intersection area of two parabolic potential curves corresponding to the PES cross-section along the straight line $Q_i Q_f$). The continuous lines show splitting of two energy profiles due to anharmonic interactions.

numbered by using subscripts $v = 1, \dots, N$; for Fig. 2 a, N is equal to 2. Their equilibrium positions for the reactants (subscript i) and products (subscript f) will be denoted by Q_{iv} and Q_{fv} . The description is simplified if the paraboloids are identical, i.e., the reactants and the products are characterised by identical systems of vibration frequencies and forms of normal vibrations (modes).

Let us denote the vectors with the components Q_{iv} and Q_{fv} by (Q_i) and (Q_f) and then form the vector

$$[Q(\lambda)] = (Q_i) + \lambda[(Q_f) - (Q_i)]; 0 \leq \lambda \leq 1, \quad (2)$$

which describes the change of the modes along the straight line connecting the projections (Q_i) and (Q_f) of the minima of the two paraboloids onto the $Q_1 Q_2$ plane (Fig. 2 a). Then the parameter λ can be considered as the ‘reaction coordinate’. If the paraboloids are identical, they intersect along some straight line in the coordinate plane. In this straight line (or in a planar hypersurface if $N > 2$), the PES cross-section passes through a minimum, which is characterised by a set of coordinates: $Q^\# = (Q_1^\#, \dots, Q_N^\#)$, the point $Q^\#$ lies in straight line (2). The cross-section of the PES along the coordinate (2) is shown in Fig. 2 b. At the intersection point of the parabolic potential curves, the reaction coordinate is found as

$$\lambda = \frac{1}{2} \left(1 + \frac{\Delta V}{E_r} \right), \quad (3)$$

where ΔV is the difference between the energies corresponding to the reactant and product minima

$$\Delta V = V_f - V_i, \quad (4)$$

E_r is the reorganisation energy characterising the energy consumption for transition from the reactant minimum to the product minimum; E_r is an additive relative to the contributions of separate modes characterised by masses m_v and frequencies ω_v :

$$E_r = \sum_v E_{rv}, \quad (5)$$

$$E_{rv} = \frac{m_v \omega_v^2}{2} (Q_{fv} - Q_{iv})^2.$$

The height of the potential barrier in this PES obeys the Marcus formula

$$\Delta V^\# = \frac{(E_r + \Delta V)^2}{4E_r}. \quad (6)$$

This PES model underlies most of the theories of multimode processes. Although the model is idealised, it can be useful for a qualitative discussion. Real PES are highly anharmonic,^{22–24} and the contributions of separate modes to the potential barrier cannot be distinguished unambiguously, as would be the case according to relations (5) and (6). There exist semiempirical interpolation-type analytical formulae, which allow one to describe the anharmonic PES and the free energy surface (FES) for PT in terms of a set of characteristic parameters.^{25, 26}

Combination of reorganisation and promoting modes. It is of interest to analyse how the allowance for reorganisation modes modifies the two-mode model described in Section II.1 a.^{27–31} For this purpose, we consider three points, (Q_i) , $(Q^\#)$ and (Q_f) , on the reaction coordinate Q . Even for a symmetrical system ($A_1 = A_2$), by fixing (Q) at the points (Q_i) and (Q_f) , we obtain asymmetrical potential energy profiles along the proton coordinate s (here we do not consider the dependence on R). This is shown schematically in Fig. 3. When $(Q) = (Q^\#)$, the $V(s)$ profile is symmetrical or nearly symmetrical even for the systems with dissimilar heavy fragments A_1 and A_2 . As noted above, in a two-mode double-well symmetrical system, the potential barrier is often relatively low and

Figure 3. Potential curves of the reaction system along the proton coordinate s with allowance for reorganisation modes; (a, d) reactant and product regions, respectively; (b, c) TS region.

transitions between the wells occur rapidly. The asymmetry brought about by the relaxation of reorganisation modes hinders the transitions and thus contributes to fixing of the reactant and product configurations. In the case of bimolecular gas-phase reactions, this fixing is possible even in a two-mode model due to the spatial separation of the reactants and products along the reaction coordinate R . In the condensed phase, the reactants and products are in relatively close contact [the R_e distance is about the van der Waals distance in complex (1)]. Therefore, stabilisation of the initial and final states owing to relaxation of the environment modes acquires a crucial role.

In view of the foregoing, the following, frequently used classification of inter- and intramolecular degrees of freedom involved in PT processes can be proposed. First, the proton coordinate s is considered, which is called the reaction mode. Second, those modes are considered that do not change (or almost do not change) in the initial and final states but appreciably change in the TS and thus modify the height of the potential barrier. There modes are called promoting. A typical example is the R coordinate; other promoting modes are discussed below. Finally, some modes change their equilibrium positions on passing from the reactant configuration to the product configuration. They are referred to as reorganisation modes.

Naturally, this classification is not universal. However, it often reflects adequately the essential features of the PT process and is widely used in model considerations. Note that the term ‘reaction mode’, introduced above for the coordinate s does not necessarily mean the ‘reaction coordinate’. For real anharmonic PES, the mode s interacts with other reaction modes and, generally, it is not an independent motion in the region of the TS, as it would be the case for a strictly defined reaction coordinate. The mode s may be identified with the reaction coordinate only in terms of the simplest models; this terminology is often encountered in the literature and below it is used in some cases without special reservations.

In reality, the reaction mode for PT and HAT is always a combination of several simple modes. This is illustrated, in particular, by the following examples. According to the data of femtosecond spectroscopy, the rate of PT for the lower singlet electronically excited state of methyl salicylate, 2-(2'-hydroxyphenyl)benzothiazole and 1,8-dihydroxyanthraquinone is 50–60 fs⁻¹ in the gas phase^{32–34} and 170 fs⁻¹ in aprotic solvents.³⁵ The reaction coordinate for the PT includes, as a first approximation, the coordinate of the OH stretching vibrations and the coordinate of the O...H...O out-of-plane vibration.³² The periods of vibration are 13 fs for the OH bond and 190 fs for the O...H...O fragment. These vibration modes interact appreciably with one another, their relative contributions to the reaction mode being dependent on the process conditions. In systems with equivalent initial and final states, PT is manifested as tunnel splitting of the ground vibration state.^{36–38} The tunnel splittings have been measured for not only the ground state but for a number of vibrationally excited states for some systems in the lower singlet electronically excited state.^{39–42} A sharp increase in the tunnel splitting was observed upon selective excitation of particular low-frequency vibrations.^{39, 40} In the case of tropolone, this active vibrational mode was the displacement of heavy atoms of the O...H...O fragment,⁴¹ and in the case of azaindole dimer, an intermolecular stretching vibration.³⁹ Data of *ab initio* calculations of the PES for intra- and intermolecular PT in various systems^{22–24, 43} confirm the experimental results.

2. Dynamics and kinetics

a. Reactions with a low potential barrier

Quantisation of the reaction mode. A key feature of PT reactions is a quantal nature of, at least, one essential mode, namely, the reaction mode s . Let ω_0 be the characteristic frequency of the mode s and $\hbar\omega_0/k_B T \gg 1$. In this case, the traditional description of the kinetics using the classical TS theory is inapplicable. Due to this fact, theoretical description of PT is a difficult task. Never-

theless, the classical approach can be used in the modified form if the height of the barrier $\Delta V^\ddagger$ on the PES is sufficiently low for the reactant well to contain only one quantum level with a frequency close to ω_0 :

$$\frac{\hbar\omega_0}{\Delta V^\ddagger} \lesssim 1. \quad (7)$$

The quantum motion along s occurs much faster than along other modes ($\omega_0 \gg \omega_i$, where ω_i are other eigenfrequencies of the system); this allows one to use the double (along both the electronic and proton coordinates) adiabatic approximation. Different modifications of this model with a classical description of the promoting mode R have been discussed.^{29–31} The Schrödinger equation for the mode s has the form

$$h_s \varphi_n(s) = \varepsilon_n \varphi_n(s), \quad (8)$$

where h_s is a Hamiltonian,

$$h_s = -\frac{\hbar^2}{2m_0} \frac{\partial^2}{\partial s^2} + V(s|R, Q). \quad (9)$$

Here, m_0 is the corresponding mass, and the potential coincides with the full PES $V(s, R, Q)$. The notation of this function in Eqn (9) emphasises that it follows a parametric dependence on the R, Q coordinates of the heavy atoms. The eigenvalues and eigenfunctions in Eqn (8) depend on R and Q . In particular, the energies $\varepsilon_n(R, Q)$ are the PES (electron–proton PES) for the coordinates R, Q . In the adiabatic limit, it is sufficient to consider the ground state ($n = 1$), i.e., the PES $\varepsilon_1(R, Q)$. In many cases, the motion of heavy atoms in such a potential can be regarded to be classical and described using the TS theory in one or another variant.

A similar approximation is widely used in hydrogen bond spectroscopy.^{44, 45} It is called the Born–Oppenheimer separation of motions of light and heavy nuclei⁴⁶ or the adiabatic separation of vibrational variables.⁴⁷ A significant feature of the calculations of the vibrational spectrum of the $A_1-H\cdots A_2$ fragment is the quantum description of the promoting mode R .^{48–53}

Evolution of heavy modes. The specificity of using the double adiabatic approximation lies in the fact that the reaction coordinate s , natural for a chemist, is excluded from dynamic consideration. The role of the reaction coordinate is played by one of the reorganisation modes Q . For example, for low-barrier PT in polar media, the collective variable $Q = y$, describing the behaviour of the medium, is used as the new reaction coordinate. According to this model, the motion along y determines the reaction dynamics and kinetics. In the simplest case, the mode R is excluded from consideration, and the equation of motion reduces to the diffusion equation for the distribution function $n(y, t)$, which determines the probability density for realisation of various y values, depending on time t

$$\frac{\partial n}{\partial t} = D \frac{\partial^2 n}{\partial y^2} - \frac{D}{k_B T} \frac{\partial}{\partial y} \left(n \frac{\partial U_a}{\partial y} \right), \quad (10)$$

where D is the corresponding diffusion coefficient, and the potential profile $U_a(y)$ should be regarded as the cross-section of the electron–proton PES (Fig. 4).[†] The subscript ‘a’ means that the potential is adiabatic, i.e., double-well. (Further, an alternative description using diabatic, single-well potentials is also discussed.) The rate constant for PT can be estimated in terms of the Kramers approximation.^{54, 55}

$$k = A \exp \left(-\frac{\Delta U^\ddagger}{k_B T} \right), \quad (11)$$

[†] From here on, one-dimensional potential profiles present in the diffusion equations are denoted by the letter U .

Figure 4. Adiabatic potential profile $U_a(y)$ obtained as a cross-section of the electron-proton PES and used in the Kramers equation.

where

$$A = \frac{(\mu_0 \mu^\#)^{1/2}}{\pi \gamma},$$

$\Delta U^\#$ is the height of the potential barrier on the electron–proton PES, μ_0 and $-\mu^\#$ are the force constants of the potential $U_a(y)$ in the bottom of the reactant well and on the top of the barrier. The friction coefficient γ is related to the diffusion coefficient D by the Einstein relation

$$D = \frac{k_B T}{\gamma}. \quad (12)$$

The Arrhenius dependence (11) with an activation energy equal to the height of the potential barrier is an immutable indication of the classical equilibrium kinetics. In more complex cases, the expression for the pre-exponential factor is modified depending on the particular dynamic model accepted for description of heavy modes instead of the simplest diffusion equation (10). For example, the common one-dimensional Kramers stochastic model proceeds from the Langevin equation

$$m_y \ddot{y} + \gamma \dot{y} + \frac{\partial U_a}{\partial y} = \text{GRF}, \quad (13)$$

where m_y is the mass corresponding to the collective mode of the medium, and GRF stands for the Gaussian random force, which gives rise to fluctuations of the variable y and is responsible for its diffusion motion. If the γ/m_y ratio is not very low, Eqn (13) corresponds to the Arrhenius rate constant (11) with the pre-exponential factor

$$A = \left\{ \left[\left(\frac{\gamma}{2m_y} \right)^2 + (\omega^\#)^2 \right]^{1/2} - \frac{\gamma}{2m_y} \right\} \left(\frac{\mu_0}{\mu^\#} \right)^{1/2}, \quad (14)$$

where $\omega^\#$ is a characteristic frequency on the top of the barrier [that is, $i\omega^\#$ is the decay frequency, $m_y(\omega^\#)^2 = \mu^\#$]. This well-known Kramers formula provides the pre-exponential factor in Eqn (11) if $\gamma/(2m_y\omega^\#) \gg 1$, i.e., in the limiting case of great friction. Further correction of the dynamic description results in a stochastic equation with a time-dependent friction coefficient (generalised Langevin equation). This equation is applicable to multimodal systems. The rate constant is calculated in terms of the Kramers–Grote–Hynes approximation (KGH).^{54–56} This procedure is briefly described in Supplement I. The standard multidimensional TS theory can also be used; with allowance made consistently for the medium modes, it is equivalent to the KGH theory.^{54–60} Finally, direct calculation of the reaction rate constant by classical molecular dynamics (MD) is also possible,^{61,62} for example, by the reaction flux method.⁵⁵

Electron–proton PES.^{63–65} A typical electron–proton PES depending on two heavy coordinates, the medium coordinate y and the promoting mode R , is shown in Fig. 5. The direction of the reaction coordinate at the saddle point coincides with the direction of the mode y . The rate constant can be estimated within the framework of the multi-dimensional KGH theory. Estimation of

Figure 5. Electron-proton PES $\varepsilon_1(y, R)$ for the ground state of the reaction system $\text{ACH}_3 + ^-\text{CH}_2\text{A} \rightarrow \text{ACH}_2^- + \text{CH}_3\text{A}$; $\text{A} = \text{C}_6\text{H}_5$.⁶⁴ Isoenergy contour lines are spaced by 1 kcal mol^{−1}. The reactant and product minima correspond to the energy −107.3 kcal mol^{−1}.

the rate constant in terms of the stochastic (or the equivalent diffusion) theory requires the knowledge of dynamic characteristics of the solvent collective mode y such as the mass m_y , the friction or diffusion coefficient, *etc.* They can be found using semiempirical continuum models of the solvent.^{65–69} The most consistent and direct way of calculating these values is based on MD.^{61–63}

To conclude, note that the classical description of the promoting mode R accepted in the multidimensional TS theory, KGH theory and classical MD calculations is an approximation which often does not correspond to the real situation.^{70–77} The quantum treatment of R is discussed in Section II.4.c.

b. Proton tunnelling as a non-adiabatic transition

Adiabatic and non-adiabatic models of reaction transitions. Section II.2.a considered the adiabatic PT model. In this context, the term ‘adiabatic’ means that a double-well potential V appears in the Schrödinger equation (8). It corresponds to the lower electronic adiabatic PES; in more detailed notation,

$$V = V_{a1}(s, R, Q).$$

The next PES $V_{a2}(s, R, Q)$ corresponds to the first electronically excited state of the system. This is a single-well surface, its minimum being close to the top of the barrier of the lower PES, which corresponds to the ground state. The profiles of these two adiabatic PES are shown in Fig. 2 b by continuous lines.

In an alternative description, the potentials V_{a1} and V_{a2} are considered as combinations of the potentials V_{d1} and V_{d2} , corresponding to single-well surfaces, which are called ‘diabatic’. The theory of this transformation was outlined in several publications.^{78–81} The diabatic and adiabatic PES are sketched in Fig. 2 b. They almost coincide near the minima. The error of the diabatic description is the highest near the TS, i.e., near the barrier top of the lower adiabatic surface or, what is the same, around the intersection of the diabatic surfaces (shown by dashed lines).

Equations (8) and (9) describe the transition from the electronic PES $V_{a1}(s, R, Q)$ to the electron–proton PES $\varepsilon_1(R, Q)$. In the same way, by substituting $V_{a2}(s, R, Q)$ into Hamiltonian (9), one can obtain the electron–proton PES $\varepsilon_2(R, Q)$ for the electron–

proton excited state. Like the initial electronic PES, ε_1 has two wells, while ε_2 has one well. These surfaces are adiabatic, and they can be transformed into two single-well diabatic electron – proton PES, which we designated by $e_1(R, Q)$ and $e_2(R, Q)$. By substituting diabatic electronic potentials, instead of V , into Hamiltonian (9), we obtain two diabatic Schrödinger equations similar to Eqn (8). The surfaces e_1 and e_2 correspond to their eigenvalues. The corresponding eigenfunctions, which we designate by $\chi_1(s)$ and $\chi_2(s)$, are referred to as diabatic states. Unlike adiabatic states $\varphi_n(s)$ ($n = 1, 2$) in Eqn (8), these are always localised in their diabatic potential wells. The difference between the lower adiabatic potential and the combination of low-energy fragments of diabatic potentials (which is substantial near the TS) is considered to be responsible for the transitions between the diabatic states χ_1 and χ_2 . These transitions, called non-adiabatic, are identified with a PT or HAT process. For reactions with high barriers, splitting of

the adiabatic potentials is extremely small (Fig. 6) and the intensity of the transitions is very low.

Two-level kinetic equation. The scenario of a PT reaction described in Section II.2.a corresponds to the situation shown in Fig. 6a. For a low-barrier potential V_{a1} , the lower adiabatic level ε_1 is located near the top of the barrier and the next adiabatic level ε_2 is located much higher [$\Delta > 1000 \text{ cm}^{-1}$ (see Ref. 82)], therefore, its population is negligibly low. In this case, it is sufficient to consider the PES $\varepsilon_1(R, Q)$.

The alternative situation shown in Fig. 6b with a high barrier and a clearly defined double-well-potential relief requires a different description. Despite the fact that the proton motion in the wells remains fast, the probability of the inter-well tunnelling transition P_{12} is low: $P_{12} \ll 1$. If it is low enough, the transition between the diabatic states $\chi_1(s)$ and $\chi_2(s)$ becomes the rate-determining step of the process. In the two-level approximation, the localised diabatic wave functions $\chi_1(s)$ and $\chi_2(s)$ are linear combinations of the adiabatic functions φ_1, φ_2 . The variable s becomes the reaction coordinate, although of the quantum type. It is represented by two diabatic states with the PES $e_1(R, y)$ and $e_2(R, y)$ (we have replaced Q by y) and their cross-sections $U_{d1}(y)$ and $U_{d2}(y)$.

The limiting cases illustrated in Fig. 6 correspond to two limiting mechanisms of PT, namely, the classical motion of heavy atoms over the adiabatic surface $\varepsilon_1(R, y)$ with the cross-section $U_{a1}(y)$ and a quantum non-adiabatic transition between the PES $e_1(R, y)$ and $e_2(R, y)$ with the cross-sections $U_{d1}(y)$ and $U_{d2}(y)$. Now we consider the competition between these reaction mechanisms at a qualitative level using a simple one-dimensional model ($Q = y$ is the medium coordinate, and promoting mode R is excluded from consideration). The equations of motion for the populations $n_1(y, t)$ and $n_2(y, t)$ of the diabatic states have the form

$$\frac{\partial n_1}{\partial t} = D \left[\frac{\partial^2 n_1}{\partial y^2} - \frac{1}{k_B T} \frac{\partial}{\partial y} \left(n_1 \frac{\partial U_{d1}}{\partial y} \right) \right] + \langle \omega \rangle (n_2 - n_1), \quad (15)$$

$$\frac{\partial n_2}{\partial t} = D \left[\frac{\partial^2 n_2}{\partial y^2} - \frac{1}{k_B T} \frac{\partial}{\partial y} \left(n_2 \frac{\partial U_{d2}}{\partial y} \right) \right] + \langle \omega \rangle (n_1 - n_2),$$

where $\langle \omega \rangle$ is the average frequency of interlevel transitions. In the standard theory of non-adiabatic transitions with a linear approximation of the diabatic energy levels (terms) in the region of their intersection (see Fig. 6b), it is usually assumed that^{83–87}

$$\langle \omega \rangle = \frac{2\pi V_{12}^2}{\hbar |\Delta F|} \delta(y - y_0), \quad (16)$$

where V_{12} is the matrix element of the interaction between terms; $\Delta F = F_2 - F_1$, where $F_n = -\partial U_{dn}/\partial y$, ($n = 1, 2$) are forces acting on the system at the intersection point $y = y_0$; $\delta(y - y_0)$ designates the Dirac δ -function.

According to this (local) transition model, the expression for the probability of transition between the terms is formally similar to the Landau–Zener approximation⁸⁸

$$P_{12} = \frac{2\pi V_{12}^2}{\hbar |\Delta F| \dot{y}}. \quad (17)$$

The value

$$j_{\text{na}} = \frac{2\pi V_{12}^2}{\hbar |\Delta F|} \exp\left(-\frac{U_c - U_e}{k_B T}\right) = |y| P_{12} \exp\left(-\frac{U_c - U_e}{k_B T}\right) \quad (18)$$

is a non-adiabatic diffusion flux at the point y_0 ,⁸⁹ $U_c = U_{d1}(y_0) = U_{d2}(y_0)$, and U_e is the energy in the reactant minimum.

Turning back to the adiabatic description in terms of the diffusion equation (10), we can express an analogous adiabatic flux near the top of the barrier of the lower PES U_{a1} (see Fig. 4). For the case where the barrier $\Delta U^\ddagger$ on the initial electronic PES is

Figure 6. Double-well potential profiles for the two limiting mechanisms of PT and HAT reactions; only the TS region is given; (a) adiabatic energy profiles for a low-barrier reaction, see Fig. 5 ($A = \text{C}_6\text{H}_5$); $U^\ddagger$ is the saddle-point energy for the ground state of the reaction system, Δ is the splitting of PES in the saddle point; (b) diabatic energy profiles for a high-barrier reaction, $A = \text{C}_{13}\text{H}_9$ (fluorenyl);⁶⁵ U_c is the level intersection point; the abscissa y_0 of this point is taken to have the coordinate 0.0. The lower and upper broken lines consisting of two diabatic ‘rays’ can be regarded as two adiabatic potential profiles (shown by dots). The splitting of PES is very small; therefore, $U_c = U^\ddagger$.

high and the splitting Δ is small (see Fig. 6b), this potential profile corresponds to a triangular potential barrier (shown by dots). For such PES, the adiabatic flux equals⁸⁹

$$j_a = \frac{D}{k_B T} \frac{|F_1||F_2|}{|F_1| + |F_2|} \exp\left(-\frac{U_c - U_e}{k_B T}\right). \quad (19)$$

A different adiabatic flux corresponds to Kramers' result (11), (14). The difference is due to the fact that the potential shown by dots in Fig 6b has a singularity (cusp) on the top and the potential in Fig. 4 is smooth. Fluxes (18) and (19) are found by solution of diffusion equation (15) in the limiting cases of weak and strong coupling between the levels. In the intermediate kinetic regime, the flux j can be expressed as the ratio of the non-adiabatic to adiabatic fluxes⁸⁹

$$j = \frac{j_{na}}{(1 + j_{na}/j_a)}. \quad (20)$$

The corresponding rate constant is found from Eqn (20) by division by the partition function of the reaction system calculated within the reactant well.

The ratio j_{na}/j_a can be estimated by taking into account the fact that, within the model of non-adiabatic transition with linear intersecting diabatic energy levels,^{65, 79–81}

$$V_{12} = \frac{1}{2} \Delta; \quad (21)$$

$$|\Delta F| = |J| \Delta.$$

Here Δ and J are characteristics of adiabatic levels:

$$\Delta = \varepsilon_2(y_0) - \varepsilon_1(y_0),$$

$$J = \left\langle \varphi_2 \left| \frac{\partial}{\partial R} \right| \varphi_1 \right\rangle_{y_0} = \Delta^{-1} \left\langle \varphi_2 \left| \frac{\partial \varepsilon_1}{\partial y} \right| \varphi_1 \right\rangle_{y_0}, \quad (22)$$

i.e., Δ is the minimum splitting of the adiabatic levels and J is the measure of their interaction calculated for $y = y_0$. If the signs of the forces F_1 and F_2 are opposite, then

$$|\Delta F| = |F_2| + |F_1|.$$

Thus,

$$\frac{j_{na}}{j_a} = \frac{2\pi}{\hbar} \frac{\Delta^2}{|F_1||F_2|} \frac{k_B T}{4D} \simeq \frac{2\pi}{\hbar} \frac{k_B T}{DJ^2}. \quad (23)$$

The above approximate equality corresponds to the symmetrical case

$$|F_1| = |F_2| = \frac{1}{2} |F_1 - F_2|.$$

Competition between adiabatic and non-adiabatic mechanisms of proton transfer. It follows from Eqns (20)–(23) than the non-adiabatic kinetic mechanism of PT takes place when the splitting of the adiabatic levels is small (in this case, $U_c = U_e$). Small Δ values are typical of double-well potential profiles of the ground electronic state with a sharp relief. They give rise to electron–proton profiles with a cusp at the intersection (see Fig. 6b). For these electronic PES, tunnelling is observed, the model of non-adiabatic transitions on the electron–proton PES being a way of describing the tunnelling phenomenon. Equation (23) expresses the relative intensities of the tunnelling (non-adiabatic flux j_{na}) and activation (adiabatic flux j_a) mechanisms of proton transition. According to (23), they depend on the temperature. At the critical temperature $T = T_c$ where $j_{na}/j_a = 1$, the reaction mechanism switches. Thus, the flux ratio (23) is the key control parameter of the simplest expression for the rate constant taking into account both PT mechanisms.⁸⁷

The inclusion of the promoting mode R substantially complicates the PT description. In this case, the cross-section profile of the reaction PES depends on R (see Fig. 1a): the barrier is relatively low in the TS region ($R = R^\ddagger$); when $R \gg R^\ddagger$, the product and reactant wells become deeper, which disturbs the adiabaticity criterion (7). Hence, according to criterion (23), the transition is either adiabatic (activated, $j_{na}/j_a \gg 1$) or non-adiabatic (tunnelling, $j_{na}/j_a \ll 1$), depending on R and the temperature. In many cases, both mechanisms occur simultaneously on the same PES.⁹⁰ If the equilibrium position R_e is close to $R^\ddagger$ and (or) the temperature is relatively high, the reaction dynamics will mainly be classical. In the case of a sharp relief of the PES cross-section along the coordinate s and (or) low temperature, the reaction mainly follows the tunnelling mechanism.

3. The principles of description of the tunnelling kinetics

a. One-dimensional and quasi-one-dimensional tunnelling

Bimolecular rate constant. The character of tunnelling transitions is substantially different for the three different types of PES cross-sections $V(s)$ (Fig. 7). In the one-dimensional model of the bimolecular reaction, the states in the reactant and product regions belong to a continuum spectrum (Fig. 7a). In a quasi-classical approximation, the rate constant for this reaction is as follows:^{55, 91–94}

$$k(T) = \frac{1}{2\pi\hbar Z(T)} \int_0^\infty \exp\left(-\frac{E}{k_B T}\right) P(E) dE, \quad (24)$$

where E is the energy referred to the threshold (a minimum in the reactant region) and $P(E)$ is the quasi-classical coefficient for barrier penetration

Figure 7. Three different types (a–c) of PES cross-sections $V(s)$ for the one-dimensional reaction scheme.

The turning points a_2, a_1 bound the classically inaccessible region, while points a_3, a_2 confine the classically accessible region; ε_i is the reactant energy level, ε_f is the product energy level, Δ is the resonance misfit.

$$P(E) = \frac{1}{1 + \exp[2W(E)]}, \quad (25)$$

$$W(E) = \frac{1}{\hbar} \int_{a_2}^{a_1} \{2m_0[V(s) - E]\}^{1/2} ds.$$

The turning points a_1 , a_2 depend on the energy E and confine the under-barrier area inaccessible for classical motion. In this case, the partition function $Z(T)$ corresponds to one-dimensional translational motion; as a result, the bimolecular rate constant has the dimensionality $(\text{time})^{-1}(\text{length})^{-1}$. In the classical limit, $P(E)$ is replaced by a stepwise function

$$P(E) = \begin{cases} 0, & (E < \Delta V^\ddagger) \\ 1, & (E > \Delta V^\ddagger), \end{cases} \quad (26)$$

where $V^\ddagger$ is the height of the potential barrier. In this case, relation (24) provides the standard result of the one-dimensional classical transition state theory, TST.

$$k_{\text{TST}}(T) = \frac{1}{2\pi\hbar Z(T)} \exp\left(-\frac{\Delta V^\ddagger}{k_B T}\right). \quad (27)$$

Relations (24)–(27) can be recommended for application to real three-dimensional PT processes if a ‘one-dimensional’ transmission coefficient

$$\kappa = \frac{k(T)}{k_{\text{TST}}(T)} \quad (28)$$

is introduced and used as a correction factor, *i.e.*, the rate constant for a real three-dimensional reaction obtained by the standard TS method is multiplied by this factor.

Decay kinetics of single-well systems. In the decomposition reaction with a potential profile shown in Fig 7b, the states of reactants are quantised, while those in the product region belong to a continuum spectrum. By designating the energies of the reactant level by ε_v and the partial decay rates by $(1/\hbar)\Gamma_v$ (Γ_v is the width of the level), we obtain the rate constant

$$k(T) = \sum_v \frac{\exp(-\varepsilon_v/k_B T)}{Z(T)} \frac{\Gamma(\varepsilon_v)}{\hbar}. \quad (29)$$

In the quasi-classical approximation,⁹⁵

$$\Gamma(E) = \frac{\hbar\omega(E)}{2\pi} \exp[-2W(E)], \quad (30)$$

where the under-barrier action integral $W(E)$ is defined in the same way as in Eqn (25); however, now $V(s)$ has the form shown in Fig. 7b. The decay frequency $\omega(E)$ is expressed in terms of the action integral $\theta(E)$, which is calculated in the region of classical motion confined by the turning points a_3 and a_2 ,

$$\theta(E) = \frac{1}{\hbar} \int_{a_3}^{a_2} ds [2m_0(E - V(s))]^{1/2}; \quad (31)$$

$$\omega(E) = \frac{\pi}{\hbar(\partial\theta/\partial E)}.$$

When the interaction of the coordinate s with the environment modes is taken into account, these relations are modified in the following way. The interaction makes the levels ε_v diffuse; in this case, it is expedient to introduce the distribution function $\rho_v(E)$ for a level v

$$\int_0^\infty \rho_v(E) dE = 1, \quad (32)$$

and the density of states

$$\rho(E) = \sum_v \rho_v(E). \quad (33)$$

The $N(E)$ value, called the ‘cumulative transition probability’,^{92–94} is defined as follows:

$$N(E) = 2\pi\rho(E)\Gamma(E). \quad (34)$$

Then the expression for rate constant (29) is reduced to the form

$$k(T) = \frac{1}{2\pi\hbar Z(T)} \int_0^\infty \exp\left(-\frac{E}{k_B T}\right) N(E) dE. \quad (35)$$

This expression formally coincides with expression (24) for the rate constant of the bimolecular reaction, the difference being in the interpretation of the partition function. The $Z(T)$ value now includes the states located in the reactant well; taking account of the level broadening due to interaction, it is found as

$$Z(T) = \int_0^\infty \exp\left(-\frac{E}{k_B T}\right) \rho(E) dE. \quad (36)$$

The quasi-classical expression for the cumulative probability (34) is similar to expression (25)^{55, 92–94}

$$N(E) = \frac{1}{1 + \exp[2W(E)]} \quad (37)$$

with an action integral defined in the under-barrier region (see Fig. 7b). This description of decay processes is almost identical to the quasi-one-dimensional theory of bimolecular reactions. However, a consistent definition of the decay model should take into account the interaction of the reaction centre with its environment not only in the reactant region but also for tunnelling under the barrier.^{55, 96} The calculation of the action integral is modified by introduction of a non-local potential brought about by the interaction. The corresponding theory^{55, 96–98} is a quantum generalisation of the classical stochastic scheme based on the Langevin equation (13) for the tunnelling coordinate s . The friction coefficient γ is a parameter of the interaction intensity; it is present in the final quantum expression for the rate constant.

The activation and tunnelling mechanisms. The classical and quantum dynamic effects are manifested in the chemical reaction kinetics as a competition between the activation (classical) and tunnelling (quantum) mechanisms of the reactive transition. This was described above within the framework of a non-adiabatic diffusion model. Now it will be considered using an alternative tunnelling dynamics language.

As in the previous case, in the simplest one-dimensional scheme, there exists a critical temperature T_c (see several studies^{55, 97–99}) such that the activation mechanism with the Arrhenius temperature dependence of the rate constant predominates above this temperature. At temperatures below T_c , the reaction mainly follows a tunnelling mechanism and in the limit $T/T_c \ll 1$, the reaction rate does not depend on the temperature. This low-temperature limit differs from zero when the reactant region is a potential well; it corresponds to transition from the ground vibrational level of the reactants. Systematic analysis of the ratio of the tunnelling and activated transitions is reduced to investigation of the integral over energy in Eqns (24) and (35). The theory can be reformulated using the language of classical dynamics, which describes the motion in the ‘inverted’ potential $\bar{V}(s)$ [$\bar{V}(s) = -V(s)$] for the total energy E .^{55, 97} In this potential, a cyclic classical trajectory with the period $\iota(E)$ is formed. The energy corresponding to the highest contribution of the integrand to integral (35) satisfies the equation

$$t(E) = \frac{\hbar}{k_B T}. \quad (38)$$

Its solution determines the energy corresponding to the cyclic trajectory as a function of temperature. This consideration underlies the calculation of integral (35) by the stationary phase method.^{97, 100, 101} The temperature-dependent extremal trajectory that satisfies condition (38) is called instanton. There exists a critical temperature above which Eqn (38) has no solution. It can be identified with the above-mentioned T_c value. Then the maximum contribution to the integral is determined by the energy near the top of the barrier, and formula (35) reduces to the result of the TS theory with slight quantum corrections. In the stochastic tunnelling model, which takes into account the interaction with the environment based on the Langevin equation, the Kramers equation for the rate constant, similar to relation (11) but with allowance for (14), is obtained in the classical limit.^{102–104} Thus, the relationship between two theories, the non-adiabatic and the tunnelling, is established; the tunnelling probability is determined in the latter case by the value of action on the instanton trajectory. The simplest equation for the critical temperature obtained for a parabolic barrier $V(s)$ with the decay frequency $\omega^\ddagger$ has the form^{99, 105}

$$T_c = \frac{\hbar \omega^\ddagger}{2\pi k_B}. \quad (39)$$

Tunnelling in a double-well potential. The calculation of tunnelling is complicated on passing to a double-well potential where it is necessary to take account of the quantisation of energy levels in both wells. Transitions between two levels take place only in the presence of interaction between the coordinate s and other degrees of freedom. Even where the levels are in resonance, *i.e.*, very close or coinciding, as in symmetrical systems, the interaction with the environment is required to ensure energy dissipation and destruction of the transition coherence, which are necessary conditions for irreversibility. Only due to these factors, can the system be fixed in the product region and a stationary flux for the two wells can be formed. In asymmetric systems, the interaction with the environment is also necessary in order to compensate for the resonance misfit (*i.e.*, the energy difference between the levels between which the transition takes place) by means of the intermode energy exchange.

Thus, double-well transitions are, in essence, multidimensional even in the case where the PES structure seems to allow the reaction mode to be considered as an independent variable. The intermode interactions, which ensure the energy exchange and phase relaxation (the latter term is equivalent to the term ‘coherence destruction’), can be small within the scale of the energy variation on the PES, but only consistent allowance for these interactions provides the possibility of correct description of the tunnelling dynamics.

b. Collinear model of simple gas-phase reactions

Quantum computation scheme. Let us consider a two-dimensional quantum problem for collinear model (1) of a PT with two coordinates s, R and the corresponding reduced masses m_0 and M . After conversion to a mass-weighted coordinates $s' = s(m_0)^{1/2}$ and $R' = R(M)^{1/2}$, it is expedient to introduce polar coordinates

$$y = [(s')^2 + (R')^2]^{1/2}, \quad (40)$$

$$\alpha = \arctan \frac{s'}{R'}.$$

The potential energy surface in these coordinates is shown in Fig. 8. The two valleys stretched along y correspond to the translational motion in the asymptotic regions, as we consider a gas-phase bimolecular reaction. This PES is confined within the angle

Figure 8. Potential energy surface of the gas-phase PT and HAT reaction in the polar coordinates.

The isoenergy contour lines of PES are shown only for the product valley ($\alpha > 0$). The potential energy in the reactant valley ($\alpha < 0$) has the same form. The point M has the polar coordinates y, α .

$$2\theta = \arctan \left(m_H \frac{m_{A_1} + m_{A_2} + m_H}{m_{A_1} m_{A_2}} \right)^{1/2}, \quad (41)$$

where m_H, m_{A_1}, m_{A_2} are the masses of the H atom and the heavy fragments A_1 and A_2 , respectively. The reduced masses m_0 and M are related to these masses in the usual way. The Hamiltonian for this problem has the form

$$H = -\frac{\hbar^2}{2} \left(\frac{\partial^2}{\partial y^2} + \frac{1}{y} \frac{\partial}{\partial y} \right) + h_\alpha, \quad (42)$$

$$h_\alpha = -\frac{\hbar^2}{2y^2} \frac{\partial^2}{\partial \alpha^2} + V(\alpha|y),$$

where the operator h_α depends parametrically on y . When y is constant, variation of the mode α is described by the Schrödinger equation

$$h_\alpha \varphi_n(\alpha|y) = \varepsilon_n(y) \varphi_n(\alpha|y). \quad (43)$$

Equations (42) and (43) are similar to Eqns (8), (9) for the coordinate s and are converted into the latter (to within a mass factor) after the substitution

$$s = y\alpha. \quad (44)$$

As a result of the coordinate scaling performed, the major dynamic feature of PT reactions, *i.e.*, the fact that the ratios

$$\frac{m_H}{m_{A_1}} \ll 1, \quad \frac{m_H}{m_{A_2}} \ll 1$$

are small, is manifested in the PES relief, in particular, the angle θ becomes a small parameter in this description

$$\theta \ll 1. \quad (45)$$

It can be seen in Fig. 8 that in this case, the reactant and product valleys are nearly parallel, the barrier separating them being narrow. This accounts for the specific features of process dynamics (1), the possibility of tunnelling along the variable α being the most important of them.

In numerical dynamic studies of system (1), the solutions $\varphi_n(\alpha)$ of Eqn (43) are used as the basis functions. The two-dimensional Schrödinger equation (43) is reduced to a set of one-dimensional coupled equations for the motion along the translational coordinate y . The solution of this set of equations provides the probabilities $P_{mn}(E)$ of reactive transitions from the reactant valley to the product valley and the probabilities $R_{mn}(E)$ of reflection in the reactant valley. The transition takes place between the states φ_m and φ_n at a given total energy E . The

procedure of such calculations has been well developed^{106, 107} and extended to the description of reaction in a real 3D space, which takes into account the interaction of the internal degrees of freedom with the rotational motion.¹⁰⁸ The results of numerical studies are reported in several reviews.^{109–112} The potential in Eqn (43) has a complex form. Depending on y , it can be either double-well (large y) or single-well (small y). For non-symmetric reactions, the potential is asymmetric. It should be emphasized that the use of eigenfunctions of the Hamiltonian h_x with this complex potential as the basis functions has a crucial impact on the success of calculations.^{106, 107} The convergence of the solution of Eqn (43) with oscillatory basis functions proved to be unsatisfactory.

The results of calculations showed that the reactions in symmetrical systems are adiabatic, *i.e.*,

$$\frac{P_{mn}(E)}{[P_{mm}(E)P_{nn}(E)]^{1/2}} \ll 1. \quad (46)$$

In the case of asymmetric reactions, transitions between the vibrational levels of the reactants ε_{im} and the products ε_{fn} characterised by the smallest in magnitude resonance misfits

$$\Delta_{mn} = \varepsilon_{fn} - \varepsilon_{im}$$

sharply predominate. This is a natural consequence of inequality (45). The small parameter θ is a measure of dynamic interaction between the coordinates α and y . Since the interaction is weak, transformation of the resonance defect energy into the energy of translational motion is unlikely and resonance or nearly resonance processes predominate.

Study of the collinear dynamics at a qualitative level. When analysing studies of the collinear dynamics at a qualitative level, we restrict ourselves to the discussion of HAT reactions that have rather high potential barriers ($V \geq 10$ kcal mol⁻¹) and can be expected to proceed in the tunnelling regime even at high temperature ($T \geq 300$ K). The early studies of these systems^{113, 114} were performed using a multi-dimensional quasi-classical approximation,^{115, 116} whose one-dimensional version is considered in Section II.3.a. Extension to multidimensional (two-dimensional, for a collinear reaction) case brings about a procedural difficulty: it is necessary to match the trajectories of a multidimensional classical motion at the boundary of classically allowed (reactant and product valleys) and classically forbidden (under-barrier region) PES sections. A rigorous solution of this problem is extremely unwieldy. It is more convenient to proceed directly from quantum equations of motion which do not face the matching problem.

The quantum interpretation becomes simple for those regions of PES where the cross-sections along the coordinate α have a rather sharp double-well profile. This is not the case in the vicinity of the saddle point, which imposes restrictions on the conditions under which the HAT process can be calculated; it is assumed to proceed in the tunnelling regime, the classical activated transitions being suppressed. In this situation, there exist diabatic states well localised in the reactant $\chi_{im}(\alpha)$ and product $\chi_{fn}(\alpha)$ regions. They can be regarded as eigenfunctions of two different one-dimensional Hamiltonians h_i and h_f :

$$h_i \chi_{im}(\alpha) = e_{im} \chi_{im}(\alpha), \quad (47)$$

$$h_f \chi_{fn}(\alpha) = e_{fn} \chi_{fn}(\alpha).$$

Single-well potentials in the Hamiltonians h_i and h_f are distorted with respect to the true double-well profile $V(\alpha|y)$ [see Eqn (42)] in such a way as to ensure localisation of eigenfunctions. In Fig. 9a, the continuous line shows the double-well adiabatic profile $V(\alpha)$ for a given value y . The diabatic potentials coincide with it in the region of one of the wells and are continued by dots to the region of the neighbouring well. As noted above, it is legitimate for considering the transitions between two diabatic states closest in energy. Let energies of these states be e_{im} and e_{fn} . This corresponds to the two-level model in which the designations can be simplified: $\chi_{im} \rightarrow \chi_i$, $e_{im} \rightarrow e_i$, $\chi_{fn} \rightarrow \chi_f$, $e_{fn} \rightarrow e_f$. The solu-

Figure 9. Model of a two-dimensional tunnelling transition for the PES shown in Fig. 8 (asymmetric case); (a) adiabatic [$V(\alpha)$] and diabatic [$V_{di}(\alpha)$ and $V_{df}(\alpha)$] energy profiles along the coordinate α ; (b) pattern of the translational motion along the coordinate y in the reactant and product valleys. The difference in the diabatic potentials $e_i(y) - e_f(y) = \Delta$ is constant. The turning points y_i , y_f correspond to the energy E .

tions of the complete Schrödinger equation (43) designated by φ_n are adiabatic states; in the two-level model, they are linear combinations of two functions, χ_i and χ_f . For symmetrical systems, $e_i = e_f = e$ and adiabatic functions possess definite symmetry properties, one of them being symmetric and the other, antisymmetric

$$\varphi_s(\alpha) = \frac{1}{[2(1 + \sigma)]^{1/2}} [\chi_i(\alpha) + \chi_f(\alpha)], \quad (48)$$

$$\varphi_a(\alpha) = \frac{1}{[2(1 - \sigma)]^{1/2}} [\chi_i(\alpha) - \chi_f(\alpha)],$$

where σ is the overlap integral of diabatic functions.

When the potential $V(\alpha, y)$ is substantially asymmetric, one of the adiabatic functions is mainly composed of function χ_i with a small portion of function χ_f , while the other, mainly of the function χ_f . Then the adiabatic states are labelled by the same subscripts i and f . In the tunnelling regime, the adiabatic energy levels ε_i , ε_f differ little from the diabatic energies e_i , e_f . In this case, the resonance misfit

$$\Delta_{if} = \varepsilon_f - \varepsilon_i \approx e_f - e_i \quad (49)$$

becomes an important dynamic parameter.

Within the framework of the model with two coordinates α and y , the potential profiles shown in Fig. 9a depend on y . Diabatic levels become the functions of y and their energies play the role of repulsive potentials $e_i(y)$ and $e_f(y)$ in the reactant and product channels, as shown in Fig. 9b. More complex potential profiles along y (with a well near the saddle point) can arise in special cases;^{106, 107, 117} however, for reactions with high potential barriers considered here, these situations are unlikely. Each vibrational state of the reaction system or ‘reaction channel’ (i and f , or s and a for a symmetrical reaction) is matched by its own potential.

Due to the small magnitude of the θ parameter [see inequality (45)], the interaction of a given pair of closest channels with other channels is negligibly small. This simplification has been suggested by the experience of full multichannel computations. In an approximation that takes into account only transitions between two reactant and product channels closest in energy, we will consider analytical expressions for the probability of reactive transitions for different limiting situations.

In the case of a symmetrical system, channels s and a also split. By solving a one-dimensional Schrödinger equation for the coordinate y for each of them, one can get the following expression for the probability of the reaction transition between the diabatic states i and f :¹¹⁸

$$P_{if}(E) = \sin^2(\xi_s - \xi_a), \quad (50)$$

where ξ_s and ξ_a are the shifts of scattering phases in the channels s and a . Quasi-classical estimate gives

$$\sin(\xi_s - \xi_a) \approx \xi_s - \xi_a \approx \frac{2}{\pi} \int_{y_0}^{\infty} \frac{e_i(y)}{p_i(y)} \exp[-W_i(y)] dy. \quad (51)$$

Here

$$e_i(y) = e_f(y),$$

$p_i(y)$ is the momentum for the translational motion along the coordinate y

$$p_i(y) = \{2[E - e_i(y)]\}^{1/2},$$

$W_i(y)$ is the under-barrier action integral calculated between the turning points α_2 and α_1 [the symmetrical variant is considered (see Fig. 9 a)].

Expression (51) can be simplified by expanding in a series near the $y_0(E)$ turning point in which $p_i(y) = 0$ (see Fig. 9 b).^{113, 114, 119–121}

In the case of an asymmetric potential profile, the transition probabilities $P_{if}(E)$ can be estimated only in terms of the perturbation theory ('golden rule'), whose applicability is ensured by low values of these probabilities ($P_{if} \ll 1$) and, finally, by the smallness of the PES parameter θ . It is convenient to accept an exponential form of diabatic repulsive potentials in channels i and f (see Fig. 9 b):

$$\begin{aligned} e_i(y) &= e_0 \exp(-cy), \\ e_f(y) &= e_0 \exp(-cy) + A, \end{aligned} \quad (52)$$

where c is the potential parameter, $A = A_{if}$ is the resonance misfit [see Eqn (49)].

For energy E , the potentials have turning points $y_i(E)$ and $y_f(E)$. When the resonance misfit $|A|$ is small, the following expression was obtained:^{119–121}

$$P_{if}(E) = P_{sif}(E) \exp\left(-\frac{A^2}{2cF}\right), \quad (53)$$

where $P_{sif}(E)$ is the probability of non-adiabatic transition [see Eqn (50)] for a symmetrical potential profile (see Fig. 9 a),

$$F = -\frac{\partial e}{\partial y} \Big|_{y_0(E)},$$

F is the force for the average potential

$$e = \frac{1}{2} [e_i(y) + e_f(y)]$$

at the turning point $y_0(E)$.

Relation (53) is valid when $|A/E| \ll 1$ and some additional conditions are met.

If $|A/E| \gg 1$, a different asymptotic estimate follows¹²²

$$\begin{aligned} P_{if}(E) &= \frac{6}{\pi^2 c |A| [(E+A)^{1/2} - E^{1/2}]} \left[\left(\frac{d \ln A}{dy} \right) A \right]^2 \times \\ &\times \exp \left\{ -\frac{2\pi}{c} [(E+A)^{1/2} - E^{1/2}] \right\}. \end{aligned} \quad (54)$$

Here $A = A(y)$ is a matrix element for the transition along the vibrational coordinate (the tunnelling transition amplitude)

$$A(y) = \int \chi_i(\alpha|y) \left[H - \frac{1}{2}(e_i + e_f) \right] \chi_f(\alpha|y) d\alpha, \quad (55)$$

where H is a two-dimensional Hamiltonian [see Eqn (42)]. The amplitude $A(y)$ is calculated at the turning point for function χ_i . The dependence of the matrix transition element along the translational coordinate y plays an important role in HAT reactions [the probability $P_{if}(E)$ vanishes if this dependence is missing].

Equations (53)–(55) reflect the main features of energy transfer between vibrational and translational degrees of freedom in collinear HAT reactions. The main parameters that determine the probability of transfer include the resonance misfit (A), characteristics of adiabatic translational potentials (c , F), the amplitude of the tunnelling transition, and its dependence on the translational coordinate.

4. Tunnelling in a multidimensional double-well potential a. Specific features of the reactive transition dynamics in double-well systems

Continuum spectrum of vibration frequencies. Up to here, the discussion has been concerned with reactions for which the states of the reactants or the products (or both) have a continuum spectrum of eigenvalues. The reactions in double-well systems where all the energy levels are discrete require a specific approach. They can proceed only due to interactions with the environment, which is assumed to be a macroscopic system and, hence, has a continuum energy spectrum. However, the continuum spectrum of the medium differs from the one-dimensional continuum spectrum inherent in the translational degrees of freedom of the reaction system. The medium can consist of subsystems, each having a discrete energy spectrum: in the simplest case, the medium can be considered as an ensemble ('reservoir') of harmonic oscillators. The continuous nature of the general spectrum of the medium is ensured by the fact that the number of its degrees of freedom is infinite, *i.e.*, we are dealing with a continuum spectrum of vibration frequencies.

The interaction of the reaction mode with the oscillator reservoir having a continuum spectrum of frequencies, as well as the interaction with the translational degree of freedom (see Section II.3.b) ensures transfer of the resonance misfit energy and destruction of the transition coherence — *i.e.*, two conditions needed for a chemical reaction to proceed. As a result of this interaction, the reservoir oscillators rearrange (*i.e.*, change equilibrium positions) and are involved in the reaction. Thus, the chemical reaction in a double-well reaction system is an essentially multimode process that includes rearrangement of the states of the medium with a continuum spectrum of frequencies.

The simplest pattern of quantum rearrangement. The theory of quantum rearrangement processes has been developed for a model in which the reaction transition occurs between two multidimensional paraboloids with shifted minima which describe the PES of the reactants and the products (see Fig. 2).^{123–129} We restrict ourselves to the case where the normal modes of the reaction system and their frequencies do not change during the transition (a more general theory is extremely cumbersome, although it still can be formulated^{123, 127}). The straight line connecting the minima of the paraboloids (see Fig. 2 a), *i.e.*, the reaction coordinate, is a linear combination of the normal modes of the reactants and the products. The change in the distance along this straight line is

measured using the scalar parameter λ [see Eqn (3)]. Let one normal mode with the frequency ω_0 be quantum

$$\frac{\hbar\omega_0}{k_B T} \gg 1. \quad (56)$$

First, this is the high-frequency proton mode; as in Sections II.1 and II.2, we designate it by s . On the harmonic PES that we consider, each mode makes its individual contribution to the height of the potential barrier; the contribution of the mode s equals

$$\Delta V_s^\# = \frac{m_0\omega_0^2}{2}(\lambda^\#)^2(s_f - s_i)^2, \quad (57)$$

where m_0 is the mass corresponding to this coordinate, $\lambda^\#$ is the value of the reaction coordinate at the point of quasi-intersection of diabatic PES (this is a minimum on their intersection hypersurface),

$$\lambda^\# = \frac{1}{2} \left(1 + \frac{\Delta V}{E_r} \right),$$

$\Delta V = V_f - V_i$ is the energy difference between the minima of the diabatic parabolooids, *i.e.*, the heat of the reaction; E_r is the reorganisation energy, s_f and s_i are the values of the coordinate s at the minima. The other modes ω_v will be considered classical

$$\frac{\hbar\omega_v}{k_B T} \ll 1. \quad (58)$$

The frequencies ω_v form continuum spectra. Then one can expect that the reaction rate constant would have the form

$$k = k_s \exp \left(- \frac{\Delta V_1^\#}{k_B T} \right), \quad (59)$$

where k_s is the one-dimensional tunnelling rate constant in a double-well potential profile that corresponds to the PES cross-section along the mode s , $\Delta V_1^\#$ is the contribution of classical modes to the height of the potential barrier. It is significant that the partial height of the barrier determined by formula (57) is much smaller than the total value $V^\#$, which is given by the Marcus formula (6) with allowance for (5).

This qualitative discussion has been extended to the case of a larger number of quantum modes.^{126–129} The quantum modes that satisfy criterion (56) form altogether the tunnelling pre-exponential factor of the rate constant, which depends only slightly on the temperature. Classical modes are responsible for the Arrhenius exponential factor in which the activation energy is equal to their contributions to the barrier height.

Turning back to the classification of modes introduced in Section II.1.b, one can state that formula (59) reflects the situation where all the rearranging modes Q_v ($v = 1, 2, \dots$) are classical in conformity with criterion (58). As the temperature decreases, condition (58) starts to be violated for some of these modes. They become quantum modes and form the tunnelling pre-exponential factor, whereas those modes that still remain classical form the ever decreasing reaction barrier. This idealised pattern is valid only for a double-well harmonic potential. In PT reactions, the PES anharmonicity is substantial and the separation of variables throughout the whole path along the reaction coordinate (*i.e.*, along the curve connecting the potential minima *via* the saddle point) is impossible. However, at a qualitative level, the idea of more or less independent contributions of the proton (s) and rearrangement (Q_v) modes to the potential barrier remains valid.

Comparison of different ways of description of the reaction transition. Let us discuss in more detail how the theory formulated in terms of normal modes (non-interacting degrees of free-

dom)^{124–129} can be correlated with the statement according to which one or several reaction modes interact with an ensemble of harmonic oscillators of the medium.^{130, 131} We have in view the following. The discrete coordinates of the reaction system are considered oscillatory in each of the two diabatic regions (those of the reactants and the products). In each of these regions, their interaction with the medium oscillators is assumed to be bilinear and is excluded by diagonalisation of the corresponding diabatic oscillatory Hamiltonian. The normal modes thus found are those used in the double-well transition model. The allowance for the interaction results in renormalisation of the initial oscillator frequencies (both discrete and medium oscillators), shift of their equilibrium positions and the change in the form of vibrations. The assumption that normal vibration frequencies and forms are the same in both diabatic regions is actually made for the system of modes resulting from the diagonalisation mentioned above. The oscillator modes of the medium change most appreciably. Their interaction with the reaction system leads to a shift in the equilibrium of the reservoir oscillators, which are different for the reactants and the products.

Thus, the chemical reaction is accompanied by reorganisation of the medium, which is a necessary item of the theory we consider. Two limiting cases are analysed below. In the first case, the promoting mode R is ignored and the reaction dynamics is entirely determined by the medium reorganisation (electron transfer). Conversely, in the second case, the role of the medium is minimised and the main dynamic features of the reaction system are determined by the interaction between the proton (s) and promoting (R) modes (HAT in non-polar media). The promoting mode is usually assumed to be classical.

b. Electron transfer as an example of multimode tunnelling

Calculation technique. We will consider multimode transitions between the reactant and product states in which the quantum numbers of oscillators in the reactant well ($im_1, im_2, \dots$) are replaced by oscillator quantum numbers in the product well ($fn_1, fn_2, \dots$); the first character implies the belonging to either the reactants or the products, while the second one is the number of the level of the corresponding oscillator. To simplify the designations, we replace the set of characters in the parentheses by a single letter (a or b) and write down the transition probability per unit time as T_{ab} (it is measured in s^{-1}). In a deep tunnelling regime, the probabilities of individual transitions are low. They can be calculated using the perturbation theory (in terms of the golden rule)

$$T_{ab} = \frac{2\pi}{\hbar} A_{ab}^2 \delta(E_b - E_a). \quad (60)$$

Here, A_{ab} is the transition amplitude

$$A_{ab} = \langle \chi_b | H - E_a | \chi_a \rangle, \quad (61)$$

where χ_a and χ_b are the wave functions of multimode diabatic states, which are the products of oscillatory functions; H is the total double-well Hamiltonian; E_a and E_b are the energies of diabatic multimode states in the reactant a and product b wells, respectively; they are the sums of energies of the levels $e_{m_1}, e_{m_2}, \dots$ and $e_{n_1}, e_{n_2}, \dots$ for separate oscillators

$$\begin{aligned} E_a &= e_{m_1} + e_{m_2} + \dots; \\ E_b &= e_{n_1} + e_{n_2} + \dots \end{aligned} \quad (62)$$

As in the one-dimensional formulation (see Section II.3.b), χ_a and χ_b are not eigenstates of H : the oscillatory functions corresponding to them are localised in the reactant and product wells and, hence, they are the eigenfunctions of two different diabatic Hamiltonians, so that the corresponding off-diagonal matrix element H_{ab} does not vanish. According to the perturbation theory, the probabilities T_{ab} are additive, and the resultant thermal rate constant for the reaction equals^{99, 124, 125}

$$k = \frac{2\pi}{\hbar} \sum_{a,b} \exp\left(-\frac{E_a}{k_B T}\right) A_{ab}^2 \delta(E_b - E_a). \quad (63)$$

In Eqns (60) and (63), the delta-function expresses the energy conservation law for the multimode transition, which is accompanied by the intermode energy exchange. The summation is carried out over all combinations of the oscillatory functions, *i.e.*, multipliers in the multimode product functions χ_a, χ_b . The use of the delta-function provides the possibility of counting all combinations that ensure energy conservation.

Like any other relation containing the delta-function, expression (63) acquires a definite meaning and can be really calculated only if the sums appearing in it contain a continuum frequency spectrum and can be reduced to integrals. Reactions in the condensed phase represent an appropriate object for the application of this calculation procedure. In the harmonic model of the medium, a continuum frequency spectrum is specified using the spectral function $J(\omega)$ (spectral density, see Supplement II).^{96, 130–132}

Let us consider the case where there is only one quantum reaction mode (with the frequency ω_0), while the other modes (modes of the medium) are reorganisation modes with a continuum frequency spectrum. Then the function $J(\omega)$ gives the frequency distribution for the intensity of interaction between the reaction mode and the medium modes

$$J(\omega) = \text{const } \Delta Q(\omega) \rho(\omega), \quad (64)$$

where $\Delta Q(\omega)$ is the shift of the equilibrium position of the medium reorganisation mode Q with the frequency ω , which is induced by this interaction and can serve as its measure; the function $\rho(\omega)$ characterises the density of oscillator levels with the frequency ω ; it is different for different condensed media; the constant in the equation does not depend on ω .

The description of the continuum frequency spectrum by means of the spectral density is considered in more detail in Supplement II.

Expression for the rate constant.^{124, 125, 127, 131} Now we list once again the key assumptions made in the model of multidimensional tunnelling transition in a medium consisting of a continuum ensemble of harmonic oscillators.

First, the reaction system is described by a single reaction mode s with the frequency ω_0 . This is a quantum mode [see criterion (56)] related to the medium modes Q_v , which are characterised by frequencies ω_v and masses m_v . All modes of the medium are reorganisation modes. In the continuum limit, $Q_v \rightarrow Q(\omega)$. This limiting transition gives rise to the spectral function $J(\omega)$ as a characteristic of the interaction between the reaction mode and the medium.

Second, the tunnelling reaction does not change the frequency spectrum of the medium [*i.e.*, the function $J(\omega)$] or the forms of normal vibrations Q_v [or $Q(\omega)$]. This assumption is not fundamental but it allows one to represent the results of the theory in a rather simple form.

Finally, one special assumption concerning the form of the amplitude of the tunnelling transition is also required

$$A_{ab} = A_0 \langle \bar{\chi}_a | \bar{\chi}_b \rangle, \quad (65)$$

$$A_0 = \left\langle \chi_i \left| H - \frac{1}{2}(e_i + e_f) \right| \chi_f \right\rangle.$$

Here, the diabatic functions are represented by the products

$$\chi_a = \chi_i \bar{\chi}_a, \quad \chi_b = \chi_f \bar{\chi}_b,$$

where χ_i and χ_f are the eigenfunctions for the reaction mode s , corresponding to the energies e_i and e_f , while $\bar{\chi}_a$ and $\bar{\chi}_b$ are the products of the wave functions of the medium oscillators. The functions $\bar{\chi}_a$ and $\bar{\chi}_b$ correspond to the energies

$$\bar{E}_a = E_a - e_i, \quad \bar{E}_b = E_b - e_f.$$

These relations follow from the energy conservation law. The overlap integral $\langle \bar{\chi}_a | \bar{\chi}_b \rangle$ is equal to the product of the overlap integrals for the shifted oscillators of each of the medium modes; it is called the multidimensional Frank–Condon factor.

Equations (65) represent the Condon approximation according to which the dependence of the matrix element A_0 on the oscillatory coordinates is not taken into account. This approximation is justified provided that the frequency ω_0 is much greater than the medium frequencies. In this case, the A_0 value is calculated for those medium coordinates that make the greatest contribution to the full transition amplitude.

When these assumptions are taken into account, the reaction rate constant given by relation (63) is transformed in the following way:^{127, 133–137}

$$k = \frac{A_0^2}{\hbar^2} \int_{-\infty}^{\infty} C(t) \exp\left(-\frac{it\Delta V}{\hbar}\right) dt, \quad (66)$$

$$C(t) = \exp\left[-\frac{1}{\pi\hbar} \times \int_0^{\infty} \frac{J(\omega)}{\omega^2} \frac{\text{ch}(\hbar\omega/2k_B T)(1 - \cos\omega t) + i\text{sh}(\hbar\omega/2k_B T)\sin\omega t}{\text{sh}(\hbar\omega/2k_B T)} d\omega\right].$$

Here, t is time; $\Delta V = V_f - V_i$ is the difference between the energies of the diabatic PES at their minima [see Eqn (4)].

Relation (66) is a typical result of the multimode oscillatory perturbation theory. It is widely used in the theory of electron transfer in polar solvents.^{127, 129, 133–137} In this case, s is the electron coordinate and the function $J(\omega)$ is proportional to the reorganisation energy of the modes of the medium, *i.e.*, the energy evolved upon the shift of the equilibrium positions of the oscillatory modes. The frequency dependence of $J(\omega)$ is determined by the function $\text{Im}\{\epsilon(\omega)/|\epsilon(\omega)|^2\}$, where $\epsilon(\omega)$ is the frequency-dependent complex dielectric constant, which is the key phenomenological characteristic of the dynamic properties of the dielectric medium. This representation of the spectral density is valid for any reactions with charge redistribution in polar disordered media. The parametrisation of $J(\omega)$ can be quite different for reactions in non-polar media or in molecular crystals (see Supplement II).

Equation (66), which seems to be complicated, holds for a broad range of temperatures including the lowest ones and describes the reorganisation dynamics for both classical and quantum modes of the medium. More precisely, this theory is valid as long as the key expression of the golden rule (60) holds. There is always a lower temperature limit depending on the resonance misfit and on the spectral density,^{130, 131} beyond which the steady-state regime (which ensures the existence of exponential decay and the rate constant) is violated and quantum beats appear, *i.e.*, coherent periodic transitions of the reaction system from the reactant well to the product well and back. This lower temperature limit is commonly considered to arise in the extremely low-temperature region.

If all modes of the medium are considered to be classical in conformity with criterion (58), expression (66) is reduced to the usual Arrhenius law (59), which was postulated above relying on intuitive considerations:

$$k = \frac{A_0^2}{\hbar} \left(\frac{\pi}{E_r k_B T}\right)^{1/2} \exp\left[-\frac{(E_r + \Delta V)^2}{4E_r k_B T}\right]. \quad (67)$$

Here, the activation energy coincides with the potential barrier (6).

Thus, in the high-temperature limit, the electron transfer kinetics is mainly determined by three key reaction parameters, namely, the transition amplitude for the reaction mode, the medium reorganisation energy E_r , and the heat of the reaction ΔV . The dependence of the rate constant on details of the frequency spectrum of the medium is manifested only in the low-

temperature quantum regime. Various approximations of expression (66) are possible, which are valid in more or less broad temperature ranges.^{99, 138–141} One of them is given below.

c. Hydrogen atom transfer in the liquid and solid phase

Reaction model. The PT and HAT reactions in the condensed phase have been considered in a number of early studies using relation (66).^{27–31, 142–147} The proton coordinate was used as the only quantum coordinate s . It can be seen from the above consideration that this approximation is inadequate and that the promoting mode R is to be taken into account.¹⁴⁸ The simplest plausible model should explicitly include the modes s , R and the medium modes Q_v .^{30, 148–151} This model is formulated as follows.^{99, 148} The interaction of modes s and R is introduced through the dependence of the proton transition amplitude A_{if} on R (recall that this dependence plays a crucial role in the energy exchange in gas-phase hydrogen atom abstraction). A convenient approximation is

$$A_{if}(R) = \bar{A}_0 \exp[-\alpha(R - R_e) - \gamma(R - R_e)^2], \quad (68)$$

where R_e is the equilibrium R value.

The second term in brackets rapidly decreases both for positive and negative values of the $R - R_e$ difference. It is necessary for providing the convergence of the perturbation theory integrals with the continuum spectrum. Then it is sufficient to assume that only the low-frequency mode R interacts with the medium oscillators. The corresponding frequency and mass will be designated by ω_R and m_R . This mode is not a reorganisation mode, *i.e.*, its equilibrium position does not change upon the reaction. Correspondingly, the modes of the medium do not change equilibrium positions and remain exclusively promoting modes. The full expression for the rate constant in this model⁹⁹ is cumbersome and unwieldy. A rather simple expression can be obtained by neglecting the squared dependence on R in the exponent in Eqn (68) and taking that $\gamma = 0$. Then

$$k = \frac{\bar{A}_0^2}{\hbar^2} \int_{-\infty}^{\infty} C(t) \exp\left(-\frac{it\Delta V}{\hbar}\right) dt, \quad (69)$$

$$C(t) = \exp\left[\frac{(\hbar\alpha)^2}{\pi\hbar} \times \int_0^{\infty} J(\omega) \frac{\text{ch}(\hbar\omega/2k_B T) (1 + \cos\omega t) - \text{ish}(\hbar\omega/2k_B T) \sin\omega t}{\text{sh}(\hbar\omega/2k_B T)} d\omega\right].$$

Here the spectral density $J(\omega)$ describes the expansion of the promoting mode R over the normal modes of the full system comprising the reaction subsystem and the medium. In the discrete representation,

$$R - R_e = \sum_v C_v Q_v.$$

The methods for the transition to the continual representation that allow one to obtain expressions (66) and (69) are considered in Supplement II.

Temperature dependence of the rate constant. One can expect that there exists, at least, one localised normal mode that makes a substantial (perhaps, the major) contribution to the coordinate R . Therefore, the expansion

$$J(\omega) = \text{const} \delta(\omega - \omega_R) + J_{\text{cont}}(\omega), \quad (70)$$

where ω_R is the frequency of the localised normal mode, can be an appropriate approximation.

The second (continuum) term remains, as usual, a smooth spectral function. Therefore, using relation (70), the factor^{99, 148, 152}

$$k \sim \exp\left\{\text{const} \left[\frac{(\hbar\alpha)^2}{\pi\hbar} \text{cth} \frac{\hbar\omega_R}{2k_B T}\right]\right\}, \quad (71)$$

which determines the temperature dependence of the rate constant in the temperature range where

$$\frac{\hbar\omega_R}{2k_B T} \lesssim 1, \quad (72)$$

can be separated in the rate constant.

This dependence is well fulfilled for photochemical elimination of a hydrogen atom by the singlet excited acridine impurity in the molecular crystal of fluorene (Fig. 10). Condition (72) determines the position of inflection point on the temperature kinetic curve; this is used to determine the resonance frequency ω_R . The value found in this way coincided with the frequency of the promoting mode ($\omega_R = 130 \text{ cm}^{-1}$) found by an independent procedure using the vibrational spectrum of the fluorene crystal.^{153, 154}

Figure 10. Temperature dependence of the rate constant for a photochemical reaction of HAT in a fluorene molecular crystal doped with acridine.

Experimental data are shown by dots.¹⁵³ The continuous line was calculated using relation (71) for $\omega_R = 131 \text{ cm}^{-1}$ (see Ref. 152).

The factor (71) can also be distinguished in the equation for the rate constant of the reaction with medium reorganisation [see Eqn (66)]. The correlation (71) cannot be extended to a too broad temperature range. With an increase in temperature, one should take into account the Gaussian exponential component in the transition amplitude (68),⁹⁹ which is ignored in expression (69). The corresponding temperature factor for $\hbar\omega_R/k_B T \ll 1$ (when the promoting mode becomes classical) has the form

$$k \sim \exp\left(\frac{1}{2} \frac{\alpha^2 l_R^2}{2l_R^2 \gamma' + \hbar\omega_R/4k_B T}\right), \quad (73)$$

where l_R is the amplitude of zero-point vibrations along the coordinate R

$$l_R = \left(\frac{\hbar}{m_R \omega_R}\right)^{1/2}.$$

This factor can be derived using simple quasi-classical consideration.¹⁴⁸ Provided that

$$2l_R^2 \gamma \ll \frac{\hbar\omega_R}{4k_B T}$$

this leads to a linear dependence of $\ln k$ on T , which was observed in many experiments. As the temperature further increases, the dependence becomes more gentle. The linear section can be clearly seen in Fig. 10. At very low temperatures ($\hbar\omega_R/k_B T \gg 1$), the continuum spectrum component $J(\omega)$ should be taken into account. The factor (71) becomes constant at this temperature. The corresponding temperature dependence, which follows from relation (69), has the form

$$\ln k \sim T^n,$$

the power n ($2 < n < 4$) being determined by the spectral density $J(\omega)$ of the condensed medium.^{99, 155} This conclusion, however, is not fully unambiguous due to the presence of a lower temperature limit below which the concept of rate constant becomes invalid in terms of the harmonic oscillatory model of the medium, and the energy exchange proceeds by an anharmonic mechanism.

The above analysis of the temperature dependence of the rate constant is wholly determined by the dynamics of the promoting mode, which interacts with the modes of the continuous spectrum, according to the accepted model [in the derivation of formula (69), it is expanded over normal vibrations of the overall system composed of the promoting mode and the medium coordinates]. The coordinate R does not pass across a potential barrier; therefore, the usual Arrhenius dependence such as (59) is not observed at all. Within the framework of a classical consideration of the coordinate R , this dependence could arise only due to the reaction mode s , but this is a quantum mode at any temperature that may be of interest and, hence, it does not make a significant contribution to the temperature dependence of the reaction rate.

III. Calculations for particular systems

1. Multidimensional quasi-classical calculations

a. Problem definition

Quasi-classical calculations are based on the quasi-one-dimensional model of tunnelling (see Section II.3.a). In the space of active coordinates of the reaction system, the reaction path curve connects the regions of reactants and products. Let us consider one-dimensional tunnelling on the energy profile along this curve and calculate the quasi-classical action $W(E)$ [see Eqn (25)] in the region under the potential barrier, which determines the amplitude of the tunnelling transition. Selection of the reaction path is the key problem in this procedure. For a rigorous definition of the problem, the curve should ensure a classical action extremum for motion of the system in the inverted potential (the potential barrier becomes a potential well, and the reactant and product minima become top points of the potential relief). The classical trajectory with specified initial and end points is calculated in the inverted potential. The trajectory depends on the initial and final quantum states between which the transition takes place. Boltzmann averaging of the initial states gives rise to a dependence of the reaction path on temperature. The paths are different for low-temperature (tunnelling predominates) and high-temperature (tunnelling effects are slight) processes; its optimisation ensures a smooth transition between these kinetic regimes. However, in practice, such advanced scheme has never been applied to particular HAT or PT reactions. Actually, calculations are always carried out for a fixed trajectory chosen by some procedure.

The equation for the rate constant in a multidimensional case has the form:^{156, 157}

$$k = A \exp[-W(E)].$$

The pre-exponential factor A can be conveniently calculated in a special coordinate system, which is usually referred to the reaction path curve, also called the reference curve. One of the coordinates (the reaction coordinate) is measured as an arc length along the reference curve. A local system of Cartesian transverse coordinates is specified at every point of the reference curve; usually, the coordinates are modelled as harmonic oscillators. In these ‘natural reaction coordinates’,^{158, 159} the PES is a multidimensional valley stretched along the reaction path and the expression for kinetic energy has a complex form depending on the curvature of the reference curve.^{158–161} The corresponding multidimensional Hamiltonian is called the reaction path Hamiltonian.¹⁶⁰ The minimum potential energy route is normally used as the reference curve: in this curve, the PES cross-sections along the transverse coordinates have minima.¹⁶¹ This path connects the TS, *i.e.*, the saddle point on the PES, with the reactant and product minima, although the action for transverse coordinates rather

than the potential cross-section profile should have a minimum on the reference curve in a consistent theory.¹⁵⁷

b. The variational transition state theory

In the variational approach, the standard minimum potential energy route on the PES is chosen as the reaction path (in some cases, insignificant modifications are made).^{162–164} The theory remains classical in this respect. The expression for the rate constant derived in terms of the classical TS theory by the variational method is used.^{91, 165} The critical point in the reaction coordinate at which the reaction flux is calculated (*i.e.*, the TS) does not coincide with the top of the barrier. According to the variational theory, it is determined by minimising the expression for the rate constant with respect to the position of the TS in the reaction coordinate. At the final stage, a transmission factor (28), determined by tunnelling along a curvilinear reaction trajectory, is introduced to the rate equation.

This method was used to study HAT reactions in the gas phase^{166–168} and in solutions^{169–172} and PT and hydride ion transfer in enzymes.^{173, 174} The calculation of a model collinear reaction (see Section II.3.a) in the presence of 250 solvent (methyl chloride) molecules is notable from the procedural standpoint.¹⁷⁵ The classical minimum energy path was calculated taking into account all degrees of freedom of the system. As noted above, the variational TS theory was implemented to calculate the transmission factor.

It is clear that this approach cannot be extended to the region of low-temperature kinetics.

c. Low-temperature instanton method

In the low-temperature instanton approach,¹⁷⁶ the reaction path corresponds to a classical action minimum on the under-barrier trajectory in the inverted potential. The start of the trajectory is chosen in the reactant minimum on the real (rather than inverted) PES. This is valid for $T = 0$ K. The classical action is calculated along such trajectory and a correction for the interaction with transverse vibrational degrees of freedom is introduced into the resulting expression (in terms of the perturbation theory).^{177–180}

The use of this method is currently restricted to the study of tunnel splittings in the microwave spectra of non-rigid molecules. The calculations of splittings have been carried out for both the ground state and the vibrationally excited states. Systems with intra- and intermolecular hydrogen bonds, namely, malondialdehyde and formic acid dimer, have been considered. Two-proton tunnelling transfer in the porphyrin molecule has been discussed.¹⁸¹ A study of splittings in the malondialdehyde molecule with 21 degrees of freedom is the utmost achievement in this series of studies.¹⁸²

d. The model instanton method

The model instanton approach¹⁵¹ employs the classical reaction path with a classical TS at the PES saddle point. This is an attempt to take into account the influence of all the other (transverse) vibration modes without resorting to the perturbation theory. This is indeed possible for a model two-dimensional PES formed by two paraboloids (see Fig. 2a).¹⁸³ Extrapolation of this model to a multidimensional situation gave the equation^{184, 185}

$$W = \frac{W_0}{1 + \sum_s \delta_s(T)} + \alpha_s \sum_a \delta_a(T), \quad (74)$$

where W is the dimensional action, unlike the dimensionless action $(1/\hbar)W$ [see, for example, relation (25)]. The action W_0 is calculated along the standard classical reaction path. The transverse degrees of freedom are separated into symmetrical (the subscript s) and antisymmetrical (the subscript a); the symmetry is determined at the point of classical TS. ‘Symmetrical’ and ‘antisymmetrical’ are synonyms for ‘reorganisation’ and ‘promoting’ modes. The corrections they introduce to the action are additive. The δ_s , α_s and δ_a values can be explicitly calculated

from a specified multidimensional PES. Expression (74) is an empirical prescription, which provides physically reasonable estimates in some limiting situations. Of interest is the appearance of a typical temperature dependence of the action

$$\delta_s(T) = \delta_s \Big|_{T=0} \text{cth} \frac{\hbar \omega_s}{2k_B T},$$

where ω_s is the frequency of the corresponding symmetrical vibration. The reaction rate constant is calculated in terms of the standard instanton procedure

$$k(T) = A(T) \exp \left[-\frac{1}{\hbar} W(T) \right]. \quad (75)$$

As in standard instanton methods, the pre-exponential factor is replaced by an effective frequency, which characterises the system vibrations in the reactant potential well.

This method was applied to study the tunnel splittings for intramolecular PT (malondialdehyde,¹⁵¹ tropolone¹⁸⁶ and 9-hydroxyphenalenone¹⁸⁵). The rate constants have been calculated for many reactions^{187–191} including two-proton transfer in porphins.¹⁸⁵ The temperature dependences of the rate constants and the isotope effects were compared with experimental data.

The tunnel splittings for malondialdehyde have been calculated taking into account all the vibrational degrees of freedom and using various modifications of the instanton method.^{192–194}

2. Two-state model with the molecular description of the medium

a. Collective coordinate of the medium

The quantum theory of PT reactions with allowance for two electron–proton states is used fairly often (see Section II.2). A Hamiltonian depending on the variables s (proton coordinate) and R (symmetrical vibration of the A_1 and A_2 fragments, promoting mode) is written down for a three-particle $A_1 \cdots H \cdots A_2$ model system. An ensemble of modes of the medium Q_v , which interact with s and R , is added to the system. The complete Hamiltonian depends on each of the variables. Quantisation of the coordinate s in the basis set of two diabatic functions $\varphi_n(s|R, Q_v)$, $n = 1, 2$, gives the matrix Hamiltonian

$$H = \begin{pmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{pmatrix}, \quad H_{12} = H_{21}. \quad (76)$$

The diagonal elements are the classical Hamiltonians for two electron–proton states

$$\begin{aligned} H_{11} &= T_R + T_Q + \varepsilon_1(R, Q_v), \\ H_{22} &= T_R + T_Q + \varepsilon_2(R, Q_v), \end{aligned} \quad (77)$$

where T_R and T_Q are the kinetic energies for the mode R and the medium coordinate Q ; ε_1 and ε_2 are the corresponding FES, which are found by solving the Schrödinger equation for the coordinate s

$$h_s \varphi_n(s|R, Q_v) = \varepsilon_n(R, Q) \varphi_n(s|R, Q_v), \quad n = 1, 2. \quad (78)$$

The proton Hamiltonian h_s is specified by Eqn (9). The potential in this case is the full PES in the coordinates s , R and Q_v , in which R and Q_v are considered as parameters. The corresponding parametric dependence appears in the solution of Eqn (78), i.e., in the eigenvalues ε_n and eigenfunctions φ_n .

A remark concerning the designations is pertinent. In the key relations (8), (9) for quantisation of the proton coordinate s , the type of representation (either adiabatic or diabatic) is not specified; therefore, the potentials $V(s)$ and the eigenfunctions $\varphi_n(s)$ can be both adiabatic and non-adiabatic. In further consideration in Section II.2, the designation φ_n is used for functions of the adiabatic basis, whereas diabatic functions were designated by χ_n . Here, it is more convenient to use the common designation φ_n for both diabatic and adiabatic functions.

It should be noted that Hamiltonian (76) can be represented in the form

$$H = \begin{pmatrix} 0 & H_{12} \\ H_{21} & \Delta\varepsilon \end{pmatrix} + H_{11}, \quad (79)$$

$$\Delta\varepsilon = H_{22} - H_{11} = \varepsilon_2(R, Q_v) - \varepsilon_1(R, Q_v).$$

The dynamics and kinetics of the interlevel transition do not depend on the scalar (non-matrix) value H_{11} . The matrix element of the transition H_{12} (equal to H_{21}) is specified empirically. The energy gap $\Delta\varepsilon$ is the only significant variable; as can be seen from Eqn (79), the dependence on the particle velocity, present in Eqn (77), has disappeared because the classical kinetic energy is the same in the states φ_1 and φ_2 . The variable $\Delta\varepsilon$ is a typical collective coordinate; calculation procedures with the use of this variable are well developed (numerical modelling by the MD or Monte-Carlo methods). This investigation scheme was first applied by Warshel and coworkers;^{195–197} subsequently, various modifications of this scheme were applied by many authors.

b. Triatomic model of a proton transfer reaction in a model solvent. Calculations by molecular dynamics

A popular investigation object is the PT reaction (acid–base equilibrium) in the molecular complex

where PT is accompanied by pronounced polarisation of the heavy fragments A and B . In the calculations described above, the fragment A is represented by phenoxide $C_6H_5O^-$, while the fragment B is the amino group [trimethylamine $N(CH_3)_3$ is a typical example]. The reactants and products in reaction (80), described by the functions φ_n , which have served as the basis for constructing Hamiltonian (76), have dipole moments $\mu_1 \approx 2$ D (covalent complex) and $\mu_2 \approx (10–15)$ D (ion pair), respectively. The solvent particles are simulated in MD calculations by methyl chloride (CH_3Cl , $\mu = 2.15$ D).

The calculation starts with explicit solution of the Schrödinger equation (78) for the diabatic proton states. The single-well diabatic potentials $V(s|R, Q_v)$ appearing in the proton Hamiltonian h_s are modelled empirically by combining the LEPS (London–Eyring–Polanyi–Sato) type schemes for the internal variables s , R in the gas-phase reactions¹⁹⁸ with the MD parametrisation of the interactions involving the solvent particles.⁶³ With respect to the proton coordinate s , the functions $V(s|R, Q_v)$ are highly asymmetric single-well potentials (see Fig. 3). With these potentials, Eqn (78) can be solved numerically. This demonstrates the unique advantage of introducing the collective variable $\Delta\varepsilon(R, Q_v)$ [see Eqn (79)]. Equation (78) is solved for a one-dimensional set of values of the coordinate $\Delta\varepsilon$ rather than for the whole set of combinations of R and Q_v (which arise, for example, in a calculation with 256 solvent particles⁶³). This gives two diabatic FES, $\varepsilon_1(R, Q_v)$ and $\varepsilon_2(R, Q_v)$, in which the explicit dependence on the medium coordinate is included through $\Delta\varepsilon$. Diagonalisation of the Hamiltonian (79) gives two adiabatic FES

$$E_{1,2} = \frac{1}{2} \left[\varepsilon_1 + \varepsilon_2 \pm (\Delta\varepsilon^2 + 4H_{12}^2)^{1/2} \right]. \quad (81)$$

The free energy surface for the ground adiabatic state E_1 is double-well (see Fig. 2b). It is significant that in the TS region, the medium coordinate $\Delta\varepsilon$ is the reaction coordinate: the FES profile along $\Delta\varepsilon$ has a maximum at the saddle point.

The way for calculating the kinetics of reaction (80) is obvious in the adiabatic approximation where the transitions between surfaces E_1 and E_2 are ignored. In the simplest version, the coordinate R is considered to be classical (the medium coordinates Q_v are always classical in this model). The rate constant is then calculated using a standard MD procedure, namely, the steady-state reaction flux method.⁵⁵ It is reduced to the calculation of

k_{TST} , *i.e.*, the rate constant in the TS approximation, and the correcting classical transmission factor κ_c :

$$k = \kappa_c k_{\text{TST}}. \quad (82)$$

For determining κ_c , the correlation functions for the coordinate $\Delta\epsilon$ and its derivative with respect to time ($\Delta\dot{\epsilon}$) have to be calculated (by MD methods).^{63, 199, 200} When these functions are known, one can also determine the friction kernel in the generalised Langevin equation (see Supplement I) and calculate κ_c within the framework of the KGH stochastic theory.⁶³

In earlier studies of reaction (80), the promoting mode R was not taken into account.^{29, 200–203} The most comprehensive study was carried out for a two-dimensional model ($R, \Delta\epsilon$) with allowance for quantisation of R .⁶³ The transmission factor varied in the range of $0.4 < \kappa_c < 0.8$ depending on the parametrisation. The attempts to take into account the non-adiabatic transitions within the framework of this scheme are not quite consistent.^{63, 200} The transition probability for a one-dimensional potential profile along the coordinate $\Delta\epsilon$ has been calculated by the Landau–Zener method.⁸⁸ Then it was averaged with allowance for the statistical distribution of the $\Delta\epsilon$ values using the MD technique. The choice of parametrisation for the transition matrix element H_{12} is significant at this stage.

c. Quantum effects

According to the accepted terminology (see Section II.2.a), reaction (80) has a low barrier. The quantum effects involved are insignificant. Conversely, HAT reactions in systems containing hydrocarbon molecules have high barriers. The quantum transmission factors for them are low ($\kappa_q < 10^{-4}$ or lower^{166–168}). The golden rule procedure for their calculation is considered in Sections II.4.a and II.4.c. This line of research was initiated by early studies performed before the mid-1980s.^{126, 143, 148} Subsequently, this approach was modified by using advanced computer simulation procedures.^{27, 28, 30, 149} However, no calculations of this type for particular systems taking account of quantum effects have been reported so far.

A complete and consistent theory for describing the kinetics of reaction systems with multidimensional double-well FES taking into account the tunnelling and non-adiabatic transitions should cover the two above-mentioned limiting cases and intermediate kinetic regimes. No theory of this type has yet been developed. Some approximate approaches are considered in Section II.2.b. Calculations of the probabilities of non-adiabatic transitions in model one-dimensional multilevel systems are documented.^{204–206} In terms of the principles inherent in them, these calculations are related to calculations of two-level systems considered in this Section and to quantum-classical calculations of PT (see below, Section III.4).

3. Continuum models of the medium

a. Definition of the problem in the adiabatic representation

A two-state model of the reaction subsystem with explicit inclusion of the surrounding solvent particles is considered in Section III.2. An alternative problem formulation is possible on the basis of a continuum description of the medium.^{64, 65, 69}

The first stage is to construct the FES for the ground state of the system spanned by the coordinates s, R, X , where X is the collective coordinate of the medium. Its definition was borrowed from the theory of electron transfer.^{66, 87, 207, 208} The corresponding Hamiltonian has the form

$$H = T_s + T_R + S + W(s, R, X), \quad (83)$$

where T_s and T_R are the kinetic energies of modes s and R ; in the general case, these are quantum-mechanical operators; the value $S = X^2/2E_r$ is the self-energy of the polarisation field of the medium. Polarisation is induced by the electric charges of the chemical subsystem, which are calculated by quantum-chemical methods. The reorganisation energy E_r appearing in the expression for the self-energy is the key parameter of the electron transfer

theory (see Sections II.1.b and II.4.b); it is calculated within the framework of continuum models of the medium.^{209–212} The three-dimensional FES $W(s, R, X)$ is constructed in terms of the semi-empirical scheme combining the quantum-chemical calculation with calculation of the polarisation effects (dependence on X) in terms of continuum models.^{213, 214} This FES is a double-well surface on which the reaction transition takes place.

The proton coordinate s is excluded at the next stage. The numerical solution of the Schrödinger equation

$$[T_s + W(s, R, X)] \varphi_n(s|X, R) = \varepsilon_n(X, R) \varphi_n(s|X, R) \quad (84)$$

for different fixed X and R values gives the eigenvalues $\varepsilon_n(X, R)$ and the eigenfunctions $\varphi_n(s|X, R)$; $n = 1, 2$. They correspond to the adiabatic representation, because $W(s, R, X)$ in Eqn (84) is the total potential of a two-level system. (In this respect, this scheme differs from the diabatic one considered in Section III.2.b, although the diabatic definition is also possible in the continuum model of the medium.²¹⁵) Two two-dimensional FES, $\varepsilon_1(X, R)$ and $\varepsilon_2(X, R)$, obtained from Eqn (84) correspond to the ground and excited states of the proton subsystem. The dynamic description of the continuum variable X is performed using stochastic or diffusion models. Two-dimensional and two-level stochastic (or diffusion) equations of motion, whose one-dimensional versions are considered in Section II.2.b and in Supplement I, are found for these surfaces.

b. Non-adiabatic transitions

The matrix element which determines non-adiabatic transitions between the levels in the adiabatic representation is an imaginary quantity^{65, 69}

$$H_{12} = \frac{\hbar}{i} (v_R J_R + v_X J_X), \quad (85)$$

where v_R and v_X are the velocities corresponding to the coordinates R, X

$$J_R = \left\langle \varphi_2 \left| \frac{\partial}{\partial R} \right| \varphi_1 \right\rangle, \quad (86)$$

$$J_X = \left\langle \varphi_2 \left| \frac{\partial}{\partial X} \right| \varphi_1 \right\rangle.$$

The intensity of non-adiabatic transitions is determined by the parameter ξ

$$\xi = \frac{|\langle H_{12} \rangle_T|}{\varepsilon_2 - \varepsilon_1}, \quad (87)$$

$$\langle H_{12} \rangle_T = \hbar \left(\frac{2k_B T}{\pi} \right)^{1/2} \left(\frac{J_R}{\sqrt{m_R}} + \frac{J_X}{\sqrt{m_X}} \right).$$

Here, the averaging $\langle \dots \rangle_T$ takes place over the Maxwell velocity distribution; m_R and m_X are the masses corresponding to the coordinates R and X (m_X is estimated on the basis of generalised Langevin equation^{64, 69}). The ξ value is calculated at the point where the surfaces ε_2 and ε_1 approach each other most closely and the energy gap $\varepsilon_2 - \varepsilon_1$ is the smallest.

c. Systems with the C–H...C reaction centre

The free energy surface $\varepsilon_1(X, R)$ for the ground (proton) state of the reaction system

is shown in Fig. 5. It bears a strong resemblance to a similar double-well FES calculated in the molecular description of the medium.⁶³ The calculation of reaction (88) showed⁶⁴ that $\xi \ll 1$, *i.e.*, the reaction is adiabatic. This is a reaction with a low barrier. If non-adiabatic transitions are neglected, the classical reaction kinetics can be derived using the KGH theory.

The opposite limiting case is represented by the reaction

where FluH is the fluorene molecule. This is a reaction with a high barrier, a very small energy gap $\varepsilon_2 - \varepsilon_1$ and $\xi \gg 1$, which complies with the non-adiabatic kinetics. The quantum transmission factor is estimated as $\kappa_q \approx 10^{-5} - 10^{-7}$ (see Ref. 65). This exceptionally low value corresponds to the deep tunnelling regime and is at variance with the insignificant isotope effect ($k_H/k_D \approx 10$) observed in the experiment. Apparently, this contradiction can be eliminated by noting that two internal coordinates s and R are inadequate for full description of the PES for reaction (89). It is necessary to take into account the dependence of PES on the reorganisation modes describing the change in the environment of the reaction centre. Their role is described in Section II.1.b. In view of this circumstance, it is possible to decrease the effective barrier to tunnelling²¹⁶ and to increase the quantum transmission factor by several orders of magnitude.

d. Coupled electron and proton transfer

The model described above was developed and applied for interpreting the features of coupled electron and proton transfer.^{215, 217–219} This type of process takes place in the system

where R is 3,3',4,4'-tetramethyl-2,2'-bipyridine. The synchronous transition of two protons is accompanied by substantial charge redistribution between fragments of system (90). For describing these effects one should circumvent the limitations of the two-level model of the reaction subsystem. A large number (4 or 8^{215, 218}) of electron–proton states corresponding to various basis structures of the valence bond method should be explicitly included into consideration. In the case of N states, a matrix ($N \times N$) Hamiltonian and N coordinates of the medium ($X_1, \dots, X_N$) appear. Before constructing the matrix Hamiltonian (*i.e.*, before excluding the coordinate s), one should proceed from the ground state Hamiltonian, similar to Hamiltonian (83) but depending on all the medium coordinates X_i , $i = 1, \dots, N$. The self-energy S of the medium polarisation field is^{208, 209}

$$S = \frac{1}{2} \sum_{ij} (T^{-1})_{ij} X_i X_j, \quad (91)$$

where T is the reorganisation matrix, which is calculated using techniques of the continuum theory of the medium.

When dealing with the given multilevel theory, non-adiabatic transitions between various pairs of basis states arise. They can be classified into transitions with electron transfer and transitions with PT. This calculation procedure has been developed in detail^{215, 220} and brought to the calculation of the rate constant in a kinetic regime such that the non-adiabatic electron transfer is treated in the usual way in terms of the golden rule and PT takes place on adiabatic FES without transitions between the FES.^{215, 219} The results provided an explanation for some features of the coupled electron and proton transfer for system (90) and other related systems. An alternative interpretation has been proposed in earlier theoretical studies,^{221, 222} but they appear less convincing.

e. Some conclusions

Little experience in using continuum models of the medium to calculate PT reactions has been accumulated so far. Apart from the studies described above, calculations of bimolecular and intramolecular PT in water should be mentioned.^{223, 224} The available material allows one to draw some conclusions concerning the prospects of the continuum method as applied to PT reactions.

First, the use of continuum models greatly facilitates the calculations compared to those done in terms of similar molecular models of the medium.

Second, description of the rearrangement of chemical subsystem in the basis set of two electron–proton states restricts the scope of the method. This is true not only for coupled electron and proton transfer where extension of the basis of quantum states is the key item of the theory.^{215, 218, 219} The calculations of FES for usual PT systems revealed characteristic situations in which the limitations of the two-level model result in serious inconsistencies.⁶⁹ The two-level approximation equally restricts the validity of calculations with the molecular description of the solvent.

Third, a substantial restriction follows from the usual two-coordinate model of PT, which takes into account only two internal degrees of freedom (coordinates s and R) of the reaction subsystem. The reorganisation of modes associated with the change in the close environment of the reaction centre is an important factor for many PT and HAT reactions with a high barrier.²¹⁶ It has a crucial influence on the kinetics of HAT reactions; when the changes in these modes are ignored, the tunnelling effect is substantially overestimated.

Fourth, it is necessary to note a serious problem of the continuum theory, which restricts its practical value. The problem lies in the basic concept of the cavity which incorporates the reaction subsystem in the continuum medium. The change in the cavity during the reaction is supposed to induce no substantial energy or dynamic effects. This hypothesis is applicable to intramolecular processes for which the change of the cavity can indeed be considered insignificant. In bimolecular systems with PT and HAT, the cavity changes during the reaction but no procedures for calculation of the concomitant effects are suggested by the continuum model of the medium. This problem does not arise in the case of molecular models of the medium; this forms the strategic advantage of the latter.

Thus, the existing continuum theories of the solvent are barely applicable to a detailed quantitative description of PT and HAT reactions, although they are attractive for a qualitative description due to their simplicity and clarity.

4. Numerical modelling of proton transfer reactions by molecular dynamics

a. Quantum-classical methods

The use of simplified structural and dynamic models for a reacting subsystem (see Sections III.2 and III.3) restricts the scope of investigation of real chemical objects. In this respect, of interest are attempts at direct computer simulation of PT dynamics based on microscopic (molecular–dynamic) description of the solvent without rigorous constraints on the form of quantum electron–proton states. These approaches consider joint dynamic evolution of quantum and classical degrees of freedom. The number of quantum variables is limited; usually, only a single proton coordinate s is considered. The list of classical variables includes several selected kinetically active coordinates of the reacting subsystem and the coordinates of several hundred of solvent particles. The general strategy for deriving the quantum–classical equations of motion is standard (the main principles are outlined in Sections II.2.a, II.2.b and III.2). The equations of motion along quantum coordinates (the Schrödinger equation for the wave function or the von Neumann equation for the density matrix) involve a parametric dependence on all the classical variables (*via* the interaction potential).

Further development of this approach includes explicit derivation of the time dependence of the classical variables by MD computation of their evolution. Substituting the resulting multidimensional classical trajectory into the quantum equation of motion, *i.e.*, expressing the parameters of the potential of a quantum variable as functions of time, gives a time-dependent Hamiltonian. It controls the quantum evolution, which is accompanied by transitions between the levels. This non-adiabatic multilevel dynamic set of equations contains, in principle, tunnel-

ling effects. The back influence of the quantum subsystem on the classical variables is taken into account using the generalised Hellmann–Feynman theorem; the corresponding classical forces are determined by differentiating the electron–proton PES along the classical coordinates. Since the total quantum state is time-dependent, *i.e.*, it contains several stationary adiabatic components with time-dependent coefficients, their contributions are averaged with time-dependent weights.

Thus, a classical MD computation gives non-pairwise multi-particle forces, which are added to the pairwise Lennard-Jones forces acting between the solvent molecules. As a result, one can obtain a closed self-consistent scheme for the calculation of combined dynamic evolution of quantum and classical coordinates adapted for the use of well-developed MD procedures. This is the main advantage of this scheme; however, the scope of its applicability is not entirely clear. The completeness and self-consistency is attained at the expense of several simplifying assumptions having no convincing substantiation. Moreover, no consistent algorithms for the calculation of reaction rate constants (similar to the reaction flux method in usual classical MD⁵⁵) have yet been formulated within the framework of this theory.

b. Some applications

Without further dwelling on the principles of quantum-classical dynamics, we would like to note that there are several versions of its computational implementation, which have been described in reviews.^{225,226} The calculations are rather laborious; most often, they are applied to oversimplified model objects. We restrict our consideration to the studies attempting to apply these procedures to real chemical or even biochemical systems.

Ester hydrolysis. Hydrolysis of esters in a neutral aqueous medium has been studied.²²⁷ The reaction complex of a dichloroacetic acid ester includes two water molecules. The following mechanism was postulated:

where R is the methoxyphenyl group. The distances d_1 (O–H, quantum variable), d_2 and d_3 (O···O and C···O, two classical variables) were included in the dynamic calculation, while the other coordinates within the complex were optimised. The PES was calculated by the AM1 semiempirical quantum-chemical method with the addition of the reactive field of the solvent to the electronic Hamiltonian. This system, together with 510 solvent (water) molecules, was included in the MD calculation. For the estimation of the rate constant, the procedure described in Section III.4.a was markedly simplified. A mechanism was postulated according to which the most probable pre-reaction configuration of the complex is formed initially and then fast PT takes place in this configuration. The structure of the pre-reaction configuration was also postulated; its formation was considered as a purely classical equilibrium process (as in the TS theory). The free energy change was calculated by the thermodynamic integration method, standard for MD. A temperature dependence of the rate constant (free activation energy is 10.7 kcal mol^{−1}) appears at this stage. The frequency of the quantum transition that contributes to the pre-exponential factor for the PT was then determined by solving the time-dependent Schrödinger equation.²²⁸ The primary result is the value of kinetic H/D isotope effect, equal to 3.9, which is consistent with experimental data.

Enzymic hydrolysis.^{229,230} The active site of the catalytic system of an enzyme (phospholipase A₂) can be represented in the form

During enzymic hydrolysis, dissociation of water molecules takes place

As a consequence, the H¹ atom moves to the imidazole fragment (shown by an arrow).

The system fragment represented in the picture was calculated by quantum-chemical methods (valence bond method calibrated against the data of *ab initio* calculations using the density functional theory). This fragment was inserted into the remaining part of the enzyme structure, which was calculated by molecular mechanics, while its dynamics was simulated by MD techniques. The coordinate of the H¹ proton was assumed to be a quantum one, while the other reaction centre coordinates were taken to be classical and were included in the MD calculation. The combined dynamic calculation of the evolution of the quantum variable and its classical environment was described in Section III.4.a; as has been noted, the reaction rate constant cannot be calculated in this way. Therefore, auxiliary characteristics of the reaction were extracted from the calculation which provided useful information for the understanding of the mechanism of catalysis.

Tentative conclusions. It can be seen from the above examples that model-free quantum-classical calculations still cannot be regarded as a routine tool for chemists. However, good prospects of this approach are beyond doubt. Its practical implementation requires higher computational facilities and development of new, more efficient and reliable calculation algorithms.

Note that in all systems studied by this method, the tunnelling effects were insignificant. They were also insignificant in the test calculations for simple systems that preceded the calculations described above {PT reactions in the [NH₃···H···NH₃]⁺ system,^{229,231} in protonated malonate ion,²²⁸ and in deprotonated water dimer [H–O–H···OH][−] (see Ref. 232) were studied}. The question of the possibility of reliable description of PT kinetics in a deep tunnelling regime in terms of the quantum-classical approach remains open. More promising in this respect is the theory in which the PT or HAT kinetics is considered on the basis of the quantum-mechanical perturbation theory, while the dynamic effect of the medium can be taken into account within the framework of classical MD.²³³ This advanced modification of the multimodal harmonic PT theory (see Section II.4) fully takes into account the anharmonic effects and removes restrictions on the shape of diabatic potentials of the reactants and products. However, practical application of this strategy to PT or HAT processes is still unknown.

IV. Experimental data and summary of calculations of the potential and free energy surfaces

Detailed description of PT and HAT kinetics in the gas phase and condensed media requires determination of the reaction rate constants and the isotope effects over a broad temperature range. These experimental data are, however, available for a small number of reactions, because the temperature range in a particular experiment is often limited due to the destruction of organic molecules and/or crystal melting. In the liquid phase, the temperature variation range is determined by the melting and boiling points of the solvent; in addition, the solubility of many substances sharply decreases with a decrease in temperature. Moreover, the reaction mechanism can change on passing from

one aggregate state to another. For example, many processes involving acids and bases do not proceed in the gas phase but easily occur in polar media;²¹ bimolecular HAT reactions which are barrierless in the gas phase are characterised by high barriers in organic crystals,^{234,235} and crystal field effects can result in asymmetric double-well PES for systems with symmetrical O–H...O fragments.²³⁶ Therefore, experimental data often cannot be interpreted unambiguously without invoking quantum-chemical calculations. In what follows, the conclusions drawn in experimental works are compared, whenever possible, with the data of calculations. Note in this connection that the applicability of quantum-chemical methods is restricted by many factors: the size of the hydrogen-bonded system (not more than 10 heavy atoms), the occurrence of PT or HAT in electronically excited states and the influence of solvation or crystal environment.

1. Gas phase

In descriptions of intramolecular PT in the lower singlet or triplet electronically excited states, the terms of PT and HAT are often used as synonyms. When intra- and intermolecular reactions are considered together and the principles outlined in the Introduction are taken into account, it is expedient to distinguish between these terms. Proton transfer usually involves a step of hydrogen bond formation.²³⁷ The PES for this process is characterised by the presence of a potential well (or two wells), whose depth can exceed the hydrogen bond energy (5–10 kcal mol^{−1}). Hydrogen atom transfer is a radical process; therefore only shallow minima can appear on the PES (about $k_B T$).

Let us consider, for example, two exothermic reactions²³⁸ for which the motion in the reactant and product valleys can be considered translational as a first approximation (see Section II.3.b). One of these reactions is HAT involving neutral molecules and radicals

The other process is an ion–molecular PT reaction

The PES profiles for these reactions are essentially dissimilar (Fig. 11). The PES (93) has a deep minimum [~ 14 kcal mol^{−1} (see Ref. 238)], which corresponds to the formation of the FHCl[−] complex. In addition, reaction (93) involves reactants with closed electronic shells and their electronically excited states lie very high (in $k_B T$ units). The radicals in reaction (92) can exist in different electronic states, F(²P_{3/2}) and F(²P_{1/2}); therefore, correct descrip-

tion of reaction (92) requires that at least two PES be considered.²³⁸

In the general case, HAT in the gas phase can be represented as follows:

where Y = H, D, F, Cl, O, CN; X = H, D, Cl, Br, I, *etc.*^{239,240}

The PT reaction in the gas phase can be described by several schemes:

(Y and X are the same as in the previous case²³⁹);

(Y is water, ammonia, *etc.*²⁴¹);

(YH⁺ is H₃O⁺, X is methylamine²⁴²);

(A and B are either heteroatoms incorporated in the same molecule and linked by an intramolecular H-bond or terminal atoms in hydrogen-bonded dimers, trimers, *etc.*);

(AH and B designate a conjugate acid–base system).

Many HAT reactions [see Eqn (94)] and ion–molecular PT reactions [see Eqns (95)–(97)] are highly exothermic and readily proceed in the gas phase. The intramolecular PT process (98), where A = B (or the synchronous transfer of two protons in dimers with two hydrogen bonds), proceeds in a symmetrical double-well potential and is accompanied by simultaneous rearrangement of the system of double and single bonds. Finally, the gas-phase PT reaction between neutral molecules [see reaction (99)] is endothermic, the equilibrium being often appreciably shifted to the left.^{20,21}

A special type of reaction is represented by hydride ion H[−] transfer, for example

where $[\text{R}^1]^+ = \text{C}_2\text{H}_5^+$, *tert*-C₄H₉⁺ and so on, and R²H are hydrocarbons with 4–8 carbon atoms containing at least one quarternary carbon atom.²⁴³

a. Intermolecular hydrogen atom transfer

A large number of experimental and theoretical works on the intermolecular HAT in the gas phase have been published.^{109–112} The corresponding rate constants and their temperature dependences are systematically summarised and discussed in monographs and reviews.^{244–246} It has been noted above that this reaction follows a radical mechanism and that the pre- and post-reaction states in the gas phase have shallow minima on the PES (depths of about $k_B T$). Therefore, the scattering cross-section is a fundamental characteristic of the process and the methods of process investigation are based on the scattering theory, which describes transition from an unbound state of the reactants into an unbound state of the product (see Section II.3.b). An adequate description of HAT dynamics requires that at least two coordinates be taken into account. In the simplest case, these are the lengths of the breaking and forming bonds of the hydrogen atom. Considerable attention has been devoted to the reaction H₂ + X, where X = H, D, F, Cl, *etc.*^{247–253}

The PES of reaction (92) has a relatively low potential barrier [~ 1 kcal mol^{−1} (Ref. 254)].

The scattering in a system comprising three atoms, ‘heavy–light–heavy’, for example,

requires particular attention because many theoretical methods developed to describe this reaction^{49,255} are applicable to the

Figure 11. PES profiles for two bimolecular gas-phase reactions. (1) radical HAT reaction, (2) ion–molecular PT reaction.

description of intramolecular PT or synchronous transfer of two protons in dimers (98). The main conclusion of the theory is the possibility of formation of the metastable IHI complex in the PES region corresponding to the TS. The complex is of a dynamic nature. The minimum on the PES is not very deep, about 2 kcal mol⁻¹ (see Ref. 49). However, calculations show that several levels corresponding to symmetric vibrations of IHI may occur in the potential well.²⁵⁶ Experimental studies confirmed the existence of a metastable IHI complex.^{257, 258}

The bimolecular elimination of a hydrogen atom from methanol and dimethyl ether

has been studied both in the gas phase and in aqueous solutions. In the gas phase, this exothermic reaction ($\Delta H \sim -10$ kcal mol⁻¹) was studied over a broad temperature range (298 to 575 °C).²⁵⁹ The H/D-isotope effect is very small; the temperature dependence of the rate constant is well described by the Arrhenius equation. Therefore, it was concluded that no tunnelling effects are involved in reaction (102).²⁵⁹

b. Proton transfer in ion–molecular reactions

Gas-phase PT in ion–molecular reactions of type (95)–(97) have been extensively studied (see reviews^{239, 241, 242, 260}). Ion cyclotron resonance, high-pressure mass spectrometry and flowing after-glow technique were used most often in these studies. The principal results of these investigations include elucidation of gas-phase acidity scales,^{260–264} basicity and proton affinity scales^{242, 264–266} and a detailed description of solvation of the H₃O⁺ ion in the gas phase.²⁶⁷

A large array of kinetic data has been obtained for PT reaction (95) (see Table III in Ref. 239). Depending on the nature of the anion and the ‘acid’ molecule participating in the reaction, its exothermic effect varies from -0.68 to -2.82 eV and the rate constant ranges from 1.5×10^{-10} to 3.7×10^{-14} cm³ (molecule)⁻¹ s⁻¹. Comparison of the kinetic parameters of this reaction with similar data for HAT reactions [see reaction (94)] shows that, with exothermic effects being similar, the rate constant for PT is two or three orders of magnitude higher than the rate constant for the corresponding HAT reaction, which is due to the presence of a deep minimum on the PES of ion–molecular reactions (see Fig. 11).

c. Intramolecular proton transfer

The intramolecular PT and synchronous transfer of two protons in carboxylic acid dimers in the electronic ground state have been studied by radiospectroscopy and vibrational spectroscopy. Symmetrical reactions, *i.e.*, those with equivalent initial and final states, are usually considered. Proton transfer in these reactions shows itself as tunnel splitting of the ground vibrational state. The experimental value of splitting is ~ 21 cm⁻¹ for malondialdehyde,³⁷ varies from 1 to 5 cm⁻¹ for mixed carboxylic acid dimers,³⁶ or equals 1 cm⁻¹ for tropolone.³⁸ Due to procedural difficulties, virtually no data on the tunnel splitting for vibrationally excited states are available.^{36, 268, 269}

The influence of H/D isotope substitution on the tunnel splitting and on the geometric structure of H-bonded systems has been studied. The tunnel splitting for deuterium was found to be strongly reduced (by an order of magnitude). The equilibrium distance between hydrogen-bonded atoms usually increases by ~ 0.02 Å. This is the so-called Ubbelohde effect,²⁷⁰ whose theoretical interpretation is based on the assumption of strong interaction between the coordinate of the tunnelling particle and low-frequency vibrations of hydrogen-bonded heteroatoms.^{3, 78} Theoretical estimates of tunnel splitting are discussed in Sections III.1.c and III.1.d.

Vibration-rotational tunnelling spectroscopy seems to be a promising method for the study of systems with H-bonds in the ground electronic state.²⁷¹ However, this method has not yet been applied to PT reactions.

Numerous publications describe the use of spectroscopy to study PT in the lower singlet electronically excited state S₁ (see Refs 90 and 272). This is due to fast development of spectral methods with high temporal or space resolution based on the use of frequency-controlled lasers.^{42, 273, 274} The studies are usually carried out for large aromatic (pseudo-aromatic) molecules containing one or several functional groups which are linked by an intra- or intermolecular H-bond. The type of PES in the ground electronic state S₀ of the H-bond varies from a symmetric or asymmetric double-well surface to a highly asymmetric single-well one. Upon excitation to the S₁ state of the $\pi\pi^*$ type, the H-bond is usually retained; however, its potential markedly changes.

For systems with a symmetric double-well PES, the potential barrier separating two minima normally decreases along the effective PT coordinate (9-hydroxyphenalenone, tropolone, benzoic acid dimer), which results in a sharp increase in the tunnel splitting of the ground vibrational state.^{40, 275, 276} This is due to substantial shortening of the distance between the atoms linked by the hydrogen bond as a result of electronic excitation and is confirmed by *ab initio* calculations for malondialdehyde and tropolone in the S₀ and S₁ states.^{24, 277, 278}

Electronic excitation of systems with highly asymmetric intramolecular hydrogen bonds often results in an inversion of the H-bond potential.²⁷² The excitation causes a sharp change in the acid–base properties of the functional groups that form the H-bond.²⁷⁹ Proton transfer is accompanied by very fast rearrangement of the system of double and single bonds; therefore, the ‘classical’ keto form is formed in the S₁ state, instead of the zwitter-ion.⁹⁰ This is confirmed by the data of *ab initio* calculations of *o*-hydroxyacetophenone, 2-(2'-hydroxyphenyl)benzimidazole and salicylic acid in the S₀ and S₁ states.^{52, 280, 281} The intramolecular PT in the S₁ state usually proceeds in such systems without a barrier³² and can be regarded as intramolecular vibrational relaxation. This accounts for the very high rate of PT in the S₁ state (more than 10¹² s⁻¹),⁹⁰ typical of systems with hydrogen bonds. The absence of H/D isotope effect for the rate of PT supports the conclusion that the reaction is barrierless. 1,5-Dihydroxyanthraquinone is, apparently, the only system with a highly asymmetric H-bond for which the intramolecular PT was proved to proceed through tunnelling.²⁸²

Transfer of several protons in various hydrogen-bonded complexes in the S₀ state has been studied in a number of theoretical works. Carboxylic acid dimers,^{43, 283–286} hydrogen fluoride oligomers,²⁸⁷ water tetramers,²⁸⁸ methanol tetramers²⁸⁹ and mixed dimers¹⁹¹ have been considered. A synchronous PT mechanism was assumed for the most stable cyclic structures.^{290–292} Various dynamic methods were used to calculate the tunnel splittings on the basis of PES determined by *ab initio* calculations. Note that the magnitude of tunnel splitting is very sensitive to calculation details. Slight variations of the PES caused by the use of different basis sets²⁸³ or insignificant modifications of the dynamic calculation procedure²⁸⁸ can change the resulting value of tunnel splitting by two orders of magnitude. Experimental determination of the tunnel splitting in cyclic molecular complexes by microwave spectroscopy is difficult because of the absence of a permanent dipole moment. It was suggested that synchronous transfer of protons in methanol-based complexes takes place only in cyclic structures with an even number of molecules.²⁸⁹

d. Proton transfer in molecular clusters in the S₀ and S₁ states

Proton transfer in isolated 1:1 asymmetric complexes with one hydrogen bond in the S₀ state is usually not observed in the gas phase.^{293–296} In neutral weak acid–base complexes (FH:NH₃ and PhOH:NH₃), the proton is localised near the ‘acid’ heteroatom. The potential profile along the proton coordinate corresponding to stretching of the O–H bond is single-well and highly asymmetric.^{297, 298} As the strength of the acid increases, the proton moves to the base; the profile remains single-well but becomes

very smooth.²⁹⁸ The potential energy surface for charged 1:1 complexes also has one minimum.^{299,300}

When considering ROH:X_n type clusters where ROH is an 'acid' molecule (phenol, 1-naphthol, *etc.*) and X_n are *n* solvent molecules that interact with the 'acid' (and with each other) through H-bonds, note that most of experimental data correspond to the electronic state S₁. Ammonia or water are used most often as solvents. In the case where X_n = (H₂O)_n for *n* from 1 to 21, no PT was detected.³⁰¹ For X_n = (NH₃)_n, PT does take place in the S₁ state when *n* = 3 for 1-naphthol and *n* = 5 for phenol,^{301,302} because ammonia is a stronger base than water. Clusters consisting of several ammonia molecules, for example (NH₃)₅, are known to have a fairly high proton affinity.²⁰ Thus, the PES of phenol or 1-naphthol clusters with ammonia in the S₁ state can have two minima.

Experimental and theoretical data allow one to draw an important conclusion, namely, there exists a threshold number of solvent (ammonia) molecules starting from which PT is possible^{301–308} and an adequate description of the PT dynamics requires explicit consideration of the collective coordinate, which describes synchronous motion of molecules forming the first solvation shell^{309,310} and ensures favourable energy characteristics for the PT process.³¹¹

2. Liquid phase

The structure of the reaction site (and the whole reaction system) in the liquid phase depends on the properties of the solvent (polarity, proton-donor or proton-acceptor characteristics), reactant concentrations, temperature and impurities. Proton or hydrogen atom transfer is accompanied by the rearrangement of the solvation shell of the system,^{312–314} which sharply complicates the process description at the molecular level. During the last five decades, enormous experimental material on liquid-phase reactions has been accumulated; however, interpretation of the results is the underbelly of most studies. The key problem is the difficulty of experimental determination of the geometric structures of reaction products in the liquid phase. In many cases, the product structures are postulated in order to bring the experimental data in the correspondence with the model used. The model is usually based on representing the isolated reaction complex as A–H...B or on placing the reaction complex in a cavity surrounded by a dielectric.

Thus, the molecular structure of the solvent and the problems caused by the presence of impurities (traces of water), counter-ion, complexation, *etc.* are usually neglected in the interpretation of experimental data.

a. Proton transfer between neutral molecules in aprotic solvents

A number of terms are used in the literature to describe the PT in organic aprotic solvents:³¹⁵ proton exchange reactions, molecular exchange between H-bonded complexes, ion–molecular PT, and reversible PT in H-bonded complexes. The last-mentioned term appears the most appropriate for describing the PT between neutral molecules [see Eqn (99)]. Phenol and carboxylic acid derivatives are usually considered as acids, and pyridine derivatives, pyridine *N*-oxides and aliphatic amines are taken as bases. Halogen-substituted hydrocarbons and acetonitrile are the most typical solvents.

The proton transfer in H-bonded complexes is accompanied most often by a substantial increase in the dipole moment (to 10 D),³¹⁶ pointing to an appreciable change in the geometric and electronic structures of the complex induced by PT. The changes are detected by NMR, IR and UV spectroscopy and by measurement of dielectric properties. It is clear that in a 'strong base–weak acid' system, the equilibrium is shifted almost entirely to the left, while in a 'weak base–strong acid' system, it is shifted to the right. The degree of shifting of equilibrium (99) can be found from a plot where the value

$$\Delta pK_a = pK_a(\text{HB}^+) - pK_a(\text{AH}),$$

where *pK_a* (the proton affinity), is laid off along the *x*-axis, while the *y*-coordinate is an observed quantity (the change in the dipole moment,³¹⁷ the ¹H, ¹³C or ¹⁵N NMR chemical shift,³¹⁸ integral intensity of the A–H stretching vibration³¹⁹ or the centre of gravity of this band,³²⁰ *etc.*). Usually, this gives an S-shaped curve whose inflection point corresponds to a 50% degree of PT. A feature of these dependences is sharp change in the spectral characteristic over a small range of variation of ΔpK_a . The proton affinity,³²⁰ the enthalpy of formation of the H-bonded complex,³²¹ or another quantity can be used instead of ΔpK_a . The plots obtained in this case will have a break. A unified theory for explaining these dependences is missing. It was suggested³²² that a mobile equilibrium of the considered type exists in the liquid phase but this hypothesis provoked a lot of debate. According to another publication,³²³ only one complex is formed in each case in which the proton shifts from A[–] to B⁺ as the base becomes stronger and the acid becomes weaker. Nevertheless, in some cases, mobile equilibrium still does exist because the dependence under discussion does not have any break in systems without PT.³²⁴

Equilibrium (99) has been repeatedly studied by UV spectroscopy.^{21,325,326} It was shown that depending on the dielectric constant of the solvent³²⁷ or the solution pH,³²⁸ different complexes with H-bonds are formed, in particular the A[–]...H–B⁺ complex with the transferred proton. The UV absorption bands of these complexes markedly differ in frequency and intensity.

Most of the studies mentioned above give only qualitative characteristics of PT: the structure with the transferred proton is detected and the degree of PT is estimated. The reported equilibrium constants of the PT process (see, for example Refs 317 and 329) are often phenomenological (*i.e.*, they characterise a complex multistep process whose detailed mechanism is unknown). In the case of relatively weak acids and bases, the following reactions are most probable:^{330–333} dimerisation of carboxylic acids or polymerisation of phenols; dissociation of the structure with a transferred proton to give free ions; and self-association of complexes with a transferred proton.

With excess free acid or base, other side reactions can also proceed to give ions like (BHB)⁺, (AHA)[–], *etc.*^{334–336} A review of the literature published before 1968 dealing with the secondary processes that accompany PT in solutions can be found in Chapter 8 of the monograph (Ref. 337).

It follows from the foregoing that experimental determination of the rate constant for a PT reaction in the conjugate acid–base system in an aprotic solvent in the S₀ state is a rather complicated task. Quantitative estimates of the PT kinetics in aprotic solvents were obtained in a number of the most recent studies.^{338,339} The kinetic H/D-isotope effect in the reaction between 2,4,6-trinitrotoluene and 1,8-diazabicyclo[5.4.0]undec-7-ene in benzonitrile was found to change from 18.3 to 14.5 as the temperature rises from 288 to 308 K.³³⁸ The ratios of the pre-exponential factors (~2.5) and the difference between the activation energies (~2.1 kcal mol^{–1}) are also reported. In is suggested that these values point to a tunnelling mechanism of PT.

In a study of the PT in the complex of 2,4-dichlorophenol with triethylamine in chloroethane,³³⁹ measurement of the temperature dependence of the chemical shift of the bridging proton made it possible to establish thermodynamic and kinetic characteristics of the PT process. It was concluded that in this case, the FES is almost symmetrical and has two minima. The free activation energy of PT at 195 K is only 8.9 kcal mol^{–1} and the heat of the reaction is 0.2 kcal mol^{–1}. The rate constant of the forward PT reaction is 605 s^{–1}. The concentration dependences of these values were not studied in this publication;³³⁹ therefore, the assignment of these characteristics to the PT process is not validated. Rather high reactant concentrations were used, 0.2 mol litre^{–1} for phenol and 0.4–0.6 mol litre^{–1} for amine. At these concentrations, dissociation of aggregates with high-molecular masses to give kinetically active components rather than the PT is the rate-determining step of the process.³⁴⁰

Subsequently, the occurrence of a competing process, namely, the formation of a complex consisting of two 2,4-dichlorophenol molecules and one triethylamine molecule was discovered.³³¹

The PT kinetics in the S_1 state has been characterised more comprehensively than that for the S_0 state.^{341–346} Depending on experimental conditions (temperature and solvent) and the nature of the reactants, the rate of this reaction can be limited by either non-adiabatic transitions or diffusion processes.³⁴⁷

The results of some other studies are briefly considered below. Study of H-bonded complexes of 7-hydroxyquinoline and methanol by UV spectroscopy³⁴⁸ showed that PT takes place in the S_1 state of the 1:2 complex. The activation energy of this process equals $0.54 \text{ kcal mol}^{-1}$. The activation energy of the 'back' PT in the S_0 state is $4.2 \text{ kcal mol}^{-1}$ in CH_3OH and $5.5 \text{ kcal mol}^{-1}$ in CH_3OD .

The PT kinetics in the S_1 state of 2-(2'-hydroxyphenyl)benzothiazole in aprotic non-polar solvents has been studied by femtosecond spectroscopy.^{35,349,350} The formation of the keto-form upon PT was confirmed by the appearance of a spectral band corresponding to the N–H stretching vibrations.³⁴⁹ The characteristic time of the PT is equal to 170 fs.³⁵ In 2-(2'-hydroxyphenyl)benzothiazole derivatives, the PT time varies from 100 to 200 fs. These times correspond to the motion of a proton with a great vibration amplitude and a frequency varying from 100 to 200 cm^{-1} (see Ref. 350). A similar procedure has been used to estimate the rate constant for the PT in a 1-pyrenol–triethylamine complex using a number of organic solvents.³⁵¹ The characteristic time was equal to 1 ps and almost did not depend on the solvent polarity; the replacement of the bridging proton by deuterium also had only a slight influence on the rate constant.³⁵¹

The kinetics of PT in the lower triplet electronically excited state has been studied in a number of publications.^{352–355} The keto–enol tautomerism in the lower triplet state of 2-(2'-hydroxyphenyl)benzothiazole in hexane has been investigated.³⁵² It was found that the observed rate constant for PT almost does not depend on temperature below 70 K. The H/D-isotope effect is 30 at 200 K and more than 100 at 100 K. Proton transfer was concluded to follow a tunnelling mechanism.

Quantum-chemical calculations of the PES of a PT reaction in the S_1 state are usually carried out without explicit allowance for the presence of a solvent. High-level *ab initio* calculations^{278,356} are used when considering model photochemical systems, for instance, CIS calculations^{357–358} are used for real systems with intramolecular PT (1-hydroxy-2-acetophenone³⁵⁷) or double PT (7-azaindole dimer^{358,359}).

A number of kinetic data have been obtained for synchronous transfer of several protons in hydrogen-bonded complexes in the S_0 state. Proton exchange in formic acid and methanol clusters in perdeuterated tetrahydrofuran has been studied by NMR spectroscopy.³⁶⁰ The acid and methanol form 1:1 and 2:1 hydrogen-bonded complexes in which transfer of two or three protons (deuterons), respectively, takes place. The rate constant was measured in the temperature range from 255 to 335 K. No deviations from the linearity of the Arrhenius plots were found. The activation energy varies from 6.5 to 10 kcal mol^{-1} .

The PT reaction in the porphyrin ion³⁶¹ and the double proton transfer in the porphyrin molecule³⁶² in various aprotic solvents have also been studied by NMR. In these systems, one or two protons move in a four-well potential. The rate constants for hydrogen, deuterium and tritium transfer were determined over a broad temperature range. The Arrhenius dependence is clearly non-linear. The kinetic H/D-isotope effect equals 93(34) at $T = 240 \text{ K}$ and 16.5(11.4) at $T = 298 \text{ K}$; the values for the porphyrin molecule are given in parentheses.

The mechanism of double PT in the formic acid dimer in the S_1 state in aprotic solvents has been studied in detail,³⁶³ although there is still no consensus about its nature.

The PT structure and dynamics in the H-complexes of the $\text{M–H}\cdots\text{H–OR}$ type, where M–H is the $(\text{PMe}_3)_2(\text{CO})_2$, $(\text{NO})\text{W–H}$ hydride ligand and H–OR is trifluoroacetic acid,

have been vigorously studied in the last decade.³⁶⁴ Low-temperature NMR and IR spectroscopy were used to obtain information on the PT kinetics and the activation barrier depending on the properties of $\text{H}\cdots\text{H}$ complexes, determined by the nature of the metal, the ligands and the medium (hexane, toluene and dichloroethane).^{365,366}

b. Proton transfer in protic solvents

Proton transfer in protic solvents (water, alcohols, *etc.*) requires special consideration because the reaction complex forms additional H-bonds with solvent molecules.³¹⁴ This complicates the PT and in some cases, also changes the reaction mechanism. Usually, four types of PT reactions in aqueous solutions are distinguished:³⁶⁷ neutralisation, protolysis, hydrolysis and PT in a conjugate acid–base system. The first three reactions are complex processes, in which one cannot distinguish the individual characteristics of an elementary PT step. The last-mentioned reaction can be described as follows

where n is the number of water molecules that interact with reacting molecules through the formation of H-bonds.

A large number of publications has been devoted to so-called abnormally high proton mobility in aqueous solutions. To interpret the obtained data, it is necessary to know the structure of the simplest stable proton hydrate. X-Ray diffraction and neutron diffraction methods as well as NMR provide little information due to the thermal motion of molecules in the liquid. Conclusions about the structure of the simplest proton solvate in aqueous solutions of acids are usually drawn by examining the vibrational spectra. It has been suggested initially that the simplest proton solvate is the hydroxonium ion, H_3O^+ (see Ref. 368). Thus, PT in the aqueous medium can be represented as

The PT process in water enriched in the ^{17}O isotope has been studied by NMR in the temperature range from 288 to 348°C .^{369,370} The rate constant was found from broadening of the spectral lines. The results were described by the Arrhenius equation in which the rate constant for the PT is

$$k = 6.0 \times 10^{11} \exp\left(-\frac{2.4}{RT}\right) \text{ litre mol}^{-1} \text{ s}^{-1}.$$

Thus, PT in water has a low activation energy. The lifetime of the simplest proton hydrate is 1 ps. (Most of modern theoretical studies rely on these experimental data; for example, see Ref. 371.) The hydroxonium ion really exists in solid and liquid systems if only one water molecule per acid proton is present.³⁶⁸ The existence of this ion, whose vibrations are both IR- and Raman-active, in dilute aqueous solutions of acids is not confirmed experimentally.^{372,373}

The IR spectra of all systems containing proton hydrates exhibit continuous intense absorption in the range from 3500 to 800 cm^{-1} (see Ref. 374). Studies devoted to this phenomenon are discussed in several reviews.^{45,375} According to Zundel's model,³⁷⁶ H_9O_4^+ is the most stable ion–molecular species whose vibrations can be observed in the IR spectrum of a solution. In this model, a special role is played by the extremely high polarisability of the hydrogen bond. This feature is postulated for the $\text{O–H}\cdots\text{O}$ fragment. The origin of the continuous absorption can be explained by assuming strong interaction of the bridging proton with the medium. This model is widely used in many theoretical and experimental works, despite the fact that continuous absorption is observed when the formation of the H_9O_4^+ ion is impossible and the solvation effects are minimised (aprotic low-field solvent).^{377,378} Thus, continuous absorption may be due not only to the influence of the medium but also to intrinsic properties of ions with a symmetrical hydrogen bond, the simplest of them being the H_5O_2^+ ion.³⁷⁹

A particular theory could, in principle, be validated by MD simulation of the IR spectra. However, applicability of MD techniques to the simulation of spectral properties of the proton in aqueous solutions is quite limited. The trajectory length found by so-called *ab initio* MD methods³¹² is several picoseconds; this is inadequate for calculating the IR spectrum of the solution.³⁸⁰ Molecular-dynamic approaches based on the valence bond method either make use of a linear approximation of the system dipole moment^{381, 382} or imply calculation of the vibrational spectrum by Fourier transform of the velocity autocorrelator.³⁸³ However, the linear approximation is inapplicable to the description of the dipole moment of the H_5O_2^+ ion^{379, 384} and the velocity autocorrelator was calculated for the Raman spectrum of this ion.³⁸⁴

Experimental data on PT reactions in protic solvents can be found in several reviews.^{385, 386} A widely used non-aqueous solvent is methanol, which makes it possible to measure the rate constant for the PT over a broad temperature range, from -97 to 64°C .³⁸⁷ The double PT in the $(\text{CH}_3)_3\text{NH}^+ + \text{CH}_3\text{OH} + \text{N}(\text{CH}_3)_3$ system in methanol has been studied by NMR spectroscopy.³⁸⁸ It was found that the activation energy decreases with an increase in the temperature: from $3.8 \text{ kcal mol}^{-1}$ at -97.8°C to $2.2 \text{ kcal mol}^{-1}$ at 25°C ; a tunnelling mechanism for double PT was proposed.

The influence of the solvent on the PT can be taken into account using the variational TS theory (see Section III.1.b), numerical MD or Monte Carlo modelling (see Section III.2.b), models in terms of the continual description of the medium (see Section III.3), or various quantum-classical methods (see Section III.4). Molecular dynamics methods have been successfully used to describe PT in acid–base equilibria¹⁹⁹ and in model systems²³¹ simulating ionisation of HCl in water³⁸⁹ and ester hydrolysis.²²⁷ Self-consistent reaction field methods were used to simulate the PT dynamics in systems with strong hydrogen bonds²²³ and in amino acids.²²⁴ Combined (hybrid) approaches were used to describe the solvation of the hydroxide ion,³⁹⁰ to model PT in systems with strong hydrogen bonds²³² and to calculate barriers to the PT reaction in water.³⁹¹

c. Hydrogen atom transfer in liquids

A large number of reactions involving HAT take place in liquids. In particular, HAT limits the chain termination during oxidation of organic compounds in the liquid phase.³⁹² Data on the rate constants for HAT and the influence of the H/D isotope effect on these constants are summarised and discussed in monographs and reviews (see, for example, Refs 393–395), although usually it is impossible to draw an unambiguous conclusion on the magnitude of the tunnelling effect on the basis of experimental data because no reliable data on the temperature dependence of the kinetic H/D-isotope effect in HAT are available.

The hydrogen atom transfer in the first step of oxidation of 4a,4b-dihydrophenanthrene with dioxygen in 2,2,4-trimethylpentane has been studied at $T = 191\text{--}263 \text{ K}$.³⁹⁶ In this case, the Arrhenius plot is essentially non-linear. The experimental H/D-isotope effect is 95 at 242 K .³⁹⁶ Arrhenius parameters were also found for the bimolecular elimination of a hydrogen atom from methanol in aqueous solutions in the temperature range from 283 to 359 K .³⁹⁷ The corresponding activation energy amounted to 30 kJ mol^{-1} and the observed rate constant at 25°C was $2.8 \times 10^6 \text{ litre mol}^{-1} \text{ s}^{-1}$. Comparison with the data for gas-phase reactions²⁵⁹ shows that the interaction with the solvent leads to some acceleration of the reaction ($\sim 25\%$).

A lot of data have been accumulated for intramolecular HAT.³⁹⁸ In most cases, the experimental values for the kinetic isotope effect do not exceed 3.³⁹⁸ The intramolecular HAT involved in the isomerisation of aryl radicals with bulky substituents has been characterised in sufficient detail.^{399, 400} Isomerisation of 2,4,6-tri-*tert*-butylphenyl into 3,5-di-*tert*-butylneophenyl in cyclopropane has been studied by EPR in the temperature range from 113 to 247 K . It was found that due to

steric hindrance, the abstraction of hydrogen from the solvent molecule is virtually impossible. Hydrogen atom transfer proceeds via a five-membered cyclic TS. The Arrhenius plot for the transfer of hydrogen and deuterium atoms is highly non-linear. The experimental kinetic H/D-isotope effect varies from 80 at 250 K to 13 000 at 120 K .

Various approaches are used for theoretical investigation of HAT reactions in the liquid phase. The variational TS theory is successfully used to calculate the temperature dependences of the reaction rate constant, H/D-isotope effect, the addition of a hydrogen atom to benzene⁴⁰¹ and elimination of a hydrogen atom from methanol⁴⁰² in aqueous solutions. Empirical models for the radical abstraction of hydrogen^{403, 404} are used to classify the results of analysis of the experimental rate constants and activation energies for HAT reactions.

d. Proton transfer in ion–molecular reactions in the liquid medium

A PT reaction results in highly reactive systems: carbanions, carbocations, carbenes and ylides, *etc.* Therefore, ion–molecular reactions involving PT play an important role in organic chemistry.^{405, 406} The rate and equilibrium constants for such reactions are determined by a variety of factors including the spatial and electronic structures of the reactants, their concentrations, the natures of the solvent and the catalyst and so on. Direct approach to the problem of elucidating the structure–reactivity relationship based on quantum chemistry and statistical physics techniques is seldom used for complex organic compounds. As a rule, methods of physical organic chemistry are used.^{337, 405–407} At this level, the mechanisms of chemical reactions are considered in terms of empirical and semiempirical rules. These rules can be formulated in a quantitative form as linear free energy relationships.³³⁷ Interpretation of the obtained results can be simplified by considering so-called intrinsic barriers (*i.e.*, barriers for symmetrical reactions²⁶) and the intrinsic rate constants for the PT in ion–molecular reactions.^{408, 409} From the kinetic standpoint, this situation occurs in the case where the rates of forward and back reactions are equal, and from the thermodynamic standpoint, where the reaction heat is zero irrespective of temperature and pressure. The use of intrinsic rate constants allows one to separate the thermodynamic effects from purely kinetic effects.

The dependences of the rate constant for PT on the nature of the solvent, the substituents and the strength of the base are studied most often.^{410–413} In the case of PT in carboxylic acids, this provides detailed characterisation for the relative contributions of the resonance and induction effects and the nature of the solvent to the increase in the CH acidity.^{411, 413} For PT reactions involving radical cations, negative activation energies and H/D-isotope effect values smaller than unity are often obtained.⁴¹² This may imply the existence of mechanisms alternative to the direct PT from the radical cation to the base. The H/D-isotope effects in the PT rate constant for the reaction of various methylarene radical cations and pyridine bases in dichloroethane have been estimated.⁴¹⁴ Depending on the structure of the reactants, they vary from 31 to 47. In the studies cited, the rate constants were usually determined at room temperature.

Numerous experimental works have been devoted to the PT from nitroalkanes to anions of various bases.⁴¹⁵ Usually these reactions are studied by spectrophotometry because the anions formed in the reaction exhibit strong absorption bands in the visible region. The PT from 1-nitro-1-(4-nitrophenyl)ethane to the hydroxyl ion has been studied. Aqueous acetonitrile was used as the solvent. The reaction was found to occur in two steps, the PT process taking place in the second step, which follows a unimolecular mechanism (irreversible decomposition of the ‘kinetically important’ intermediate). The PT kinetics has been studied in detail in the temperature range from 289 to 319 K . The rate constant for the PT (289 K) is 11.5 s^{-1} and the primary isotope effect is 26. As the temperature increases to 319 K , the isotope effect decreases to 16.9. The difference between the activation energies and the ratio of the pre-exponential factors for proton

and deuteron transfer have been estimated.⁴¹⁵ The researchers believe that the obtained data point unambiguously to the tunnelling mechanism of the PT reaction.

e. Coupled electron and proton transfer

Coupled electron and proton transfer can occur for the electronically excited states of organic molecules containing two functional groups (for example, 6-hydroxyquinolinone) in aqueous solutions of acids or bases;⁴¹⁶ in donor–acceptor pairs such as Ru(bipyridine)₃²⁺–3,5-dinitrobenzene;⁴¹⁷ in ruthenium complexes on a polycrystalline gold electrode;⁴¹⁸ in triads consisting of carotenoid–porphyrin–quinone molecules;⁴¹⁹ in proteins;⁴²⁰ in photoactive centres of bacteria.⁴²¹

The reaction in question takes place in a complex system which includes an electron and proton acceptor (Ac), several H-bonds and heteroatoms with a free electron pair and a proton donor (H-Dp). Its mechanism includes several successive steps:⁴²² (i) electron transfer on Ac to give a radical anion having a high proton affinity; (ii) the formation of a covalent bond between the radical anion Ac^{•−} and the proton; (iii) rearrangement of the system of hydrogen bonds resulting in elimination of the proton from the H-Dp donor to give the Dp^{•−} anion; (iv) recovery of Dp^{•−} to Dp; (v) the reverse rearrangement of hydrogen bonds resulting in the formation of the initial Ac and H-Dp.

The central point of this scheme is a sharp enhancement of the proton-acceptor properties of the molecule (functional group Ac) and the proton-donor properties of the molecule (functional group H-Dp) upon their oxidation. The rate-determining step of the reaction is electron transfer;⁴¹⁷ nevertheless, the rate constant changes when the bridging H atoms are replaced by D in the Ru(bipyridine)₃²⁺–3,5-dinitrobenzene donor–acceptor pairs.⁴¹⁷ Experimental value for the H/D-isotope effect in the electron transfer varies from 1.34 to 1.7.⁴¹⁷

The theory of these reactions is considered in Section III.3.d; the key references to theoretical studies are also given.

f. Proton and hydrogen atom transfer in biologically active compounds

Proton, hydrogen atom, and hydride ion transfer underlie a large number of processes which take place in biologically active compounds.

First, proton transfer plays a key role in bioenergetics,⁴²³ which is concerned with the mechanisms of energy conversion in redox processes in living organisms. The modern views in this field are based on the ‘chemiosmotic theory,’ which implies the presence of an electrochemical potential difference (‘proton gradient’) in protein complexes^{424,425} and in cytochrome *c*-oxidase.^{426,427} Proton transfer through membranes takes place against the proton gradient, the thickness of biological membranes being about 40–60 Å.⁴²⁵

Second, proton and hydride ion transfer are key steps in one of the most versatile biological oxidation reactions, namely, dehydrogenation of an alcohol to give a ketone or an aldehyde.^{428,429} The process is catalysed by dehydrogenase enzymes. These are dimers or tetramers composed of subunits with a molecular mass of 20 000–40 000. The removed hydrogen atoms (or hydride ions, or protons) migrate to hydrogen-transporting coenzymes, for example, nicotinamide adenine nucleotide, *etc.* The mechanism of this process is not entirely clear.⁴³⁰

Third, a large number of studies have been devoted to the role of strong (short) hydrogen bonds in enzyme-catalysed reactions.¹³ These hydrogen bonds are assumed to stabilise intermediates and/or transition states in the reactions under interest.¹⁴ On the PES of these H-bonds, two wells are separated by a very low barrier (~ 2 kcal mol^{−1}).¹⁵

For the first two of the above-mentioned types of process, detailed description of the thermodynamics and kinetics of PT and hydride ion transfer is missing. Therefore, of considerable interest are kinetic studies of HAT in enzymes.⁴³¹ Enzyme-catalysed C–H bond cleavage has been studied in detail.^{432–433} A specific

feature of this reaction is a very high kinetic H/D-isotope effect, which varies from 17 (see Ref. 434) to 56 (see Ref. 432). Hydrogen atom transfer in these systems is a rate-determining step of the complex process of C–H bond oxidation,⁴³⁴ the rate constant for HAT ranging from several to several hundred reciprocal seconds. Study of the temperature dependence of the rate constants for H and D made it possible to estimate the activation energy, which can reach 24.5 kcal mol^{−1} (see Ref. 433) and the pre-exponential factor. These experimental data suggest that HAT follows a tunnelling mechanism.

Extensive literature is devoted to the theoretical study of PT and HAT reactions in enzymic systems. In order to give a general idea of the methods and approaches used in this, rather specific field, we will mention the results of some most recent studies. Widely used are hybrid approaches^{435–437} which combine quantum-chemical calculations of the PES in the models of reaction centres with calculation of the medium effects using MD or molecular mechanics methods. Oxidation of the enzyme cytochrome P450eryF has been studied;⁴³⁵ proton tunnelling is described as a one-dimensional process (see Section III.1.a). The rate constants for HAT for three model enzymic reactions were calculated in terms of the variational transition state theory;⁴³⁶ the calculated kinetic H/D-isotope effect is in satisfactory agreement with the experiment. The energy profiles of the PT involved in the hydrolysis of peptide bonds by a model enzyme have been obtained.⁴³⁷ Phenomenological models have been used to describe the PT through biological membranes.⁴³⁸

3. Solids

The tunnelling mechanism of PT and HAT reactions in solids has been proved experimentally for a relatively small number of systems. These processes include both intermolecular and intramolecular reactions taking place in molecular crystals and in glasses. The results obtained are analysed in several reviews.^{99,157,439–442} The conclusion concerning the tunnelling mechanism of the reactions is based on three facts:

- the temperature dependence of the reaction rate constant *k* found experimentally deviates from the Arrhenius dependence over a broad temperature range, the Arrhenius dependence (*i.e.*, a linear dependence of log *k* on the reciprocal temperature) being observed at relatively high temperatures;
- a large H/D-isotope effect for the PT and HAT rate constants is found;
- the rate constants reach a plateau at relatively low temperatures.

a. Proton transfer reactions

The intramolecular PT in the molecular crystals of 9-hydroxyphenalenone derivatives has been studied by IR spectroscopy.^{443,444} At 5 K, the IR spectra of 5-bromo- and 5-iodo-9-hydroxyphenalenone exhibit intense bands at 83 and 68 cm^{−1}, respectively. These bands disappear when the bridging proton is replaced by deuterium. It was suggested^{443,444} that these bands correspond to tunnel splitting of the ground vibrational state in non-deuterated molecules.

The proton transfer in carboxylic acid dimers in the solid state often differs sharply from similar processes in the gas phase or in solutions. The reason is the crystal field effect, resulting in asymmetry of the FES along the PT coordinate for the O–H $\cdots$ O fragment, as opposed to the symmetric FES for the gas phase.^{73,74} In the case of a molecular crystal of the benzoic acid dimer, the asymmetry was 35 cm^{−1} (non-deuterated compound) and 108 cm^{−1} (deuterated compound).²³⁶ By passing to crystals doped with dye molecules, the crystal field effects can be minimised.⁴⁴⁵ The double proton transfer in the crystals of benzoic acid dimer was studied by optical spectroscopy,⁴⁴⁶ NMR^{73,74} and quasi-elastic neutron scattering^{446,447} over a broad temperature range. A sharp increase in the rate of proton transfer upon excitation of definite low-frequency vibrations has been established experimentally.⁷³ It was shown that the exper-

imental data (the NMR longitudinal relaxation time) can be adequately interpreted only using at least two-dimensional FES.⁷⁴

Some data on PT dynamics have been obtained by non-elastic neutron scattering for various crystals with intra- and intermolecular hydrogen bonds.^{448–454} Alternative models for the $N\cdots H\cdots O$ hydrogen bond, ionic^{448,449} and neutral ones,^{451,452,454} have been proposed for PT in *N*-methylacetamide crystals (this process is a prototype of PT in peptides). The reasons for choosing these models are not analysed and remain obscure.

b. Hydrogen atom transfer

Apparently, a tunnelling mechanism of the HAT reaction in a solid was observed experimentally for the first time by Wang and Williams,⁴⁵⁵ who studied the kinetics of hydrogen atom capture by methyl radicals in crystalline methyl isocyanate using EPR in the temperature range from 77 to 125 K. The Arrhenius plot for the corresponding rate constant is non-linear. The observed activation energy for the HAT reaction was 1.4 kcal mol^{−1} at 77 K and increased to 4.5 kcal mol^{−1} at 120 K. The isotope effect at 110 K exceeded 1000. It was impossible to obtain a more precise value, as the rate of abstraction of a deuterium atom was too low in the given temperature range to be measured by EPR. Later, a low-temperature limit of the HAT reaction rate has been found experimentally.⁴⁵⁶ Detachment of a hydrogen atom from a methanol molecule (in glasses) by a methyl radical was studied by EPR in the temperature range from 15 to 89 K. At 40 K, a low-temperature plateau was reached. Analogous results have been obtained in a study of hydrogen atom elimination by a methyl radical from acetonitrile,⁴⁵⁷ methanol⁴⁵⁸ and other molecules.^{399,400,459}

A large body of experimental data on the rate constant and H/D isotope effect in the temperature range from 1.4 to 300 K and for pressures from 1 to 30 atm has been obtained for HAT in the fluorene molecular crystals doped with acridine molecules.¹⁵³ In the lower triplet electronically excited state of the acridine admixture, the hydrogen atom is detached from the nearest fluorene molecule and passes to the acridine nitrogen atom. A typical feature of this reaction is the presence of several low-frequency (intra- and intermolecular) modes whose excitation accelerates HAT. This conclusion is based on investigation of the Raman spectra of these crystals at different temperatures.¹⁵⁴ For this reaction, calculations of the PES,⁴⁶⁰ in particular those with explicit allowance for the crystal environment²¹⁶ were published. (The interpretation of the temperature dependence of the rate constant¹⁵² is discussed in Section II.4.c.)

This review was written with financial support of the Russian Foundation for Basic Research (Project Nos. 02-03-33049, 00-15-97295 and 02-03-07029-ANO), and the RFBR–INTAS Foundation (Project No. 97-03-71049).

V. Supplement I. Generalised Langevin equation

For a stochastic variable x corresponding to an oscillator with the mass m_x , the frequency ω_x and the force constant $\mu_x = m_x\omega_x^2$, the generalised Langevin equation (GLE) is written in the form^{55,56,132,461}

$$m_x\ddot{x} + \int_0^t \beta(t-\tau)\dot{x}(\tau)d\tau + \mu_x x = \text{GRF}, \quad (\text{I.1})$$

where GRF is the Gaussian random force (time-dependent). Due to the presence of the dissipative integral term, the dynamics of the coordinate $x(t)$ at time t is dictated by its preceding evolution during the time period $(0, t)$. Such equations are called equations with memory or non-Markov equations. The function $\beta(\tau)$ is called the memory kernel. The regular force $\mu_x x$ is linearised; as a result, Eqn (I.1) describes a harmonic oscillator in a medium. The force linearisation is not obligatory; if the corresponding potential $U(x)$ is not quadratic, the force $(-\partial U/\partial x)$ is used. The generalised

Langevin equation with a double-well potential corresponds to the Kramers equation (13) and reduces to the latter if $\beta(t-\tau) = \gamma\delta(t-\tau)$. This particular case is called the local or Markovian limit. Equation (I.1) can be written in an alternative form

$$m_x\ddot{x} + \int_0^t \phi(t-\tau)x(\tau)d\tau + \bar{\mu}_x x = \text{GRF}, \quad (\text{I.2})$$

with a renormalised force constant

$$\bar{\mu}_x = \mu_x + \beta(\tau=0).$$

The dissipative force in Eqn I.2 depends on the coordinate rather than on the rate. The memory kernels $\beta(\tau)$ and $\phi(\tau)$ are related as follows:

$$\beta(\tau) = \int_\tau^\infty \phi(\tau')d\tau'. \quad (\text{I.3})$$

Important in the GLE theory is the Fourier–Laplace transform^{462,463}

$$\phi(\omega) = \int_0^\infty \exp(i\omega t)\phi(t)dt = \phi_1(\omega) + i\phi_2(\omega), \quad (\text{I.4})$$

where $\phi(\omega)$ is a complex function, its real $[\phi_1(\omega)]$ and imaginary $[\phi_2(\omega)]$ components being even and odd functions of frequency, respectively.

In the steady-state regime, the average $\bar{x} = \langle x \rangle_T$ value is constant. Here $\langle \dots \rangle_T$ means averaging over an equilibrated ensemble with temperature T . The correlation function of the coordinate x is the fluctuation thermal average

$$C(t) = \langle [x(0) - \bar{x}][x(t) - \bar{x}] \rangle_T. \quad (\text{I.5})$$

When $t = 0$, this gives a statistical distribution of the stochastic variable x with the variance $D[x] = C(t=0)$. The Fourier transform of the function $C(t)$

$$C(\omega) = \int_{-\infty}^\infty \exp(i\omega t)C(t)dt \quad (\text{I.6})$$

is related to the imaginary part of the Fourier image of the memory kernel by the relation

$$C(\omega) = \hbar\phi_2(\omega)\text{cth}\frac{\hbar\omega}{2k_B T}. \quad (\text{I.7})$$

This relation is called fluctuation-dissipation theorem (FDT).^{132,461–463} Relation (I.7) holds for quantum systems, its range of applicability being wider than that for the classical GLE (I.2). At the classical limit ($\hbar\omega/k_B T \ll 1$), equation (I.7) assumes the form

$$C(\omega) = \frac{2k_B T}{\omega}\phi_2(\omega). \quad (\text{I.8})$$

Since the function $C(t)$ can be calculated by molecular dynamics methods, relations (I.7) and (I.8) open up the way to microscopic calculation of the key GLE parameters. According to the KGH theory, in the case of GLE with a double-well potential $U(x)$ having a barrier with the height $U^\ddagger$, the following approximate expression for the reaction rate constant is valid:^{55,60,464–469}

$$k_{\text{KGH}} = \frac{\Omega}{2\pi} \sqrt{\frac{\mu_x}{\mu^\ddagger}} \exp\left[-\frac{U^\ddagger}{k_B T}\right]. \quad (\text{I.9})$$

Here, Ω is the decay frequency, which is determined by the characteristic equation

$$\begin{aligned}
-m_x \Omega^2 + \phi(\Omega) + [\mu^\neq - \phi(\omega = 0)] &= 0, \\
\mu^\neq &= m_x (\omega^\neq)^2, \\
\mu_x &= m_x \omega_x^2.
\end{aligned} \tag{I.10}$$

The function $\phi(\omega)$ is defined in Eqn (I.4); it is real for $\omega = 0$. The values μ_x and $\mu^\neq$ are force constants at the bottom of the reactant well and on the top of the barrier. On the barrier, the force constant is negative and the value $\mu^\neq$ is found as its absolute value. In a special case where the memory kernel $\beta(\tau)$ is proportional to the delta-function (Markovian limit), expressions (I.9), (I.10) lead to Eqns (11) and (14) for the rate constant. There exists a multimode generalisation of the KGH theory.^{55, 60, 464–469} Its use is mentioned in Section III.3.a.

VI. Supplement II. Spectral density

In the linear approximation, the collective coordinate of the medium which interacts with the coordinate of the reaction subsystem is the linear combination

$$Q = \sum_v C_v Q_v, \tag{II.1}$$

where Q_v are modes of the medium corresponding to masses m_v and frequencies ω_v . The spectral density^{96, 131}

$$J(\omega) = \frac{\pi}{2} \sum_v \frac{C_v^2}{m_v \omega_v} \delta(\omega - \omega_v). \tag{II.2}$$

is associated with the coordinate Q .

This formula can be used to calculate the sums over the modes of the medium containing the C_v^2 coefficients. It is equivalent to the sum rule:

$$\frac{2}{\pi} \int J(\omega) F(\omega) d\omega = \sum_v \frac{C_v^2}{m_v \omega_v} F(\omega_v), \tag{II.3}$$

where $F(\omega)$ is an arbitrary (rather smooth) function. The combination appearing in the right-hand part is often found in applications [see relation (69)]. By using the sum rule, one can pass from the discrete (simpler and more obvious) to a continuum (more convenient for calculations and transformations) description of the medium coordinates.

A different formulation is also useful. Let us consider a ‘chemical’ variable x which interacts with modes of the medium according to a bilinear law. The interaction potential is

$$h_{x\Omega} = \text{const } xQ = x \sum_v \bar{C}_v Q_v. \tag{II.4}$$

Here, const has the dimensionality of a force constant:

$$\bar{C}_v = \text{const } C_v.$$

In this case, the spectral density $\bar{J}(\omega)$

$$\bar{J}(\omega) = \frac{\pi}{2} \sum_v \frac{\bar{C}_v^2}{m_v \omega_v} \delta(\omega - \omega_v) = \text{const}^2 J(\omega), \tag{II.5}$$

is determined;^{96, 131} here, the sum rule is derived from (II.3) by replacing C_v by $\bar{C}_v$ and J by $\bar{J}$.

The function $J(\omega)$ is often specified parametrically. It should disappear ($J = 0$) when $\omega = 0$ and should rapidly decay at frequencies exceeding some critical value, ω_∞ . The typical representation for non-polar media is

$$J(\omega) = J_0 \left(\frac{\omega}{\omega_\infty} \right)^n \exp \left(- \frac{\omega}{\omega_\infty} \right). \tag{II.6}$$

The power n is usually 1 for processes in disordered media (liquids). In three-dimensional molecular crystals, relation (II.6)

corresponds to the Debye type phonon spectrum, $n = 2$. The frequency ω_∞ cutting the spectrum in the crystal corresponds to the Debye frequency.⁴⁶² In a similar representation for $\bar{J}(\omega)$, the constant factor J_0 is modified.

The spectral density is closely related to the classical generalised Langevin equation, which describes, in the case of interaction (II.4), the relaxation kinetics for the collective variable x . For the GLE in form (I.2), the key result is that

$$\bar{J}(\omega) = -\phi_2(\omega), \tag{II.7}$$

where $\phi_2(\omega)$ is the imaginary component of the memory kernel [see Eqn (I.4)]. It allows one to calculate the spectral density for microscopic models of the medium by MD methods because, according to FDT (I.7), (I.8), the function $\phi_2(\omega)$ can be determined from the correlation function $C(t)$ (I.5) available from an MD computation.

I. Introduction	35
II. Main types of quasi-homogeneous structures	35
III. Structures with atomic point defects (type I)	36
IV. Structures with atomic volume defects (type II)	38
V. Structures with atomic planar and linear defects (type III)	41
VI. Conclusion	45

Abstract. Main types of crystal structures with different atomic defects (point, volume, planar and linear) are considered using inorganic compounds as an example. The review presents the results of composite analysis of such real structures. Their symmetry, ordering, ways of description, nomenclature and the possibility of the diagnostics from diffraction patterns are discussed. The results of studies provide evidence that polymorphism is typical of real crystal structures. The bibliography includes 101 references.

I. Introduction

Crystalline compounds are generally chemically inhomogeneous because they contain impurities (atoms, ions, vacancies), which disrupt the three-dimensional periodicity of the host crystal structure. Numerous atomic defects are often distributed over the crystal rather uniformly. In these cases, systems are quasi-homogeneous and can be characterised by a single atomic structure, which is established by diffraction methods. The present review surveys such real crystal structures and the related views on isomorphism, polysomatism, solid solutions, mixed crystals and compounds with non-stoichiometric or variable compositions.

Extensive investigations of the real structures of chemically inhomogeneous crystals are currently underway both in Russia and abroad. In the last decades, new experimental analytical methods (synchrotron radiation, EXAFS spectroscopy, high-resolution electron microscopy, *etc.*) and powerful computer facilities have been developed and designed. Besides, a number of lines of theoretical research dealing with diffraction in quasi-homogeneous systems and their symmetry have been further elaborated. All these advances have provided a higher level of detailed information on real crystal structures. The amount of available information obtained by these methods has increased dramatically and fine details of the local structures of real crystals have been revealed. As a consequence, there is a common impression that each crystal has a unique structure and that it is

impossible to characterise real crystal structures using precise mathematical laws. In addition, a number of complex structures with non-stoichiometric compositions, which could not be described by three-dimensionally periodic models, were studied by diffraction methods and it was reported that these structures can be used for the construction of new composite crystalline materials possessing useful properties.

The aim of the present review is to analyse the available data on real crystal structures of inorganic compounds with atomic defects. Initially, types of distortion of the long-range order in chemically inhomogeneous structures and their basic classification are considered. Then the characteristic features of the main structural types (symmetry, composite character, ordering, *etc.*), the accepted nomenclature and characteristic diffraction features are discussed using inorganic compounds as an example.

The need for such generalisations became apparent long ago. Researchers from different scientific schools often use different nomenclatures for the description of analogously organised real crystal structures, which hinders mutual understanding and does not allow one to obtain the general structural picture. In the present review, relationships between numerous real crystal structures with atomic defects are revealed on the basis of precise mathematical (symmetry) laws and ways of simplifying and generalising their nomenclature are proposed.

II. Main types of quasi-homogeneous structures

Let us consider types of distortions in the ideal three-dimensional long-range order caused by impurity atomic complexes of different sizes (Fig. 1): point (zero-dimensional), linear (one-dimensional), plane (two-dimensional) and volume (three-dimensional) defects.¹

Figure 1. Types of atomic defects formed as a result of normal (a) and anomalous (b–d) isomorphous replacements; (a) point (atom or complex), (b) linear (chain), (c) planar (layer), (d) volume (block) defects.

Figure 2. Types of atomic rows in crystal structures with atomic defects (main and impurity atoms are represented by empty and solid circles, respectively);²

(a) structures without impurity atoms; main atoms follow translational symmetry with the parameter a ; (b) main and impurity atoms obey statistical translational symmetry with the parameter a ; (c) main and impurity atoms follow different translational symmetries with the parameters a and a_1 , respectively ($a_1 = na$, where n is an integer); (d) main and impurity atoms obey different translational symmetries with the parameters a and a_1 , respectively ($a_1 = \sigma a$, where σ is an irrational number); (e) a non-periodic atomic distribution.

The insertion of impurity atoms, ions or vacancies into the ideal lattice of the host crystal gives rise to atomic point defects. Such structures contain rows of main and impurity atoms in addition to regular atomic rows along which an ideal translational symmetry with the lattice parameter a of the host crystal is retained (Fig. 2a).² The atom distribution along such rows does not violate the statistical translational parameter, which is equal to the host crystal constant a (in real structures, close to a) (Fig. 2b). This means that the distance X_n between the first (A_0) and n th (A_n) atoms in the row of n atoms approaches na when $n \rightarrow \infty$, whereas the distances between the adjacent atoms may substantially vary. Guinier³ called this type of distortions in the long-range order the ‘replacement disorder’ and considered it as a manifestation of disorder of the first kind. This type of disorder is also associated with thermal vibrations of atoms due to which ideal atomic rows are wholly absent in real crystal structures.

Atomic volume defects appear in crystal structures if the distribution of atomic impurities obeys a three-dimensional translational symmetry, which differs from the symmetry of the host crystal. In this case, the structure necessarily has at least one direction along which the major and impurity structural units are distributed with different periodicities (Fig. 2c,d). As a consequence, the crystal has the superperiods na . If the co-existing three-dimensional sublattices are essentially incommensurate

(Fig. 2d), the parameters of the common crystal lattice can reach several hundred angstroms.

The disorder of another type, *viz.*, disorder of the second kind,³ occurs in the host crystal structure, when the distribution of atomic impurities obeys a translational symmetry in less than three directions, *i.e.*, when structural units in real crystal structures are distributed non-periodically along particular directions and only local regularities take place (Fig. 2e). The difference between X_n and na increases with increasing n . However, the fluctuations of the distances between the adjacent atoms may be of the same order as those observed in the structures with the above-described types of disorder. Disorder of the second kind is typical of structures with atomic planar or linear defects. In the former case, the periodicity of the host crystal structure is distorted only in one direction. In the latter case, the periodicity is violated in two directions.

Hence, only three types of disorder can occur in chemically inhomogeneous structures under consideration. Correspondingly, three types of real crystal structures can be distinguished based on the translational symmetry retained in the crystal (see Fig. 2).^{2,4}

In structures of type I (with atomic point defects), the three-dimensional lattice of the host crystal is statistically retained.

In structures of type II (with atomic volume defects), the disorder is associated with the fact that the major and impurity atoms obey different translational symmetries (Fig. 2c, d). These structures are characterised by two or more three-dimensional sublattices (commensurate or incommensurate) or by a single three-dimensional lattice with superperiods, which are multiples of the lattice parameters of the host crystal.

Structures of type III (with atomic planar or linear defects) are periodic in less than three (in two or one) directions. These structures are characterised by two or more two-dimensional or one-dimensional sublattices (commensurate or incommensurate), which generally contain point defects.

III. Structures with atomic point defects (type I)

1. General views

Point defects, which do not disturb the three-dimensional statistical lattice, are present in virtually all crystals of both natural and synthetic origin. These defects occur due to continuous replacements of structural elements in the host crystal (atoms, ions, vacancies and their associates) as well as through other order–disorder processes. These crystal-chemical effects correspond to the modern views on isomorphism (see, for example, Ref. 5). Order–disorder transformations can be considered as a special case of isomorphism, *viz.*, autoisomorphism, which is characterised by the redistribution of atoms and vacancies in the crystal structure. If the isomorphous replacement is accompanied by a change in the structural type of the crystal, this phenomenon is called isodimorphism.

The isomorphism and related problems were the subject of numerous reviews, including classical monographs by Russian scientists.^{6–10} The morphological aspect of isomorphism, which was described by Mitscherlich¹¹ as a manifestation of the similarity in habits of crystals with different chemical compositions, is already a history. The crystal-chemical interpretation of this phenomenon, which assumes the similarity in the sizes of particles replacing each other as well as the similarity in some of their properties (Goldschmidt’s rule), has also been essentially refined as the notion of the real crystal structures became deeper and more general. The history of evolution of these notions has been described in detail (see, for example, Ref. 12). It is common practice to consider quasi-homogeneous structures, which appear due to isomorphous replacements of different types, as solid solutions (replacement, insertion, subtractions, *etc.*). Besides, such systems are called mixed crystals, isomorphous mixtures, crystals, phases and compounds with variable compositions (see, for example, Refs 6, 10 and 13). The last-mentioned three terms

are less general because they do not take into account autoisomorphism.

2. Composite analysis. Way of description

Idealised structures of solid solutions consist of statistically alternating modules as 'unit cells', which correspond to the real or hypothetical end members of isomorphous (or isodimorphous) series (Fig. 3).² Consequently, crystal structures with atomic point defects are composed of at least two statistically alternating substructures, which are generally isostructural and differ only in composition. Hence, such real structures can be considered as composite structures. If vacancies serve as atomic point defects (Fig. 3b), the corresponding real structures represent one of the possible forms of non-stoichiometry.¹⁴ Due to local displacements induced by impurity atoms, the co-existing 'unit cells' undergo substantial local deformations (Fig. 4).¹⁵

Figure 3. Schematic representation of the structures of the solid solutions $A(B_{0.5}C_{0.5})$ (a) and $A(B_{0.5}\square_{0.5})$ (b); empty cells represent vacancies in the positions of the atoms C.²

The relationship between the parameters of two 'unit cells' of solid solution (a_1, b_1, c_1 and a_2, b_2, c_2) can be described by the following matrix equation

$$A_2 = \sigma A_1, \quad (1)$$

$$\text{where } A_i = \begin{bmatrix} a_i \\ b_i \\ c_i \end{bmatrix}, i = 1, 2; \quad \sigma = \begin{bmatrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33} \end{bmatrix}.$$

In the general case, the components of the matrix σ are irrational due to local deformations. Since a system statistically retains the three-dimensional long-range order, the average relational matrix $\bar{\sigma}$ is always a unit matrix and the structure of a solid solution can be described by an averaged unit cell with a mixed occupancy of at least one crystallographic site. This means that the site is occupied in a particular ratio by at least two elements,

Figure 4. Local deformation of unit cells of a host crystal induced by impurity atoms.¹⁵

such as atoms, ions or vacancies. Partially vacant crystallographic sites are the necessary element in the crystal structures with non-stoichiometric compositions.

3. Symmetry

The symmetry of an average structure is statistically overestimated and is characterised by one of the space groups, viz., G_3^3 . The parameters of a statistical three-dimensional periodic lattice are similar to those of the host crystal. It should be noted that the symmetry of the solid solution can be either higher or lower than the symmetry of the host crystal depending on the ordering of the distribution of impurity elements over regular point systems. If a solid solution is in the middle of an isomorphous (isodimorphous) series or it is formed through order–disorder processes, the notion of the host crystal loses its meaning. The symmetry of a solid solution can change both on crystal growth and in the course of its post-crystallisation transformations. Structural transformations can proceed either stepwise or continuously, both with changes (type I or II isodimorphism) and retention (type I or II polymorphism) of the overall composition of the crystal.^{5, 16}

4. Chemical deformations of average structures

Changes in the composition of a solid solution as a result of isomorphous replacements lead to chemical deformations of the average crystal structure^{9, 12} characterised by changes in the lattice constants, interatomic distances and bond angles. The mutual dependence between these changes enables one to study selected structural features of solid solutions on the basis of the crystal lattice parameters and interplanar distances (see, for example, the studies^{17–20}).

Deformations of coordination polyhedra caused by changes in the chemical composition, temperature or pressure often show traits of similarity (primarily, in crystals with essentially ionic bonds).^{9, 21, 22} Chemical deformations can be quantitatively characterised by the coefficient γ_a (%⁻¹)

$$\gamma_a = \frac{1}{a} \frac{da}{dx},$$

which characterises the relative increment of a particular structural parameter a as the impurity concentration (x) is increased by 1%, by analogy with the thermal expansion coefficients.^{9, 21}

Deformations of different nature can be quantitatively compared by calculating their mutual equivalents. For example, it is convenient to use the ratio γ_a/α [(°C (at.%)⁻¹)]⁻¹, where γ_a is the coefficient of chemical deformations and α is the thermal expansion coefficient, as the thermal equivalent of the chemical deformation of the structure (on the basis of the parameter a for a particular isomorphous replacement).⁹

Local displacements of atoms from ideal sites lead to deviations of both the lattice parameters and average interatomic distances in the solid solution from Vegard's rule, i.e., from the strictly additive behaviour,²³ which lies at the basis of the virtual

Figure 5. Changes in the B—C and A—C interatomic distances depending on the composition of the solid solution $(A_{1-x}B_x)C$ determined within the virtual crystal model (1) and bond length alternation model (2, 3) and on the basis of experimental data (4, 5) (after V S Urusov²³); (2 and 4) R_{BC} ; (3 and 5) R_{AC} .

crystal model (Fig. 5). These characteristics also do not obey the bond length alternation model according to which the bond lengths in a solid solution are equal to those in pure compounds (end members of the isomorphous series). These models are the hypothetical limiting cases. The actual parameters and interatomic distances in a solid solution are intermediate between the above-mentioned limiting values and the determination of these parameters is the subject of a special experimental study. The degree of structure relaxation of a solid solution can be characterised by the following parameter

$$\varepsilon = \frac{R_{BC} - R_{AC}^0}{R_{BC}^0 - R_{AC}^0},$$

where R_{BC} are the bond lengths in the structure of the solid solution $(A_{1-x}B_x)C$, R_{BC}^0 and R_{AC}^0 are the bond lengths in the structures of the corresponding pure components.²³ Relaxation of the virtual crystal AC with a very small impurity BC approaches zero, whereas relaxation of the crystal with the bond-length alternation is maximum (equal to unity). In real structures of solid solutions, relaxation is incomplete ($0 < \varepsilon < 1$).

5. Short-range order

In crystals of compounds with ionic bonds, the electroneutrality condition requires that atomic defects be generated in pairs (Fig. 6), *viz.*, a vacancy and the corresponding interstitial ion (Frenkel defect), two vacancies of opposite charges (Schottky

Figure 6. Point defects in the NaCl-type crystals.¹⁵

(1) Frenkel defects, (2) Schottky defects, (3) antipode of the Schottky defect; vacancies and interstitial ions are indicated by squares and circles, respectively.

defect) or two interstitial ions of opposite charges (antipode of the Schottky defect). The formation of defects is accompanied by migrations of the surrounding atoms. Atoms about the vacancies are shifted primarily toward the vacant lattice point, whereas interstitial ions, by contrast, push aside the adjacent atoms. Hence, the fulfilment of the electroneutrality condition for a solid solution primarily through a local charge compensation gives rise to a short-range order (appearance of block isomorphism¹⁵). In non-stoichiometric solid solutions, statistically distributed associates of atoms and vacancies (simple and complex clusters) whose compositions and structures differ from those of the host crystal can occur. Due to the presence of such defect complexes, impurity atoms in the host crystal structure can create coordination conditions typical of the structures of real or hypothetical end members of isomorphous (isodimorphous) series.² If several structural modifications of the compound can occur, the impurity atoms tend to give rise to the coordination typical of the modification that is the nearest to the phase of the host crystal in the phase diagram.²⁴ The possibility of the presence of statistically distributed cluster groups in the structure of a solid solution is often evidenced by unreasonably shortened interatomic distances.

6. Diffraction patterns

Diffraction patterns of quasi-homogeneous structures with atomic point defects represent three-dimensional reciprocal lattices and differ from the patterns of ideal three-dimensionally periodic crystals only by generally insignificant effects of diffusion scattering associated with manifestations of a short-range order.

7. Ordering

The insertions of atomic point defects into an ideal three-dimensional lattice leads to lowering of the internal order of the system. If all symmetry elements, except for translations, are ignored, the crystal structure with these defects can be described as a combination of intersecting translationally equivalent atomic sublattices, into some of which impurity atoms are inserted. The larger is the portion of such statistical atomic sublattices, the lesser is the degree of internal order. It should be noted that crystal structures with atomic point defects are the most ordered form of the naturally occurring condensed state.

IV. Structures with atomic volume defects (type II)

1. General notions

Crystal structures with atomic volume defects (multilattice structures) were found among minerals and can be prepared under laboratory conditions by performing the synthesis in multicomponent systems. These structures show considerable promise in searching for new materials with useful properties. These structures are poorly studied primarily because of the fact that classical X-ray diffraction methods on the basis of three-dimensional space symmetry groups are not sufficiently efficient to solve superstructures (particularly, with large periods). Due to the design of special computer programs involving N -dimensional descriptions of superspace symmetry groups, considerable progress has been made in the determination of multilattice crystal structures in the last decade.

The structures under consideration can appear due to isomorphism, if atomic point defects are inserted into the host lattice in an ordered fashion. This is a way in which superstructures of ordered solid solutions are formed (Fig. 7). In such crystals, the co-existing sublattices are commensurate. Quasi-homogeneous systems with essentially incommensurate three-dimensional sublattices can occur, if the host crystal structure contains periodically distributed fragments (layers or columns) with other structures (Fig. 8). Frank-Kamenetskii^{1,10} related the formation of such structures to anomalous (lamellar) isomorphism (see Fig. 1). According to the modern notions, this is a manifestation of polysomatism.

Figure 7. Schematic representation of the formation of a supercell (shown by dashed lines) of an ordered solid solution.²

Figure 8. Schematic illustration of the packing of the two sublattices (A, B) in composite structures: column (a) and layer (b) (after P Coppens²⁵). The appearance of a modulation of the sublattice B with the period of the sublattice A is exemplified by columnar structures.

The term ‘polysomatism’ was proposed by Thompson²⁶ for the description of the formation of complex mineral structures from fragments (modules) of different simpler (really occurring in nature) compounds. The commonly accepted extended concept of

polysomatism (see, for example, Refs 27–30) is applied to various series of crystal structures consisting of modules of at least two types. Generally, modules (layers, columns or blocks) differ both in the structure and composition, but they can differ only in one of these parameters. Polysomatism is very widespread in nature and is often, along with isomorphism, responsible for non-stoichiometry of compounds. Apparently, the mechanisms of formation of members of polysomatic series (polysomes) can be described with the use of models developed for polytypes.³⁰ Polysomatic structural series are often described as homologous series.^{31,32}

Crystal structures with incommensurate sublattices are typical of minerals and synthetic (both inorganic and organic) compounds. In nature, such structures most often occur in small amounts and in mixtures with other minerals. These structures are variously referred to as hybrids,³³ intergrowth structures,³⁴ misfit layered structures,^{35–37} incommensurate ladder structures,^{38–41} intercalates,⁴² etc. Due to the structural similarity of multilattice compounds, they are assigned to one group and considered as composite structures.^{25,43,44}

Composite structures were surveyed in the monograph⁴⁵ and reviews.^{25,34–37,44} Unfortunately, data on the structures of this type containing more than two components are very scarce.

The minerals koeninite $[(\text{Mg},\text{Al})(\text{OH})_2]_x[(\text{Na},\text{Ca},\text{Mg})\text{Cl}_2]$ ($x \approx 1.78$)⁴⁶ and valleriite $[(\text{Mg},\text{Al},\text{Fe})(\text{OH})_2]_x[(\text{Fe},\text{Cu})_2\text{S}_2]$ ($x = 1.37–1.56$)^{33,47} are examples of layered composite structures. In the crystal structures of these minerals, the brucite-like octahedral layers alternate with the NaCl-like layers or tetrahedral sulfide layers, respectively. Figure 9 shows the fragment of the composite layered structure of valleriite represented as polyhedra. The minerals cylindrite $[(\text{Pb},\text{Ag},\text{Sn},\text{Sb},\text{Fe})\text{S}]_x \cdot [(\text{Sn},\text{Sb},\text{Fe})\text{S}_2]$ ($x \approx 1.38$),⁴⁸ cannizzarite $[(\text{Pb},\text{Bi})\text{S}]_x[(\text{Pb},\text{Bi})_2\text{S}_3]$ ($x \approx 1.70–1.71$)⁴⁹ and their synthetic analogues provide examples of layered composite structures characterised by superperiods of length > 100 Å. Layered composite structures are known also for graphite intercalates exhibiting high conductivity,⁴² for example, for FeCl_3 -graphite.⁵⁰ Layered structures of superconducting bismuth cuprates $\text{Bi}_2\text{Sr}_2\text{CuO}_{6+x}$ and $\text{Bi}_2(\text{Sr},\text{Ca})_3\text{Cu}_2\text{O}_{8+x}$ can also be described as composite structures $[\text{Bi}_2\text{Sr}_2\text{CuO}_4][\text{O}]_y$ and $[\text{Bi}_2(\text{Sr},\text{Ca})_3\text{Cu}_2\text{O}_6][\text{O}]_y$ ($y \approx 2.2$), respectively.⁵¹

Figure 9. Fragment of the layer composite structure of valleriite.³⁵

The known columnar composite structures are much less in number. For example, these structures are typical of the compounds $\text{Ba}_p(\text{Fe}_2\text{S}_4)_q$.⁵² In the structures of these compounds, the chains of the edge-sharing Fe–S tetrahedra alternate with columns of barium ions. Composite structures containing zigzag chains as two-leg ladders occupy a special place. For example, the structures of $[\text{M}_2\text{Cu}_2\text{O}_3]_{0.714}[\text{CuO}_2]$ ($\text{M} = \text{Bi}, \text{Sr}, \text{Ca}, \text{Y}$ or lanthanides)^{39–41,53} (Fig. 10) contain the Cu_2O_3 layers composed of two-leg ladders, which alternate along the [010] direction with the layers consisting of the CuO_2 chains. If interactions between the ladders are ignored, these structures can be considered as columnar structures, which consist of two types of chains parallel to the [001] direction. One of these phases with composition $\text{Sr}_{0.4}\text{Ca}_{1.6}$.

Figure 10. The composite structure of $[M_2Cu_2O_3]_{0.714}[CuO_2]$ ($M = Bi, Sr, Ca$);⁴¹
(a) layers of the CuO_2 chains, (b) layers of the cations M , (c) Cu_2O_3 layers built from two-leg ladders.

$Cu_{24}O_{41+x}$ is transformed into the superconducting state at 9–12 K and 4.5 GPa.⁵⁴ Two-leg ladders are present also in numerous composite structures of intermetallics,³⁸ for example, in $[V]_{17}[Ge]_{31}$, $[Mo]_9[Ge]_{16}$, $[Re]_{17}[Ge]_{22}$, $[Te]_{17}[Si]_7$, etc. In these chimney-ladder structures (often with superperiods of length > 100 Å), chains of Group III and IV metals (ladders) are inserted into the channels of the frameworks of transition metals.

Frank-Kamenetskii¹ considered real crystal structures containing extended chemical defects as solid solutions. These views have been further developed in the study.²⁷ The authors of the cited study proposed that series of structures consisting of analogous modules be considered as fragmentary solid solutions composed not of individual atoms or ions but of structural fragments arranged with different degrees of order. In usual solid solutions, which are formed as a result of isomorphous replacements, the structures are changed due to variations in the chemical composition. By contrast, structural changes are responsible for the formation of fragmentary solid solutions, whereas variations in the composition are manifested only in relation to these structural changes. In the light of these concepts, crystal structures with atomic volume defects can be considered as ordered fragmentary solid solutions.

2. Composite analysis. Ways of description

Crystal structures with atomic volume defects (regardless of the commensurability of the co-existing sublattices) can always be described as superstructures (the lengths of the superperiods can reach hundreds of angstroms) or as composite structures consisting of two or more mutually penetrating three-dimensionally periodic substructures. Ionic-covalent bonds between atoms within substructures are often much stronger than those between atoms belonging to different substructures.²⁵ In many cases, the requirement of electroneutrality is ensured by variable-valence elements. The stronger are interactions between the substructures, the more substantial are mutual periodic distortions (modulations). Modulations of the sublattice B occur with the period of the co-existing sublattice A (see Fig. 8a) and *vice versa*. Hence, composite structures of this type represent the most general case of modulated structures. If the co-existing sublattices are essen-

tially incommensurate and the ratios between the volumes of the subcells deviate from integer values, the structures characterise one of the possible forms of manifestation of non-stoichiometry.^{14, 25, 43}

The co-existence of different substructures in one crystal imposes certain conditions on the components of the matrix σ in Eqn (1). In the case under consideration, Eqn (1) describes the relations between the sublattice parameters.^{25, 43}

If the composite structure consists of columns of two types parallel to the axis c (see Fig. 8a), it is necessary to avoid their overlapping. Columns must fit together into an infinite array in the plane perpendicular to the column axis. For this purpose, the axes a_2 and b_2 are chosen in the planes a_1c_1 and b_1c_1 , respectively. Hence, the minimum requirements for the commensurability of the parameters of the co-existing sublattices are determined by the following matrix

$$\sigma = \begin{vmatrix} n_1 & 0 & \sigma_{13} \\ 0 & n_2 & \sigma_{23} \\ 0 & 0 & \sigma_{33} \end{vmatrix}, \quad (2)$$

where n are integers or rational fractions and σ are irrational values. Consequently, five basis vectors are required for the description of columnar composite structures.

In the case of layered composite structures (see Fig. 8b), the parallel planes cannot overlap, and the minimum requirements for the space fitting of the co-existing sublattices are determined by the following matrix

$$\sigma = \begin{vmatrix} \sigma_{11} & \sigma_{12} & 0 \\ \sigma_{21} & \sigma_{22} & 0 \\ \sigma_{31} & \sigma_{32} & n \end{vmatrix}. \quad (3)$$

Six basis vectors are required for the description of such structures. If the axes a and b of two sublattices can be chosen parallel to each other ($a_1 \parallel a_2$, $b_1 \parallel b_2$), the matrix (3) takes the form

$$\sigma = \begin{vmatrix} \sigma_{11} & 0 & 0 \\ 0 & \sigma_{22} & 0 \\ \sigma_{31} & \sigma_{32} & n \end{vmatrix}. \quad (4)$$

In this case, four basis vectors are sufficient for the description of a layered composite structure.

Composite structures cannot be unambiguously classified according to the type of the matrix relating the co-existing sublattices. If the matrix σ is reduced to a diagonal form, the structure cannot be assigned to rod or layered structures (without considering the characteristic features of chemical interactions). For example, the structures of $[M_2Cu_2O_3]_{0.714}[CuO_2]$ ($M = Bi, Sr, Ca, Y$ or lanthanides)^{39–41, 53} (see Fig. 10) whose sublattices are related by a diagonal matrix can be considered as structures composed of either alternating layers perpendicular to the axis b or alternating columns (rods) parallel to the axis c . Besides, the structure identified according to the corresponding relational matrix as a rod structure can, in fact, contain a framework formed by one of the components through strong hydrogen or covalent bonds. In this case, the second component is located as a guest in the channels of the framework. For example, such guest–host structures are typical of urea-based complexes.²⁵

3. Symmetry

Average structures of all substructures co-existing in the same crystal (without considering possible modulations) and the superstructure as a whole are characterised by the space groups G_3^3 . The space group of the superstructure is determined by the intersection of the symmetry groups of the substructures at their given orientations. If sublattices co-existing in the same crystal are substantially incommensurate, the lengths of the superperiods can reach hundreds of angstroms. In this case, it is reasonable to consider the system as periodic in more than three directions (Fig. 11).²⁵ Then, taking into account mutual modulations whose periodicity is determined by the parameters of the co-existing sublattices (see Fig. 8a), the symmetry of each of the substructure

Figure 11. Schematic representation of a two-component composite crystal in the four-dimensional space.²⁵

$R3$ is the three-dimensional space with two different periodicities a_1 and a_2 , e is the unit vector. Lines in the fourth dimension are strings representing the atoms of two substructures without taking into account the modulations.

tures and the system as a whole can be characterised by the superspace groups G_{3+d}^{3+d} (Refs 25, 44). Composite structures with commensurate sublattices can also be described with the use of superspace symmetry groups (see Ref. 44 and other publications).

The theory of superspace groups, which has been extensively developed in the last decades, was considered in the studies^{55–62} and the expressions for structure factors corresponding to these concepts were published in the studies.^{44, 63}

4. Diffraction patterns

In the general case, the diffraction pattern of a composite crystal^{25, 44} is very complicated due to overlapping of the diffraction patterns of all co-existing substructures. In such a pattern, there are the so-called main reflections among which are mixed reflections serving simultaneously as main reflections for one of substructures and as satellite reflections for another substructure. In addition, weak satellite reflections should be present, which are unambiguously indicative of the occurrence of modulations caused by interactions between the substructures. However, satellite reflections are often impossible to reveal by X-ray diffraction methods and mixed reflections are the only source of information on modulations of sublattices. Depending on the incommensurability of sublattices co-existing in the crystal, the diffraction pattern can be virtually indistinguishable from that of either an oriented intergrowth or an ideal three-dimensionally periodic crystal.

In the general case, $3 + d$ basis vectors are required for indexing diffraction patterns of a composite crystal (Fig. 12). The relationship between the parameters of two reciprocal sublattices a_1^* , b_1^* , c_1^* and a_2^* , b_2^* , c_2^* can be described by the following matrix equation:²⁵

$$A_2^* = (\sigma^{-1})^T A_1^* = \sigma^* A_1^*, \quad (5)$$

where $A_i^* = \begin{bmatrix} a_i^* \\ b_i^* \\ c_i^* \end{bmatrix}$, $i = 1, 2$; σ is the matrix from Eqn (1);

T is a transpose operation.

In the case of columnar composite structures for which the relationship between the sublattices is determined by the matrix (2), the matrix σ^* takes the form

$$\sigma^* = \begin{bmatrix} 1/n_1 & 0 & 0 \\ 0 & 1/n_2 & 0 \\ -\sigma_{13}(n_1\sigma_{33}) & -\sigma_{23}(n_2\sigma_{33}) & 1/\sigma_{33} \end{bmatrix}. \quad (6)$$

Figure 12. Schematic representation of the four-dimensional reciprocal space of a two-component composite crystal.²⁵

$R3$ is the three-dimensional space with two sets of reflections with different periodicities, b_4^* is an additional coordinate axis. Main reflections of two sublattices are shown by circles. Satellite reflections are indicated by asterisks.

Hence, the axes a_1^* and b_1^* are parallel to the axes a_2^* and b_2^* , respectively (in the reciprocal space, the $hk0$ plane is common to both substructures), and the diffraction pattern can be described by four basis vectors ($d = 1$).

In the case of layered composite structures for which the relationship between the sublattices is determined by the matrix (4), the matrix σ^* takes the form

$$\sigma^* = \begin{bmatrix} 1/\sigma_{11} & 0 & -\sigma_{31}(n\sigma_{11}) \\ 0 & 1/\sigma_{22} & -\sigma_{32}(n\sigma_{22}) \\ 0 & 0 & 1/n \end{bmatrix}. \quad (7)$$

Here, only the axis c^* is common to both substructures, and the diffraction pattern is described by five basis vectors ($d = 2$).

5. Ordering

The appearance of superperiods decreases the homogeneity of the crystal structure. In different structures, the degree of ordering varies substantially and decreases with increasing incommensurability of the co-existing sublattices (with increasing volume of the unit cell characterising the superstructure). It should be remembered that structures with atomic volume defects virtually always contain atomic point defects as well. Therefore, structures of type II are characterised by lower degrees of internal ordering compared to those observed in the above-described structures of type I (usual solid solutions).

V. Structures with atomic planar and linear defects (type III)

1. General views. Probability-statistical models

Chemically inhomogeneous structures, which consist of modules (layers or columns) with different compositions alternating in a disordered fashion, are also rather widespread among natural and synthetic compounds. According to the results of high-resolution electron microscopy (see, for example, Refs 64 and 65), structures with two-dimensional defects represent one of the most widespread types of crystal inhomogeneity. Irregularly alternating modules can have either different or identical atomic structures. Structures of the first type are characteristic of members of polysomatic series, whereas structures of the second type are typical of intermediate compositions of isomorphous series. The weaker are interactions between atoms belonging to different modules, the more substantial is the deviation of the real crystal structure from a homogeneous three-dimensionally periodic structure. If the scale of structural inhomogeneity, *i.e.*, the maximum possible thickness of the packet of impurity modules, is smaller than the average size of the coherent scattering domains (CSDs) and if numerous defects are rather uniformly distributed over the crystal, interactions between alternating modules are

rather strong and the irregular structure is quasi-homogeneous. Such structures can be described within the framework of a single probability-statistical model whose parameters characterise the ratios between the co-existing one- or two-dimensional fragments and their distribution along directions that lose periodicity.

Probability-statistical models have been developed only for one-dimensionally disordered structures. The first of these models allowed one to describe only completely disordered layer packings without considering possible interactions between the layers.^{66–68} Later on, it has been proposed that interlayer interactions be characterised by the factor of the short-range order R , which is equal to the number of layers responsible for the probability of the occurrence of a particular layer in the crystal.^{69–72} More recently, the probability parameters were suggested for the description of the character of alternation of the layers at $R = 0$ or 1.^{73–75} Probability-statistical models of irregular layered structures and the diffraction theory based on these models were generalised and developed in the studies.^{76–78} Unfortunately, irregular mixed-layer structures studied with the use of probability-statistical models are few in number. Most of these structures were surveyed in the monograph⁷⁷ and reviews.^{78–80} Examples of the application of these models to the description of irregular mixed-layer structures of chemically inhomogeneous crystals are given in Table 1.

Quasi-homogeneous structures with two- and one-dimensional defects can arise in the course of both crystal growth (in particular, in the course of formation of a composite zoning) and post-crystallisation changes, for example, upon decomposition of solid solutions or metasomatic replacements. Irregular mixed-layer structures are often generated in the course of transformations of layered silicates at high p and T .⁸¹

Disordered mixed-layer structures are typical of various natural and synthetic compounds, *viz.*, silicates, sulfides, carbonates, graphite intercalates, perovskite-like cuprates and other oxides and hydroxides. Mixed-layer layered silicates (see Refs 66, 67, 77, 78 and other publications) were studied in most detail. Since the latter minerals are widespread in nature and very sensitive to changes in the thermodynamic conditions, they are successfully used as indicators of the geochemical conditions of formation. Their crystal structures are built from layers of different clay minerals, which are present in variable amounts (Fig. 13).³⁰ The interlayer space can be filled either with com-

Figure 13. Diagrammatic structure of the chlorite/serpentine interlayering (S is serpentine, Chl is chlorite).³⁰ Layers of tetrahedra (T) and octahedra (O) are shown.

plexes of cations with water molecules or with potassium and sodium cations. Quasi-homogeneous structures with the maximum possible degree of short-range order are widespread among mixed-layer layered silicates. The structures with a very low degree of order were found among illite- and kaolinite-montmorillonites.⁸² Probability-statistical models of irregular mixed-layer structures were applied also to the investigation of the chemical imperfection in the structures of non-stoichiometric perovskite-like cuprates $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+4}$ ($n = 1-3$)^{80, 83, 84} (Fig. 14)

Figure 14. Crystal structures of members of the polysomatic series $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+4}$.⁸⁰ (a) Bi-2201, $n = 1$, $T_c \approx 20\text{K}$; (b) Bi-2202, $n = 2$, $T_c \approx 90\text{K}$; (c) Bi-2203, $n = 3$, $T_c \approx 110\text{K}$ (T_c is the superconducting transition temperature, h is the height of the layer).

and $\text{YBa}_2\text{Cu}_3\text{O}_x$ ($x = 6, 7$)⁸⁵ (Fig. 15). This approach made it possible to estimate the concentration and characteristic features of the distribution of impurity layers, which belong to phases with other n or differ from matrix layers due to the in-layer distribution of cations and vacancies (see Table 1). The relationships between the probability characteristics of the real structure, synthesis conditions and post-growth treatment of the crystals were revealed and their correlations with the average temperature and the width of the temperature range of the transformation into the superconducting state were found.^{86, 87} Besides, probability-statistical models were successfully used in studies of the fine oscillatory zoning in crystals of garnets of the grossular-andradite series $\text{Ca}_3(\text{Al}, \text{Fe})_2(\text{SiO}_4)_3$ (see Ref. 88) and the decomposition structure of the solid solution $(\text{K}, \text{Na})(\text{Ca}, \text{Na})_2(\text{Mg}, \text{Fe})_5(\text{Si}, \text{Al})_8\text{O}_{22}(\text{OH}, \text{F})_2$, *viz.*, the calcium amphibole edenite.⁸⁹ Investigations of irregular structures formed as a result of layer isomorphism^{79, 80} demonstrated that the common feature of these structures is a high degree of segregation of layers with the same

Note. h_i is the height of the layer of type i ($i = 1, 2$); M is the total number of layers in the coherent scattering domain (CSD); W_i is the portion of the layers of type i in CSD; P_{ii} is the conditional probability of the layers of type i following the layer of type i ; K_s is the segregation coefficient; L is the average size of CSD along the normal to the layers; l is the maximum possible thickness of the packets of impurity layers.

symmetry groups of layers G_2^3 or rods G_1^3 , respectively. The determination and analysis of these groups were reported, for example, in the monograph.⁹³

Two-component mixed-layer structures can be divided into two groups according to the symmetry of alternating layers.^{45, 78} The first group includes structures consisting of alternating layers with hexagonal and trigonal symmetry. The second group involves structures built from alternating layers with hexagonal and tetragonal symmetry. Examples of the first group are provided by disordered varieties of valleriite and koenenite. The second group involves, for example, cylindrite and cannizzarite.

4. Diffraction patterns

The weaker are the interactions between the co-existing two- or one-dimensionally periodic substructures, the more similar is the diffraction pattern of the real crystal to a two- or one-dimensional reciprocal lattice, respectively. However, perturbations in the periodicity are most often insignificant and are manifested in the broadening, asymmetric shape, non-integer indices and weaker intensities of particular groups of diffraction reflections. The detection of these characteristic features presents a serious experimental problem, which becomes more complicated at lower concentrations of impurity modules disturbing the long-range order.

Diffraction patterns of irregular mixed-layer structures were discussed in the monographs^{76, 77, 90} and reviews.^{78–80} Analysis of basal reflections made it possible to distinguish three families of real structures characterised by different ratios between the heights of alternating layers.^{78, 80}

1. The heights of layers with different structures differ substantially from each other (by several angstroms). Diffraction patterns of such structures are characterised primarily by non-integer values of basal reflections. If this effect is not observed at low concentrations of impurity layers, the asymmetry of the profiles of different reflections of a series, which is manifested to a variable extent and on different sides of reflections (and is often accompanied by broadening of some reflections), serves as a diagnostic indicator. These diffraction features are characteristic of members of different polysomatic series. Non-integer indices are often observed in diffraction patterns of mixed-layer silicates.

2. The heights of layers with different structures are multiple of each other. In this case, the positions of basal reflections generally correspond to integer indices, but their intensities can be changed in parallel with l . Such diffraction patterns are often difficult to distinguish from those of the corresponding structures with regular superperiods. For example, these patterns are typical of hypothetical mixed-layer structures (see Fig. 13) with the irregular alternation of 7 and 14 Å thick layers.

3. The heights of layers, which differ only in occupancies of crystallographic sites, are nearly identical (differ by only hundredths or tenths of angstroms). In this family, the asymmetry of reflection profiles (in the case of integer basal reflections), which is manifested on the same side and increases in parallel with the diffraction angle, serves as the major criterion for the occurrence of perturbation in the periodicity. These diffraction patterns are typical of intermediate members of isomorphous series and are also obtained for some layered silicates consisting of layers, which differ in the distribution of cations occupying octahedral positions.

5. Ordering

Real structures periodic in less than three directions are less homogeneous compared to all the structures described above. One-dimensionally periodic structures consisting of irregularly alternating columns are not only less ordered than irregular mixed-layer structures but also represent the least homogeneous real form of the crystalline state.

In addition, it should be remembered that the disordered alternation of two- or one-dimensionally periodic modules generally differs from the statistical distribution and tends to be either

ordered or segregated. Hence, the degree of order within each of two subgroups, *viz.*, the structures with planar and linear defects, varies substantially. The degree of order in the real structures under consideration is additionally reduced due to the insertions of atomic point defects and also due to the non-identity of the co-existing sublattices giving rise to mutual modulations.

VI. Conclusion

The present review surveys real crystal structures, which remain rather homogeneous (quasi-homogeneous) in spite of the presence of numerous atomic impurities (atoms, ions or vacancies). In the structural classification of condensed states (see, for example, Ref. 94), such systems occupy an intermediate place between ideal crystals and one-dimensional periodic structures (polymers and liquid crystals) according to the degree of order. In spaces of dimension m ($m \geq 3$), the main types of real structures, which are categorised according to the characteristic features of disorder induced by atomic impurities, are characterised by the symmetry groups G_n^m periodic in n dimensions ($m \geq n$, $n \geq 1$). Real structures of different types differ in the degree of internal order and, in most cases, are reliably identified from diffraction patterns. These real structures represent all possible structural forms of non-stoichiometry of compounds. In each of three structural types, the degree of order varies substantially and the boundaries between these types overlap.

Atomic impurities present in the structures of host crystals are nucleations of other (real or hypothetical) compounds.¹³ Hence, the characteristic feature of the real crystals under considerations is their composite nature. Structures of types I and II consist of two or more three-dimensionally periodic substructures, which are distributed statistically or in an ordered fashion, respectively. Structures of type III are composed of two- or one-dimensionally periodic substructures alternating with different degrees of order. Consequently, real structures of the first type can be described by an average unit cell with mixed occupancies of certain crystallographic sites. Real structures of the second type (without considering mutual modulations) can be represented by two or more types of unit cells, which differ in the structure and/or composition. Real structures of the third type can be described within the framework of probability-statistical models.

Due to the composite properties, quasi-homogeneous structures with atomic defects of different types can be considered as solid solutions (in essence, always fragmentary), because these compounds are characterised, first, by a rather uniform distribution of components over the bulk of the compound and, second, by the theoretical possibility to vary their ratio (in most cases, this possibility is realised). In principle, these chemically inhomogeneous crystals can be called mixed, if this rather uncertain and seemingly archaic notion is assigned a real structural meaning. It should be remembered that the boundary between composite quasi-homogeneous structures and crystal overgrowths, including epitaxial and syntaxial overgrowths, is substantially blurred.

Crystal structures with atomic defects surveyed in the present review are widespread among minerals and synthetic inorganic compounds (including new promising materials). The above-considered basic classification enables one to substantially simplify their nomenclature.

Taking into account the diversity and specificity of defects found in real crystal structures in exact agreement with their morphogenesis (see, for example, Ref. 80), Zorkii raised the question as to whether it is adequate to discuss the polymorphism of real crystalline substance.⁹⁵ The basic classification of crystal structures with atomic defects on the basis of symmetry (primarily, translational symmetry)^{2, 4} allows one to state that such a phenomenon as polymorphism actually occurs. Analysis of thermodynamic and energy characteristics of the above-considered types of real crystal structures is beyond the scope of the present review. One can become acquainted with the energy theory of classical solid replacement solutions by reading the monographs

by Urusov^{8,96} and publications of his colleagues (see, for example, Refs 97 and 98). The possibilities of the use of superspaces for calculations of the energies of incommensurate composite structures were discussed in the review.²⁵

The polymorphism of amorphous compounds was studied.^{99,100} The data published in the literature provide evidence that this phenomenon is typical of all structural forms of the condensed state.

Early in the 20th century, when discussing the real crystal structures, E S Fedorov wrote: 'When we dealt with perfect crystals, we operated with one of the most precise sciences of the mathematical field, the so-called theoretical crystallography. When our attention is directed to imperfections in the crystal formation, we go beyond the scope of this science and enter in the field of empirical sciences. There is no doubt that new areas of the science will be developed, which will allow one to study such phenomena using precise mathematical laws'.¹⁰¹

The data surveyed in the present review provide evidence that the accumulated knowledge enables one to make steps forward in this direction. The above-described basic classification on the symmetry basis can be considered as the starting point for developing the notion of the polymorphism of real crystals.

I am grateful to Professors F F Grekov, B B Zvyagin, P M Zorkii, Yu O Punin and S K Filatov for helpful discussion and valuable advice.

Skeletal rearrangements of monoterpenoids of the carane series

V A Chuiko, O G Vyglazov

Contents

I. Introduction	49
II. Rearrangements of carane monoterpenoids occurring by the ionic mechanism	49
III. Rearrangements occurring by the radical mechanism	52
IV. Concerted reactions	54

Abstract. Data on rearrangements of monoterpenoids with the bicyclo[4.1.0]heptane skeleton occurring by ionic, radical and concerted mechanisms are generalised and analysed. The bibliography includes 135 references.

I. Introduction

One of the most widespread monoterpene hydrocarbons is 3-carene, or 3,7,7-trimethylbicyclo[4.1.0]hept-3-ene (**1**), which is a constituent of many essential oils and turpentine.^{1,2}

The interest in 3-carene stems from the presence in its molecule of a *gem*-dimethylcyclopropane ring, a unique fragment, which is an important structural unit of many biologically active compounds. These include, for example, natural and synthetic pyrethroids, stercularic acid and its esters, aminocyclopropanecarboxylic acid derivatives, *etc.* In addition, 3-carene and related compounds, like other bicyclic terpenoids, can undergo various skeletal rearrangements. As a result, they are very promising models for studies in fundamental organic chemistry and are useful starting compounds for the synthesis of valuable products: sesquiterpenoids,³ pheromones,⁴ juvenoids,⁵ pyrethroids^{6,7} and fragrance compounds.^{7–9}

The currently known skeletal rearrangements of compounds of the carane series result in several types of structure, namely, with bicyclo[3.1.0]hexane, bicyclo[3.2.0]heptane, *p*- and *m*-menthane and 1,1,4-trimethylcycloheptane skeletons. According to their mechanisms, these rearrangements are classified as ionic, radical and concerted.

The available reviews on carane-type monoterpenoids were mainly written more than 25 years ago. They do not reflect the diversity of skeletal rearrangements studied over the past decades. A detailed review by Arbuzov and Isaeva¹⁰ dealt with rearrangements that occur by the ionic mechanism. Yet another review¹¹ mainly describes rearrangements of carane monoterpenoids in which the cyclopropane ring opening affects the 'external' bonds to give compounds of the *p*- and *m*-menthane series.

The extensive monograph 'Chemistry of Monoterpenes' by Erman¹² provides an excellent and systematic description of data on reactions of monoterpenes and on the mechanisms of these reactions; however, the experimental data on the transformations of terpenoids belonging to the carane series only includes literature data published before 1976. Since then, new results have been obtained, and new concepts on the mechanisms of certain reactions discussed in the monograph cited have appeared. The reviews that are published from time to time^{13,14} just state the facts rather than analyse them, therefore they generally do not consider or discuss the mechanisms of the transformations described. The most recent reviews dealing with the rearrangements of terpenoids^{3,15,16} give almost no consideration of the transformations of compounds with the carane skeleton.

The purpose of the present review is to generalise data on the skeletal rearrangements of terpenoids belonging to the carane series accumulated over the time period since the publication of reviews by Arbuzov and Isaeva¹⁰ and by Erman.¹² Earlier publications are only considered if the history of the problem is of interest or if a new understanding of the known facts has appeared. The rearrangements are discussed according to their mechanisms. The most thorough attention is given to concerted rearrangements, because these data have not been generalised or discussed so far.

II. Rearrangements of carane monoterpenoids occurring by the ionic mechanism

The realisation of the ionic mechanism in molecular rearrangements of carane monoterpenoids is due to the interaction of the cyclopropane ring with the electron-deficient carbenium centre at the α - or β -position with respect to the ring. Rearrangements of this type are of interest because they can provide intermediates with a delocalised charge. According to the classification suggested in the review by Arbuzov and Isaeva,¹⁰ ionic rearrangements of carane structures are divided into homoallylic rearrangements, rearrangements with the transannular involvement of the cyclopropane ring (CPR) and the Wagner–Meerwein rearrangements with contraction of the six-membered ring. However, this classification does not reflect the diversity of ionic

rearrangements of carane structures and is arbitrary. The homoallylic rearrangement is not the only one of the possible skeletal transformations *via* a carbocation with a delocalised charge: carane structures containing double bonds can also contain a pentadienyl-type cation; the latter may be formed in different ways from different compounds. In addition, we believe that it is more correct to consider rearrangements with transannular involvement of the CPR and the Wagner–Meerwein rearrangements together with concerted reactions because they involve alkyl shifts in charged systems.

1. Carbenium-ion rearrangements

A molecule of 3-carene contains two reactive fragments: a double bond and a cyclopropane ring. Both of these fragments have enhanced electron density, which makes the molecule reactive with respect to electrophilic agents. The rearrangement of 3-carene which occurs under the action of acids to give compounds of the *p*- and *m*-menthane series is well known.¹² It is likely that in this case the cyclopropane ring acts as an isolated reaction centre to form carbenium ions **2** or **3** (Scheme 1). The double bond is remote and does not interact with the carbon atom which carries a positive charge. The ions are stabilised by elimination of a proton or by capture of a nucleophile.

This transformation occurs in those cases where the CPR is initially protonated. Obviously, the addition of a proton to the double bond of the hydrocarbon **1** should give a tertiary ion **4**.

Ions of this type can undergo a rearrangement due to the so-called 'transannular cyclopropyl participation'¹⁰ (see Section IV.4), but this would result in an ion **5** and other products.

The fact that it is the CPR rather than the double bond that is protonated in the case of 3-carene can be rationalised in terms of the HSAB (Hard–Soft Acid–Base) principle. Cyclopropane is a harder base than the double bond (the ionisation potentials are 10.9 and 9.3 eV, respectively). In a molecule of 3-carene, the difference between the energies of the highest occupied molecular orbitals (HOMO) of the corresponding fragments is somewhat

smaller but still rather high (9.16 and 8.61 eV).¹⁷ A hard acid, *viz.*, a proton, is first added to the hard base, *viz.*, the CPR. In fact, the reaction between equimolar amounts of 3-carene and hydrogen chloride gives derivatives with *p*- and *m*-menthane skeletons.¹⁸ The similarity of the electronic structures of the double bond and the CPR¹⁹ predetermines the similarity of their reactivities.²⁰ The existence of a cationoid site at the α -position with respect to the cyclopropane ring results in their conjugation and formation of a homoallylic ion. The direction of the reaction of this ion with a nucleophile depends on spatial factors, on the nature of the leaving group and on the degree of solvation of the molecule (in solvolysis reactions), *etc.*

If the subject of the attack in the homoallylic ion is the CPR, the latter is opened; in carane derivatives, a skeletal rearrangement occurs.

For example, under conditions of acid catalysis, caran-5-ol (**6**) and caran-2-ol (**7**) are isomerised to *m*- (**8**) and *p*-menthen-8-ols (**9**), respectively, as a result of a hydroxide attack on the C(8) atom in homoallylic ions **10** and **11**.^{21,22} These reactions can be considered as regiospecific.

Deamination of 5- (**12**)- and 2-aminocaranes (**13**) occurs in a similar way; however, the presence of bicyclic alcohols among the products shows that the reaction was not completed in this case.²³

Homoallylic rearrangements can occur along with other ionic rearrangements. For example, the Prins condensation of 3-carene with formaldehyde gives, among other reaction products, two cyclic ethers **14** and **15**. Their formation is explained by the occurrence of the Wagner–Meerwein rearrangement followed by a homoallylic rearrangement.^{24,25}

In this case, the Wagner–Meerwein rearrangement, which occurs as an alkyl shift, does not change the carane structure. However, the alkyl shift is only possible because the charge delocalisation in the secondary ion **16** with involvement of the cyclopropane ring results in ring opening to give the homoallyl ion **17** which has a lower energy. The ion **17** is stabilised by elimination of a proton from one of the geminal methyl groups giving the ether **14**. In an acidic medium, this ether isomerises to the ether **15** via the classical cation **18**.

2. Rearrangements that occur via ions with a high degree of charge delocalisation

Obviously, the system CPR–charged carbon atom can comprise one or more double bonds. The resulting homopentadienyl ion has a higher degree of charge delocalisation, and hence a lower energy, than the homoallyl ion. Therefore, reactions involving homopentadienyl ions occur more readily than those involving homoallyl ions. The isomerisation of 4-carene-3-ol (**19**) to hydroxydiene **20** occurs upon boiling in water, even in the absence of acid catalysts:²⁶

As in the isomerisation of compounds **6** and **7**, the irreversibility of the attack on the cyclopropane fragment of the ion **21** makes the reaction regiospecific.

It should be noted that the neighbourhood (and, possibly, conjugation) of the double bond and CPR in a neutral molecule is not prerequisite for the formation of a homopentadienyl ion and hence, for a skeletal rearrangement. From the viewpoint of the reaction mechanism, the selective isomerisation of car-3-en-5-ol (**22**) to *m*-mentha-1,3-dien-8-ol (**20**) is of interest: the double bond and the CPR are united in a conjugated system by a carbocationic centre that is formed between them.²⁷

The conjugated system cationoid centre–CPR can involve not only the adjacent double bond but also the second three-membered carbocycle. The involvement of such an intermediate in the reaction results in the rearrangement of the tricyclooctane skeleton into a substituted cycloheptadiene.²⁸ This rearrangement is interesting because in this case it is the internal bond of the *gem*-dichlorocyclopropane ring that cleaved, whereas it is the external bond that cleaved in the *gem*-dimethylcyclopropane ring.

It is evident from the examples of ionic rearrangements presented above that the cleavage of the ‘external’ bond is a rule, which has almost no exceptions, for the *gem*-dimethylcyclopropane ring. On the contrary, the three-membered ring with two halogen atoms behaves in different ways. In the methanolysis of the adduct of 3-carene with dibromocarbene, the CPR opens in two ways, giving rise to both products with the retention of the carane structure and to rearrangement products.²⁹

The fact that different bonds of the three-membered rings are cleaved in ionic reactions may be due to the nature of geminal substituents. The *gem*-dimethyl group shortens (and strengthens) the opposite cyclopropane bond,³⁰ whereas two geminal chlorine atoms lengthen and weaken this bond. The effect of geminal bromine atoms has the same direction but is weaker.³¹

Acetolysis of toluene-*p*-sulfonate **23** occurs extremely readily;³² in this case, the degree of charge delocalisation in the intermediate (homoheptatrienyl ion **24**) is even higher than that in the homopentadienyl ion.

It was mentioned above that homoallylic and homopentadienyl rearrangements are irreversible; however, this statement is not quite correct. In fact, such transformations of carane derivatives can be carried out with a 100% degree of conversion. This is due to the geometry of the ion and the resulting molecule. The C(2) atom of the CPR, which is not involved in the conjugation chain, changes its hybridisation from sp^2 to sp^3 in the process of stabilisation of the homoallyl ion. As a result, the C(1)–C(2)–C(3) angle, which equals 60° in the cyclopropane molecule, increases to 109° in the molecule formed; in turn, this increases the distance between C(1) and C(3). However, if these

atoms are brought closer in some way, the formation of a homoallyl ion becomes possible again.

In practice, compounds with the menthane skeleton are never transformed into carane-type compounds. However, it was in the carane structures (owing to their specific features) that it was possible to observe the retro-homoallylic rearrangement, in which a homoallyl ion is formed from a linear fragment of the molecule and the three-membered ring is closed. Such an effect was observed in the reaction of toluene-*p*-sulfonate **25** with lithium aluminium hydride³³ or triethylaluminium,³⁴ as well as upon its solvolysis.³⁵

Obviously, in an ideal case, this reaction should occur according to the S_N1 mechanism. However, it is likely that the reaction involves contact ion pairs: very strong polarisation of the substrate occurs, with an almost complete charge separation; however, the resulting cation is stabilised by the counter-ion. Elimination of the toluene-*p*-sulfonate group from compound **25** gives a cation with a charge on the primary carbon atom; it is much less stable than the tertiary ions formed upon protonation of the CPR. The ion can be stabilised due to conjugation of the charged atom with the double bond; in this case, the *p*-orbitals overlap through space rather than through the σ -bond. The tight solvate environment favours the approach of these fragments, because the process is likely to be fast. This pathway gives the homoallyl ion **26** and/or the dihomopentadienyl ion **27**. If the reaction occurs *via* the intermediate ion **27**, quite an unusual rearrangement occurs: in fact, one molecule undergoes two rearrangements in different directions simultaneously, *viz.*, a homoallylic rearrangement, which results in the cyclopropane ring opening, and a retro-homoallylic rearrangement where a new three-membered carbocycle is closed.

It is appropriate here to note a very interesting fact: both 2-tosyloxymethyl-3-carene (**28**) and 4-tosyloxymethyl-2-carene (**25**) give the same ether **29** upon acetolysis.³⁶

The mechanism of the formation of the acetate **29** remains obscure so far. It is also of note that no products are formed which might be expected based on the data on the transformations of the ester **25**. The authors of the present review have observed yet another, rather unusual transformation of the toluene-*p*-sulfonate **28**: its pyrolysis results in the same hydrocarbon as that formed from the toluene-*p*-sulfonate **25**, *viz.*, 1-methyl-4-isopropenyl-bicyclo[4.1.0]hept-2-ene (**30**).³⁶

The pyrolysis mechanism of the ester **25**³⁷ will be discussed below, along with the possible mechanism of the pyrolysis of the toluene-*p*-sulfonate **28**.

Certainly, the mechanisms of ionic rearrangements involving ions with charge delocalised along the conjugation chain are hypothetical and are based on the structures of the final products. It is still unclear whether conjugation in such systems is really possible. As shown below when discussing hydrogenation of 2-carene (**31**), the neighbourhood of a double bond and the CPR by no means ensures their conjugation, at least for a neutral molecule in the ground state.^{17,38} It would be highly important to use modern quantum-chemical calculation methods in order to check whether charge delocalisation is possible in a conjugation system, which involves a CPR as an element, in rearrangements of compounds belonging to the carane series.

III. Rearrangements occurring by the radical mechanism

Generally, radical rearrangements of monoterpenoids belonging to the carane series occur in photochemical reactions. The photochemical transformations of such compounds have been reviewed in detail.¹² Here we consider only those which involve radicals, with emphasis on non-trivial skeletal rearrangements.

For 3-carene, no rearrangements under irradiation have been observed. Only its photochemical oxidation to give three hydroperoxides has been reported.³⁹ Upon irradiation in the presence of a sensitizer, the isomeric 2-carene is rearranged into 1,4,4-trimethylbicyclo[3.2.0]hept-2-ene (**32**), which has been employed in the synthesis of grandisole.⁴

The rearrangement mechanism was not studied in this case; however, the mechanism for a related compound, *viz.*, 2-norcaradiene (**33**), has been reported.⁴⁰ Irradiation of compound **33** resulted in *cis*-hepta-1,3,6-triene as the main product, *i.e.*, the $[2\pi + 2\omega + 2\sigma]$ -process predominated. The formation of a small amount of bicyclo[3.2.0]hept-2-ene (**34**) allowed the authors to assume a common biradical intermediate **A** with a seven-membered ring:

There is a viewpoint^{12,41} that the formation of compounds with the bicyclo[3.2.0]heptane skeleton from certain carane terpenoids upon irradiation can occur as a photo-induced sigmatropic rearrangement. This assumption is supported by the fact that a bornene structure is formed in parallel from ketone **35**.

The concerted mechanism of rearrangement of ketone **35** is indirectly supported by the results of irradiation of 4-hydroxymethyl-2-caradiene (**36**) with a high-pressure mercury lamp:⁴² if a sensitizer is present, only stereoisomeric bicyclic alcohols **37** and **38** are formed, whereas direct irradiation in hexane gives rise to a monocyclic alcohol, *viz.*, compound **39**, in addition.

Kropp, who studied this reaction,⁴² drew an analogy with a 1,3-conjugated system and postulated the formation of allyl radicals. In this case, the CPR can undergo homolytic opening

with cleavage of an internal and of one of the external bonds. Probably, if a sensitizer is present, the molecule is transformed to biradical **40** from the triplet state: in this case, the weakest bond in the CPR is cleaved. In the singlet excited state, the molecule has higher energy, resulting in the cleavage of both possible bonds in the CPR. In this case, cleavage of the C(1)–C(7) bond occurs rather than its shift. Obviously, recombination and formation of a new bond between the C(1) and C(8) atoms in radical **41** (which would result in a bornane skeleton) are impossible because the distance between these atoms is larger than that between the atoms with unpaired electrons in biradical **40**.

Irradiation of 4-acetyl-2-caradiene (**42**) in the presence of a sensitizer gives products with the bicyclo[3.2.0]heptane structure,⁴³ *i.e.*, replacement of a hydroxymethyl group by an acyl group does not alter the mechanism.

However, irradiation of the ketone **42** in the absence of sensitizers results in a fundamentally different rearrangement leading to the product of a 1,3-acyl shift [2-acetyl-3-caradiene (**43**)] and to tricyclic alcohols, *i.e.*, the Norrish type II cyclisation products of both ketones present in the reaction medium.⁴³

A somewhat unusual behaviour of *cis*- (**44**) and *trans*-4-caradiene (**45**) is observed in their irradiation. Although the structures of these molecules enable the Norrish type II cleavage of two bonds, *viz.*, C(3)–C(4) and C(4)–C(5), the phototransformation products of *cis*-caradiene (**44**) only contained compounds formed as a result of the C(4)–C(5) bond cleavage.⁴⁴

Contrary to expectations, no formation of aldehyde **46** or epimerisation of the ketone **45** was observed. However, upon irradiation of the latter in the presence of *tert*-butylamine, the reaction products contained a small amount ($> 1\%$) of amide **47**, which indicated that homolytic cleavage of the C(3)–C(4) bond does occur but quite insignificantly.

Formally, the photochemical behaviour of ketones **44** and **45** is very similar to the allylic rearrangements of β,γ -unsaturated ketones.⁴⁵ Kropp *et al.*⁴⁴ believed that the photochemical rearrangement of caranones **44** and **45** is the first example of the cyclopropyl analogue of the photochemical allylic rearrangement. However, the reaction is reversible for β,γ -unsaturated ketones and irreversible for ketones **44** and **45**.

By analogy with β,γ -unsaturated ketones, the direction of α -cleavage of carbon–carbon bonds is presumably determined by the ‘allylic’ effect of the CPR, which weakens the C(4)–C(5) bond owing to either the conjugation or inductive effect. In the radicals **48** and **49** formed, the C(1)–C(6) or C(1)–C(7) bonds should be cleaved. The ratio of cyclopentanones and cyclobutanones in the reaction products (3 : 1) reflects the preferential cleavage of the more substituted C(6)–C(7) bond and the comparative stability of the tertiary (**50**, **51**) and secondary (**52**, **53**) radicals.

There is yet another difference between allylic photochemical rearrangements of β,γ -unsaturated ketones and similar rearrangements of cyclopropyl ketones. The allylic rearrangement is believed to be a concerted process.⁴⁵ However, Heckert and Kropp⁴⁴ consider that the transformations of caranones **44** and **45** cannot be a concerted reaction, at least as judged by the formation of epimeric cyclobutanones.

The direction of the skeletal photochemical rearrangement of terpenoids belonging to the carane series depends on the orientation of substituents: direct irradiation of *trans*-3-methoxy-4-caranone (**54**) in ethanol occurs with opening of the six-membered ring with cleavage of the C(3)–C(4) bond (which is non-typical of β,γ -cyclopropyl ketones) and addition of ethanol.³⁹

In the case of *cis*-3-methoxy-4-caranone (**55**) with an equatorial methoxy group, the only reaction observed is the Norrish type II elimination, resulting in the caranone **44**; the required planar

six-membered transition state (TS) **A** is formed readily, and the formation of the ketone **44** competes successfully with the cleavage of the C(3)–C(4) bond.³⁹

When exposed to light, the ketone **44** undergoes homolytic cleavage of the C(4)–C(5) bond and homoallylic rearrangement, which is typical of β,γ -cyclopropyl ketones.^{44, 46} This reaction gives cyclopentanone **56** and cyclobutanone **57**.

Thus, the photochemical rearrangements of carane monoterpenoids may be divided in two groups, *viz.*, those where the cyclopropane part of the carbon skeleton and the double bond serve as the chromophores, and those where this role is played by a functional substituent. In the presence of sensitizers, rearrangements of the former type occur, giving rise to bicyclo[3.2.0]heptane derivatives. Irradiation in the absence of sensitizers generally results in rearrangements of the latter type; in this case, the following reactions are possible: opening of the large or small ring, contraction of the large ring or formation of a tricyclic structure. In each specific case, the direction of the reaction depends on the nature and position of the substituent which acts as the chromophore.

IV. Concerted reactions

Ionic reactions of carane compounds are dealt with in numerous publications and these works have repeatedly been systematised, whereas concerted transformations have been studied to a much lesser extent, and the results have not been generalised so far. To be fair, it should be noted that not all reactions attributed to the concerted type actually correspond to this type. For example, in the case of 2,4-caradiene (**58**), the 1,5-thermal shift is formally a concerted sigmatropic reaction. However, first, this occurs *via* a biradical intermediate rather than *via* a cyclic TS (with simultaneous cleavage and formation of C–C bonds); second, it is not a sigmatropic process in essence. In certain cases, the concerted mechanism involves a strongly polarised TS or is coupled with the ionic mechanism. However, the reaction classification would be overcomplicated if these features were taken into account; therefore, in this section we shall discuss the transformations which are traditionally attributed to concerted reactions.

We believe that a survey of such reactions of carane monoterpenoids is especially interesting because it is these that sometimes result in unique transformations that are characteristic only of these compounds (for example, the Berson–Willcott rearrangement⁴⁷). Studies of concerted reactions expand substantially our knowledge about the mechanisms of chemical reactions in general.

1. Norcaradiene–cycloheptatriene interconversion

One of the most interesting skeletal transformations of carane structures, *viz.*, rearrangements which relate terpenoids of the carane and 1,1,4-trimethylcycloheptane series, attracted the attention of researchers; this resulted in the discovery of such a remarkable phenomenon in organic chemistry as the norcaradiene–cycloheptatriene ‘rapid’ equilibrium. Many studies on this subject have been carried out in the last third of the twentieth century.^{47–55} The fast equilibrium of the valence tautomers of norcara-2,4-diene (**59**) and cyclohepta-1,3,5-triene (**60**) is caused

by a typical concerted reaction, *viz.*, disrotatory opening and closure of the three-membered carbocycle; this process obeys the conservation of orbital symmetry rules formulated by Woodward and Hoffmann.⁵⁶

For the unsubstituted hydrocarbon ($R^1 = R^2 = H$), this equilibrium is so much shifted to the monocyclic tautomer **60** that norcaradiene could not be detected by any physical method. Its existence was postulated on the basis of the behaviour of substituted analogues ($R^1 = CN$, $R^2 = CF_3$; $R^1 = CO_2Me$, $R^2 = Ph$; $R^1 = CO_2Me$, $R^2 = C_6H_4OMe-4$), which were found as equilibrium mixtures with the corresponding cycloheptatrienes in low-temperature NMR studies of the latter.⁵⁵ It was only in 1981, a quarter of a century after the hypothesis about the valence tautomerism of cycloheptatriene appeared, that unsubstituted norcaradiene was detected during the low-temperature (77 K) photolysis of tricyclo[3.2.2.0^{2,4}]non-6-ene-8,9-dione.⁵⁷

It was found experimentally that the bicyclic structure can be stabilised by π -accepting substituents at position 7.⁵⁵ An elegant explanation of the nature of this stabilisation was given by R Hoffmann within the framework of the frontier MO method.⁵³ Obviously, methyl substituents cannot serve as stabilisers; therefore, the equilibrium for the system 2,4-caradiene (**58**)–3,7,7-trimethylcyclohepta-1,3,5-triene (**61**) is always shifted towards the monocyclic partner. However, these valence tautomers are different compounds that really exist. They possess different reactivities, which should be reflected (and is actually reflected, as will be shown below) in chemical reactions.

Rearrangements caused by valence tautomerism described above will be discussed in more detail than ionic rearrangements, because the tautomerism of norcaradiene has almost not been considered in Russian scientific literature. Unfortunately, even researchers who work in the field of terpenoid chemistry employ insufficiently substantiated hypotheses to explain the expansion of the carane skeleton to the cycloheptane one.^{12, 58}

The cycloheptatriene–norcharadiene rearrangement has been discovered in a study of the chemical transformations of eucarvone [2,6,6-trimethylcyclohepta-2,4-dienone (**62**)], a terpenoid first synthesised by Baeyer⁵⁹ and then discovered in the essential oils of various plants.⁶⁰

The hypothesis about the valence tautomerism of mono- and bicyclic enols **63** and **64** as a possible explanation of the skeletal rearrangement of the ketone **62** during the formation of 3,7,7-trimethyl-5-hydroxy-3-carene-2-one (**65**) and 3,7,7-trimethyl-5-oxyimino-3-carene-2-one (**66**) was put forward in 1956.^{61, 62} It was then found that rearrangements of carane derivatives into trimethylcycloheptane ones are much more common, because the equilibrium in the dynamic interconversion of the two tautomers is strongly shifted toward the monocyclic partner.⁶³

2,5,5-Trimethylcyclohepta-2,4-dienone (**67**), like the ketone **62**, has been found in the turpentine obtained from *Pinus silvestris* L.⁶⁴ Probably, the presence of these ketones in turpentine oil is explained by the formation, during plant growth, of carane-type unsaturated ketones from 3-carene (one of the major turpentine components); these are then transformed into monocyclic dienones in a concerted electrocyclic reaction. This is supported by the results of liquid-phase oxidation of 3-carene: the percentage of ketones **62** and **67** in the reaction products was 20% and 28%, respectively.⁶⁵

It should be noted that the $64 \rightarrow 63$ and $68 \rightarrow 69$ rearrangements represent the only currently feasible explanation of the presence of seven-membered ketones in essential oils. The general scheme of the biogenesis of terpenes^{66, 67} does not envisage any formation of such compounds at all. However, the widespread occurrence of 3-carene and its derivatives in nature and also the fact that trimethylcycloheptanes are only present in those essential oils which contain carane-type terpenoids, may be considered as indirect evidence in favour of the assumption about the formation of terpenoids with a seven-membered ring. We believe that the assumption that eucarvone (**62**) can be formed during biosyn-

thesis¹² in the same way as Baeyer⁵⁹ had synthesised it, *viz.*, by hydrobromination of carvone followed by dehydrobromination of the resulting 8-bromo-1-menthen-6-one, is much less likely.

Finally, a serious argument in favour of the **58** → **61** rearrangement as the reason for the formation of cycloheptane terpenoids both *in vitro* and *in vivo* is the detection of triene **61** in pine turpentine oil and in oleo-resin from certain pine (*Pinus silvestris*) trees.⁶⁸ Since this triene coexists with cara-2,4-diene, which is present in turpentine and in oleo-resin, it may be concluded that 2-carene, which is also present in turpentine, can undergo catalytic (enzymic) dehydrogenation.

The dual nature of triene **61** is very evident in its hydrogenation: reaction products of incomplete hydrogenation contain not only trimethylcycloheptadienes and trimethylcycloheptenes but also 3-carene (**1**) and 2-carene (**31**). Exhaustive hydrogenation results in a mixture of 1,1,4-trimethylcycloheptane (**70**, 96%) and carane **71** (4%).⁶⁹

Certainly, the ratio of the final hydrogenation products (**70**:**71** = 96:4) does not reflect the content of the tautomers in the original equilibrium mixture. A comparatively large percentage of carane **71** may be due to the fact that the planar diene system of caradiene **58** competes successfully with non-planar diene parts of the triene **61** in the 1,4-addition of hydrogen.

3-Carene is hydrogenated in an unusual way. Cocker *et al.*⁷⁰ discovered in 1966 that hydrogenation of 3-carene over platinum results in a mixture of compounds **71** (98%) and **70** (2%), whereas hydrogenation over palladium gives rise to the hydrocarbon **70** as the major product (74%).⁷⁰ It was found later that hydrogenation of 3-carene on a copper–nickel catalyst results exclusively in 1,1,4-trimethylcycloheptane (**70**).⁵⁸ The authors of both studies believed that this reaction pattern was due to the isomerisation of 3-carene (**1**) to 2-carene (**31**) and 1,4-addition of hydrogen to the vinylcyclopropane system of the latter to give a hydrocarbon with a seven-membered ring.

It was implied that the possibility (or impossibility) of 1,4-addition, which is the key step of the rearrangement, depends on the nature of the catalyst. However, 1,4-addition is only possible if there is conjugation in the diene fragment (or a homodiene fragment in the hydrocarbon **31**). However, the molecule of terpene **31** is in the planar chair-like conformation,³⁸ which casts doubts that such conjugation is possible. The photoelectron spectrum shows that the π -orbital and the HOMO of the dimethylcyclopropane ring in the molecule of compound **31** essentially do not interact.¹⁷ The impossibility of 1,4-addition for the 2-carene molecule (**31**) has been confirmed experimentally.⁷¹ It was shown that the reaction of singlet oxygen, which is an extraordinarily reactive dienophile, with this terpene gives only allylic hydroperoxides, whereas its other reactions, *e.g.*, with α -phellandrene and α -terpinene, give endoperoxides, which are 1,4-addition products.

In their discussion of the reaction mechanism, Cocker *et al.*⁷⁰ did not take their own results into account: if palladium was used as the catalyst, the content of hydrocarbon **70** increased with the increase in the hydrogenation temperature and was 100% at temperatures above 70 °C, *i.e.*, the ratio of the reaction products is primarily affected by temperature. A similar temperature

dependence was established later for hydrogenation over platinum: at 20 °C, the percentage of hydrocarbon **70** is 2%–3%, whereas at 70 and 90 °C, it is 37% and 46%, respectively.⁷²

The rationale for the skeletal rearrangement of 3-carene during hydrogenation is that both platinum and palladium catalyse both the direct and reverse reactions and can fulfil dehydrogenation in the presence of free hydrogen.⁷³ Hydrogenation of 3-carene upon addition of hydrogen to the double bond gives rise to carane; dehydrogenation of 2-carene, which always exists in the reaction medium (due to isomerisation of 3-carene, which occurs on the catalyst in the presence of hydrogen), results in the diene **58**, triene **61** and other compounds with modified skeletons.⁷⁴ An increase in temperature favours endothermic dehydrogenation and hence increases the content of rearranged products. It should be noted that hydrogenation on a copper–nickel catalyst carried out at high temperatures (180 °C) gave the hydrocarbon **71** as the only product.⁵⁸

The direct proof that it is this mechanism that is actually realised is that 2- and 3-carenes undergo disproportionation over palladium and platinum in the absence of free hydrogen. In this case, the triene **61** was identified among the products, which confirms the assumption that dehydrogenation of 2-carene (**31**) is a step which is responsible for the formation of rearranged products.⁷⁵ In addition, the reaction mixture contained trimethylcycloheptadienes **72** and **73**. However, none of the known pathways of the isomerisation of terpenes **1** and **31** (including catalytic reactions) results in such ring expansion.

Based on the above considerations, it may be concluded that rearrangement of carane structures into trimethylcycloheptane structures occurs if the formation of the diene **58** (or its derivatives) is possible during the reaction. The simplest way to caradiene **58** is that from 2- and 4-carene derivatives with a functional group in the allylic position. Thus, dehydrochlorination of 4-chloro-2-carene (**74**) results in the triene **61**.⁷⁶ The transformation products of epoxide (**75**) in the presence of

rhodium catalysts contained 4-carene-3-ol (**76**), which also gives the hydrocarbon **61** upon dehydration.⁷⁷

Theoretically, dehydration of the alcohol **76** can also follow another direction, *viz.*, with the formation of a terminal methylidene group. The corresponding hydrocarbon, 3(10),4-caradiene (**77**), was in fact detected among the reaction products formed from the epoxide **75**.⁷⁷ Hydrocarbon **77**, which was originally obtained by dehydrochlorination of 4-chloro-3(10)-carene (**78**),⁷⁸ is the first stable diene with the carane skeleton.

Dehydration of the alcohol **36** in the presence of potassium hydroxide resulted in the second compound of this series, *viz.*, 4-methyl-3(10),4-caradiene (**79**).⁷⁹

Dienes **78** and **79** are stable (*i.e.*, they do not undergo tautomeric transformations), as, unlike compound **58**, they have a transoid diene system, which cannot undergo electrocyclic closure, and hence, concerted rearrangement. However, these compounds are highly reactive: even weak acids, such as salicylic and benzoic acid, isomerise the transoid diene system into a cisoid system; after that, a concerted rearrangement into cycloheptatrienes occurs.⁸⁰ The dehydration products of the alcohol **36** with Al_2O_3 (Lewis acid) were found not to contain even traces of the diene **79** (unlike its alkaline dehydration⁷⁹); however, 3,4,7,7-tetramethylcyclohepta-1,3,5-triene (**80**) was present.⁸¹

Hydrogenation of the diene **79** over platinum black at 20 °C also occurs with a rearrangement, which obviously results from its isomerisation on the catalyst.⁸⁰ In this case, of note is that the exhaustive hydrogenation products contain a rather high percentage of compounds **81** and **82** with a bicyclo[4.1.0]heptane skeleton. This means that the rate of hydrogen addition to the diene **79** is higher than the rate of its isomerisation, which is a side process (at least, at room temperature).

As a result of the three reactions altogether, *i.e.*, dehydration, isomerisation and hydrogenation, the catalytic hydrogenation of the alcohol **36** under drastic conditions yields 1,4,4,5-tetramethyl-

cycloheptane (**83**).⁸² Over platinum at 20 °C, the reaction does not involve isomerisation; it occurs by simple hydrogen addition to the double bond and gives rise to 4-hydroxymethylcarane (**84**).⁸³

The rearrangement which occurs due to the valence tautomerism makes it possible to obtain functional derivatives of cycloheptatriene. For example, the diene **79** undergoes the Prins reaction to give two hydroxymethylation products, *viz.*, a mono- (**85**) and bicyclic one (**86**).⁸⁴

Electrophilic attack on the terminal double bond in compound **79** by a protonated formaldehyde molecule results in homodienyl ion **87**, which is stabilised by deprotonation (i) from C(5) to give the alcohol **88**, or (ii) from C(10) to give the allylic alcohol **86**. The alcohol **86**, when treated with an acid, is isomerised to caradiene alcohol **88**, which then rearranges into the alcohol **85**.

The monocyclic alcohol **85** can also be formed by yet another mechanism. If the initial hydrocarbon adds a formaldehyde molecule, the first reaction step occurs as a concerted process *via* a six-membered polarised TS (**89**)⁸⁵ to give the bicyclic alcohol **88**. Subsequent rearrangement yields the reaction product **85**. Thus, the transformation of the diene **79** into the trienic alcohol **85** can occur as a sequence of two concerted reactions.

It should be noted that the attack of an electrophilic agent (a charged molecule or a dipole) is directed to the C(10) atom in compound **79**, *i.e.*, to one end of the conjugated homotrienyl system, which is more accessible spatially. However, in the reaction with 2-carene (**31**), the protonated formaldehyde mole-

cule adds to the least substituted end of the double bond to give homoallylic alcohol **90**,⁸⁶ which is additional evidence for the absence of conjugation in the 2-carene molecule.

It should be noted that dehydration of 2-hydroxymethyl-3-carene (**90**) with potassium hydroxide does not give a caradiene with an exocyclic double bond (**91**) as the main product; instead, this yields 2,3,7,7-tetramethylcyclohepta-1,3,5-triene (**92**), which is obviously formed *via* intermediates **93** and **94**.⁸⁶

Dehydration of the alcohol **36** gave not only the triene **80** but also the diene **79** as the reaction products.⁸⁴ Charge is delocalised to a greater extent in the pentadienyl anion **93** than in the allylic anion **95**; therefore, the transformation of the diene **91** into the final product **92** occurs more readily than the transformation of the diene **79** into the diene **96** and further into cycloheptatriene **80**.

Generally, concerted rearrangements of transoid caradienes occur very readily, therefore special measures are to be taken to avoid this reaction and obtain very labile non-rearranged dienes. For example, thermal decomposition of *N*-oxide **97** was the only approach that allowed hydrocarbon **91** to be prepared from the alcohol **90**.⁸⁶

Turning back to the Prins reaction, it may be noted that when a hydrocarbon molecule that has the bicyclo[4.1.0]hept-2-ene system contains an additional isolated double bond (as in com-

pound **30**), the initial attack of formaldehyde is directed at this bond. However, under conditions of acid catalysis, the bicyclic alcohol formed initially readily isomerises to give a bicyclo[4.1.0]hepta-2,4-diene system (*e.g.*, compound **98**), in which a concerted rearrangement occurs.⁸⁶

2. Sigmatropic rearrangements

Thermal rearrangement of 2-carene (**31**) and its derivatives was the first example of the transformations which were later called the 1,5-homodienyl shift.⁸⁷

It is well known that vinylcyclopropane is transformed into cyclopentene at temperatures above 330 °C; the reaction occurs as a homolytic bond cleavage followed by isomerisation of the biradical formed and subsequent recombination.⁸⁸ The activation energy of this rearrangement is rather high and equals 208 kJ mol⁻¹ (see Ref. 89).

However, 2-carene and its derivatives, whose molecules contain the vinylcyclopropane moiety, undergo a rearrangement at a temperature as low as 180 °C to give the corresponding derivatives of *trans*-isolimone **99a–c**.^{90,91} 4-Carene (**100**) reacts similarly.⁹²

R = H (**99a**), OH (**99b**), CH₂OH (**99c**).

This transformation is determined by specific features of the structure of 2- and 4-carene derivatives: just as the 1,5-dienyl shift of hydrogen is possible in *cis*-1,3-diene systems, a 1,5-homodienyl shift is possible in carene compounds which have a vinylcyclopropane fragment. The reaction occurs *via* a six-electron transition state and obeys the selection rules for thermal hydrogen shifts.⁵⁶ No homolytic cleavage of the carbon–carbon bond occurs, since the activation energy of the 1,5-homodienyl shift is much lower than the energy of the vinylcyclopropane rearrangement; in the case of 2-carene, it equals 118 kJ mol⁻¹ (see Ref. 91).

The prerequisite for the 1,5-shift is the *endo*-orientation of the C–H bond and the vinyl group involved in the formation of the transition state.⁹³ This is the only stereochemical requirement for the thermal rearrangement of *cis*-1-methyl-2-vinylcyclopropane; the positions of the substituents in its molecule do not cause any additional strain. This requirement is also met for the 2-carene (**31**) molecule; however, the double bond is part of the six-membered ring and therefore it deviates from the direction

which is optimal for conjugation with the CPR and formation of the TS. The distance between C(3) and the hydrogen atom at C(8) is ~ 3.1 Å in the planar chair-like conformation.³⁸ This means that the molecule of 2-carene (**31**) on heating should first change its conformation [as a result, the C(3)–H(8) distance decreases to 2.3 Å], and only then undergoes the 1,5-homodienyl shift.

The nature of the substituent at position 4 can affect the activation energy of the conformation transition, but even bulky substituents do not prevent the 1,5-shift; however, the thermal rearrangement of such compounds requires higher temperatures.⁹⁴

α -Thujene (**101**), whose molecule also contains a vinylcyclopropane fragment, remains unchanged when heated above 300 °C. However, experiments using a deuterium label showed that a degenerate vinylcyclopropane rearrangement actually occurs. In this case, the TS required for the 1,5-homodienyl shift is hard to access: the distance between D(4) and C(5) or C(3) is ~ 2.8 Å.⁹⁵

It should be noted that, owing to the geometry of their molecules, it is the carane structures that turned out to be suitable models for studying the 1,5-homodienyl shift. In the thermal isomerisation of terpenoids with the bicyclo[4.1.0]hept-2-ene skeleton, the 1,5-homodienyl shift occurs regio- and stereospecifically; this makes it possible, *e.g.*, to synthesise new oxygen-containing terpenoids from 2-carene derivatives.⁹⁶

The presence of an *endo*-oriented vinylcyclopropane fragment and an appropriate C–H bond in compounds of the carane series does not necessarily mean that thermal 1,5-hydrogen shift is possible. For example, heating of caradiene **77** at 120 °C gave the triene **61** as the major (or the only one, at relatively low temperatures) transformation product.⁹⁷ At higher temperatures (170–190 °C), small amounts of *p*- and *m*-cymenes (up to 3%) formed as well.

It might seem that the 1,5-homodienyl shift should be the most likely process under these conditions: the vinyl group and one of the C(8)–H bonds have an *endo*-orientation; the C(4)–H(8)

distance is ~ 2.2 Å, *i.e.*, it is easy to attain the ideal TS for the 1,5-shift calculated theoretically.⁹³ However, such a transformation should give *m*-mentha-1(7),4,8-triene, which is not formed in reality. A vinylcyclopropane rearrangement is also impossible at these temperatures, as they are not high enough for a radical reaction. It might be assumed that valence tautomerism is responsible for skeletal rearrangement. Then the thermal isomerisation **77** $\rightarrow$ **61** is actually reduced to the transformation of the transoid diene **77** to the cisoid diene **58**. This is formally a 1,3-sigmatropic shift.

It is generally believed that the non-catalysed hydrogen 1,3-shift does not occur in thermal reactions, since the transition state of the allowed antarafacial shift is hardly accessible because of the high angular strain in the propene fragment.⁹⁸ The suprafacial shift, which is quite possible as regards spatial aspects, is forbidden due to the orbital symmetry conservation rules. However, an *ab initio* calculation of the 1,3-shift in propene showed that the forbidden suprafacial hydrogen transfer requires a lower activation energy than the allowed antarafacial transfer.⁹⁹ This unexpected result was explained using a hypothesis about the subjacent orbital control.¹⁰⁰ This hypothesis underlies the assumption that a 1,3-shift occurs in the molecule of the diene **77**.

The mechanism of the thermal isomerisation of caradiene **77** was also studied by kinetic methods.⁹⁷ The transformation of the hydrocarbon **77** into the triene **61** is a sequence of two concerted reactions; for quite obvious reasons, the first one (the assumed 1,3-shift) is the limiting step. Kinetic studies showed that this step is described by a first-order equation. The activation energy determined from experimental data is 112 kJ mol^{–1}, which is close to the calculated activation energy of the antarafacial 1,3-shift (115 kJ mol^{–1}).⁹⁹ The high negative activation entropy, which equals 96 kJ mol^{–1} deg^{–1} (–23 eu), suggests that a 1,3-shift is possible in this reaction. Comparison of this value with the corresponding parameter for the 1,5-shift (–8 to –16 eu) shows that the transition state of the thermal rearrangement of caradiene **77** is highly ordered and that the participating atoms are bound very strongly. The activation energy of 1,5-shift in 2-carene (**31**) (118 kJ mol^{–1})⁹¹ is somewhat higher than the activation energy of the thermal isomerisation of the diene **78**; this may explain why the 1,5-shift does not occur in this case.

Of special interest is the thermal rearrangement discovered by Berson and Willcott.⁴⁷ Formally, it is migration of the methyl group over all the possible positions of the triene system in the molecule of the hydrocarbon **61**. Nevertheless, this should be considered in the series of carane rearrangements, because, in fact, it is a 1,5-shift of the dimethylmethylene group rather than a 1,3- or 1,5-alkyl shift that occurs in the caradiene tautomer **58**, as shown using deuterium labelling.

This specific reaction served as the impetus for the development of experimental and theoretical studies, which expanded considerably, and changed somewhat, the classical concepts of sigmatropic reactions. The triene **61** turned out to be an excellent model for these studies, since the rearrangement only occurs if a *gem*-dimethyl group is present: in the absence of geminal sub-

stituents, cycloheptatriene undergoes 1,5-hydrogen shift at temperatures above 100 °C.¹⁰¹ The presence of the third methyl group, which ‘walks’ along the triene system of the seven-membered ring, made it possible to detect this rearrangement (‘walk rearrangement’).

It should be noted that the mechanism of this shift does not allow the rearrangement of the heptatriene **61** to be considered completely concerted, because it occurs *via* a biradical intermediate at temperatures ~ 400 °C. This rearrangement involves a shift of the cyclopropane bond, which is not a σ -bond in the original molecule; this does not allow this rearrangement to be considered sigmatropic. Still, it was considered for a rather long time that the rearrangement of the triene **61** meets completely the selection rules for concerted sigmatropic migrations of alkyl groups, *i.e.*, it occurs as a suprafacial rearrangement with retention of the configuration of the migrating group. Elegant studies by Klärner *et al.*^{102–104} rebutted these concepts completely: they replaced one methyl group by an alkoxy carbonyl, nitrile or alkoxyalkyl group and proved that the rearrangement occurs with retention of the configuration, *i.e.*, by a ‘forbidden’ pathway.

Recently, this phenomenon was explained on the basis of *ab initio* calculations in two theoretical papers issued almost simultaneously.^{105,106} In the case of non-substituted norcaradiene **102**, the methylene group with an unpaired electron is somewhat more remote from the six-membered ring in the biradical TS **A** for the forbidden thermal 1,5-alkyl shift than in the TS **B** of the allowed shift, which decreases the energy of the TS for the forbidden shift by ~ 4 kJ mol^{–1} (see Ref. 105).

The transition states **C** and **D** for the 1,5-shift in *cis*- (**103**) and *trans*-7-cyano-7-methylnorcaradienes (**104**), which occurs with reversal of the configuration (and is therefore forbidden), is 12 and 13 kJ mol^{–1}, respectively, more favourable than the TSE of a similar shift with retention of the configuration (which is therefore allowed). The distance between the hydrogen atoms of the methyl group and the ring in the forbidden TS **C** and **D** is by 0.12 and 0.37 Å shorter than that in the allowed TS **E**.¹⁰⁶

On these grounds, Houk *et al.*¹⁰⁶ conclude that when sigmatropic rearrangement occurs *via* a biradical intermediate, steric factors can dominate over electronic factors, resulting in a violation of the fundamental orbital symmetry conservation rules. It is appropriate to remind here that the studies which have led to this amazing result started with an investigation of terpenoids, *viz.*, the triene **61** and its valence tautomer, the diene **58**.

3. Thermal elimination

Attempts to dehydrate the alcohol **36** with boric acid gave a mixture of hydrocarbons **30**, **105** and **106**, instead of the expected diene **79**.¹⁰⁷

It was later found that these hydrocarbons are also formed upon thermal decomposition of mono-, di- and triesters of boric acid and the alcohol **36** (*i.e.*, intermediates of the dehydration described above), and that bicyclic hydrocarbon **30** is formed initially; other transformation products were identified as well.¹⁰⁸ Toluene-*p*-sulfonate and chloroacetate of the alcohol **36** reacted similarly; the corresponding acetate and aminoacetate underwent the 1,5-homodienyl shift.¹⁰⁹

Thermolysis of esters is a well-studied reaction, which is used as a route to olefins by elimination of an acid residue and a hydrogen atom bound with the β -carbon atom. Elimination occurs *via* a six-electron (aromatic) TS. However, pyrolysis of the alcohol **36** and its derivatives results not in the formation of a double bond but rather in cleavage of one of the bonds in the *gem*-dimethylcyclopropane ring with simultaneous closure of a new three-membered carbocycle. Additional studies were carried out in order to study the mechanism of this unusual rearrangement: the kinetics of the thermal decomposition of the toluene-*p*-sulfonate **25** in pyridine³⁷ and its solvolysis³⁵ were studied.

These studies made it possible to propose the mechanism of this rearrangement.³⁷ This occurs as a concerted rearrangement *via* an aromatic ten-electron transition state, unlike the classical six-electron TS. Although the hypothesis about a ten-electron TS has not been used before in organic chemistry, it does not suffer fundamental self-inconsistencies. Recently, a ten-membered TS was calculated for the Cope [5,5]-sigmatropic rearrangement using the B3LYP/6-31G* method.¹¹⁰ A calculation using the density functional shows that a ten-membered TS may be non-planar but maintains aromaticity.¹¹¹

We believe that the spatial factor is responsible for this unusual reaction pathway. The formation of a six-membered TS upon elimination of acid fragments requires that the acid residue in ester **107** have an eclipsed conformation with respect to the H(4) atom. This allows the oxygen atom of the acid residue and a hydrogen atom of the *endo*-methyl group, which is linked with the cyclopropane ring, to approach each other and ensures that the vinylcyclopropane fragment is involved in the transition state. The aromaticity criterion (*i.e.*, fulfillment of the Hückel rule) requires that the p-orbitals of non-neighbouring atoms [C(3), C(11)] overlap. The formation of the cyclopropane ring and simultaneous transformation of the vinylcyclopropane fragment into the 1,4-diene system occur as a result of such through-space overlap.

This viewpoint was confirmed experimentally.³⁷ A detailed study of the decomposition of esters **107–109** showed that these

reactions result in various products. For example, the pyrolysis products of the ester **108** also contained water (3%–5%):

The first pyrolysis step occurs as the fragmentation of the molecule of the diester **108** via a ten-membered TS **110**, which includes a hydroxy group. This results in the bicyclic hydrocarbon **30**, water and ester **107**. Further, the ester **107** decomposes according to the scheme described above to give boric acid and a second molecule of the hydrocarbon **30**. The pyrolysis products of the ester **109** contained (in addition to the hydrocarbon **30** and its transformation products) 2- and 3-carenes, menthadienes and the alcohol **36**:

The first stage gives the hydrocarbon **30** and also the ester **107** (which decomposes according to the scheme described above) and the alcohol **36**. The latter undergoes partial deformation under the reaction conditions (380 °C) to give 3-carene (**1**).⁹¹ As a result of acid isomerisation of this terpene, 2-carene and menthadienes appear among the products.

It should be noted that pyrolysis of *N*-oxide **111**, whose structure is similar to that of esters **107**–**109**, gave quantitatively the hydrocarbon **79** containing an exocyclic double bond.¹¹² This result may be considered as an indirect proof that the spatial factor plays a decisive role in such rearrangements.

In the oxide **111**, the functional group has one member less than that in esters **107**–**109**; as a result, the formation of a five-membered (but six-electron, *i.e.*, still aromatic) transition state becomes possible; this is smaller in size and its C(4) atom has a *gauche*-conformation.

Undoubtedly, the TS in the thermal decomposition of esters is highly polarised; its structure depends on the nature of its

constituent atoms. Therefore, the acetate, borate and toluene-*p*-sulfonate of the alcohol **36** manifest different reactivities in this reaction. The reactivity even depends on the secondary effects of the heteroatoms: acetate and aminoacetate undergo a 1,5-homodiényl shift; thermolysis of the toluene-*p*-sulfonate occurs at 90 °C, that of chloroacetate at 180 °C, and that of mono-, di- and triborates at 225, 282 and 380 °C, respectively.¹¹³

Pyrolysis of borate **112**, in which 1,2-elimination is impossible *a priori*, gives rise to 3-carene (**1**), formed presumably upon acid isomerisation of the initial pyrolysis product, *i.e.*, tricyclic hydrocarbon **113**. None of the esters of 3,6,6-trimethylbicyclo[3.1.0]hexan-3-ylmethanol tested in this reaction (toluene-*p*-sulfonate, acetate, amino- and chloroacetates) behaved in this way.

As we noted in Section II.2, the solvolysis of toluene-*p*-sulfonates **25** and **28** results in the same product **29**.³⁶ Pyrolysis of these compounds also affords a single reaction product **30**, although the pyrolysis of the ester **28** requires a higher temperature (180–200 °C) than that of the ester **25** (70–100 °C). We assume that this can be explained by preliminary 1,3-shift of the tosyloxymethyl group, which occurs at high temperature. A similar shift of the acyl group was observed in the photolysis of the ketone **42**⁴³ (see Section III).

4. Ionic reactions and valence tautomerism

We have already mentioned the ionic transformations of carane monoterpenoids (*e.g.*, compounds **74** and **76**) to give a 2,4-caradiene structure, which underwent electrocyclic opening of the three-membered ring with rearrangement into a trimethylcycloheptatriene structure. In such cases, the skeletal rearrangement occurs due to valence tautomerism. Compounds of the carane series, which have a more complex carbon skeleton, can undergo ionic rearrangements of another type, giving rise to structures that are prone to tautomeric transformations.

For example, the adduct of 3-carene with dibromocarbene undergoes dehydrobromination on treatment with a superbasic system KOR–DMSO ($\text{R} = \text{H}, \text{Bu}^t$) with selective formation of 1,8,8-trimethyl-5-methylenecycloocta-1,3,6-triene (**114**).¹¹⁴ When the concentration of the dehydrobrominating agent was decreased, additional products were isolated from the reaction mixture; this allowed a scheme of the rearrangement to be proposed.¹¹⁵

Elimination of the first molecule of hydrogen bromide is accompanied by the isomerisation of the three-membered ring to give bromides **115** and **116**. Bromide **115** with an intact carane skeleton is formed by opening of the three-membered ring with cleavage of the external bond and does not undergo further transformations on treatment with the KOH–DMSO system. Compound **116** isomerises to give bromide **117**, which contains a *cis*-divinylcyclopropane system. This undergoes the Cope rearrangement¹¹⁶ by concerted opening of the CPR to give a valence tautomer **118**. Dehydrobromination of compound **118** results in cyclopropene **119**, which isomerises to a more stable cyclooctatriene derivative **120**. The latter is methylated by the dimsyl anion under the reaction conditions.

This reaction involves yet another concerted rearrangement. Bromide **121** is formed due to a 1,5-homodienyl shift; subsequent ionic isomerisation of this compound results in bromides **122** and **123**.

5. Sigmatropic shifts in charged systems

The transformations of carane structures on treatment with superacids are of considerable interest. In superacidic media, the life time of carbocations increases, enabling their more profound secondary transformations and involves all the possible reaction centres (CPR, double bonds if any, functional groups) in rearrangements. One of these possibilities comprises the sigmatropic shifts of hydrogen or alkyl groups. This gives new cations, each with its own destiny. Certainly, the diversity of the intermediates involved in these rearrangements predetermines the diversity of the reaction products.

The reaction of the alcohol **36** or its derivatives with the superacid system $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ affords a mixture of products, the formation of which is explained by sigmatropic shifts in the ions **124** and **125** formed initially (Scheme 2).³⁶

The rearrangement of the isomeric alcohol **90** occurs similarly.³⁶

This type of cyclisation requires a 1,2-hydrogen shift in the *p*-menthene ion **126**, since the oxygen atom of the hydroxymethyl group is remote from the C(8) atom where the initial charge appears. In systems where the oxygen atom of the hydroxymethyl group is closer to the C(8) atom, cyclisation occurs *via* the *m*-menthene ion **127** formed initially. Certainly, the 1,2-shift occurs in the ion **127** as well, but the oxygen atom and the C(3) atom (where positive charge is localised after the shift) are too close, therefore cyclisation cannot occur because of the steric strain.

Cyclisation of diol **128** occurs, without initial hydrogen shift, *via* the *p*-menthane ion **129**, in which the oxygen atom is closer to the charged carbon atom than in ion **126**. This reaction involves selective opening of the cyclopropane ring with cleavage of the C(1)–C(7) bond; the reason for such selectivity has not been elucidated yet.³⁶

Tricyclic alcohol **130** rearranges in superacidic media with cleavage of the C(4)–C(5) bond, giving rise to compound **131**. The cyclisation occurs due to the 1,2-hydrogen shift in cation **A**.³⁶

Scheme 2

$\text{R}^1 = \text{H, Me; R}^2 = \text{H, Me, CH}_2\text{CH}=\text{CH}_2$.

A characteristic feature of the rearrangement of the alcohol **130** is that its molecule has two three-membered rings, but only one of them opens on treatment with a superacid. This may be due to the difference between the HOMO energies of both cyclopropane fragments having different substituents, although the electrostatic effect of the hydroxymethyl group on the process, which is charge-controlled, seems unexpectedly strong.

Rearrangements accompanied by cyclisation occur in superacidic media for secocarane structures as well.³⁶ In this case, the positive charge should approach the oxygen atom in order that a bond can be formed:

In the rearrangements of α -*trans*-3,4-epoxycarane[†] (**75**) in superacidic media, the intermediate ions undergo not only hydrogen but also alkyl shifts; these shifts are responsible for the transformation of the carane skeleton.¹¹⁷

Pathway a

Pathway b

The 4-hydroxycarane-derived ion **132** should undergo a 1,2-alkyl shift with contraction of the six-membered ring to give ion **133**; elimination of a proton and ionisation of the CPR make cyclisation possible (pathway a).

The second pathway of the transformation of ion **132**, which formally occurs as a 1,3-alkyl shift and results in ion **134** (path-

way b), is more interesting. However, 1,3-alkyl shifts cannot occur in charged systems: the C(2) atom lacks an appropriate p-orbital. Thus, a 1,2-alkyl shift actually occurs, but the formation of the TS involves non-adjacent carbon atoms [C(1) and C(3)]. Through-space rather than through- σ -bond overlap occurs; this shift may be called homoenylic. This eventually results in the closure of the three-membered ring and gives ion **134** (β -cyclopropyl rearrangement¹¹⁸), which successively undergoes a hydrogen shift and an alkyl shift to give the final ketone (+)-**135**.¹¹⁷

In order to explain the rearrangements of β -*cis*-3,4-epoxycarane (**136**) in superacidic media, a mechanism was suggested which involves bicyclic ion **137** isomeric to ion **134**.¹¹⁸ This results in the stereospecific formation of the ketone (–)-**135**; the latter is not only a stereoisomer but also an enantiomer of the ketone (+)-**135**, which is formed due to rearrangements of the epoxide **75**.

The different reactivities of epoxides **75** and **136** are explained¹¹⁸ by thermodynamic and orbital factors: the orientation of the migrating bond and the vacant orbital in ions **132** and **138** is favourable for ring contraction. For ion **132**, ring contraction is more energetically favourable, whereas β -cyclopropyl rearrangement (via cations **137** and **139**) is favourable for ion **138**, since the orientation of the vacant orbital in this cation is more favourable for the rearrangement than that in **132**.

The above transformation schemes of epoxides **75** and **136** only cover the most probable ways for the formation of the final products. No compounds with the 4-isopropyl-1-methylbicyclo[3.1.0]hexane skeleton, which might have formed from ions **134** and **137**, were found in the transformation products of epoxycaranes in superacidic media. However, diol **140** with the same skeleton was obtained in 1962 by acid-catalysed hydration of *cis*-epoxide **136**,¹¹⁹ and its structure was confirmed in 1972.¹²⁰

As shown in 1966, dehydration of 3 β ,4 α -caranediol monoacetate **141** gives rise to *trans*-4-isopropenyl-1-methylbicyclo[3.1.0]hexan-2-ol acetate (**142**) as one of the products.¹²¹

Kropp who studied this reaction¹²¹ regarded it as the first documented example of rearrangement with transannular cyclopropyl participation.¹⁰ He believed that CPR in nucleophilic substitution reactions acts as an internal nucleophile and the role of stereochemical factors is very high in such reactions: it is required that there is a spatial possibility for the dimethylcyclopropane ring to attack the C(3) atom, which carries a β -substituent. Also of importance is the existence of an α -sub-

[†]In the chemistry of terpenoids, the α and β symbols traditionally designate the spatial arrangement of functional groups in carane derivatives: α substituents and the three-membered ring are located on different sides of the cyclohexane ring (*trans*), whereas β substituents are located on the same side as the CPR (*cis*).

stituent at the C(4) atom, required for fixing the six-membered ring in the 'syn-boat' conformation **A**.¹²¹

Different opinions existed regarding the stereochemical conditions of 'cyclopropyl participation' stated by Kropp. For some time, his interpretation of the spatial features of such reactions was considered generally accepted and was cited in special literature.¹² However, subsequent studies^{10, 122–128} made it possible to put forward a statement (and confirm it experimentally) that the molecules of the reacting carane compounds have the 'anti-boat' conformation (**B–D**) in the transition state; the orientation of the substituent at C(4) does not matter.^{122, 123, 129}

In fact, the 'transannular participation of CPR' is reduced to the 1,2-homoenyl shift, which can occur (and does occur) in charged systems. The absence of 'transannular cyclopropyl participation' products upon rearrangement in superacids is caused by the fact that, owing to the very low nucleophilicity of the medium and low temperatures, ionic processes occur to a greater extent and are highly selective. Therefore, transformations in superacids do not stop in ion **137**, but proceed further to give ion **139**, which leads to the final reaction product.

This approach explains the similarity of transformations of the epoxide **136** under the conditions of usual acid catalysis and in superacids, but new questions arise. The transformation of the epoxide **75** in superacids gives products which imply the intermediate formation of ion **134**, whereas solvolysis of compound **75** does not yield 4-isopropyl-1-methylbicyclo[3.1.0]heptane structures. As a side process, ring contraction occurs due to an alkyl shift in the ion **132** giving the ion **133**, which is stabilised by elimination of a proton; in a superacid, the ion **133** rearranges.^{125, 130}

Undoubtedly, epoxides **75** and **136** react differently under usual conditions due to differences in their spatial structures. However, in superacids this difference is insignificant with respect to 'transannular cyclopropyl participation', or at least this does not play an important role. It may be assumed that charges are separated more deeply in superacids, which alters the geometry of the carane skeleton and enables the 1,2-shift. In usual acids, only partial charge is located on the involved atoms,¹²¹ therefore the geometry of the carane skeleton is changed insignificantly. However, it should be noted that the ion **133** is formed under conditions of usual acid catalysis, which at present cannot be explained in terms of the above argumentation.

The reactions of α -epoxycarane with aldehydes over ascanite-bentonite clay (an alumosilicate catalyst) do not give any products which would imply that the ion **134** is involved in the reaction.¹³¹

In this case, no profound transformations of ions occur, as the aldehyde traps the ion **132**, and the reaction follows a different pathway. On the other hand, under similar conditions the epoxide **136** gives products which imply that ion **138** undergoes not only a 1,2-homoenyl but also a 1,2-alkyl shift to give the ion **133** (which was not observed in superacids¹¹⁸), which is then rearranged.

As a result of the specific features of catalytic transformations on solid surfaces, the reaction of the epoxide **136** does not give an acetal with a carane skeleton; instead, it yields the ketone **44**, which is absent in the products of the reaction starting from the epoxide **75**.

3-Carene does not react with aldehydes on ascanite-bentonite clay,¹³¹ but under these conditions the alcohol **36** yields a series of rearranged products, the structure of which depends on the aldehyde used.¹³²

The suggested reaction mechanism¹³² involves the attack of protonated butyraldehyde on the more substituted end of the double bond to give a secondary cation **143** rather than a more stable tertiary cation. Rearrangement of the former with opening of the CPR gives ions **144**, **145** and then the reaction products. Section II.1 gives a different viewpoint on the formation of products with a similar skeleton.^{24,25} The mechanism proposed by Barkhash *et al.*¹³² is supported by the formation of tricyclic products in the reaction of the alcohol **36** with α -methylacrolein (Scheme 3).

The proximity of the double bond to the cationic centre in ion **146** can result in cyclisation, which is believed to be due to the presence of a methyl group at the α -position of methylacrolein.

We have already described the rearrangements of the carane skeleton into the bicyclo[3.1.0]hexane one, for epoxycaranes as examples. A formally similar rearrangement of the carane skeleton is observed during the transformation of car-2-en-4-one oxime (**147**) on treatment with nitrous acid.¹³³ Considering the nature of the functional substituent, the most probable pathway for the transformation of oxime **147** involves intermediates **148**–**152**.

Obviously, it is the shift of the alkyl group in the charged system that is responsible for the rearrangement of the carane skeleton. Using quantum-chemical calculations, it was concluded¹³³ that the 1,2-alkyl shift in ion **152** is impossible from the viewpoint of its spatial structure and from thermodynamical considerations. As regards ion **151**, it is assumed that concerted elimination of nitrogen occurs in it, with simultaneous attack of the acetate group and migration of the C(5)–C(6) bond. Cation **153** is stabilised by capturing a NO₂[−] anion. A transition state of the type **151** has been postulated earlier^{130,134} in order to explain the pyrolysis of caranediol monoacetate **141**.

Scheme 3

However, the suggested cyclic intermediate **154** accounts for the rearrangement of bonds but formally and schematically. It is obvious that the thermal shift of the C(2)–C(3) bond can only occur in an ion. Probably, acetic acid that has already been eliminated (by a concerted mechanism) and is present in the reaction mixture favours the formation of intermediate ions.

An even more surprising example of skeletal rearrangements caused by the participation of the oximine group has been reported.¹³⁵ 3 α -Hydroxyaminocaran-4-one oxime (**155a**) and 3 α -(*O*-acetyl)hydroxyaminocaran-4-one oxime (**155b**) react with sodium borohydride in acetonitrile resulting in reaction product **156** with a fused seven-membered ring.

R = H (a), Ac (b).

In this case, acetonitrile is probably not only a solvent but also a reagent, because rearrangement does not occur when it is absent. The authors postulate two possible intermediates of this reaction (**A** or **B**) but note that the mechanism of their formation is not clear yet.

* * *

The vast material considered in this paper indicates that studies of the chemical transformations of carane derivatives goes far beyond the scope of the area of organic chemistry which is customary to regard the chemistry of terpenoids. 3-Carene is a really unique natural compound that offers wide opportunities to scientists. Owing to the accessibility of this compound, a lot of new compounds are being obtained from it; these are interesting both by themselves and as excellent models for studying reaction mechanisms. We believe that only benzene can compare with 3-carene as regards its contribution to theoretical and synthetic chemistry. The authors are far from thinking that nature has deliberately taken care of organic chemists, but it is hard to overestimate the generosity of this natural gift. We do hope that our readers feel the same way.

Although we attempted to consider the mechanisms of the known rearrangements, attentive readers have surely noticed that these mechanisms are often hypothetical and sometimes questionable. There is no doubt that studies in this field will be continued and will not only provide answers for the today's questions but also raise new ones.

Multicomponent cascade heterocyclisation as a promising route to targeted synthesis of polyfunctional pyridines[†]

V P Litvinov

Contents

I. Introduction	69
II. Cascade heterocyclisation involving α,β -unsaturated carbonyl compounds	70
III. Cascade heterocyclisation involving 1,3-dicarbonyl compounds	73
IV. Cascade heterocyclisation involving pyridinium ylides	76
V. Cascade heterocyclisation in the synthesis of fused heterocycles	78

Abstract. The review surveys the state-of-the-art in the methodology of multicomponent cascade heterocyclisation and its prospects as applied to the targeted synthesis of polyfunctional pyridines and their hydrogenated and fused analogues. The bibliography includes 405 references.

I. Introduction

A fundamental problem of synthetic organic chemistry is to design new chemo-, regio-, stereo- and enantioselective methods for the synthesis of polyfunctional carbo- and heterocycles possessing practically important properties. Such methods should not only be based on simple and commercially available substrates and reagents and characterised by low cost of the final products but also be ecologically safe.

In this connection, recent years have witnessed a rapidly growing interest in the one-pot synthesis involving two groups of reactions. One group includes successive reactions in the course of which another reagent, substrate or catalyst is added or the reaction temperature is changed without isolation of intermediates. Another group includes cascade reactions proceeding under the same conditions without the addition of any other reagents or catalysts. In these processes, the functional groups that are formed in earlier steps are transformed in each subsequent step. This type of processes is referred to as domino or tandem reactions. It should be noted that there is no strict difference between these terms.

Multicomponent cascade processes are of particular interest, which is reflected in the reviews^{1–11} that have been published. These reactions can serve as the basis for both targeted organic synthesis and combinatorial chemistry, which allows one to synthesise simultaneously several thousand samples for biological screening with the use of automated efficient approaches.^{12–20}

Analysis of named reactions in organic chemistry shows that many of these reactions, particularly, those giving rise to heterocyclic compounds, are based on the methodology of multicomponent cascade heterocyclisation. Examples are the Hantzsch

reaction involving cyclocondensation of β -keto esters or β -diketones with aldehydes and ammonia to form substituted pyridines,^{21,22} the Gattermann–Skita reaction, *viz.*, the synthesis of pyridine derivatives by condensation of sodium malonate with dichloromethylamine (as a version of the Hantzsch reaction),²³ the Guareschi–Thorpe reaction, *viz.*, the preparation of pyridine derivatives by cyclocondensation of ester (amide) of cyanoacetic acid or α -allylacetoacetic ester with ammonia,^{24,25} the Doebner reaction involving condensation of aromatic, heteroaromatic or fused polycyclic amines with aldehydes or pyruvic acid to yield quinolinecarboxylic acids,²⁶ the Ullmann–Fetvadjan reaction, *viz.*, the synthesis of benzacridines by condensation of β -naphthol with aldehydes and aromatic amines²⁷ and many other reactions.

In the last 15 years, the chemistry of functionalised pyridine-chalcogenones has been extensively developed, which is reflected in many reviews^{28–41} and dissertations^{42–54} that have been published. This is associated with both a theoretical interest in this class of organic compounds and a very broad spectrum of the practical uses of pyridine derivatives. For example, more than 10% of the most commonly used modern medicines contain pyridine or the hydrogenated pyridine ring.⁵⁵ A new class of calcium antagonists was constructed on the basis of 1,4-dihydropyridines^{56,57} (in particular, the drug nifedipine used for the treatment of high blood pressure and stenocardia⁵⁵). Among these compounds are highly efficient cardiotonics^{58–107} (including the drugs amrinone and milrinone^{98–107}), tranquilisers^{108–118} and compounds possessing antiinflammatory, hypoglycemic, antiulcer, antispasmodic, antifungal, antibacterial, pesticide and other biological activities.^{112–142} Pyridine derivatives are used as the starting substrates for the construction of new CH-antioxidants,^{143–146} analogues of folic acid,¹⁴⁷ vitamin B₆,¹⁴⁸ other biologically active compounds^{143, 147–151} and models of the redox coenzymes NAD and NADP.¹²⁵ Here, it is worthwhile mentioning that substituted cyclopentaspiperidone is used in the synthesis of the known anxiolytic buspirone which prevents drug adaptation.¹⁵² The only known natural alkaloid containing a nitrile group, *viz.*, 3-cyano-4-methoxy-1-methyl-1*H*-pyridin-2-one,¹⁵³ also belongs to this class of compounds.

In the last decade, the development of the chemistry of functionally substituted pyridines was stimulated mostly by the fact that among compounds of this class are highly active inhibitors of HIV-1 specific reverse transcriptase (potent agents

Uspekhi Khimii 72 (1) 75–92 (2003); translated by T N Safonova

[†]Dedicated to Professor Salo Gronowitz (Department of Organic Chemistry 1, Lund University, Sweden), in whose laboratory I worked in 1979–1980, on his 75th birthday.

for AIDS treatment),^{154–166} agents for protection of skin during UV radiation (diethone), an antihypertensive and antianginal drug [foridone (riodipine)], a neurotropic and antidiabetic drug (cerebrocrast), a neuroprotective agent (glutapryrone), an agent promoting growth of agricultural animals (diludin) and amphiphilic compounds possessing properties of cell-transfection agents necessary for gene therapy.¹⁶⁷

Besides, compounds of this class can be used as stabilisers for polymers and lacquers,¹⁶⁸ pigments and diazo components in the synthesis of dyes,^{169–176} acid–base indicators in titrimetric analysis,¹⁷⁷ liquid crystals¹⁷⁸ and other compounds of practical importance.

Considerable practical potential of pyridinechalcogenones and their derivatives have given impetus to the development of procedures for their synthesis, which would enable one to overcome inactivity of the pyridine core in functionalisation with the use of electrophilic substitution. It appeared that this purpose could be accomplished by performing the synthesis under conditions of one-pot multicomponent cascade heterocyclisation.

The success of this methodology depends radically on the starting substrates and reagents, which should be readily available and possess polyfunctional properties. The simplest and most convenient procedures for the synthesis of functionalised pyridinechalcogenones are based on the use of cyanoacetamides and their thio and seleno analogues, malononitrile, cyanoacetic ester and other CH-acids as reagents. The presence of several reactive centres in these compounds is responsible for the diversity of their highly regioselective (often stereoselective) chemical transformations, which proceed under mild conditions and with the use of rather simple apparatus. The tremendous synthetic potential of these reagents was considered in the monograph³⁴ and reviews.^{28, 39, 40}

Aliphatic, aromatic and heteroaromatic mono- and dicarbonyl compounds, their enamines, cycloalkanones, *etc.* are used as substrates in multicomponent heterocyclisation.

The direction of the reactions can be easily changed by varying the reaction conditions or the nature of the substituents in the substrates and reagents.

The successful use of the methodology of multicomponent cascade heterocyclisation is exemplified primarily by the development of regio- and stereoselective procedures for the preparation of previously unknown partially hydrogenated pyridinechalcogenones, polyfunctional 1,4- and 3,4-dihydropyridines, 1,2,3,4-tetrahydropyridines, 6-oxo-1,2,3,4-tetrahydropyridine-2-thiolates of non-betaine origin, 4,5-*trans*-6-hydroxy-1,4,5,6-tetrahydropyridine-2-thiolates, tetrahydropyridones, spiro-fused partially hydrogenated pyridines and quinolines and other compounds of the pyridine series, which potentially possess biological activities and are promising substrates for fine organic synthesis. The main procedures for the preparation of partially hydrogenated pyridinechalcogenones involve the same approaches that were successfully used in the synthesis of their aromatic analogues, *viz.*, condensation of α,β -unsaturated carbonyl, 1,3-dicarbonyl compounds and their enamines, α,β -unsaturated nitriles and other substrates with CH-acids (cyanoacetamide, its thio and seleno analogues, malononitrile, derivatives of cyanoacetic acid, *etc.*).^{28, 42–46, 179–194} It was postulated that Michael adducts and partially hydrogenated pyridinechalcogenones are formed as intermediates of cascade heterocyclisation. In many cases, these intermediates were isolated as stable compounds and their structures and reactivities were studied in sufficient detail.

It should be emphasised that the tremendous synthetic potential of this methodology is based on the possibility of varying the nature of the starting substrate with retention of the structure of the reagent, by changing the nature of the reagent with retention of the type of substrate used, by varying simultaneously the nature of both components of the reaction or by changing their ratio and number.

The present review surveys for the first time data on the application of multicomponent cascade heterocyclisation to the

synthesis of pyridine derivatives, which have been published in the last 15 years. The synthesis methods are classified according to the nature of the reagents and substrates used. Emphasis is given to the development of optimum methods for the preparation of partially hydrogenated pyridinechalcogenones and their derivatives, which show the most promise from the practical viewpoint.

II. Cascade heterocyclisation involving α,β -unsaturated carbonyl compounds

The reactions of α,β -unsaturated carbonyl compounds **1** with CH-acids of type **2** in the presence of organic bases proceed through the cascade heterocyclisation mechanism. The first step affords Michael adducts, whose subsequent cyclocondensation gives rise to 3,4-dihydro-1*H*-pyridine-2-chalcogenones **3**.

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{Alk, Ar, Het}; \text{X} = \text{O (a), S (b), Se (c)}$
 B is an organic base.

The formation of 3,4-dihydro-1*H*-pyridine-2-chalcogenones **3b** as intermediates in the reactions of arylideneacetone or arylideneacetophenone with cyanothioacetamide (**2b**) was described for the first time in 1980.¹⁹⁵ Later on, it was demonstrated that treatment of compounds **1** with amide **2b** in ethanol in the presence of an equimolar amount of an organic base at 20 °C afforded hydrogenated 3-cyano-1*H*-pyridine-2-thiones **3b**, which were isolated and characterised as stable salts **4** and **5**.^{196–202} Substituted 3,4-dihydropyridinethiones **3b** can be formed by treating salts **5** with hydrochloric acid. These compounds are rather stable, although they are oxidised with atmospheric oxygen on storage in solution to form 3-cyano-1*H*-pyridine-2-thiones **6**.

$\text{R}^1 = \text{Ph, 4-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, 4\text{-FC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4, 3\text{-NO}_2\text{C}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4, 3\text{-Py, 4-Py}$; $\text{R}^2 = \text{H, Me, Ph, COMe, CO}_2\text{Me, CO}_2\text{Et}$; $\text{R}^3 = \text{Me, Ph}$.

Salts **4** and **5** were also prepared by the reactions of amide **2b** with ketones **7**²⁰³ and **8**,²⁰¹ respectively.

The reactions of chalcones **9** with cyanoselenoacetamide (**2c**) in the presence of an excess of *N*-methylmorpholine afforded Michael adducts **10**. Under the reaction conditions, the latter underwent cyclisation to give 1,4-dihydropyridine-2-selenolates (**11**) in 60%–90% yields.^{45, 46, 204, 205} The latter compounds were also prepared by the reactions of chalcones **9** with malononitriles followed by the reactions of the resulting δ -keto dinitriles **12** with hydrogen selenide.

Ar¹ = Ph, 3-FC₆H₄, 4-FC₆H₄, 2-thienyl;
Ar² = Ph, 4-ClC₆H₄, 2-Py; B is *N*-methylmorpholine.

Condensation of aryl(hetaryl) chalcones with amides **2a,b** in the presence of alkali metal alkoxides or amines as catalysts was used also for the preparation of a series of 3,4-dihydro derivatives of 3-cyano-1*H*-pyridin-2-ones and -2-thiones.^{206, 207}

The reactions of ketones **9** with thiocarbamoylacetamide (**13**) in the presence of piperidine or sodium methoxide produced substituted piperidones **14**, which were transformed into pyridones **15** in an acidic medium.^{208, 209}

Ar¹ = Ph, 4-ClC₆H₄, 4-NO₂C₆H₄; Ar² = Ph; B = MeONa, piperidine.

The use of sodium methoxide as a catalyst in the reactions of substituted methyl acrylates **16** with malononitrile gave rise to 3,4-dihydro-1*H*-pyridin-2-ones **17** in 49%–85% yields.²¹⁰

R = Alk, Ar.

The reactions of 3-phenyl- and 3-(2-furyl)acrylonitriles (**18**) with cyanothio(seleno)acetamides (**2b,c**) in the presence of a twofold excess of *N*-methylmorpholine at room temperature afforded substituted 1,4-dihydropyridine-2-thiolates (selenolates) **19**.^{45, 46, 211} The reactions of amides **2b,c** with ethyl 3-phenylacrylate and ethyl 3-(2-furyl)acrylates proceeded analogously.

R = Ph, 2-furyl; X = S, Se; B is *N*-methylmorpholine.

The reactions of anilides of 2-cyanoacetic acid and other 3-aryl-2-cyanoacrylic acids **20** with CH-acids were successfully used for the preparation of various 3,4-dihydro-1*H*-pyridin-2-ones.²¹²

Ar = 4-MeOC₆H₄.

Condensation of α,β -unsaturated carbonyl compound **21** with amide **2a** in the presence of sodium methoxide in methanol proceeded through the intermediate formation of Michael adduct

22 with elimination of methanethiol to give 5-cyano-6-methylthio-4-phenyl-3,4-dihydro-1*H*-pyridin-2-one (**23**) in 70% yield.²¹³

With the aim of preparing substituted 3-cyano-3,4-dihydro-1*H*-pyridin-2-ones **24**, a mixture of pentadienone **25** and cyanoacetamide (**2a**) was heated at 170 °C without a solvent in a sealed tube. Pyridones **24** were obtained in 32%–37% yields.²¹⁴

Ar = Ph, 4-MeOC₆H₄.

Multicomponent cascade heterocyclisation involving α,β -unsaturated ketones and amides **2b,c** was used with advantage in the synthesis of functionalised naphthyridines, which possess a broad spectrum of biological activities.^{215,216} In particular, these compounds were used for the design of drugs exhibiting cardio-tonic,⁶³ antitubercular,²¹⁷ antitumour,^{218,219} anti-HIV^{220–222} and other activities. However, available procedures for the synthesis of naphthyridines are rather complicated and involve many steps, whereas sulfur- and selenium-containing analogues remain virtually unknown. Studies performed by our research group showed for the first time that condensation of unsaturated ketones **26** with amides **2b,c** and alkyl halides **27** in the presence of *N*-methylmorpholine proceeded as cascade heterocyclisation to

R¹ = Ar, Het; R² = COMe, CO₂Et; R³ = Alk, CH₂CH=CH₂;
X = S, Se; Hal = I, Br, Cl; B is *N*-methylmorpholine.

yield previously unknown polyfunctionalised 1,6-naphthyridines **28**.^{53,223–228} In the first step, amide **2** undergoes Thorpe dimerisation to form imino nitrile **29**, which is involved in the Michael addition with ketone **26** to form adduct **30**. Under the reaction conditions, the latter undergoes cyclocondensation to produce salt **31**, which is regioselectively alkylated with alkyl halides **27** giving rise to 1,4-dihydro-1,6-naphthyridines **28**.

Multicomponent cascade heterocyclisation of benzaldehyde with malononitrile and its dimer in the presence of a twofold excess of piperidine or morpholine afforded previously unknown 2,5-diamino-3,8-dicyano-4-phenyl-7-piperidino(morpholino)-1,6-naphthyridines (**32**) in high yields. The reaction not only gave rise to the complex naphthyridine system but also was accompanied by the insertion of a fragment of the saturated nitrogen heterocycle, which was used as the catalyst, into the naphthyridine system.^{53,224}

X = CH₂, O.

The reactions of 2-arylidenequinclidin-3-ones **33** with cyanothioacetamide (**2b**) in the presence of piperidine also proceeded through a mechanism of cascade heterocyclisation to form piperidinium 4-aryl-3-cyano-5,8-ethano-1,4,5,6,7,8-hexahydro-1,5-naphthyridine-2-thiolates **34**, whose treatment with hydrochloric acid gave rise to 4-aryl-3-cyano-5,8-ethano-3,4,5,6,7,8-hexahydro-1*H*-1,5-naphthyridine-2-thiones **35**, which were in tautomeric equilibrium with betaines **36**.²²⁹ Heating of salts **34** or thiones **35** in ethanol in the presence of hydrochloric acid led to their dehydrogenation to form naphthyridinethiones **37**.

Ar = Ph, 4-FC₆H₄; B is piperidine.

Another example of the highly regioselective synthesis of the 1,5-naphthyridine system is condensation of the sodium salt of 2-formylquinclidone (**38**) with cyanothioacetamide (**2b**) giving rise to 3-cyano-1*H*-1,5-naphthyridine-2-thione (**39**).²³⁰

4-Cyano-6,7,8a-trimethyl-3-thioxo-1,2,3,5,6,7,8,8a-octahydro-2,7-naphthyridin-1-one (**40**) was synthesised by cascade heterocyclisation of the sodium salt of 3-formyl-1,2,5-trimethyl-4-piperidone (**41**) with amide **2b**.^{45, 231}

Condensation of β -enamino carbonyl compounds **42** with substituted cyanoacetamides **43a,b** proceeds through a mechanism of cascade heterocyclisation with elimination of methanethiol followed by the formation of 4-dialkylaminopyridones **44a,b** containing the β -enaminoamide fragment. Pyridone **44b** reacts with the second molecule of *N*-methylcyanoacetamide (**43b**) to give naphthyridinedione **45**.²³²

$R^1 = \text{Me, Ph, 4-ClC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$; $R^2 = \text{Et, Ph, CH}_2\text{CH(OEt)}_2$, Bn; $R^3 = \text{H}$; $R^3 - R^4 = (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$; $R^4 = \text{H (a), Me (b)}$.

Benzylidene- and 2-furfurylideneacetoacetic esters (**26**) smoothly reacted with selenoamide **2c** under mild conditions (anhydrous ethanol, 20 °C), the reagent ratio playing an essential role.^{45, 233–235} When the reagents were taken in a ratio of 1 : 1, the reaction afforded adducts **46**, which underwent cyclisation to 1,4-dihydropyridine-2-selenolates **47**. Treatment of the latter with hydrochloric acid yielded 1,4-dihydropyridine-2-selenols **48**.

$R = \text{Ph, 2-furyl}$; B is a base.

The reaction of 1-phenylacetylcyclohexene with thioamide **2b** in the presence of sodium ethoxide in alcohol afforded pyridine-thione **49** containing a fragment of the alkaloid papaverine.²³⁶

III. Cascade heterocyclisation involving 1,3-dicarbonyl compounds

Like α,β -unsaturated analogues, 1,3-dicarbonyl compounds **50** and their enamines react with cyanothioacetamide derivatives, *viz.*, arylidenecyanothioacetamides **51**, in the presence of base catalysts to form 3-cyano-1*H*-pyridine-2-thiones or their salts.^{33, 237–254} In some cases, intermediate tetrahydropyridine-2-thiolates **52** were isolated. Subsequent elimination of water from these compounds affords 3-cyano-1,4-dihydropyridine-2-thiolates **53**. Acidification of salts **52** and **53** gave rise to 3-cyano-3,4-dihydro-1*H*-pyridine-2-thiones **54**. In solutions, the latter compounds underwent dehydrogenation to form 3-cyano-1*H*-pyridine-2-thiones **55**.

$R^1 = \text{Ph, OEt}$; $R^2 = \text{Me, CF}_3$; Ar = Ph, 3-FC₆H₄, 4-FC₆H₄, 4-ClC₆H₄, 4-BrC₆H₄, 4-NO₂C₆H₄; B is a base.

β -Enamine derivatives of 1,3-dicarbonyl compounds reacted with amides **51** also in the absence of base catalysts to produce the corresponding 1,4-dihydropyridine-2-thiolates in high yields.

The reaction of acetylacetone (**56**) with 2-furfurylideneacyano-selenoacetamide (**57**) or the reaction of an unsaturated carbonyl compound, *viz.*, 2-furfurylideneacetylacetone (**58**), with cyano-selenoacetamide (**2c**) afforded 5-acetyl-3-cyano-4-(2-furyl)-6-methyl-1,4-dihydropyridine-2-selenol (**59**) in ~80% yield.^{45, 255} These reactions proceeded through a mechanism of cascade heterocyclisation and involved the intermediate formation of

Michael adduct **60** and stable selenolate **61**, whose acidification gave selenol **59**. The reactions of amide **57** with acetoacetic ester or its enamine proceeded analogously to form 5-ethoxycarbonyl-substituted selenol of type **59**.

R is 2-furyl.

It should be emphasised that due to their diversity and high reactivity, 1,3-dicarbonyl compounds are the most convenient building blocks for the regio- and stereoselective synthesis of hydrogenated sulfur- and selenium-containing pyridines and their fused analogues that are difficult to prepare. For this purpose, acetylacetone, benzoylacetone, dibenzoylmethane, 2-thenoyltrifluoroacetone, β -keto amides (acetylacetamide, acetylacetanilides), ethyl butyrylacetate, acetoacetic and malonic esters and cyclic mono- and diketones were successfully used.^{45, 46, 256–303}

Thus, the use of 2-acylcycloalkanones **62** as substrates and cyanoacetamides **2a** as reagents made it possible to develop convenient procedures for the regioselective synthesis of fused 3-cyano-1*H*-pyridine-2-chalcogenones **63**.^{44, 188, 304–316}

R = Alk, Ar; $n = 1, 2$; X = O, S, Se.

The reactions of amides **2a,b** with 2,4-diacetyl-3-aryl-5-hydroxy-5-methylcyclohexanones **64** afforded 7-acetyl-8-aryl-4-cyano-6-hydroxy-1,6-dimethyl-5,6,7,8-tetrahydro-2*H*-isoquinolin-3-ones **65**, corresponding thiones **66** and their sodium salts **67** and **68** in high yields.³¹⁴

Of numerous reactions of amide **2a** with 2-acylcycloalkanones,^{269, 272, 315–318} noteworthy is the condensation with tetrahydropyrans or -thiopyrans **69** in ethanol in the presence of triethylamine giving rise to previously unknown 6-oxopyrano(thiopyrano)[3,4-*c*]pyridines **70**.^{117, 315, 316}

R = Alk, Ar; X = O, S.

Derivatives of coumarin or its fused analogues exhibit antibacterial, cardiovascular and hypothermal activities. Procedures for the synthesis of substituted coumarins are being developed with the aim of searching for new drugs. Thus, the reactions of 3-acetylcoumarin (**71**) with amides **2a,b** in the presence of bases giving rise to oxo and thioxo derivatives of benzopyrano[3,4-*c*]pyridine **72** have been studied.³¹⁸

X = O, S.

Cascade heterocyclisation of amides **2b,c** with sodium salts of 2-hydroxymethylidenecycloalkanones **73** was examined. It was demonstrated that these reactions proceeded regioselectively to produce fused 3-cyano-1*H*-pyridine-2-thiones(selenones) **74**.^{44, 308, 319–326}

$n = 1, 2$; $X = S, Se$.

The methodology of cascade heterocyclisation is unique as can be exemplified by the synthesis of previously unknown quinoline- and pyridine-thiones containing a spiro-fused fragment. For instance, three-component condensation of dimedone (**75**), cyanothioacetamide (**2b**) and cyclohexanone in the presence of piperidine in ethanol or the reaction of diketone **75** with cyclohexylidenecyanothioacetamide (**76**) in ethanol in the presence of morpholine afforded previously unknown 3-cyano-7,7-dimethyl-5-oxospiro[cyclohexane-1,4'-octahydroquinoline]-2-thione (**77**).^{45, 293} The use of benzene as the solvent changed the direction of the latter reaction with the resulting formation of 2-iminopyran **78**.

Spiro-fused partially hydrogenated pyridine-2-thiolates (sele-nolates) were also prepared with the use of other reagents. For example, the reaction of cyclohexylidenemalononitrile (**79**) with cyanoselenoacetamide (**2c**) or the reaction of cyclohexylidenecyanothioacetamide (**76**) with amides **2b,c** or malononitrile in ethanol in the presence of *N*-methylmorpholine gave rise to salts **80**, which were transformed into 6-amino-3,5-dicyanospiro[cyclohexane-1,4'-dihydropyridine]-2-thiol(selenol) (**81**) upon treatment with hydrochloric acid.^{45, 282, 327, 328}

$X = S, Se$; B is *N*-methylmorpholine.

The reaction of dinitrile **79** with anilide **82** afforded partially hydrogenated polyfunctionalised spiro-fused pyridinethione **83**.³²⁸

In turn, spiro[cyclohexane-1,4'-pyridine]-2-thione **84** was prepared in 87% yield by the reaction of thioamide **76** with acetoacetanilide (**85**) in ethanol in the presence of *N*-methylmorpholine.^{46, 263}

B is *N*-methylmorpholine.

An analogous reaction of cyclopentylidenecyanothioacetamide (**87**) with cyanothioacetamide (**2b**) produced 6-amino-3,5-dicyanospiro[cyclopentane-1,4'-dihydropyridine]-2-thiolate (**88**).²⁸³ The reaction of amide **87** with cyanoacetic ester or the reaction of amide **2b** with cyclopentylidenecyanoacetic ester (**89**) afforded 3,5-dicyano-6-oxospiro[cyclopentane-1,4'-tetrahydropyridine]-2-thiolate (**90**).³²⁹

Benzylidenemalononitrile (**91**) reacted with anilides of 2-oxo-cycloalkanethiocarboxylic (**92**) and 3-oxo-2,3-dihydroindene-2-thiocarboxylic acids (**93**) to form spiro-fused pyridinethiones **94** and **95**, respectively.^{330, 331}

Ar = Ph, 4-MeC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄, 4-BrC₆H₄; *n* = 0–2.

On refluxing in ethanol in the presence of piperidine, cyanoacetamide (**2a**) added to chromenylidenemalononitrile (**96**) to give adduct **97**, which underwent intramolecular cyclisation *in situ* yielding spiro-fused pyridone **98**.³³¹

Three-component heterocyclisation of diketone **99**, amide **2b** and malononitrile in ethanol in the presence of piperidine giving partially hydrogenated pyridine-thione **100** provides another example of the synthesis of spiro-fused pyridinechalcogenones.³³²

R = Alk.

It should be noted that in the last decade, three-component cascade heterocyclisation of amides of cyanoacetic acid or its thio and seleno derivatives with aliphatic, aromatic or heterocyclic aldehydes and 1,3-dicarbonyl compounds in the presence of an excess of an organic base was successfully used in the synthesis of 1*H*-pyridine-2-chalcogenones, their hydrogenated analogues and salts (see Refs 44–46, 199, 233, 241, 243, 244, 256, 257, 259, 262–268, 270, 271, 274, 276, 279, 284–286, 289–291, 293, 294, 302 and 333–339). The synthesis of salts of 4-(aryl,hetaryl)-3-cyano-6-methyl-5-phenylcarbamoyl-1,4-dihydropyridine-2-thiolates **101** from aromatic or heterocyclic aldehydes, amide **2b** and acetoacetanilide (**85**) in the presence of an excess of *N*-methylmorpholine^{257, 259, 337} provides an example.

R = Ph, 2-ClC₆H₄, 4-MeC₆H₄, 3-Py, 2-thienyl; B is *N*-methylmorpholine.

Cyclic diketones [cyclohexane-1,3-dione, dimedone, isopropylidenemalonate (Meldrum's acid)] were also used as 1,3-dicarbonyl substrates in three-component heterocyclisation.^{262, 285, 286, 295} For example, 4-(aryl,hetaryl)-3-cyano-6-oxo-1,4,5,6-tetrahydropyridine-2-thiolates **102** were prepared by refluxing an equimolar mixture of the corresponding aldehyde, amide **2b** and Meldrum's acid in alcohol in the presence of *N*-methylmorpholine for 3 h. Acidification of thiolates **102** with 10% hydrochloric acid to pH 5 afforded 4-(aryl,hetaryl)-5-cyano-6-thio-3,4-dihydro-1*H*-pyridin-2-ones **103**.²⁸⁵

R = 4-MeC₆H₄, 1-naphthyl, 2-furyl, 2-thienyl; B is *N*-methylmorpholine.

IV. Cascade heterocyclisation involving pyridinium ylides

Pyridinium ylides, which are generated *in situ* from quaternised pyridines, are widely used in fine organic synthesis.^{340–343} including the preparation of 4,6-disubstituted 3-cyano-1*H*-pyridine-2-thiones (see Refs 43, 44, 126, 327 and 344–354). It was noted that the nature of the final products depends on the reaction conditions. Thus, heating of arylidenecyanothioacetamides **51** with pyridinium salts **104** in the presence of ammonium acetate in acetic acid gave rise to 4,6-disubstituted 3-cyano-1*H*-pyridine-2-thiones **105**.³⁴⁶ By contrast, the reactions of pyridinium ylides **106** generated from salts **104** with amides **51** in ethanol in the presence of triethylamine at room temperature afforded *trans,trans*-1,4,5,6-tetrahydropyridine-2-thiolates **107**, which were isolated and characterised as stable crystalline salts.^{345–348, 351, 355–367} The high selectivity of these reactions results from the stereoselectivity of the addition of ylides **106** to amides **51**. Subsequent cyclisation of adducts **108** proceeded with retention of the *trans* arrangement of the hydrogen atoms.^{44, 346, 362} Heating of salts **107** in acetic acid in the presence of ammonium acetate afforded thiones **105**.

R = Me, OMe, NH₂, Ph, 3-Py; Ar = Ph, 3-FC₆H₄, 4-FC₆H₄, 4-ClC₆H₄, 4-NO₂C₆H₄, 3-Py; X = I, Br; B is a base.

Thiolates **107** were also synthesised without the preliminary preparation of thioamides **51** by three-component condensation of pyridinium ylides **106**, cyanothioacetamide (**2b**) and aromatic aldehydes ^{346, 347, 351} as well as by the reaction of pyridinium salt **109** with amide **2b**.³⁶⁰ The use of malononitrile instead of amide **2b** in the reaction with the *E* isomer of compound **109** resulted in the formation of *trans*-adducts **110**, whose treatment with hydrogen sulfide produced *trans*-substituted tetrahydropyridines **107**.

R = Me, OMe, NH₂, Ph; Ar = Ph, 4-ClC₆H₄, 4-BrC₆H₄, 4-FC₆H₄, 4-MeOC₆H₄, 3-Py, 4-Py; X = Cl, Br.

Isoquinolinium ylides also found application in the synthesis of thiolates.³⁴⁷

Stereoselective three-component condensation of pyridinium ylides **106**, aromatic aldehydes and 2-amino-1,1,3-tricyanopropene afforded *trans*-6-R-4-aryl-3-cyano-6-hydroxy-5-pyridinio-1,4,5,6-tetrahydropyridine-2-dicyanomethylides **111**, which are difficult to prepare.^{345, 346}

Ar = Ph, 4-FC₆H₄, 4-ClC₆H₄, 4-BrC₆H₄, 4-MeOC₆H₄; R = Me, OMe, NH₂, Ph, 3-Py.

The reactions of *meta*-substituted pyridinium ylides **112** with arylidenecyanothioacetamides **51** provided the basis for regio- and stereoselective procedures for the synthesis of *trans*-4-aryl-3-cyano-6-oxo-5-pyridinio-1,4,5,6-tetrahydropyridine-2-thiolates (**113**).^{44, 223, 345, 353–355} Tetrahydropyridines **113** were also syn-

R¹ = Me, Br, NH₂; R² = Me, Ph, NH₂, OMe; Ar = Ph, 4-FC₆H₄, 4-ClC₆H₄, 4-BrC₆H₄, 4-HOC₆H₄, 4-MeOC₆H₄, 2-NO₂C₆H₄, 3-Py, 4-Py.

thesised by one-pot heterocyclisation of pyridinium ylides **112** with aromatic aldehydes and cyanothioacetamide (**2b**) without the preliminary preparation of unsaturated amides **51**.^{44, 345}

Various pyridinium ylides are used for the preparation of 4-aryl-3-cyano-6-oxo-5-pyridinio-1,4,5,6-tetrahydropyridine-2-olates.^{346, 353–356, 368}

Cascade heterocyclisation of pyridinium ylide **114** with amides **51** gave rise to *trans*-substituted 6-thioxo-1,4,5,6-tetrahydropyridine-2-thiolates **115**.^{223, 346, 353, 355}

Ar = 4-HOC₆H₄, 4-MeOC₆H₄, 4-FC₆H₄, 4-ClC₆H₄, 4-BrC₆H₄, 3-Py.

It was found that the direction of cascade heterocyclisation involving pyridinium ylides depends on the reaction temperature. For example, the reactions of 3-bromopyridinium ylide **116** generated from salt **117** with unsaturated nitriles **51** and **118** at room temperature in ethanol in the presence of triethylamine proceeded stereo- and atroposelectively to yield *trans*-substituted 1,4,5,6-tetrahydropyridines **119**. Heating of the latter compounds in ethanol led to alcoholysis and opening of the tetrahydropyridine ring at the amide bond to give the corresponding intermediates **120**. The subsequent intramolecular nucleophilic substitution proceeded with elimination of 3-bromopyridine and retention of the *trans*-arrangement of the hydrogen atoms and produced the corresponding *trans*-dihydrofurans and -thiophenes **121**.^{43, 44, 344, 349, 350, 354, 369} Five-membered heterocycles **121** were also generated in high yields without isolation of intermediates **119** and **120** by the reactions of ylide **116** with nitrile **51** or **118**, respectively, in ethanol at ~80 °C.

Ar = 3-Py, 4-FC₆H₄, 2-MeOC₆H₄; X = S (**51**), O (**118**).

Three-component cascade heterocyclisation of ylide **122**, aromatic aldehydes and amide **2b** in ethanol in the presence of triethylamine at room temperature gave previously unknown adamantylcarbonyldihydrothiophenes **123** in 62%–95% yields.^{43, 343, 349}

R¹ is 1-adamantyl; R² = 4-Py, 4-FC₆H₄, 4-ClC₆H₄.

Considerable synthetic potential of pyridinium ylides enables one to use these compounds for the development of fundamentally new approaches to functionalised cyclopropanes. For example, heating of betaines **124**, which were generated by the reactions of pyridinium ylides **106** and **122** with arylidenemalononitriles **125**, in DMSO at 30–40 °C led to intramolecular 1,3-elimination of pyridine to form *trans*-cyclopropanes **126** in 80%–96% yields.^{43, 344, 357, 370, 371} Compounds **126** can also be prepared in 78%–94% yields by three-component condensation of salts **104** or **127** with aromatic aldehydes and malononitrile in DMSO in the presence of triethylamine at 25–30 °C.

R¹ = NH₂, Me (**104**, **106**), 1-adamantyl (**122**, **127**);

R² = 4-ClC₆H₄, 4-BrC₆H₄, 4-IC₆H₄, 3-Py, 4-Py, 2-thienyl.

The synthesis of nicotine, viz., 2,4-bis(3-pyridyl)pyridine, which is a minor alkaloid from tobacco *Nicotiana tabacum*,^{43, 44, 344, 351} provides yet another example of the successful use of the methodology of cascade heterocyclisation involving pyridinium ylides. Thus, the reaction of ylide **106** (R = 3-Py) with amide **51** (Ar = 3-Py) in ethanol at room temperature gave rise to 4,5-*trans*-3-cyano-6-hydroxy-4,6-bis(3-pyridyl)-5-pyridinio-1,4,5,6-tetrahydropyridine-2-thiolate (**128**) in 98% yield. This compound was also synthesised in 92% yield by three-component condensation of ylide **106** (R = 3-Py), 3-pyridinecarbaldehyde and amide **2b** under analogous conditions. Heating of thiolate **128** in acetic acid in the presence of ammonium acetate afforded thione **129** in 83% yield. The latter was transformed into nicotine **130** in 82% yield by successive alkylation, hydrogenolysis in

the presence of Raney nickel and decyanation in an acidic medium.

V. Cascade heterocyclisation in the synthesis of fused heterocycles

Functionalised fused heterocycles are of equal or even higher practical interest than the corresponding mononuclear heterocyclic systems. However, most of the available procedures for their synthesis are rather laborious, involve many steps and often require drastic conditions, which eventually leads to a substantial decrease in the yields and an increase in the cost of the final products. The use of the strategy of cascade heterocyclisation allows one not only to eliminate these drawbacks but also to construct polyfunctional annelated heterocycles, which are impracticable to prepare by conventional methods. The methodology of cascade heterocyclisation involving simple and available substrates and reagents provided the basis for the development of convenient procedures for the synthesis of different classes of fused heterocycles, such as thieno[3,2-*b*]pyridines, thieno[3,2-*d*]pyrimidines, thiazolo[4,5-*b*]pyridines, thiazolo[4,5-*d*]pyrimidines, pyrido[3',2':4,5]thieno[3,2-*b*]pyridines, pyrido[3',2':4,5]thieno[3,2-*d*]pyrimidines, pyrido[3',2':4,5]thieno(selenopheno)[3,2-*d*]pyrimidines, quinuclidino[2'',3'':5',6']pyrido[3',2':4,5]thieno[3,2-*d*]pyrimidines, pyrimido[4',5':4,5]thieno[2,3-*c*]-2,7-naphthyridines, pyrido[2'',3'':4',5']thieno[3',2':4,5]thieno[3,2-*b*]pyridines, etc.^{50, 52, 371–390}

The successful application of the strategy of cascade heterocyclisation can be exemplified by regioselective procedures for the synthesis of thieno-, selenopheno- and thiazolodiaminopyrimidines on the basis of vicinal mercapto(hydroseleno)nitriles **131** and *N*-cyanochloroacetamide (**132**). The reactions start with regioselective alkylation at the chalcogen atom to form intermediates **133**, which undergo Thorpe–Ziegler cyclisation giving rise to compounds **134**. The latter are transformed into hetarylpyrimidines **135** by heating in ethanol in the presence of sodium ethoxide or by treatment with hydrochloric acid in methanol.^{50, 373, 375}

R = NHPh, NHCH₂CH=CH₂; X = N, CCN; Y = S, Se;

B is a base.

An analogous reaction of amidine **132** with 1*H*-pyridine-2-chalcogenones in DMF in the presence of an excess of KOH involved two successive steps, *viz.*, nucleophilic substitution and Thorpe–Ziegler condensation, and produced thieno(selenopheno)[2,3-*b*]pyridines **136**.³⁷³ Refluxing of the latter compounds with sodium ethoxide in ethanol afforded 2,4-diaminopyrido[3',2':4,5]thieno(selenopheno)[3,2-*d*]pyrimidines **137**. The latter compounds can also be synthesised without isolation of intermediates **136**.^{372, 373}

$R^1 = \text{H, Me, CF}_3, 4\text{-ClC}_6\text{H}_4$; $R^2 = \text{H}$; $R^3 = \text{Me, Ph, 4-MeC}_6\text{H}_4$;

$R^2-R^3 = \text{pyridine ring}, (\text{CH}_2)_4$; $X = \text{S, Se}$.

The reaction with the use of sodium 2,2-dicyanoethylene-1,1-dithiolate (**138**) as the nitrile component proceeded through the successive formation of compounds **139** and **140** to give tetraannelated heterocycle **141** as the final product.^{50, 373, 375}

Of other numerous examples of the employment of cascade heterocyclisation in the synthesis of fused heterocyclic systems, noteworthy is the preparation of pyridothienopyridines, pyridothienopyrimidines and their hydrogenated analogues.^{52, 380–383, 387, 391, 392} For example, the reactions of piperidinium 3-cyano-1,4-dihydropyridine-2-thiolates **142** with 2-bromo-1-arylethylidenemalononitriles **143** produced 2,5-dihydropyrido[3',2':4,5]thieno[3,2-*b*]pyridines **144** in high yields.^{52, 381} This procedure can also be used for the synthesis of functionalised pyrido[3',2':4,5]thieno[3,2-*d*]pyrimidines.

$R^1 = 4\text{-MeOC}_6\text{H}_4, 2\text{-NO}_2\text{C}_6\text{H}_4, 2\text{-thienyl}$; $R^2 = \text{Me, OEt}$;
 $\text{Ar} = \text{Ph, 4-BrC}_6\text{H}_4$; B is piperidine.

Tetrahydropyridothienopyridines **145** were synthesised by three-component cascade heterocyclisation of tetrahydropyridine-2-thiolates **102**, malononitrile and acetone in refluxing ethanol. These compounds were also prepared by the reactions of precursors of thiolates **102**, *viz.*, the corresponding Michael adducts **146**, with malononitrile and acetone, by condensation of 2-chlorobenzaldehyde, Meldrum's acid, cyanothioacetamide (**2b**), malononitrile and acetone in the presence of *N*-methylmorpholine or by refluxing a mixture of thiolate **102**, isopropylidenemalononitrile and acetone in ethanol.^{391, 392}

$R = \text{Ph, 4-MeC}_6\text{H}_4, 2\text{-ClC}_6\text{H}_4, 2\text{-MeOC}_6\text{H}_4, 2,5\text{-(MeO)}_2\text{C}_6\text{H}_3, 3,4\text{-(MeO)}_2\text{C}_6\text{H}_3, 3,4,5\text{-(MeO)}_3\text{C}_6\text{H}_2, 4\text{-EtOC}_6\text{H}_4, 3,4\text{-(OCH}_2\text{)}_2\text{C}_6\text{H}_3, 1\text{-naphthyl, 2-thienyl}$; B is *N*-methylmorpholine.

Recent advances in cascade heterocyclisation have been discussed in the reviews^{389, 390, 393–395} and studies.^{396–405}

* * *

Due to elaboration of fundamentals of one-pot cascade heterocyclisation of carbonyl compounds and CH-acids under the conditions of base catalysis, one can easily perform the regio- and stereoselective synthesis of polyfunctional heterocycles, in particular, of substituted pyridinechalcogenones and their hydrogenated and fused analogues. An important advantage of this

approach is the simplicity and accessibility of substrates and reagents, viz., of aromatic and heteroaromatic aldehydes, cycloalkanones, acyclic and cyclic mono- and dicarbonyl compounds, α,β -unsaturated carbonyl compounds, cyanoacetamides and their thio and seleno analogues.

Undoubtedly, this methodology shows promise for the development of procedures for the preparation of new classes of heterocyclic compounds.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 02-03-32063).

Abstract. The published data on the methods for the synthesis of furazans fused to six-membered heterocycles with two heteroatoms in positions 1 and 4, their reactivities and practical applications are considered and systematised. The bibliography includes 89 references.

I. Introduction

The first paper devoted to the synthesis of compounds of the furazanopyrazine series was published in 1969.¹ However, intense development of this branch of chemistry began only in the mid-1980's when nitro derivatives of furazanopyrazines were recommended for use as explosives. High operating characteristics of this class of compounds attracted the attention of the specialists and gave impetus to comprehensive studies of their miscellaneous derivatives. Systematic studies of high-energy materials based on furazanopyrazine have led to the development of a vast variety of effective components of explosives and propellants. These studies provided profound insight into the chemistry and reactivities of furazanopyrazines and made accessible their polyfunctional derivatives. These achievements stimulated investigations into other properties of furazanopyrazines, *viz.*, biological activity, photosensitivity, *etc.* Obviously, furazanopyrazine analogues where one or both pyrazine nitrogen atoms are replaced by oxygen or sulfur atoms are promising candidates for medicinal drugs. However, the methods for their synthesis are still poorly studied. The lack of efficient procedures for the preparation of such compounds impedes further investigations into their properties.

Four structural types in which the furazan (1,2,5-oxadiazole) ring is fused to a six-membered ring containing two heteroatoms in positions 1 and 4 are presently known, namely furazano[3,4-*b*]pyrazine (**A**), furazano[3,4-*b*][1,4]oxazine (**B**), 1,4-dioxino[2,3-*c*]furazan (**C**) and 1,4-dithiino[2,3-*c*]furazan (**D**).

Uspekhi Khimii 72 (1) 93–107 (2003); translated by R L Birnova

The presence of three contiguous heteroatoms in the furazan structure determines the pronounced electron-withdrawing character of this heterocycle. The bond localisation in the heterodiene fragment of furazan is strongly fixed; therefore, its derivatives are not prone to annular-group tautomerism. These features of the furazan ring determine the reactivities of all of its derivatives.^{2–5}

This review is an attempt to generalise the whole body of available data on the synthesis, properties and applications of furazanopyrazines and their analogues. The review is intended mostly for organic chemists and is aimed at stimulating further studies in this field.

II. Furazano[3,4-*b*]pyrazine derivatives

1. Synthesis

The furazanopyrazine system can be built starting from furazan or pyrazine derivatives. Condensation of α -dicarbonyl compounds with aromatic and heterocyclic *o*-diamines is the most popular procedure for the synthesis of fused pyrazines. For the first time, this reaction was used for the preparation of furazanopyrazines **1** in 1969.¹ 3,4-Diaminofurazan (**2**) was used as a diamine.

Compound 1	R ¹	R ²	Reaction conditions	Yield (%)	Ref.
a	Ph	Ph	AcOH, 110 °C	35	1
	Ph	Ph	BF ₃ ·OEt ₂ , 130 °C, 10 min	84	6
b	Me	Me	AcOH, 50 °C	51	7
c	Ph	H	AcOH, EtOH (1 : 3), Δ, 2 h	92	6
	Ph	H	AcOH, EtOH (1 : 1), Δ, 1 h	68	8
d	Ph	H	AcOH, Δ, 2.5 h	53	9
	4-ClC ₆ H ₄	H	AcOH, EtOH (1 : 1), Δ, 1 h	69	8

Compound 1	R ¹	R ²	Reaction conditions	Yield (%)	Ref.
e	4-BrC ₆ H ₄	H	AcOH, EtOH (1 : 1), Δ, 1 h	73	8
f	4-MeOC ₆ H ₄	H	AcOH, EtOH (1 : 1), Δ, 1 h	65	8
g	4-O ₂ NC ₆ H ₄	H	AcOH, EtOH (1 : 1), Δ, 1 h	78	8
h	Ph	Me	AcOH, EtOH (1 : 3), Δ, 2 h	79	6

The nucleophilicities of amino groups in compound **2** are much lower than those in aromatic *o*-diamines (e.g., *o*-phenylenediamine); therefore, more drastic reaction conditions are required. Later, this method and its modifications were used for the synthesis of the furazano[3,4-*b*]pyrazine derivatives **1a–h**.^{6–9}

Table 1. Reaction conditions and yields of the reaction products of cyclic α-diketones with the diamine **2**.

α-Diketone	Reaction conditions with the diamine 2	Product	Yield (%)	Ref.
	AcOH, ^a EtOH, Δ, 1 h		45	8
	AcOH, ^a EtOH, Δ, 1 h		39	8
	AcOH, Δ		60	1
	AcOH, Δ		80	1
	EtOH, Δ, 10 min		86 83	8 11
	AcOH, ^a EtOH, Δ, 6 h		46	10
	AcOH, ^a EtOH, Δ, 4 h		19	10
	AcOH, ^a EtOH, Δ, 4 h		33	10

^a AcOH : EtOH = 1 : 1.

This reaction is carried out by heating the reactants in acetic acid or in a mixture of acetic acid and ethanol. The preparation of the derivative **1a** by melting of benzil with the diamine **2** in the presence of boron trifluoride etherate has been described.⁶ Under these conditions, the target product was obtained in 84% yield after 10 min. However, this single example of the use of a Lewis acid as a promoter of this reaction does not allow one to judge on the applicability of this approach to other subjects.

Cyclic α-diketones react with the diamine **2** under similar conditions to yield polycyclic derivatives **3–10** (Table 1).^{1, 8, 10, 11}

Glyoxal reacts with the diamine **2** in water in the presence of hydrochloric acid at 60 °C to give the tetracycle **11** in a quantitative yield.^{12–17} The reaction proceeds *via* intermediate dihydroxy derivative **12**.

Preformed glyoxal adducts with NH₄Cl or weakly basic amines can be used in a reaction with diamine **2** in the presence of acids. This approach was used for the synthesis of partially hydrogenated furazanopyrazines **13–16**,^{16, 18, 19} however, the yields of reaction products seldom exceeded 60%. Compound **14b** was obtained in 55% yield by condensation of the dihydroxy derivative **12** with nitroguanidine.¹⁹

Heating of ethyl oxaloacetate with the diamine **2** for 1 h at 140–150 °C affords a mixture of *Z,E*-isomers of ethoxycarbonylmethylidene pyrazinone **17** (yield 54%).²⁰ If the condensation is carried out in boiling acetic acid, the product yield increases to 85%.²¹ Pyrazinone **17** was also synthesised by boiling the amine **2** with diethyl acetylenedicarboxylate (AcOH, EtOH, 45 min; yield 74%).⁸

Cyclic α -keto ethers, *viz.*, 2,3-dihydrofuran-2,3-diones, condense with the diamine **2** in boiling dioxane to yield pyrazinones **18a–d**. The nature of the substituent in the phenyl ring of the starting furandione does not influence the yields of reaction products which are in the range 60%–75%.^{22,23}

R = Me (**a**), Br (**b**), Cl (**c**), OMe (**d**).

In contrast to α -keto acids used in the form of esters for the preparation of hydrogenated furazanopyrazines (furazanopiperazines), oxalic acid reacts with the diamine **2** on boiling in dilute hydrochloric acid. The reaction product (yield 30%) exists as an equilibrium mixture of tautomers **19a–c**.¹

Reaction of phosphoryl-substituted chloroaldehyde **20** with the diamine **2** yields hemiaminal **21**; treatment of the latter with sodium ethoxide results in cyclocondensation to give C-phosphorylated furazanopyrazine derivative **22**.²⁴

Condensation of the amine **2** with chloro-substituted 1,5-diketone **23** gives a mixture of a tricyclic compound **24** (75%) and its dihydro derivative **25** (15%). Compound **25** is readily aromatised under the action of MnO_2 ; the yield of the reaction product **24** is 60%.²⁵

3-Amino-4-nitrosfurazan (**26**) is yet another furazan derivative suitable for the design of furazanopyrazines.²⁶ Carbonyl compounds containing a reactive methylene group, which are more accessible than α -dicarbonyl compounds, are used as the second component.²⁷ The one-pot reaction is carried out first in an alkaline medium (NEt_3 , Na_2CO_3) which is then changed to an acidic one (AcOH). The yields of furazano[3,4-*b*]pyrazines **27–30** are 50%–90%. The attempts to introduce compounds with reactive methylene groups but devoid of the ketone function (*e.g.*, malononitrile, ethyl cyanoacetate, nitroacetoneitrile, *etc.*) into the condensation did not result in the formation of the pyrazine ring.

Furazanopyrazines can also be prepared from pyrazine precursors by fusing the furazan ring. 2,3-Bis(hydroxyimino)piperazines, which are usually prepared by reaction of dichloroglyoxime with aliphatic,^{15,28,29} aromatic^{30–32} or heterocyclic^{33–35} 1,2-diamines, are the key compounds in this procedure.

Cyclisation of the dihydroxyimine fragment involves treatment with dehydrating agents to give the corresponding furazans or with oxidants resulting in furazan *N*-oxides (furoxans). Thus heating of an equimolar mixture of dioximes **31a–d** with NaOH in ethylene glycol yields the corresponding furazanopiperazines **32a–d**.^{15,29}

R = H (**a**, 50%), Me (**b**, 52%), Pr^i (**c**, 60%), Bu^t (**d**, 75%).

Treatment of dioximes **33a–c** with sodium hydroxide results in closure of the second furazan ring and formation of difurazanopiperazines **34a–c**. Under these conditions, unsubstituted difurazanopiperazine **34a** is formed in ~80% yield on heating of dioxime **33a** in aqueous alkali.^{35–37} Long-term treatment of the dioximes **33b,c** containing substituents at nitrogen atoms of the

piperazine ring with sodium hydroxide in ethylene glycol yields the tricyclic products **34b,c**.^{33, 34}

R = H (a), Bn (b), CH₂C₆H₄OMe-4 (c).

Dehydration of quinoxaline dioximes **35a-c** can be carried out by treatment with ethyl chloroformate in boiling benzene. In this case, dehydration is accompanied by aromatisation of the piperazine ring. The yields of furazanoquinoxalines **36a-c** do not exceed 50%.³⁸

R¹ = R² = R³ = H (a); R¹ = R² = H, R³ = Me (b);
R¹ = H, R¹ = R² = Me (c).

Treatment of the dioximes **35a,d,e** with bis(trifluoroacetoxy)-λ³-iodanylbenzene results in the oxidation of both the dioxime fragment and the piperazine ring to give furoxans **37a-c**.³⁹ The dioxime **35f** is oxidised with lead tetraacetate, but the corresponding furoxan **37d** is formed in low yields.³¹ However, the position of the *N*-oxide oxygen atom in compounds **37a-d** has not been established.^{31, 39}

Com- pound 35	R ¹	R ²	R ³	Reaction conditions	Com- pound 37	Yield (%)
a	H	H	H	PhI(OCOCF ₃) ₂ , CH ₂ Cl ₂ , 20 °C	a	94
d	Me	H	H	PhI(OCOCF ₃) ₂ , CH ₂ Cl ₂ , 20 °C	b	66
e	(CH=CH) ₂	H	H	PhI(OCOCF ₃) ₂ , CH ₂ Cl ₂ , 20 °C	c	66
f	H	Cl	H	Pb(OAc) ₄	d	24

Furoxanopiperazines **38b-d** are easily prepared by oxidation of the dioximes **31b-d** with potassium ferricyanide in aqueous alkali.¹⁵ If the starting piperazine has no substituents at nitrogen atoms (as in the case of the dioxime **31a**), no furoxan is formed.

R = Me (**b**, 72%), Prⁱ (**c**, 90%), Bu^t (**d**, 98%).

Thermolysis of the nitroso tetrazolopiperazine derivative **39** in AcOH–MeOH triggers a cascade of reactions which include the tetrazole ring opening, formation of the tautomer **40**, liberation of the nitrogen molecule, cyclisation of the resulting nitrene with the

nitroso group and abstraction of hydrogen atoms from the solvent molecule. Difurazan **34a** is formed in 36% yield.⁴⁰

Until recently, thermolysis of *o*-azidonitro compounds as a method for the synthesis of fused furoxans^{4, 5, 41} has not been used for the preparation of furoxanopyrazines. However, it was found that gentle heating of chloropyrazine **41** with sodium azide in acetonitrile results in an immediate formation of furoxan **42**; no intermediate azide could be isolated. Furoxan **42** is unstable and is rapidly hydrolysed by the atmospheric moisture to pyrazinone **43** (the authors' data).

The data presented suggest that the furazanopyrazine system can be formed using different approaches. The applicability of particular approach depends on the accessibility of the starting compounds and is sometimes limited by the absence of knowledge of the processes involved.

2. Chemical reactions

The data on reactions of furazanopyrazines are scarce. It is known that furazanopiperazine **32a** reacts with copper nitrate or perchlorate to give coordination compounds with the complex-forming cation linked to the nitrogen atom of the furazan rather than of the piperazine ring.⁴²

Heating of furazanopyrazinone **17** in 4 M hydrochloric acid for 1 h leads to the destruction of the six-membered cycle; the reaction product, diaminofurazan **2**, is formed in 22% yield.⁸

Hydrolysis of furoxanopiperazines **38b-d** is complete in 5 min upon heating in 50% ethanol. Here, the furoxan ring is opened to give the corresponding 1,4-dialkyl-2,3-dioxopiperazines.¹⁵

One furazan ring in difurazanopiperazine **34a** is hydrolysed to produce two carbonyl groups (Δ, HNO₃, AcOH).³⁵

Treatment of compounds **14b**,¹⁹ **32a**,⁴³ and **34a** with sodium nitrite in acidic media results in their *N*-nitrosation.³⁵

The overwhelming majority of published data are devoted to the synthesis and investigation of properties of nitro derivatives of furazanopyrazine. As mentioned above, some compounds of this series are promising components of explosives, propellants and gunpowders.

Treatment of compounds **11**,¹²⁻¹⁵ **13b**,¹⁶ **14a**,^{16, 19} **14b**,¹⁹ **15**,¹⁶ **16** and **32a,d**^{15, 29, 37} with a mixture of 100% HNO₃ and acetic or trifluoroacetic anhydride, HNO₃–H₂SO₄ or N₂O₅–HNO₃ at low temperatures results in their nitration.

X = O (a), NNO₂ (b).

Treatment of the tetracycle **44** with an HNO₃–(CF₃CO)₂O mixture results in oxidation of the C–H fragment of the triazole rings and nitration at two nitrogen atoms to give *N*-nitrotriazolone.⁴⁴ Like the aforementioned nitro compounds, this nitro derivative is easily hydrolysed.

It should be noted that the diamine **13a** when treated with nitric acid forms a salt and is not nitrated.¹⁸ At the same time,

treatment of the corresponding aromatic diamine **45a** with a nitrating mixture results in its conversion into the mononitro compound **46a**. Reactions of the diamines **45a,b** with HNO₃–(CF₃CO)₂O or BF₄NO₂ lead to the triazole ring closure and the formation of tricyclic *N*-oxides **47a** (yield 92%) and **47b** (yield 75%).⁴⁵

R = H (a), Me (b).

Treatment of bis(alkylamino)-substituted compounds **48a–c** with a mixture of HNO₃ and sulfuric acid or acetic anhydride gives *N,N'*-dinitro derivatives **49a–c**.^{44,45} The yields of the reaction products do not depend on the nature of the substituent R. In the case of the hydroxymethyl derivative **48b**, the nitration affects both the nitrogen and the oxygen atoms.

48: R = Me (a), CH₂OH (b), CH₂C(NO₂)₃ (c);

49: R = Me (a, 79%), CH₂ONO₂ (b, 82%), CH₂C(NO₂)₃ (c, 79%).

The nitration of compound **50**, containing an amino and a carbonyl group in the pyrazine ring, with an HNO₃–Ac₂O mixture gives *N*-nitroimine **51** (yield 37%). The starting compound **50** is mostly converted into dioxopiperazine **19**.⁴⁶

Upon treatment with an HNO₃–H₂SO₄ mixture, compound **1b** is nitrated and nitrosylated at the methyl group of the pyrazine ring to give nitrolic acid **52** which either undergoes further nitration with HNO₃–H₂SO₄ to give the trinitromethyl derivative **53** or eliminates the HNO₂ fragment to give furoxan **54**.⁷ The ratio of the products **52–54** depends on the concentrations of the acids and the temperature; however, the total yields of the three compounds do not exceed 40%.⁷

Compound **55** containing two trinitromethyl groups is prepared in three steps by stepwise introduction of nitro groups into the derivative **56**.⁴⁷

Dehydrogenation of furazanopiperazines results in their aromatisation. Thus oxidation of compound **32a** resulted in the first member of this series, viz., furazano[3,4-*b*]pyrazine **57**. PhIO, AgO, PbO₂ or MnO₂ are used as oxidants (the authors' data).

The oxidation of the tetracycle **11** by such oxidising agents as K₃Fe(CN)₆, KMnO₄ and SeO₂–H₂O₂ in water gives the dihydro derivative **58**; treatment of the latter with a nitrating mixture affords the biradical **59** in a total yield of ~ 50%. Treatment of the tetracycle **11** with trifluoroacetic acid leads to the destruction of the six-membered cycles and the formation of furazan **60**.⁴⁸

The stable biradical **61** is formed in quantitative yield by treatment of the tricycle **34a** with nitrating agents of any kind.^{35, 48}

Special mention should be made of an unusual reaction of diamine **62** with oxidants which also yields the biradical **61**.⁴⁹

Treatment of compound **63** with MnO₂ or 60% nitric acid results in the aromatisation of the piperazine ring and formation of furazanopyrazinotriazole **64**, whereas various nitrating mixtures cause the destruction of the triazole ring to the dioxo derivative **19**.⁵⁰

Furazanopiperazine derivatives undergo reduction. Thus furoxanoquinoxalines **37a–c** are converted into the corresponding furazans **36a,d–f** upon boiling with triethyl phosphite in ethanol.³⁹ Triphenylphosphine in CH₂Cl₂ causes rapid reduction of furoxan **37d** to furazan **36d**.³¹ A mixture of furazans **36a** and **36d** is formed from furoxan **37a** in boiling chloroform.³¹

Compound 37	Reaction conditions	Product	R ¹	R ²	R ³	Yield (%)
a	P(OEt) ₃ , EtOH, 4 h	36a	H	H	H	35
	PCl ₃ , CHCl ₃ , Δ, 5 h	36a	H	H	H	22
		36d	H	Cl	H	16
b	P(OEt) ₃ , EtOH, 4 h	36e	Me	H	H	35
c	P(OEt) ₃ , EtOH, 4 h	36f	(CH=CH) ₂	H	H	50
d	PPh ₃ , CH ₂ Cl ₂ , 20 °C	36d	H	Cl	H	35

Reaction of furoxanoquinoxaline **37a** with ethoxycarbonyltriphenylphosphoniomethanide (**65**) yields a mixture of the furazan **36a** and the tricyclic derivative **66**.⁵¹ In turn, the furazan **36a** reacts slowly with the ylide **65** to yield dihydro derivative **67** and a novel ylide **68**.³¹ The formation of dihydro derivatives of the type **67** is the main reaction for furazanoquinoxalines **36d–f** containing substituents in the phenyl nucleus.³¹

It is of note that treatment of compound **67** with bis(trifluoroacetoxy)-λ³-iodanylbenzene results in its aromatisation and the formation of the starting furazan **36a** (yield 75%), whereas the reaction of the ylide **68** with the same reagent affords tetracyclic derivative **69** containing a fused furan ring.³¹

Electrochemical reduction of the furoxan ring in compounds **37a,b** has been studied.⁵² The dioximes **35a,d** are readily formed; they can undergo more profound reduction.

Treatment of compounds **1a,c,h** with sodium borohydride in boiling ethanol for 1 h leads to selective reduction of the pyrazine ring. The yields of piperazines **70a–c** are 84%–87%. Higher yields of compounds **70a–c** were obtained using LiAlH_4 as the reducing agent in boiling THF.⁶ Catalytic reduction of compounds **1a,c,h** (10% Pd/C, H_2 , 1 atm, ethyl acetate, 20 °C, 20 h) results in furazan ring opening and the formation of diaminopyrazines **71a–c** in 65%–97% yields.⁶

R = H (**1c**, **70a**, **71a**), Me (**1h**, **70b**, **71b**), Ph (**1a**, **70c**, **71c**).

Hydrogenolysis (PtO_2 , H_2 , ~50 atm, AcOH, 7 days) of N- CH_2Ph bonds in compound **34b** competes with hydrogenation of the phenyl (but not furazan) rings.³⁴

Furoxanoquinoxaline **37a** reacts with alkenes and alkynes upon long-term (up to 80 h) boiling in CHCl_3 to yield the same

37: $\text{R}^1 = \text{H}$ (**a**), Me (**e**);

products, viz., di- N,N' -oxides **72a–e**.⁵³ This transformation proceeds in accordance with the so-called Beirut reaction⁴¹ where the *o*-dinitroso compound **73**, a valent tautomer of furoxan, plays the role of an intermediate.

Unusual tri- N,N',N'' -oxides **74a–d** were prepared by reaction of furoxans **37a,e** with arenecarbonitrile oxides. This reaction also involves the dinitroso intermediate **73**. A feasible mechanism of the formation of compounds **74a–d** has been proposed.⁵⁴

Presumably, the formation of bis(azoxy)quinoxalines **75** (yields ~50%) in the reaction of furoxans with N,N -dibromoamines catalysed by Cu(I) ions proceeds *via* the corresponding dinitroso intermediates.⁵⁵ Unfortunately, no details of the experimental protocol have been reported.

Of special interest is the use of the dichloro derivative **76** in the synthesis of various furazano[3,4-*b*]pyrazines. Compound **76** is prepared on heating of the diketone **19a** with thionyl chloride,^{47,56} POCl_3 in the presence of a catalytic amount of DMF or a $\text{POCl}_3\text{--PCl}_5$ mixture.⁵⁶

Since the furazano[3,4-*b*]pyrazine system is a typical π -acceptor, the halogen atoms in compound **76** manifest high activity towards nucleophiles. The reactivity of the dichloride **76** exceeds markedly those of its analogues containing 1,2,5-thiadiazole and triazole rings instead of the furazan ring as well as 2,3-dichloroquinoxaline and tetrachloropyrazine.⁵⁶

Thus reactions of dichloride **76** with ammonia, alkyl- and arylamines,⁵⁶ hydroxylamines,^{35,36,56} hydrazines,^{47,56} azide ion,⁵⁷ alcohols,^{56,58} phenols,⁵⁶ hydroxyfurazans⁵⁸ and thiols^{56,59} proceed smoothly with substitution of both chlorine atoms. The corresponding products are formed in high yields. Selective substitution of only one chlorine atom can sometimes be achieved by varying reaction conditions^{40,56} and using weak or sterically hindered nucleophiles.^{56,60–62} The second chlorine atom in the monosubstitution products can be replaced by another nucleophile.^{40,56,60,61} Thus the one-pot reaction of the dichloride **76** with the malonodinitrile anion yields dicyanomethylidene derivative **77** which cyclises into tricyclic aminonitriles **78** upon treatment with amines.^{60,61} The yields of compounds **78** are 90%–95%.

R = Alk, Ar, Het *etc.*

An original procedure for the synthesis of non-symmetrical furazanopyrazine derivatives involves the substitution of the azido groups for the chlorine atoms in compound **76** and subsequent reaction of the azido derivative **79** with nucleophiles.^{57,63}

Owing to azido–tetrazole tautomerism, one of the azido groups in compound **79** exists in a cyclic form. This stabilises the remaining azido group of the tautomer **80** and makes it less mobile than the chlorine atoms in the dichloride **76**. Replacement of one azido group is complete in ~ 1.5 h at 20 °C. Incubation of the reaction mixture for ~ 24 h results in replacement of the second azido group. The yields of monosubstitution products, such as compounds **81–83**, are 76%–85%.^{57,63} Subsequent long-term (~ 24 h) treatment with another nucleophile yields non-symmetrical compounds **45b**, **84–86**, which can be difficult to synthesise by other methods.

High reactivities of both the chlorine atoms in compound **76** were employed in the synthesis of polycyclic heterocycles incorporating a furazanopyrazine fragment. Thus reactions of the dichloride **76** with 1,3- and 1,4-dinucleophiles, such as diamines, amino and mercapto alcohols, aminothiols, thiourea, 2-aminoazoles, 2-aminoazines and *N*-benzoylglycine in acetonitrile at 20 °C yield polycyclic compounds **87–121** (Table 2). In the majority of cases, these reactions occur in the absence of a base (method A). However, the use of weakly nucleophilic reagents requires addition of triethylamine or other analogous bases (method B). The yields of reaction products depend on the nucleophilicities and steric characteristics of the starting reagents.

The amino groups of the diamine **45a**, which is readily prepared from the dichloride **76**,⁵⁶ are deactivated owing to the electron-withdrawing effect of the fused ring system. Attempts at alkylation of the amine **45a** with alkyl and aryl halides, halogeno ketones, diethyl carbonate and dichloroglyoxime were unsuccessful. This amine does not form stable salts even with strong acids.⁴⁴ Its treatment with oxidising mixtures based on H₂O₂ causes its degradation. At the same time, the electron-withdrawing nature of the ring allows replacement of the amino groups upon treatment with hydrazine to give bishydrazine **122**. Treatment of the diamine **45a** with formaldehyde yields the bis(hydroxymethyl) derivative **48b** which is stable owing to the electron-withdrawing character of the bicyclic fragment. Treatment of compound **48b** with trinitromethane gives the Mannich base **48c**.⁴⁴ Analogous Mannich bases were prepared from cyclic compounds containing NH groups.⁴⁶

A series of fused furazanopyrazine derivatives were synthesised from the diamine **45a**. Its reaction with ninhydrin in AcOH results in the dihydroxy derivative **123**.¹¹ Heating of compound **123** in ethanol, DMF or H₂SO₄ for more than 3 h is accompanied by dehydration and formation of a pentacyclic product **124**. Thiadiazole **125** was prepared by treating the amine **45a** with sulfur monochloride.⁴⁴ Condensation of the amine **45a** with triethyl orthoformate in the presence of a Lewis acid gives tricyclic compound **126** which is converted into imidazolone **127** on oxidation with MnO₂.⁴⁴

Treatment of the bishydrazine **122** with HNO₂ gives the tetrazole **80**,⁵⁷ while its heating with acids, acid anhydrides⁴⁴ or imidates⁴⁷ results in simultaneous formation of two triazole rings. The tetracyclic derivatives **56** and **128a–c** are formed in 60%–90% yields. The methyl groups in compound **128b** were oxidised to carboxy groups with potassium permanganate.⁴⁴

An unusual polycyclic system **129** was obtained upon oxidation of amine **130** with subsequent thermolysis of azo derivative **131**.⁶³ However, the total yield of compound **129** did not exceed 20%.

Note. A, in the absence of a base; B, in the presence of a base. ^a The authors' data.

Polycyclic compounds containing NH groups represent acids of moderate strength. For example, pK_a^1 for the difurazanopiperazine **34a** is 6.96, whereas pK_a^2 is 10.17.^{35, 48} It is acylated^{35, 48} or alkylated (arylated)^{35, 48, 50} under ordinary conditions. Compound **34a** reacts specifically with tetranitromethane in an alkaline medium to give disodium salt of dinitromethyl derivative **132** in 75% yield.³⁵ Trinitromethyl reagents react in a similar way.

$X^+ = Na$ (**132a**), K (**132b**); Hal = F (**133a**, 78%), Cl (**133b**, 90%).

Reaction of the disodium salt **132a** with XeF_2 or Cl_2 gives the corresponding halogen derivatives **133a,b**.³⁵ Compound **133a** is also formed upon treatment of the dipotassium salt **132b** with XeF_2 .⁴⁷

Compounds **134a–c** containing two furazanylamine fragments were prepared by a reaction of a dianion **135** with the corresponding fluorofurazans.^{65, 66} By varying the reaction conditions, one can direct the reaction to the predominant formation of the monoaddition product.

Oxidation of the diamine **134c** with dibromoisocyanurate results in intramolecular crosslinking of the amino groups into an azo group to yield macrocycle **136**.^{65, 66}

Reactions of polycyclic compounds containing NH groups with formalin give *N*-hydroxymethyl derivatives; treatment of the latter with HNO_3-Ac_2O or $HNO_3-(CF_3CO)_2O$ results in their conversion into the corresponding nitroxymethyl derivatives.^{44, 48, 50} It should be noted, however, that both mono- (**137**) and tris(hydroxymethyl) derivatives (**138**) yield the same nitrate **139**.⁵⁰

N-Hydroxymethyl derivatives are acylated with acetic anhydride; their treatment with SOCl_2 yields chloromethyl derivatives. The chlorine atom in the latter can be substituted for the azido group under the action of sodium azide.⁴⁸ Mannich bases **140a–c** were obtained in nearly quantitative yields using a three-component reaction of the difurazanopiperazine **34a** with CH_2O and amines.⁴⁸

$\text{R}^1\text{R}^2\text{N} = \text{NH}(\text{CH}_2)_2\text{SH}$ (**a**), $\text{NHC}_6\text{H}_4\text{Cl-4}$ (**b**), N (c).

Short-term heating of the tetracyclic compound **11** with formaldehyde in a methanol–formic acid mixture results in the polycycle **141** in quantitative yield. Boiling of the reaction mixture for 36 h results in partial reduction of compound **141** to the tetramethyl derivative **142**.⁶⁷

Polycyclic compounds containing NH groups are aminated upon treatment with hydroxylaminosulfonic acid to give *N*-amino derivatives.^{48, 49, 63} *N,N'*-Diaminopiperazine **62** reacts with aldehydes to yield bishydrazones; its acylation gives a *N,N,N',N'*-tetraacetyl derivative.⁴⁸ The conversions of bis(bishydroxymethylamino)piperazine **143** prepared in the reaction of the diamine **62** with formaldehyde have been studied.⁴⁸

Thus nitration of compound **143** with an HNO_3 – Ac_2O mixture gave nitrate **144**. Reaction with thionyl chloride yields

tetrachloride **145**, the chlorine atoms in which are reactive enough to be substituted by the azide ion.⁴⁸ Reaction of the hydroxymethyl derivative **143** with nitroform results in splitting of two hydroxymethyl groups to give bis(trinitroethylamino)piperazine **146**, which affords trinitroacetaldehyde **147** instead of nitramine upon nitration with various nitrating reagents.^{48, 63}

In contrast to oxidation of the diamine **62**, which generates the biradical **61**, treatment of monoaminopiperazine **148a** with *tert*-butyl hypochlorite affords an unstable tetrazene **149**.⁴⁹ A similar monoamine **148b** undergoes oxidation by sodium persulfate in trifluoroacetic acid to the oligomer **150**.⁴⁹

$\text{R} = \text{H}$ (**a**), $\text{CH}(\text{NO}_2)_2$ (**b**).

3. Properties and applications

The biological activities of furazano[3,4-*b*]piperazines have been little studied. Compound **1c** has been patented as a herbicide.⁹ The oxo derivatives **18a–d** have been recommended as tranquilizers.²³ Furazanopiperazine **151** and its derivatives were found to possess biocidal activities.⁶⁸

The macrocyclic compound **136** was used as an inhibitor of the soluble form of guanylate cyclase.⁶⁵

The sulfur-containing macrocycle **152** was regarded as a candidate complexone,⁵⁹ but compound **153** proved to be more efficient. The latter forms adducts with alkali metal nitrates and perchlorates as well as with dinitramine salts (the authors' data).

Furazanopiperazine **32a** possesses interesting photoelectric properties which are manifested as specific effects during electron movements in thin layers.^{69–71}

However, nitro and other polynitrogenous furazanopyrazane derivatives attract the most attention. Various thermochemical and explosive properties of their derivatives have been studied. Although most of these data are known to specialists only, some evidence can be found in popular literature. Characteristics of some compounds, *viz.*, detonation rate;^{12, 13, 16, 29, 37} shock, friction and flame sensitivity;^{12, 14, 16, 29} enthalpy;^{14, 29, 27, 72} thermal stability and thermal degradation^{16, 63, 72–78} and combustion,^{46, 63} have been established and documented. Such parameters as density,^{12, 13, 29, 33, 37, 46, 79} enthalpy,^{37, 46, 79, 80} detonation rate,^{12, 13, 29, 33, 79} detonation pressure,^{12–14, 29, 33} temperature and other combustion characteristics have been studied using computer methods.^{46, 63} The possibility of using nitro derivatives as components of explosive and pyrotechnical compositions and propellants has been considered.^{12–14, 16, 29, 37, 46, 63, 80, 81}

III. Furazano[3,4-*b*][1,4]oxazine derivatives

Both methods presently employed in the synthesis of furazanoxazine derivatives are based on the use of compounds of the furazan series. Thus 3-amino-4-hydroxyfuran **154** reacts with α -halogeno ketones in the presence of NEt_3 to give the intermediates **155** which undergo *in situ* cyclisation upon heating in an ethanol–AcOH mixture to give bicyclic derivatives **156a–d**.²

R = Me (**a**), CH_2Cl (**b**), Ph (**c**),  (**d**).

Thermolysis of 4-aryloxy-3-azido-furazans **157a–g** in decalin was used to obtain tricyclic compounds **158a–g** (the authors' data). It is of note that cyclisation occurs smoothly only with the *para*-substituted derivatives **157a–g**; reaction products are formed in 43%–72% yields. Attempts to use compounds with an *ortho*- or *meta*-substituent in the phenyl ring resulted in a complex mixture of products. The possibilities of this method are also limited by accessibility of the starting azides **157a–g**.

R = Cl (**a**), F (**b**), NMe_2 (**c**), Me (**d**), OMe (**e**), Ph (**f**),

The structural similarity of phenoxazine derivatives endowed with physiological activities and compounds of the type **158** makes them attractive targets for synthesis. However, attempts to fuse the furazan ring to the benzoxazine ring by treatment of dioximes **159** with ethyl chloroformate (which has been employed in the synthesis of the furazanoquinoxalines **36a–c**) were unsuccessful.³⁸

$\text{R}^1, \text{R}^2 = \text{H}, \text{Me}, \text{Cl}$.

There is still no information on the reactivities of furazanoxazine derivatives in the literature.

IV. 1,4-Dioxino[2,3-*c*]furazan derivatives

Only one method for the construction of 1,4-dioxino[2,3-*c*]furazan derivatives is known. The key building block is 3,4-dihydroxyfuran **160**.^{58, 82} Its treatment with oxalyl chloride in the presence of triethylamine in CH_2Cl_2 gives dioxo derivative **161**.⁶³ Reaction of compound **160** with 3,4-dinitrofurazan affords a mixture of products from which the tricyclic derivative **162** was isolated in 12% yield.⁸³

Compounds **163–165** were synthesised by the reaction of salts prepared from compound **160** with the corresponding halogeno pyrazines under conditions of phase-transfer catalysis.^{58, 84–86} The pyrazine ring in compound **163** was oxidised to di-*N,N'*-oxide upon treatment with peroxy acids.⁸⁴

V. 1,4-Dithiino[2,3-*c*]furazan derivatives

1,4-Dithiino[2,3-*c*]furazan derivatives were prepared starting from compounds of both the furazan and dithiine series. Both approaches were used for the synthesis of dithiinodifurazan **166**. This is the reaction product of 3,4-dinitrofurazan with potassium thiocyanate (yield 27%).⁸⁷ Dehydration of tetroxime **167** with thionyl chloride also yields compound **166**.⁸⁸

Oxidation of dioxime **168** (prepared from dichloroglyoxime and 1,2-ethanedithiol) with nitrogen oxides affords furoxan derivative **169**, which is recommended as a cardiostimulator along with acyclic thio-substituted furoxans.⁸⁹

No other data on the possible applications and reactivities of heterocyclic derivatives are available.

* * *

The data presented suggest that the most impressive success has been achieved in the chemistry of furazanopyrazine derivatives, whereas furazans fused to other six-membered heterocycles with two heteroatoms in positions 1 and 4 have been little explored. Further efforts in this branch of chemistry will be aimed at the search for useful properties of furazan fused to pyrazines, oxazines, dioxines and dithiines which, in turn, will stimulate the development of convenient methods for their synthesis. We hope that this review will be helpful for both chemists and specialists in other fields.

Abstract. The review surveys main chemical properties of technetium, methods of its isolation and determination and its behaviour during reprocessing of spent nuclear fuel and in environmental objects. Methods for extraction and isolation of technetium as a hazardous long-lived radionuclide are described. Prospects of using technetium in industrial processes and in medicine are considered. The bibliography includes 276 references.

I. Introduction

Technetium is a Group VII element, which was first prepared by nuclear synthesis in the mid-twentieth century. The characteristic feature of technetium is that all its isotopes with mass numbers from 90 to 110 are radioactive. Technetium is an artificial element and does not occur in nature. However, more than 60 tonnes of Tc have accumulated in the world because spent nuclear fuel (SNF) has a high Tc content (0.6 g per kilogram of ^{235}U in the case of 50% burn-up).¹ Large amounts of fission products (FP), including Tc, were released into the environment from nuclear weapon production and nuclear power engineering. Since the ^{99}Tc isotope has a long half-life, it is a very hazardous radioactive element. Besides, technetium shows a high migration ability and some of its compounds are volatile.

The main chemical and physicochemical properties of technetium are well known and were described in monographs and reviews^{2–9} as well as in the handbook published in 1999.¹⁰ However, many new studies published in recent years require generalisation. Besides, progress in nuclear power engineering has generated a need for additional studies of the behaviour of Tc

during reprocessing of spent nuclear fuel and in environmental objects. The lack of the necessary information on important radiochemical properties and behaviour of technetium in natural objects has already led to contamination of the environment by a large amount of Tc.

The present review surveys the main properties of technetium responsible for its behaviour during reprocessing of SNF and in environmental objects. These data may be of use for improvements in present-day technologies for reprocessing of SNF from the viewpoint of optimisation and complete extraction of Tc as well as for the prediction of its behaviour in natural objects.

II. Discovery, methods of preparation and main properties of technetium

D I Mendeleev was the first to suppose that a chemical element with the atomic mass of 99 should be present between manganese and rhenium in the Periodic Table (and gave it the name ekamanganese).^{11,12} However, the discovery of this element in manganese-containing ores and minerals appeared to be a difficult problem. All attempts to isolate the new element with the atomic number 43 failed. The Russian chemist Shchukarev¹³ and German physicist Mattauch¹⁴ formulated the ‘prohibition rule’ stating that the isobars of two adjacent elements in the Periodic Table cannot be stable, *i.e.*, one of these elements is necessarily radioactive. This led to the conclusion that the element with the atomic number 43 could not have stable isotopes and, consequently, could not occur in nature.

1. Preparation and nuclear properties of technetium isotopes

In 1937, Perrier and Segre^{15,16} carried out the first experiments on isolation of the element with the atomic number 43 from a molybdenum target bombarded with deuterons on a cyclotron according to the reaction

The new element was named technetium (for the Greek word ‘τεχνηος’, which means artificial).

Later on, another procedure was developed for the preparation of Tc by irradiation of molybdenum-containing samples in slow neutron flux¹⁷

Kilogramme amounts of either spectrally pure MoO₃ or molybdenum metal are used as a target. The target is irradiated in a reactor for one year and kept until the parent ⁹⁹Mo isotope completely decays. Irradiation of 1 kg of molybdenum with a flux of 8×10^{13} neutrons cm⁻² s⁻¹ makes it possible to accumulate up to 60 mg of Tc. Isolation of technetium must be carried out in 'hot' chambers operating under remote control at a hot laboratory, whereas the yields remain low.

In this connection, isolation of technetium in the course of SNF reprocessing is presently a more convenient procedure, because technetium is a fission product accumulated upon irradiation of nuclear fuel in a reactor. The accumulation of Tc depends on the nature of the fissionable nuclide and the depth of burn-up and reaches ~1 kg per tonne of fuel in fast-neutron reactors.¹⁸ The yield of ⁹⁹Tc during fission of ²³⁵U or ²³⁹Pu is about 6.1%.¹⁹ Other Tc isotopes with the mass numbers from 99 to 110 inclusive were also found among fission products of uranium. These isotopes are produced through β⁻-decay or neutron capture.⁸ However, nuclear reactors produce these isotopes in insignificant yields.

Of technetium isotopes, the long-lived ⁹⁹Tc isotope ($\tau_{1/2} = 2.14 \times 10^5$ years) is of particular importance. This isotope serves as a β-ray emitter with the energy $E_{\beta\text{max}} = 292$ keV, and its decay is not accompanied by γ-radiation.²⁰ The ^{99m}Tc isotope ($\tau_{1/2} = 6.6$ h) is widely used in medicine. This radionuclide is most commonly isolated with the use of chromatographic,²¹ extraction²² or sublimation^{23,24} generators based on ⁹⁹Mo. Generators based on sublimation separation of Tc outperform generators of other types in many respects. Their construction assumes heating of MoO₃ to 850 °C in a flow of O₂. The yield of ^{99m}Tc obtained by sublimation of volatile technetium oxide and its condensation in a cooled receiver followed by dissolution of the condensate reaches 1 Ci ml⁻¹. The type of ^{99m}Tc decay is the isomeric transition of the nucleus from a metastable state to a lower-energy level. In studies of ^{99m}Tc, it was demonstrated that the chemical state of the element has only a slight effect on the rate of decay of an unstable nucleus. Thus, the half-life of technetium metal is 1.003 times longer than that of K₂TcO₄.²⁵

For technetium, 21 isotopes with the mass numbers from ⁹⁰Tc to ¹¹⁰Tc are known, seven of these isotopes being isomers. Most Tc isotopes have short half-lives (from 0.81 s for ¹¹⁰Tc to 61.2 days for ^{97m}Tc). The exceptions are the above-mentioned ⁹⁹Tc isotope and two long-lived isotopes, viz., ⁹⁷Tc ($\tau_{1/2} = 2.6 \times 10^6$ years) and ⁹⁸Tc ($\tau_{1/2} = 4.2 \times 10^6$ years), which are prepared by irradiation of molybdenum with deuterons or protons.

2. Technetium metal

The main properties of technetium metal were studied predominantly in the 1960s. It was demonstrated that it has a hexagonal close-packed structure with the parameters $a = 2.7409$, $c = 4.3983$ Å.^{19,26} In polycrystalline films prepared by ion deposition at liquid nitrogen temperature, technetium has a face-centred cubic structure with the lattice parameter $a = 3.68 \pm 0.05$ Å.²⁷

The hexagonal crystal lattice of technetium has a small number of easy-slip planes due to which the as-cast metal is brittle and cracks even at small degrees of reduction upon rolling at 20 °C. Nevertheless, technetium was prepared as rods, strips, foil and wire by the corresponding technological processing.²⁸

Technetium is a refractory metal with the melting point of >2000 °C.²⁹ It forms continuous series of solid solutions with metals, which crystallise in the hexagonal system, viz., with ruthenium, osmium and rhenium (analogue of Tc).³⁰ Technetium is a superconductor ($T_c = 8.24$ K). The magnetic susceptibility of Tc remains constant in the temperature range of 80–1300 K and is close to that of rhenium.³¹

Technetium metal is generally prepared by thermal decomposition of pertechnetates with organic cations under a stream of inert gas^{32,33} or thermolysis of other Tc compounds (for example, of NH₄TcO₄) in a reducing medium.^{34–37}

The metal thus prepared is insoluble in HCl or H₂SO₄. However, it is readily oxidised with nitric acid.

3. Behaviour of technetium in solutions

The electronic structure of the Tc atom ([Rn]3d¹⁰4s²4p⁶4d⁶5s¹) is responsible for its transition-metal properties. Due to such an electron shell structure, technetium can exist in a wide range of oxidation states from +7 to -1 and has a tendency to disproportionation. Besides, equilibrium systems containing Tc in different oxidation states can occur in solutions. This is manifested in the behaviour of technetium in chemical reactions and different technological processes.

The scheme of the Latimer potentials in an acidic medium was reported in the study:³⁸

The formal oxidation potentials of technetium [relative to the normal hydrogen electrode (NHE)] in acidic and alkaline media are given below.³⁹

Medium	+7/+6	+6/+5	+6/+4	+5/+4	+4/0	-1/0
HClO ₄ (1 mol litre ⁻¹)	0.56	—	1.39	0.71	0.28	-0.5
NaOH (1 mol litre ⁻¹)	-0.64	-0.1	—	-0.88	-1.35	—

The standard oxidation potential E for the Tc(VII)/Tc(IV) pair is 0.738 V (vs. NHE).⁴⁰

In HNO₃ solutions, the stability of Tc ions increases in the following series: Tc(VII) > Tc(IV) > Tc(V) > Tc(VI).⁴¹

In acidic media, Tc(IV) is stable only in the presence of complex-forming compounds. For example, Tc(IV) forms the well-studied TcCl₆²⁻ complex in HCl solutions (6 mol litre⁻¹).⁴²

Technetium(V) is unstable and undergoes disproportionation in acidic media according to the following scheme:

In the HCl + NaCl system (ionic strength $\mu = 1.0$), the reaction rate is proportional to the square of the Tc(V) concentration.¹⁸ Although prone to disproportionation, pentavalent technetium is more stable than hexavalent technetium and its compounds can be isolated from aqueous solutions.^{43–44} Technetium(VI) also undergoes disproportionation according to the reaction

the reaction proceeding with a very high rate (at 25 °C, the rate constant is $\sim 3 \times 10^6$ litre mol⁻¹ s⁻¹).¹⁸ The stability of technetate ions in aprotic solvents provides evidence that its disproportionation proceeds with the involvement of protons.⁴⁵

The pertechnetate ion is stable in solutions. This ion acts as a rather strong oxidising agent and can be reduced with a number of reducing agents, such as ascorbic acid,^{46–49} hydroxylamine,^{50,51} urea⁵² and the chloride, bromide and iodide ions.^{53–55} In an alkaline medium, the TcO₄⁻ ion is catalytically reduced in the presence of PdCl₂ (0.001 mol litre⁻¹) to Tc(IV) at 65 °C during 4 days.⁵⁶

Reduction of pertechnetate ions with different reagents in the presence of complex-forming agents is used in many procedures for the qualitative and quantitative determination of Tc.⁵⁷

Only Tc(VII) and Tc(IV) compounds are of practical importance, because these ions are thermodynamically stable and can exist in solution. It is in these oxidation states that technetium can be present both in wastes of radiochemical production facilities and in environmental objects. Unstable and reactive intermediate

forms, viz., Tc(V) and Tc(VI), cannot exist under normal conditions but can be involved in redox reactions.

4. Chemical and physicochemical properties of selected technetium compounds

Abundant data on the synthesis, investigation and use of a number of simple and complex technetium compounds are available in the literature (see, for example, the recent review⁵⁸). Hence, we shall take a quick look at the properties of technetium compounds, which determine the behaviour of technetium in nuclear technology and environmental objects. Special attention is given to technetates and Tc(IV) compounds.

The TcO_4^- anion is stable in acidic, neutral and alkaline media.⁴¹ Pertechnetates MTcO_4 belong to a class of ionic crystals stabilised primarily through Coulombic interactions between ions.⁵⁹ Since the electronic structure of TcO_4^- and its size are similar to those of ReO_4^- , pertechnetates are analogues of perrhenates and, in some cases, these compounds are isostructural. Pertechnetates are more similar to permanganates in thermal stability rather than to perrhenates. The physicochemical properties of polycrystalline MTcO_4 depend substantially on the nature of the M cation. Probably, this is partially associated with a distortion of the tetrahedral symmetry of the pertechnetate ion and the type of the crystal system. According to the data from vibrational spectroscopy and ^{17}O and ^{99}Tc NMR spectroscopy, the pertechnetate ion in aqueous and non-aqueous solutions has a regular tetrahedral symmetry regardless of the nature of the cation.⁶⁰ According to the results of vibrational spectroscopy and X-ray diffraction studies, the island anionic polyhedron TcO_4^- in crystals is distorted, the degree of distortion being decreased with increasing cation radius.

Pertechnetates may be divided into three groups.^{60–62}

1. Pertechnetates of alkali metals (Na, K, Rb) whose crystals have scheelite-like structures and are characterised by a small angular distortion of the TcO_4^- anion ($1–2^\circ$).

2. Ammonium pertechnetate whose tetragonal lattice is built from the isolated TcO_4^- and NH_4^+ groups linked through hydrogen bonds. The unit cell parameters of NH_4TcO_4 vary substantially in the temperature range of $100–340\text{ K}$.

3. Pertechnetates with onium cations whose structures are poorly known (except for Me_4NTcO_4 , in which the anionic polyhedron TcO_4^- is strongly distorted); the Tc–O bond lengths in these compounds differ by 0.04 Å and the bond angles are 105.5 and 111.7° .⁶⁰

Alkali metal pertechnetates are readily soluble in water. Thus, the solubility of NaTcO_4 is $11.3\text{ mol litre}^{-1}$ at 20°C .³⁹

Technetium(IV) dioxide TcO_2 , which is the most important and stable Tc(IV) compound, occurs as a paramagnetic black powder with a density of 6.9 g cm^{-3} . At 298.16°C , this compound is characterised by the following thermodynamic parameters: $-\Delta H_{\text{form}} = 434.59\text{ kJ mol}^{-1}$; $S^\circ = 62.5\text{ J mol}^{-1}\text{ deg}^{-1}$; $-\Delta S^\circ = 173.9\text{ J mol}^{-1}\text{ deg}^{-1}$; $-\Delta G_{\text{form}} = 382.76\text{ kJ mol}^{-1}$. Technetium(IV) dioxide TcO_2 crystallises in the monoclinic system with the following unit cell parameters: $a = 5.53$, $b = 4.79$, $c = 5.53\text{ Å}$, $\beta = 120^\circ$.⁶³ According to the results of EXAFS measurements, the Tc–Tc distance in the structure of TcO_2 is 2.61 Å .⁶⁴

Technetium(IV) dioxide is quite stable in air at 20°C . In deaerated neutral and acidic aqueous solutions, this compound is stable, whereas in aerated aqueous solutions, TcO_2 rapidly oxidises with subsequent dissolution (with a rate of $\sim 1\text{ mass \%}$ during 10 days) to give $\text{Tc}^{\text{VII}}\text{O}_4^-$.⁶⁵

Technetium(IV) dioxide occurs in two forms, viz., non-hydrated (TcO_2) and hydrated ($\text{TcO}_2 \cdot n\text{H}_2\text{O}$). The hydrated form is less stable (compared to TcO_2) both in solutions and in air.

In alkali solutions, TcO_2 dissolves to give $\text{Tc}(\text{OH})_6^{2-}$ ions, which have a characteristic orange colour. The hydroxo technetate ions, whose solutions absorb light at $\lambda = 410\text{ nm}$, are readily oxidised with atmospheric oxygen to Tc(VII).

The solubility of $\text{TcO}_2 \cdot n\text{H}_2\text{O}$ at pH 7–10 in the absence of oxidising and complex-forming agents is close to $10^{-8}–10^{-9}\text{ mol litre}^{-1}$ and increases substantially as the pH of the solutions increases. In air, the solubility of $\text{TcO}_2 \cdot n\text{H}_2\text{O}$ in a NaOH solution ($1–3.6\text{ mol litre}^{-1}$) containing N_2H_4 ($0.02\text{ mol litre}^{-1}$) is $(1.1 \pm 0.1) \times 10^{-5}\text{ mol litre}^{-1}$. Under the same conditions, the solubility of $\text{Tc}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ is $6.1 \times 10^{-6}\text{ mol litre}^{-1}$.^{41,66}

III. Methods of isolation of technetium from solutions

1. Liquid–liquid extraction

Liquid-liquid extraction is most commonly used for the isolation of technetium from solutions with different compositions. Abundant data on the extraction properties of Tc(VII) have been accumulated. Different extractants were proposed for extracting technetium from acidic, neutral and alkaline solutions, among which are alcohols, ketones, ethers, nitro compounds, organophosphorus compounds,^{67,68} nitriles, amines,⁶⁹ etc.^{70–72}

The extractants characterised by the best distribution coefficients of Tc(VII) in acidic media are listed in Table 1.

Table 1. Distribution coefficients of Tc(VII) (D_{Tc}) in acidic media.

Extractant	Acid	Concentration /mol litre ⁻¹	D_{Tc}	Ref.
Triisooctylamine ($0.2\text{ mol litre}^{-1}$) in syntin	HNO_3	1	270	39
Acylidimethylbenzylammonium chloride	H_2SO_4	1	105	73
Diisopentyl methylphosphonate	HNO_3	0.1	117	39
Tri-n-octylamine ($0.1\text{ mol litre}^{-1}$) in cyclohexane	H_2SO_4	1	110	73
Tri-n-octylphosphine oxide ($0.5\text{ mol litre}^{-1}$)	HNO_3	0.1	78	39
Cyclohexanol	H_2SO_4	1	32	73

A solution of tetraphenylarsonium chloride in chloroform ($10^{-4}\text{ mol litre}^{-1}$) is the most efficient extractant in neutral and weakly alkaline media. The distribution coefficient $D_{\text{Tc(VII)}}$ for this agent is 106 (Na_2CO_3 , pH 10).^{74,75}

α -Picoline ($D = 1840$), 5-ethyl-2-methylpyridine ($D = 1000$), 2,4-dimethylpyridine ($D = 700$) and quinoline ($D = 523$) are the most promising extractants for the extraction of technetium from alkaline solutions ($0.5\text{ mol litre}^{-1}\text{ NaOH} + 1\text{ mol litre}^{-1}\text{ Na}_2\text{CO}_3$).⁷⁵

2. Sorption and extraction chromatography

Data on sorption extraction of technetium(VII) by both synthetic organic sorbents and inorganic materials are available in the literature.

It was demonstrated that Tc(VII) as the TcO_4^- ion has a high affinity for different granulated anion-exchange resins. Strongly basic anion-exchange resins of the AV-17 type, Dowex-1 $\times 8$ or vinylpyridine ion-exchange resins show the highest efficiency for absorption of Tc(VII). Polyfunctional ion-exchange resins, for example, EDE-10, are less efficient for absorption of Tc(VII).⁷⁶ The plot of the distribution coefficient $[K_d^{\text{Tc(VII)}}]$ vs. the pH of the solution for sorption of Tc(VII) with the AV-17 anion-exchange resin⁷⁷ is shown in Fig. 1.

The distribution coefficient $K_d^{\text{Tc(VII)}}$ for sorption of TcO_4^- from NaOH solutions ($0.25\text{ mol litre}^{-1}$) by the Dowex-1 $\times 8$ ion-exchange resin is $4500\text{ cm}^3\text{ g}^{-1}$, but this coefficient decreases substantially as the salt background increases. Thus, an increase in the concentration of NaNO_3 from 0.5 to $5.0\text{ mol litre}^{-1}$ leads

Figure 1. Plot of $K_d^{Tc(VII)}$ vs. pH upon sorption on the AV-17 anion-exchange resin in the Cl form.⁷⁷

to a decrease in $K_d^{Tc(VII)}$ from 575 to 122 $\text{cm}^3 \text{g}^{-1}$, all other factors being the same. In the case of sorption of Tc(VII) on the VP-1AP anion-exchange resin, the distribution coefficient $K_d^{Tc(VII)}$ changes from 6233 to 5193 $\text{cm}^3 \text{g}^{-1}$ in the range of the NaOH concentrations from 1 to 4 mol litre^{-1} .³⁹

Sorption of technetium(VII) from aqueous solutions with pH 2–12 by granulated monofunctional AV-17-based anion-exchange resins containing amine and amide functional groups or nitrogen heterocycles was studied. It was demonstrated that the AV-17 anion-exchange resin and resins containing different functional groups can be arranged in the following order of increasing affinity for the pertechnetate ion: AV-17 > NC(O)Et₂ > NC(O)Bu₂ⁿ > S(CH₂)₂NMe₂ > NMe₂. The pH of solutions providing the maximum sorption of technetium increases in the same order. Thus, the maximum distribution coefficients of Tc(VII) (in $\text{cm}^3 \text{g}^{-1}$) corresponding to the maximum pH are as follows: 1.3×10^4 at pH 5 [NC(O)Et₂], 1.2×10^4 at pH 4 [NC(O)Bu₂ⁿ], 1.1×10^4 at pH 3 [S(CH₂)₂NMe₂] and 0.4×10^4 at pH 2.5 (NMe₂).⁷⁷

Sorption of TcO_4^- from acidic solutions should be considered as an acid–base interaction according to the reaction

where R~ is the functional group of the resin.

Sorption of technetic acid by basic anion-exchange resins is accompanied by localisation of the proton at the functional group giving rise to $\text{RH}^+ \cdots \text{TcO}_4^-$ ion pairs. The logarithm of the constant of proton association in the HCl–LiCl system ($\mu = 5$) is 0.033.^{77, 78}

Sorption of the TcO_4^- ions was studied⁷⁹ on the radiation-stable styrene–vinylpyridine anion-exchange resin ReillenTM–HPQ (30–60 mesh granules) containing 75% of highly basic methylated ion-exchange amino groups and 25% of weakly basic non-methylated ion-exchange amino groups. If the equilibrium was established within 30 min, the distribution coefficients $K_d^{Tc(VII)}$ in HNO₃ solutions with concentrations of 10, 5 and 1 mol litre^{-1} were estimated at 11.5, 55.7 and 415 $\text{cm}^3 \text{g}^{-1}$, respectively. These values are substantially higher than the corresponding values for the commercial Dowex-1 $\times 8$ anion-exchange resin (under the same conditions, 5, 15 and 135 $\text{cm}^3 \text{g}^{-1}$, respectively). The ReillenTM–HPQ sorbent can also be used for the extraction of technetium(VII) from salt solutions. Thus, the distribution coefficients K_d of TcO_4^- with the use of this sorbent at an HNO₃ concentration of 0.001 mol litre^{-1} are 162 $\text{cm}^3 \text{g}^{-1}$ (in a solution containing 4 mol litre^{-1} of NaNO₃), 515 $\text{cm}^3 \text{g}^{-1}$ (1 mol litre^{-1} of NaNO₃) and 138 $\text{cm}^3 \text{g}^{-1}$ (4 mol litre^{-1} of LiNO₃). At an HNO₃ concentration of 0.5 mol litre^{-1} , K_d are 109 $\text{cm}^3 \text{g}^{-1}$ (4 mol litre^{-1} of NaNO₃), 553 $\text{cm}^3 \text{g}^{-1}$

(1 mol litre^{-1} of NaNO₃) and 423 $\text{cm}^3 \text{g}^{-1}$ (1 mol litre^{-1} of LiNO₃).⁷⁹

Not only granulated ion-exchange resins but also fibrous complex-forming sorbents are used in procedures for isolation and extraction of technetium. The latter sorbents exhibit high selectivity for particular ions. Such sorbents have advantages over granulated materials, because they not only possess high selectivity for metal ions but also have a large surface, which ensures their good kinetic properties. In addition to traditional fibrous complex-forming sorbents prepared by a modification of the starting matrices, fibrous materials filled with powdered complex-forming sorbents also show promise. The latter sorbents are composed of fine porous polyacrylonitrile fibers (30–40 μm in diameter), within which a complex-forming sorbent or an ion-exchange agent (filling agent) is held. Fibrous complex-forming sorbents are used for the extraction of rare and noble metals^{80–82} as well as of transuranium elements.^{83, 84} Fibrous complex-forming agents of the POLYORGS type, which were developed at the V I Vernadsky Institute of Geochemistry and Analytical Chemistry of the Russian Academy of Sciences, were also used for the sorption of Tc(VII) from acidic, neutral and alkaline media.⁸⁵ Data on extraction of technetium from solutions with different compositions are given in Table 2. The filled fibrous complex-forming sorbents AV-17 and POLYORGS-17 virtually completely absorb trace amounts of Tc both from acidic and alkaline solutions. Other known sorbents also extract technetium from acidic solutions, though to a lesser degree. Under the optimum conditions, the equilibrium distribution coefficients [$K_d^{Tc(VII)}$] for the filled fibrous sorbents of choice are $\geq 10^4 \text{ cm}^3 \text{g}^{-1}$, and these sorbents are highly competitive with commercial granulated materials (Table 3).

Table 2. Sorption of Tc(VII) by various fibrous ‘filled’ sorbents.⁸⁵

Sorbent	Functional groups	Degree of sorption (%)	
		HNO ₃ (see ^a)	NaOH ^a
AV-17	quaternary ammonium	92	91
AN-31	secondary and tertiary amine	88	23
POLYORGS-17	1,(3)5-dimethylpyrazole	96	96
POLYORGS-33	amidoxime and hydrazide	67	6
POLYORGS-35	hydrazide	79	0

Note. $V/m = 100 \text{ cm}^3 \text{g}^{-1}$, 20 °C, the contact time was 2 h.

^a The concentration was 0.1 mol litre^{-1} .

Table 3. Sorption of Tc(VII) by fibrous ‘filled’ sorbents.⁸⁵

Solution	Concentration / mol litre^{-1}	$K_d^{Tc(VII)} / \text{cm}^3 \text{g}^{-1}$	
		AV-17	POLYORGS-17
HNO ₃	10^{-3}	3.7×10^4	1.0×10^3
	10^{-2}	1.3×10^4	2.5×10^3
	0.1	1.2×10^3	2.2×10^3
	0.5	382	189
NaOH	0.1	1.0×10^3	277
	1.0	900	—
NaNO ₃	0.1	861	432

Note. $V/m = 100 \text{ cm}^3 \text{g}^{-1}$, 20 °C, the contact time was 2 h.

Fibrous sorbents of the POLYORGS type were used for the extraction of technetium from water samples from the Karachai Lake (Russia) located in the territory of the Mayak Production Association and also from wells located in the neighbourhood of this lake.⁸⁶

It was noted that Tc(VII) is efficiently sorbed by activated carbon from acidic solutions, which model compositions of high-level radioactive waste.⁸⁷ The distribution coefficient $K_d^{\text{Tc(VII)}}$ in solutions containing HNO_3 at a concentration of $0.5 \text{ mol litre}^{-1}$ is $\sim 10^3 \text{ cm}^3 \text{ g}^{-1}$. For comparison, the sorption of Tc(VII) on other inorganic sorbents, including SiO_2 , Al_2O_3 and aluminosilicates, was also studied. Activated carbon appeared to be the sorbent of choice, the use of activated carbon being most efficient in strongly acidic media. The mechanism of sorption and the possibility of the recovery of activated carbon were discussed.⁸⁷ The authors of the cited study believed that activated carbon acts as an ion-exchange agent, anion-exchange centres being formed on its surface in solutions with pH 2–5 resulting in an increase in $K_d^{\text{Tc(VII)}}$. An increase in the salt background leads to a ~ 100 -fold decrease in the sorption of Tc.⁸⁷

Sorption of Tc(VII) and Tc(IV) on aluminium hydroxide was investigated.⁸⁸ The experiments were carried out under an atmosphere of N_2 . Under experimental conditions, the sorption of technetium was insignificant and K_d decreased to zero at pH > 7. In hydrochloric solutions, Tc(IV) is sorbed on $\text{Al}(\text{OH})_3$ as the TcCl_6^{2-} anions. The sorption maximum is observed in neutral media.

The distribution coefficient $K_d^{\text{Tc(VII)}}$ for extraction of Tc(VII) from a solution of HNO_3 ($0.05 \text{ mol litre}^{-1}$) with the use of a solid extractant, which is composed of a Polysorb-1 or Chromosorb-W matrix incorporating a solution of trioctylphosphine oxide in cyclohexanone, is $\sim 3500 \text{ cm}^3 \text{ g}^{-1}$. An increase in the concentration of HNO_3 to 1 mol litre^{-1} causes a decrease in the distribution coefficient to $1060 \text{ cm}^3 \text{ g}^{-1}$. In solutions containing HCl (1 mol litre^{-1}) and SnCl_2 ($0.03 \text{ mol litre}^{-1}$), $K_d^{\text{Tc(VII)}}$ is 2.8. The distribution coefficient $K_d^{\text{Tc(VII)}}$ of Tc(IV) in solutions containing HCl (5 mol litre^{-1}) and SnCl_2 ($0.3 \text{ mol litre}^{-1}$) is even lower (<1). In neutral and alkaline media, $K_d^{\text{Tc(VII)}}$ are $110 \text{ cm}^3 \text{ g}^{-1}$ (pH 6.4) and $10 \text{ cm}^3 \text{ g}^{-1}$ ($0.5 \text{ mol litre}^{-1}$ of NaOH + $2.5 \text{ mol litre}^{-1}$ of NaNO_3).⁷⁰

With the aim of isolating technetium from plant materials, the sorption of the following anions was studied: TcO_4^- , technetium diethylenetriaminepentaacetate as well as the $[\text{Tc}^{\text{VO}}_2(1,4,8,11\text{-tetraazacyclotetradecane})]^+$ cationic complex on polydextran gel Sephadex G-25, hydrophilic silica gel Zorbax GF-250 and polymeric gel HEMA-SEC BIO1000. It was found that HEMA-SEC BIO1000 is the matrix of choice for isolation of Tc(VII). In solutions of NaCl with a concentration of $0.04 \text{ mol litre}^{-1}$, $K_d^{\text{Tc(VII)}}$ for these ions have close values (4, 1.5 and $0.8 \text{ cm}^3 \text{ g}^{-1}$, respectively).⁸⁹

The sorption of Tc on TiO_2 , cadmium sulfide, zirconium phosphate and complex inorganic materials⁹⁰ was studied upon contact between a sorbing material (1 g) and a solution of Tc(VII) (10 ml) at 20°C (Table 4). At pH 6.5, Termoxid-34 and GSK (see Table 4) are the most efficient sorbents. After irradiation of samples using a ^{60}Co γ -source ($\sim 10^7 \text{ rad}$) at 20°C for 20 h, their total sorption capacity was almost halved.

Table 4. Distribution coefficients $K_d^{\text{Tc(VII)}}$ for different composites.⁹⁰

Sorbent	$K_d^{\text{Tc(VII)}} / \text{cm}^3 \text{ g}^{-1}$		
	pH 1.27	pH ~ 6.5	pH 12.7
GSK (crystalline CdS)	11.0	13.4	2.16
Termoxid-34 (high-density crystalline TiO_2)	5.3	31.3	0.73
SPSK ($\text{Sb}_2\text{O}_5 \cdot n \text{ SiO}_2 \cdot m \text{ P}_2\text{O}_5$)	4.7	9.4	<0.1
ISMA ($n \text{ LiO} \cdot m \text{ MnO}_2 \cdot l \text{ Al}_2\text{O}_3 \cdot k \text{ H}_2\text{O}$)	4.0	10.25	~ 1

Sorption methods are being developed for the extraction of technetium from alkaline wastes (pulp) of radiochemical production facilities. It is known that high-level radioactive wastes were accumulated during 50 years as a result of weapon plutonium

production and still remain unprocessed both in Russia (Mayak Production Association, Ozersk)⁹¹ and abroad, particularly, in the USA (Hanford Site, Savannah River Site, Idaho National Engineering and Environmental Laboratory, West Valley Staffing Group and Oak Ridge National Laboratory).^{92–94} Thus, thousands of tonnes of alkaline pulps, which have the overall activity of $\sim 2 \times 10^5 \text{ Ci}$ and contain Np (50–100 kg), Pu (540–860 kg), Am ($\sim 30 \text{ kg}$) and Tc ($\sim 2 \text{ t}$), were accumulated at the Hanford Site of the Westinghouse Hanford Company (Richland, USA).^{92–94} It is also necessary to extract technetium during reprocessing of alkaline pulps followed by burial of hazardous long-lived radionuclides. Main problems associated with the development of sorption methods for the extraction of technetium from these wastes are a high concentration of alkali ($[\text{OH}^-] \approx 1\text{--}4 \text{ mol litre}^{-1}$), high salt background ($[\text{Na}^+] \approx 2\text{--}5 \text{ mol litre}^{-1}$, $[\text{Al}^{3+}] \approx 0.8 \text{ mol litre}^{-1}$; $[\text{K}^+] \approx 0.1 \text{ mol litre}^{-1}$; $[\text{NO}_3^-] \approx 1.6 \text{ mol litre}^{-1}$; $[\text{NO}_2^-] \approx 1 \text{ mol litre}^{-1}$), high density of the liquid phase ($\approx 1.1\text{--}1.3 \text{ cm}^3 \text{ g}^{-1}$) and high radiation background.

Selective organic granulated anion-exchange resins and inorganic materials (including metals) are used for the extraction of technetium from alkaline solutions with high salt concentrations.

The SuperLig 639 sorbent was specially constructed for the extraction of technetium from alkaline high-level radioactive waste stored at the Hanford Site (USA). This sorbent was tested on real solutions from the waste tanks AN-103 ($[\text{Na}^+] \approx 4.9 \text{ mol litre}^{-1}$, $[\text{NO}_3^-] \approx 1.6 \text{ mol litre}^{-1}$, $[\text{OH}^-] \approx 1.9 \text{ mol litre}^{-1}$), AZ-102 ($[\text{Na}^+] \approx 2.7 \text{ mol litre}^{-1}$, $[\text{NO}_3^-] \approx 0.27 \text{ mol litre}^{-1}$, $[\text{OH}^-] \approx 0.1 \text{ mol litre}^{-1}$) and AN-102 ($[\text{Na}^+] \approx 5.3 \text{ mol litre}^{-1}$, $[\text{NO}_3^-] \approx 1.5 \text{ mol litre}^{-1}$, $[\text{OH}^-] \approx 1.25 \text{ mol litre}^{-1}$).⁹⁵ This sorbent occurs as 20–70 mesh granules (200–800 μm) and is made up of the groups of crown ether DCH-18-C-6 covalently bonded to a polystyrene matrix. The distribution coefficients $K_d^{\text{Tc(VII)}}$ for sorption of technetium from radioactive wastes from the tanks AN-103, AZ-102 and AN-102 with the use of this anion-exchange resin are 530, 886 and $287 \text{ cm}^3 \text{ g}^{-1}$, respectively.

Extraction chromatography was applied to the isolation of technetium from alkaline wastes with the use of the ABECTM-5000 ion-exchange resin made up of monomethylated poly(ethylene glycol) (PEG-5000) covalently bonded to a polystyrene support, which efficiently adsorbed TcO_4^- from solutions. Sorption of Tc(VII) was carried out from NaOH solutions ($2\text{--}4 \text{ mol litre}^{-1}$). The desorption of Tc followed by its concentration were performed with the use of distilled water. The addition of the NO_3^- and NO_2^- ions to the eluent leads to an increase in the rate of elution of TcO_4^- from a sorbent layer. By contrast, the citrate, carbonate and aluminate ions facilitate the retention of TcO_4^- by the resin. An increase in the temperature from 25 to 40°C has only a slight effect on this process. The ABECTM-5000 ion-exchange resin appeared to be resistant to ^{60}Co γ -irradiation up to the dose of 131 mrad .⁹⁶

3. Currentless electrochemical deposition

The static contact between granulated Zn metal and solutions containing 0.5, 2.0 or $3.5 \text{ mol litre}^{-1}$ of NaOH and $(6 \pm 3) \times 10^{-5} \text{ mol litre}^{-1}$ of Tc(VII) in the presence of complex-forming agents led to sorption of technetium on the metal surface with $K_d^{\text{Tc(VII)}}$ of 1.4, 3.9 and $5.7 \text{ cm}^3 \text{ g}^{-1}$, respectively.⁹⁷ In the dynamic mode, the distribution coefficients $K_d^{\text{Tc(VII)}}$ were 1.9, 4.7 and $8.9 \text{ cm}^3 \text{ g}^{-1}$, respectively (Fig. 2). The sorption of technetium from NaOH solutions with concentrations from 0.5 to $3.5 \text{ mol litre}^{-1}$ with the use of Cr or Sn metals both in the static or dynamic modes in the presence of complex-forming agents is characterised by low distribution coefficients $K_d^{\text{Tc(VII)}}$ ($< 1.2 \text{ cm}^3 \text{ g}^{-1}$). The authors of the cited study⁹⁷ believed that interactions of Zn, Cr or Sn with Tc in alkaline solutions caused reduction of Tc(VII) to Tc(IV) followed by sorption of the resulting $\text{TcO}_2 \cdot n \text{ H}_2\text{O}$ on the metal surface. The solubility of $\text{TcO}_2 \cdot n \text{ H}_2\text{O}$ thus precipitated in a deaerated NaOH solution (4 mol litre^{-1})

Figure 2. Sorption of Tc(VII) on zinc granules depending on the duration of the contact between the granules and a NaOH solution.⁹⁷ (1) 1M NaOH, (2) 2M NaOH, (3) 4M NaOH.

was nearly 6×10^{-7} mol litre⁻¹, which is 50 times lower than the solubility of $\text{TcO}_2 \cdot n\text{H}_2\text{O}$ prepared by reduction of Tc(VII) with hydrazine. The high reactivities of the metals used (Zn, Cr, Sn, Pb and Sb) are associated with the fact that these metals do not form oxide films (which hinder the contact) in alkaline media. Because of this, the oxidation potentials of these metals are sufficient for reduction of Tc(VII) to $\text{TcO}_2 \cdot n\text{H}_2\text{O}$. The degree of Tc deposition (contrast to actinides) increases with increasing NaOH concentration. An increase in the temperature from 20 to 60 °C and the removal of dissolved O_2 have virtually no effect on the final results.

4. Electrochemical separation

Electrochemical methods are used along with traditional chemical methods for the preparation of solutions with the aim of stabilising technetium and actinides in the desired oxidation states when using the extraction technology of reprocessing of spent nuclear fuel.^{98,99} It was demonstrated that the rate of electrolytic oxidation of Pu(0) to Pu(IV) and the yield of the product increased in the presence of technetium(VII) ions. Thus, the addition of Tc(VII) (70 mg litre⁻¹) to a solution containing Pu(III) and hydrazine caused acceleration of oxidation of plutonium by a factor of ~1.5 due, apparently, to catalytic decomposition of hydrazine with technetium ions.¹⁸ Electrolysis of solutions of Tc(VII) in H_2SO_4 (1 mol litre⁻¹) in a diaphragm cell led to reduction of technetium partially to metal that deposited on the cathode and partially to Tc(IV) accumulated in the electrolyte as a colloidal suspension of TcO_2 .

Data on the electrochemical separation of technetium from solutions which model compositions of liquid radioactive wastes were reported in the study.¹⁰⁰ In HNO_3 solutions (0.1–1.0 mol litre⁻¹), electrochemical reduction of Tc(VII) to Tc(III) involves two electrode reactions. The first reaction proceeds at 0.069 to –0.205 V (relative to SHE) and is associated with reduction of technetium. The second reaction proceeds at –0.71 V and results in decomposition of nitric acid catalysed by Tc(III) cations. Electrochemical reduction of the pertechnetate ions by polarographic methods on a mercury electrode in an acetate buffer (pH 3.5–6.0) was studied. It was noted that the Tc(VII)/Tc(III) reduction proceeded through the formation of Tc(V) followed by its disproportionation to give water-insoluble suspensions of Tc(IV) compounds. Technetium(IV) present in precipitates adsorbed on the electrode was reduced to Tc(III). An original scheme of separation of technetium from solutions which model wastes from the PUREX process ($[\text{Tc(VII)}] = 200$ mg litre⁻¹, $[\text{HNO}_3] = 2\text{--}4$ mol litre⁻¹) was proposed in the study.¹⁰⁰ This method involves denitration of the starting solution with formic acid on heterogeneous platinum catalysts followed by electrolytic reduction of technetium on a graphite electrode at -1.3 ± 0.1 V to give $\text{TcO}_2 \cdot n\text{H}_2\text{O}$ (pH 6.0–7.5, the ionic strength was 0.5–1.0 mol litre⁻¹, the yield was 92%–95%).¹⁰⁰

5. Precipitation and coprecipitation

It is known that Tc(VII) is efficiently precipitated with hydrazine in the presence of FeCl_3 . The presence of complex-forming agents (for example, of sodium phosphate or sodium ethylenediaminetetraacetate at concentrations of 0.01 and 0.1 mol litre⁻¹, respectively) leads to a decrease in the degree of precipitation of technetium.¹⁰¹ Reduction of Tc(VII) with hydrazine can be accompanied by sorption of technetium on metals, such as Zn or Al.⁴¹ Up to 99.5% of Tc was precipitated in alkaline media (0.5–4.0 mol litre⁻¹ of NaOH) in the presence of $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O}$ (0.17 mol litre⁻¹) and FeCl_3 (0.025–0.15 mol litre⁻¹). However, only 76% of Tc was extracted from model solutions of high-level radioactive wastes under analogous conditions, which indicates that Tc(VII) is only partially reduced in the presence of salts.¹⁰¹ In some cases, technetium was successfully isolated as Tc(IV),(V) hydroxides.¹⁰²

In wastes of radiochemical production facilities, Tc is present together with platinum-group elements. A procedure was developed for the separation of Tc from these elements using denitration of a solution of nitric acid with formic acid.^{87, 103, 104} Under these conditions, Pd and Rh are reduced with formic acid to metals, and Tc is reduced to Tc(IV) and is isolated as hydrated dioxide. It was found that more than 90% of Tc was precipitated in the presence of Pd and Rh (> 0.005 mol litre⁻¹) at a concentration ratio $\text{HCOOH}/\text{HNO}_3 > 1.8$. Then technetium(IV) dioxide is dissolved in the presence of different oxidising agents. Refluxing of technetium(IV) dioxide in the presence of O_2 , O_3 , H_2O_2 or HNO_3 afforded Tc(VII) in 23%, 34%, 76% or 90% yields, respectively. Storage with sodium hydroxide during 24 h afforded Tc(VII) in only 6% yield. Hence, nitric acid proved to be the most efficient oxidising agent.

The coprecipitation of Tc(VII) and Re(VII) with FeS belonging to the tetragonal system was studied.¹⁰⁵ In this process, TcO_4^- was reduced to Tc(IV) to give a TcS_2 -like phase.

The separation of technetium from Mo and Ru was achieved by its coprecipitation in the presence of tetraphenylarsonium.⁴¹ It was also demonstrated that technetium(VII) was reduced to Tc(IV) and Tc(V) and coprecipitated with the latter upon contact with $\text{Mn}(\text{OH})_2$, $\text{Co}(\text{OH})_2$ or $\text{Cr}(\text{OH})_3$, which allowed one to separate ⁹⁹Tc from impurities of ¹³⁷Cs.

IV. Methods of determination of technetium

1. Radiometry

Generally, ^{95m}Tc and ^{99m}Tc are detected from their γ -activity.¹⁰⁶ In a number of studies, ⁹⁹Tc was determined from the β -activity on a Packard 2750 TR/LL scintillation counter.^{106–108} A scheme was proposed for the determination of ⁹⁹Tc in natural samples. This scheme involves annealing of a sample at 550 °C and treatment of the residue with solutions of nitric acid followed by extraction of technetium with a 5% solution of tri-*n*-octylamine in xylene. In an aqueous reextract, Tc is concentrated by the anion-exchange method, the concentrate is dissolved in a scintillation cocktail and the ⁹⁹Tc content is determined from its β -activity in the sample.

At low concentrations in natural samples, Tc is isolated with the use of carriers (generally, ^{99m}Tc). The radiometric determination of the initial ⁹⁹Tc is performed only after the complete decay of the carrier within two weeks. The sensitivity of the method is 1.7 Bq kg⁻¹. The sample weight necessary for the determination of Tc is ~10 g.

2. Spectrophotometry

Spectrophotometry is used for the determination of the oxidation state of technetium. Thus, the state of Tc(V) in complicated complex compounds was studied by spectrophotometry.^{109, 110} The spectrophotometric determination of technetium as complexes with thiourea after separation on a strongly basic anion-exchange resin was described in the studies.^{111, 112}

To determine the concentration of technetium in sea water, it is concentrated in aqueous samples by coprecipitation with $\text{Fe}(\text{OH})_3$. After two purification cycles, *viz.*, the extraction and chromatographic purification, Tc is determined in the raffinate by spectrophotometry.¹¹³

A combination of photocalorimetry and potentiometry was used for calculating the thermodynamic characteristics of technetium and its compounds. The heat of formation of Tc_2O_7 was determined ($1115.0 \pm 10.9 \text{ kJ mol}^{-1}$) and the standard oxidation potential of the $\text{TcO}_4^-/\text{TcO}_2$ pair was measured ($-0.782 \pm 0.011 \text{ V}$).³⁸

3. Other methods

The X-ray fluorescence method is used for the detection of technetium in different technological solutions. The sensitivity of serial X-ray fluorescence instruments to Tc is $\sim 2 \text{ mg litre}^{-1}$. The level of sensitivity to technetium is increased to $90 \text{ } \mu\text{g litre}^{-1}$ with the use of a paper backing. However, this leads to an increase in the time of analysis.¹¹⁴

A method for the crystalless X-ray fluorescence determination of technetium was described in the study.¹¹⁴ This method has a substantially lower threshold of sensitivity due to scattering of the exciting radiation in the analysed sample. The sample volume is 3.5 cm^3 . Technetium cannot be detected in the presence of a large amount of plutonium due to overlapping of the peaks of the excited radiation of these elements. In mixtures with uranium, Tc is reliably determined up to the U/Tc concentration ratio of ~ 100 .

The technetium concentrations of an order of several $\mu\text{Bq litre}^{-1}$ are determined by inductively coupled plasma mass spectrometry (ICP-MS).^{115, 116} The concentrations of stable ruthenium in samples are generally much higher than the concentrations of Tc, which hinders the determination of the latter element. Hence, the complete removal of ^{99}Ru as well as of ^{98}Mo and ^{100}Mo is essential for the successful determination of Tc. Initially, technetium is concentrated by chromatography using the TEVATM Spec resin sorbent and then Tc is determined by ICP-MS. The limit of determination of technetium in samples is $0.3 \text{ } \mu\text{Bq g}^{-1}$.^{115, 117}

Electrothermal vaporisation inductively coupled plasma mass spectrometry (ETV-ICP-MS) holds the most promise for determining the Tc concentrations in samples. The main advantage of this method is that ultrasmall volumes of samples ($10\text{--}100 \text{ } \mu\text{l}$) are required for the determination of Tc, which is of particular importance in the analysis of biological objects or high-level radioactive samples. This method allows one to determine technetium without separation of ^{99}Ru . After the addition of modifying agents, such as aqueous solutions of HNO_3 (1%) or NaClO (0.7%), to analysed samples, the limit of determination of Tc is 1.4 pg ml^{-1} (0.9 mBq ml^{-1}) in the presence (which is particularly important) of a more than a thousand-fold excess of Ru.¹¹⁸

The properties of the $\text{Zn}[\text{Tc}(\text{OH})\text{Cl}_3]$ complex were studied by IR and NMR spectroscopy, powder X-ray diffraction analysis, ESR spectroscopy and thermal analysis and it was demonstrated that this compound is paramagnetic and contains Tc in the oxidation state IV.¹¹⁹

A Waters Quanta 4000 capillary electrophoresis system was developed for studying the effect of γ -radiolysis on the oxidation state of technetium in the $\text{K}^{99}\text{TcO}_4$ compound in solutions modelling groundwaters. This system consists of two electrolytic cells joined to a capillary column $75 \text{ } \mu\text{m}$ in diameter and 60 cm long (the potential difference is 30 kV). This method enables one to perform the quantitative separation of $\text{Tc}(\text{VII})$ and $\text{Tc}(\text{IV})$ in solution.^{120, 121}

To establish the crystal structures of pertechnetates with different compositions, the dependence of the quadrupole coupling constant on the temperature in the ^{99}Tc NMR spectra was studied.^{59, 122, 123}

The *in situ* behaviour of technetium in radioactive wastes was investigated by Mössbauer absorption spectroscopy.^{124, 125} This method was also used to establish the correlation between the

observed chemical shifts of technetium in the NMR spectra and its oxidation states. It was noted that the chemical shift of technetium depends on its formal oxidation state.⁶⁴

The state of technetium in a cement matrix, which is used for the isolation of radioactive wastes from the environment, was studied by XAFS Mössbauer absorption spectroscopy. This method not only enables one to determine the oxidation state of Tc in the solid state but also makes it possible to identify the compositions and structures of the resulting technetium-containing compounds. The advantage of this method is that it allows one to determine the element directly without its pre-isolation from the matrix regardless of its crystal structure.¹²⁵

In some cases, the Tc concentrations in natural objects can be estimated from the ^{137}Cs concentrations in the same materials, because these fission products are generated in close yields ($\sim 6\%$) upon uranium fission. Thus, the levels of technetium contamination in the irradiated exclusion zone surrounding the Chernobyl reactor were estimated from the ^{137}Cs concentration.^{126, 127}

V. Behaviour of technetium during reprocessing of spent nuclear fuel

1. Distribution of technetium in the PUREX process

In Russia, spent nuclear fuel is reprocessed with the use of the so-called PUREX process (Fig. 3). This process involves dissolution of irradiated fuel in nitric acid and coextraction of U and Pu with a 30% solution of tributyl phosphate (TBP) in synthetic saturated hydrocarbons followed by reductive reextraction of Pu into an aqueous phase. The process is carried out in a series of mixer-settlers with pulse or mechanical mixing of the phases. Plutonium and uranium are isolated as dioxide and uranyl nitrate, respec-

Figure 3. Scheme of the classical strongly acidic PUREX process; SAA is sulfamic acid and HAN is hydroxylamine nitrate.¹²⁸ Flows of aqueous and organic solutions are indicated by solid and dashed arrows, respectively.

tively.⁹¹ The process can be performed in two structurally identical modifications ('weakly acidic' and 'strongly acidic').¹²⁸

Upon dissolution of spent nuclear fuel in nitric acid, technetium passes into solution as pertechnetate ions. In the first step of extraction of uranium and plutonium under the conditions of the technological scheme used, technetium(VII) goes into the organic phase. In the Japanese modification of the PUREX process, the degree of extraction varies from 30% (see Ref. 129) to 80% (see Refs 111, 114 and 130) depending on the conditions of the extraction process. In the process performed according to the scheme of the RT-1 plant (Mayak Production Association, Russia), the degree of extraction reaches 94%–98%.¹³¹ Due to coextraction of Tc(VII) and U(VI), technetium goes into the organic phase as the $\text{UO}_2(\text{TcO}_4)(\text{NO}_3)(\text{TBP})_2$ complex.¹³² Data on the extraction of technetium into the organic phase depending on the concentration of nitric acid and composition of the aqueous phase are presented in Fig. 4.⁶⁵

Figure 4. Plots of distribution coefficients D of Tc(VII) vs. the HNO_3 concentration and the composition of the aqueous phase upon the extraction with 30% TBP in *n*-dodecane.⁶⁵

(1) 1M $\text{UO}_2(\text{NO}_3)_2$, (2) 1M $\text{UO}_2(\text{NO}_3)_2 + 1\text{M}$ NH_4NO_3 ;
(3) 1M $\text{UO}_2(\text{NO}_3)_2 + 2\text{M}$ NH_4NO_3 .

Technetium forms mixed solvates not only with uranium but also with Pu and Zr.¹²⁹ The calculated distribution coefficients of Tc change in parallel with the experimental values, which indicates that coextraction proceeds by the hydration–solvation mechanism.

Technetium also forms a complex with tributyl phosphate

The stability and structural transformations of the latter complex were described in the study.¹³³

In the second step of the extraction process, plutonium and uranium are separated from each other. For this purpose, plutonium is subjected to reductive reextraction, generally, with U(IV) or Fe(II) in the presence of hydrazine. This process affords Pu(III), which goes into the aqueous phase, while uranium(VI) remains in the organic phase. In this step, it is very important to choose adequate conditions for stabilisation of U(IV) and Pu(III) in the presence of technetium in the organic phase and, consequently, to calculate the required amount of the reducing agent.^{133, 134}

If an aqueous solution of U(IV) is used as the reducing agent, Tc is partially reextracted together with Pu into the aqueous phase and partially remains in the organic phase. The Tc(VII) ions have a strong effect on the stability of low-valence forms of uranium and plutonium in media of nitric acid.

The TcO_4^- anions oxidise U(IV).

The Tc(VII) ions oxidise Pu(III) according to a reaction, whose rate is described by the following equation:

$$-\frac{d[\text{Pu(III)}]}{d\tau} = k [\text{Pu(III)}] [\text{Tc(VII)}] [\text{H}^+]^{2.3},$$

where $k = (3.82 \pm 0.11) \times 10^{-2} \text{ litre}^{3.3} \text{ mol}^{-3.3} \text{ at } 50^\circ\text{C}$ and $\mu = 4$.¹³⁵

In addition, the technetium(VII) ions catalyse oxidation of Pu^{3+} with nitric acid according to a reaction described by a first-order equation with respect to both Pu(III) and Tc(VII).¹³⁶

This reaction proceeds also in the presence of hydrazine nitrate ($\sim 0.1 \text{ mol litre}^{-1}$). It was demonstrated that Tc(VII) serves as the catalyst also for oxidation of U(IV) with nitric acid.^{133, 134}

Technetium(VII) ions have been proved to catalyse the decomposition of hydrazine used for stabilisation of Pu(III) and U(IV) in the course of the technological process.^{134, 137} In solutions, technetium(VII) is successively reduced with hydrazine to Tc(V) and Tc(IV), which are again oxidised with nitric acid to the initial state.¹³⁸

In this process, the concentration of Tc(VII) remains constant, while hydrazine is completely consumed.

For decomposition of hydrazine in the presence of Tc(VII) ions at concentrations of 0.4×10^{-2} , 1.0×10^{-2} and $2.0 \times 10^{-2} \text{ mol litre}^{-1}$, the apparent zero-order rate constants k_0 are 0.0140, 0.0415 and $0.0800 \text{ h}^{-1} \text{ litre}^2 \text{ mol}^{-1}$, respectively, and the formal rate constants $k_c = k_0/[\text{Tc(VII)}]$ are 3.5, 4.1 and $4.0 \text{ h}^{-1} \text{ litre}^2 \text{ mol}^{-1}$, respectively.

The reaction is zero order with respect to hydrazine and first order with respect to technetium, which indicates that oxidation of Tc is, most likely, the rate-determining step of this process.

The rate of Tc oxidation sharply increases with time, and the process becomes autocatalytic. The autocatalytic mechanism assumes that certain products, which accelerate oxidation of hydrazine, are accumulated in the course of the reaction. Apparently, intermediate forms, *viz.*, Tc(V) and Tc(VI), serve as such products. A mathematical model was considered and kinetic calculations were performed for oxidation of hydrazine in solutions of nitric acid catalysed by technetium ions.¹³⁹

Apparently, the above-mentioned reactions proceeding in a heterogeneous system exert an effect on the completeness of reductive reextraction of plutonium by uranium(IV).

If Fe(II) is used as a reducing agent in the step of reextraction of plutonium(III), Tc is virtually completely reextracted together with Pu into the aqueous phase. The concentration of the reducing agent has a substantial effect on the extraction ability of technetium. For example, the yield of the extracted forms of Tc decreases from 28% to 6% as the concentration of Fe(II) increases from 0 to $0.1 \text{ mol litre}^{-1}$, respectively. Under these conditions, technetium is virtually not retained in the uranium-containing organic phase. In the next step of purification of plutonium extracted, Tc passes into aqueous medium-level radioactive wastes, from which Tc can be quantitatively extracted. Thus, from 94% to 98% of Tc is separated in the step of plutonium refining involved in the technology which is employed at the RT-1 plant.¹³¹

It should be noted that the PUREX process has been initially developed and used instead of the REDOX process for reprocessing of irradiated uranium metal produced for military purposes. The drawback of the REDOX process was accumulation of large quantities of high-salt wastes, which cannot be subjected to reprocessing and utilisation. The aims and problems of reprocessing changed substantially when spent nuclear fuel from nuclear power stations appeared. At nuclear power stations, spent nuclear fuel burns up to a substantial degree (from 0.5–1 to 40–100 GW days t^{-1}).¹²⁸ An increase in the degree of burn-up complicates the extraction and separation of components with the

use of TBP solutions. In the course of the extraction reprocessing of spent nuclear fuel from nuclear power stations, the behaviour of Tc (and Np) in the extraction and redox processes is of importance. Hence, the necessity of achieving the completeness of separation of actinides extracted in the presence of technetium dictates both the modern technological schemes of reprocessing of spent nuclear fuel from nuclear power stations and trends in their development.

The elaboration of the modified PUREX process that met this requirement gave rise to different technological schemes both in Russia and abroad. One of the main aims is to separate and concentrate technetium in a single flux. Of new technologies, noteworthy is a process providing the complete extraction of U, Pu, Tc and the major portion of Np, while Zr passes into a high-level radioactive raffinate due to extensive washing of the extractant.^{140, 141} The characteristic feature of this scheme is the involvement of the step of pre-reextraction of Tc with strong acid, in which 80%–85% of Tc is removed. This makes it possible to perform reductive reextraction of plutonium under the conditions of complete removal of Np together with U followed by their separation in the uranium cycle II.

The technological scheme employed at the RT-2 plant (Russia) holds promise.^{142–144} This scheme involves the coextraction of U, Np, Pu, Tc and Zr with TBP solutions as the first step, reextraction of Zr (with a portion of Np and Tc), reextraction of Pu and Np with strong acid (Tc remains in the organic phase together with uranium), reductive separation of Pu and Np with the use of U(IV) in the cycle I, reextraction of Np and Tc into a single flux using a salt-free complex-forming agent, *viz.*, acetohydroxamic acid (AHA), followed by reextraction of uranium. This is the first scheme of such a type. However, this scheme has some drawbacks, because it is rather cumbersome and has a large number of links within the cycle.

Further progress in these investigations was achieved in the study,¹⁴⁵ in which the authors proposed that the coextraction of U, Pu, Np and Tc with dilute TBP should be followed by reductive reextraction of Np and Tc with *n*-butanol and separation of Pu and U.

However, actual success was achieved only in the SuperPUREX scheme^{128, 146} (Fig. 5) involving the extraction of U, Pu, Np and Tc as well as Zr followed by reextraction of Zr together with Tc and Np under the action of hydrazine at the corresponding concentration of HNO₃. This scheme allows one to perform any modification of isolation of uranium and plutonium, *viz.*, either their deep separation and purification within a one-cycle scheme or their simultaneous reextraction in the course of processing of plutonium – uranium fuel for fast-neutron reactors.

It should be noted that the extraction of Zr together with Tc and Np provides the basis for their subsequent incorporation into matrices for radioactive waste immobilisation.¹²⁸

With the aim of intensifying the extraction reprocessing of spent nuclear fuel, scientists are looking into the possibility of using equipment with a high specific output, *viz.*, centrifugal extractors and vibrating columns, in the key operations of fuel reprocessing.

Thus, some aspects of the behaviour of U, Tc and Zr in the extraction of uranium from solutions in nitric acid with 30% TBP solutions in *n*-alkanes were examined on a column-type vibrating extractor. It was demonstrated that the uranium front was shifted to the middle part of the column in the presence of zirconium and the concentration of uranium in the raffinate increased. It was hypothesised that the hydrodynamics of the process in extractors of this type are impaired due to formation of a structure-mechanical barrier on the drop surface and retardation of coalescence. The behaviour of Tc in this process is adequately described by the mechanism of coextraction with uranium and zirconium and by the hydration–solvation mechanism. The degree of Tc extraction was ~80%. The use of hydrogen peroxide in this process leads to a decrease in the degree of Tc extraction

Figure 5. Scheme of the cycle I of reprocessing of spent nuclear fuel from nuclear power stations in the SuperPUREX process.¹²⁸

and reduces the influence of zirconium on the uranium extraction.¹¹¹

2. Isolation of technetium during fractionation of radiochemical wastes

All countries that develop their civil nuclear industry face the problem of fractionation of high-level radioactive wastes and separation of long-lived radionuclides. Many procedures were proposed for the extraction fractionation of wastes. Since most of the technologies developed in the last decade have been oriented primarily toward the deep separation of transuranium elements, not all processes of extraction fractionation of high-level radioactive wastes involve the step of separation of the technetium fraction. In this connection, studies of the behaviour of technetium in methods developed for the fractionation of high-level radioactive wastes are of interest.

a. Partitioning of high-level radioactive wastes using organophosphorus acids

The most well-known process of fractionation of high-level radioactive wastes involving organophosphorus acids is the technology developed at the Japan Atomic Energy Research Institute. This technology is based on the use of diisodecylphosphoric acid [(iso-C₁₀H₂₃O)P(O)OH, DIDPA] as the extractant.

This extractant is an analogue of the widely known di-2-ethylhexylphosphoric acid (D2EHPA), but it allows one to perform the process in more acidic media.

The recent version of the technological process with the use of DIDPA,¹⁴⁷ whose development was started 24 years ago, provides a way of separating the following fractions from radioactive wastes: transuranium elements (TUE); ⁹⁹Tc + platinum metals (PM); ¹³⁷Cs + ⁹⁰Sr and the remaining radionuclides.

This process involves the step of the preliminary correction of the composition of high-level radioactive wastes in the course of which the concentration of nitric acid is decreased from 2–3 mol litre⁻¹ to 0.5 mol litre⁻¹ by denitration with formic acid. This makes it possible to extract tervalent transplutonium elements (TPE). Then actinides and lanthanides are extracted with a mixture of DIDPA and TBP in *n*-dodecane. Hydrogen peroxide is added to a solution to improve the extraction of neptunium. Fission and stable elements, including technetium, platinum metals, caesium and strontium, remain primarily in the raffinate. Americium, curium and lanthanides are reextracted from the organic phase with nitric acid (4 mol litre⁻¹). Plutonium and neptunium are reextracted with oxalic acid. Uranium is extracted with sodium carbonate. The acidity of the reextract containing Am, Cm and lanthanides is again decreased from 4 mol litre⁻¹ to 0.5 mol litre⁻¹ by denitration and then these elements are extracted with a mixture of DIDPA and TBP in *n*-dodecane. Americium and curium are washed away with a mixture of diethylenetriaminepentaacetic acid (DTPA) and lactic acid. Lanthanides are washed away with nitric acid. In another modification, U and Pu are extracted with tributyl phosphate in the early step of the process and then the acidity is decreased. Then Am and Cm are extracted as described above followed by separation of lanthanides and TPE involving the reextraction of the latter with a mixture of DTPA and lactic acid. The extraction scheme is supplemented by the extraction of ⁹⁹Tc and platinum metals from the first raffinate after the extraction of all TUE by sorption on a column with activated carbon and subsequent extraction of strontium-90 and caesium-137 by inorganic ion-exchange resins (titanic acid and zeolite, respectively). The extraction affords 99.99% of Am, Cm, Pu and U and 99.95% of Np. After sorption, 99.90% of technetium and more than 99.9% of Cs and Sr are extracted. The overall volume of four fractions is 3.3 times smaller than the volume of vitrified wastes without partitioning.^{148, 149}

In the technological CTH process developed in Sweden,^{150, 151} D2EHPA is used and another way of decreasing the solution acidity is employed. Initially, U, Pu, Np and major portions of Zr, Nb, Mo and Fe are extracted with a solution of D2EHPA in a hydrocarbon diluent from a solution of high-level radioactive wastes pre-acidified to the HNO₃ concentration of 6 mol litre⁻¹. The organic phase is washed with a solution of a mixture of HNO₃ and HF to remove Zr and Nb. Then actinides are removed by ammonium carbonate. The reextract is concentrated and acidified. Then U, Pu and Np are extracted. The acidity of the first raffinate is decreased from 6 to 0.1 mol litre⁻¹ by removing nitric acid with the use of a solution of TBP in the same diluent, Pd, Ru and Tc being removed together with nitric acid. The latter elements are extracted by the ion-exchange method. Thereafter Am, Cm and lanthanides are extracted with a solution of D2EHPA followed by their reextraction with a solution of nitric acid with a rather high concentration. Caesium and strontium are isolated from the raffinate by sorption on inorganic ion-exchange resins. There is also a modification of the process, in which americium and curium are washed away by a mixture of DTPA and lactic acid, while lanthanides are washed away by nitric acid. When this scheme was tested on real high-level radioactive wastes, the factors of purification from α - and β -emitters were $\sim 10^5$ and $\sim 3 \times 10^4$, respectively.

With the aim of excluding the steps of denitration and neutralisation of a raffinate, which are involved in the two above-described processes to decrease the acidity of the high-level radioactive raffinate, a technological scheme was proposed¹⁵² for reprocessing of high-level radioactive wastes with the use of *n*-alkyl phenylphosphonic acids [PhP(O)(OH)OR, where R = *n*-C₈H₁₇–C₁₀H₂₁, (APPA)] and their zirconium salts.

The latter scheme includes two cycles. In the first of them, transplutonium and rare-earth elements are extracted from high-level radioactive wastes containing nitric acid at a concentration of 2 mol litre⁻¹ with a solution of APPA (0.9 mol litre⁻¹) in the RED-1 diluent (preferentially, 0.5 mol litre⁻¹). Transplutonium

elements are reextracted with a solution of DTPA in lactic acid. Rare-earth elements are reextracted with HNO₃ (3–5 mol litre⁻¹). In the second cycle, ⁹⁰Sr and Ca are extracted from solutions of nitric acid with a concentration of 0.1 mol litre⁻¹ by zirconium salt of APPA. It is known that zirconium improves the extraction of metals by alkylphosphonic acids.¹⁵³ Reextraction of ⁹⁰Sr and Ca is carried out using HNO₃ solutions (3–4 and 7 mol litre⁻¹, respectively). Data on the behaviour of molybdenum are lacking in the literature.

The use of APPA instead of D2EHPA made it possible to prevent the precipitation in the organic phase in the course of extraction of iron.

b. Partitioning of high-level radioactive wastes by neutral organophosphorus compounds

Mono- and bidentate neutral organophosphorus compounds (MNOPC and BNOPC, respectively) allow one to extract a series of long-lived radionuclides, including actinides and technetium, from acidic high-level radioactive wastes.

Phosphine oxide bearing different substituents [R¹R²R³P(O), PODS], where R¹, R² and R³ are the C₆H₁₃–C₉H₁₉ alkyl groups, is one of the most efficient MNOPC.

The technological scheme, which has been developed in China^{154, 155} and Germany¹⁵⁶ and tested on real high-level radioactive wastes, provides a way of extracting actinides from high-level radioactive wastes in quantitative yields (99.9%) using solutions of PODS in kerosene. Solutions of high-level radioactive wastes containing nitric acid at concentrations, generally, higher than 2.5 mol litre⁻¹, should be pre-neutralised to a concentration of no higher than 1 mol litre⁻¹. To achieve the complete extraction of neptunium, Np(V) is electrochemically oxidised to Np(IV). Technetium is extracted together with actinides and lanthanides (and also partially, with Zr and Mo), which are selectively washed away from the organic phase. Thus, Am, Cm and lanthanides are washed away with HNO₃ (5.5 mol litre⁻¹), Pu and Np (together with Zr and Mo) are washed away with oxalic acid and U (together with Tc) is washed away with sodium carbonate. The overall purification from α -emitters is $> 10^3$. Different modifications of this process have also been developed in Russia. The advantages of this method are low prices of the reagents and diluent and the possibility of the efficient extraction of Tc along with actinides.

The use of bidentate neutral organophosphorus compounds for the extraction of long-lived radionuclides, *viz.*, actinides and technetium, makes it possible to eliminate the main drawbacks of the above-described processes involving alkylphosphoric acids and monodentate neutral organophosphorus compounds, among which are the necessity of performing neutralisation of high-level radioactive wastes before the extraction of actinides and the use of solutions of nitric acid for reextraction of TPE from the organic phase. Bidentate neutral organophosphorus compounds extract actinides from acidic solutions, and TPE are reextracted with dilute solutions of nitric acid. The so-called TRUEX process developed at the Aragon National Laboratory (USA) is based on one of BNOPC, *viz.*, octylphenyl(*N,N*-diisobutylcarbamoylmethyl)phosphine oxide (C₈H₁₇)PhP(O)CH₂C(O)NBu₂ (OctPhBu₂).¹⁵⁷ Different versions of this process involving the same reagent were also developed in other countries, primarily in Japan and India.^{158, 159} Another BNOPC, *viz.*, diphenyl(*N,N*-di-*n*-butylcarbamoylmethyl)phosphine oxide (Ph₂Bu₂), is also often used in this process.

In the TRUEX process, solutions of OctPhBu₂ (0.2 mol litre⁻¹) in a mixture with TBP (1.0–1.4 mol litre⁻¹) in saturated hydrocarbons are used for the extraction of actinides and lanthanides from high-level radioactive wastes containing nitric acid at a concentration of 0.7–5 mol litre⁻¹ to which a complex-forming compound (most often, oxalic acid) is added to suppress the extraction of zirconium. After washing of the extract with a solution of a mixture of nitric acid with either aluminium nitrate or oxalic acid, transplutonium elements and lanthanides are

reextracted by dilute solutions of nitric acid. Thereafter plutonium and neptunium are extracted with a solution of ammonium carbonate or a mixture of dilute nitric acid with HF or oxalic acid. If high-level radioactive wastes contain uranium, the latter is washed away by a solution of sodium carbonate (together with Tc). The factor of purification of high-level radioactive wastes from actinides is $> 10^3$. Japanese researchers plan to improve this process with the aim of separating lanthanides and transplutonium elements by selective reextraction of the latter by a DTPA– NaNO_3 mixture.¹⁶⁰

In the Russian version of the TRUEX process developed at the Mayak Production Association, the V I Vernadsky Institute of Geochemistry and Analytical Chemistry of the Russian Academy of Sciences and the V G Khlopin Radium Institute, polar diluents are used. This makes it possible to do away with the addition of TBP and to use cheaper diphenyl(*N,N*-di-*n*-butylcarbamoylmethyl)phosphine oxide.¹⁶¹ Investigations demonstrated that Ph_2Bu_2 in polar diluents possesses higher extracting ability with respect to actinides and lanthanides than that in a mixture of hydrocarbons with TBP. The higher distribution coefficients are observed throughout the concentration range of nitric acid from 0.01 to 10 mol litre⁻¹.

The U.S. version of the TRUEX process was used for reprocessing of real wastes of different origin and with different compositions, *viz.*, wastes of analytical laboratories, wastes from reprocessing of zirconium jackets that hold the fuel rods as well as wastes from the PUREX process employed at the plutonium production plants at the Hanford Site (USA).¹⁵⁷ The Russian version of the TRUEX process was tested at the Mayak Production Association under both dynamic and static conditions with the use of simulators and real solutions of raffinates from the PUREX process and high-level radioactive wastes.¹⁶¹

c. Partitioning of high-level radioactive wastes by solutions of diamides

The process of extraction of actinides from high-level radioactive wastes by diamides of the general formula $[\text{R}^1\text{R}^2\text{NHC(O)}]_2\text{CHR}^3$, where R^1 , R^2 and R^3 are alkyl substituents, is called the DIAMEX process. Di-*n*-butyl-*N,N'*-dimethyl-*N,N'*-1,2-tetradecylmalonamide was proposed and used in France.^{162,163} The extraction properties of diamides are similar to those of bidentate neutral organophosphorus compounds, in particular, of OctPhBu_2^1 , used in the TRUEX process.

Actinides(III, IV, VI) together with lanthanides are extracted from solutions of high-level radioactive wastes containing nitric acid at concentrations of 3–5 mol litre⁻¹ to which oxomalonic acid and hydrogen peroxide are added to suppress the extraction of zirconium and molybdenum. After washing of the organic phase, actinides together with lanthanides are reextracted with a solution of nitric acid (0.5 mol litre⁻¹) and a solution of potassium nitrate (0.01 mol litre⁻¹). In addition to the DIAMEX process, a technological scheme was developed for the separation of actinides and lanthanides from dilute HNO_3 solutions by solutions of 2,6-bis(1,2,4-triazin-3-yl)pyridine with saturated hydrocarbons and octanol. This process has advantages over the known TALSPEAK and TRAMEX processes (USA) used for the separation of actinides and lanthanides, because it does not require the strict maintenance of pH and the use of salts, whereas the extraction equilibrium is rapidly reached.

d. Extraction of technetium from high-level radioactive wastes

In the best-developed procedures for the extraction of actinides from high-level radioactive wastes, no provision was made for separating fractions of other hazardous long-lived radionuclides (^{99}Tc , ^{90}Sr , ^{137}Cs and ^{129}I) within the framework of a single technological extraction scheme.

In the course of reprocessing of fuel from early Russian fast-neutron reactors, uranium was regenerated by sublimation followed by separation of fluorinated fission products by sorption with the use of fluorine condensers and columns with NaF.

Technetium was trapped by a lime absorber, thus being separated from virtually all fission products.⁷ Later on, a Russian technology was developed for the extraction of technetium from wastes from nuclear fuel reprocessing based on sorption of technetium on the AV-17 anion-exchange resin from a solution pre-neutralised to pH 7–9. The factor of purification from the fission products was $\sim 2 \times 10^2$. After desorption with concentrated nitric acid and neutralisation of the eluate, technetium was extracted with acetone. Further purification was carried out by precipitation of technetium as poorly soluble Tc_2S_7 and tetraphenylarsonium pertechnetate and their annealing under a stream of hydrogen to reduce these compounds to metal.¹⁶⁴

In recent years, the PUREX process was supplemented by a scheme of the deep recovery of technetium and neptunium in the course of extraction by tributyl phosphate together with uranium and plutonium followed by their separation and combination with the TPE + REM fraction isolated from the raffinate of the first cycle.¹⁶⁵

The so-called PARK process (Partitioning Conundrum Key),¹⁶⁶ which is another improved version of the PUREX process, was developed at the Japan Atomic Energy Research Institute. This scheme provides the extraction of neptunium and technetium (together with uranium and plutonium), which are subsequently separated from uranium and plutonium by two successive reextractions by a reducing agent, *viz.*, butyraldehyde, and concentrated nitric acid. In the PARK process, iodine is also removed by distillation and sorption concentration.

3. Methods for utilisation and disposal of technetium

Being a long-lived radionuclide, technetium-99 released from nuclear power stations must be extracted and reliably isolated from the biosphere. For this purpose, either the so-called transmutation of Tc, *i.e.*, the transformation of Tc into stable isotopes, is performed or Tc is incorporated into the corresponding matrices, which provides reliable isolation for thousands of years until Tc completely decays.

a. Transmutation of technetium

In full measure, technetium can be rendered harmless only by transmutation into stable nuclides under neutron irradiation. Since the ^{99}Tc nucleus has high neutron-capture cross-sections in the thermal and, particularly, epithermal energy ranges (main resonance peaks are in the range of 2–20 eV), thermal reactors, which generally have a sufficient spectral hardness ($\gamma = 0.3 \pm 0.1$), hold promise for burning this radionuclide.¹⁶⁷ In the above-mentioned neutron energy range, the process is described by the following scheme:

The contribution of other nuclear reactions is virtually insignificant. The dynamics of transmutation of the ^{99}Tc point target at $\gamma = 0.3$ is shown in Fig. 6.

The ^{100}Ru , ^{101}Ru and ^{102}Ru isotopes are stable. The ^{103}Ru isotope has a half-life of 39.3 days and decays to stable ^{103}Rh . Consequently, after the extraction of non-burned Tc from the irradiated technetium target, the product occurs as stable ruthenium with impurities of rhodium and palladium.¹⁹

It is presently assumed that technetium metal or its carbide TcC , which are rather stable at high temperatures in the absence of oxygen, are the forms of Tc most probable for transmutation. Graphite, potassium hydride, D_2O , *etc.* were proposed as neutron moderators.¹⁶⁷

In most cases, calculations of the transmutation of long-lived nuclides in modern reactors are based on the assumption that these reactors provide the conditions for the formation of an appropriate neutron spectrum and/or for an increase in the neutron flux density. Calculations of the transmutation of ^{99}Tc in light-water, thermal-water and fast reactors demonstrated that

Figure 6. Dynamics of transmutation of ^{99}Tc upon thermal neutron irradiation with the spectrum hardness $\gamma = 0.3$.¹⁶⁷
(1) ^{99}Tc , (2) ^{100}Ru , (3) ^{101}Ru , (4) ^{102}Ru , (5) impurities.

this problem cannot be solved in light-water reactors. In thermal-water and fast reactors (neutron moderation), the half-life of ^{99}Tc burning varies in the range of 15–25 years at loadings of 2.5–4.0 t and the rate of transmutation of technetium of 100–140 kg year⁻¹. Simultaneously, ~20 kg of ruthenium are produced per year.¹⁶⁸ These half-lives of burning are close to half of the service life of the reactor. In addition to technetium, it is also planned to burn a series of other radionuclides, including neptunium, americium and other actinides. Energy reactors are of no use for solving this problem of transmutation. This was confirmed by irradiation of a technetium target for 193 days on the HFR research reactor in the Netherlands under conditions more favourable than those provided in a fast-neutron nuclear reactor without substantial construction changes. Irradiation of a technetium target with the use of the total neutron fluence of $1.5 \times 10^{22} \text{ cm}^{-2}$ and thermal component of $2.5 \times 10^{21} \text{ cm}^{-2}$ led to the burn-up of only ~5% of ^{99}Tc .¹⁶⁹

Hence, it is necessary to design special fast-flux transmutation systems providing a high rate of transmutation of technetium into stable nuclei to burn-up ^{99}Tc . In the experiments carried out at the Scientific Research Institute of Atomic Reactors (Dimitrovgrad, Russia) on an SM-3 experimental reactor, a much higher degree of technetium burning was achieved (under particular conditions, up to 15%).¹⁷⁰

Apparently, the full-scale solution of the problem of ^{99}Tc burning should involve one of the modes of transmutation of early actinides using their irradiation with thermal neutron fluxes with the density of $10^{15} - 10^{16} \text{ cm}^{-2} \text{ s}^{-1}$.¹⁷¹ In the Accelerator-Driven Transmutation of Waste (ATW) Programme (USA) and the ACTINEX Subprogramme of the SPIN Programme of the French National Agency for Radioactive Waste Management,¹⁷² the possibility of the simultaneous burning of minor actinides and ^{99}Tc as well as of some other nuclides was considered.^{173, 174} The transmutation of ^{99}Tc not only makes it possible to convert it into the safe form but also serves as a source of the valuable metal of the platinum group, *viz.*, stable ruthenium, which is used in the electronics and electrotechnical industry (the price of ruthenium is ~\$10 per gramme).¹⁷⁵ The total reserves of ruthenium in ores are estimated at ~3100 t, whereas the world demand for this element is about 7.4 t per year and is close to the rate of accumulation of ^{99}Tc in nuclear power engineering.¹⁷⁶

b. Incorporation of technetium into solid matrices

One of the procedures for isolating technetium from the biosphere is based on its cementation to form matrices stable on storage.

These studies were carried out at the Savannah River Site (USA).¹²⁵ It appeared that technetium-containing cement matrices are unstable upon storage because they include Tc as pertechnetate ions readily soluble in water. Hence, cementation of technetium-containing high-level radioactive wastes requires the transformation of technetium into a water-insoluble form, for example, into TcO_2 . Either an ash or additives of FeS or Na_2S can be used as reducing agents. These reagents reduce pertechnetate to a stable form with equal ease. However, it was believed¹²⁵ that only partial reduction of Tc(VII) to Tc(IV) could be achieved with the use of these reagents. Hence, this process is not sufficiently efficient.

Incorporation of technetium into a cement-like matrix, such as bentonite, also does not lead to stabilisation of Tc. For example, up to 40% of technetium is leached when the matrix is exposed to water during 20 days. Thereafter, the rate of leaching decreases due, apparently, to the formation of a new mineral phase involving technetium.^{173, 177} It is believed that cement based on Al oxides without bentonite is more stable than a mixed cement.¹⁷³ The best results were obtained with the use of cement annealed in a furnace. However, all the above-mentioned materials appeared to be unstable, as a result of which cementation methods were rejected. Hence, the examination of new ceramic, mineral-like or other matrices for reliable disposal of technetium remains an urgent problem.

VI. Behaviour of technetium in environmental objects

1. Main sources of the release of technetium into the environment

Problems associated with the control of the behaviour of technetium in the environment are becoming increasingly important.^{178, 179} The ^{99}Tc isotope has accumulated in the geosphere since the 1950s. This isotope is one of the long-lived radionuclides released into the environment (along with ^{14}C and ^{129}I).

The main sources of the release of Tc into the environment are nuclear weapons testing (180 TBq), wastes from nuclear power stations (4 GBq), atmospheric fallout after the Chernobyl accident (0.75 TBq) and wastes from nuclear fuel processing plants.^{180–182} One more source of the release of technetium into the environment to the use of $^{99\text{m}}\text{Tc}$ in medicine, the scale of which will increase.¹⁸³

The world annual accumulation of Tc from nuclear power station operation is about 6 t, and ~60 t of Tc have already been produced.¹ An increase in the degree of burn-out of nuclear fuel will lead to further accumulation of technetium. Hence, one would expect that the contribution of technetium to the population radiation dose will be substantially increased with the development of nuclear power engineering. For example, the level of ^{99}Tc contamination of forest soil in the 30-km zone around the Chernobyl reactor is ~1.1–14.1 Bq kg⁻¹.^{184–187}

2. Forms of the existence of technetium in environmental objects

Forms of the existence of technetium in a multicomponent system of the geological medium depend primarily on the following factors: the redox potential (E_h) and pH of the system, interactions with inorganic compounds, the influence of organic complex-forming agents and microorganism action.

The redox conditions in the geological medium are responsible for stabilisation of technetium in particular oxidation states and forms of its occurrence. The $\text{Fe}^{2+} - \text{e}^- = \text{Fe}^{3+}$ ($E^\circ = 0.77 \text{ V}$) and $\text{O}_2 + 4\text{e}^- + 2\text{H}_2\text{O} = 4\text{OH}^-$ ($E^\circ = 0.401 \text{ V}$) pairs are the main potential-forming pairs having influence on the redox behaviour of technetium in environmental objects.

Iron is involved in many rock-forming minerals. In the areas with a low water exchange or under anaerobic conditions, iron is stabilised as Fe(II) . The reduced form of iron loses stability when exposed to atmospheric oxygen (aerobic conditions) dissolved in

groundwaters in the zone of active water exchange and stabilises in the Fe(III) state.

The formal oxidation potential of the pair

is higher than 0.8 V.^{101, 188} In the zone of a low water exchange and in its absence, TcO_4^- can be reduced to Tc(IV) in groundwaters according to the reaction

Electrophoresis measurements and atomic absorption spectroscopy revealed the presence of the following forms of Tc(IV) under reducing conditions and at alkaline pH: TcO^{2+} , $\text{TcO}(\text{OH})^+$, $\text{TcO}(\text{OH})_2$, $\text{TcO}_2 \cdot 2\text{H}_2\text{O}$ and $\text{TcO}_2 \cdot n\text{H}_2\text{O}$ (Fig. 7). These forms of technetium would be expected to undergo hydrolytic adsorption or co-precipitation on Fe(III) hydroxide to give complexes with Fe—O—Tc bonds.^{189, 190}

Under aerobic conditions, Tc(IV), occurring in the form of TcO_2 in aqueous solutions, is oxidised by atmospheric oxygen to Tc(VII) with a rate of ~ 1 mass % during two months followed by

Figure 7. Forms of the existence of technetium in an aqueous solution depending on E_h and pH.⁶⁵

Figure 8. Effect of E_h and pH on the redox equilibrium $\text{Tc(VII)} \rightleftharpoons \text{Tc(IV)}$ in a rock–water system. Samples of argillaceous slates or clays (Conasauga, USA) (1–3); granites: Westerly granite, USA (4, 7); Climax Stock granite, USA (6); Sentinel Gap basalts, USA (5, 8).¹⁹¹

dissolution of the precipitate.⁶⁵ The resulting pertechnetate ions are quite stable under aerobic acidic, neutral or alkaline conditions.

The data from the E_h –pH diagram are widely used for the prediction of the sorption behaviour of Tc in environmental objects. By way of example, let us consider the results of the determination of the Tc(VII)–Tc(IV) redox equilibrium, which depends on E_h and pH and was calculated taking into account the maximum allowable (in USA) concentration of technetium in drinking water ($0.3 \mu\text{Ci litre}^{-1}$)^{191, 192} (Fig. 8). Under real geological conditions, Tc in groundwaters is stabilised in the tetravalent state and is sorbed onto different granites (New Hampshire, USA) and basalts (Mattawan, USA). By contrast, technetium in argillaceous slates or clays (Catasauqua, USA) occurs as pertechnetate ions and is not sorbed onto soils.

Data on the complex formation of technetium with inorganic and organic ligands are of great interest.

a. Sulfide ions

In addition to $\text{TcO}_2 \cdot n\text{H}_2\text{O}$, other stable technetium compounds, for example, Tc sulfides, can also be sorbed onto soil (Fig. 9). Technetium(IV) sulfide TcS_2 is precipitated by hydrogen sulfide generated upon plant degradation. Natural sulfur-containing organic compounds serve as another source of sulfide ions in water-saturated soil.^{183, 193}

Figure 9. Behaviour of Tc in the Tc–S–OH system, 25 °C, ~ 1 atm (thermodynamic data).¹⁹³

Technetium(IV) sulfide is also formed upon reductive precipitation of the TcO_4^- ions onto the FeS surface in a rock layer. The structures of the mixed FeS–Tc(VII) and FeS–Tc(IV) compounds were studied by EXAFS spectroscopy and it was found that technetium is present as an individual phase structurally similar to TcS_2 rather than being incorporated into the FeS phase.^{191, 194}

The reaction of the TcO_4^- and S^{2-} ions in a solution of Na_2S afforded technetium(VII) sulfide Tc_2S_7 , the type of the precipitate being dependent on the concentration of sodium sulfide. If the concentration of $\text{Na}_2\text{S} > 0.33 \text{ mol litre}^{-1}$, large precipitate particles form spontaneously. At lower concentrations of sodium sulfide, a suspension of colloidal Tc_2S_7 is produced, the formation of the suspension being completed within ~ 3 days.¹⁹⁵ The solubility of Tc_2S_7 in water is $0.257 \text{ g litre}^{-1}$.⁹⁰

b. Carbonate ions

Only in carbonates (unlike many other aqueous media), internal γ -irradiation of Tc(VII) samples does not lead to its self-reduction to Tc(IV). The possible reoxidation of Tc(IV) to Tc(VII) is accounted for by the fact that radiolysis in solution affords $\text{CO}_3^\cdot$ radicals, which can transform technetium into the heptavalent state.^{23, 121}

c. Humic acids

It is assumed that technetium in deep beds of groundwater occurs primarily in complexes with humic acids (Tc–HA). Their percentage was estimated at ~50–70% (Fig. 10).^{196–199}

Figure 10. Different forms of the existence of ^{95m}Tc depending on the initial concentration of humic acids $[\text{HA}]_0$ at $[\text{Sn}^{2+}] = 10^{-5}$ mol litre $^{-1}$.¹⁹⁶

The indices 'p' and 'l' correspond to the precipitate and mother liquor, respectively.

The compositions of the complexes depend on the pH of the solution, concentration of humic acids, salt background and the presence of reducing agents. Under aerobic conditions, the Tc–HA complexes in solutions of pH 9–11 occur as poorly soluble precipitates. An increase in the salt background leads to suppression of Tc sorption on minerals. The presence of reducing agents [hydrazine and Fe(II)] gives rise to readily sorbable forms and a precipitate of hydrated TcO_2 .¹⁹⁶

Finally, microorganisms also have an effect on the forms of the existence of Tc in environmental objects. Microorganisms absorb oxygen dissolved in water and shift the redox equilibrium in the system to small E_h .^{200, 201}

3. Sorption of technetium on natural materials

In studies of the sorption of technetium by natural systems, the following three types of processes should be taken into account: sorption on the outer surface of solid particles, sorption on porous particles and irreversible precipitation or coprecipitation.²⁰²

Under aerobic conditions, sorption of technetium by natural minerals is low. At pH 6, the distribution coefficients $K_d^{\text{Tc(VII)}}$ were determined for sandstone ($2.57 \text{ cm}^3 \text{ g}^{-1}$), peat ($1.89 \text{ cm}^3 \text{ g}^{-1}$), feldspar ($1.66 \text{ cm}^3 \text{ g}^{-1}$), phosphorite ($1.05 \text{ cm}^3 \text{ g}^{-1}$), bauxite, basalt ($0.98\text{--}1.01 \text{ cm}^3 \text{ g}^{-1}$) and pyrite ($0.32 \text{ cm}^3 \text{ g}^{-1}$).⁹⁰ At pH 5.8–7.4, the coefficients of sorption of Tc on minerals decrease by a factor of $\sim 10^4$ as E_h in solution increases from 180 to 220 mV (Fig. 11).^{65, 203–205}

It is assumed that technetium occurs as the TcO_4^- anions, which are poorly adsorbed on different rocks, in aerated solutions with high E_h . This assumption was supported by studies of the extraction of technetium by tetraphenylarsonium chloride. It was also demonstrated that colloidal particles of Tc do not occur in solution, which was confirmed by ultrafiltration of solutions.^{65, 189, 204}

It is known that $K_d^{\text{Tc(VII)}}$ is proportional to the initial concentration of TcO_4^- and depends only slightly on the specific surface of the sample. Hence, it was hypothesised^{65, 130, 189, 205} that technetium in deep layers is stabilised as $\text{TcO}(\text{OH})_2$ or TcO_2 under anaerobic conditions at reduction potentials E_h and its sorption by minerals is, apparently, associated with irreversible precipitation of poorly soluble forms of Tc(IV).^{89, 205} To test this assumption, experiments were carried out on sorption of technetium(VII) from flowing groundwater (pH 9; $E_h = 158 \text{ mV}$; conductivity $1340 \mu\text{S cm}^{-1}$) by finely dispersed (180–850 μm) strongly metamorphosed rocks taken from the fracturing zone at a depth of 250 m without contact with the atmosphere.²⁰³ The material filling the column consisted of quartz, alkaline feldspar, plagioclase, biotite, chlorite and trace amounts of magnetite. It was found that about 40% of technetium was sorbed on fractions of ferrous minerals, which are composed primarily of biotite and other so-called mafic minerals, such as hematite, magnetite and iron hydroxides (7% of the overall weight). It was demonstrated that sorption on mafic minerals occurs through chemisorption rather than being due to precipitation in the bulk of groundwater.²⁰³ It can be assumed that sorption of technetium proceeds in two steps, *i.e.*, through reduction of Tc(VII) to Tc(IV) by divalent iron present in rocks and chemisorption on their surfaces. This assumption was confirmed by the results of the studies,^{101, 189, 194, 199, 206, 207} in which it was found that technetium(VII) was not sorbed by Fe(III)-containing minerals, whereas sorption of TcO_4^- increased on Fe(II)-containing minerals.

Figure 11. Plot of the coefficient of sorption of technetium by minerals from solutions of groundwaters (pH 5.8–7.4) vs. E_h . $[\text{TcO}_4^-] = 10^{-6}$ mol litre $^{-1}$. The ratio of the volume of the solution to the weight of the sample is $2.5 \text{ cm}^3 \text{ g}^{-1}$.⁶⁵

tium(VII) from flowing groundwater (pH 9; $E_h = 158 \text{ mV}$; conductivity $1340 \mu\text{S cm}^{-1}$) by finely dispersed (180–850 μm) strongly metamorphosed rocks taken from the fracturing zone at a depth of 250 m without contact with the atmosphere.²⁰³ The material filling the column consisted of quartz, alkaline feldspar, plagioclase, biotite, chlorite and trace amounts of magnetite. It was found that about 40% of technetium was sorbed on fractions of ferrous minerals, which are composed primarily of biotite and other so-called mafic minerals, such as hematite, magnetite and iron hydroxides (7% of the overall weight). It was demonstrated that sorption on mafic minerals occurs through chemisorption rather than being due to precipitation in the bulk of groundwater.²⁰³ It can be assumed that sorption of technetium proceeds in two steps, *i.e.*, through reduction of Tc(VII) to Tc(IV) by divalent iron present in rocks and chemisorption on their surfaces. This assumption was confirmed by the results of the studies,^{101, 189, 194, 199, 206, 207} in which it was found that technetium(VII) was not sorbed by Fe(III)-containing minerals, whereas sorption of TcO_4^- increased on Fe(II)-containing minerals.

Sorption of Tc on samples of soils taken in the region of the production site of the Mayak Production Association was studied (Table 5).¹⁹⁹ It was demonstrated that the distribution coefficients of technetium in water–soil sample systems $[K_d^{\text{Tc(VII)}}]$ depend on the content of organic components in the soil. Thus, the distribution coefficients $K_d^{\text{Tc(VII)}}$, which are in the range of $\sim 6\text{--}$

Table 5. Coefficients of sorption of Tc in soil–water systems.¹⁹⁹

Sample	Organic component (%)	pH after sorption	$K_d^{\text{Tc(VII)}}$ / $\text{cm}^3 \text{ g}^{-1}$
Sand	0	7.1	10
Kaolin clay	0	7.5	12
Loam	2	7.3	14
Grey soil	5	7.3	18
Humus	35	6.9	25
Bottomset bed (Uvildy lake)	43	7.4	30
Deciduous foliage (birch)	52	7.2	140
Mushroom chitin	—	6.5	39

Note. The starting concentration of technetium was 45 mg litre^{-1} , $V/m = 50 \text{ cm}^3 \text{ g}^{-1}$, 20°C , the duration of the contact was 8 weeks.

$12 \text{ cm}^3 \text{ g}^{-1}$ for samples of sand and kaolin clay devoid of organic compounds, slowly increase as the percentage of the organic component increases. High distribution coefficients of Tc in soil samples were observed for humus ($25 \text{ cm}^3 \text{ g}^{-1}$) and bottomset beds ($30 \text{ cm}^3 \text{ g}^{-1}$) containing organic components (algae, fungi, etc.). Biosorption by bacterial cell walls and fungal melanins makes the major contribution to bioaccumulation of Tc. Thus, the anomalously high coefficient $K_d^{\text{Tc(VII)}} = 140 \text{ cm}^3 \text{ g}^{-1}$ was found for deciduous foliage.

Hence, the available experimental data indicate that, occurring in the anionic form at high reduction potentials E_h , technetium is very poorly sorbed by minerals. Apparently, the fixation of technetium by soils and rocks under reductive conditions results, primarily, from chemical precipitation.²⁰⁸ An increase in $K_d^{\text{Tc(VII)}}$ for samples containing organic compounds is proportional to their percentage. Taking into account that organic components of soil are, primarily, humus and various cell organisms and that humus, in turn, consists of humine and humic acids, it was hypothesised¹⁹⁹ that it is these components that are favourable for active fixation of Tc by soil samples.

4. Diffusion properties of technetium

It is commonly assumed that ^{99}Tc possesses high mobility in environmental waters. As mentioned above, oxidised technetium occurs in the water-soluble anionic form and is sorbed by neither minerals nor clay–sand soils to a noticeable degree. According to in-field observations,²⁰³ technetium can be transferred by ground-water through the water-bearing sand bed in the form of TcO_4^- ions.²⁰⁹ In the case of crystalline rocks, water-filled cracks serve primarily as migration channels. Generally, walls of these cracks are covered with a layer of metamorphised minerals. It was demonstrated that the coefficient of diffusion of $^{99}\text{TcO}_4^-$ in samples of metamorphised granite and bentonite taken from the fractured zone of Precambrian batonite at a depth of about 250 m is $1.4 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$.^{117,210}

5. Distribution of technetium in the World Ocean

The World Ocean serves as an indicator of the ecological state of the main Earth shells. Hence, data on the presence of particular pollutants, including radionuclides released into the hydrosphere, in the World Ocean are of great importance.

The specific activities of ^{99}Tc in coastal sea waters of the World Ocean are presented in Fig. 12. In seas and the Pacific Ocean, the specific activities are in the ranges of 1.0–7.4 and 0.49–3.33 $\mu\text{Bq litre}^{-1}$, respectively. The ^{99}Tc concentrations in the Irish Sea and the North Sea are higher than the average level due to their pollution with industrial wastes from the Sellafield plant, where spent nuclear fuel is reprocessed. The authors of the

Figure 12. Specific activity of ^{99}Tc in waters from different seas.¹¹³ (1–3) Pacific Ocean (1, 1992; 2 and 3, 1993); (4) and (5) Baltic Sea [4, 1986, 5, 1988]; (6), Norwegian Sea (1980); (7) Barents Sea (1980); (8) Greenland Sea (1988); (9) Davis Strait (1984); (10) Baltic Sea (1983, 1986); (11) Mediterranean Sea (1985–1987); (12) and (13) Japan Sea (1987).

study¹¹³ believed that the occurrence of Tc in other regions of the World Ocean is associated primarily with the global fallout.

Being constant in different regions of the World Ocean, the activity ratio $^{99}\text{Tc}/^{137}\text{Cs} = (2.7 \pm 0.6) \times 10^{-4}$ depends on the release of fission products from nuclear explosions, mechanical dispersion of nuclear explosion products and chemical and physical fractionation of radionuclides.

6. Behaviour of technetium in biosystems

The behaviour of technetium in biosystems has been studied in detail. Most of the available data indicate that Tc is readily transferred from soils (or waters) into plants or organisms under anaerobic conditions, which is, apparently, associated with high solubility of pertechnetates and their mobility in soils.^{88, 210–212} It was demonstrated^{106, 211, 213, 214} that the mechanism of transfer of Tc into biosystems involves the transport of TcO_4^- through a plant cell membrane⁸⁹ (energy consumption is $\sim 9.4 \text{ kJ mol}^{-1}$) as the first step²¹¹ followed by photoreduction of Tc(VII) to Tc(IV) in chloroplasts by plant gelatin serving as the complex-forming reducing agent present in plants.¹⁰⁶

The equilibrium concentration of Tc in a biomass, for example, in duckweed *Lemna minor*, is established very rapidly (already within 2 h). The kinetics of bioaccumulation of Tc in plants depends on the intensity of their illumination, the concentrations of technetium and nitrate ions in solution and temperature. At 25°C , the rate of Tc reduction under solar illumination is close to $200 \mu\text{mol m}^{-2} \text{ s}^{-1}$.²¹¹

Generally, the absorption of radionuclides from soil by vegetables is characterised by the transport factor (TF)^{126, 215, 216} or concentration factor (CF), which are determined as the ratio of the radionuclide concentration in a fresh plant to its concentration in dry soil (Bq kg^{-1}). The transport factor is among the most important parameters used for the estimation of the intake of radionuclides into the human body. The transport factors depend on the nature of the plant. For example, the transport factors for foliar vegetables are much higher than those for root vegetables. The transport factors for old leaves are much higher than those for young leaves. Since root and stalk tissues cannot retain technetium that enters into plants, it is transferred to leaves and accumulated there when water is evaporated. Apparently, the transfer of technetium together with photosynthesis products, for example, with carbohydrates, from leaves to tubers, fruits and follicles is insignificant.

As can be seen from Table 6, the transport factor of technetium calculated for the weight of dry samples of the plants under

Table 6. Transport factors of ^{99}Tc (Bq kg^{-1}) from soil to different organs of vegetables (radionuclide label was introduced into soil when cropping).²¹⁵

Plant	Non-edible part/ edible part	TF / Bq kg^{-1}	
		wet plant	dry plant
Lettuce (<i>Lactuca sativa</i> L.)	lower/upper leaves	16/2	340/26
Sweet pepper (<i>Capsicum annuum</i> L.)	old leaves/fruits	30/0.03	184/0.03
Aubergine (<i>Solanum melongena</i> L.)	old leaves/fruits	5/0.01	22/0.1
Kidney bean (<i>Phaseolus vulgaris</i>)	old leaves/follicles	16/0.02	127/0.2
Cauliflower (<i>Brassica oleracea</i> L. var. botrytis)	lower leaves/flowers	135/0.1	456/0.9
Yam (<i>Dioscorea japonica</i> Thunb)	leaves/tubers	—/1	218/4
Soya (<i>Glycine max</i> L.)	leaves/legumes	—/—	1416/0.8

examination changes from 5 to 1416 Bq kg⁻¹ (dry soya leaves)²¹⁵ and even to 2600 Bq kg⁻¹ (dry spinach leaves).¹²⁶

It is reasonable to compare the above-mentioned transport factors of Tc into edible parts of plants with the safe level of technetium recommended by the International Atomic Energy Agency (5 Bq kg⁻¹).

Of sea organisms, annelida (*Fucus serratus*, **I**), crustacea (*Perinereis cultrifera*, **II**) and brown algae (kelps) (*Homarus gammarus*, **III**) intensively accumulate Tc. The corresponding concentration factors are 1500 (**I**), 1200 (**II**) and 1000 Bq kg⁻¹ (**III**). The concentration factors for other sea plants and animals (fish, shellfish, phytoplankton, etc.) are much lower (1–10 Bq kg⁻¹). In studies of the concentrations of Tc in sea organisms taken in the region of the La Hague Strait (European Continent), the following concentration factors were found: 44.4, 155.4 and 125.8 Bq kg⁻¹ for **I**, **II** and **III**, respectively. The concentrations of technetium in fish, for example, in *Blenius pholis* or *Labrus bergultra*, varied from 0.92 to 1.48 Bq kg⁻¹, respectively.²¹⁷

Microorganisms readily adsorb technetium through interactions with the sulfur atoms of amino acids and proteins. From this viewpoint, Tc is similar to iodine, which also readily interacts with microorganisms. For example, the data on bioaccumulation of Tc and other long-lived radionuclides by bottom sediments from different basins under the action of microorganisms were analysed in the studies.^{200, 202, 217–223}

7. Influence of radiolysis on the behaviour of Tc in environmental objects

It is known that the migration properties of Tc and other radionuclides in the biosphere can depend on self-irradiation of the samples, which has an effect on the stability of their oxidation state and diffusion in geological formations.^{23, 121} For example, γ -irradiation of solutions of Tc(VII) leads to its reduction to Tc(IV) depending on the composition of the medium. It was demonstrated that a neutral solution of TcO₄⁻ turned brown and TcO₂ or TcO₂ · nH₂O colloidal particles with the grain size of 30–130 nm formed at the irradiation dose of 2 kGy. In deaerated solutions, TcO₄⁻ is reduced at lower doses. It was found that the yield decreased in the course of reduction with increasing concentration of carbonate ions in solution.²²⁴

VII. Use of technetium in technological processes and medicine

1. Catalytic properties

The catalytic activity of technetium metal has been predicted by Balandin²²⁵ on the basis of a sextet model of dehydrogenation of cyclohexane. Since technetium metal has a hexagonal crystal structure and the smallest distance between the atoms (~2.74 Å) is in the range of distances for known catalysts (2.49 Å for Ni or 2.77 Å for Pt), it should serve as a catalyst for the transformations of six-membered cyclic hydrocarbons.

It was demonstrated that a catalyst containing 1 mass % of Tc on SiO₂ or Al₂O₃ support, like a rhenium catalyst, accelerates hydrogenation of benzene to form cyclohexane and hydrogenolysis of benzene at 100–350 °C, the best results being achieved with the use of γ -Al₂O₃ as the support.²²⁶ In the above-mentioned processes, the specific catalytic activity of metals changes in the series Ru > Pt > Tc > Pd > Re and Ru > Tc > Re.^{227, 228}

The promotion action of technetium was studied in hydrogenation and dehydrogenation of hydrocarbons on applied catalysts based on platinum metals (Pt, Pd, Rh, Ru).^{229–231} It was found that the catalytic activity was substantially increased upon the addition of technetium (synergistic effect). The physicochemical properties of technetium-metal catalysts were examined.

Technetium serves as a catalyst for hydrogenation of anhydrides (for example, the transformation of succinaldehyde into tetrahydrofuran²³²), conversion of aliphatic hydrocarbons (for

example, dehydrocyclisation of heptane to form toluene²³³) and decomposition of aliphatic alcohols to hydrogen and the corresponding aldehyde.²²⁶

The Standard Oil Corp. (USA) developed catalysts involving technetium and its dioxide as the activator for petroleum reforming, and these catalysts were covered by patents. The concentration of technetium on an Al₂O₃ support was 0.01%–0.2%. The noble metal served as the major component.²³⁴

Catalysts based on complex Tc compounds are of particular interest from both the theoretical and practical standpoints. In many cases, these compounds proved to be more efficient than catalysts based on metals or their oxides.²³⁵ One of the most promising applications of complex catalysts is the activation of molecular nitrogen, which opens up possibilities for the direct synthesis of ammonia under mild conditions. For example, the complex technetium compound with composition TcCl₄(PPh₃)₂ catalyses reduction of molecular nitrogen to ammonia under the action of lithium naphthalide.²³⁶

2. Superconducting properties of technetium and its compounds

The superconductivity of technetium was discovered in 1953 when studying the magnetic susceptibility of powdered metal with purity of no lower than 99.9%.²³⁷ The superconducting transition begins at 11.2 K and is completed at 7.7–7.8 K. Hence, technetium is the second best superconductor, exceeded only by niobium ($T_c = 9.25 \pm 0.02$ K). Technetium differs from other metals in the degree of anisotropy of the superconducting properties. Technetium is the only representative of type II superconductors belonging to the hexagonal system.²³⁸ It should be noted that although Tc in the bulk state is somewhat inferior to niobium as a superconductor, its films exhibit better superconducting properties. Superconducting Tc films have obvious advantages over niobium films. That was the reason why technetium was chosen as a material for superconducting RF cavities for an accelerator in the USA.²³⁹

Technetium is of interest because its alloys combine phases typical of rhenium and manganese. Since technetium alloys can simultaneously possess physical properties exhibited by rhenium and manganese alloys, they can be considered as materials with special properties.²⁴⁰ The so-called 'rhenium effect' is of obvious interest for superconducting technetium-based materials. This effect lies in the fact that both the strength and plasticity of the metal increase simultaneously upon the addition of Tc or Re.²⁴¹

An alloy containing 5%–75% of Mo is the first commercial Tc-containing alloy (Western Electric Company, USA; covered by a UK patent), which can be used for the construction of electromagnets.²⁴²

3. Technetium as an inhibitor of corrosion

High inhibiting ability of the pertechnetate ion was first established by Cartledge as early as 1955^{243–245} and then confirmed by investigations of Russian researchers.^{246–248} It was demonstrated that the pertechnetate ion (like other known inhibitors of the MO₄ⁿ⁻ type, where M = Cr, Mo or W) is among the most efficient inhibitors of corrosion of carbon and stainless steels, the action of TcO₄⁻ being observed even at a concentration of ~10⁻⁵ mol litre⁻¹ at 250 °C.²⁴³ It was established that the mechanism of action of TcO₄⁻ is identical to that of CrO₄²⁻ and WO₄²⁻.²⁴⁹ However, the required protective concentration of the pertechnetate ions is ~10 times lower.²⁵⁰ Besides, the TcO₄⁻ ion is more resistant to radiation than the CrO₄²⁻ and WO₄²⁻ ions. These results opened up possibilities for the use of Tc as an inhibitor of corrosion of water-cooled nuclear reactors. Thus, K₂TcO₄ (0.5 kg) was introduced into the bulk of a D₂O core coolant (47 m³) to prevent corrosion of the CANDU energy reactor with an output of 200 MW.²⁵¹

Technetium coatings were also proposed for the protection of the underside of oceangoing ship hulls from microorganisms.²⁵² The commercial Technetium Corp. (USA) established in 1976 was

aimed at extending business activity in the design, use, sale and licensing of technetium coatings for their application in marine and industrial media.

4. Use of technetium compounds in medicine

Radionuclide methods of examination and treatment are widely used in different fields of scientific and practical medicine. Radionuclides used in these fields and the corresponding radiopharmaceuticals based on them are classified as diagnostic therapeutic according to the areas of their application. Diagnostic radiopharmaceuticals, in turn, are divided into groups of radionuclides for single photon emission computed tomography (SPECT, γ -emitters with energies in the range of 100–200 keV and half-lives from several minutes to several days) and positron emission tomography (β^+ -emitters with half-lives from several seconds to several hours). In the last two decades, the overwhelming majority of diagnostic procedures (up to 80%) employing the SPECT technique were carried out with the use of radiopharmaceuticals containing ^{99m}Tc (see Refs 253, 254), which is called the 'work horse' of nuclear medicine.²⁵⁵

The ^{99m}Tc isotope belongs to the category of short-lived isotopes, whose application allows one to study the same object repeatedly at short intervals without overirradiation.

Numerous studies demonstrated that ^{99m}Tc can be used for the diagnosis of diseases of the liver, thyroid,²⁵⁶ kidneys and adrenals,²⁵⁷ spleen,²⁵⁶ respiratory system,²⁵⁸ cerebrum,²⁵⁶ spinal cord,²⁵⁹ bone marrow,²⁶⁰ salivary glands, digestive system,²⁵⁶ bones and joints of the skeleton²⁶¹ and also for studies of the physiological functions of the cardiovascular system,²⁵⁶ lymphatic system²⁶² and urological system,²⁶³ investigations of the glomerular filtration rate and plasma volume.^{264,265} In addition, ^{99m}Tc can be used for examining internal cavities,²⁶⁶ infectious heart diseases,²⁶⁷ infectious brain diseases,²⁶⁸ infectious eye diseases,²⁶⁹ infectious dermal diseases²⁷⁰ and skin transplantation.²⁷¹

The synthesis of efficient ^{99m}Tc radiopharmaceuticals is of considerable importance for using technetium in medicine. In Russia, a methodology was developed for the design of generators for ^{99m}Tc and technological schedules were applied to the production of various radiopharmaceuticals, among which are $^{99m}\text{TcO}_4^-$, ^{99m}Tc citrate, groups of colloidal ^{99m}Tc pharmaceuticals, etc.^{272,273}

Pharmaceuticals containing ^{99m}Tc are prepared in different forms specific for particular organs, groups of organs or systems. The possibility of the use of a drug for the diagnosis of diseases of a particular organ depends substantially on both the oxidation state of the radioactive label and the properties of the drug into which it is incorporated.

Radiopharmaceuticals containing ^{99m}Tc can be divided into three groups according to their biological specificity: Na or K pertechnetates, technetium(VII) complexes with various ligands and technetium(IV) complexes with various ligands. Sodium pertechnetate is accumulated primarily in glandular organs of the human body, viz., in the thyroid gland, gonads, parotid gland and kidneys.²⁷⁴ Since the pertechnetate ion is biologically non-specific, radiopharmaceuticals of the first group can be used for the diagnosis of almost all organs and systems. These pharmaceuticals are removed from the organism during one day.²⁵⁵ In the radiopharmaceuticals of the second group, which are more biologically specific than pertechnetate, Tc is involved in micelles in the hepta- or tetravalent state.^{275,276} The third group containing  the largest number of representatives includes complex compounds, which are prepared by reduction of the pertechnetate ion to lower oxidation states. The biological specificity of Tc complexes is most pronounced. Many of these complexes involve organic compounds of different classes, viz., alcohols, sugars, nucleic acids, nucleoproteins, amino sugars, polysaccharides, drugs containing phytin, penicillamine acetazolamide, bleomycin, dihydrothioctic, glucoheptonic, gluconic and other acids^{94,276} as well as Tc chelate complexes.¹⁶⁶

In Russia, the problem of the production of a standard list of reagent sets has already been solved. These reagents are produced by virtually all corporations. Thus, the Medradiopreparat Plant of the Ministry of Health of the Russian Federation produces reagent sets for the preparation of the drugs Pentatech (^{99m}Tc complex with diethylenetriaminepentaacetic acid used for the determination of glomerular filtration rate in kidney disease or visualisation of brain tumours), Pyrphotech (^{99m}Tc complex with pyrophosphate used for scintigraphy of the skeleton or acute myocardial infarction), Coren (^{99m}Tc complex based on rhenium sulfide used for scintigraphy of the liver, spleen or bone marrow). The Diamed Plant produces the above-mentioned pharmaceuticals along with Technephor (^{99m}Tc complex with oxabiphor used for scintigraphy of the skeleton), etc.²⁵³

Extensive studies are being conducted on the design of new pharmaceuticals based on ^{99m}Tc complexes with the $\text{N}_2\text{S}_2-\text{NS}_3$, S_3N ligands, carbonyl ligands and peptides.²⁵³

Abstract. Chemical methods for the exfoliation of transition metal dichalcogenides in a liquid medium to give single-layer dispersions containing quasi-two-dimensional layers of these compounds are surveyed. Data on the structure of dispersions and their use in the synthesis of various types of heterolayered intercalation compounds are discussed and described systematically. Structural features, the electronic structure and the physicochemical properties of the resulting intercalation compounds are considered. The potential of this method of synthesis is compared with that of traditional solid-state methods for the intercalation of layered crystals. The bibliography includes 192 references.

I. Introduction

A crystal structure of layered transition metal dichalcogenides TX_2 consists of the alternating infinite triatomic layers $\text{X}-\text{T}-\text{X}$ (where T is a transition metal atom, X is a chalcogen atom — S, Se or Te).¹ The neighbouring metal and chalcogen atoms are strongly bound by covalent bonds within the layers, while the layers are weakly bonded to each other due to van der Waals interactions. These compounds have found practical applications as materials used in electronics (e.g., in power sources), in different fields of technology (e.g., as lubricants) and in petrochemistry (as catalysts). They also attract attention in the fundamental research of physical and chemical properties of the low-dimensional compounds.

Approaches common to dichalcogenides of different metals can be used in studies (and for the modification) of their properties, because of their structural similarity. One of the approaches makes use of the ability of these substances to form intercalation compounds due to the existence of the interlayer space between

the adjacent TX_2 layers. This allows one to obtain systems with alternating TX_2 monolayers and layers of different (inorganic or organic) nature. In such heterolayered structures both the electronic structures and the properties of the TX_2 layers can be modified due to charge transfer between the components and changes in the nature and concentrations of intercalated substances (which consequently changes interlayer distances).

An unusual chemical property of transition metal dichalcogenides discovered recently is their ability to form rather stable systems containing quasi-two-dimensional monomolecular layers separated by the solvent molecules (single-layer dispersions). To some extent, this property is analogous to the ability of layered aluminosilicates and zirconium hydrogen phosphates² to exfoliate in aqueous media. A general character of this phenomenon for the layered systems can be supposed, and based on this a versatile method can be developed for the preparation of intercalation compounds and nanocomposite materials including films.

This method is of particular importance for the synthesis of heterolayered systems that cannot be obtained by traditional procedures of solid-state chemistry. In this respect, formulation of the basic principles of the synthesis of intercalation compounds with the use of TX_2 single-layer dispersions is the subject of current interest, and the present review is expected to provide additional insights into the problem.

In this review, the data on the nature of TX_2 single-layer dispersions and their use in the synthesis of new heterolayered materials as well as the data on the types, properties and structural features of these materials published in the few last years are considered. To reveal the reactivity of the single-layer dispersions, it was appropriate to compare it with that of the solid-state intercalation reactions of crystalline layered metal dichalcogenides. It should be mentioned that different aspects of solid-phase intercalation were discussed in several reviews published in the 1980–1990's (see, e.g., Refs 3–9), while the studies of single-layer dispersions have up to now been surveyed in only one review¹⁰ dealing with molybdenum disulfide chemistry.

II. Characteristic features of the layered metal chalcogenide structures

Many transition metals characterised by the oxidation state +4 [Group IVB, VB and VIB metals and some Group VIIB (Tc, Re) and VIIIB (Pt) metals] form dichalcogenides of the layered

structure.¹ Their crystal structure can be described as stacking of closely packed hexagonal sheets of chalcogenide anions with each second interlayer space occupied by metal atoms (Fig. 1). With the close packing, the stacking of the anions accords with the principle ‘an atom is placed over the centre of the triangle formed by the atoms of the adjacent layer’, and this principle is held in all cases where the adjacent chalcogen sheets with no metal atoms in between are stacked and bound to each other only by the van der Waals forces (to form a van der Waals gap). This arrangement causes the existence of octahedral and tetrahedral vacant sites in the ratio of 1 : 2 in the interlayer space between the neighbouring triatomic X–T–X...X–T–X layers. The electron configuration of the metal atom T determines the intralayer mutual arrangement of the chalcogen sheets and specifies its octahedral (which corresponds to the close packing of the anions) or trigonal prismatic (where the packing of the anions is not close) nearest-neighbour surrounding the chalcogen atoms. According to quantum-chemical calculations,^{11–13} a trigonal prismatic coordination is favoured by a d² metal atom electron configuration (the Group VIB metals, Mo and W) while the octahedral coordination is characteristic of a d⁰ metal atom configuration (Group IVB metals, Ti and Zr). For the Group VB metals (Nb and Ta) with d¹ electron configuration, both coordination surroundings are energetically close to each other. For this reason, both trigonal prismatic and octahedral coordinations are usually present in real structures.

In addition to the type of coordination polyhedron (octahedron or trigonal prism), the motives of the X–T–X layer packing can vary as well as the relative positions of the metal cations in the adjacent layers with respect to each other in the structures of metal dichalcogenides.¹⁴ These three factors taken together determine the syngony [hexagonal (H), trigonal (T) or rhombohedral (R)] and the space group of the crystalline compound. Thus in the case of an octahedrally surrounded metal atom, the sole one-layered packing, which corresponds to the

trigonal space group *P3m* (1T polymorph), is realised. In the case of trigonal prismatic coordination, much more variation in the packing exist. For two-layered packing, three structural types differing in the relative positions of the metal cations in the adjacent filled layers are possible (2H polymorph, 2H_a, 2H_b and 2H_c polytypes).³ Three-, four- and six-layered sequences in packing as well as more exotic long-period structures are also known. Some compounds exhibit structures with a mixed coordination environment. They contain alternating layers with octahedral and trigonal prismatic nearest-neighbour surrounding of a metal atom.^{1,3} The main polymorph modifications and polytypes of layered dichalcogenides are listed in Table 1 and schematically depicted in Fig. 1.

Table 1. Structural types of transition metal dichalcogenides.³

Poly-morph	Poly-type	Coordination type	Layer stacking motif ^a	Space group	Examples
1T	1T	O	AbC	<i>P3m</i>	TiS ₂ , VS ₂ , TaS ₂
2H	2H _a	TP	AbACbC	<i>P6₃/mmc</i>	NbS ₂ , TaS ₂
	2H _b	TP	AbABcB	<i>P6m2</i>	NbSe ₂ , TaSe ₂
	2H _c	TP	AbABaB	<i>P6₃/mmc</i>	MoS ₂ , WS ₂
3R	3R	TP	AbACaCBcB	<i>R3m</i>	MoS ₂ , WS ₂
4H	4H _a	TP	BcBAcABcBCaC	<i>P6m2</i>	NbSe ₂ , TaSe ₂
	4H _b	O + TP	BcBCaBCaCBaC	<i>P6₃/mmc</i>	TaS ₂ , TaSe ₂
	4H _c	TP	BcBAcABaBCaC	<i>P6₃mc</i>	TaSe ₂
6R	6R	O + TP	BcBCaBCaCABcABcA	<i>R3m</i>	TaS ₂ , TaSe ₂

Note. The following notations are used: O, octahedral coordination; TP, trigonal prismatic coordination; O + TP, mixed coordination.

^a Upper- and lower-case letters designate the location of the chalcogen and metal atoms, respectively. Coincidence of the letters corresponds to the situation where the atoms in the adjacent layers are disposed exactly one below the other.

The electronic structures of layered dichalcogenides TX₂ are also determined by the nature of the metal T. The TX₂ valence band structure was found to consist of two sub-bands, where the lower sub-band is composed mainly by *ns*- and the upper sub-band by *np*-states of the chalcogen atom (*n* = 3 for X = S and *n* = 4 for X = Se) (Fig. 2). The lower free states of the vacant band (conduction band) consist mainly of d-orbitals of the transition metal. Due to the splitting of d-orbitals of the metal T by a crystal field of the chalcogen, the d_{z²}-orbital becomes the lowest in energy and forms a separate sub-band. In the case of Group IVB metal chalcogenides (d⁰ configuration), this orbital is situated entirely in the vacant band, whereas for Group VB metal chalcogenides (d¹ configuration) this orbital is half-filled, and for Group VIB metal dichalcogenides (d² configuration), the d_{z²}-orbital is completely occupied and lies in the valence band.^{11, 15–17} Thus, according to the calculations and experimental data [measurements of conductivity, magnetic properties,^{18, 19} photoelectronic spectra,^{17, 20} X-ray absorption near-edge structure (XANES),²¹ and optical reflection spectra²²], the occupied and vacant levels are separated by a very narrow energy gap (0.1–0.2 eV) in 1T-TiS₂, while they overlap in 2H-TaS₂. In 2H-MoS₂ and 2H-WS₂, the energy gap reaches ~ 1.5 eV.

Figure 2. Band structures for dichalcogenides of Group IVB (a), VB (b, c) and VIB (d) transition metals with octahedral (a, b) and trigonal prismatic (c, d) coordination of the central atom.¹¹

Let us consider the structure of MoS₂ in more detail, because this compound is inert in solid-state intercalation reactions, and it is the most common subject of studies on single-layer dispersion phenomenon. Molybdenum disulfide is a unique naturally occurring layered metal dichalcogenide. The mineral molybdenite contains its most stable 2H-modification (2H_c polytype, see Table 1), which has two-layered packing AbABaB with a trigonal prismatic coordination of molybdenum atoms [the space group *P6₃/mmc*, *a* = 3.16 Å, *c* = 12.30 Å, *Z* = 2 (see Ref. 23)]. Another thermodynamically stable modification of MoS₂ is 3R, which is characterised by three-layered packing and also has a trigonal prismatic coordination of molybdenum atoms [space group *R3m*, *a* = 3.16 Å, *c* = 18.37 Å, *Z* = 3 (see Ref. 24)]. Virtually amorphous molybdenum disulfide consisting of strongly disordered fragments of the 2H structure can be obtained by ion-exchange reactions of molybdenum chloride with alkali metal sulfides in non-aqueous solvents.²⁵ Recently, the preparation of molybdenum disulfide in the form of multi-layered polyhedral structures, resembling carbon ‘onions’ and nanotubes, by sulfidation of ultra-dispersed molybdenum oxide^{26,27} or by reduction of MoS₃ with hydrogen has been reported.²⁸ Though today the atomic structures of these systems are not known in detail, they are presumably close to the 2H-modification and have a certain number of defects needed for deformation of the flat S—Mo—S layer to the given curvature. The minimum diameter of such MoS₂ particles (containing 2–3 layers) is approximately 30–50 Å.²⁹ Flat one-layered nanosized MoS₂ clusters of approximately the same diameter have

been obtained by the reaction of MoCl₄ with H₂S in a micellar solution.³⁰

Synthesis of a metastable molybdenum disulfide modification, in which the octahedral coordination of molybdenum atoms and one-layered packing are assumed, has been reported.³¹ This modification can be assigned to the 1T polymorph (see Table 1). For the synthesis of this compound, the intercalation compound K_{0.7}MoS₂ was subjected to controlled hydrolysis up to the composition of K_{0.33}(H₂O)_{0.6}MoS₂ followed by its electrochemical or chemical oxidation (using potassium dichromate in dilute sulfuric acid or iodine in acetonitrile). According to the powder X-ray diffraction analysis, the structure of the obtained compound belongs to a hexagonal syngony and has the unit cell dimensions *a* = 5.597 Å, *c* = 5.994 Å.³¹ The structure is characterised by a shorter interlayer distance (by ~0.16 Å) than 2H-MoS₂, and by the existence of a superstructure $\sqrt{3}a \times \sqrt{3}a$ in the *ab* plane of the layer. This compound possesses a negative temperature coefficient of electronic conductivity and exhibits the Pauli paramagnetism, *i.e.*, displays metallic properties. Thermal analysis showed that decomposition of the compound proceeds at ~100 °C with a small exothermic effect resulting in the formation of strongly disordered 2H-MoS₂. The structural study of 1T-MoS₂ by electronography³² confirmed the retention of a hexagonal symmetry of the MoS₂ layer and the formation of the superstructure $\sqrt{3}a \times \sqrt{3}a$ due to the displacement of the molybdenum atoms from their ideal positions in the layer. This structural model is consistent with the data from scanning tunneling microscopy³³ and with the results of quantum-chemical calculations.³⁴ Nevertheless, since the atomic structure of the MoS₂ modification under consideration has not been determined up to now, the notation ‘1T-modification’ has to be used with care. In particular, ‘1T-MoS₂’ was suggested³⁵ to be a product of proton insertion into molybdenum disulfide — H_x⁺(MoS₂)^{x-}. (Similar intercalation compounds with hydrogen are known for some chalcogenides of the Group VB metals.^{36,37})

III. Solid-phase intercalation of metal dichalcogenides and the types of their intercalation compounds

In the literature, TX₂ intercalation compounds with various electron donors such as alkali metals and their complexes with solvating molecules, transition and post-transition metals, organic molecules (Lewis bases) and metal complexes of low ionisation potentials are described. The main traditional methods applied for the intercalation of powdered crystalline dichalcogenides, TX₂, are as follows: thermally activated insertion of the guest (metal atoms, molecules of electron-donating substances) into the TX₂ interlayer space, intercalation under electrolysis conditions where TX₂ is used as a cathode, and, in the case of alkali metals, the action of reducing agents (for instance, *n*-butyllithium or NaBH₄) on TX₂. The early publications concerning the methods of synthesis and the structures of certain classes of intercalation compounds are summarised in several reviews (see, for example, Ref. 3–6, 38).

It has been repeatedly noticed that the crystals of Group IVB and VB metal dichalcogenides can be intercalated by each of the above-mentioned types of the compounds using classical methods of solid-state chemistry, while molybdenum and tungsten dichalcogenides can only be intercalated with alkali metals under the same conditions. The different reactivities of the matrices can be explained by the distinctions in their electronic structures. Actually, taking into account the TX₂ valence band model considered above and in the framework of the rigid band model (RBM) (which is obeyed fairly well for the majority of dichalcogenides), the filling of the vacant matrix levels by the electrons of the guest is expected to proceed most easily in the cases of matrices based on the Group IVB and VB metals and should be most hindered in the case of Group VIB metal dichalcogenides where

d_{z^2} -orbitals are occupied and the electrons have to fill higher non-bonding levels.

According to this model, a new molybdenum disulfide 1T-modification, which exhibits a metal-type conductivity, should be more reactive in the intercalation than 2H-MoS₂. This is consistent with the fact that 1T-MoS₂ undergoes intercalation with metallic mercury³⁹ as well as with Ag⁺ and Cu⁺ cations (see Ref. 40).

However, even with TX₂ the electronic structures of which favour the acceptance of electrons, the key step of intercalation that limits the rate of the process, is apparently a transfer of the electrons to the matrix layers. The data on the kinetics of the gas-phase intercalation of hydrazine into NbSe₂⁴¹ as well as of the solution intercalation of cobaltocene into TaSe₂⁴² shows that the filling of the interlayer space is preceded by an induction period, which is needed for the 'activation' of the matrix due to its interaction with the absorbed molecules. The limiting influence of this step also follows from the effect of the acceleration of TiS₂ intercalation with various amines upon introduction, in the reaction system, of lithium amides or butyllithium, which can easily reduce the matrix layers. Probably, activation occurs due to weakening of the layer attraction because of the transfer of a certain number of electrons into the layers, which results in Coulombic repulsion. This facilitates the entering of the cations into the interlayer space.⁴³

It is important for the next steps of the process that cations should easily diffuse into the interlayer space, liberating the edge positions for the entering of new atoms or molecules (Fig. 3). The mobilities of compounds intercalated evidently diminish with the increase in their radii and with the augmentation of covalence of the guest–matrix bonding. This causes rather severe conditions for the insertion of many of the guest compounds into the interlayer space, thus limiting the range of compounds that can be intercalated in the crystalline dichalcogenides TX₂.

Figure 3. Schematic representation of the activation of a crystalline layered matrix in intercalation reactions;
(1) a cation; (2) a neutral molecule; (3) negative charge on the layer.

1. Compounds with molecular electron donors

In most cases, the intercalation of molecular compounds in the dichalcogenide matrices demands long (often, for many days) heating of a TX₂ powder in contact with a liquid or vaporous intercalant.³ Steric factors play an important role in this process. For this reason, two-stage synthetic methods are often used. For instance, TaS₂ was intercalated with ammonia, which was then replaced by bulkier molecules of pyridine⁴⁴ or *n*-alkylamines.⁴⁵

Entering of guests in the van der Waals gap leads to a significant increase in the interlayer spacing (Δc), which can vary from 3 Å (in the case of NH₃) to 50 Å (in the case of stearamide),⁴⁴ and to the essential lowering of the overall structural ordering of the materials. In the compounds obtained, the interlayer arrangement of the matrix layers is determined by the van der Waals guest–matrix interactions and by the orientation of the guest molecules. Therefore, there are no correlations in the stacking of adjacent matrix layers in these compounds, *i.e.*, the layers are packed turbostratically. In most cases, the guest molecules are almost closely packed in the interlayer space of the matrix, which

implies van der Waals guest–guest interaction. As a rule, the periodicity in the guest layer appears quite weakly or not at all in the diffraction pattern.

Intercalation compounds of this type were initially believed to contain only neutral molecules which interact with the matrix due to the overlap of the heteroatom lone pair of the electrons with vacant orbitals of the matrix.^{44,46,47} Such a viewpoint can sometimes be found in the current literature (see, for instance, Ref. 48) though it contradicts the known data on the substantial electron transfer from an intercalant to the vacant band of the matrix (in particular, up to 0.3 $\bar{e}$ per atom of Ta in a compound of TaS₂ with pyridine⁴⁹). Further studies revealed the presence of ions along with neutral particles in the interlayer space. The former are produced in various reactions accompanying the intercalation. For instance, in the case of ammonia intercalation into TaS₂ at 25 °C in the absence of oxygen and water, the formation of molecular nitrogen has been found by mass spectrometry. This suggests the occurrence of a redox reaction between the matrix and the intercalant resulting in the formation of ammonium cations, which are intercalated into TaS₂ together with neutral NH₃ molecules (see Ref. 6).

The composition of a compound of TiS₂ with ammonia where the cationic species amount to 20% (Ref. 50) can be formulated as (NH₄⁺)_{0.2}(NH₃)_{0.8}(TiS₂)^{0.2-}. On heating at 147 °C, all the neutral ammonia molecules can be removed and the compound becomes an ammonium analogue of the entirely ionic TX₂ intercalation compounds with alkali metals.

2. Compounds with alkali metals

Alkali metals (A) can be introduced into the interlayer space of crystalline dichalcogenides TX₂ by several methods:

- (1) from vapour phases of alkali metals;⁴
- (2) from the alkali metal solutions in liquid ammonia;^{38,51,52}
- (3) from the alkali halide melts;⁵³
- (4) by electrochemical intercalation using non-aqueous solutions of alkali metal salts;³⁸
- (5) by the reaction of TX₂ with some alkali metal compounds (BuⁿLi/hexane, ABH₄);^{54,55}
- (6) by other methods that do not imply direct intercalation.

It should be mentioned that in the cases of heavy alkali metals the vapour-phase synthesis (1) is carried out at elevated temperatures, which is accompanied by a side reaction, *viz.*, the reduction of TX₂ to a lower chalcogenide with the formation of the corresponding A₂X.⁴ In most cases, the method (2) allows the preparation of TX₂ intercalation compounds with alkali metals solvated by ammonia.³⁸ The reduction of alkali metal thiomolybdates, A₂MoS₂, by hydrogen provides example of the synthesis of intercalation compounds according to the method (6).³²

Intercalation compounds A_xTX₂ obtained in these reactions undergo spontaneous hydration in the presence of traces of moisture and self-ignite upon exposure to air. This makes the investigation of their structure and properties very difficult. The available structural data were obtained with polycrystalline samples. The attempts to synthesise single crystals of A_xTX₂ failed. It was noted⁵⁶ that single crystals of titanium disulfide were destroyed during intercalation due to strong local stresses and deformations of its layers.

The content of alkali metals in A_xTX₂ varies from 0.3 to 1 atom per T atom depending on the nature of A and the method of preparation. The maximum content of alkali metal ($x \geq 1$) has been achieved for A = Li.⁵⁷ For all the A_xTX₂ compounds, interlayer spacing augments as the ionic radius of A⁺ increases.

Solid-state NMR studies of Li_xTiS₂ showed that the guest atoms are virtually fully ionised in the compounds with alkali metals.^{58,59} Thus, taking into account the maximum stoichiometry of these compounds, charge transfer to the vacant orbitals of the matrix can reach 1 $\bar{e}$ per titanium atom. In spite of the fact

that the sulfur atoms are involved in the acceptance of the electron density (XAFS data²¹), this comes mainly to d-orbitals of titanium since they form a lower-energy vacant band. According to X-ray spectroscopic data, this leads to a formal reduction of titanium. Thus, using X-ray emission Ti $K_{\alpha 1}$ spectra it was established⁶⁰ that the charge states of titanium in LiTiS_2 and in $\text{TiS}_{1.5}$ are identical.

Electrophysical properties of the materials are changed in the expected way due to a charge transfer. In particular, the intercalation of Group IVB metal dichalcogenides results in a change in the conductivity character from semi-conducting to metallic. On the contrary, the properties of dichalcogenide phases containing Group VB metals change from metallic to semi-conducting with an increase in the guest metal concentration.⁶¹ Many compounds of this type were found to be superconductors. To our knowledge, the maximum transition temperature (~ 6.9 K) was found for MoS_2 compounds with rubidium and caesium.⁴

Intercalation with alkali metals cannot always be reduced to mere filling of the vacant tetrahedral or octahedral sites in the initial TX_2 structure since this often triggers structural transformations. For instance, the shift of the S—Ti—S layers one with respect to another occurs upon intercalation of 1T- TiS_2 , so that the environment of the guest atoms becomes trigonal prismatic for certain guest: host ratios. A similar structural transition has been described for Na_xTiS_2 and K_xTiS_2 .⁵¹

Yet another type of transformation changing the geometry of the TX_2 layer itself occurs in the intercalation of lithium into 1T- TaS_2 . In this case, the transition octahedron—trigonal prism was found to occur in the local environment of tantalum.⁶² It seems likely that the reverse change in the T metal coordination is induced by the intercalation of Group VIB metal dichalcogenides with alkali metals. As was found in the study of electrochemical insertion of lithium into 2H- MoS_2 , the structural phase transition appeared as a plateau in the voltammogram for the composition $\text{Li}_{0.1}\text{MoS}_2$.⁵⁷ An X-ray diffraction study of the resulting polycrystalline phase with the composition LiMoS_2 showed that intercalation of lithium not only leads to an increase in the lattice parameters ($a = 3.36$ Å, $c = 6.30$ Å) with respect to those of 2H- MoS_2 ($a = 3.16$ Å and $c = 2 \times 6.15$ Å), but also changes the layer stacking from the two-layered sequence to one-layered and, consequently, the coordination surrounding the molybdenum atoms from trigonal prismatic to octahedral. For the intercalates with high lithium content (Li_xMoS_2 , $x > 1$), electronography revealed the formation of a $2a \times 2a$ superstructure which disappears irreversibly on heating of the sample.⁶³ This effect was construed to be a consequence of lithium ion ordering within octahedral vacant sites. However, the reason for the appearance of the superstructure reflections is most likely the ordering not only in the intercalated layer, but also in the matrix layers. This viewpoint is supported by the Mo K -edge EXAFS data,^{39, 64} which demonstrated significant redistribution of the Mo—Mo bond lengths in LiMoS_2 , and by the analysis of atomic pair distribution function (PDF)⁶⁵ for this compound as well.

Probably, charge transfer from the other guest alkali metals to the MoS_2 matrix layers results in similar changes in these layers. For instance, electron microdiffraction and X-ray powder diffraction studies of the intercalation compound $\text{K}_{0.7}\text{MoS}_2$ obtained by reduction of potassium thiomolybdate with hydrogen, revealed the existence of a $2a \times 2a$ superstructure in the MoS_2 layer.³² Taking into consideration the stacking of neighbouring layers, the crystal structure of $\text{K}_{0.7}\text{MoS}_2$ [also as in the case of LiMoS_2 (Ref. 65)] does not have hexagonal symmetry and was described using a triclinic unit cell with the following parameters: $a = b = 6.6$ Å, $c = 8.0$ Å, $\alpha = 76.2^\circ$, $\beta = 88.3^\circ$, $\gamma = 60.3^\circ$ (the space group $P1$).³²

3. Layered solvates

Layered solvates of the TX_2 intercalation compounds with alkali metals, $\text{A}_x(\text{solv})_y\text{TX}_2$, can be obtained in the reaction of solvating reagents (water, liquid ammonia, dimethyl sulfoxide, dimethoxy-

ethane, dimethylformamide) with A_xTX_2 or in the direct intercalation reaction, if it is carried out in the required solvent.^{66–70} These compounds are of much interest as the direct precursors of single-layer dispersions.

Normally, the content of alkali metals in solvated phases is lower than in the intercalation compounds with the same non-solvated metals. Typical x values lie in the range 0.1–0.33. For this type of compound, the guest and host charges remain separated, *i.e.* the atoms of the alkali metals remain virtually fully ionised. For these compounds, the expansion of interlayer spacing with respect to the interlayer spacing in the initial TX_2 structure depends weakly on the ionic radius of the alkali metal and is mainly determined by the van der Waals thickness of solvating molecules. For this reason, the distance between the adjacent layers may change in a stepwise manner depending on whether the solvating molecules form a monolayer, bilayer *etc.* In the case of water as a solvent, it was found that Li^+ and Na^+ ions, which have a high energy of hydration (the ions characterised by the ratio $n/r \geq 1$, where n is the cation charge, r is the ionic radius/Å), tend to form intercalation compounds containing two water layers, whereas all the other cations stabilise only one-layered packing of water in the interlayer space (Fig. 4).^{66, 71}

Figure 4. Coordination of the intercalated alkali metal cation with water molecules arranged in one-layer (a) or bilayer (b) packing in compounds $\text{A}_x(\text{H}_2\text{O})_y\text{TX}_2$.⁷¹

For the majority of layered solvates, only a periodicity in the direction normal to the layers was determined by structural methods. Structural data are known in greater detail only for the isolated examples. One of them represents the intercalation compound $\text{K}_{0.33}(\text{H}_2\text{O})_{0.66}\text{MoS}_2$, which has a monoclinic unit cell with the parameters $a = 5.70$ Å, $b = 3.24$ Å, $c = 9.46$ Å, $\beta = 100.5^\circ$ as was found by XRPD and electron microdiffraction methods.^{31, 32} Thus, the interlayer spacing in this compound is larger than in 2H- MoS_2 by 3.15 Å, which is close to the van der Waals thickness of the monolayer of water molecules.

For the series of intercalation compounds $\text{A}_x(\text{H}_2\text{O})_y\text{MoS}_2$ ($\text{A} = \text{Li}, \text{Na}, \text{K}, \text{Cs}$), the ordering and dynamic behaviour of water molecules and alkali metal cations have been investigated by magic-angle-spinning NMR (^1H , ^7Li , ^{23}Na , ^{133}Cs).⁷¹ It was found that alkali metal cations have a strongly distorted octahedral environment and that water molecules possess high mobility in the intercalated layer where their chaotic motion can be observed even at 20 °C.

In these compounds, the cations of alkali metals can be involved in ion-exchange reactions (for instance, with alkylammonium cations) giving rise to new intercalation compounds.⁶⁷

4. Compounds with transition and post-transition metals

Compounds with the composition M_xTX_2 (M is a 3d-metal, Cu, Ag *etc.*) are usually obtained by thermal synthesis at 600–1100 °C in tubes containing a mixture of TX_2 and M or a mixture of three elements T, M and X in the appropriate stoichiometry. Note that

this reaction, in particular, in the latter combination, can hardly be considered as the intercalation of a layered matrix. However, the compositions of these ternary metal chalcogenides can be considered as intercalation compounds from the structural point of view, because the host matrix and the guest layers can be distinguished in their structure. Due to strong covalence of the M–X bond, the accommodation of M atoms in the interstitial sites of these compounds results in a small increase or, for some 3d-metals (Co, Ni), even in a decrease in the interlayer distance.⁷² The crystallinity of M_xTX_2 compounds is usually high. Using gas-transport reactions (for instance, in the presence of iodine or chlorine), single crystals of $Co_{0.25}TiS_2$,⁷³ $Fe_{0.34}TiSe_2$,⁷⁴ $Ag_{0.6}NbS_2$ (Ref. 75) and $In_{0.67}TaS_2$ (Ref. 76) could be grown.

In most M_xTX_2 compounds described, the guest M atoms are localised in the octahedral sites formed by chalcogen atoms of the adjacent layers, though filling of the tetrahedral sites is also known [Cu, Ag (see Ref. 77)]. Ultimate concentration of the guest atoms in M_xTX_2 is limited not only by the number of available sites, but also by the ‘capacity’ of the d_{z^2} -sub-band part, which is vacant in the non-intercalated matrix. According to RBM, this sub-band can adopt 2 and 1 e per T atom in cases of Group IVB and VB metal dichalcogenides, respectively. Actually, the maximum x values found experimentally for M_xTX_2 are close to the expected values. For instance, the x values are equal to 0.75 and 0.5 for TiS_2 and NbS_2 , respectively,^{78,79} when they are intercalated with 3d-metals (Mn, Fe, Co, Ni), having a formal charge $2+$ over the whole x range. The approach of the d_{z^2} -sub-band to its full occupancy may induce structural transformations as was observed, for instance, for Ga_xNbSe_2 and Ga_xTaSe_2 systems the structures of which transformed to the spinel structure at $x = 0.12$ (Ref. 80). Depending on the M_xTX_2 phase composition, various modes of guest metals ordering are realised or the structures without long-range order in the guest layer are formed. The ordering occurs where the guest atoms’ concentration exceeds a certain value, that is, where guest–guest interactions become significant. For instance, for intercalation compounds with the compositions of $M_{0.25}TX_2$ and $M_{0.33}TX_2$, the superstructures $2a \times 2a$ and $\sqrt{3} \times \sqrt{3}a$, formed due to the occupation by the guest atom of each fourth or third octahedral vacant site, respectively, are often observed (see, e.g., Refs 78 and 79). In the series of related compounds $(Cr,Ni)_{0.33}TX_2$ (where T = Nb, Ta and X = S, Se) containing the atoms of two different metals in the TX_2 interlayer space, a number of structural transitions were found⁸¹ by X-ray and neutron diffraction upon change of the Cr:Ni ratio. According to XAFS data,⁸² these transitions are accompanied by a change in the ordering of the local environment of T atoms.

Layered ternary molybdenum sulfides with 3d-metals having the stoichiometry $M_{0.5}MoS_2$ were obtained by high-temperature synthesis.^{83–89} Complete X-ray single-crystal investigations were performed for some of these compounds.^{85,87,88} The data obtained, for instance, for $Co_{0.5}MoS_2$ (as well as for structurally similar $Fe_{0.5}MoS_2$)^{85,87} demonstrate that molybdenum atoms inside the layer have a distorted octahedral environment composed of the sulfur atoms and that the closest Mo–Mo interatomic distances are not equivalent (as in 2H- MoS_2), but are broadly scattered over the range from 2.75 Å to 3.8 Å. The interlayer spacing in this compound is somewhat smaller than in 2H- MoS_2 . Syntheses of other layered molybdenum sulfides were reported^{90,91} (in particular, with indium and tin) with interlayer spacings virtually coinciding with that of 2H- MoS_2 , although no detailed structural data for these compounds were given. It is noteworthy that interaction of a $TaReSe_4$ matrix isoelectronic to 2H- MoS_2 with indium or tin results in its intercalation, whereas interaction with 3d-metals or with gallium leads initially to disproportionation into $TaSe_2$ and $Ta_{1-y}ReSe_{4-2y}$ and then to intercalation of the phases formed.⁹¹

Since intercalated metals donate electrons to TX_2 , systems with various types of magnetic orderings [see, for instance,

Refs 61, 89, 92] as well as spin glasses^{93,94} are formed with 3d-metals.

Intercalation compounds Hg_xTS_2 (T = Ti, Ta; $x = 1–1.3$) containing mercury atoms in the interlayer space^{95–97} can formally be assigned to the class considered owing to their compositions. In contrast to other chalcogenides with the composition M_xTX_2 , these compounds are formed even at 20 °C. In the interlayer space, mercury atoms form chains or closely packed hexagonal sheets⁹⁷ with a ‘thickness’ close to the atomic radius of Hg(0). Guest-to-host charge transfer is small in these compounds and amounts to 0.2 e per Hg atom in $HgTiS_2$.⁹⁶ It is of note that 2H- MoS_2 does not react with mercury, whereas a metastable phase of molybdenum disulfide obtained from $LiMoS_2$ by lithium deintercalation (presumably, 1T modification) does react. The formation of the chains and closely packed hexagonal sheets stabilised by partial charge transfer is probably the characteristic property of mercury. This feature is inherent in related layered compounds of graphite $KHgC_4$ (Ref. 98) and in crystalline complexes of low-valent mercury with a hexafluorometallate anion Hg_3MF_6 , (M = Nb, Ta).⁹⁹

IV. Single-layer dispersions of metal dichalcogenides

The exfoliation of crystalline TX_2 intercalation compounds in a solvent under certain conditions, which gives highly dispersed systems containing X–T–X single layers, was first observed for the case of TaS_2 intercalated with hydrogen. The H_xTaS_2 phase was prepared by electrolysis of a sulfuric acid solution using tantalum disulfide as a cathode.³⁶ Hydration of the compound obtained with a large excess of water led to the formation of opalescent dark-brown solutions stable for ~ 1 h.⁶⁹ X-Ray studies of these solutions and of solutions of NbS_2 formed under similar conditions have shown that the interlayer ordering is absent in these systems.⁶⁹

The formation of dark-blue colloid solutions was also observed upon solvation of the intercalation compound Na_xTiS_2 by *N*-methylformamide.⁶⁶ It was noticed that these solutions remained stable in an inert atmosphere for a long time and that the constituent single-layer species carried negative charges, which was deduced from their movement to the positive electrode in the electrophoresis.⁶⁶

Yet another popular method of layer separation consists of the ultrasound promoted hydration of TX_2 -lithium intercalation compounds. Frindt *et al.*¹⁰⁰ pioneered the use of this method for dispersion of $LiMoS_2$. An analogous procedure was later used to prepare dispersions from lithium intercalation compounds of TiS_2 ,¹⁰¹ $NbSe_2$,¹⁰² TaS_2 ,¹⁰³ WS_2 (Refs 104, 105) and $MoSe_2$.¹⁰⁶

The structure of MoS_2 single layers in an aqueous solution has been studied in detail by various methods.^{107–111} Total decomposition of a three-dimensional structure has been reliably confirmed by powder diffraction.^{106–109} Such typical features of the two-dimensional diffraction as the absence of the reflections corresponding to translational periodicity along the c axis (00/ lines series) as well as broadening and asymmetry of $hk0$ lines (the Warren effect¹¹²) were found to be characteristic of a single-layer dispersion. Based on the shape analysis of $hk0$ reflections, it was suggested¹¹⁰ that T atoms in MoS_2 , $MoSe_2$ and WS_2 dispersions have octahedral coordination (which was additionally confirmed in the case of molybdenum disulfide by Raman spectroscopy) instead of a trigonal prismatic coordination of the initial TX_2 . Moreover, diffraction patterns of these dispersions were found to contain additional $hk0$ lines which can be assigned to a superstructure in the TX_2 layers.^{106,107,109} For dispersions of the same metal dichalcogenides, significant distortions of the local environment of molybdenum and tungsten atoms, in particular, the appearance of short T–T contacts (~ 2.8–2.9 Å) corresponding to metal–metal bonds were revealed by the EXAFS technique.^{106,109} Rearrangement of the energy band structure of the $(MoS_2)^{x-}$ layers in single-layer dispersions is indicated by optical

absorption spectra where no absorption maximum corresponding to a transition between valence and conduction band at 700 nm typical of the initial matrix was present.¹⁰⁹

The presence of a negative charge on the layers of disulfide TS₂ dispersed in aprotic media (for instance, in the above-mentioned system Na_xTiS₂–*N*-methylformamide) appears to be evident. As for dispersions obtained by hydration of lithium-intercalated compounds, they were originally considered as containing only neutral TX₂ layers.^{100, 113, 114} However, experimental facts support the idea that dispersions prepared by the latter procedure are also ionic systems which contain macroanions (TX₂)^{x–}, retaining partial negative charge, solvated lithium cations and hydroxide anions.^{115, 116} Actually, the interaction between water and the initial ionic compound, for instance, Li⁺(MoS₂)[–], in which valence electrons are present on the molybdenum disulfide layers, should include two processes, *viz.*, hydration of lithium cations leading to separation of the matrix layers,

and redox interactions between the negatively charged (MoS₂)^{x–} layers and water molecules leading to precipitation of MoS₂.

Slowing down of the redox interaction (3) as the number of electrons on the layers decreases leads to retention of a partial negative charge on these layers for a long time. This appears to be the reason for the prolonged (up to 24 h) aggregative stability of aqueous dispersed systems [Li⁺ + (MoS₂)^{x–} + (1–*x*) OH[–]]_{aq}. This suggestion is supported by the fact that acceleration of crystalline MoS₂ precipitation occurs on removing the layer negative charge under the action of acid or air on the single-layer dispersion.^{115, 117} In the case of acid, the process goes rapidly to completion and results in immediate precipitation of neutral molybdenum disulfide at low pH values. In the case of air, the process occurs much more slowly and includes initial precipitation of the layered compound Li_{0.1}(H₂O)_y(MoS₂)^{0.1–} (see Ref. 115).

The composition of this compound shows directly the number of electrons remaining on the layers of the matrix at the moment of coagulation. Thus, the minimum negative charge needed to maintain stability of this dispersed system in water is close to 1 *e* per 10 molybdenum atoms.

V. Layered compounds obtained from single-layer dispersions

As was noted above, the intercalation of TX₂ crystals using traditional solid-state chemistry methods implies activation of the matrix by electron transfer to its vacant band. Because of a rather broad band gap for the Group VIB metal dichalcogenides, their activation can only be achieved in reactions with strong reducing agents. Therefore, many types of heterolayered compounds based on these matrices cannot be obtained by traditional methods. In addition, such methods are of limited utility also for other dichalcogenide matrices if potential guests are not sufficiently thermally stable or their diffusion in the interlayer space of the matrix is substantially hindered, as, for instance, in the case of polymers. The use of single-layer dispersions as precursors for the preparation of intercalation compounds allows one to eliminate

activation and diffusion restrictions, since the single-layers in dispersions bear negative charge and their entire ‘surface’ is available for absorption and chemical binding with an intercalant. That is why single-layer dispersion is most often used for both the preparation of the layered compounds based on molybdenum or tungsten disulfides and the synthesis of the nanocomposites containing polymeric molecules.

1. Compounds with organic and metal complex molecules

The formation of intercalation compounds with organic guest molecules was observed on adding water-immiscible organic solvents to aqueous single-layer dispersions of molybdenum disulfide.¹¹⁸ In this case, thin films of layered compounds containing molecules of the solvent or dissolved organic compounds are formed on the interface. This method has been employed to prepare large series of intercalation compounds with benzene, styrene, hexane,¹¹⁸ tetrachloroethylene,^{119, 120} ferrocene¹¹⁸ and its derivatives,¹²¹ and clusters Co₆X₈(PR₃)₆ (X = S, Se, Te, R = Alk)¹¹⁴ as the guest molecules. Unfortunately, experimental data reported in the cited publications do not allow one to make conclusions concerning the formation mechanism of the compounds obtained and, in particular, to answer the question whether the negative charge is retained on the matrix layers. Actually, according to the ionic model of the single-layer dispersion structure, the layers of metal dichalcogenides are negatively charged. If this charge rests, at least partially, in the intercalation compounds with neutral molecules listed above (what is more, most of them are not electron donors) on the matrix layers, the cations, as, for instance, Li⁺ or H⁺, have to be present along with these molecules. Thus the lithium cations are very likely to balance a residual negative charge of the matrix layers in the compounds Li_{0.1}(HNR₂)_yMoS₂,¹²² which was found to be formed in the reaction of neutral dialkylamines with dispersed MoS₂.

It cannot also be excluded that macroanions (MoS₂)^{x–} are completely discharged during the formation of the layered compounds. The driving force of the occlusion of neutral molecules between the non-charged matrix layers may lie in lowering the surface energy of quasi-two-dimensional layers due to the sorption of the guest molecules. The possibility of this mechanism is deduced, for instance, from the precipitation of a layered compound with naphthalene from aqueous lithium-containing MoS₂ dispersion and a solution of naphthalene in CH₂Cl₂. It was reported¹²³ that storage of the dispersion–organic phase system for a long time (up to 14 days) did not result in precipitate formation, but a precipitate of compound (C₁₀H₈)_x(H₂O)_yMoS₂ containing only traces of lithium was obtained upon acidification to pH 2. As the time of stirring increased, the *x*-value in the compounds obtained increased from 0.07 to 0.20.

Unambiguous proof of the ionic structures of aqueous MoS₂ and WS₂ dispersions was obtained in the studies of their interactions with cationic compounds. It was reported¹¹⁵ that the replacement of lithium cations in the dispersions by cations less prone to hydration (*e.g.*, tetraalkylammonium cations) results in virtually immediate precipitation of the layered compounds containing monolayers of the corresponding cations. These compounds contain neither water molecules as the hydration shell of the cations between the layers nor noticeable amounts of the halogen, which is consistent with the ionic mechanism of their formation.

An analogous conclusion concerning the ionic mechanism of the reaction was made from the study¹²⁴ of the intercalation of a cationic cluster [Al₁₃O₄(OH)₂₄(H₂O)₁₂]⁷⁺ (AL13) into MoS₂ and WS₂ matrices using their aqueous dispersions obtained by hydration of lithium-containing intercalation compounds and washed with water up to neutral pH. The same mechanism is supported by the results of intercalation of AL13, Fe₆S₈(PEt₃)₆²⁺ and Cp₂Co⁺ into TaS₂ using single-layer dispersions obtained by exfoliation of Na_xTaS₂ in a water–*N*-methylformamide medium.^{125, 126}

As might be expected from the ionic mechanism of the reaction (5), the content of the intercalated cations in precipitated products depends on the negative charge retained on the layers at the moment of formation of a given compound as well as on the geometrical sizes of the cations (more precisely, on the minimum matrix layer area occupied by the corresponding cation). As was shown for the series of compounds $(R_4N)_xMoS_2$,^{115,127} this charge can reach $\sim 0.3 \bar{e}$ per Mo atom for the intercalation of Me_4N^+ or RMe_3N^+ cations, which form closely packed monolayers between the neighbouring MoS_2 layers. In this case, the long-chain *n*-alkyl substituents *R* in RMe_3N^+ are oriented perpendicular to the MoS_2 layers (Fig. 5). For the cations occupying a greater layer matrix area (*e.g.*, for *R* = Et, Pr, *etc.*), the content of the cation $x = 0.3$ cannot be achieved in a closely packed monolayer for steric reasons. Therefore, even with the excess of R_4NX salt, the charge on the MoS_2 single layers decreases in the course of formation of the compounds up to the sterically permitted value (Table 2). It can also be noted that the packing of organic cations between the layers of molybdenum disulfide depends on the content of cations in the compound and that in all cases the packing giving minimum interlayer spacing

Figure 5. Orientation of intercalated tetraalkylammonium cations in the layered compound $(C_{18}H_{37}Me_3N)_{0.25}MoS_2$.¹²⁷

	0.05	4.9

with the given guest content is realised. Thus, varying the nature and the concentration of intercalated cations, the thickness of organic layer in the compound may be changed from its minimum value of $\sim 5 \text{ \AA}$ which is characteristic of all tetrasubstituted ammonium cations (and corresponds to the NC_4 tetrahedra orientation shown in Fig. 6) to $\sim 29 \text{ \AA}$ for the case of $n-C_{18}H_{37}Me_3N^+$ (see Ref. 127).

Nitrogen-containing bases may also serve as sources of cations that initiate the formation of intercalation compounds from MoS_2 single-layer dispersions. Upon protonation in aqueous solution, these bases are intercalated as mixtures of cationic species and neutral molecules. For instance, the synthesis of two types of MoS_2 intercalation compounds with 1,10-phenanthroline (phen) has been described.¹²⁸ Their structures depended on the acidity of the reaction medium. In $(phen)_{0.1}MoS_2$, the flat phenanthroline molecules are parallel to molybdenum disulfide layers ($\Delta c = 3.5 \text{ \AA}$), whereas, in $(phen)_{0.35}MoS_2$ ($\Delta c = 8.8\text{--}9.4 \text{ \AA}$), they are inclined and probably form piles (Fig. 7). Structural models proposed for compounds with phenanthroline were confirmed by EELS data obtained on the oriented particles. Calculations of the volumes occupied by the guest showed that in both cases phenanthroline molecules are closely packed in the interlayer space of MoS_2 . Close packing was also observed upon MoS_2 intercalation with another compound, *viz.*, hexamethyltetraazacyclotetradecaneacetic acid. In this case, guest molecules were oriented parallel to the matrix layers.¹²⁹

However, the examples where the space between the guest molecules is occupied by solvent molecules are also known for the intercalation compounds obtained from single-layer dispersions. In particular, this was observed for the above-mentioned co-

Figure 6. Orientation of Et_4N^+ cations with respect to the matrix layer corresponding to the minimum guest layer thickness.¹²⁷ Projections onto the *ac* (a) and *ab* (b) planes.

intercalation of naphthalene and water into MoS₂.¹²³ In the case of MoS₂ intercalation with polyoxoanions AL13, their content (0.04 mol per mol MoS₂) was lower than the maximum allowed for a closely packed monolayer (0.06 mol per mol MoS₂) and up to 20 water molecules per cluster was contained in the interlayer space.¹²⁴ In the compound [Fe₆S₈(PEt₃)₃]_{0.05}TaS₂, there are up to 40 molecules of H₂O or *N*-methylformamide for each intercalated cation (according to the elemental and thermogravimetric analysis data).¹²⁶

It is worth noting that single-layer dispersions were found to be a rather convenient 'tool' for the intercalation of cationic complexes. In addition to the above-mentioned examples, preparation of the MoS₂ intercalation compounds with cationic tris(phenanthroline)- and tris(bipyridine)-3d-metal complexes,¹³⁰ the Fe(III) complex with porphyrin¹³¹ as well as with the ruthenium-arene aqua complexes¹³² may also be noted.

In a number of examples, intercalation of complexes at room temperature is accompanied by their chemical transformations. For instance, the elimination of three phosphine ligands occurred in the formation of the layered compounds from cobalt phosphine chalcogenide clusters Co₆X₈(PR₃)₆²⁺ (Refs 114, 133) and their iron-containing analogue Fe₆S₈(PEt₃)₆²⁺ (Ref. 125). The intercalated layer thickness in the layered systems formed varied from 9.5 to 15.3 Å depending on the structural features of the ligands. It is thought that the liberated coordination sites around the metal atom were initially occupied by solvent molecules and not by the sulfur of the TX₂ layers. This follows from the orientation of the complexes in the interlayer space [with the C₃ axis of the Fe₆ octahedron perpendicular to the layers (Fig. 8a)] proposed on the basis of the X-ray diffraction study of the electron density distribution along the *c* axis in compound [Fe₆S₈(PEt₃)₃]_{0.05}TaS₂ ($\Delta c = 11.5$ Å).^{125, 126} Heating at 200 °C (Refs 114, 126) as well as the action of the electron beam in the electron microscope¹³³ results in the removal of residual phosphine ligands and in the decrease in the intercalated layer thickness up to 6–8 Å. Based on these facts, it was suggested that the species with composition Co₆X₈ or Fe₆S₈ remain in the interlayer space. Note that such clusters are most likely chemically bound to the sulfur atoms of the matrix layers.

Interaction of an MoS₂ single-layer dispersion with ruthenium-arene aqua complexes [(arene)Ru(H₂O)₃]²⁺ may also be accompanied by their chemical transformations. It was shown¹³² that, depending on the pH of the reaction media, the complexes are intercalated in a monomeric form (weakly acidic

medium) or in the form of dimeric complexes [(arene)Ru(μ-OH)₃Ru(arene)]⁺ produced *in situ* due to condensation if the reaction is carried out in a weakly basic medium. Interatomic Ru–C, Ru–O and Ru...Ru distances in the intercalated complexes found by EXAFS for the benzene derivative corresponded to the distances in the known dimeric complex [(C₆H₆)Ru(μ-OH)₃Ru(C₆H₆)]⁺. Interlayer spacings and compositions observed for intercalation compounds with binuclear complexes [(arene)Ru(μ-OH)₃Ru(arene)]⁺ depended on the substituents in the ligands and were found to be 6.0 Å (*x* = 0.12), 10.6 Å (*x* = 0.11), and 5.8 Å (*x* = 0.06) for benzene, 1,2,4,5-tetramethylbenzene and 1-methyl-4-isopropylbenzene derivatives. These data agree well with the structural model in which arene ligands are oriented perpendicular to the matrix layers (Fig. 8b) and the complexes completely fill the interlayer space.¹³²

Filling of the interlayer space of molybdenum disulfide by tris-phenanthroline- and tris(bipyridine)-metal complexes M(chel)₃²⁺ (M = Fe, Co, Ni, chel = 2,2'-bipyridine, 1,10-phenanthroline) in their reactions with an aqueous MoS₂ single-layer dispersion is accompanied by partial dissociation of these complexes.¹³⁰ It is evidenced by the presence of metal oxides (hydroxides) in the reaction products found by Mössbauer spectroscopy for iron complexes as examples. The oxide compounds present as an admixture are removed by treatment with acid. Mössbauer parameters of the complexes remaining in the interlayer space conform to those of their low-spin crystalline analogues and suggest somewhat greater distortions in ligand surrounding of the metal in the intercalated cationic complexes.¹³⁰ Interlayer spacings in [M(chel)₃]_{*x*}MoS₂ (*x* = 0.02–0.03) with phenanthroline (8 Å) and bipyridine (8.5 Å) ligands are consistent with the orientation of the C₃ axis of the corresponding complexes perpendicular to the layers (Fig 8c).

It was also reported¹³⁴ that MoS₂ is intercalated with alkali metal complexes of crown ethers (12-crown-4, 15-crown-5 and 18-crown-6). However, the obtained layered compounds were unstable and washing with water resulted in the extraction of the intercalant.

2. Nanocomposites with polymers

A wide range of compounds in which the interlayer space of TX₂ is filled with polymeric molecules are currently known.^{101–103, 134–148} Such compounds, which consist of two extended structures differing in chemical nature, belong to nanocomposite materials. Experimental data for nanocomposite materials based on TX₂ and polymers are given in Table 3. It should be mentioned that synthesis of polymer-inorganic matrix hybrid composite materials is now taking features of the whole line of inquiry which continues to grow in popularity (*e.g.*, see Ref. 149). Such nanocomposites based on metal dichalcogenides are mostly obtained by adding aqueous solutions of a polymer to aqueous TX₂ single-layer dispersions. Sometimes, other solvents are also used as, for instance, *N*-methylpyrrolidinone for PANI,¹³⁵ CF₃CH₂OH for Nylon-6 and decalin for polyethylene.¹³⁸ In this case, the formation of nanocomposites can proceed in a water-organic solvent biphasic system. For pyrrole¹⁴⁷ and styrene,¹⁴⁸ *in situ* polymerisation was carried out. Pyrrole was introduced in an aqueous dispersion as a monomer along with FeCl₃, and macromolecules formed upon its oxidative polymerisation filled the space between the molybdenum disulfide layers. Polymerisation of styrene is believed to occur in the interlayer space.¹⁴⁸ An interesting modification of a procedure for the preparation of these materials is a layer-by-layer deposition of the MoS₂ layers from dispersions and the layers of a polymer from its solution in poly(allylamine hydrochloride).¹⁴³ It was noted¹⁴³ that, independent of the absorption time, the increase in the film thickness in each cycle corresponded to one monolayer in agreement with a growth mechanism based on the mutual compensation of the charges of polyanions of single-layer (MoS₂)^{x-} and the polycationic polymer.

^a The composition displays the content of monomer units per TX₂ formula unit. ^b Low-molecular polymer with $M_w < 10\,000$ is used. ^c Film obtained by layer-by-layer deposition of polymer and MoS₂.

Most polymer-containing nanocomposites were obtained with the use of molybdenum disulfide single-layer dispersions (see Table 3). The same approach was also used for other dichalcogenide matrices which can form dispersions, such as, NbSe₂,¹⁰² TaS₂,¹⁰³ TiS₂ (Ref. 101) and MoSe₂.¹⁰¹ A misfit compound (PbS)_{1.18}(TiS₂)₂ has also been used as a matrix in the synthesis of nanocomposites with polymers.¹⁴⁶ In the structure of this compound, uncommensurate layers¹⁵⁰ alternate in the sequence S—Ti—S...S—Ti—S...PbS. Synthesis of the nanocomposite was carried out by intercalation of lithium followed by the exfoliation performed directly in an aqueous PEO solution. The data from X-ray and electron diffraction analysis¹⁴⁶ are consistent with the viewpoint that the polymer molecules fill the van der Waals gaps only between the adjacent TiS₂ layers.

It was noted for many examples, that alkali metal cations enter into the interlayer space (0.1–0.2 atom per T atom) along with a polymer.^{101, 103, 139, 140, 144, 145} This agrees with the retention of the charge separation between the guest and the host in these intercalation compounds as in the case of compounds with molecular guests.

The cations situated in the interlayer space of metal dichalcogenides may form complexes with polymers. This is particularly characteristic of PEO. Based on the analysis of ²³Na NMR spectra, it has previously been noted that strong cation–polymer interactions take place in related systems with aluminosilicates.¹⁵¹ Similar conclusion has been made from the study of ⁷Li NMR spectra and electron density distribution in Li_x(PEO)_yMoS₂ phases¹⁰³ as well as from the data from IR spectroscopy obtained for Li_x(PEO)_y(PbS)_{1.18}(TiS₂)₂.¹⁴⁶ Complexing properties of poly(ethylene oxide) with respect to alkali metals have been specially

used for the preparation of the nanocomposites with MoS₂.¹³⁴ Precipitation was carried out from aqueous solutions of PEO and ACl (A is an alkali metal). The nanocomposites obtained contained no chlorine and relative amounts of A and PEO depended on the nature of the alkali metal. Thicknesses of the polymer-containing layers also depend on the nature of the metal and vary in the reaction products from 3.3 to ~10 Å (see Table 3). This is apparently due to the difference in geometry of the complexes formed by the metal with the polymer units.

¹³C NMR studies of the conformation of poly(ethylene oxide) in the nanocomposite Li_{0.09}(PEO)_{1.28}MoS₂ do not give an unambiguous answer to the question about the polymer packing. It was found that ~90% of the O—C—O fragments of the polymer chain are in the *gauche* conformation, whereas, according to the calculations, the content of such fragments in stretched polymer molecules inscribed into the tunnels of 8 Å diameter should be 50% and 100% upon chaotic and spiral packings, respectively (in the latter case, all the *gauche* conformers are of the same sign).¹⁴⁴ It should be mentioned that spiral packing is characteristic of PEO–ACl complexes.¹⁵² Yet another model accounting for possible solvation of lithium cations by oxygen atoms of the polymer is that polymer units form flat rings resembling crown ethers, with the oxygen atoms being directed inward. In this case, the content of O—C—C—O fragments in *gauche* conformations (with the alternating signs) may amount to 75%. This percentage may be exceeded which requires that the conformational equilibrium of C—O—C—C chain fragments are shifted from *trans* to *gauche* conformers.

As was pointed out in many publications dealing with nanocomposites of molybdenum disulfide and polymers, the electrical

conductivity (σ) of the nanocomposites markedly increases with respect to that of MoS_2 ; σ values were found to be $\sim 6 \times 10^{-6}$ (Ref. 134) or $2 \times 10^{-7} \Omega^{-1} \text{cm}^{-1}$ (Ref. 145). Despite the differences in the σ values (*cf.* Table 3, compounds with PEO), this increase has been well established for the nanocomposites with both conducting (*e.g.*, PANI) and non-conducting (*e.g.*, PEO) polymers. The exception is provided by the compounds with nylon and polyethylene for which no increase in conductivity was observed. The fact that electrical conductivity of nanocomposites slightly increases with temperature and that these materials exhibit Pauli paramagnetism at 50–300 K^{136,138} allow one to attribute them to semimetals. The increase in electronic conductivity in the nanocomposites based on MoS_2 is usually associated with a structural rearrangement of the layers of the initial MoS_2 (and a corresponding change in the type of its electronic structure) from 2H (semiconductor) to 1T (semimetal) modification during the dispersion process. In some cases, the conductivity of the compounds was found to decrease gradually on ageing or on heating at 100–200 °C. This is interpreted as a gradual structural reverse transition 1T $\rightarrow$ 2H which has earlier been observed³¹ for pure 1T- MoS_2 . However, it should be noted that the 1T modification is apparently stabilised in the presence of a polymeric guest or/and the charge on the matrix layers. This is deduced from the fact that the transition to the 2H-structure manifested as an exothermic effect in the curves of differential thermal analysis occurs at higher temperatures (up to 177 °C) for the nanocomposites than for pure 1T- MoS_2 (94 °C).¹³⁸

Conductivity is noticeably higher for polymer-containing nanocomposites based on the Group VB metal dichalcogenides than for their analogues based on MoS_2 . However, conductivity of the former is lower than that of the corresponding non-intercalated TX_2 , as could be expected from band structure considerations.

The nanocomposites considered also possess ionic conductivity (σ_i) along with electronic conductivity (σ_e). It was shown¹⁴⁵ that the ionic conductivity of $\text{Li}_{0.1}(\text{PEO})_1\text{MoS}_2$ is $\sim 10^{-6} \Omega^{-1} \text{cm}^{-1}$, while σ_e/σ_i is 10^3 . The ionic conductivity of this compound is obviously caused by the mobility of lithium ions which is significantly higher in the nanocomposites than in Li_xMoS_2 . For instance, at 25 °C the diffusion coefficient of lithium in $\text{Li}_{0.1}\text{MoS}_2$ equals $4 \times 10^{-13} \text{cm}^2 \text{s}^{-1}$, whereas it reaches 5×10^{-12} and $10^{-10} \text{cm}^2 \text{s}^{-1}$ in $\text{Li}_{0.1}(\text{PEO})_1\text{MoS}_2$ and $\text{Li}_{0.1}(\text{PEO})_{0.5}\text{MoS}_2$, respectively.¹⁴⁵

At a temperature of 14–15 K, a metal–insulator transition is observed for MoS_2 -based nanocomposites,¹³⁸ while NbSe_2 - and TaS_2 -based compounds exhibit superconductivity at cryogenic temperatures.^{102,103} The highest temperature of the transition to the superconducting state, $T_c = 7.1$ K, which is virtually equal to T_c for a non-intercalated matrix [7.2 K (see Ref. 3)] was found for $(\text{PVP})_{0.14}\text{NbSe}_2$.¹⁰² In the cases of TaS_2 nanocomposites with PEO, PVP and PEI, an increase in T_c (up to 2.5–2.9 K) as compared with T_c of the initial 2H- TaS_2 (0.8 K) was observed.¹⁰³

3. Compounds with metals and metal hydroxides

The formation of precipitates upon addition of metal salts to single-layer dispersions has been observed in the earliest publications describing the behaviour of dispersed TX_2 . Thus Lerf and Schöllhorn⁶⁶ pointed to the precipitation of compounds with non-established structures upon action of lanthanum salts on TiS_2 dispersion in *N*-methylformamide. The precipitation of powdered compounds upon action of salts of various metals (Al, In, Ni, Co, Ce, Sr, Cd, Zr, Zn, Pb) on single-layer dispersions was observed by Gee *et al.*¹⁵³ In the authors' opinion, these were the 'inclusion compounds' containing metal hydroxides distributed throughout the MoS_2 matrix.

However, more recent studies on the reactivity of molybdenum disulfide dispersed in water showed that the compounds formed may differ in their nature, the latter being determined by both the nature of metal cations involved in the interaction and the reaction conditions. If the alkali metal cations are present in

solution, the corresponding layered solvates $\text{A}_x(\text{H}_2\text{O})_y\text{MoS}_2$ ($\text{A} = \text{Li}$, $x = 0.12$; $\text{A} = \text{K}$, $x = 0.2$) are precipitated from single-layer dispersions, the same solvates are also formed in the exchange of intercalated organic cations with cations A^+ (see Ref. 115). In the presence of metal (M) cations able to form coordination bonds with sulfur atoms of the MoS_2 layers, two reaction pathways are possible. One of them leads to the formation of compounds similar to the above-described ternary molybdenum sulfides M_xMoS_2 , the other leads to the filling of the interlayer space with metal hydroxo compounds (Eqns 6a, 6b).

Obviously, the type of the compound formed is determined by the tendency of metal cations to form sulfide derivatives with MoS_2 or oxo(hydroxo) compounds in an aqueous medium. Thermodynamic characteristics of sulfide macroanions $(\text{MoS}_2)^{x-}$, in particular the stability constants of their complexes are not known, while the characteristics of binary sulfides are well known. Therefore, for a large series of metals, the compositions of intercalation compounds formed were correlated with the difference in solubility products (pK_{sp}) of the corresponding metal sulfides MS_y and hydroxides $\text{M}(\text{OH})_n$.¹⁵⁴ It was noted that, if $K_{\text{sp}}[\text{MS}]$ and $K_{\text{sp}}[\text{M}(\text{OH})_2]$ differ by 2–4 orders of magnitude (Mn^{2+} , Fe^{2+} , Co^{2+} , Ni^{2+}), compounds with alternating S–Mo–S and hydroxide-like $\text{M}(\text{OH})_{2-x}(\text{H}_2\text{O})_x$ layers are formed [see Eqn (6b)]. The cations characterised by $K_{\text{sp}}[\text{MS}] - K_{\text{sp}}[\text{M}(\text{OH})_2] \approx 10^{11} - 10^{14}$ (Pb^{2+} , Cd^{2+}) exhibit a strong tendency to form coordination bonds with sulfur atoms of MoS_2 , but can yet be intercalated in the form of hydroxo compounds upon increase in pH. It is only in the case where the difference mentioned exceeds 16 orders of magnitude that the formation of ternary sulfides (6a) dominates in single-layer dispersions.

a. Phases intercalated with hydroxo compounds

Upon precipitation of aqueous MoS_2 single-layer dispersions in the presence of hydrated rare-earth $[\text{La}^{3+}$, Er^{3+} , Th^{4+} (see Ref. 155)] or 3d-metal cations, aqua(hydroxo) compounds fill the interlayer space.^{153,155} Freshly precipitated compounds with rare-earth elements possess distinct layered structures and are characterised by a large increase in the interlayer distance (for instance, in the case of Er^{3+} , Δc value reaches 9.8 Å). However, amorphisation of these compounds occurs in a few hours. This may be explained by the tendency of intercalated cations to form compounds with a high (up to 8–12) and variable content of water molecules in the hydration shell and it is the loss of these molecules on ageing that causes amorphisation.

The parameters of layered MoS_2 compounds with 3d-metals remain invariable at room temperature for a long time. For the substances formed in the interlayer spaces of these compounds, both the composition (atomic M:O ratio determined by EELS¹¹⁶) and the local structure [interatomic M–O and M...M distances determined by EXAFS for the compounds with Mn, Co, Ni (see Refs 64, 156–158)] are close to those of the corresponding metal hydroxides $\text{M}(\text{OH})_2$. These hydroxides themselves are known to have a layered hexagonal structure in which the metal atoms occupy the octahedral sites between two closely packed layers of the hydroxide ions (which corresponds to the polytype 1T in the classification of transition metal dichalcogenides).¹⁵⁹ For some crystalline 3d-metal (Mn, Fe, Co, Ni) hydroxides, the parameters *a* of their hexagonal lattices, defining the M...M and anion–anion distances inside the layer, are close to those of MoS_2 , the deviation being in the range of a few percents (Table 4). Commensurability of the lattices of two substances

Table 4. Structural parameters (Å) of intercalation compounds $[M(OH)_2]_{1/2}MoS_2$ and the corresponding metal dihydroxides $M(OH)_2$ determined by powder diffraction and EXAFS.¹⁵⁸

different in nature obviously favours the formation of the structure with alternating metal sulfide and metal hydroxide layers (Fig. 9) in a single-layer dispersion.

Presumably, in the formation of compounds with 3d-metals, the extended two-dimensional aqua-hydroxo-clusters $[Mo_{0.5}(OH)_{1-x}(H_2O)_x]^{x+}(MoS_2)^{x-}$, which compensate the negative charge of the disulfide monolayer, are initially produced on the surface of $(MoS_2)^{x-}$ single layers [Eqn (7)]. During precipitation and ageing, the structure of these intercalated clusters is transformed into a thermodynamically more stable structure of pure metal hydroxide through replacement of water molecules by OH^- anions. Such a transformation can occur upon oxidation of part of the ions $M(II)$ in the guest layer by oxygen leading to a mixed hydroxide $M(II,III)(OH)_2$ [reaction (7a)] and also upon reduction of water molecules with evolution of molecular hydrogen [reaction (7b)].¹³⁰

It is obvious that the reaction (7a) is favoured by the ability of metal ions to adopt a higher oxidation state. It has been shown by means of ⁵⁷Fe Mössbauer spectroscopy and electron microscopy that the reaction of single-layer dispersion with $Fe(II)_{aq}$ follows this pathway and that the product contains $Fe(II)$ and $Fe(III)$ in the oxygen environment.¹¹⁶ Temperature dependence of the Mössbauer spectra of the iron-containing compound indicates that magnetic ordering occurs simultaneously for both iron forms

in a narrow temperature range (~ 10 K). This suggests the presence of both these forms in a single structure. The character of the transition points to a small size of magnetic domains and their narrow size distribution. The formation of a joint structure by both forms of iron is also deduced from the occurrence of a thermally activated fast electronic exchange between them, which results in the appearance of an iron state with intermediate Mössbauer parameters at 300–380 K.^{160, 161}

The reaction pathway (7b) is realised in the case of compounds with $Co(II)$ and $Ni(II)$. Measurements of magnetic characteristics of the precipitated products point to the occurrence of both the Co^{2+} ($\mu = 5.2 \mu_B$) and Ni^{2+} ($\mu = 3.2 \mu_B$) ions in the octahedral environment characteristic of the corresponding metal hydroxides,¹⁶² while the interatomic distances in the intercalated layer are consistent with those in $M(OH)_2$ as was mentioned above. Complete substitution of OH^- for H_2O probably takes a long time, so the MoS_2 layer in the intercalation compounds continues to bear partial negative charge. This agrees with the prolonged conservation of characteristic distortions in the matrix layer (the set of non-equivalent $Mo-Mo$ distances^{64, 157, 158} and a superstructure in the plane of the layers¹⁶³) in these compounds.

b. Phases intercalated with metals

Compounds with the composition M_xMoS_2 ($M = Cu, Ag, Cd, Hg, Pd, Pb$) formed where the $(MoS_2)^{x-}$ layers act as polysulfide macroligands were obtained by precipitation of single-layer dispersions in the presence of the cations noted.^{154, 164–166} Judging from the $M-S$ distances, the intercalated metal atoms form direct covalent or ionic-covalent bonds with sulfur atoms of the matrix layers (EXAFS data^{154, 165, 166}). It is of note that there are no direct analogues to the above-mentioned compounds among the known ternary molybdenum sulfides obtained by high-temperature synthesis where the $S-Mo-S$ layers are only present in the structures of compounds with 3d-metals [V, Cr, Fe, Co (see Refs 83–89)]; the other metals [*e.g.*, Ga and Al (see Ref. 167)] form compounds with a spinel structure.

In the dispersions, the charged molybdenum disulfide single-layers exhibit reducing properties with respect to the cations characterised by the positive redox potentials.¹⁵⁴ For instance, for Ag^{2+} , Pd^{2+} and Hg^{2+} , their reduction products $[Ag(0), Pd(0), Hg_2^{2+}]$ were obtained along with the M_xMoS_2 phases.^{154, 165, 166} In the case of Cu^{2+} , the reduced Cu^+ cations were incorporated into the layered compound formed. Hence, all the copper atoms in the prepared $Cu_{0.35}MoS_2$ had the oxidation state $+1$.¹⁶⁵ Experimental data show that the single-layers $(MoS_2)^{x-}$ reduce metal cations if the layer charge x exceeds some threshold value. The maximum layer charge equal to $1\bar{e}$ per Mo atom in $LiMoS_2$ decreases during the dispersion (which is accompanied by hydrogen evolution) and subsequent ageing, thus lowering the reducing ability of the $(MoS_2)^{x-}$ layers. The composition of compound $Cu_{0.35}MoS_2$ formed upon the action of Cu^{2+} ions on the MoS_2 single-layer dispersion indicates that this charge can reach $\sim 0.7\bar{e}$ per Mo atom in the freshly prepared dispersions and that the single-layer no longer reduces Cu^{2+} when the charge decreases to $\sim 0.35\bar{e}$ per Mo atom (see Ref. 165).

Structural parameters for the M_xMoS_2 phases are given in Table 5. It is clear from the Table that the increase in the interlayer spacing is small for various metal atoms introduced into the MoS_2 matrix, but it increases with the increase in the sizes of the guest cations. It is of note that a comparison of either Δc for this compound or the radii of the intercalated cations with the sizes of the interstitial vacant sites between the sulfur atoms (octahedral of ~ 0.7 Å radius and tetrahedral of ~ 0.4 Å radius) does not allow unambiguous determination of the type of occupied vacancies since the MoS_2 matrix itself may be essentially distorted and 'the thickness' of its layers may change. For instance, in the crystalline $Co_{0.5}MoS_2$ (prepared by high-temperature synthesis), the coordination environment of molybdenum is octahedral and the interlayer distance is 5.72 Å,⁸⁷ *i.e.*, the thickness of the $S-Mo-S$ layers is smaller by ~ 0.5 Å in this compound than in non-

Figure 9. Alternating monolayers of MoS_2 and $M(OH)_2$ in the layered compound.

intercalated 2H- MoS_2 in which the environment of molybdenum is trigonal prismatic.

EXAFS data has been used to estimate the type of coordination environment of intercalated metals.^{154, 165, 166} The type of coordination of the guest atoms M with sulfur atoms is primarily determined by the preferable coordination polyhedra of M, both in TX_2 compounds with metals prepared by high-temperature synthesis and in M_xMoS_2 compounds obtained from single-layer dispersions. Thus Pb^{2+} ions occupy the octahedral vacancies while Cd^{2+} , Pd^{2+} , Cu^+ and Ag^+ ions have tetrahedral surroundings, non-distorted for cadmium and distorted to a variable degree for palladium, copper and silver. For the two last-mentioned metals, the displacement of their atoms to one of the vertices inside a tetrahedral vacancy is assumed based on both the experimental results and comparison with the structures of related sulfide compounds. The strongest distortion of coordination polyhedron in the interlayer space of M_xMoS_2 is probably characteristic of mercury compounds because the basic site occupied by mercury is strongly deformed to realise the most suitable near-linear coordination for Hg(II) with S atoms.

The Mo K -edge EXAFS^{154, 165, 166} and, in some cases, X-ray and electron diffraction¹⁶⁵ data showed that the layer matrix in M_xMoS_2 sulfides obtained from single-layer dispersions is distorted owing to the formation of Mo–Mo bonds. At the same time, due to covalent guest–matrix bonding, these compounds are distinguished among the intercalation compounds prepared from single-layer dispersions by their most structural ordering. In particular, X-ray diffraction data¹⁶⁸ indicate that three-dimensional correlations in the layer stacking (rather than turbostratic packing) for the distances of 50–70 Å is characteristic of copper and silver compounds.

VI. Structural transformations of the chalcogenide matrices in the formation of single-layer dispersions

A study of the atomic structure of the TX_2 layers in both the dispersions and the layered materials precipitated from them is a non-trivial task because the subjects of investigation are layered nanostructured species, in many cases thermodynamically metastable, characterised by the absence of a long-range order and by a strong anisotropy of the interatomic interactions. Only scarce information can be obtained by XRPD for such compounds (even for those precipitated) since the diffraction is essentially two-

dimensional in character owing to turbostratic packing and does not allow the unit cell structure to be completely determined. For this reason, structural studies of these materials require the application of a combination of instrumental and calculation methods. These were mainly carried out for materials based on molybdenum and tungsten disulfides because of their potential practical use and also owing to unusual structural transitions found in their quasi-two-dimensional layers.

The distinctions between the atomic structures of the MoS_2 (WS_2) layers present in single-layer dispersions or in the precipitated products and those of the most stable 2H-modifications have repeatedly been observed using physical methods, first of all, EXAFS,^{64, 109, 154, 157, 158} and X-ray and electron diffraction.^{109, 163, 165, 169} The main feature of the local order in the layered compounds formed is the redistribution of T...T distances. For MoS_2 compounds, three non-equivalent Mo...Mo distances (~ 2.8 , ~ 3.2 and ~ 3.8 Å) were observed in the EXAFS spectra instead of one (3.16 Å) distance in 2H- MoS_2 . The shortest Mo–Mo contact in the modified layer corresponds to the formation of a metal–metal chemical bond.

Currently, it is agreed that the Mo(W) atoms in the layered compounds prepared from the single-layer dispersions have an octahedral rather than a trigonal prismatic (as in 2H- MoS_2 and 2H- WS_2) coordination environment. Though this supposition is not experimentally verified to date, it appears to be quite probable taking into account the partial retention of the negative charge on the TS_2 layer in all the following consecutive transformations: $\text{LiTS}_2 \rightarrow \text{dispersions} \rightarrow \text{precipitated layered compound}$. Even the first calculations of the band structure carried out in the early 1970's showed that the octahedral coordination becomes more energetically advantageous for the molybdenum atoms upon adding of 1 $\bar{e}$ per Mo atom to the conduction band formed mainly by the 4d-orbitals of molybdenum. Thus, at least part of the atoms in the charged $(\text{TS}_2)^{x-}$ layer should be in the octahedral environment. Indirect evidence for the octahedral coordination has been reported.⁵⁷ In addition, this coordination is well established by X-ray diffraction analysis for single crystals of ternary sulfides $\text{M}_{0.5}\text{MoS}_2$ prepared by high-temperature synthesis.^{83–88} As in LiMoS_2 , the formal oxidation state of molybdenum in these layered derivatives of molybdenum disulfide remains +3. For LiMoS_2 and materials prepared from dispersions, all the structural models are based on the octahedral coordination of molybdenum postulated for the metastable modification 1T- MoS_2 .³¹

Calculations by the extended Hückel method in the rigid band approximation showed¹⁷⁰ that the Fermi surface is characterised

by nesting[†] in the case of the layered systems with an octahedrally coordinated central atom with d^2 or d^3 electron configuration. In such systems, the metal atom sublattices are unstable, they undergo distortions to form charge density waves (CDW) unrigging this symmetry. In same sense, CDW formation is analogous to the Jahn–Teller distortions in molecular systems,¹⁷¹ while the splitting of the partially filled degenerate orbitals leading to lowering of the overall energy of the system may serve as an analogue of the splitting of partially filled d-sub-band of the metal atom causing the appearance of an energy gap between the filled valence band and the conduction band in the case of infinite quasi-two-dimensional layers. The most probable result of the distortions is the formation of triangular clusters or infinite zigzag chains built of metal atoms.^{13, 170, 171}

The calculations of the LiMoS_2 structure with optimisation of the geometry by DFT FLAPW (Density Functional Theory, Full-Potential Linearised Augmented Plane Wave) method showed¹⁷² that the formation of a $2a \times 2a$ superstructure (zigzag chains formed by rhombus-shaped clusters of molybdenum atoms) lowers the energy of the system. The results obtained, namely, the lengths of the contracted and elongated (with respect to the lengths in the initial 2H-MoS_2) Mo–Mo bonds in the optimised LiMoS_2 structure are consistent with the EXAFS results obtained at the Mo K -edge.³⁹ The same type of ordering is present in the structure of LiMoS_2 , which was simulated based on the analysis of PDF obtained from X-ray diffraction data (Fig. 10 *a*).⁶⁵ According to this model, the structure as a whole is characterised by a triclinic symmetry ($a = 6.963 \text{ \AA}$, $b = 6.386 \text{ \AA}$, $c = 6.25 \text{ \AA}$, $\alpha = 88.60^\circ$, $\beta = 89.07^\circ$, $\gamma = 120.06^\circ$; the space group $P\bar{1}$).

According to the data from X-ray single crystal analysis, the clusters consisting of molybdenum atoms are also present in the molybdenum ternary sulfides obtained by high-temperature synthesis.⁸⁷ For instance, the zigzag chains with direct Mo–Mo bonds exist in the $\text{Co}_{0.5}\text{MoS}_2$ structure, which contains four symmetrically independent molybdenum atoms in the unit cell (Fig. 10 *b*). Taking into account the layer stacking, the crystal lattice of $\text{Co}_{0.5}\text{MoS}_2$ belongs to a face-centered monoclinic syngony (the space group Cc , $Z = 4$, $a = 11.793$, $b = 6.548$, $c = 12.680 \text{ \AA}$; $\beta = 115.5^\circ$) and the relationships between its parameters and the parameters of 2H-MoS_2 (a_0 , c_0) are as follows: $a \approx 2\sqrt{3}a_0$ and $b \approx 2a_0$, $c \sin \beta \approx c_0$. Thus, the displacements of the molybdenum atoms in $\text{Co}_{0.5}\text{MoS}_2$ with respect to their

Figure 10. Schematic representation of the chains formed by molybdenum atoms in the ab plane in LiMoS_2 (*a*)⁶⁵ and $\text{Co}_{0.5}\text{MoS}_2$ (*b*).⁸⁷ Figures indicate (in $\text{\AA}$) the values of interatomic distances contracted as compared with 2H-MoS_2 .

positions in the 2H-MoS_2 layer can also be approximated with a $2a \times 2a$ superstructure.

From EXAFS and X-ray diffraction studies carried out on the single-layer dispersions themselves, it was suggested that the molybdenum atoms in the single layers are displaced from their positions in the hexagonal $a \times a$ structure and form rhombuses (Fig. 11 *a, b*). This should result in two Mo–Mo distances (2.8 and $3.8 \text{ \AA}$) and multiplication of the in-layer parameters of the unit cell to $2a \times 2a$.^{107, 109} Such a model fits the experimental data best of all provided the molybdenum atoms are displaced by $0.45 \text{ \AA}$ along the a -axis of the unit cell ($a = 3.27 \text{ \AA}$). Redistrib-

[†] The regions of the Fermi surface coinciding with each other upon parallel transfer of the electron quasi-pulses in space.

Figure 11. Dispositions of molybdenum atoms in the ab plane for a hexagonal unit cell $a \times a$ (*a*) and models of its ordering with formation of tetramers ($2a \times 2a$) (*b*), trimers ($\sqrt{3}a \times \sqrt{3}a$) (*c*), trimers connected in the networks ($2a \times 2a$) (*d*), infinite chains ($2a \times a$) (*e*). The Mo–Mo bonds are given in bold.

ution of the Mo–Mo distances and the superstructure $2a \times 2a$ were also observed in the MoS₂ layered compounds with intercalated metal hydroxides^{157, 158} and metals (Cu, Ag)¹⁶⁵ obtained from dispersions. For the latter compounds, the comparison of X-ray diffraction and electron diffraction data showed that the $2a \times 2a$ superstructure was characteristic of most particles of the sample, however, yet another type of a superstructure, namely, $\sqrt{3}a \times \sqrt{3}a$ was present. The latter type of ordering, also found by scanning tunneling microscopy and electron diffraction in 1T-MoS₂ [the oxidation product of the layered solvates $K_x(H_2O)_yMoS_2$ (see Ref. 32 and 33)], can be described as a result of trimerisation of the molybdenum atoms giving triangular clusters (Fig. 11 c).

Based on the data obtained by EXAFS and electron diffraction for the precipitated MoS₂ dispersion, another variant of the cluster-like ordering of molybdenum atoms was proposed (Fig. 11 d).⁶⁴ This model assumes the displacement of molybdenum atoms in the *ab* plane of the 2H-MoS₂ layer by ~ 0.5 Å to form a trigonal unit cell (space group *P3*, $a = 6.5$ Å) containing 2 and 4 independent molybdenum and sulfur atoms, respectively. Thus, this type of ordering can be considered as being derived from a $2a \times a$ superstructure in the hexagonal cell. It is worth noting that the above-considered models imply an existence of only two M–M distances in the matrix layer, the short and the long (2.8 and 3.8 Å for MoS₂ derivatives), and do not imply the intermediate distance (~ 3.2 Å) which is usually detected by EXAFS in the products precipitated from dispersions. This contradiction can be caused by the inhomogeneity of the nano-materials in which both distorted and non-distorted fragments of the layers are present⁶⁴ or by the inadequacy of the models.

Based on the data from scanning tunnelling microscopy for the MoS₂ films precipitated from the dispersions,^{111, 173} a less symmetrical model of the atom ordering which includes the formation of infinite chains (Fig. 11 e) was proposed. This type of ordering can be described by using $2a$ and a as the periods of translation along the *a*- and *b*-axis of the initial hexagonal structure or by taking an orthorhombic unit cell with the parameters $\sqrt{3}a \times a$ in the *ab* plane (where a is a parameter of the initial hexagonal cell). It should be mentioned that this type of superstructure was found by scanning tunnelling microscopy and electron microdiffraction also in the layered solvates with potassium $K_x(H_2O)_yMoS_2$ at $0 < x < 0.3$.^{32, 33} Based on the analysis of electronograms, a similar type of ordering was proposed for precipitated MoS₂ and WS₂.¹⁶⁹ In this case, the symmetry of the layer was described using a two-dimensional group *pg* and the following parameters for the unit cell (for MoS₂): $a = 5.47$ Å, $b = 3.16$ Å, $\gamma = 90^\circ$. This corresponds to the shortest Mo–Mo distance of 2.92 Å, which is larger by ~ 0.1 Å than the distance inferred from the EXAFS spectra. In the electronograms of the multi-layered particles of the materials studied, the same authors¹⁶⁹ often observed a hexagonal $2a \times 2a$ superstructure which can appear due to stacking of three orthorhombic $\sqrt{3}a \times a$ structures rotated by 120° with respect to each other.

It is of note that only displacements of the molybdenum atoms in the *ab* plane are allowed for in the above-considered models. Meantime, the well established metal dichalcogenide structures are known, where the CDW modulations lead to puckering of the TX₂ layers. An example is given by the rhenium diselenide structure¹⁷⁴ representing a strongly distorted 1T polymorph with puckered layers (space group *P1*, $a = 6.72$ Å, $b = 6.60$ Å, $c = 6.73$ Å, $\alpha = 104.9^\circ$, $\beta = 91.8^\circ$, $\gamma = 118.9^\circ$). The mean deviation of the rhenium atoms from the layer plane is ~ 0.1 Å. The rhenium atoms have a strongly distorted octahedral environment consisting of selenium atoms (interatomic Re–Se distances are in the range of 2.35–2.66 Å), and form zigzag chains of irregular Re₄ rhombuses with Re–Re bonds along the *b*-axis. The motif of ‘clustering’ in ReSe₂ is close to that proposed for LiMoS₂ based on the calculations and PDF data, though the MoS₂ layer is flat in the latter case.

Figure 12. Projections onto the *ab* (a) and *ac* (b) planes and determination of the parameter of puckering for the T atom layer with puckering of WT_{e2} type.

Another type of structure ordering with puckered layers was found for WT_{e2} (Ref. 175) in which the tungsten atoms are also in strongly distorted octahedral environment and form infinite chains (Fig. 12 a, b). Using the model with such puckered layers and considering the diffraction and EXAFS data altogether, the parameters of layer puckering (h , in Fig. 12 c) were found¹⁰⁶ to be 0.46, 0.45 and 0.09 Å for single-layer dispersions of MoS₂, MoSe₂, and WS₂, respectively. It is of note that, upon precipitation of MoSe₂ from dispersion, the chains of the atoms are retained in the layer, while the puckering disappears.

In fact, the same type of chain (a structural motif of WT_{e2}) but a flat variant was earlier used to describe the structure of the precipitated WS₂ on the basis of PDF data analysis.¹⁷⁶ The structure was characterised as monoclinic (space group *P112*₁, $a = 3.27$ Å, $b = 5.71$ Å, $c = 12.31$ Å, $\gamma = 88.48^\circ$). It is important that the existence of all the three metal–metal distances in the distorted layer can be explained employing this model.

Thus, the in-layer structure of the molybdenum- and tungsten-based dichalcogenide matrices dispersed to single layers is modulated by regular distortions with formation of direct metal–metal bonds and these modulations extend for at least tens of Ångströms. It is noteworthy that the electronic interactions of the initial MoS₂ and MoSe₂ matrices with dopant atoms on their surfaces also result in the modulation of their structures, but in this case the modulations are of local character and do not extend for more than one Mo–Mo distance.¹⁷⁷ Note that the variations of superstructure proposed by various researchers may display real dissimilarity in the geometry of the layer in different compounds or even in different particles of the same material. Modification of the layer structure depending on the charge retained on the layer after the formation of the intercalation compound (or, on the time of ageing for precipitation of non-intercalated dichalcogenides TX₂) appears to be quite probable. This follows, for instance, from the difference in the layer geometry between the dispersed and precipitated MoSe₂,¹⁰⁶ as well as from the dependence of the relation between three Mo–Mo distances on the guest content, which has been found in the study of a large series of MoS₂ compounds with various guests.¹⁷⁸

VII. Possible applications of the materials obtained with the use of single-layer dispersions

Layered nanostructured TS_2 -based materials prepared through single-layer dispersions have considerable potential in heterogeneous catalysis,^{179–185} as lubricants,¹⁸⁶ reagents for the extraction of heavy metals,¹⁶⁴ chemical sensors,¹⁸⁷ novel magnetic materials,^{188, 189} and superconductors.¹⁰²

Currently, highly-dispersed molybdenum disulfide doped with 3d-metals (Co, Ni) is the most efficient commercial catalyst for oil hydrotreating. That is why the attempts to use the materials based on the re-precipitated MoS_2 in the hydrodesulfurisation processes appears to be justified.^{180, 190} Moreover, these materials were proposed as highly active and selective catalysts for hydrogenation of carbon monoxide to methane^{181, 184} and for coal liquefaction.¹⁸³ The increase in activity of the $\text{Pt}/\text{Al}_2\text{O}_3$ supported catalysts of methane oxidation are also achieved with the MoS_2 monolayer deposited onto the Al_2O_3 particles.¹⁸⁵

In industry, pure molybdenum disulfide has a large-tonnage application as the base for antifriction composites and solid lubricants exploited in wide temperature and pressure ranges as well as in chemically corrosive media and vacuum. Intercalation of MoS_2 with organic compounds, which has become possible with the advent of the single-layer dispersion technique, allows preparation of tribomaterials with enhanced properties as compared with those of materials obtained by mixing the components in the same composition.¹⁸⁶ An approach to produce magnetic lubricants for ferromagnetic surfaces based on the precipitated molybdenum disulfide doped with 3d-metals appears to be of interest.¹⁹¹

The single-layer dispersions of MoS_2 are able to bind the heavy-metal cations (first of all, Hg^{2+}) and thus can be considered as potential extractants, for instance, in waste-water purification.¹⁶⁴ In this case, the original MoS_2 and metallic mercury can easily be regenerated on heating the Hg_xMoS_2 formed at relatively low temperature ($\sim 400^\circ\text{C}$) under vacuum, and molybdenum disulfide can be repeatedly used in, at least, 3–5 working cycles with retention of its binding capacity.

It was proposed¹⁸⁷ to use thin partially crystalline, oriented MoS_2 films supported on Al_2O_3 and doped with platinum metals in sensitive and selective detectors of molecular hydrogen. Electroconductivity of such films depends linearly on the concentration of H_2 in the environment. Unlike the traditional sensors based on semiconducting transition-metal oxides, the systems mentioned can operate in the temperature range of $25\text{--}150^\circ\text{C}$. They are stable in many oxidising and reducing gaseous media.

Upon thermolysis of metal-containing intercalation compounds of metal dichalcogenides, nanosized metal clusters distributed within the layered TX_2 matrix are formed. Such materials may exhibit unique magnetic properties and are thus candidates for various applications in microelectronics.^{188, 189} In addition, the oriented films in which the interlayer distance can be widely varied are of potential interest for optics, *e.g.*, for developing novel X-ray mirrors and monochromators.¹⁹²

The currently available heterolayered compounds based on TX_2 and polymers have attracted the attention of many researchers as nanostructured conductors and ionic conductors. It has been mentioned that NbSe_2 -based nanocomposites can be used for designing plastic superconductors.¹⁰²

VIII. Conclusion

At present, the method for intercalation of metal chalcogenides based on their dispersion to single layers has gained acceptance among the techniques of solid-state chemistry. With this method, it is quite easy to construct layered compounds at room temperature using extended TX_2 structural units and the reagents introduced into solution.

It should be mentioned that the studies performed to date have mainly been focused on the synthetic aspects. Their prospects have

been showed and the advantages of a single-layer dispersion technique for the synthesis of novel intercalation compounds have been revealed. As shown above, this method permits one to introduce a rather wide variety of the guests in the materials, *viz.*, cations and neutral molecules of organic substances, polymers, polynuclear organometallic complexes, metal cations and metal hydroxide clusters. The method allowed one to extend essentially the range of TX_2 -based layered compounds, first of all, the intercalation compounds of molybdenum and tungsten disulfides as well as nanocomposite materials based on different TX_2 and polymers.

Coincident with manifestation of the advantages, the directions of method perfection have been revealed. It appears that they include, in particular, the use of new non-aqueous solvents providing stability to dispersed systems and possibilities of carrying out further operations for ‘assembling’ layered compounds. In most studies, aqueous (or aqueous-organic) media were used, which imposes special requirements on the nature of the guest. This problem can partly be overcome by performing the reaction in two-phase systems using aqueous media for dispersion and water-immiscible solvents for dissolving the guest. However, the guests sensitive to hydrolytic decomposition cannot be used even in this combination. Besides, such a procedure, which implies the formation of layered compounds on the interface, makes its isolation difficult and was used until now only for the preparation of materials in the form of films.

Yet another direction of method perfection is the enhancement of structural ordering of the compounds obtained. Usually, this is not high because the ‘assembling’ of layered compounds proceeds under non-equilibrium conditions. This may have the following consequences:

- non-uniformity in filling of the interlayer spaces by the guest and difficulties in the regulation of the chemical composition, especially with a low guest content (typically, the minimum content is limited by the composition for which the system does not yet contain the macroscopic phase of non-intercalated TX_2 under the given conditions of synthesis; besides, the solvent molecules or alkali metal cations can enter into the interlayer space along with the guest molecules);

- turbostratic stacking of the layers;

- in most cases, the impossibility of raising structural ordering of the materials obtained by annealing, because heating even at moderate temperatures ($100\text{--}200^\circ\text{C}$) often initiates structural transformations and deintercalation processes.

It is obvious that further optimisation of the characteristics of the compounds should be conducted taking into account the specific fields of application (*e.g.*, electronics, catalysis, coating production) of each type of material, since the specialists working in these fields make different demands to the degree of ordering of the nanostructures obtained.

It should be noted that information on the structure of novel intercalation compounds is fragmentary. Often, new compounds are characterised by the only structural parameter, *viz.*, by the interlayer spacing expansion obtained from the XRPD data. More detailed studies of the atomic structures of both the intercalated layer and matrix layers are not numerous yet. The investigations of the material morphology are almost absent. Nevertheless, a comprehensive approach applied in some cases allowed one to establish the chemical nature and local structure of the guest layer, to reveal and to analyse distortions of the host matrix induced by intercalation and to propose the structural models for the studied classes of intercalation compounds not contradicting the body of experimental data.

In our opinion, yet another prospective direction of research exists which has not been sufficiently developed yet. This is the study of the reactivities of two-dimensional structures of TX_2 and the guest in the layered compounds precipitated from dispersions. The ability of such ultra-dispersed systems to undergo chemical transformations may differ essentially from the reactivity of the corresponding components in a bulk sample and this can also be

used for producing novel materials with various practically valuable characteristics.

The research was financially supported by the Russian Foundation for Basic Research (Project No. 00-03-32544) and the Russian Academy of Sciences (in the framework of the programme 'Nanomaterials and supramolecular systems').

VIII. Practical applications of vinyltetrazole derivatives	160

Abstract. The published data on the synthesis of *C*- and *N*-vinyltetrazoles and their chemical transformations (homo- and copolymerisation) involving the heterocycle and the vinyl group are systematised and generalised. The areas of possible application of these compounds are considered. The bibliography includes 194 references.

I. Introduction

The first representatives of vinyltetrazoles were obtained 40 years ago by Finnegan and Henry^{1,2} who proposed to use tetrazole-containing polymers as binding agents in the production of gunpowders and matches. A number of comprehensive reviews on the chemistry of tetrazoles have been published since then,^{3–13} but the preparative procedures and properties of tetrazoles containing unsaturated substituents have not been detailed. At the same time, these compounds, particularly vinyl-substituted tetrazoles, can serve as a basis for new in principle polymeric materials possessing unusual and valuable properties. Thus one of the reasons for increased interest in vinyltetrazoles is the possibility of obtaining polymers with high energy characteristics as can be evidenced from numerous patents devoted to the construction of polymeric binding agents for jet engine fuels, gunpowders, explosives, *etc.*^{2, 14–20}

This paper is an overview of the published data and the first attempt to generalise the results of investigations into the synthesis, structures, physicochemical properties and polymerisability of vinyltetrazole derivatives.

II. Synthesis of vinyltetrazoles

The choice for a procedure for the synthesis of vinyltetrazole derivatives depends on the position of the vinyl group in the ring, but two main approaches stand apart among other methods. One of them consists of the formation of the tetrazole ring by cyclisation of open-chain compounds containing a vinyl group, while the second approach, which is more common, includes the formation of a double bond at the heterocycle.

1. Synthesis of *C*-vinyltetrazoles

Reaction of acrylonitrile with sodium azide in the presence of aluminium chloride occurs in one step and results in 5-vinyltetrazole (**1**) (conversion 55%). However, the yield is low and unstable due to polymerisation of the starting and target vinyl compounds. Using this approach, 5-isopropenylnitrazole (**2**) was prepared from methacrylonitrile in a somewhat better yield (conversion 71%, yield ~ 45%), since the C=C bonds in methacrylonitrile and isopropenylnitrazole are less prone to polymerisation.²¹

R = H (**1**), Me (**2**).

Cycloaddition of the azide ion to the C≡N bond of nitriles is significantly facilitated if the reaction is carried out in the presence of compounds able to form hydrazoic acid salts from sodium azide soluble in the solvent used. In addition, these salts increase the reactivity of the azide ion. They are prepared using ammonium chloride,^{22,23} alkylamine hydrochlorides,^{14,15} tetramethylguanidinium chloride,²⁴ boron trifluoride etherate²⁵ and aluminium chloride.²¹

Temporary protection of the double bond of acrylonitrile by addition of dimethylamine has made it possible to avoid polymerisation and resinification in the reaction of the azide ion with the nitrile group of 3-dimethylaminopropionitrile: 5-(2-dimethylaminoethyl)tetrazole (**3**) was prepared in high yield.^{14,15} The Hoffmann deamination of the quaternary salt **4** gives 5-vinyltetrazole (**1**).

Preparation of *N*-alkyl-*C*-vinyltetrazoles **5a–e** is more difficult because of the impossibility of direct introduction of the alkyl substituent into 5-vinyltetrazole (**1**) due to spontaneous polymerisation under the reaction conditions. Therefore, the formation of the vinyl group by deamination of the quaternary ammonium salt is preceded by alkylation of the heterocycle in the tetrazole derivative **3**.^{14, 15, 26–28}

R = 1-Me (**a**), 2-Me (**b**), 2-Et (**c**), 2-Prⁱ (**d**), 2-Bu^t (**e**).

Hydrohalogenation of acrylonitrile resulting in 3-chloropropionitrile, its reaction with the azide ion and subsequent dehydrochlorination of the 5-(2-chloroethyl)tetrazole formed with potassium hydroxide in aqueous methanol is a more convenient approach to the synthesis of unsubstituted 5-vinyltetrazole (**1**).²¹ In order to increase the yield of the vinyl compound and to suppress its spontaneous polymerisation, it was proposed to perform dehydrochlorination with a twofold excess of an alkali in the presence of ionol as the polymerisation inhibitor.²⁹

Ethylene cyanohydrin can be used as a starting material in the synthesis of vinyltetrazoles **5a,b**. Cycloaddition of the azide ion to the nitrile group results in 5-(2-hydroxyethyl)tetrazole (**6**),^{16, 17} which is methylated with dimethyl sulfate and the hydroxyethyl group in compound **7** is further modified. Subsequent dehydrochlorination of the chloroethyl derivative **8** with methanolic KOH affords vinyltetrazoles **5a,b**.

R = 1-Me (**a**), 2-Me (**b**).

The use of dehydrochlorination for the synthesis of vinyltetrazoles has a number of advantages. Deamination of the quaternary salts of 2-dimethylaminoethyltetrazoles proceeds upon heating, while dehydrochlorination of 2-chloroethyl compounds is usually carried out with potassium hydroxide solutions at low temperatures, which significantly decreases the risk of polymerisation of the target product. This method ensures repro-

ducible and satisfactory yields of 5-vinyltetrazole (**1**) and its alkyl derivatives.^{1, 2, 16–19, 21, 29–31}

A procedure for the synthesis of 5-vinyl-1-methyltetrazole (**5a**) starting from 2-*tert*-butyl-5-vinyltetrazole (**5e**) via the quaternary salt **9** has been proposed.³²

The aforementioned methods cannot be extended to the synthesis of *N*-aryl-substituted *C*-vinyltetrazoles. The vinyl group was introduced into position 5 of the tetrazole ring containing a phenyl substituent at the nitrogen atom using the Wittig reaction.³¹ Phosphonium salt **10** was prepared from 1-phenyl-5-chloromethyltetrazole (**11**); its dehydrochlorination gave the ylide **12**. The latter readily reacts with various aldehydes according to a common scheme to give compounds **13a,b**.

R = H (**a**), Ph (**b**).

This reaction affords tetrazolyl-substituted alkenes in good yields.

2. Synthesis of *N*-vinyltetrazoles

The major difference between the approaches used in the synthesis of *N*-vinyltetrazole derivatives and those described above is that the former makes use of compounds with preformed heterocycles as starting substrates.

N-Vinyltetrazoles **14** and **15** are synthesised from 2-chloroethyltetrazoles using three different approaches.

The first of them includes alkylation of tetrazoles **16a–d** with ethylene chlorohydrin with subsequent replacement of the hydroxy group in 2-hydroxyethyltetrazoles **17a–d** by chlorine under the action of thionyl chloride^{1, 2, 17, 18} and dehydrochlorination of 2-chloroethyl derivatives **18a–d**. Vinyltetrazole **14c** can be prepared by dehydration of compound **17c**.³³

R = H (**a**), Me (**b**), Ph (**c**), NH_2 (**d**).

As in the case of *C*-vinyltetrazoles, dehydrochlorination is more preferable for the formation of the vinyl group.

The second approach to the synthesis of *N*-vinyltetrazoles has been described in the studies,^{34–36} where 1- and 2-(2-halogenoethyl)tetrazoles were synthesised by alkylation of tetrazole (**16a**) and 5-nitrotetrazole (**16e**) with 1,2-dichloro- or 1,2-dibromoethane under conditions of phase-transfer catalysis.

R = H (**14a**, **15a**, **16a**), NO_2 (**15e**, **16e**); X = Cl, Br.

2-(2-Halogenoethyl)-5-nitrotetrazoles are prepared from the nitro derivative **16e**; their dehydrohalogenation was used for the synthesis of 2-vinyl-5-nitrotetrazole (**15e**).³⁶ It is of note that the alkylation yields a mixture of isomers in the majority of cases, the separation of which is often problematic.

The third approach to the synthesis of 2-(2-halogenoethyl)tetrazoles has recently been proposed.³⁷ This consists of selective alkylation of tetrazole and its 5-substituted derivatives with halo-substituted alcohols or allyl halides. Subsequent dehydrohalogenation of the intermediate compounds yields 2-isopropenyltetrazoles **19a-c,f**.

R = H (**a**), Me (**b**), Ph (**c**), CF_3 (**f**);
(a) $\text{MeCH}(\text{OH})\text{CH}_2\text{X}$ (X = Cl, Br), H_2SO_4 ;
(b) $\text{CH}_2=\text{CHCH}_2\text{Br}$, H_2SO_4 .

Reaction of vinyl acetate^{31,38–43} or butyl vinyl ether⁴² with tetrazoles **16a-d,f-i** is a convenient approach to the synthesis of *N*-vinyltetrazoles.

R = H (**a**), Me (**b**), Ph (**c**), NH_2 (**d**), CF_3 (**f**), NO_2Ph (**g**), CH_2Cl (**h**), $\text{CH}=\text{CH}_2$ (**i**).

The synthetic procedures proposed by different authors utilise different catalytic systems, but all of them make use of mercuric acetate in the presence of acetic^{31,38–42} or sulfuric acids,³¹ boron trifluoride etherate⁴¹ and palladium – sodium acetate mixture as a catalyst.⁴² The yields of the vinylation products and the position of the vinyl group in the substituted tetrazoles depend on the nature of the substituent at the carbon atom. Small-size or potent electron-withdrawing substituents direct the vinyl group to position 1 of the tetrazole ring predominantly. Electron-withdrawing substituents shielding the vicinal nitrogen atom favour the formation of 2-vinyltetrazoles **15**. In addition, such substituents decelerate or fully inhibit the reaction.

The catalytic system $\text{Hg}(\text{OAc})_2 - \text{CF}_3\text{CO}_2\text{H}$ was recommended for the preparation of 1-vinyltetrazole (**14a**).⁴³ The use of trifluoroacetic acid prevents secondary polymerisation. If the reaction time is small, the yield of the vinylation product is close to quantitative; the target product contains predominantly 1-vinyltetrazole (**14a**) and only a small amount (no more than 10%) of 2-vinyltetrazole (**15a**). Irrespective of the catalytic system used, vinylation of unsubstituted tetrazole gives two isomeric vinyltetrazoles **14a** and **15a** which are readily separated by vacuum distillation. A method for separation of 1- and 2-vinyl-substituted tetrazoles has been developed^{40,44–46} which entails selective formation of CuCl_2 complexes; their subsequent degradation affords 1-vinyl-substituted tetrazoles.

Vinylation of tetrazoles under the action of isopropenyl acetate was used in the synthesis of 1-isopropenyltetrazole in 30% yield.⁴³

Some tetrazolyl-substituted alkenes were prepared by reaction of 5-trifluoromethyltetrazole **16f** with arylacetylenes. This reaction proceeds vigorously upon mixing of the reagents in the absence of the solvent and the catalyst.⁴⁷

R = H, 4-Cl, 4-Me.

In contrast to the 5-vinyl derivative where the double bond must be protected, the synthesis of 1-vinyltetrazole allows the introduction of substituents into the heterocycle without preliminary protection of the vinyl group. Thus mercuration of 1-vinyltetrazole (**14a**) yields the mercury derivative **20**. Subsequent replacement of the mercury atom by iodine gives 1-vinyl-5-iodotetrazole (**21**).⁴⁸

Several other approaches to the synthesis of vinyltetrazoles exist. These are based on reaction of vinyl isocyanide⁴⁹ or vinyl-oxazolones⁵⁰ with hydrazoic acid, reaction of *N*-methylacrylonitrile fluoroborate²⁵ with sodium azide, reactions of acrylonitrile with organotin azides⁵¹ or cross-coupling of 1-benzyl-2-bromotetrazole with vinylboronic acid.⁵² However, these methods have no preparative significance.

III. Electronic structures and geometry of vinyltetrazoles

Vinyl derivatives of five-membered nitrogen-containing heterocycles including vinyltetrazoles can be regarded as bifunctional compounds containing two unsaturated fragments, *viz.*, the vinyl group and the azole ring. The intramolecular interactions in vinyltetrazoles and their effects on the electronic structure have been documented in numerous papers.^{27, 53–59} In many of them, the authors did not restrict themselves to consideration of charge and energy characteristics of interacting molecules, but attempted to estimate their reactivities on the basis of calculations.

The distribution of the total charges ($\sigma + \pi$) calculated by the SINDO/S method based on the planar structure of vinyltetrazole molecules is shown in Figure 1.⁴³

Calculations of total ($\sigma + \pi$) electron densities have shown^{60, 61} that both carbon atoms in the vinyl group of *C*-vinyltetrazoles bear a negative charge, while the charge of the α -carbon atom of *N*-vinyltetrazoles is positive due to σ -electron-withdrawing properties of the nitrogen atom at the double bond. In both cases, the total electron density on the β -carbon atom of the vinyl group is higher than that on the α -atom. The π -electron distribution is characterised by reverse polarisation^{60, 61} (the negative π -electron charge is concentrated on the α -carbon atom of the C=C bond), which testifies to the π -electron-withdrawing effect of the tetrazolyl substituent. Polarisation of the vinyl group ($\Delta q_{\beta\alpha}$) in *N*-vinyltetrazoles is more pronounced than in *C*-vinyltetrazoles. Introduction of electron-donor substituents, such as Me and NH₂, into position 5 of the tetrazole **14a** (compounds **14b,d**) reduces the electron-withdrawing effect of the tetrazolyl substituent on the vinyl group. Consequently, the total ($\sigma + \pi$) negative charge of the α -carbon atom and complete polarisation of the double bond of the vinyl group are increased. Similar changes in the distribution of electron density are induced by introduction of an alkyl substituent (compounds **5c** and **5b**) into position 2 of the tetrazole **1**; this effect does not depend on the size or structure of the alkyl group.²⁷

Introduction of a methyl substituent into the vinyl group changes drastically the charge distribution pattern. The total ($\sigma + \pi$) negative charge of both 1-isopropenyl- (**22**) and 5-isopropenyltetrazole (**2**) is concentrated on the β -carbon atom, whereas the positive charge on the α -atom of the isopropenyl group. Special mention should be made of the much higher polarity ($\Delta q_{\beta\alpha}$) of the C=C-bond of isopropenyl derivatives in comparison with the corresponding vinyl compounds.

An analysis of distribution of the electron density in the heterocyclic fragment has shown that, in contrast to unsubstituted tetrazole, the vinyl group at C(5) has virtually no effect on the atomic charges in the ring.^{55, 62} The carbon and the 'pyrrole' nitrogen atoms both bear positive charges, whereas 'pyridine'

Figure 1. The distribution of total charges in vinyltetrazole molecules.⁴³ (a) 1-Vinyltetrazole (**14a**); (b) 1-isopropenyltetrazole (**22**); (c) 5-methyl-1-vinyltetrazole (**14b**); (d) 5-amino-1-vinyltetrazole (**14d**); (e) 5-acetyl-1-vinyltetrazole (**14f**); (f) 5-vinyltetrazole (**1**); (g) 5-isopropenyltetrazole (**2**); (h) 2-methyl-5-vinyltetrazole (**5b**).

nitrogen atoms are charged negatively. The vinyl group at N(1) slightly changes the distribution of electron density in the tetrazole ring. As the 'pyrrole' nitrogen atom manifests σ -electron-withdrawing properties, the vinyl group localised in this position imparts a small negative charge to it. The positive charge of *N*-vinyltetrazole molecules is accumulated predominantly on the carbon atom, while in 1- (**14a**) and 5-vinyltetrazole (**1**) it is concentrated on the N(4) atom. Introduction of electron-donor substituents, such as Me and NH₂, into position 5 of 1-vinyltetrazole (**14a**) further increases the electron density at N(4). In contrast to 5-vinyltetrazole (**1**), the presence of a methyl substituent in position 2 of 5-vinyl-2-methyltetrazole (**5b**) slightly diminishes the negative charge on N(4), but increases it on N(1).

Studies of mutual effects of two unsaturated fragments in vinyltetrazole molecules should include an analysis of their spatial structures. According to quantum-chemical calculations, the optimised geometry of the monomers is planar. *s-cis/s-trans*-Isomerism is more characteristic of compounds in which the heteroaromatic nuclei are conjugated with the acyclic unsaturated fragment. Both conformers are typical of *C*- and *N*-vinyltetrazoles.^{63–72}

A correlation dependence has been found between integral intensities of stretching vibrations of the C=C bond in the vinyl group of some unsubstituted *N*-vinylazoles and the difference in the electron charges on their carbon atoms.⁶⁴ This finding has allowed the authors to conclude that these compounds exist predominantly in the *s-trans*-conformation. At the same time, data from ¹³C NMR spectroscopy do not exclude the *s-cis*-conformation.⁶⁵ More recent studies of stereochemical dependences of direct spin–spin coupling constants of ¹³C–¹H in the vinyl group of vinylazoles revealed that the proportion of the *s-trans*-form in the conformer mixture increases with an increase in the number of nitrogen atoms in the heterocycle.^{67,68} It may thus be concluded that 1-vinyltetrazole (**14a**) exists predominantly in the *s-trans*-conformation. Introduction of substituents into position 5 of the heterocycle results in stabilisation of the *s-trans*-conformation of *N*-vinyltetrazoles.^{68,73} Both conformers of unsubstituted 5-vinyltetrazole (**1**) are equivalent as can be judged from the IR spectroscopic data.⁷² The effect of the alkyl substituent in position 2 of *C*-vinyltetrazole on the conformer ratio is interpreted differently by different authors. According to study,⁶⁹ 5-vinyl-2-methyltetrazole (**5b**) represents a mixture of *s-cis* and *s-trans*-conformers whose ratio varies depending on the temperature and the nature of the solvent. According to electron-diffraction analysis data, 5-vinyl-2-methyltetrazole (**5b**) exists exclusively in the *s-cis*-conformation in the gas phase.⁶⁶ Quantum-chemical calculations have shown that the content of 5-vinyl-2-R-tetrazole rotamers has virtually no dependence on the substituent size, whereas the conformation equilibrium of 5-vinyl-1-R-tetrazoles is mainly determined by the steric effect of the substituent: the amount of the *s-trans*-conformer increases with an increase in the size of the alkyl substituent.⁶³

IV. Physicochemical and spectroscopic properties of vinyltetrazoles

Recent advances in the synthesis of vinyltetrazole derivatives have stimulated studies into their physicochemical and spectroscopic properties. These studies and quantum-chemical methods may help establish a quantitative correlation between structural, physicochemical and spectroscopic properties and reactivities of vinyltetrazoles, including their radical polymerisation. It is from this standpoint that spectroscopic characteristics on vinyltetrazoles are considered in the overwhelming majority of published papers.^{27, 53, 55, 65, 69, 74, 75}

1. Dipole moments of vinyltetrazoles

The experimental values of dipole moments of vinyltetrazoles (μ) (Table 1) significantly exceed those of vinylazole derivatives containing fewer nitrogen atoms in their rings. For example, the dipole moments of 1-vinylimidazole, 1-vinylpyrazole and 1-vinyl-1,2,4-triazole are equal to 3.2, 1.9 and 3.05 D, respectively.^{76,77} These data point to a higher polarity of vinyltetrazole molecules in

Table 1. Dipole moments (μ), polarographic reduction potentials ($E_{1/2}$) and characteristics of the absorption bands in the UV spectra of vinyltetrazoles (MeCN).⁴³

Compound	μ /D	$E_{1/2}$ /V	UV spectra	
			$\lambda_{\max}$ /nm	$10^{-3} \epsilon$
1-Vinyltetrazole (14a)	5.34	−2.52	223 (224) ^a	7.30 (6.10) ^a
5-Methyl-1-vinyltetrazole (14b)	5.71	−2.59	218	6.45
5-Amino-1-vinyltetrazole (14d)	7.10	−2.70	242	6.0
5-Acetylamino-1-vinyltetrazole (14f)	4.05	−2.67	228, 196	8.78, 7.63
5-Phenyl-1-vinyltetrazole (14c)	—	—	239 ^a	11.80 ^a
1-Isopropenyltetrazole (22)	—	—	232.5	5.0
5-Vinyltetrazole (1)	5.21	−2.0	218	10.75
2-Methyl-5-vinyltetrazole (5b)	2.34	−2.42	218	10.30
5-Isopropenyltetrazole (2)	4.77	−2.03	223	8.60

^a Data from Ref. 33.

comparison with other vinylazoles. High values of dipole moments of unsubstituted tetrazoles are usually assigned to the polarising effect of unshared pairs of nitrogen atoms and the resulting nonuniform distribution of electron density in the tetrazole ring.⁶² Introduction of a vinyl group further enhances the nonuniformity of the charge distribution. The values of dipole moments of unsaturated tetrazole derivatives (see Table 1) usually exceed those of the corresponding non-vinylated substituted tetrazole derivatives. Thus the μ values for tetrazole, 5-methyltetrazole and 5-aminotetrazole are equal to 5.14, 5.17 and 5.71 D, respectively.^{4,5} Contrariwise, introduction of the isopropenyl group into position 5 decreases the polarity of a molecule in comparison with unsubstituted tetrazole. 2-Methyl-5-vinyltetrazole (**5b**) has a low dipole moment characteristic of tetrazole derivatives (including 2,5-disubstituted ones) with a substituent in position 2 of the heterocycle.⁷⁸ The hypothesis on the 1*H*-tautomeric conformation of unsubstituted tetrazole is based on the significant difference in the polarities of 1- and 2-substituted tetrazoles. A comparison of the experimental dipole moment of tetrazole (5.14 D) with theoretically calculated values of μ for the 1*H*- and 2*H*-tautomeric forms of tetrazole (4.8–5.23 and 1.63–2.35 D, respectively) corroborates this hypothesis.⁵ Taking into account high values of μ for 5-vinyl- (**1**) and 5-isopropenyltetrazole (**2**) and their comparison with the corresponding value for unsubstituted tetrazole, one may conclude that both vinyltetrazoles exist predominantly in the 1*H*-conformation.

2. Polarographic analysis of vinyltetrazoles

The mutual effect of two unsaturated fragments in the vinyltetrazole molecule is especially pronounced in their polarographic analysis.^{43,60,79} Vinyltetrazoles are polarographically active, but the mechanisms of reduction of *N*- and unsubstituted *C*-vinyl derivatives are different.

The vinyl group in *N*-vinyltetrazoles, as in other alkenes,⁸⁰ in particular vinylazoles,⁸¹ is completely reduced by a two-electron mechanism in the presence of proton donors.

Introduction of various groups, such as Me and NH₂, into position 5 of the tetrazole ring increases the electron density on the vinyl group and causes a shift of $E_{1/2}$ for the vinyl group towards more negative values in comparison with 1-vinyltetrazole (**14a**) (see Table 1). Under these conditions, the change in $E_{1/2}$ correlates with the electronic effects of the substituents present in the ring. Thus a satisfactory correlation was found between $E_{1/2}$ and the charge of the β -carbon atom (q_β), the difference of charges on the carbon atoms of the vinyl group ($\Delta q_{\beta\alpha}$)⁴³ and the values of induction constants (σ_1) (see Ref. 82) of the corresponding tetrazolyl substituents.

$$E_{1/2} = (-1.04 \pm 0.10) + (27.33 \pm 2.77)q_\beta \quad (r = 0.93, n = 3),$$

$$E_{1/2} = (-5.02 \pm 0.48) + (24.66 \pm 0.79)\Delta q_{\beta\alpha} \quad (r = 0.99, n = 3),$$

$$E_{1/2} = (-4.32 \pm 0.43) + (2.71 \pm 0.51)\sigma_1 \quad (r = 0.97, n = 3),$$

where r is the correlation coefficient and n is the number of compounds tested.

A quite unexpected [in comparison with 1-vinyltetrazole (**14a**)] shift of $E_{1/2}$ for 5-acetylamino-1-vinyltetrazole (**14f**) towards the negative region testifies to the electron-donor nature of the AcNH group.

A completely different reduction mechanism is observed in the case of 5-substituted tetrazoles, particularly 5-vinyltetrazole derivatives. In contrast to *N*-vinyltetrazoles, the double bond of the vinyl fragment in 5-vinyl- (**1**) and 5-isopropenyltetrazole (**2**) is not reduced. The polarographic activity of tetrazole ($E_{1/2} = -2.13$ V) and its 5-substituted derivatives is determined by their acidic properties; the polarographic wave is associated with proton reduction⁷⁹ which proceeds by a single-electron mechanism. Substitution of the methyl substituent for the acid proton favours reduction of the vinyl group in compound **5b**. It is of note that this process is characterised by a lower value of the negative potential in comparison with *N*-vinyltetrazoles (see Table 1).

R = CH=CH₂, CMe=CH₂.

3. Ultraviolet spectra of vinyltetrazoles

The conjugation between the π -systems of the heterocycle and the vinyl group determines the presence of intense absorption bands of both *N*- and *C*-vinyltetrazoles in the near UV-region (see Table 1). Introduction of substituents into position 5 of 1-vinyltetrazole (**14a**) results in slight reduction of the extinction coefficient (ϵ), which can be attributed to the decrease in the conjugation between unsaturated fragments in compounds **14b,d** due to deviation of the vinyl group from the plane. A similar effect is observed after introduction of a methyl substituent into the α position of the vinyl group, the values of extinction coefficients ϵ of isopropenyltetrazoles being lower than those of vinyltetrazoles. Introduction of a methyl substituent into position 2 of tetrazole **1** has virtually no effect on the wavelength and intensity of the UV absorption band which testifies to the lack of conformational changes.

It is known that 5-dialkylamino-substituted tetrazoles undergo amine-imine rearrangements.^{4,5} Evidence for the existence of the imine form can be derived from a more significant bathochromic shift of the UV absorption bands of these compounds in comparison with tetrazoles with unsubstituted amino groups which are thought to exist exclusively in the amino form. The absorption maximum in the UV spectrum of 5-amino-1-vinyltetrazole (**14d**) is noticeably shifted towards the longwave region relative to other vinyltetrazoles⁴³ and lies in the region close to the absorption band of the imino (rather than the amino) form (see Table 1). It may thus be concluded that in contrast to

other tetrazole derivatives containing an unsubstituted amino group, 5-amino-1-vinyltetrazole (**14d**) undergoes amine-imine rearrangement.

The parameters of UV absorption bands of *N*-vinyl- and substituted *C*-vinyltetrazoles do not depend on the nature of the solvent, the concentration and pH of the reaction medium. The dependence of spectroscopic characteristics on the aforementioned parameters was observed for 5-vinyltetrazole (**1**) which can be ionised: in aqueous solutions, a change in the concentration of a compound or an increase in pH caused a further shift of the absorption band towards the longwave region. In the ionised form, 5-vinyltetrazole (**1**) is absorbed at $\lambda = 226$ nm ($\epsilon = 9900$).⁴³ In contrast to aqueous solutions, the position of the absorption band in acetonitrile and ethanol did not change with concentration. This finding suggests that 5-vinyltetrazole does not dissociate in these solvents.

4. Infrared spectroscopy of vinyltetrazoles

There is little evidence on vibrational spectra of vinyltetrazoles. Among a variety of other studies, only two papers devoted to a detailed analysis of IR spectra of unsubstituted 1- and 5-vinyltetrazoles^{71,72} and a few publications where spectral analysis of vinyltetrazole compounds was used to confirm the structures of the polymers prepared from them deserve mention.^{79,83,84}

The IR spectra of vinyltetrazoles contain three main regions. The shapes and positions of low-frequency absorption bands around 600–1000 cm⁻¹, induced by extraplanar vibrations of C–H or by deformation and torsion vibrations of the tetrazole ring⁸⁵ change appreciably depending on the place of attachment of the vinyl group and the nature of the substituent in the heterocycle. Skeletal vibrations of the tetrazole rings are observed around 1000–1500 cm⁻¹ and are characterised by several intense absorption bands around 1030–1090, 1125–1150, 1250–1270, 1320–1390 and 1430–1470 cm⁻¹ irrespective of the vinyltetrazole structure. There is no unanimous opinion about the origin of the intense absorption band around 1560–1580 cm⁻¹ in the IR spectra of tetrazole (**16a**) and its 5-vinyl derivative (**1**). Judging from quantum-chemical calculations,^{72,85} this band has been assigned to the C=N vibrations of the ring. However, analysis of the IR spectra of vinyltetrazoles, model 1-, 2-, 1,5- and 2,5-substituted tetrazoles and 5-substituted tetrazolium salts revealed⁸³ that these spectra contain no band around 1560–1580 cm⁻¹. This finding led us to suggest that this band should be assigned to deformation vibrations of the tetrazole ring induced by the N–H bond characteristic exclusively of non-ionised forms of 5-substituted tetrazoles.

Vibrations of the double bond of the vinyl group in the IR spectra of all vinyltetrazoles under study are manifested as a narrow band around 1645–1655 cm⁻¹. The absorption intensity of various vinyl-substituted tetrazoles correlates with the previously observed dependence of integral intensities of stretching vibrations of the C=C bond on the polarity of the vinyl group.⁶⁴ Higher polarity of the vinyl fragments of *N*-vinyltetrazoles determines higher intensity of the absorption bands around 1645–1655 cm⁻¹ in comparison with those in *C*-vinyltetrazole derivatives. A more detailed analysis of absorption spectra of 2-methyl-5-vinyltetrazole (**5b**) revealed two absorption bands in the region of C=C bond vibrations: a singlet band around 1656 cm⁻¹ and a doublet band around 1648 and 1645 cm⁻¹ (see Ref. 69). These bands were assigned to stretching vibrations of the vinyl groups of two different rotamers of compound **5b**. Deformation vibrations of the =CH-bond of the vinyl group are observed around 960–980 cm⁻¹.

The difference between the IR spectra of vinyltetrazoles is especially pronounced in high-frequency regions (2200–3700 cm⁻¹). The simultaneous presence of an acid proton and ‘pyridine’ nitrogen atoms in 5-vinyl- (**1**) and 5-isopropenyltetrazole (**2**) rings gives rise to intermolecular interactions typical of NH-unsubstituted azoles.^{4,86} The IR spectra of *C*-vinyltetrazoles contain a broad absorption band around 3000–3500 cm⁻¹ corresponding to stretching vibrations of NH⋯N and a band around 2300–2800 cm⁻¹ assigned to the quaternary nitrogen atom, ≡N⁺H (see Ref. 87). No such bands are observed in the IR spectra of *N*-vinyltetrazoles. This suggests that condensed forms of compounds **1** and **2** contain, along with molecular forms, two additional forms, one of which is bound by hydrogen bonds and the other one is ionised as a result of complete proton transfer.

The IR spectra of *N*-vinyltetrazoles and *N*-alkyl-5-vinyltetrazoles contain absorption bands around 2900–3200 cm⁻¹ due to stretching vibrations ν(CH). The complex structure of the absorption band in this particular region of the IR spectrum of 1-vinyltetrazole (**14a**) is attributed to association of molecules *via* the ≥CH⋯N bond.⁷¹

The high-frequency region of the IR spectrum of 5-amino-1-vinyltetrazole (**14d**) contains absorption bands corresponding to the amino group (3150 and 3330 cm⁻¹). The existence of amine–imine rearrangement in compound **14d** is confirmed by IR (see Ref. 43) and UV spectral data: the presence of an absorption band in the IR spectrum around 1670–1680 cm⁻¹ can be assigned to vibrations of the exocyclic C=N bond of its imino form.

5. NMR spectra of vinyltetrazoles

Structural studies of vinyltetrazole derivatives widely employ ¹H and ¹³C NMR spectroscopy. Chemical shifts (δ) of the characteristic proton signals for the vinyl groups of all *N*-vinyltetrazoles studied lie in the range of δ 7.20–7.40 (H_A, q), 5.96–6.05 (H_B, d) and 5.30–5.50 (H_C, d), while signals for the carbon atoms lie around δ 126–128 (C_α) and 106–114 (C_β).^{41,43,53,88,89} Greater shielding (relative to the carbon atom in ethylene) of the C_β atom [δ(C) = 123.3] testifies to effective conjugation of the vinyl group and the tetrazole ring.⁶⁷ Introduction of electron-donor substituents into the tetrazole ring induces a regular upfield shift of the C_β signal commensurate with an increase in the calculated total electron density on the β-carbon atom. The changes in δ(C_β) correlate with the values of the induction constants of σ_I of the tetrazolyl substituents.⁴³

$$\delta(\text{C}_\beta) = (70.1 \pm 10.2) + (60.9 \pm 8.8)\sigma_I \quad (r = 0.999, n = 3).$$

Of special note are parallel changes in *E*_{1/2} and ¹³C_β chemical shifts in the ¹³C NMR spectra. This dependence is described by equation:⁶⁰

$$E_{1/2} = (0.044 \pm 0.016)\delta(\text{C}_\beta) - (7.360 \pm 1.780) \quad (r = 0.883, n = 4).$$

The effect of the tetrazolyl substituent on the chemical shifts of the vinyl group atoms is also determined by its position in the heterocycle. However, it is difficult to establish the difference between the δ values of the vinyl group in the ¹H and ¹³C NMR spectra of 1- and 2-vinyltetrazoles.⁴¹ An insignificant (1–3 ppm) upfield shift of the C_β signal was observed⁶⁷ for 2-vinyltetrazole (**15a**) and its derivatives in comparison with the corresponding 1-vinyl derivatives. In the presence of a vinyl group in position 5, the pattern of the ¹³C NMR spectra of vinyltetrazoles changes considerably: the signal for the β-carbon atom of 5-vinyltetrazole (**1**) is more appreciably shifted downfield [δ(C_α) = 119.99 and δ(C_β) = 124.70]. The polarity of the C=C bond in the vinyl group

(Δ*q*_{αβ}) of compound **1** is much lower than that of the 1-vinyl derivative **14a**.^{60,61} As a result, the difference between the chemical shifts (Δδ_{αβ}) diminishes correspondingly.^{27,31,43,53} Introduction of an alkyl substituent into position 1 of 5-vinyltetrazole (**1**) has virtually no effect on the δ values of the vinyl group [δ(C_α) = 118.87 and δ(C_β) = 126.85].^{53,89} The signal of the C_α atom [δ(C_α) = 122.49, δ(C_β) = 121.48] in the ¹³C NMR spectra of 2-alkyl-5-vinyltetrazoles and 1-vinyltetrazoles is shifted downfield, but the difference in the chemical shifts Δδ_{αβ} is even less pronounced than in the case of unsubstituted 5-vinyltetrazole (**1**).²⁷ The methyl group in the α-position of the vinyl substituent strongly increases the polarity of the C=C bond in both *C*- and *N*-isopropenyl derivatives resulting in a drastic increase in Δδ_{αβ} (see Ref. 43).

The shapes of the proton signals in the ¹H NMR spectra of 5-vinyl- and 1-vinyltetrazoles are similar; the signals of 5-vinyltetrazoles lie in a narrower range (δ 5.62–6.91).^{27,31,43,53} The H_B (δ 6.05 and 5.74, respectively) and H_C (δ 5.58 and 5.23, respectively) signals in the ¹H NMR spectra of isopropenyltetrazoles **2** and **22**, which represent a superposition of two quadruplets, are shifted upfield in comparison with the corresponding signals of the vinyl derivatives. The signals of the methyl group in the NMR spectra of compounds **2** and **22** are manifested as a superposition of two doublets (δ 2.24 and 2.40, respectively).⁴³

The electronic effect of the vinyl group on the heterocycle is manifested in ¹H and ¹³C NMR spectra of vinyltetrazoles. Thus the difference in the position of the vinyl group of 1- and 2-vinyltetrazoles determines the difference in the shielding of C(5), being by 12 ppm more protected in 1,5-disubstituted tetrazoles in comparison with 2,5-isomers. This effect was used for identification of isomeric vinyltetrazole derivatives.⁴¹

¹⁵N NMR spectra of vinyltetrazole derivatives are less studied. A linear correlation was found⁸⁸ between δ and the electron density on nitrogen atoms, which allowed unambiguous interpretation of signals in the NMR spectra of vinyltetrazoles (Table 2). According to quantum-chemical calculations, the nuclei of ‘pyrrole’ nitrogen atoms of vinyltetrazoles resonate in a higher field in comparison with ‘pyridine’ nitrogen atoms.

Table 2. Chemical shifts in the ¹⁵N NMR spectra of vinyltetrazoles (MeNO₂ as a standard).⁸⁸

6. Acid–base properties of vinyltetrazoles

Acid–base properties of nitrogen-containing heterocyclic compounds are related to their most essential characteristics, which determine in many respects their reactivities and physiological activities. Unfortunately, vinylazoles fall out of this area of research. The values of basicity (p*K*_{BH⁺}) and acidity (p*K*_a) constants of azoles and their vinyl derivatives are given in Table 3. Acidic properties of azole rings are increased with an increase in the number of nitrogen atoms, tetrazole being the strongest acid. As mentioned above, introduction of a vinyl group into position 5 of the tetrazole ring further increases the acidity of the heterocycle. Contrariwise, the basicity of azoles decreases with an increase in the number of nitrogen atoms in the ring, tetrazole being the weakest base among other azoles. An analysis of experimental data on basicities of various vinylazoles allows one to establish certain regularities in reactions between heterocyclic

Table 3. The values of pK_{BH^+} and pK_a for azoles and vinylazoles.^{90–92}

Compound	pK_{BH^+}	pK_a

5-Methyl-1-vinyltetrazole (14b)	−2.56	—
5-Vinyltetrazole (1)	−2.91 ^a	4.10 ^a
2-Methyl-5-vinyltetrazole (5b)	−2.77	—

^a Data from Ref. 43.

and vinyl fragments. First, introduction of a vinyl group into imidazole and 1,2,4-triazole rings increases their basicities, while the vinyl group present in the tetrazole ring decreases it. This suggests that the mode of transfer of electronic effects changes on going from vinylimidazole and -triazole to vinyltetrazole derivatives. Second, like alkyl derivatives,⁹⁰ the corresponding *N*-vinyltetrazoles are weaker bases than *C*-vinyltetrazoles. On the whole, vinylazole derivatives are weaker bases in comparison with alkyl derivatives, which is confirmed by polarographic and NMR spectroscopic data. Third, introduction of a methyl substituent into 1- and 5-vinyltetrazoles enhances basic properties of the heterocycle, which is especially pronounced in the former case.

Numerous studies into protonation of various tetrazole derivatives provide support that the nitrogen atom in position 4 is the most basic site in the heterocycle.⁹⁰

V. Reactions of vinyltetrazoles

The chemistry of vinyltetrazoles has not been studied in depth. One possible reason is that vinyltetrazole derivatives are used as monomers for preparation of high-energy polymeric products and are seldom used as starting compounds for other chemical reactions. Modification of the heterocycle is usually confined to reactions which have no appreciable influence on the energy characteristics of the tetrazole ring; reactions involving the vinyl group have not been sufficiently studied either. However, despite the obvious paucity of experimental data, certain conclusions can be made about the correlation between the structural and chemical properties and reactivities of vinyltetrazoles in order to compare them with those of vinyl derivatives of other five-membered nitrogen-containing heterocycles.

1. Reactions involving the vinyl group

As mentioned above, conjugation of the tetrazole ring with the vinyl group results in its pronounced polarisation. Taking into account the electron-withdrawing character of the heterocycle, it may be expected that the vinyl group will manifest higher (in comparison with alkenes) reactivity towards the nucleophilic reagents and lower reactivity in an electrophilic attack. However, it has been shown that the reactivity of the vinyl group is largely determined by its position in the ring. Whereas 5-vinyltetrazoles readily enter into addition reactions at the double C=C bond under the action of both nucleophilic and electrophilic reagents, the vinyl group of 1-vinyltetrazoles is virtually inert to both types of reagents.

Hydration of the vinyl group of 1-methyl-5-vinyl- (**5a**) and 2-methyl-5-vinyltetrazoles (**5b**) resulting in the corresponding alcohols is an example of nucleophilic addition to the double bond.¹⁹

R = 1-Me (**a**), 2-Me (**b**).

In the presence of copper catalysts, compounds **5a,b** add trichloroacetonitrile surprisingly smoothly.⁹³

It is known that 2-methyl-5-vinyltetrazole (**5b**) reacts with hypobromous acid. Slow addition of an aqueous suspension of *N*-bromosuccinimide to compound **5b** in the presence of perchloric acid occurs regiospecifically and gives rise to 5-(2-bromo-1-hydroxyethyl)-2-methyltetrazole (**23**) in quantitative yield.⁹⁴

NBS is *N*-bromosuccinimide.

Reaction of vinyltetrazole **5b** with *N*-bromosuccinimide in aqueous dioxane yields an equimolar mixture of isomeric bromohydrins,⁹⁵ presumably as a result of stabilisation of the bromonium ion by dioxane as an electron donor.

Reaction of 1-methyl-5-vinyltetrazole (**5a**) performed under analogous conditions yields polymerisation products, which is attributed⁹⁵ to higher ability of the isomer **5a** for radical polymerisation in comparison with compound **5b**.

Electrophilic addition of bromine to the vinyl group of 5-vinyltetrazole (**1**) and its homologues proceeds rather smoothly.³⁰

R = H, Me, Et.

Selective oxidation of the vinyl group in vinyltetrazoles has been studied with a view to obtaining epoxy derivatives of tetrazoles.^{96,97} It was found that 2-methyl-5-vinyltetrazole (**5b**) is not oxidised by hydrogen peroxide, *tert*-butyl hydroperoxide or hydrogen peroxide in the presence of sodium tungstate as a catalyst or by sodium hypochlorite in alkaline media under conditions of phase-transfer catalysis. Compound **5b** is also inert with respect to hypochlorous acid. The C=C bond of vinyltetrazole **5b** could only be oxidised with trifluoroperacetic acid. Epoxide **24** was obtained in 25%–30% yield.

Selective hydrogenation of 5-vinyltetrazoles at the vinyl group occurs under relatively mild conditions.⁴³

R = H (**1**), Me (**5b**).

These few examples of chemical reactions of 5-vinyltetrazoles do not reveal any unusual behaviour of the vinyl group substituted by an aromatic heterocycle. The oxidation of the double bond resulting in epoxide **24** is the only exception.

2. Reactions involving the tetrazole ring

Reactions of vinyltetrazoles involving the heterocyclic fragment are more extensively documented in the literature. The tetrazole ring has several reaction centres, *viz.*, the 'pyrrole' nitrogen atom (in unsubstituted 5-vinyltetrazoles), 'pyridine' nitrogen atoms, the carbon atom of unsubstituted 1- and 2-vinyltetrazoles manifesting CH-acidic properties. The diversity of reactions involving this heterocycle significantly expands the range of vinyltetrazole-containing monomers as starting materials for the synthesis of polymeric products. Therefore, reactions involving the heterocyclic fragment have attracted more attention than reactions involving the vinyl group.

a. Reactions involving the nitrogen atom

Quaternisation reactions of tertiary nitrogen atoms of azole compounds and their vinyl derivatives by alkyl halides or dimethyl sulfate are well known.^{98–100} It was found that the ability to undergo quaternisation reactions decreases with an increase in the number of nitrogen atoms in the heterocycle: quaternisation of tetrazole derivatives occurs under more drastic conditions than that of imidazoles or triazoles. Introduction of electron-donor substituents into the tetrazole ring increases slightly the reactivity of vinyltetrazoles in this reaction. Thus introduction of NH_2 or Me groups makes it possible to prepare quaternary salts of 5-amino-1-vinyl- (**14d**) and 2-methyl-5-vinyltetrazole (**5b**) by reaction with methyl iodide or dimethyl sulfate.^{43, 88} At the same time, 1-vinyltetrazole (**14a**) can form salts exclusively under the action of dimethyl sulfate. A wide variety of quaternary salts of 5- and 1-vinyltetrazoles have been prepared by treatment with Me_2SO_4 in the presence or absence of solvents (20–80 °C).⁸⁸ Notably, 5-vinyl-2-R-tetrazoles are quaternised much more easily than 1-vinyl- and 5-vinyl-1-R-tetrazoles. ¹³C and ¹⁵N NMR spectroscopic studies revealed another interesting peculiarity, *viz.*, selective formation of 1,3-dialkyl-5-vinyltetrazolium salts in reactions of 5-vinyl-2-R-tetrazoles with dimethyl sulfate.⁸⁸

R = Me (**b**), Bu^t (**e**).

1-Vinyl- and 5-vinyl-1-R-tetrazoles yield a mixture of isomeric salts.⁸⁸

R = H (**a**), Me (**b**).

The isomeric ratio of the reaction product strongly depends on the structure of the starting vinyltetrazole.

Quaternary salts of 2-*tert*-butyltetrazole derivatives, *e.g.*, those prepared from compound **5e**, are readily transalkylated upon heating with the loss of the *tert*-butyl substituent. This reaction occurs regioselectively with intermediate formation of trisubstituted tetrazolium salts to give 1,5-disubstituted tetrazoles in 78%–96% yields.³²

The salts prepared by reaction of vinyltetrazoles with Me_2SO_4 are prone to spontaneous polymerisation upon standing.⁸⁸ In contrast, the salts prepared by quaternisation of vinyltetrazoles with methyl iodide are not polymerised even under radical initiation conditions.

Vinyltetrazoles are as prone to complexation with metal ions as vinylazoles containing two or three nitrogen atoms in their rings. In most cases, such complexation occurs smoothly even at the stage of mixing of vinyltetrazole solutions with metal salts and does not require long-term heating. The structure and properties of the complexes formed depend on the nature of the ligand and the metal ion.

Reactions of 1-vinyl- (**14a, d**) and 5-vinyltetrazoles (**5a, b**) with Cu(II), Ni(II), Co(II) and Pd(II) chlorides yield donor–acceptor complexes (**25, 26**) of the composition ML_2Cl_2 irrespective of the ratio of the starting reagents.

A complex of the composition CrL_3Cl_3 was prepared using chromium(III) chloride.¹⁰³ Complex derivatives of 1-methyl- (**5a**) and 2-methyl-5-vinyltetrazoles (**5b**) with Rh(III), Ti(IV) and V(IV) ions have been prepared and characterised¹⁰⁴ using NMR and IR spectroscopy and X-ray diffraction analysis. It was found that in all cases studied coordination of the metal ion occurs to the nitrogen atom in position 4 of the heterocycle.^{101, 105, 106} The vinyl group is not involved in the complexation: the positions of the signals for the carbon atoms of the $\text{C}=\text{C}$ bond in the ^{13}C NMR spectra and the position of the absorption band in the IR spectra did not change upon complexation.^{101, 103, 105, 106} The 1-methyl-5-vinyltetrazole (**5a**)– PdCl_2 complex in which the vibration frequency of the $\text{C}=\text{C}$ bond of the vinyl group decreased from 1642 to 1625 cm^{-1} was the only exception (see Ref. 105).

The behaviour of 5-vinyltetrazole (**1**) is similar to that of above-mentioned compounds. This forms complex **27** [PdL_2Cl_2 with palladium(II) chloride] due to a donor–acceptor interaction with the formation of an $\text{N}–\text{Pd}$ bond.^{101, 107}

The low-frequency region of the IR spectrum of the complex **27** contains an absorption band around 365 cm^{-1} which is characteristic of the $\text{Pd}–\text{Cl}$ bond where the metal ion is coordinated to another atom (in our case, the nitrogen atom).¹⁰⁸

A different situation is observed in reaction of 5-vinyltetrazole (**1**) with copper and nickel chlorides in water.¹⁰¹ In this case, reaction products appear as salt-like complexes; the vinyltetrazole anion plays the role of a ligand.

M = Cu, Ni.

An unusual effect was observed in reactions of 5-vinyltetrazole with CuCl_2 in organic solvents: complexation was accompanied by elimination of the vinyl group; the metal–unsubstituted tetrazole complex was formed as the final product.

Preservation of the vinyl group in the aforementioned complexes determines the interest in these compounds as candidate monomers for the synthesis of metal-containing polymers. Polymeric complexes prepared by polymerisation of PbCl_2 complexes with 2-methyl-5-vinyltetrazole have been studied.¹⁰⁷

b. Reactions involving the carbon atom of the heterocycle

It has recently been shown that reactions of vinyltetrazoles involving the carbon atom of the heterocycle are possible. By virtue of their high CH-acidities ($\text{p}K_a$ 23–25), 1-substituted tetrazoles enter into the Mannich reaction. Thus 1-vinyltetrazole

(**14a**) is aminomethylated under mild conditions as a CH-acid to give 5-dimethylaminomethyl-1-vinyltetrazole (**28**).^{63, 109}

Like other compounds with pronounced CH-acidities, 1-vinyltetrazole (**14a**) is mercured by mercury(II) salts at the carbon atom of the tetrazole ring in the presence of bases to give symmetrical bistetrazolymercurials (**20**).^{48, 63}

c. Recyclisation reactions

Some reactions of vinyltetrazole derivatives are accompanied by recyclisations; the heterocyclic products of these reactions contain fewer nitrogen atoms in their rings.

For the first time, such a reaction was described for 5-vinyltetrazole (**1**) by Arnold *et al.*²¹ Reaction of compound **1** with acetic anhydride gives the corresponding 2,5-disubstituted 1,3,4-oxadiazole **29** in good yield.

Some 1- and 2-vinyltetrazoles eliminate nitrogen upon photolysis or thermolysis to give diazole derivatives. 1-Vinyl-substituted tetrazoles afford imidazole derivatives.³³

$\text{R}^1, \text{R}^2 = \text{H, Ph.}$

Heating of 2-isopropenyl-5-phenyltetrazole results in pyrazole **30**.¹¹⁰

In certain cases, chemical transformations lead to destruction of the tetrazole ring. Several thermal degradation reactions of vinyltetrazoles are known. Kinetic parameters of monomolecular thermal degradation of a series of isomeric tetrazoles including 1-methyl-5-vinyl- (**5a**) and 2-methyl-5-vinyltetrazoles (**5b**) under isothermal conditions were studied using manometric methods.¹¹¹ It was found that the degradation of both isomers is characterised by high values of entropy of activation (on average, $33.5\text{ J mol}^{-1}\text{ K}^{-1}$). The activation energies of compounds **5a** and **5b** are equal to 180.0 and 198.9 kJ mol^{-1} , respectively. In the authors' opinion, monomolecular degradation occurs stepwise. For 1,5-disubstituted tetrazoles, reversible formation and subsequent degradation of intermediate azidoazomethines is the limit-

ing step, whereas the limiting step in the case of 2,5-disubstituted isomers is degradation of azodiazocompounds.

The rate of self-propagating high-temperature decomposition of 5-amino-1-vinyltetrazole (**14d**) was estimated to be equal to 0.5 mm s^{-1} , *i.e.*, virtually coincides with the combustion rate of unsubstituted tetrazole.¹¹²

3. Reactions of substituents in the ring

Substitution of the halogen in 5-chloromethyl-2-vinyltetrazole (**31**) by reactions with phthalimide, urotropin and other nucleophiles was used for the synthesis of functionalised 2-vinyltetrazoles.⁴¹

Thus reactions of compound **31** with secondary amines and aniline afford 5-aminomethyl-2-vinyltetrazoles (**32a,b**) in good yields. 5-Mercaptomethyl-2-vinyltetrazole (**32c**) was prepared by reaction with thiourea with subsequent decomposition of the thiuronium salt. The chloromethyl derivative **31** readily forms salt **33** with urotropin; treatment of compound **33** with hydrochloric acid yields the primary amine hydrochloride **34**. Substitution of the primary amino group for chlorine in the Gabriel reaction proceeds successfully: treatment of chloromethyltetrazole **31** with sodium phthalimide gives 5-phthalimidomethyl-2-vinyltetrazole which is hydrolysed into amine **34** upon treatment with hydrochloric acid. Substitution of the azido group for the chlorine atom and the formation of the derivative **32d** occur under conditions of phase-transfer catalysis in the presence of benzyltriethylammonium chloride. Treatment of the chloromethyl derivative **31** with sodium alkoxides under conditions of phase-transfer catalysis yields ethers **32e-g**, while its reaction with sodium acetate affords an ester (**32h**).

4. Reactions of 5-vinyltetrazole with amines

Tetrazole and its 5-substituted derivatives manifest acidic properties and give salts upon reactions with bases including organic bases.^{4,5} It was expected that 5-vinyltetrazole (**1**) would also react with bases to give monomeric salts. This reaction was studied in more detail with triethylamine as an example.¹¹³ The formation of monomeric salts in the first step was confirmed by conductometric, UV spectroscopic and ^1H NMR data.

However, this reaction is accompanied by an increase in the viscosity of the reaction system and a drastic decrease in the relative intensities of signals for the protons of the vinyl group in ^1H NMR spectra. This suggests that polymerisation occurs in the system. Treatment of the reaction mixture with diethyl ether yields a viscous mass; its storage (and vacuum drying) leads to resinification or vitrification. Reactions of 5-vinyltetrazole (**1**) with ammonia, hydrazine, trimethylamine, diethylamine and pyridine proceed in a similar way.^{114,115} Depending on the nature of the amine and reaction conditions, one can prepare polymeric 5-vinyltetrazole salts which are readily soluble or moderately swelling in water.

VI. Polymerisation of vinyltetrazoles

Vinyltetrazoles constitute a relatively novel class of monomers. The first vinyltetrazole derivatives were synthesised in the early 1960's in an attempt to construct promising polymeric materials. High polymerisability of these monomers and valuable properties of polymers prepared from them have stimulated further progress in the chemistry of vinyltetrazoles. Owing to high intrinsic energy and unique physicochemical and operation characteristics, polyvinyltetrazoles have attracted attention as promising to give impetus to organisation of large-scale production of some monomeric and polymeric tetrazole-containing products.^{12,116,117}

Despite the high polymerisability of vinyltetrazoles reported in the very first publications, in-depth studies into polymerisation activities and properties of polymers prepared from them began in the 1980's. Both *N*- and *C*-vinyltetrazole derivatives manifest high polymerisability under conditions of radical initiation. Bulk polymerisation or polymerisation in solvents is carried out in the presence of thermally unstable initiators [*e.g.*, azobisisobutyronitrile (AIBN) and benzoyl peroxide (BP)],^{1,16,17} ammonium persulfate (AP),⁷⁹ H_2O_2 ,¹¹⁸ transition metal acetylacetonates⁴² and redox systems [H_2O_2 - FeSO_4 ,¹¹⁸ FeSO_4 -(NH_4)₂ $\cdot\text{S}_2\text{O}_8$ - $\text{K}_2\text{S}_2\text{O}_5$ (see Refs 1 and 17)]. Radical polymerisation of vinyltetrazoles induced by γ -irradiation¹¹⁹ and electrochemically^{120,121} has been described. The possibility of polymerisation of 5-vinyl-2-methyltetrazole under the action of cationic and anionic catalysts has been demonstrated.¹²² A method for solid-phase polymerisation of 5-vinyltetrazole by exposure to high pressure has been developed.¹²³ Preparation of polymers from 1-methyl-5-vinyl- and 2-methyl-5-vinyltetrazoles grafted onto cellulose is also possible.¹¹⁸

The diversity of structural variants of vinyltetrazole derivatives and the vast body of evidence on quantitative aspects of their radical polymerisation have made it possible to study the effects of the structure of the vinyl monomer, the nature of the reaction medium and the initiator on the polymerisabilities of vinyltetrazoles.

1. Structures and activities of vinyltetrazoles in radical polymerisation

a. Effect of the position of the vinyl group on the activity of vinyltetrazoles in polymerisation

A comparative study of polymerisabilities of unsubstituted *C*- and *N*-vinyltetrazole derivatives has been carried out.^{43,124} Acetonitrile was selected as a medium, since unsubstituted 5-vinyltetrazole behaves as a non-ionisable monomer in this solvent. In the presence of AIBN, polymerisation of 1- and 5-vinyltetrazoles proceeds as a steady-state reaction without an induction period with initial rates depending on the concentration of the reactants and the temperature. The orders of the reaction rates with respect

Table 4. Kinetic parameters of the polymerisation of vinyl-^{43, 124} and isopropenyltetrazoles^{43, 61} in MeCN (AIBN, 60 °C).

Monomer	E_{ef} (see ^a)	$10^4 K_{\text{ef}}$ (see ^b)	$10^5 K_{\text{in}}$ /s ⁻¹	$K_{\text{p}}/K_{\text{t}}^{0.5}$ (see ^c)	$E_{\text{p}} - 0.5 E_{\text{t}}$ (see ^a)

1-Isopropenyl- tetrazole (22)	84.3	0.32	1.30	0.009	—

Note. E_{ef} is the effective activation energy of polymerisation; K_{ef} is the effective rate constant of polymerisation; K_{in} is the initiation rate constant; E_{p} and E_{t} are the activation energies for the propagation and termination of the polymeric chain.

^a kJ mol⁻¹; ^b litre mol^{-0.5} s⁻¹; ^c litre^{0.5} (mol s)^{-0.5}.

^d The polymerisation kinetics was studied in water in the presence of AP.

to the monomer and the initiator are 1 and 0.5, respectively, which suggests a bimolecular chain termination mechanism.

The reactivity criterion $K_{\text{p}}/K_{\text{t}}^{0.5}$ (where K_{p} and K_{t} are the rate constants for chain propagation and termination, respectively) (Table 4) suggest the higher activity of the *C*-vinyl monomer in the radical polymerisation; in addition, polymerisation of 5-vinyltetrazole is less energy-consuming.¹²⁴ A similar ratio of activities of *C*- and *N*-vinyltetrazole derivatives in the polymerisation reaction is consistent with the existing criteria for the estimation of polymerisation activities of vinyl monomers.^{125–127} The electronic structure of 5-vinyltetrazole is characterised by a smaller charge, q_{β} , and a lower charge difference, $q_{\alpha} q_{\beta}$, in comparison with 1-vinyltetrazole.^{60, 61} Moreover, a small reduction of the acceptor induction effect of the substituent at the double bond of 5-vinyltetrazole is accompanied by a considerable decrease in the donor mesomeric effect in comparison with 1-vinyltetrazole. Thus, the tetrazolyl substituent in the *C*-vinyl monomer manifests stronger acceptor properties which accounts for higher activity of 5-vinyltetrazole.

The difference in the reactivities of *C*- and *N*-isopropenyltetrazoles is even more pronounced.⁶¹ Polymerisation of 1- (**22**) and 5-isopropenyltetrazole derivatives (**2**) and their vinyl analogues occurs as a steady-state process without an induction period and is described by the kinetic equation:

$$W = K[M][I]^{0.5}.$$

The $K_{\text{p}}/K_{\text{t}}^{0.5}$ values (see Table 4) suggest that the activity of 5-isopropenyltetrazole (**2**) in radical polymerisation is 20 times higher than that of its isomer **22**.⁶¹ As in the case of vinyltetrazoles, the polymerisation activity correlates with the smaller charge q_{β} and the smaller charge difference, $q_{\alpha} q_{\beta}$, of 5-isopropenyltetrazole (**2**) in comparison with 1-isopropenyltetrazole (**22**).

A comparison of kinetic and energetic characteristics of polymerisation of vinyl- and isopropenyltetrazole derivatives demonstrates a significant decrease in the activities of the latter in radical polymerisation. A 4–10-fold change in the polymerisation activity (*i.e.*, the $K_{\text{p}}/K_{\text{t}}^{0.5}$ ratio for the vinyl and isopropenyl derivatives⁶¹) of 5-vinyl- vs. 5-isopropenyltetrazole is, in general, typical of the transition from *C*-vinyl to *C*-isopropenyl compounds.¹²⁵ A change in the activity in the polymerisation of *N*-substituted vinyltetrazoles [1-vinyl- (**14a**)–1-isopropenyltetrazole (**22**) pair] is more pronounced (see Table 4). These differences are attributed⁶¹ to the regular changes in the electronic structures of the monomers on going from 1-vinyl- to 1-isopropenyltetrazole or from 5-vinyl- to 5-isopropenyltetrazole. Introduction of a methyl substituent into the α -position of the vinyl group both decreases the reactivities of both 5- and 1-isopropenyltetrazoles in comparison with vinyl monomers and reduces the molecular masses (MM) of the polymeric products.

b. Effect of substituents in the heterocycle on the polymerisation activities of vinyltetrazoles

Polymerisation of vinyltetrazole methyl derivatives differing in the position of the substituent in the heterocycle has been studied in the greatest detail.^{43, 124, 128–130} Introduction of a methyl group into the tetrazole ring of 1- and 5-vinyltetrazoles does not change the character of the polymerisation of the monomers: as for unsubstituted vinyltetrazoles, the orders of the reaction with respect to the monomer and the initiator remain equal to 1 and 0.5, respectively.^{43, 124, 128–130} However, the polymerisabilities of substituted vinyltetrazoles vary considerably. The methyl group in position 1 has virtually no effect on the activity of the monomer in comparison with unsubstituted 5-vinyltetrazole: the value of $K_{\text{p}}/K_{\text{t}}^{0.5}$ changes only insignificantly in the polymerisation in CHCl₃, whereas polymerisation in DMF is characterised by a slight increase in the activity despite the increase in the efficient polymerisation energies (Table 5). This does not contradict the results of quantum-chemical calculations of 5-vinyl- and 1-methyl-5-vinyltetrazole,⁵⁵ which points to the lack of the electron-donor effect of the methyl group in position 1. Moreover, the results of ¹³C NMR studies and the values of induction and resonance constants^{27, 131} testify to a slight enhancement of the electron-withdrawing properties of the tetrazolyl substituent upon the introduction of the methyl group into position 1, which enhances the polymerisability of 1-methyl-5-vinyltetrazole in comparison with unsubstituted 5-vinyltetrazole.

^a kJ mol⁻¹; ^b litre^{0.5} (mol s)^{-0.5}.

In contrast, the introduction of a methyl group into position 2 of *C*-vinyltetrazole or into position 5 of *N*-vinyltetrazole decreases the activities of methyl-substituted monomers in radical polymerisation (see Table 5). The difference in the $K_{\text{p}}/K_{\text{t}}^{0.5}$ values for the 5-vinyltetrazole–2-methyl-5-vinyltetrazole pair is 2.2, while that for the 1-vinyltetrazole–5-methyl-1-vinyltetrazole pair is 1.6.^{43, 124} Reduced activities of methyl-substituted monomers are also explicable in terms of the electronic effect of the methyl group, which being present in position 2 or 5, behaves as a potent electron donor. As a result, the electronic structures of 2- and 5-substituted monomers differ from those of unsubstituted vinyltetrazoles. This difference is more pronounced for the 5-vinyl- and 2-methyl-5-vinyltetrazole pair than for the 1-vinyl- and 5-methyl-1-vinyltetrazole pair, which probably determines the greater difference in the radical polymerisability of the former monomer pair.

The effects of substituents in the heterocycle on polymerisation activities of vinyltetrazoles have been clearly demonstrated for the polymerisation of *N*-vinyltetrazoles in water in the presence of AP.^{60, 84} According to kinetic data, polymerisation activities of *N*-vinyltetrazoles decrease in the following order: 1-vinyltetrazole (**14a**) > 5-methyl-1-vinyltetrazole (**14b**) > 5-amino-1-vinyltetrazole (**14d**) > 5-acetylamino-1-vinyltetrazole (**14f**) (Table 6). The changes in the activities of the first three compounds correlate with the decrease in the electron-withdrawing properties of the tetrazolyl substituent with respect to the

Table 6. Kinetic parameters of the polymerisation of *N*-vinyltetrazoles in water (AP, 60 °C).^{43, 60, 84}

Monomer	E_{ef} /kJ mol ⁻¹	$10^4 K_{\text{ef}}$ /litre ^{0.5} mol ^{-0.5} s ⁻¹	$10^5 K_{\text{in}}$ /s ⁻¹	$K_{\text{p}}/K_{\text{t}}^{0.5}$ /litre ^{0.5} (mol s) ^{-0.5}	$E_{\text{p}} - 0.5 E_{\text{t}}$ /kJ mol ⁻¹	σ_{I}	σ_{R}

5-Acetylamino-1-vinyl-tetrazole (14f)	85.0	41.4	1.40	1.16	24.2	—	—

double bond (*i.e.*, σ_{I} and σ_{R} values), which results in regular changes in their electronic structures. 5-Acetylamino-1-vinyltetrazole (**14f**), the polymerisation activity of which would not differ from that of unsubstituted 1-vinyltetrazole, falls out of this series. Presumably, the presence of such a bulky substituent as NHCOMe in position 5 creates steric hindrance in the act of chain propagation. It should be noted that $K_{\text{p}}/K_{\text{t}}^{0.5}$ values depend not only on charge characteristics and σ_{I} and σ_{R} of substituents, but also on the values of polarographic reduction potentials ($E_{1/2}$) and chemical shifts of signals for β -carbon atoms of the vinyl group in ¹³C NMR spectra.^{57, 81} The dependences of $\log(K_{\text{p}}/K_{\text{t}}^{0.5})$ on σ_{I} , $E_{1/2}$ and $\delta(\text{C}_{\beta})$ for 1-vinyl-, 5-methyl-1-vinyl- and 5-amino-1-vinyltetrazoles are linear.⁸⁴ The activity of 5-acetylamino-1-vinyltetrazole (**14f**) in polymerisation reactions is much lower than that expected based on these correlations. The reason is the aforementioned steric hindrance in the chain propagation step.

As regards their activities in radical polymerisation, vinyltetrazoles stand with methyl acrylate, acrylonitrile and acrylamide. Their high reactivities do not contradict the general concepts on the activating effect of electron-withdrawing substituents at the double bond. However, there exist other viewpoints as to high polymerisation activities of vinyltetrazoles. In terms of the chemical structures, 1-methyl-5-vinyl- and 2-methyl-5-vinyltetrazoles are considered to be similar to styrene,^{128, 129} although at 40 °C $K_{\text{p}}/K_{\text{t}}^{0.5}$ values for 1-methyl-5-vinyltetrazole and 2-methyl-5-vinyltetrazole exceed that of styrene 25- (see Ref. 129) and 17.5-fold, respectively. This is explained¹²⁸ by either a significant decrease in the chain termination rate in the polymerisation of vinyltetrazoles or, alternatively,⁶⁹ by rotational isomerism of 2-methyl-5-vinyltetrazole which is absent in styrene and helps favourable orientation of the vinyl group in the chain propagation. However, the first assumption is not experimentally proved and the reason for the significant difference between the K_{t} values for styrene and vinyltetrazoles is unclear. The second assumption does not stand up to criticism, because despite hindered rotational isomerism of 1-methyl-5-vinyltetrazole, its reactivity is high. The most probable reason for the enhanced activity of vinyltetrazoles in comparison with styrene is higher electron-withdrawing activity of tetrazolyl substituents at the double bond compared to the phenyl group. As is known, electron-withdrawing substituents with the same degree of conjugation increase the activity of monomers in homopolymerisation.¹²⁵

2. Effect of the nature of the solvent on radical polymerisation of vinyltetrazoles

Vinyltetrazole derivatives are related to polar (and, in the majority of cases, water-soluble) monomers. Heterocyclic substituents at the double bond contain nitrogen atoms of both 'pyrrole' and 'pyridine' types. Depending on the position of the vinyl group in the heterocycle, vinyltetrazoles manifest the properties of ionisable (unsubstituted *C*-vinyltetrazoles, such as 5-vinyl- and 5-isopropenyltetrazoles) or non-ionogenic monomers (protected *C*-vinyl- and *N*-vinyltetrazoles) because of their low basicities. However, even the latter compounds are not inert with respect to the reaction medium owing to the presence of unshared electron pairs of nitrogen atoms and an aromatic π -system of the hetero-

cycle. This determines the existence of different interactions between the monomer and the solvent which is manifested in the polymerisation activities of vinyltetrazoles. There is evidence that self-association of 1-vinyltetrazole and 1-methyl-5-vinyltetrazole in various solvents affects the polymerisation activity of the monomers^{86, 124} along with accelerating effects of water^{124, 130, 132} and some low-molecular-weight additives¹³³ on polymerisation of vinyltetrazoles. The nature of the polymerisation medium also significantly affects the MM characteristics of the polymers synthesised. Thus MM of the polymeric products prepared in water-containing systems were found to be substantially increased.^{79, 124, 130} Varying the nature of the solvent is the most efficient way to achieve control over polymerisation of vinyltetrazoles and of the effect on the structures and properties of the polymers obtained. The data listed in Table 7 confirm the important role of the solvent in the polymerisation of both the ionogenic (5-vinyltetrazole) and non-ionogenic (*C*- and *N*-vinyltetrazoles) monomers. A transition from the solvent-free polymerisation to the solution polymerisation favours, as a rule, higher yield of the polymeric product but differently affects the reactivities of the monomers. Thus the activities of 2-methyl-5-vinyltetrazole in solvent-free polymerisation and in polymerisation in chloroform were practically identical,¹²⁸ while characteristic viscosities of the polymers obtained significantly decreased with a decrease in the initial concentration of the monomer in the polymerisation system. Polymerisation in more polar solvents, especially in water, increases the activities of vinyltetrazoles and MM of the polymers formed.^{43, 124} The activating effect of water is also manifested in the polymerisation in mixed solvents. The addition of water to DMF or acetonitrile causes a monotonic increase in the polymerisation rate and $K_{\text{p}}/K_{\text{t}}^{0.5}$ parameters for 5-vinyl-, 1-methyl-5-vinyl- and 2-methyl-5-vinyltetrazoles^{43, 124, 130, 132} and increases the degree of polymerisation of the polymers obtained (Fig. 2). A sharp increase in $K_{\text{p}}/K_{\text{t}}^{0.5}$ was

Figure 2. The dependence of the relative rate constant for chain propagation, $K_{\text{p}}/K_{\text{t}}^{0.5}$ (a) and the degree of polymerisation of the polymeric products ($\bar{p}$) obtained (b) by polymerisation of 5-vinyltetrazole (1), 1-vinyltetrazole (2) and 2-methyl-5-vinyltetrazole (3) on the composition of the MeCN–H₂O mixture (60 °C).^{43, 124}

Note. AIBN was used as the initiator in organic solvents; AP was used as the initiator in water. ^a Water content was 9.2 mol litre^{−1}.

observed in the AIBN-induced polymerisation of 1-vinyltetrazole and 2-methyl-5-vinyltetrazole in an H₂O–MeCN system with the water content > 0.8 vol.% (see Fig. 2a).^{43, 124} In aqueous solutions, the polymerisation activities of nonionogenic 2-methyl-5-vinyl-, 1-vinyl- and 5-methyl-1-vinyltetrazoles characterised by the parameter $K_p/K_t^{0.5}$ exceed those in acetonitrile 6-, 7.5- and 10-fold, respectively (see Table 7). In acetonitrile, the activities of the aforementioned monomers are lower than that of unsubstituted 5-vinyltetrazole, while the $K_p/K_t^{0.5}$ values of *N*-vinyltetrazoles in H₂O are higher than that of *C*-vinyltetrazole. Apparently, the most probable reason for enhanced polymerisation activity of non-ionogenic vinyltetrazoles in water is the increase in the concentration of the monomer in the microenvironment of the active centres of the growing macroradicals as a result of sorption of the hydrophobic monomer.¹²⁴ Selective sorption of organic monomers by polymeric coils and the resulting increase in polymerisation rates have repeatedly been observed for other water-soluble monomers.^{134, 135} In water, the molecular masses of polyvinyltetrazoles formed increase severalfold (see Fig. 2b).

Of special note is the effect of water on polymerisation of ionisable 5-vinyltetrazoles. The values of $K_{\text{ef}} = W[M_0]^{-1}$ and the initiation rate constant K_{in} for reactions performed in acetonitrile and water depend differently on the monomer concentration (Fig. 3).¹²⁴ The initial concentration of 5-vinyltetrazole does not affect K_{in} and K_{ef} in acetonitrile, but for polymerisation in water in the presence of AP, these constants depend on the monomer

concentration. Moreover, the formal kinetic expression for the rate of polymerisation in water and the energy characteristics of the reaction depend on the monomer concentration. The classical equation $W = K[M][I]^{0.5}$ is observed only at the initial concentrations of 5-vinyltetrazole below 0.3 mol litre^{−1}. In this case, the effective activation energy, E_{ef} , is equal to 65.8 kJ mol^{−1} (see Ref. 124). K_{in} and K_{ef} values increase with an increase in the initial concentration of the monomer from 0.5 to 2.0 mol litre^{−1}. The formal order of the reaction with respect to the monomer in the given concentration range is > 1, whereas the effective activation energy is 49.3 kJ mol^{−1} (see Refs 43 and 136). With these concentrations of the monomer, redox initiation involving 5-vinyltetrazole takes place.

5-Vinyltetrazole manifests the properties of a weak acid; therefore, its polymerisability, *e.g.*, expressed through the reduced polymerisation rate, depends on the pH of the reaction medium (Fig. 4).^{124, 136} The maximum reaction rates and the molecular masses of the polymers formed are observed at pH values corresponding to self-dissociation of the monomer, whereas their minimum values are observed at pH close to the point of complete neutralisation of the NH-acid. Such a parallel dependence of the kinetic and molecular-mass characteristics on pH is also observed for unsaturated carboxylic acids and is determined by changes in the electronic structures of the polymerising monomers in the course of ionisation.¹³⁷

Figure 3. The dependences of the effective rate constant (K_{ef}) for the polymerisation of 5-vinyltetrazole (a) in acetonitrile (1) and water (2) and of the initiation rate constants (K_{in}) in water (b) on the concentration of the monomer (60 °C).

Figure 4. The pH dependence of the reduced rate constant (W/W_{min}) for the polymerisation of 5-vinyltetrazole (a) and the intrinsic viscosity $[\eta]$ of the polymers formed (b) (H₂O, 60 °C). $W_{\text{min}} = 0.13 \times 10^{-4}$ mol litre^{−1} s^{−1}. Concentrations: monomer, 0.25 mol litre^{−1}; AP, 10^{-3} mol litre^{−1}.

Figure 5. The effect of pH of the aqueous solution on the relative rate constant for chain propagation, $K_p/K_t^{0.5}$ (a) and the intrinsic viscosity $[\eta]$ of the polymeric products obtained (b) upon polymerisation of 5-amino-1-vinyltetrazole (60 °C).

Among other *N*-vinyltetrazoles, 5-amino-1-vinyltetrazole is the most sensitive to pH changes in the course of polymerisation, which is probably related to the enhancement of the basic properties of the tetrazole ring and its ability to be protonated in acidic media. The $K_p/K_t^{0.5}$ values for this monomer increase with a decrease in pH (Fig. 5).⁴³ In contrast, the characteristic viscosities of the polymers formed increase with pH. The polymers synthesised at pH > 11 are insoluble.

Polymerisation of vinyltetrazoles is also affected by addition of some low-molecular-weight salts, *e.g.*, sodium thiocyanate.¹³³ In aqueous solutions of this salt, 1-vinyl-, 5-methyl-1-vinyl- and 2-methyl-5-vinyltetrazoles yield polymeric products of much higher molecular masses than in the absence of solvents or in organic media.

The structures of synthetic polymers also depend on the nature of the reaction medium. Under conditions of radical initiation, the polymerisation of 2-methyl-5-vinyltetrazole occurs by an isomerisation mechanism with simultaneous cleavage of the C = C bond of the vinyl group and the C = N bond of the tetrazole ring and formation of the C = C bond in the main polymeric chain.

An increase in the solvent polarity leads to the predominant formation of form **A**, while the proportion of form **B** in the final polymeric product increases in less polar solvents.

Thus, by varying the nature of the reaction medium one can gain reliable control over polymerisation of vinyltetrazoles and MM characteristics of the polymers synthesised.

3. Effect of the method of initiation on the polymerisation of vinyltetrazoles

The use of various methods of initiation for the polymerisation of vinyltetrazole derivatives allows control over polymerisation and

modification of structural and molecular-mass characteristics of the polymeric products.

Polymerisation of 5-vinyl-2-methyltetrazole under conditions of anionic catalyst, BuONa, and cationic catalyst, $\text{Ph}_3\text{C}^+\text{ClO}_4^-$, initiation afforded a polymer with a high content of structures **B**.¹²² The molecular masses of the polymers synthesised are $(5-50) \times 10^3$, *i.e.*, by one order of magnitude lower than those of polymers prepared under the conditions of the radical initiation. In addition, ionic polymerisation leads to the opening of the tetrazole ring with cleavage of the C = N bond and formation of cross-linked structures. High-molecular-weight poly(5-vinyltetrazole) was prepared by electrochemical radical polymerisation of the monomer in water at 20 °C in the presence of potassium persulfate using a glass electrode.¹²¹ A chelate-type polymeric complex of poly(5-vinyltetrazole) with Fe^{2+} (see Refs 138 and 139) was synthesised under analogous conditions using an iron electrode. γ -Radiation-induced polymerisation of 2-methyl-5-vinyltetrazole occurs by a radical mechanism: the reaction rate is proportional to the dose rate to the power 0.5.¹¹⁹ All other factors being the same, the reactivity of the tetrazole-containing monomer in the radiation polymerisation exceeds those of styrene, acrylonitrile, methyl methacrylate and vinyl acetate.^{119, 140} Varying the irradiation conditions in the polymerisation of 2-methyl-5-vinyltetrazole allows preparation of polymeric products in a broad range of molecular masses ($2 \times 10^4 - 20 \times 10^5$). Radiation polymerisation was accompanied by radiolytic degradation of the tetrazole ring with elimination of nitrogen.¹¹⁹

Radical polymerisation of vinyltetrazoles in the presence of initiators which enables a high degree of conversion and formation of high-molecular-weight products ($\text{MM} \sim 10^6$) is of particular practical interest. For the majority of monomers, the highest yields and MM were achieved by polymerisation in water in the presence of AP. In some cases, the use of redox systems permits one to increase the yields of the polymers with simultaneous reduction of the reaction time and the temperature. The increases in the reaction rates and conversion are especially pronounced in the case of 1-vinyl- and 5-methyl-1-vinyltetrazoles in the presence of redox systems in water: at 20 °C, polymerisation occurs virtually instantaneously with high self-heating and quantitative yields of the polymers.⁷⁹ In the presence of AP and BP, the polymerisation of 5-vinyltetrazole occurs even at 20 °C (where no thermolysis of the initiator occurs) and affords polymers of the highest MM.¹⁴¹ The structures of tetrazole-containing monomers enable their donor–acceptor interactions with compounds containing a peroxide O–O fragment, which affects the polymerisation of vinyltetrazoles in the presence of peroxide initiators.

a. Polymerisation of 5-vinyltetrazole under the action of peroxide initiators

It was noted in one of the early papers¹¹⁸ that the polymerisation of 1-methyl-5-vinyl- and 2-methyl-5-vinyltetrazoles with simultaneous grafting onto cellulose initiated by H_2O_2 is characterised by extraordinarily low values of activation energies (49.6 and 43.2 kJ mol⁻¹, respectively). This is also typical of polymerisation reactions occurring under redox initiation conditions. As mentioned above, the K_{in} and E_{ef} values for the polymerisation of 5-vinyltetrazole in water under the action of AP depend on the concentration of the monomer.¹²⁴ Obviously, the tetrazole-containing monomer is involved in the initiation step in the presence of peroxide initiators. As expected, 5-vinyltetrazole containing both nitrogen atoms with an unshared electron pair and a proton-donor NH bond interacts with the initiator the most actively.

The results of kinetic studies of the polymerisation of 5-vinyltetrazole induced by various initiators are presented in Table 8. Under conditions of thermolysis of BP, the reaction of the monomer with the initiator does not influence the polymerisation kinetics of 5-vinyltetrazole. As can be seen from Table 8, the polymerisation induced by BP under identical conditions is more energy-consuming and occurs at a lower rate than that in the presence of AIBN due to a much lower (*ca.* fivefold) initiation rate

Table 8. Kinetic parameters of the polymerisation of 5-vinyltetrazole in the presence of AIBN, BP and AP.^{43, 141}

Initiator	Solvent	$T/^{\circ}\text{C}$	Kinetic orders		$E_{\text{ef}}/\text{kJ mol}^{-1}$	$10^4 K_{\text{ef}}/\text{litre (mol s)}^{-1}$	$10^5 K_{\text{in}}/\text{s}^{-1}$
			[M]	[I]			
AIBN	EtOH	60	1.5	0.5	83.3	28.0	0.96
BP	EtOH	60	1.5	0.6	92.0	12.9	0.20
	EtOH	20	1.9	0.8	22.1	0.87	0.007
AP	H ₂ O	60	1.8	0.26	49.3	16.4	1.67
	H ₂ O	20	1.85	0.5	25.4	2.2	0.16

constant. Such a correlation of K_{in} for the polymerisation initiated by BP and AIBN is characteristic of vinyl monomers.¹²⁵

A different situation is observed in the polymerisation of 5-vinyltetrazole in water at 50–70 °C in the presence of AP as the initiator. In addition to the concentration dependence of K_{in} and K_{ef} in the range of the monomer concentrations of 0.5–2 mol litre⁻¹ (see Table 8), the kinetic order with respect to the monomer is increased, while the E_{ef} value is commensurate with the values of the activation energies for the reactions initiated by redox systems. In this case, K_{in} exceeds the corresponding value for the polymerisation in the presence of AIBN and BP (two- and eightfold, respectively), which ensures higher reaction rates. These data suggest the feasibility of an interaction of 5-vinyltetrazole with AP, which is manifested in the polymerisation kinetics.

Polymerisation of the vinyl monomer in the 5-vinyltetrazole–BP and 5-vinyltetrazole–AP systems occurs at the temperatures where no thermolysis of the initiators takes place.¹⁴¹ The AP-induced low-temperature (10–30 °C) polymerisation of 5-vinyltetrazole in water proceeds at significantly higher rates than that in the presence of BP, which can be attributed to higher values of the initiation constant, K_{in} , for the 5-vinyltetrazole–AP system (see Table 8). This suggests that the donor–acceptor interaction of 5-vinyltetrazole with AP, which results in the formation of radicals initiating the polymerisation, proceeds more smoothly than with organic peroxides.

A mechanism of involvement of 5-vinyltetrazole in the generation of radicals initiating the polymerisation of the monomer in the presence of BP at reduced temperatures has been proposed.^{43, 141}

Tetrazole derivatives are weaker electron donors than tertiary amines, therefore, 5-vinyltetrazole is less prone to donor–acceptor interactions with peroxide than, *e.g.*, alkylamines or *N,N*-dimethylaniline. However, the presence of an acid proton in the tetrazole ring favours decomposition of the charge-transfer complexes formed to yield radical species initiating the polymerisation. If a heterocycle contains no acid proton (*e.g.*, as in the cases of *N*-methyl- or *N*-vinyl derivatives), no polymerisation in the presence of AP or BP in aprotic solvents at 20 °C occurs. The addition of water to these systems induces polymerisation of both 2-methyl-5-vinyltetrazole and 1-vinyltetrazole. This fact points to the crucial role of the proton in reactions of tetrazole-containing compounds with AP or BP.

b. Spontaneous polymerisation of 5-vinyltetrazole

A characteristic feature of 5-vinyltetrazole is its spontaneous polymerisability in the absence of initiators at 20 °C and lower

temperatures upon dissolution in water, ethanol, formamide, DMF and DMSO.¹⁴² No spontaneous polymerisation of the monomer occurs in acetone or acetonitrile. The rate of spontaneous polymerisation of 5-vinyltetrazole and the polymer yields depend on the nature of the solvent and pH of the medium, reaching maximum values in water at pH 4.3. The logarithmic dependence of the polymerisation rate of 5-vinyltetrazole in water at 60 °C on the monomer concentration appears as:

$$\log W = (-5.79 \pm 0.05) + (1.90 \pm 0.11) \log [M].$$

The E_{ef} value for spontaneous polymerisation of 5-vinyltetrazole determined from the temperature dependence of K_{ef} [1.13×10^{-6} (at 50 °C), 1.49×10^{-6} (at 60 °C), 1.98×10^{-6} litre (mol s)⁻¹ (at 70 °C)] is 25.8 kJ mol⁻¹ (see Refs 43 and 142), which accounts for the occurrence of this reaction at 20 °C and lower temperatures.

The molecular masses of the polymeric products synthesised by spontaneous polymerisation of 5-vinyltetrazole in water do not depend on the initial concentrations of the monomer and are commensurate with those of poly(5-vinyltetrazole) specimens prepared by initiator-induced polymerisation.

VII. Copolymerisation of vinyltetrazoles

Copolymerisation, like chemical modification, is used for changing physicochemical, physicomachanical, chemical and other properties of polymeric compounds as well as for conferring novel properties that are sometimes atypical of homopolymers. Vinyltetrazole derivatives are promising starting compounds for the synthesis of novel polymeric products by copolymerisation with other vinyl monomers. The activities of vinyltetrazoles in copolymerisation reactions allow easy variation of the composition, and, correspondingly, properties of the polymeric products obtained.

An analysis of results of copolymerisation studies involving vinyltetrazoles should be started from the consideration of reactivities of vinylazoles, which are thought to depend on the number of nitrogen atoms in the heterocycle.

An analysis of a vast body of experimental (often, contradictory) data on copolymerisation of vinylazoles^{53, 54, 143–158} revealed that these compounds manifest lower activities in the copolymerisation with standard comonomers, such as styrene and methyl methacrylate (MMA). At the same time, an increase in the number of nitrogen atoms in the heterocycle of vinylazoles, which enhances the π -electron-withdrawing effect of the azolyl substituent on the double bond, is accompanied by enhancement of activities of vinylazoles in the reaction with a macroradical having a terminal styrene fragment.⁵³ In the copolymerisation with MMA, an opposite trend is observed.¹⁵⁸ In our opinion, the most correct approach to the study of structure–activity relationships of vinylazoles in copolymerisation was proposed by Smirnov *et al.*^{54, 144} Thus for the *N*-vinylazole–diethyl maleate (DEM) and *N*-vinylazole–1-vinylpyrrolidone (VPD) systems, the activities of the monomers in the reaction of vinylazoles with the DEM radical are the higher the higher is the polarity of the C=C bond and the negative charge of the β -carbon atom of the vinyl group of the vinylazole. In contrast, the activities of vinylazoles in the reaction with the VPD radical increase with a decrease in polarity

Table 9. Constants of copolymerisation of vinyltetrazoles with other vinyl monomers in the presence of AIBN.

^a The redox system Fe²⁺ – H₂O₂. ^b Graft copolymerisation onto cellulose. ^c In the presence of AP.

and q_B . Thus, the activities of *N*-vinylazoles in reactions with electron-withdrawing radicals (DEM and MMA) decrease with

an increase in the number of nitrogen atoms in the heterocycle, while those in reactions with donor radicals (VPD) increase. This

suggests that the activity of *N*-vinyltetrazole is the lowest (compared to those of other vinylazoles) in the copolymerisation with electron-withdrawing monomers and the highest in the copolymerisation with electron-donating monomers. However, the *N*-vinylazole–styrene system does not fit into this series. The activities of vinylazoles in the reaction with a macroradical containing a terminal styrene unit characterised by parameter $1/r_2$ (where r are effective relative activity constants) decrease in the following order: 1-vinylimidazole [0.1 (see Ref. 145)] < 1-vinyltetrazole [0.27 (see Ref. 149)] < 1-vinyl-1,2,4-triazole [0.67 (see Ref. 148)].

C-Vinyltetrazoles are more reactive in copolymerisation with styrene and MMA than *N*-vinyl derivatives (Table 9); their activities depend critically on the presence and positions of substituents in the molecule of the monomer. The presence of a methyl group in the vinyl fragment or in position 1 of *C*-vinyltetrazole changes the reaction pattern so that 5-isopropenyltetrazole is as active as styrene in the copolymerisation and the activity of 1-methyl-5-vinyltetrazole exceeds those of styrene and MMA (see Table 9). 2-Methyl-5-vinyltetrazole is less reactive towards the styrene radical ($1/r_2 = 0.84$)⁸⁶ than unsubstituted 5-vinyltetrazole ($1/r_2 = 1.28$).¹⁵² In this case, the size of the alkyl substituent in position 2 does not affect the activities of the monomers in the copolymerisation.²⁷

The interest of investigators in tetrazole-containing polymers has long been determined by the possibility of technological applications of these high-energy compounds. However, the properties of polymers based on tetrazole are very diverse owing to the presence of several reactive sites in the tetrazole ring. In some copolymers of vinyltetrazoles with other vinyl monomers, these properties are more pronounced. For this reason, copolymerisation reactions hold especially great promise in the synthesis of novel tetrazole-containing polymeric materials of practical importance.

VIII. Practical applications of vinyltetrazole derivatives

Despite diverse properties of vinyltetrazoles and their polymeric derivatives, their practical applications are not an issue of broad discussion. In this section we consider the prospects of practical applications of vinyltetrazoles.

Vinyltetrazoles present interest for organic synthesis as intermediates. They were used in the synthesis of tetrazole-containing bromohydrins,⁹⁴ epoxytetrazoles,⁹⁴ hydroxyethyltetrazole,¹⁹ aziridine derivatives,⁹⁷ 2-(tetrazol-5-yl)bicyclo[2.1.2]hept-5-ene and 2-methyl-5-vinyl-1,3,4-oxadiazole.²¹ The approaches to the synthesis of 5-iodo- and mercury-substituted vinyltetrazoles⁴⁸ have been outlined and the possibility of alkylation of 5-vinyltetrazole under electrophilic conditions has been demonstrated.³² Various functionalised derivatives based on 5-chloromethyl-1-vinyltetrazole have been synthesised; for some of them biological activity is anticipated.⁴¹ As vinyltetrazoles can easily form complexes with metal ions including Ni^{2+} and Pd^{2+} , it may be expected that these complexes will manifest catalytic activity in hydrogenation reactions.¹⁰¹

The construction of novel polymeric materials endowed with unique properties on the basis of tetrazole derivatives is the most promising line of research. High-energy characteristics of tetrazole polymers, their relatively low sensitivity to shock and friction, rather high thermal stability, low toxicity and evolution of a large volume of neutral gas upon decomposition make polymers and copolymers based on vinyltetrazoles promising components for gunpowders, explosives and propellants.^{1, 14–20, 28} The majority of published papers confirm the fact that tetrazole-containing polymers used in various fuel systems differ favourably from analogous polymeric materials in enhanced intrinsic energy, good compatibility with other composition components and handling safety.

Meanwhile, other properties of vinyltetrazole-containing polymers are currently attracting the attention of investigators. Thus ternary copolymers of 2-methyl-5-vinyltetrazole with acrylic acid and its esters were recommended as components of rubber compositions possessing high mechanical characteristics.¹⁶⁹ Preparation of a film-forming substance for cosmetics based on hydroxyethylammonium salt of poly(5-vinyltetrazole) has recently been claimed.¹⁷⁰ A copolymer of 2-methyl-5-vinyltetrazole with 1-vinylpyrrolidone, methyl methacrylate and α,ω -hexamethacryloyl oligoacrylate has been recommended for the production of vision correcting lenses.¹⁷¹ A cellulose acetate composition comprising polyvinyltetrazole can be used for the preparation of ultrafiltration membranes.¹⁷² A copolymer of 2-methyl-5-vinyltetrazole with *N,N*-diallyl-*N,N*-dimethylammonium chloride has been patented as a film-forming substance possessing semiconducting and antistatic properties.¹⁷³ Graft copolymerisation of 2-methyl-5-vinyltetrazole was recommended to improve absorption properties of cotton and cellulose fibres.¹⁷⁴ A copolymer of butyl acrylate with acrylonitrile and 5-vinyltetrazole can be used as a polymeric binder of operating layers of magnetic storage media and an adhesive.¹⁷⁵ Taking into consideration high complex-forming ability of polyvinyltetrazoles with respect to heavy metal ions in aqueous media,^{43, 176–178} it may be expected that these polymers will find use as efficient sorbents for the solution of various environmental problems or for the isolation of precious metals. Sodium salt of poly-5-vinyltetrazoles forms hydrogel compositions in the presence of Cr^{3+} ions; this polymer has been patented as a thickening agent in water-filled explosives.^{179, 180}

The results of studies of physiological activities of tetrazole-containing polymers are promising, which opens new opportunities for the preparation of novel medicinal drugs based on them.

Unsubstituted poly-*C*-vinyltetrazoles manifest acidic properties and enter into interpolymeric reactions with natural high-molecular-weight compounds, which determines their anticoagulant properties.^{181, 182} The anticoagulant activity can be varied significantly by combining structural fragments of vinyltetrazoles with other comonomers in the polymeric chain.^{183, 184} Quaternary salts of polyvinyltetrazoles exert an opposite effect: they bind heparin in the circulating blood and thus favour blood coagulation.¹⁸⁵ The antiheparin activity of tetrazole-containing polycations compares favourably with that of currently employed medicinal drugs. Sodium salt of poly(5-vinyltetrazole), a polyelectrolyte endowed with pronounced antiinflammatory and aseptic properties, accelerates wound healing and suppresses cicatrization.^{43, 186, 187}

Tetrazole-containing polyelectrolytes manifest pronounced, sometimes extraordinarily high, immunoadjuvant activity towards a vast range of antigens.^{183, 188–190} Homo- and copolymers of poly-5-vinyl- and poly-5-isopropenyltetrazoles were recommended for the construction of antigenic diagnostic preparations surpassing in activity those currently in practice.^{191–194}

Thus, the broad spectrum of properties of vinyltetrazole-based polymers leaves hope that these compounds will soon find application in miscellaneous areas of human activity. In our opinion, studies aimed at the preparation of tetrazole-containing monomers and polymers will eventually lead to reduction of their production costs, which is undoubtedly important for the practical application of these novel products.

* * *

This review deals with generalisation of the known methods for the synthesis of *C*- and *N*-vinyltetrazole derivatives based on the formation of the tetrazole ring from open-chain compounds containing a vinyl group and formation of an unsaturated fragment in the preformed heterocycle. Some of these methods have been implemented in the flexible production system 'Tetrazoles' designed and launched at the pilot plant of St Petersburg State

Technological Institute (the Engineering and Design Department 'Tekhnolog', Russian Federation).

An analysis of structures and geometry of vinyltetrazole molecules, generalisation of their physicochemical and spectral properties and study of mutual effects of the two unsaturated fragments, viz., the vinyl group and the heterocycle, make it possible to predict chemical properties of these compounds in addition reactions involving the vinyl group as well as in alkylation, quaternisation, complexation, etc.

The radical polymerisability of vinyltetrazoles is one of their most essential features. A detailed analysis of effects of various factors (monomer structure, reaction medium, initiation procedure, etc.) on the polymerisation of vinyltetrazoles allows development of novel polymeric materials. Pilot-plant production of polyvinyltetrazoles has been started in two enterprises in Russia. A broad spectrum of valuable properties of vinyltetrazoles and their polymers leaves hope that this class of compounds will find application in various branches of science and technology.

Abstract. Applications of NMR imaging to studies of chemical reactions including polymerisation reactions and the Belousov–Zhabotinsky oscillating reaction are considered. Publications concerning applications of NMR imaging to studies of the temperature and electric current density distributions in various specimens are discussed. NMR investigations of hyperpolarised gases and gases with equilibrium nuclear spin polarisation are described. NMR imaging studies of solids (in particular, polymers and elastomers) are briefly outlined. The bibliography includes 275 references.

I. Introduction

Investigations of chemical reactions *in situ* is a promising field of application of NMR tomography (or magnetic-resonance imaging, MRI). Currently, this field has attracted considerable attention of researchers. In this review we present a detailed consideration of the studies concerned with applications of NMR imaging to the determination of the temperature and electric current density distributions within various objects. Most of these studies were carried out to address biomedical problems; however, experimental MRI techniques can undoubtedly be useful for physicochemical investigations and chemical technology. A large section of this review concerns MRI of gases. A vast area of MRI studies of solid materials is only briefly outlined owing to specific features of solid-state NMR spectroscopy. However, some solid materials, such as polymers and elastomers, allow liquid-phase NMR techniques to be employed. In this connection mention may be made that applications of NMR imaging to studies of liquid-containing materials and mass transfer investigations have been the subject of our recent reviews.^{1,2}

II. Chemical reactions

1. General remarks

Currently, NMR spectroscopy is widely used in studies of chemical reactions. However, there are only a few reports on the use of NMR imaging for these purposes despite a steady interest in this kind of experimental research.

Currently, there are only two fields of application that have attracted considerable attention of researchers. One of them is the application of NMR microimaging, or magnetic resonance microimaging (MRM), to studies of polymerisation processes. Polymerisation is often accompanied by slowing down the molecular mobility, which can lead to substantial reduction of the spin–spin relaxation times (T_2) of the nuclei under study. This allows one to selectively follow variations of the spatial distribution of the initial reagents with time. Usually, polymers are characterised by short T_2 times and, hence, NMR signals of these substances are not often observed. The polymer matrix reduces the mobility of the residual monomer, and the T_2 time of the latter shortens as well. To enhance the NMR signal of the polymer, one can use the fact that an increase in temperature accelerates the molecular mobility. In the case of gel formation the system can be imaged using the signal of the more mobile, liquid dispersion medium. Yet another approach involves introduction of various tracers into the initial mixture. Tracers are not involved in the reaction, but reflect variations of the local viscosity of the medium during polymerisation.

Another field of successful application of the MRM technique is the study of the Belousov–Zhabotinsky (B–Z) oscillating reactions, *i.e.*, metal ion-catalysed oxidation of organic compounds by bromate ions.³ In this case the water proton chemical shifts and relaxation times are linear functions of the concentration of the paramagnetic metal ion present in the aqueous solution and are affected by the oxidised and reduced states of the metal ion in a different manner.

Some other reactions have also been studied using MRI techniques. Of particular importance is the possibility of determining the local chemical composition of the reaction mixture by recording spatially resolved NMR spectra and selective NMR imaging using a particular NMR signal.

2. Thermal polymerisation

The formation of poly(methyl methacrylate) (PMMA) was monitored⁴ by the disappearance of the signal of methyl methacrylate (MMA) mixed with the initiator in a mould pre-heated to 60 °C.

Received 20 June 2002

Uspekhi Khimii 72 (2) 183–212 (2003); translated by A M Raevsky

The two-dimensional (2D) NMR images obtained revealed mainly homogeneous propagation of the polymerisation process from the centre of the sample towards its periphery. However, the images clearly exhibit a small 'defect', namely, a region in which the polymerisation proceeds at a lower rate. The presence of this defect was confirmed visually.⁴ Homogeneous polymerisation of MMA was also reported by other authors (see, *e.g.*, Ref. 5). Polymerisation in the course of the formation of an aqueous gel of cross-linked poly(methacrylic acid) was investigated by recording T_2 -weighted 2D images.⁶ An increase in the sample viscosity with time was found to shorten the T_2 time of the sample.

Copolymerisation of methacrylamide with N,N' -methylene-bisacrylamide in water has also been studied.⁷ The process began upon the addition of ammonium persulfate (initiator) and tetramethylethylenediamine (accelerator). Polymerisation reduces the T_1 time of the signals observed. Two-dimensional NMR images obtained using the NMR signal of water revealed homogeneous gel formation throughout the sample (no polymerisation front was observed).⁷

When preparing epoxy resin based composites, it is of great importance to have a means for monitoring variations of the state of the composite during the cross-linking of polymer chains at elevated temperature.^{8,9} Raising the temperature causes an increase in the T_2 time of the resin; therefore, at temperatures above 55 °C one can obtain NMR images during the cross-linking of resin reinforced with carbon fibres using the signal from the resin protons.⁸ At times of the order of 5 min after heating to 100 °C, the cross-linking degree of the polymer chains is low and the viscosity of the sample is a function of the temperature only. Therefore, the use of corresponding calibration allows the viscosity or temperature distribution to be mapped throughout the sample. Analysis of a set of NMR images acquired at 90 °C revealed that the cross-linking at the periphery of the sample proceeds at a higher rate.

To prepare a composite material, layers of aligned carbon fibres soaked with partially cured polymer were stacked in such a manner that the fibres in each layer have different orientation.⁴ The stack obtained was placed in a mould and hot vulcanised. Before vulcanisation the polymer exhibited a short time T_2 which increased during the heat treatment procedure due to an increase in the polymer mobility. As a result, an NMR signal appeared in the corresponding regions of the 2D NMR image. Further vulcanisation led to a decrease in T_2 and to disappearance of the NMR signal. Such a signal variation in the case of unilateral heating allows one to observe how the vulcanisation process propagates throughout the sample as a single wave.⁴ Rubber vulcanisation has also been studied.^{10,11}

If a chemical reaction is coupled to molecular diffusion, a reaction front moving at a constant velocity can appear in the system. Autocatalytic polymerisation of methacrylic acid¹² is due to the exothermic character of free-radical polymerisation and to thermal decomposition of the initiator (benzoyl peroxide), which is accompanied by generation of free radicals. Polymerisation causes a substantial shortening of the T_2 time for both the polymer and the solvent. The reaction was initiated by adding accelerator (N,N -dimethylaniline) on the surface of the methacrylic acid–benzoyl peroxide mixture. Then, an induction period was observed, where the reaction front moved downward slowly with variable velocity. The duration of the induction period (4–14 min) appeared to be related to the mixing degree of the reagents in the surface layer upon addition of the accelerator. After the induction period the reaction suddenly accelerated, but rapid movement of the reaction front settled into a constant velocity of $\sim 0.6 \text{ cm min}^{-1}$. NMR imaging studies using the ^1H NMR signal of the monomer (and aniline) and companion experiments using the ^{19}F nuclei of 1,4-dibromotetrafluorobenzene (tracer) led to similar results. The front length exceeded 1 mm while its shape remained unchanged with time. An NMR signal with good signal-to-noise ratio was observed in the region immediately behind the reaction front. This indicated the presence of the residual mono-

mer after passage of the reaction front. The experiments were carried out at room temperature; the temperature near the reaction front increased to 176 °C. Attempts at detecting the effect of the magnetic field on the reaction rate failed.¹²

3. Photoinduced and radiation induced polymerisation

Various types of radiation induced polymerisation are widely used in technological processes. Fabrication of various polymeric coatings, use of photosensitive dental materials for stomatology, creation of relief images in lithography can serve as examples of practical implementation of photoinduced polymerisation. Flexible photopolymer printing boards comprise layers of a rubber-like polymer, bifunctional monomer, photoinitiator, dyes and stabilisers. The unexposed regions of the plate are usually removed by solvent. In this case NMR imaging can be used for visualisation of the irradiated region before developing the board.⁴

Photoinduced polymerisation of a resin containing methacrylic monomers has been studied (the process was induced by irradiation with visible light at 470 nm).¹³ This material is used in stomatology. Shrinkage of the material due to polymerisation can be as high as 10%, thus shortening its lifetime and deteriorating properties. The polymerisation kinetics of the resin was studied by spatially resolved NMR imaging techniques. It was found that the polymerisation rate increases with the distance from the irradiated free surface of the sample due to the inhibiting action of dioxygen. As a result, after irradiation the surface layer of the sample (layer thickness 500 μm) was found to contain a large amount of the monomer.

Photoinduced polymerisation of hexamethylene dimethylacrylate using various concentrations of benzyl-dimethyl ketal as photoinitiator has been studied¹⁴ by means of chemical shift selective NMR imaging techniques with different monomer proton groups. As the content of the initiator was 1.5%, the degree of conversion was 20% and a gel-like state was formed; the T_2 times for different proton groups varied in a different manner. Lengthening the exposure time led to a sharper boundary between the polymer and the rest of the sample. An NMR imaging study of photoinduced polymerisation of 1,6-hexanediol dimethacrylate using the same initiator has been reported.¹⁵ In this case NMR images were acquired at different exposure times. Polymerisation began at the centre of the ampoule because of light focussing at the bottom. The polymerisation front was $\sim 50 \mu\text{m}$ long. The residual monomer was observed in the near-wall region. In some instances a rather thick monomer layer (due to oxygen diffusion) was observed adjacent to the free surface through which it was irradiated.^{14,15}

Radiation-induced polymerisation can be used for dosimetry in the case of irradiation with X- or γ -rays, proton beams, *etc.* An important application of MRI is the determination of the spatial distribution of the absorbed dose when using stereotaxic irradiation in radiation therapy of various diseases. Modern experimental methods allow high irradiation doses to be delivered to a small volume of a complex shape. The MRM technique¹ permits spatial (3D) visualisation of the irradiated zones using various gel-based dosimeters.¹⁶ Applications of gels containing the Fricke dosimetric solution is based on the radiation-induced transformation of Fe(II) into Fe(III), which causes reduction of the spin–lattice relaxation time, T_1 , of the solvent (ferrous-based MRI dosimetry, or FeMRI). The amount of newly formed Fe(III) is a linear function of the irradiation dose. The 'null-point' technique, which allows one to follow the movement of the region with the prescribed concentration of the paramagnetic tracer, was used to study the diffusion of Fe^{2+} and Fe^{3+} ions in agarose gel.¹⁷ Due to fast diffusion displacements of the ions the irradiation dose distribution over the sample should be studied within several hours after the irradiation. The sensitivity of the FeMRI technique to irradiation is low. NMR images of the X-ray or proton beam irradiated samples have been obtained and an improved T_1 mapping procedure has been reported.¹⁸

MRI applications of polymer gels, whose properties are similar to those of tissues in living organisms, are based on irradiation-induced polymerisation of a monomer dispersed in the gel (the so-called 'Polymerisation Based Dosimeter Gel Evaluated Using MRI' procedure, or PoMRI). This kind of dosimeter can be based on, *e.g.*, an aqueous gelatin gel with the addition of acrylic comonomers and cross-linking agents. Irradiation causes the generation of free radicals that initiate both polymerisation and cross-linking of the monomer molecules.^{19,20} Analysis of the T_2 maps obtained for irradiated polyacrylamide gels showed that polymerisation is not complete even several weeks after irradiation. Oxygen inhibits polymerisation; however, this was observed only in the near-surface layer due to slow oxygen diffusion. For thoroughly prepared samples the relaxation rates $1/T_1$ and $1/T_2$ appeared to be linear functions of the irradiation dose in the range from 0 to 10 Gy.²⁰ In the non-irradiated gels the T_2 value also decreased with time, which seems to be due to the presence of impurities in freshly prepared samples (radicals capable of initiating polymerisation).¹⁹ For N,N' -bisacrylamide gels the relaxation rate $1/T_2$ is a linear function of the irradiation dose up to saturation levels of 10 to 15 Gy.^{16,21} The T_2 maps obtained for these gels were converted into the spatial irradiation dose maps using the formula

$$\frac{1}{T_2} = 6.0 + 0.48 D,$$

where D is the irradiation dose (in Gy).¹⁶ N -Vinylpyrrolidone-based gels (VIPAR) exhibit lower toxicity; however, they are less sensitive to radiation.²¹

$$\frac{1}{T_2} = \frac{1}{T_{20}} + 0.09 D,$$

where T_{20} is the T_2 time of the gel before irradiation. A linear response was observed up to 32 Gy doses. The spatial distribution of the irradiation dose in these gels has also been studied.

4. The Belousov–Zhabotinsky reaction

A number of publications have been concerned with the NMR imaging studies of 'chemical' (concentration) oscillations and waves observed in the manganese-catalysed oxidation of malonic acid by bromate ion (Fig. 1). The system under study is optically transparent, which makes visual monitoring of various processes difficult. However, there is a linear correlation between the water proton chemical shift and relaxation times and the concentration of the paramagnetic metal ion in the aqueous solution. The reduced state of the manganese ion (Mn^{2+}) is known to affect these parameters more than the oxidised state (Mn^{3+}).²² The spin–spin relaxation time is most sensitive to the change in the oxidation state of manganese. Therefore, usually T_2 -weighted NMR images are used, in which the regions with higher concentrations of Mn^{3+} ions (reaction front or oxidation stage) give a stronger NMR signal compared to the regions with lower concentrations of Mn^{3+} ions. Instability of manganese in the $3+$ state in aqueous solutions can lead to a loss of image contrast; therefore,

Figure 1. Travelling concentration waves in the oxidation of malonic acid in an ampoule 5 mm in diameter filled with glass beads 0.5 mm in diameter.

A spherical wave is created in the bottom region of the sample (see the right side of the NMR image) and then partially annihilated upon collision with the ampoule wall. The remaining part of the wave front continues to propagate through the medium (see the left side of the NMR image). The 2D NMR image was obtained using the axial slice selection technique.

the reaction mixture is doped with orthophosphoric acid ($\sim 1 \text{ mol litre}^{-1}$) to stabilise the Mn^{3+} ion due to the formation of the metal–phosphate complex.²² The formation of more stable chelate complexes in the case of polydentate phosphate ligands causes a substantial increase in the T_2 time of the water protons in the oxidation stage even when much smaller amounts of dopants ($\text{Na}_4\text{P}_2\text{O}_7$ or $\text{Na}_5\text{P}_3\text{O}_{10}$) are used. This offers some advantages.²³ At the same time, the water proton relaxation time T_1 also increases, thus leading to a loss of image contrast or to image inversion.²³ In addition, variation of stability of the metal–ligand complex can cause changes in the period of the concentration oscillations.²³ To prevent gas liberation (*via* bubbling), the experiments are often carried out in tightly closed containers.

When studying the behaviour of trigger waves in the excitable (non-oscillating) B–Z system, agar is added to the solution to form gels and to suppress undesired convective flows in the medium due to an increase in the medium viscosity. 2D NMR images of the spiral waves in pseudo-2D thin gel layers and the 2D cross-sections of spherical waves in a cylindrical ampoule acquired at different instants have been reported.²⁴ This allowed visualisation of wave propagation and collisional annihilation. The advantage of the NMR imaging technique is the possibility of obtaining 3D images of the wave front. In combination with the achievements of modern computer graphics this makes it possible to construct 3D images of complex waves (*e.g.*, a twisted scroll wave) and thus investigate the evolution of the organising filamentary singularities of the wave concentration structures.²⁵

A simple procedure for fast imaging of the wave front propagation has been proposed by Tzalmona *et al.*²⁶ taking cerium-catalysed oxidation of citric acid by potassium bromate as an example. The technique involves 1D slice selective NMR imaging with slice projection on an axis in the slice plane. One-dimensional NMR images are successively acquired at a constant time delay (Fig. 2). By stacking the 1D NMR images one can obtain a 2D image in the displacement–time coordinates, where the regions of highly intense signals form inclined bands, their slopes being a measure of the wave front propagation velocity. If a concentration wave propagates at a constant velocity, the bands look like slant lines. Menzinger *et al.*²⁷ studied chemical waves in the Belousov–Zhabotinsky reaction in a non-viscous solution containing no agar. They found that the ascending portion of the spherically expanding wave becomes unstable and drastically accelerates, being developed in a plume-like cloud. At the same time, the descending portion of the wave travels unperturbed and at a constant velocity. The reason for instability of the ascending wave is an isothermal decrease in the medium density in the region after the oxidation front, resulting in the appearance of convective flows. Simultaneously, subsidiary pacemakers appear in the instability region, emitting new waves.²⁷ The 1D projection

Figure 2. Concentration oscillations and concentration waves in the oxidation of citric acid.

Bright bands correspond to higher concentrations of Ce(III) and dark bands correspond to the oxidised state, Ce(IV). The reaction was conducted in water doped with starch (1%); the 1D projections of the reaction mixture on the axis of an ampoule 5 mm in diameter were obtained without slice selection.

technique was also employed to determine the activation energies for wave front propagation and wave emission by the pacemaker²⁸ and to obtain a dispersion curve that illustrates the interrelation between the wave propagation velocity and the pacemaker activity period.²⁹

Chemical waves in the B–Z system can also be used as an indicator of the fluid motion in the imaging of, *e.g.*, temperature-gradient driven convective flows. NMR imaging experiments using the 1D projection technique (see above) revealed wave-front distortions due to convection in a cylindrical sample which was heated and then allowed to gradually cool inside the probe of the NMR spectrometer.²⁸ An increase in the temperature gradient (Rayleigh number) due to the heating of the sample to higher temperatures led to the onset of the principal and then the lowest excited critical convection modes.

NMR imaging was also used for studying the self-oscillatory B–Z system in which not only trigger, but also phase waves are observed. The latter are not accompanied by mass transfer and represent a purely optical effect, which is due to the phase or frequency difference between the oscillations at different points of space. Kinematic waves (a kind of phase wave) originate from the temperature difference between different points of the sample. The 1D wave projection technique has been successfully employed in the investigations of the wave dynamics in the self-oscillatory B–Z system. Here, kinematic waves arose from frequency gradients in an anisotropically cooling sample.³⁰

An increase in the oscillation phase gradients is always accompanied by an increase in the concentration gradients in the sample. This gradually makes the role of diffusion increasingly important. As a result, conversion occurs of kinematic waves into diffusion-driven ones and the wave propagation velocity no longer decreases, thus reaching a limiting value corresponding to the velocity of chemical waves. A study of the interaction between trigger waves and kinematic waves showed that wave collision patterns can be incorrectly interpreted as a sudden acceleration of trigger waves.²⁶

Armstrong *et al.*³¹ reported an NMR imaging study of kinematic waves in the B–Z reaction catalysed by various metal ions. The technique requires that the effects of the oxidised and reduced states of the catalyst on the NMR parameters of water protons be different. In the case of cerium-catalysed oxidation of malonic acid the proton relaxation times of water in the presence of Ce(III) and Ce(IV) differ insignificantly, so only the 1D projections of the wave front were recorded. When ruthenium ($[\text{Ru}(\text{bipy})_3]^{2+}$, where bipy is bipyridyl) was used to catalyse the same reaction, the relaxation times of water varied over a somewhat wider range compared to the Ce-catalysed reaction and 2D NMR images of waves were also obtained. It should be noted that, in contrast to manganese and cerium, shorter relaxation times for the Ru-catalysed reaction were obtained for the oxidised state, Ru(III), rather than the reduced state, Ru(II). Therefore, the best contrast for the reaction with ruthenium should be expected for T_1 -weighted images. Attempts at NMR imaging a ferroin-catalysed B–Z reaction (ferroin is $[\text{Fe}(\text{phen})_3]^{2+}$, where phen is phenanthroline) failed despite considerably different effects of ferroin and ferriin ($[\text{Fe}(\text{phen})_3]^{3+}$) on the T_2 time of water. Armstrong *et al.*³¹ suggested that in this case the relaxation times are mainly affected by the Fe^{3+} ions that accumulate in the course of the reaction due to the decomposition of ferroin and ferriin; however, this does not correspond to actual wave dynamics of the medium.

5. Other reactions

Propagation of a single reaction front can also be observed in non-oscillating chemical systems, *e.g.*, in those characterised by rather large initial concentration gradients. The use of gels with high content of water allows one to suppress convection and, at the same time, permits experimental procedures typical of liquid-phase NMR studies to be employed for imaging using the proton signal of water. In particular, diffusion-controlled redox processes were studied using a hollow, thick-walled cylinder made of

polyacrylamide gel saturated with aqueous $\text{Fe}_2(\text{SO}_4)_3$ solution at pH 1.³² Filling the cylinder cavity with aqueous sodium bromate solution (pH 1) causes diffusion of the reagent into the cylinder walls and, as a consequence, oxidation of Fe^{2+} to Fe^{3+} . In the presence of Fe^{3+} ions the T_1 time of the water protons is shortened to a much greater extent compared to the Fe^{2+} ions. Because of this, T_1 -weighted NMR images obtained at different stages of the process exhibit a noticeable increase in the amplitude of the signal of water present in the cylinder walls as a result of propagation of the reaction front towards the outer surface of the cylinder.

In another series of experiments Fe^{3+} was reduced to Fe^{2+} with an aqueous ascorbic acid solution (pH 1), which led to a decrease in the signal amplitude. An identical cylinder made of polyacrylamide gel was used to obtain the 2D NMR image of the copper ion release process occurring upon variation of the pH value of the medium.³³ First, the material the cylinder was made of was doped with a chelate complex of copper with ethylenediaminetetraacetic acid. Then the cavity of the cylinder was filled with a sulfuric acid solution (pH 1.2). Proton diffusion into the bulk of the gel caused protonation of the ligand present inside the walls of the cylinder and shifted the complexation equilibrium towards the formation of free copper ions. In the presence of a chelate copper complex the T_1 time of water is shortened to a much lesser extent than in the presence of free Cu^{2+} ion due to poor contact of copper and the hydration shell. Therefore, the formation of free Cu^{2+} ions led to substantial enhancement of the NMR signal of water in the T_1 -weighted images. Analysis of a set of 1D profiles acquired during the propagation of the reaction front along the axis of the continuous cylinder showed that the displacement of the reaction front is proportional to the square root of the time, which is typical of a diffusion process.

Introduction of calcium ions into aqueous sodium alginate solution³⁴ causes cross-linking of the alginic acid molecules by calcium ions, resulting in the formation of a rigid gel. As a consequence, the T_2 time of the water molecules is shortened from 0.8 to 0.1 s. In the experiments sodium alginate and the solution of calcium ions were separated by a dialysis membrane. The process was studied with planar and cylindrical geometries at different concentrations of the reagents by acquiring the 1D and 2D NMR images. It was found that the reaction front moves in proportion to $t^{1/2}$ (t is time) and the diffusion coefficient of calcium ions depends on the concentration of calcium (due to different pore sizes and electrostatic interactions in the gel).

Gelation can be reversed by adding an aqueous solution of a sodium salt of ethylenediaminetetraacetic acid, since the acid favours removal of calcium owing to the formation of chelate complexes.³⁵ Depolymerisation-induced changes in the molecular mobility cause substantial variations of the spin–lattice relaxation times of the water molecules ($T_{1\text{sat}}$), measured at external saturation of the nuclear magnetic resonances of gel macromolecules, as a result of magnetisation transfer. This served as the basis for monitoring the movement of the sol/gel interface along the axis of a cylindrical sample during gel destruction. A combination of a 1D ‘null-point’ technique (here, the NMR signal of water molecules with prescribed time T_1 becomes zero due to incomplete magnetisation recovery after inversion) with selective saturation of the resonance signal from macromolecules was employed. The authors suggested that the process is controlled by diffusion transport of the acid towards the sol/gel interface. This technique allows one to selectively follow the movement of the region with any pre-selected gel concentration, since the $T_{1\text{sat}}$ time depends on the local concentration of gel. An increase in the initial gel concentration causes the movement of the sol/gel interface to slow down.³⁵

Studies of reactions in the solid phase require the use of solid-state NMR spectroscopy techniques. An anisotropic acid–base reaction of substituted benzoic acid with ammonia gas was investigated using a multipulse line-narrowing technique that allowed elimination of the dipolar coupling and chemical shift effects to second order.³⁶ The authors expected that

2D T_1 -weighted images of the molecular single crystal will correspond to very slow conversion of 4-bromobenzoic acid into ammonium 4-bromobenzoate on the (100) crystal face, where the carboxylic group is less accessible compared to other faces. However, the experiments revealed only weak anisotropy; this was rationalised by the poor quality of the crystal. In another experiment ammonium gas was blown over a thick layer of powdered toluic acid to give ammonium toluate. Using a series of 1D MRI projections acquired at different times, the authors showed that deeper layers of the acid sample begin to react later and at a lower rate than do the surface layers. Both experiments were carried out with the proton T_1 time governing the image contrast, since the T_1 time of the initial acid was much longer than the T_1 time of the reaction products.

A feature of some photoinduced radical reactions in solutions is the effect of chemically induced dynamic nuclear polarisation (CIDNP), or the nonequilibrium population of nuclear spin sublevels in the reaction products due to the spin dynamics in the short-lived radical pairs.^{37,38} As a result, the NMR signal of the reaction products can be substantially enhanced and even change its sign in the case of population inversion. Spatially resolved studies of this effect observed during the UV photolysis of *tert*-butyl methyl ketone in CCl_4 revealed spatially inhomogeneous variations of the signal amplitude in the sample due to inhomogeneous light absorption.³⁹ Intense irradiation of the sample initiated mixing of the solution. A possible reason is convection owing to heating of the sample.

Hydrogenation of unsaturated compounds with dihydrogen with nonequilibrium ratio of molecules with different total nuclear spin (ortho- and para-hydrogen) can cause dramatic enhancement of the NMR signal of the reaction product.^{40,41} Variation of the magnetic field can be used for polarisation transfer from the ^1H to the ^{13}C nuclei in the reaction product.⁴² In particular, this allowed an angiogram of a living rat to be generated in 0.9 s after introducing the reaction product in the caudal vein.⁴³ The experiments were carried out at the natural abundance level of the ^{13}C isotope (1.1%) and the NMR signal enhancement due to the polarisation of the ^{13}C nuclei was 10^4 .

Figure 3 presents the 2D images acquired during catalytic decomposition of hydrogen peroxide on a cylindrical catalyst granule ($\text{Pt}/\text{Al}_2\text{O}_3$) 3.6 mm in diameter. Figure 4 illustrates the capabilities of NMR imaging for studying the liquid phase distribution inside a catalyst granule during the evaporation of

Figure 3. A 2D NMR image of a cylindrical ampoule filled with a H_2O_2 solution. A catalyst granule ($\text{Pt}/\gamma\text{-Al}_2\text{O}_3$) is located at the centre of the ampoule.

Clearly seen are the gas bubbles formed on the ampoule walls and on the surface of the catalyst granule. A bright circle surrounding the catalyst granule corresponds to the domain with a strong NMR signal due to a decrease in the T_1 time in the near-surface region.

Figure 4. Liquid phase distribution inside a $\text{Pt}/\gamma\text{-Al}_2\text{O}_3$ granule during the evaporation of AMS accompanied by its vapour-phase hydrogenation.

The supply of liquid AMS increased from 0 to 0.71 mg s^{-1} . The temperature of the granule/ $^\circ\text{C}$: 109 (1, 2), 141 (3), 167 (4), 148 (5), 113 (6), 100 (7) and 64 (8). Brighter regions correspond to a higher content of liquid. The formation of an AMS droplet under the catalyst granule can be seen in the image (8).

α -methylstyrene (AMS) accompanied by its catalytic hydrogenation.[†]

III. Magnetic resonance thermometry

Variable-temperature NMR studies allow one to obtain a much greater body of information; however, this requires reliable methods for measuring the temperature of samples. In some experiments, this can be done using a thermocouple. However, this technique can introduce errors into the results of the NMR experiments. Pulsed field gradients induce eddy currents, thus increasing NMR signal distortion. In addition, variation of the geometry of the object under study in the presence of a thermocouple affects the temperature field distribution over the entire sample. Finally, experiments in nonzero magnetic fields can make the results of temperature measurements less reliable.

The NMR technique provides a means for using the molecules of the object under study as thermal sensors to measure the temperature inside the object. There is a set of reference samples for which the temperature dependencies of the chemical shift, linewidths or their splittings in the NMR spectra have been studied in detail. In particular, methanol and ethylene glycol serve as references in the case of ^1H NMR spectroscopy; these compounds are used in different temperature ranges.⁴⁴

A new era in the development of magnetic resonance thermometry is associated with the possibility of using the NMR imaging technique for constructing the spatial temperature distribution maps, which is of particular interest for biology and medicine. For instance, low-temperature hyperthermia involves heat treatment of tissues at elevated temperatures ($43\text{--}45^\circ\text{C}$) during tens of minutes either to kill malignant cells or to enhance their susceptibility to cytotoxic agents and/or irradiation. To induce necrosis of tissues due to protein denaturation after short-term heat treatment, even higher temperatures ($50\text{--}80^\circ\text{C}$) are used.⁴⁵ At 43°C , 100% necrosis occurs in several tens of minutes.^{45,46} On further increases in temperature the time taken to necrotise tissues nearly halves as the temperature increases by 1°C .

and reaches ~ 1 s at 57°C .⁴⁵ NMR imaging allows real-time assessment of temperature-induced variations in tissues in the course of thermal therapy procedures, which can be used for feedback creation in automated systems.⁴⁷ MRI also allows visualisation of changes in tissues after the completion of the therapeutical procedure. In addition, by using open-design devices one can also monitor the position of the applicator during the insertion in tissues.⁴⁸

NMR-Assisted temperature measurements are based on the fact that such parameters as the molecular diffusivity (D), nuclear magnetisation (signal amplitude), spin relaxation times and the resonance frequency of a nucleus (chemical shift) are sensitive to the local temperature. The characteristic temperature sensitivity of these parameters for tissues in living organisms and corresponding phantom objects in the physiological temperature range are of the order of $0.8\% - 2\% (\text{C}^\circ)^{-1}$ for T_1 , $2.4\% (\text{C}^\circ)^{-1}$ for D , -0.007 to -0.01 ppm $(\text{C}^\circ)^{-1}$ for the chemical shift of water molecules⁴⁹ and ~ 0.01 ppm $(\text{C}^\circ)^{-1}$ for both the ^{19}F nuclei in fluorinated hydrocarbons and ^2D nuclei (see Refs 50 and 51). The ^{13}C and ^{59}Co nuclei are also used.⁵¹ For Co(III) compounds the temperature coefficient of the chemical shift is $1.5 - 3$ ppm $(\text{C}^\circ)^{-1}$. Similarly to other types of experiments, the main problem of these studies is to select the temperature-induced contribution to overall variations of the parameters investigated. Therefore, methods based on variation of the NMR resonance frequency, which is less sensitive to side processes, are usually employed.

Many experiments have been carried out using the so-called proton resonance frequency (PRF) technique based on the resonance frequency variation when recording the ^1H NMR spectra of, e.g., water. Temperature-induced variations of the water proton resonance frequency are mainly due to variation of the shielding constant caused by the cleavage, stretch or bending of hydrogen bonds.⁵² There is a linear correlation between the chemical shift of water and the temperature at least up to 80°C . The advantage of the PRF technique is a constant value of the corresponding temperature coefficient for many samples, which was demonstrated in the studies of phantom objects and various types of tissues *in vivo*⁵² and *ex vivo*.⁴⁵ Low sensitivity can be compensated by mapping the phase of the magnetisation instead of acquiring the resonance frequency variations.⁵³⁻⁵⁶ To correct the phase of the signal (in particular, to include the magnetic field drift), the object under study is often surrounded by reference samples that are kept at room temperature.⁵⁷⁻⁵⁹ If a number of signals with comparable amplitudes is observed (in, e.g., water-fat systems), the chemical shift selective phase mapping allows one to avoid phase measurement errors for the total NMR signal and provides an internally referenced measurement tool (to this end, the signal of, e.g., fat can be used).⁶⁰ In some instances acquisition of a complete NMR spectrum is followed by numerical simulation to exactly determine the resonance frequencies.^{61,62}

In practice, the situation is complicated by the fact that the local magnetic field depends not only on the chemical shift, but also on the magnetic susceptibility of the sample, which in turn is a function of temperature. If temperature-induced variations of the volume magnetic susceptibility are large, variation of the local resonance frequency is not proportional to the local temperature and is determined by the temperature distribution over the entire sample.⁶³ In this case the heat source geometry and orientation in the magnetic field are of great importance.⁶⁴ In contrast to water, typical of fat is a relatively small temperature-induced variation of the resonance frequency, which is mainly due to local variations of the diamagnetic susceptibility rather than chemical shift.⁵³ On the one hand, this hampers temperature measurements in fatty tissues,⁵⁸ but, on the other hand, allows the fat tissue signal to be used as a reference,^{52,60,61} which can be of value in measuring the absolute temperature. However, it should be noted that magnetic susceptibility variations in fatty tissues can distort the local fields and introduce errors when measuring temperature in neighbouring muscle tissue.⁶³ For this reason one should also avoid the use

of paramagnetic substances (conventional water dopants for thermostating the object under study).

Other sources of errors in tissue temperature measurements can be:^{52,58,61,65} low signal-to-noise ratio, limited spectral resolution, inhomogeneity of the magnetic field, variation of the magnetic field due to eddy current magnetic field, field drift, variation of tissue perfusion and oxygen concentration in blood and temperature-induced variation of the magnetic susceptibility of tissues. Position shift, as well as a change in the size or geometry of the object under study (e.g., muscles) can introduce rather large errors into the results of temperature measurements.^{52,66-68} The drawbacks of the technique is low spatial and temperature resolution.⁵² Despite this fact the temperature map can be obtained using the proton phase shift imaging technique even on an open-configuration, low-field (0.2 T) scanner with a rather large field drift during the experiment.⁶⁹ The error of measurements can be less than 0.5°C for temperature variation by 10°C .⁵²

Stollberger *et al.*⁷⁰ reported separate measurements of the temperature coefficients of the diamagnetic susceptibility and chemical shift for water, gel, brain tissue and fat tissue. Both numerical simulation and test experiments showed that the contribution of temperature-dependent magnetic susceptibility to the variation of the NMR resonance frequency depends on the orientation of the laser applicator and on the distance from the applicator and can be large, especially for tissues with high fat content. In contrast to other authors, experiments with a human calf muscle revealed no effects due to variation of the diamagnetic susceptibility of fat.⁵⁷ At the same time, a complex response of living tissues to temperature variation was pointed out. The NMR signal of water in a living organism can be affected by both blood flow and magnetic susceptibility variations due to the change in the concentration of paramagnetic substances, e.g., the oxy/deoxy state ratio of hemoglobin and myoglobin in blood. As a result, the temperature dependencies of the NMR signal parameters have the shape of hysteresis curves.⁵⁷

De Poorter⁶³ evaluated the relative contributions of the temperature dependencies of the chemical shift and magnetic susceptibility to the temperature dependence of the proton resonance frequency in agarose gel and in porcine muscle tissue and fat tissue. In the experiments cylindrical gel samples were oriented both parallel and perpendicular to the magnetic field direction. The relative temperature-induced change in the magnetic susceptibility of fat tissue was shown to be close to the relative variation of the chemical shifts in muscle tissue and agarose gel. The temperature coefficients of the chemical shift in fat tissue and of the magnetic susceptibility in muscle tissue and gel appeared to be very small.

Temperature distribution studies during the heating of a rat hindleg⁵⁸ and cooling of a human leg⁶¹ ($5 - 37^\circ\text{C}$) using a water jacket have been reported. It was found that the temperature decreases to a greater extent in the regions with a thinner layer of fat tissue. The results obtained suggested that the cooling-heating cycle was accompanied by muscle deformation and/or muscle position shift.⁵⁸ Spatial temperature distributions were also monitored in the course of interstitial magnetic resonance-controlled laser-induced thermal therapy of head and neck tumours,⁷¹ human brain tumours⁵⁴ and during microwave-induced interstitial heating and thermal lesions in rabbit brain *in vivo*.⁵⁵ The methods employed were often tested on phantom objects (e.g., agarose gel⁵⁸); however, calibration of the water proton chemical shift for practical thermal surgery was carried out *in vivo* for ultrasound-heated rabbit tissues.⁷²

Fast MRI techniques allow mapping the temperature distribution in $1 - 2$ s.⁵⁶ Two-dimensional temperature maps for water-heated agarose gel were obtained in fractions of a second with an accuracy of 0.2°C .⁷³ The temperature distribution over the sample was calculated by converting the phase change relative to the initial NMR image acquired at the known temperature using a calibration curve.

NMR spectra exhibiting several signals with different chemical shifts allow internal-referenced (or self-referenced) temperature determination by measuring the chemical shift differences between two particular NMR lines.⁶² This approach was illustrated by the experiment with a double cylinder filled with ethylene glycol. The inner part of the cylinder was microwave heated. The local temperature in the sample was determined from the chemical shift difference between the OH and CH₂ groups of ethylene glycol molecules (the corresponding temperature dependencies are well known). A feature of an *in vitro* study of a porcine liver sample placed in a vessel filled with continuously heated water was the use of the effect of temperature on the chemical shift difference between the proton signals of lipids (polymethylene chain, $-\text{CH}_2-$) in water and in liver; the time for acquiring 2D temperature maps varied from 10 s to 3 min. The authors pointed out that, in contrast to other methods involving voxel-by-voxel comparison of two NMR images, their self-referenced method is less sensitive to translational motion of the sample in the course of the experiments.⁶²

Nott *et al.*⁵³ reported on mapping the temperature distributions induced in food by heating to 120 °C and even higher temperatures. To confirm that the changes in the signal phase were due to the variations of the temperature of the sample, additional experiments were carried out with a vessel containing pre-heated homogeneous gelated suspension of starch which was allowed to cool. The temperature distribution maps obtained revealed clearly seen radial temperature gradients in the vessel. In the experiment with less viscous agar gel the temperature distribution map was significantly distorted by stochastic convection effects. Food sauce was chosen as an example of an heterogeneous medium. The chemical shift was shown to be insensitive to structural inhomogeneities of the sample. The experiments provided data on both temperature distribution over the sample and structural inhomogeneity, which allows suggestions about interrelations between heat transfer processes and the structure of the product. The temperature dependencies of the spin relaxation times and diffusion coefficients have also been reported.⁵³

The possibility of acquiring separate NMR images of the volumes of water kept at different temperatures using the chemical shift difference between water protons was demonstrated taking two ampoules filled with water heated to 32 and 75 °C as an example.⁷⁴ The same study also reported separate NMR images of three coaxial cylinders containing an inorganic phosphate solution with different pH values (12, 7 and 3) obtained with the ³¹P NMR signal detection.

The chemical shifts of atomic nuclei in paramagnetic complexes are usually much more temperature sensitive compared to the chemical shifts of nuclei in diamagnetic compounds. In addition, the former substantially differ from the latter in magnitude, which allows one to avoid the overlap of lines in the NMR spectrum. For instance, the temperature sensitivity of the chemical shift of ¹H and ³¹P nuclei in a thulium complex with a macrocyclic cycloaza ligand is 0.89 ppm (°C)⁻¹ for the former and 2.18 ppm (°C)⁻¹ for the latter nucleus (two orders of magnitude higher than for water protons).⁷⁵ A method of simultaneous measurements of the temperature and the pH value of the medium using this paramagnetic thulium complex has been proposed.⁷⁶ This approach was practically implemented for the measurement of the temperature within the sample when thermostating the NMR probe or applying heteronuclear decoupling and was based on measuring the resonance frequency difference between two lines in the ¹H NMR spectrum of the water-soluble thulium complex.⁷⁷ In principle, the technique allows temperature variations of the order of 0.01 °C to be measured.

The advantage of a paramagnetic praseodymium complex is the large proton chemical shift (-24.1 ppm) relative to the conventional values.⁷⁸ The temperature sensitivity of the chemical shift, -0.131 ppm (°C)⁻¹, is independent of both the pH value of the medium ($5.6 \leq \text{pH} \leq 9.6$) and the concentration of the com-

plex. The possibility of using the complex was demonstrated in the *in vivo* experiments with rat liver. Yet another advantage of paramagnetic complexes is the short T_1 times of the magnetic nuclei. Aime *et al.*⁷⁹ developed a paramagnetic complex Yb-DOTMA [DOTMA is ($\alpha, \alpha', \alpha'', \alpha'''$)-tetramethyl-1,4,7,10-tetraazacyclodecane-1,4,7,10-tetraacetic acid] and studied its behaviour in human blood serum. They found that the chemical shift of the most intense line from four Me groups is -14.2 ppm, the temperature coefficient is 0.04 ppm (°C)⁻¹ and that the chemical shift difference between a prescribed pair of spectral lines is even more temperature sensitive [-0.42 ppm (°C)⁻¹].

Another method of temperature measurements is based on the temperature dependence of the spin relaxation time T_1 . For many types of tissues the T_1 time of water protons is a nearly linear function of the temperature in the range between 20 and 50 °C. However, the temperature coefficients of T_1 for different tissues are also different and therefore a preliminary calibration and knowledge of the chemical composition of tissues to be studied are required.⁶⁵ In addition, living organisms respond to temperature variations in a complex manner, so that the relation between T_1 and the temperature can be nonlinear.⁸⁰ Nevertheless, it was found that the temperature coefficient of the T_1 time is 13 ms (°C)⁻¹ ($T_1 \approx 1$ s) for sheep mammary glands and 3.2 ms (°C)⁻¹ ($T_1 \approx 360$ ms) for fatty tissues.⁸¹

A temperature distribution study using a fast T_1 mapping technique has been carried out with an agar-gel cylinder in which a radial temperature gradient was created.⁸² A calibration curve for converting the local T_1 values into temperature was obtained.

Signal amplitude in the T_1 -weighted image can also serve as a measure of temperature distribution over the sample. In this case one should take into account the fact that a decrease in the signal amplitude with an increase in temperature is a consequence of both the increase in T_1 and the decrease in the equilibrium magnetisation. To construct the temperature map, one should acquire the NMR image of the sample at ambient temperature and have a calibration curve, $T_1(T)$, for a particular type of tissue or use known data for this type of tissues. This method was used for construction of the temperature map in muscle tissue heated by placing the tissue in contact with a heated glass tube or by deposition of focussed ultrasound energy.⁸³ In the latter case the focal spot was inside the tissue, which was clearly seen in the NMR images acquired (region with very low signal intensity). All experiments were carried out at 20–45 °C. The difference between the MRI data and the temperature values measured using fibre-optic probes was at most 0.6 °C. The technique was also implemented in studies of the temperature distribution in gel or bovine muscle tissue *in vitro* or in rabbit muscle tissue *in vivo* during focussed ultrasound therapy treatment.^{84,85} The focal spot size and the thermal diffusivity were determined.⁸⁵ It was shown that temperature variation in the axial direction was asymmetric and that the near-field zone was heated to higher temperatures than the far-field zone. The near-field zone also cooled slower than the focal spot, which can lead to overheating upon repetition of ultrasound pulses.

Inversion–recovery T_1 measurements for a flowing fluid can be complicated since flow can cause additional changes in the signal amplitude.⁸⁶ It was proposed to create an inverted signal in a set of slices separated by slices with equilibrium nuclear magnetisation rather than in the entire sample. In this case the signal amplitude in the non-inverted regions in the immediate vicinity of the slice with inverted magnetisation can be used for normalising the signal amplitude. This approach is similar to the tagging technique employed in the studies of fluid flows;² single experiments additionally allow one to obtain information on the character of the flow. The method was implemented using a model comprising two tubes, a tube through which water was pumped ($T = 40.2$ °C at the inlet) and an external jacket through which a fluorinated cooling agent was pumped in a parallel direction ($T = 9.8$ °C). A 2D temperature distribution map was obtained. The accuracy of measurements was 15% of the temper-

ature difference between the inlet and outlet (which was equal to 15 °C).

The T_1 time of solid *cis*-polybutadiene at room temperature is 16 ms. This allows observation of the NMR signal of the polymer.⁸⁷ Based on the results of T_1 measurements, a temperature map was obtained for a *cis*-polybutadiene block through which cold (10 °C) and hot (70 °C) water was pumped using two tubes. The temperature coefficient of T_1 was $\sim 12 \text{ ms } (^\circ\text{C})^{-1}$ at the T_1 times ranging from 0.2 to 0.8 s. The maps obtained exhibited reasonable agreement with the results of calculations.

Local temperatures can also be determined from the molecular diffusion coefficients. Temperature variations upon heating of a polyacrylamide gel with an RF hyperthermia applicator were monitored using the 2D map of the diffusion coefficient of water molecules.⁸⁸ The local temperatures determined from the images averaged over a volume of 1 cm³ were found to be in good agreement with those recorded using implanted fibre-optic probes or a thermocouple (the difference was 0.2 °C). Temperature-related changes in the NMR signal intensity of agarose gel and rabbit brain tissue *in vivo* irradiated by a Nd:YAG laser were visualised by acquiring diffusion-weighted 2D images in 150 ms.⁸⁹ This method was also employed for *in vivo* temperature measurements of a human calf muscle.⁹⁰ The authors pointed out that the regional blood volume decreased by a factor of 3.5 on cooling and increased by a factor of 2.7 on heating as the temperature varied by several degrees.

A number of comparative studies of the above-mentioned temperature measuring techniques has been reported. Bertsch *et al.*⁶⁵ implemented and evaluated two methods based on the chemical shift and T_1 relaxation measurements taking external heating of samples in the range 22–50 °C using a water jacket and local (focal) laser heating in the range 22–35 °C as examples. MRI data were then compared with the results of fibre-optic temperature readings. The chemical shift method is usually more convenient than T_1 relaxation measurements for constructing more accurate 2D temperature distribution maps in shorter times. In agarose gel, the error was 0.6 °C; however, for more heterogeneous samples the error increased to 1–3 °C, especially in the presence of fat. In the latter case, the T_1 relaxation method gave better results. Cline *et al.*⁹¹ reported construction of temperature maps for heating of tissues *via* focussed deposition of ultrasound energy using simultaneous information on the chemical shift and T_1 variations (the error of measurements was 0.7 °C).

Comparison of the methods based on the chemical shift and water diffusion coefficient measurements revealed⁵⁹ higher accuracy of the former (the root-mean-square deviation was 0.1–0.15 °C) in the case of short-term measurements (measuring time less than 1 h) with inclusion of magnetic field drift correction (to this end, additional reference samples kept at a constant temperature in the course of the experiment were placed around the sample under study).

The sensitivity and other characteristics of the three above-mentioned methods have also been compared.^{49,53} Experiments were carried out with agarose gel in the temperature range 35–45 °C. It was shown that only two methods, namely, those based on the water proton chemical shift and T_1 relaxation measurements, permit construction of the temperature distribution map with an accuracy better than 1 °C at 15 s acquisition time, the former being more accurate than the latter.⁴⁹ Model calculations for the three methods have been reported.⁶⁷ The necessity of taking into account tissue perfusion variation and blood flow effects was pointed out.

Other parameters of the NMR signal can also be used for temperature measurements. For instance, the 1D temperature profile along the length of the NMR ampoule thermostatted by flowing air was constructed using variation of the ¹H NMR linewidth of dibromomethane dissolved in a nematic thermotropic liquid crystal as a 'thermometer'.⁹² It was shown that placing the NMR ampoule with the sample in a static bath

(perfluorinated oil of high heat capacity) causes no decrease in the longitudinal temperature gradient but makes it more uniform and, probably, eliminates transversal temperature gradients. The dipole and quadrupole splittings in the NMR spectra of molecules dissolved in nematic liquid crystals are also temperature sensitive.^{93,94} A 5% benzene solution in a nematic liquid crystal was used for temperature measurements in the range 290–330 K.⁹³ The frequency difference between the outermost spectral components varied from 7300 to 5300 Hz. The corresponding temperature coefficient increased from 52.5 Hz (K)^{−1} at 296 K to 111 Hz (K)^{−1} at 330 K. The linewidth can serve as a measure of the temperature field inhomogeneity within the sample.

The operating temperatures of cryosurgery can be as low as −180 °C. Obtaining information on the temperature distributions in frozen tissues using NMR spectroscopy seems to be highly improbable. Nevertheless, NMR imaging can be used for determining the cryoprobe position upon introduction into tissues as well as the position and displacement of the phase transition boundaries.⁹⁵ This permits assessment of the temperature distribution based on solution of the equations derived from inclusion of thermal conductivity, metabolism and blood flow effects.

MRI also allows imaging of frozen tissues during and after defrosting.⁹⁶

In conclusion, NMR spectroscopy of various nuclei is used in measuring low and ultralow temperatures.^{97,98}

IV. Magnetic resonance current density imaging

NMR imaging can be used for visualisation of static and radio-frequency magnetic fields produced within the sample by external sources.¹ In contrast to this, current density imaging (CDI) technique allows visualisation of local magnetic fields created within a sample by an electric current flowing through the sample. This permits calculations of the spatial current density distribution over the sample. It should be emphasised that, similarly to other experiments considered in this review, the CDI method is based on acquisition of NMR signals from certain types of atomic nuclei. Therefore, the electric current density can be determined only in those regions of the sample which produce observable NMR signals.

If a direct current flows through a sample, the phase of the precessing transverse magnetisation varies in proportion to the projection of the current-induced local magnetic field on the direction of magnet's field. Experiments are carried out using direct current pulses synchronised with the NMR pulse sequences.^{99,100} Generally, measurements of the three mutually perpendicular components of the local magnetic field require repetition of the experiments at three different orientations of the sample. However, usually it is sufficient to construct two-dimensional cross-sections of the spatial current density distribution maps in the plane perpendicular to the direction of the electric current flowing through the sample. To date, the sensitivity of corresponding experimental techniques, optimum current pulse duration and amplitudes^{99,100} and possible artifacts^{100,101} have been studied. Model experiments^{99,100,102} with a cylinder filled with aqueous NaCl solution confirmed theoretical conclusions. More rigorous tests of experimental methods involved measurements of the three spatial components of the electric current density around a spherical volume of the solution placed at the centre of the cylinder and encapsulated in an insulating sphere.¹⁰¹ The results obtained were in good agreement with the MRI data and current density calculations. The measured magnetic field amplitudes obeyed Maxwell's equations. The distribution of direct current flowing through plant stem fragments (*Pelargonium zonale*, *Rosa arvensis*) pre-soaked in a 10% saline solution in order to enhance the conductivity has been studied.⁹⁹

Electric current through a fragment of a hen thighbone immersed in physiological saline containing Gd–DTPA (DTPA is diethylenetriaminepentaacetic acid) has been studied in order to study osteoporosis and to evaluate the feasibility of electrical

stimulation of bone tissue growth to recover damaged regions in the case of bone fracture.¹⁰³ Changes in the current density upon artificial demineralisation or mechanical damage were visualised. The magnitude and spatial distribution of the current density are of great importance for electrotherapy and electrochemotherapy of tumours. Mice tumours and the effects of electrode geometry on the electric current distribution within the tumours have been studied.¹⁰⁴ Joy *et al.*¹⁰² detected a change in the signal phase in the NMR image of the cross-section of a human forearm (one of the authors of the study¹⁰² volunteered) in the experiments with application of a 2 mA electric current (pulse duration was 40 ms) flowing from the elbow towards the wrist.

Yet another possible application of the CDI technique is the investigation of chemical reactions and other physicochemical processes which are accompanied by changes in the electrical conductivity due to changes in the local concentration of ions (e.g., dissolution of a NaCl crystal in agar gel¹⁰⁵). The current density maps obtained revealed an increase in the concentration of mobile ions in gel followed by diffusion-induced redistribution of the ions during the dissolution of the crystal. The NMR images allowed changes in the size of the crystal to be monitored, which is NMR silent in contrast to the surrounding gel and looks at the region with very high noise level. The current density imaging technique was also employed to study the formation and subsequent dissolution of calcium carbonate.¹⁰⁵ Diffusion of carbon dioxide through a membrane into the bulk of agar gel doped with a saturated calcium hydroxide solution resulted in insoluble calcium carbonate. As a result, the conductivity of the sample reduced due to a decrease in the concentration of calcium ions and hydroxide ions. The dynamics of gas diffusion into the gel bulk was monitored by inhomogeneity of the conductivity within the sample. Further treatment of the gel with gaseous hydrogen chloride, which reacted with calcium carbonate to give soluble calcium chloride, led to recovery of gel conductivity.

Alternating currents flowing through samples at the Larmor frequency are studied by the RF-CDI method.^{106, 107} The RF field component with circular polarisation in the plane perpendicular to the external magnetic field affects the magnetisation analogously to the RF field of the spectrometer. The corresponding pulse sequence includes the alternating current pulse coherent to other RF pulses. Usually, the proton decoupling channel is used in the experiments with ¹H nuclei. Under particular conditions (e.g., in the experiments with cylindrical geometry) all the necessary components of the current-induced RF field can be determined at a single orientation of the sample. Further data processing allows mapping not only of the alternating current density, but also of the current phase which depends, in particular, on the relative contributions of the conduction and displacement currents. An RF-CDI study of a plastic cylinder filled with CuSO₄-doped aqueous NaCl solution has been reported.¹⁰⁶ Unambiguous determination of the matrix describing the rotation of the magnetisation vector during the current pulse requires a series of experiments at different initial orientations of the magnetisation vector (this extends the measuring time).

Similar to the above-mentioned method of mapping direct current density distribution is the rotating frame RF-CDI approach proposed to study alternating current density distributions.¹⁰⁸ In this case the current pulse is applied simultaneously with the RF pulse created by the transmitter coil. If the coil field amplitude is sufficiently large, only the projection of the current-induced field on the direction of the RF field of the spectrometer contributes largely to the nutation of the magnetisation vector. Scott *et al.*¹⁰⁸ reported the analysis of the problems concerning the finite amplitude and inhomogeneity of the RF field of the spectrometer as well as artifacts and of the sensitivity analysis. Trials have been performed using a three-compartment cylindrical model object containing an aqueous NaCl solution doped with CuSO₄ (mainly the conduction current was detected), a CuSO₄ solution (detection of the displacement current) and a mineral oil (no current was detected). In addition, the spatial distribution of

the current density and phase in the cross-section of a rat body *ex vivo* was obtained and the feasibility of the imaging procedure with tissue-dependent contrast (due to the electrical properties of biological tissues) was demonstrated. The experiments were carried out at 85.6 MHz.^{106, 108} It was pointed out that the technique can also be useful for the determination of the absorbed dose rate in the case of RF pyrotherapy and NMR imaging. The RF-CDI method was also employed in studies of the dynamics of changes in the brain conductivity of a living rat upon a decrease in the membrane potential due to the introduction of kainate into a lateral ventricle of the brain.¹⁰⁹ An increase in the alternating current density at a frequency of 100 MHz was mainly observed in the hippocampal area. Kainate affects the central nervous system inducing epilepsy; therefore the results of these experiments demonstrate the feasibility of the technique for studies of epileptic attacks and the action of antiepileptic pharmaceuticals.

Both CDI and RF-CDI investigations were mostly carried out at current densities ranging from 25 to 2500 A m⁻², however, theoretical estimates¹⁰⁰ suggest the possibility of measuring current densities of the order of 0.1 A m⁻².

Electric current can also be induced by the piezoeffect intrinsic in various animal and plant tissues and by neuronal firing. Taking a model sample (isolated copper conductor immersed in an aqueous NaCl solution doped with copper sulfate) as an example, the feasibility of detecting phase changes of the proton NMR signal images was demonstrated.¹¹⁰ The phase change detected corresponded to a change in the magnetic field by a value of 1.7 nT, which is equivalent to simultaneous firing of nearly a million neurons.

Finally, mention should be made that the magnetic field of electric current can be measured not only in the laboratory frame, but also in a moving frame of reference if the NMR signal is detected using the nuclei of the ions creating the electric current through the sample.¹¹¹

V. NMR imaging of gases

1. General remarks

The sensitivity and resolution of the MRI techniques employed in studies of gases is usually much lower as compared to fluids, since the gas density is three orders of magnitude lower than the density of water under normal conditions. In addition, for many gases efficient spin-rotational interactions cause the relaxation time T_2 ($T_2 \approx T_1$) to fall in the millisecond range¹¹² and be shorter than the minimum time needed to create the echo signal, which leads to a considerable loss of signal. Finally, the diffusion coefficients of gases at atmospheric pressure are 4–5 orders of magnitude higher than the self-diffusion coefficient of water. A decrease in the NMR signal amplitude due to stochastic molecular motion in inhomogeneous magnetic fields is well known and serves as the basis for a widely used method of measuring diffusion coefficients using NMR.² Since the imaging procedure requires the use of magnetic field gradients, fast gas diffusion causes further reduction of the signal-to-noise ratio. In addition, gas diffusion imposes limitations on the achievable spatial resolution, which cannot be better than the characteristic distance of the diffusion displacements of molecules over the time taken for spatial localisation of spins. High diffusion coefficients of gases can be the reason for substantial distortion of NMR images due to the edge enhancement effect.²

Fortunately, there are some ways to partially overcome these difficulties. Short relaxation times T_1 of many gases (SF₆, CF₄, C₂F₆, CH₄) allow multiple accumulation of the NMR signal over a relatively short time to improve the signal-to-noise ratio.^{112–114} In addition, the spin relaxation times of these gases are virtually insensitive to the presence of dioxygen and solid surfaces.¹¹³ Moreover, sometimes the relaxation times of gas molecules in porous media can increase due to frequent collisions of the gas molecules with the walls and/or due to the surface adsorption.^{115, 116} By recording the free induction decay (FID) or

implementing various versions of the single-point imaging technique (SPI, SPRITE) it is possible to compensate the loss of signal due to short relaxation times T_2 and fast diffusion¹¹² or flow effects.¹¹⁷

The spin relaxation times of relatively large gas molecules can approach those typical of many liquids. For instance, the relaxation times of butane are $T_1 = 1.27$ s and $T_2 = 0.75$ s at 1 atm and room temperature. Long relaxation times T_2 allow signal acquisition over a long period of time including multiple refocussing of the echo signal to improve the sensitivity or implement rapid imaging techniques. In addition, large molecules have smaller diffusion coefficients (for propane, $D = 6.6 \times 10^{-2}$ cm² s⁻¹ at 22 °C).

Experiments with molecules containing a large number of magnetic nuclei (*e.g.*, SF₆, C₄H₁₀) also permit improvement of the sensitivity of NMR imaging. In this case possible differences between the chemical shifts of nuclei are insignificant, since the chemical shift difference between inequivalent groups of atomic nuclei is often not resolved due to substantial line broadening. High adsorption of gases by porous materials also leads to substantial enhancement of the signal (Fig. 5); therefore, NMR imaging of adsorbed gases can be employed for measuring the local adsorption isotherms. By increasing the gas pressure one can increase the spin concentration and spin relaxation times and reduce the diffusion effects. However, this faces some problems, *e.g.*, one should use thick-walled ampoules or specially designed probes, an increase in the gas pressure can damage brittle samples (this also causes an increase in not only the relaxation time T_2 , but also T_1 , which requires the duration of the experiment to be extended due to the necessity of lengthening the relaxation delay between the pulse sequence repetitions).

Figure 5. A 2D NMR image of the cross-section of a butane-filled cylindrical ampoule 10 mm in diameter with an alumina granule inside (a) and a 1D section of the NMR image (b); due to adsorption of butane the amplitude of the NMR signal from the alumina granule is an order of magnitude higher than the signal amplitude from the surrounding butane gas.

Another method of improving the sensitivity of NMR, which has recently gained wide acceptance, is the use of hyperpolarised gases¹¹⁸ for which the population difference between the spin sublevels much exceeds the equilibrium population in the magnetic field of a spectrometer. This is achieved using non-radioactive isotopes ¹²⁹Xe and ³He (for both the nuclear spin is 1/2). There are two approaches for creating the nonequilibrium population of nuclear spin sublevels. One involves optical pumping of the D1-transition of the optical absorption of rubidium vapours at a wavelength of 794.7 nm (the use of cesium can be even more efficient). Irradiation with circularly polarised light creates a nonequilibrium population of one of the two electron spin sublevels in the magnetic field and then the rubidium electron spin polarisation is collision transferred to the nuclear spins of noble gases. This technique allows one to achieve a 30% of polarisation of gas (in this case the signal of the gas at a pressure of 1 atm is an order of magnitude more intense than the ¹H signal of a water sample of the same volume). Often, mixtures of xenon

and other gases (N₂, ⁴He) are used at the natural abundance level of the ¹²⁹Xe isotope (26.44%) or using isotope enrichment. The natural abundance of the ³He isotope is very low (1.3×10^{-4} %); therefore, experiments are carried out only with isotopically enriched samples.

The other method for polarising the nuclear spins of ³He involves optical excitation (at a wavelength of 1083 nm) of metastable helium states created in the gas discharge, followed by collisional transfer of the nuclear polarisation to the ground state. Pumping occurs at a gas pressure of about 10^{-3} atm and then the pressure is increased to the operating values.¹¹⁹ Yet another method of NMR signal enhancement by a factor of 100 involves storage of helium at 2–4.2 K in a strong magnetic field (several T) followed by transfer in the magnetic field of the spectrometer and heating to room temperature.¹²⁰

Unlike many other gases, spin-rotational relaxation of monoatomic noble gas molecules is often inefficient due to spherical symmetry of the electron cloud; therefore, the spin relaxation times of these isotopes are rather long.^{121, 122} NMR studies of non-polarised noble gases are often carried out using their mixtures with oxygen to substantially reduce the relaxation time T_1 .^{123, 124} On the contrary, in the experiments with hyperpolarised gases long relaxation times T_1 allow one to appreciably extend the lifetime of the nuclear polarisation, which permits polarised xenon to be obtained in the solid, liquid¹²⁵ and supercritical¹²⁶ states and its transportation over long distances. Phase transitions cause no considerable loss of the spin polarisation while depolarisation of liquid xenon is insignificant even in the weak geomagnetic field.¹²⁵ Long relaxation times T_2 allow multiple refocussing of the magnetisation and acquisition of a large number of echo signals during each repetition of the pulse sequence.

Application of RF pulses causes irreversible loss of spin polarisation.^{127, 128} Therefore, experiments are designed in such a way that the loss of polarisation occurs portionwise due to the use of low-flip pulses. In some experiments the flip angle is gradually increased after each pulse as the longitudinal magnetisation decreases.¹²⁹ Fast gas diffusion can partially compensate the loss of magnetisation owing to the polarised gas present outside the slice under study.¹³⁰ A number of experimental setups has been designed to permit 'on-the-fly' polarisation of the ¹²⁹Xe nuclei up to 3% and thus to provide continuous circulation of the hyperpolarised gas through the sample and fast recovery of the magnetisation destroyed by the RF pulses.^{117, 131–133}

The nuclear magnetisation of hyperpolarised nuclear spins is independent of the applied magnetic field, B_0 . In this case the signal-to-noise ratio is proportional to B_0 instead of B_0^2 under the equilibrium polarisation conditions (see Ref. 134). Therefore, experiments with hyperpolarised gases are particularly efficient when operating in weak magnetic fields^{135, 136} that are used in, *e.g.*, biomedical studies. Lower magnetic fields cause substantially lower field gradients due to the difference between the volume magnetic susceptibility of materials and, hence, considerable reduction of NMR image distortion and the signal decay rate ($1/T_2^*$). In addition, one can use lower field gradient amplitudes, simpler and cheaper MRI scanners and operate at lower resonance frequencies. This causes an increase in the thickness of the skin layer for conducting materials and makes it possible to study, *e.g.*, gases in metallic containers, which cannot be done in strong-field experiments.

High spin magnetisation of hyperpolarised gases was shown¹³⁴ to induce radiation damping effects^{137–140} (the so-called RF maser effect¹⁴¹). In particular, placing a helium-filled cell (2.5 atm, 15% polarisation) into an RF coil in a homogeneous magnetic field caused fast spontaneous loss of polarisation despite the low Q -factor ($Q = 10$) and low filling factor (2%) of the RF coil.¹³⁵ Similar effects can introduce errors into the experimental results. After acquiring the NMR signal the magnetic field gradient pulses destroy the transverse magnetisation, thus weakening the radiation damping effects.¹³⁴

2. Gases with equilibrium nuclear polarisation

Despite the above-mentioned difficulties accompanying NMR imaging of gases, interesting results have been obtained in a number of studies using gases with equilibrium nuclear polarisation at both elevated and normal pressure. Rinck *et al.*¹⁴² seem to report a pioneering study concerning NMR imaging with gas signal acquisition. They studied dog lungs using a $\text{CF}_4 - \text{O}_2$ [80:20 (vol.%)] mixture and ^{19}F NMR signal acquisition in a weak magnetic field (938 G). The frontal, sagittal and transversal NMR images of the lung volume revealed poor ventilation of the upper part of the left lung induced by pneumonia. Considerable promise of the application of physiologically inert perfluorinated gases in real-time studies of perfusion and lung ventilation in stronger magnetic fields was pointed out.¹⁴²

A $\text{C}_2\text{F}_6 - \text{O}_2$ (80:20) mixture was used for forced ventilation of rat lungs. Lungs were imaged with a spatial resolution of 700 μm at 4.3 h acquisition time.¹¹⁴ The fluorine relaxation times at a rat body temperature of 39 °C were $T_1 = 5.9$ and $T_2 = 5.3$ ms. Two-dimensional NMR images of rat lungs were also obtained with a spatial resolution of 4.4 mm by acquiring a total of 64 successive echo signals of thermally polarised ^3He in 8 min.¹⁴³

Varying the concentration of oxygen in gas mixtures allows one to reveal regions of lungs with low alveolar ventilation-to-blood perfusion ratio.¹¹³ These regions are characterised by an increased relative concentration of the blood insoluble gas (a two- or threefold increase if gas mixtures with high concentration of oxygen are used). NMR imaging experiments with a $\text{SF}_6 - \text{O}_2$ mixture with different component ratios demonstrated a marked difference between the images of a normal rat lung and the lung partially blocked by inserting a glass bead with a lumen into the left bronchus.¹¹³

The SPRITE technique was employed to acquire a 1D NMR image of a methane-filled cylindrical glass ampoule divided by Teflon disks into cylindrical layers 2 and 3 mm thick and a 3D image of a fragment of the *Diploria labyrinthiformis* coral placed in a rubber balloon filled with SF_6 at a pressure that was somewhat higher than atmospheric pressure.¹¹² In the latter case the relaxation times ($T_1 = 1.8$ and $T_2^* = 0.6$ ms) were shorter than for pure SF_6 ($T_1 = 2$ and $T_2^* = 1$ ms at 1 atm), which was attributed to the interaction of gas with the developed surface of the porous sample.

The opposite trend was observed in studies of CF_4 and C_2F_6 in the pores of a layered composite ceramic material similar to mullite in chemical composition.¹¹⁵ The relaxation times T_1 of both gases in the pore space of the sample at gas pressures of 0.5 to 5 atm exceeded those of the bulk phase gases by more than an order of magnitude and became much less pressure dependent. The relaxation times T_2 exhibited similar changes. The decrease in the relaxation rate can be rationalised by the adsorption of gases and by reduction of the rotational correlation time of the molecules at small pore sizes, where the frequency of collisions with the ampoule walls becomes comparable with the frequency of intermolecular collisions. The 2D NMR images demonstrated the layered structure of the sample, delamination regions and inner voids. Considerable changes in the spin relaxation times, spin density and effective diffusion coefficient of the gas in the pore space ($D = 6 \times 10^{-3} \text{ cm}^2 \text{ s}^{-1}$ for the bulk phase C_2F_6 gas at 5 atm and 295 K and $D = 10^{-4} \text{ cm}^2 \text{ s}^{-1}$ for gas occluded in pores of the sample) allows the use of these parameters as the basis of the image contrast related to the characteristic dimensions of the morphology and to the local values of the specific surface of the pore space. In particular, an increase in the amplitude of the field gradients used for image acquisition causes suppression of the signal of the gas outside of the sample and allows selective visualisation of gas within the pore space characterised by relatively slow diffusion.¹¹⁵ The surface adsorption of C_2F_6 and C_4F_8 was also observed in studies of partially sintered, tetragonal Y-stabilised zirconia powders.¹¹⁶ The sample porosities were determined based on the results of relaxation time measurements.

Intercalation of AsF_5 into highly oriented pyrolytic graphite was studied using fluorine-detected NMR imaging.¹⁴⁴ The concentration of AsF_5 uniformly increased with time throughout the sample. After equilibration, the diffusion coefficients of the fluorine atoms involved in the exchange processes were measured.

Studies of the structure of mesoporous silica-based material (M41S) showed that the pores in the sample with strongly disordered structure are almost inaccessible to xenon, whereas the samples with more ordered structure exhibited the presence of physisorbed xenon.¹⁴⁵ The experiments revealed fast exchange of xenon in the interparticle space with physisorbed xenon.

Variation of the chemical shift of ^{129}Xe over a wide range (300 ppm depending on the environment) in combination with various selective NMR imaging techniques¹ permits chemical shift selective MRI investigations using the ^{129}Xe atoms in a particular environment. For instance, Gregory *et al.*¹²³ studied silica aerogel samples sealed in an ampoule filled with xenon (30 atm). The NMR images acquired using the lines at $\delta = 46$ and 52 corresponded to ^{129}Xe in aerogel, while the images acquired using the line at $\delta = 17$ allowed visualisation of the volume of the ampoule around aerogel.¹²³ In addition, it was found that optically transparent and translucent samples correspond to different chemical shifts of the ^{129}Xe lines, thus indicating considerable differences in the pore structure of these samples. Shorter relaxation time T_2 points to smaller pore size in the translucent samples characterised by a lower concentration of ^{129}Xe . Two-dimensional NMR images of the periphery of aerogel revealed regions containing almost no xenon due to mechanical breakdown of pores.¹²³ The sensitivity of the chemical shift of adsorbed ^{129}Xe to the presence and concentration of co-adsorbates was used in diffusion studies of the adsorbed water in NiNaY zeolite at 100 °C.¹⁴⁶

The ^{131}Xe quadrupole nucleus with a spin of 3/2 can be more sensitive to the character and state of the surface of a material, despite a smaller gyromagnetic ratio and a lower natural isotope abundance compared to the ^{129}Xe nucleus. A study of liquid xenon in mesoporous aluminosilicate aerogels at 285 K (this temperature is close to the critical temperature, 289 K) showed that the chemical shift and especially the spin relaxation times of ^{131}Xe depend on the density of the aerogel.¹⁴⁷ In addition, ^{131}Xe in the regions outside of aerogel is characterised by a different chemical shift value and longer relaxation time T_1 , which allows selective suppression of the NMR signal from the environment. It was also shown¹⁴⁷ that the relaxation time T_1 of the ^{131}Xe isotope in the gel changes upon removal of the adsorbed water, whereas the relaxation times of ^{129}Xe remain unchanged. The results obtained demonstrated considerable promise of the use of quadrupole relaxation of the ^{131}Xe nuclei as a sensor in studies of the state of various surfaces and of the presence of non-paramagnetic substances on the internal surface of the pores.¹⁴⁷

3. Hyperpolarised gases

The potential of NMR imaging of hyperpolarised gases has been demonstrated using a number of phantom objects. For instance, NMR images of $^3\text{He}^*$ (3 atm) in a glass cell¹³⁴ and of $^{129}\text{Xe}^*$ in capillary tubes^{130, 131} or in nested glass tubes (with a spatial resolution of $\sim 0.1 \text{ mm}$)¹³⁰ have been reported. Hyperpolarised gas flow was also imaged.¹³¹ NMR images of a cylindrical aerogel sample revealed the presence of regions with characteristic millimetre-scale dimensions, which are hardly accessible to xenon.¹³⁰

Using chemical shift selective MRI of a sample of NaY zeolite powder in a porous glass tube, separate NMR images of xenon gas, xenon in NaY zeolite and xenon in porous glass were obtained.¹¹⁷ Separate NMR images of xenon in NaY and CaA zeolite granules were also acquired based on the difference in pore size and in the nature of the cation. All the experiments were carried out at a total gas mixture pressure of ~ 1 atm using a continuous flow of hyperpolarised xenon for continuous renewal of the spin polarisation within the sample and demonstrated the possibility of real-time investigations of the adsorption of xenon.¹¹⁷

Transport of xenon towards the inside of SiO₂ aerogels or spherical zeolite 13X granules was studied by acquiring separate NMR images of bulk phase xenon ($\delta = 130$) and xenon occluded in pores ($\delta = 25$).¹³³ When a continuous flow of the gas is used, the reduction of xenon polarisation by the RF pulses can be utilised to selectively observe the signal of the fresh, inflowing portion of gas. Therefore, by varying the repetition time of the pulse sequence one can obtain NMR images corresponding to different penetration depths of xenon in the porous sample. Experiments with aerogel at long pulse repetition times revealed a homogeneous distribution of hyperpolarised xenon over the sample. For zeolite, fast spin relaxation of xenon occluded in pores allowed acquisition of the Xe NMR signal only from a narrow near-surface region of the granules. The signal amplitude rapidly decayed towards the granule centres. Both samples exhibited obstructed penetration of xenon into the granules in the areas of close interparticle contact and near the walls of the sample container.¹³³

Long spin relaxation times of xenon and helium are convenient for diffusion studies² and provide the possibility of studying molecular displacements at times as long as several tens of seconds.¹⁴⁸ Diffusion coefficient measurements have been reported for ³He* in a glass cell¹²¹ ($D = 1.8 \text{ cm}^2 \text{ s}^{-1}$ at 1 atm) and in a glass cylinder,¹⁴⁹ as well as for ¹²⁹Xe* in a glass sphere¹²⁹ ($D = 0.057 \text{ cm}^2 \text{ s}^{-1}$ at 1.04 atm). Investigations of transport of hyperpolarised xenon towards the inside of a porous glass sample permitted the determination of the diffusion coefficient of adsorbed xenon ($D = 2.2 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ at 293 K) and the activation energy for diffusion ($4\text{--}5 \text{ kJ mol}^{-1}$).¹²⁷ A continuous-flow system was used in studies of ¹²⁹Xe* diffusion in narrow channels of nanoporous crystallites.¹⁴⁸ The temporal dependence of the NMR signal corresponded to a 'single-file' diffusion.

Using the cross-polarisation (CP) or spin polarisation induced nuclear Overhauser effect (SPINOE) techniques, the polarisation of xenon can be transferred to adjacent nuclei including the nuclei of the atoms of a solid surface.^{150–154} In particular, CP studies of the transfer of xenon polarisation to protons of polymer films¹⁵⁵ or to the surface of bulk polymer samples¹⁵⁶ have been reported. With a continuous flow system Seydoux and Pines¹⁵¹ studied the polarisation transfer from the ¹²⁹Xe* nuclei to the surface protons of aerosil. The CP technique is more efficient on less mobile atomic groups, whereas SPINOE works better with more mobile ones. The CP ¹H NMR spectrum exhibited a broad polarised line, while a much narrower signal was observed in the SPINOE experiment. By using the CP technique the proton polarisation thus obtained can be transferred to the ²⁹Si nuclei. In addition, direct SPINOE-induced polarisation transfer from the xenon nuclei to the ²⁹Si nuclei causes enhancement of the ²⁹Si NMR signal from the surface atoms by a factor of 20 to 30.

Navon *et al.*¹⁵⁰ also reported the nuclear polarisation transfer of ¹²⁹Xe* dissolved in benzene to the solvent protons. Due to the low efficiency of the cross-relaxation mechanism the maximum enhancement factor of the ¹H signal varied from 10% (for C₆H₆) to 50%–200% for a C₆D₆–C₆D₅H (3 : 1) mixture. The dynamics of changes in the 2D images of the ¹²⁹Xe* signal in the ampoule suggested that initially the dissolved xenon is accumulated in the bottom region of the ampoule rather than at the open upper end contacting the bulk gas phase. This is due to an increase in the fluid density upon the dissolution of xenon. The NMR images obtained using the signal from the solvent protons were in good agreement with those obtained by acquiring the ¹²⁹Xe signal. This demonstrates the possibility of indirectly mapping the spatial distribution of xenon and studying the properties of the medium through which xenon penetrates.

Most publications have been concerned with applications of hyperpolarised gases in biomedical studies and, first of all, in studies of pathologies of respiratory organs. Experiments on animal and human lungs are usually carried out with ³He* for which one can obtain a higher nuclear spin polarisation.¹²² In

addition, the polarisation can last over a long period of time due to very long relaxation times T_1 ($\sim 100 \text{ h}$ under normal conditions).¹⁵⁷

Hyperpolarised ³He was used for imaging rat lungs¹³⁴ and guinea pig lungs¹⁵⁷ *ex vivo*. In the latter case helium also penetrated into the myocardium (because of the use of a large volume of gas). Experiments with living guinea pigs^{158–160} showed that the chemical shift of ³He in their lungs is sensitive to the volume magnetic susceptibility of the surrounding tissues.¹⁶¹ This can be employed in studies of the microstructure of lungs and of various lung pathologies.

Helium was used in studies of rat lungs *in vivo*,¹⁶² human lung parenchyma,^{119, 160, 163–166} upper respiratory tract¹⁶⁴ and paranasal sinuses.¹⁶⁷ Experiments were carried out on healthy volunteers and patients with various lung diseases diagnosed using conventional methods.^{168, 169} The different abilities of helium and air to penetrate into partially blocked regions of internal organs have been pointed out.

The possibility of functional imaging of lungs by acquiring a set of 2D images of ³He* in different stages of the respiratory cycle with a temporal resolution of 50 ms has been demonstrated taking guinea pigs as examples.¹⁷⁰ Using fast imaging techniques (acquisition times 40–120 ms) allows real-time studies of the ventilation dynamics of human lungs during one respiratory cycle.¹³⁶

To optimise the NMR parameters, the diffusion coefficients and the T_2^* relaxation times of ³He* and ¹²⁹Xe* in lungs of a living guinea pig were measured.¹⁷¹ The relaxation time T_2^* of ³He* in human lungs was also determined.¹⁷² It was found that the diffusion coefficients of these gases in lungs are 3–10 times lower than in the trachea due to geometric restrictions on the molecular diffusion displacements and to different amounts of residual air.¹⁷¹ The T_2^* relaxation time in lungs is also shorter due to rather large local inhomogeneities of the magnetic field and the presence of the residual air.¹⁷²

Acceleration of the relaxation of ³He* in the presence of oxygen can be used for measuring the local partial pressure of O₂ as a function of time.¹⁷³ This was demonstrated taking measurements of the partial pressure of oxygen in a phantom object with the known oxygen concentration as an example. Analogous *in vivo* studies of ³He* in porcine and human lungs revealed a linear decrease in p_{O_2} with time upon breath holding. The error of measurements of p_{O_2} was $\sim 3\%$. The concentration of oxygen in lungs strongly depends on gas exchange, regional blood flow and oxygen uptake; therefore, this experiment offers new possibilities of studying lung work and diagnosing lung diseases.

The spin relaxation time T_1 of xenon gas is of the order of tens of minutes. This is much shorter compared to helium but sufficient for the use of xenon for NMR imaging of lungs. In addition, the T_1 and T_2 relaxation times of xenon are very sensitive to the environment and can be employed as the basis of image contrast agents.¹²² Xenon was used in, *e.g.*, the *in vitro* studies of forced ventilation of lungs on mice lungs (different stages of the filling of a lung were investigated),¹⁷⁴ lungs of a living mouse during unobstructed breathing¹⁷⁵ and lungs of a living rat.¹⁷⁶ Intensive research has also been carried out on volunteers; in particular, NMR images of lungs¹⁷⁷ and the oral cavity¹⁷⁸ have been obtained.

Guinea pig lungs were studied *in vivo* to compare the NMR images obtained using hyperpolarised xenon and helium.^{179, 180} Helium allows acquisition of high-quality images at higher spatial resolution.¹⁸⁰

At the same time, xenon also has some advantages over helium. It has high solubility in blood and various tissues and binds strongly to proteins. The solubility of xenon in blood and lipids is one and two orders of magnitude higher than that of helium, respectively.¹²² A study of the dynamics of changes in the NMR signal revealed rapid transport of xenon gas from lungs into the vascular system,¹⁸¹ which permits investigations of blood circulation in the organism and in various organs.¹⁷⁷ The spin

relaxation time T_1 of ^{129}Xe dissolved in blood strongly depends on the concentration of oxygen in blood due to the change in the interaction of xenon with hemoglobin ($T_1 = 4$ s in the absence of oxygen and 6.5–13.5 s in oxygen-saturated blood^{182, 183}). Taken together with good solubility of xenon in lipid-rich brain structures, this can be used as a promising technique for functional MRI, which is based on the variation of regional cerebral blood flow upon regional activation, and for investigations of the mechanisms of the action of anesthetics on living organisms.

In vivo experiments on rats showed that a fraction of the nuclear polarisation of $^{129}\text{Xe}^*$ survives transport from lungs to blood and then through myocardium to the brain.¹⁸⁴ Two-dimensional NMR images of xenon in brain tissue were obtained using the difference between the chemical shifts of xenon gas and xenon dissolved in tissues and blood. The signal from cerebellum was less intense than the signal from the cerebral hemispheres, which can be due to different blood flow velocities. Further experiments revealed four xenon resonances in the rat organism,¹⁸¹ which were attributed to bulk phase xenon gas and to xenon dissolved in blood, fat and tissues. Different chemical shifts of xenon in plasma and erythrocytes have been reported.¹⁸³ By combining the spatial resolution of the NMR images and spectral information it was possible to follow the transport of $^{129}\text{Xe}^*$ from rat lungs into lung parenchyma and pulmonary blood, and then with blood flow through heart ventricle into myocardium, brain and kidneys.¹⁸¹

Model estimations¹²⁸ showed that after intracarotid injection of a $^{129}\text{Xe}^*$ solution the peak concentration of Xe^* in the brain will be several times higher compared to Xe^* transport through lungs. Specific features of xenon delivery to tissues by intravenous injection of a xenon solution compared to xenon respiration have been documented.¹²² The potential and drawbacks of various biocompatible solvents for delivery of xenon to blood and tissue using xenon solution injection have been reported.¹⁸⁵ The spin relaxation times of xenon in various environments have also been measured.¹²²

Rat hindleg was imaged using intramuscular injection of xenon dissolved in saline.¹²⁸ Fresh human blood in an ampoule was imaged after addition of a xenon solution in an aqueous suspension of lipid vesicles.¹⁸⁵ Intrinsic exchange of xenon between erythrocytes and the plasma–saline mixture has been studied.¹⁸⁵ Intravenous injection of xenon dissolved in a 30% soya oil-in-water emulsion into the tail of a living rat with simultaneous acquisition of MR angiograms of the abdominal and pelvic veins was used¹⁸⁶ for visualisation of the vascular system (MR angiography²). This allowed selective imaging of relatively large veins and estimation of the velocity of blood flow through them. In contrast to proton MR angiography, the xenon-based technique does not require the elimination of the signal of immobile nuclei.

Compared to xenon, the solubility of helium in blood and biocompatible solvents is 10–100 times lower, which poses some problems. To overcome them, a suspension of hyperpolarised ^3He microbubbles in a biocompatible fluid (Hexabrix) was introduced into the caudal vein or the aorta of a living rat to provide visualisation of the venous and arterial system, respectively.¹⁸⁷ In the preliminary stage (prior to injection) the effective spin relaxation time T_1 of xenon in suspension was 42 s and partially reflected the loss of the signal due to rapid rise of bubbles out of the suspension. Hand-agitated suspension contained relatively large bubbles (mean bubble diameter was 31.8 μm and the standard deviation was 10.4 μm). A narrower size distribution centred at 8 μm , which can be achieved by modern techniques, seems to be more preferable. This would provide safe transport of bubbles through the pulmonary circulation and obviate the risk of embolism. The amount of suspension (7 ml or 25% of the total rat blood volume) can be substantially reduced due to an increase in both the concentration of bubbles and the polarisation of helium nuclei. A possible application of this approach is the quantitative assessment of blood circulation in myocardium.

VI. Magnetic resonance imaging of solids

The main problem of the MRI studies of solids is that the lines in the NMR spectra of solids are 3 to 5 orders of magnitude broader than those in the NMR spectra of liquids. For instance, the linewidth in the NMR spectrum of polyethylene depends on the properties of the material and varies between 20 and 60 kHz.¹⁸⁸ This imposes severe restrictions on the achievable spatial resolution. In addition, broad lines correspond to a short signal decay time, which substantially reduces the sensitivity. On the other hand, the decay time can be lengthened using various procedures for creating the spin echo signal in a solid material.¹⁸⁹ Molecular diffusion in solids is usually insignificant and has no effect on the spatial resolution of the technique.

From the standpoint of NMR, the so-called ‘soft’ solid materials such as polymers and elastomers occupy an intermediate position between liquids and ‘hard’ solid materials. That is, they are characterised by linewidths ranging from 100 to 3000 Hz and contain a large number of protons.¹⁸⁹ Therefore, ‘soft’ materials can sometimes be studied by the above-mentioned experimental methods. The spectral lines can be narrowed by increasing the mobility of macromolecules as a result of an increase in temperature or swelling of the material in a solvent.^{190, 191} For instance, heating of a polypropylene block to 330 K substantially improves the signal-to-noise ratio in the 2D NMR image.⁴ In the case of ‘rigid’ materials a high degree of orientational ordering and low concentration of the isotopes of the nuclei under study can substantially reduce the contribution of the homonuclear dipole–dipole coupling to the linewidth.¹⁸⁹

There is a number of methods for efficient eliminations of various types of interactions which contribute to the linewidths in the NMR spectra of solids.^{188, 189, 192, 193} For instance, the magic-angle spinning (MAS) technique is widely used to suppress the chemical shift anisotropy. In this case the imaging procedure requires synchronisation of the rotating (or pulsed) field gradients with the sample rotation. Magic-angle spin-lock allows averaging of anisotropic interactions without mechanical rotation of the sample.¹⁹⁴ Decoupling with composite pulses permits suppression of heteronuclear dipolar spin coupling while various multipulse techniques are used for suppression of homonuclear dipolar couplings and for line narrowing up to three orders of magnitude.^{195, 196} In particular, a signal dephased due to homonuclear dipole–dipole coupling can be rephased using the magic echo pulse sequence.^{188, 197} By combining the magic echo pulse sequence and the CPMG pulse sequence to eliminate the chemical shift effects the adamantane NMR line was narrowed from 13 kHz to 3–8 Hz.^{196, 198}

The so-called constant time imaging (CTI) techniques involve obtaining spatial information by phase encoding of the signal. Because of this, the linewidth does not impose limitations on the spatial resolution. For instance, the single point imaging (SPI) technique^{1, 199, 200} involves measurements of the FID amplitude at a single point 10–100 μs after application of the RF pulse, which allows studies of objects with short relaxation times T_2 , and T_2^* (gases, solid materials and samples with large internal magnetic field gradients). Such gradients are typical of, e.g., samples with numerous interfaces between phases with different magnetic susceptibilities (porous media, animal and plant tissues, etc.). In the SPI technique, the signal at the centre of the k -space ($k = 0$) is acquired at a zero external field gradient, so that diffusion causes no additional loss of the signal even in the studies of fluids and gases. Nevertheless, the signal-to-noise ratio decreases due to short relaxation times T_2 and T_2^* . SPI experiments with the phase encoding of the NMR signal instead of the frequency encoding elongate the image acquisition times.¹ In some instances the SPI method is employed in combination with fast imaging techniques (e.g., the turbo spin echo SPI technique).²⁰¹ This approach was used, in particular, for investigating heterogeneous samples including hardened cement. The SPRITE technique¹ is a

version of the SPI procedure, which also allows considerable reduction of the measuring time.^{202–206} It has been used in studies of various materials including cement, concrete, bone tissues, rigid polymers and gases with short spin relaxation times (including H_2).

Often, for short- T_2 materials acquiring the FIDs rather than echo signals provides a means for improving the sensitivity of the experimental technique. Therefore, in some instances the NMR images are reconstructed using a method similar to X-ray computerised tomography. The technique is based on recording the FID in the presence of a magnetic field gradient and multiple repetition of the experiment at different directions of the field gradient. The results obtained (1D projections) are then used for reconstruction of 2D or 3D NMR images from the projections using relevant software.¹⁹² Continuous-wave MRI can also offer some advantages over the pulsed techniques in studies of materials with submillisecond relaxation times T_2 .²⁰⁷

Broad-line effects on the spatial resolution can be eliminated using large-amplitude field gradients. NMR probes have been developed, which permit creation of pulsed field gradients up to $60\,000\text{ G cm}^{-1}$ (see Ref. 208). Finite inductance of gradient coils and the eddy currents induced in conducting materials cause the gradient switch on/off time to extend, thus shortening the minimum achievable echo time. In this situation one can use sinusoidal field gradients and a gradient coil incorporated into the resonant circuit.^{209–211} In this case, the RF pulses are applied at the instant when the gradient passes through zero. Using a doubly resonant coil, one can adjust the shape of the field gradient in such a way that it has an inflection point at zero, which permits an increase in the duration of the RF pulse, thus improving NMR image quality.^{211,212} Oscillating field gradients allow reduction of the echo time down to $\sim 100\text{ }\mu\text{s}$. For instance, a 3D image of a plastic LEGO[®] brick has been obtained (characteristic relaxation time T_2 of the material was $760\text{ }\mu\text{s}$).^{209,212}

A number of stray field imaging (STRAFI)¹ studies have been reported.^{213–217} The method involves placing the NMR probe in the region where the magnetic field amounts to *ca.* 40% of the maximum magnetic field value but the field gradient can exceed $10\,000\text{ G cm}^{-1}$. At such gradient amplitudes, even a short RF pulse affects nuclear spins only within a narrow slice of the sample. 1D STRAFI images are obtained by mechanically moving the sample along the field gradient direction through the sensitive slice. Stepwise rotation of the sample permits 2D and 3D NMR imaging. The method allows studies of samples with metallic inclusions and of paramagnetic materials.²¹⁸ Using an additional coil, one can vary the magnetic field, thus displacing the sensitive region within the limits of 1 cm without moving the sample.²¹⁹

Multiquantum NMR imaging involves creation of a coherence in the system of interacting spins (n th order coherence; $n > 1$).²²⁰ The evolution frequency of the multiquantum coherence is n times higher than the Larmor frequency of spin precession ($n = 1$) in the magnetic field. Because of this, at $n = 10–20$ the effective amplitude of the field gradients employed increases by an order of magnitude during acquisition of NMR images.²²¹

Using selective pulses for slice selection and chemical shift selective imaging also face some difficulties, since the pulse duration can exceed the signal decay time in solid materials.²²¹ Application of large field gradients permits slice selection with short RF pulses (several microseconds). Slice selection can also be achieved by spin-lock in the presence of a field gradient²¹⁰ and by selective saturation of the nuclear magnetisation outside the slice under study due to long relaxation times T_1 in solid materials. The above-mentioned line narrowing techniques allow the use of long pulses and pulse sequences for selection of a particular slice or spectral line.¹⁸⁹ Some other slice selection methods have been developed.^{222–224} Heteronuclear polarisation transfer²²⁵ between, *e.g.*, the ^1H and ^{13}C nuclei offers considerable promise for selection of a particular group of atomic nuclei in multi-component systems.

Short, large-amplitude RF pulses that are used in solid-state NMR studies require high RF power. This imposes limitations on the size of the sample (usually, the sample is no larger than 1 cm). Samples that can be as large as one likes (*e.g.*, the Earth) are studied using surface coils²²⁶ or a device which combines the RF coil and the magnetic field source. Local studies of the properties of large samples can be performed with a surface scanner ('NMR Mouse'), which is suitable for exploring almost any solid materials^{227,228} including metal-supported polymeric coatings, human skin and tendons, *etc.* Small size and weight make the device mobile. Because of this the spectrum of possible applications of the method is broadened and includes, in particular, studies of aircraft wings, auto-tyres reinforced with steel-wire cord, buildings, bridges and conveyor belts.¹⁰ The device comprises two permanent magnets and a surface coil which produce a static and an RF field in the near-surface layer of the sample. Inhomogeneity of the fields produced defines the size of the sensitive volume (characteristic dimensions are $4 \times 9\text{ mm}$ at a thickness of 0.5 to 1 mm). By varying the frequency of the alternating field the sensitive zone can be displaced over a distance of 0 to 5 mm from the surface. An additional gradient coil allows 1D spatially resolved NMR imaging within the field of view (15 mm) without mechanically moving the probe.²²⁹

An NMR image can be obtained using radiofrequency field gradients (B_1 -imaging technique) in combination with static magnetic field gradients or instead of them.¹⁹² The advantage of this approach is insensitivity to static magnetic field inhomogeneities typical of heterogeneous samples.

Feasibility of using MRI techniques to obtain information on solid materials (including real-time monitoring of technological processes) is of considerable interest in spite of technical problems and complexity of practical implementation. The major advantage of NMR imaging is the possibility of targeted variation of image contrast by choosing appropriate pulse sequences. It is this feature that allows one to collect information on the structure and state of the samples and processes occurring in them. This also holds for solids. Using theoretical and empirical relationships, one can estimate such characteristics of materials as the degree of homogeneity, the dynamics and degree of molecular ordering, chemical composition, molecular velocities and reaction rates, mechanical stress and deformations, degree of cross-linking of polymers, filler agglomerate distribution, ageing, temperature, viscosity, *etc.*, from the quantities measured experimentally (*e.g.*, relaxation times, chemical shifts, linewidth and lineshape). The most important procedures for creating image contrast in solids and methods of practical implementation have been well documented.^{230–232} Only a few examples are presented below.

NMR imaging of solids is most widely used in studies of polymers and elastomers (Figs 6 and 7). In particular, MRI experiments revealed the presence of inhomogeneously distributed spherical microvoids of different sizes in cross-linked poly-(isobutylene-*p*-methylstyrene-*p*-bromomethylstyrene) terpolymer.^{190,191} It was found that the concentration of microvoids correlates with the mechanical properties of the material. In particular, high concentrations of microvoids can cause early destruction of the material under mechanical stress.

The relaxation times are often used as the basis of image contrast. The T_2 and $T_{1\rho}$ values (see Ref. 1) are sensitive to the cross-linking density of polymers (the latter allows characterisation of the size of defects and the molecular dynamics of the polymer).²³³ The relaxation time T_2 nearly linearly decreases with an increase in the cross-link density, linearly increases with temperature and depends on the degree of tension of the sample.¹⁸⁸ This permitted studies of the local cross-link density in elastomers (including those during vulcanisation processes).^{10,188,234} Spatial inhomogeneity of cross-linking of the polymer chains in a composite sample of butadiene-styrene rubber was investigated by measuring the effective relaxation time T_1 .²³⁵ The degree of cross-linking and orientational ordering of macromolecules can be determined from measurements of

Figure 6. A 2D NMR image of the cross-section of a porous cylindrical alumina granule saturated with cyclohexane. The image was obtained using the spin echo technique. A sealing tape (bright ring around the granule) was wrapped around the granule.

Figure 7. 3D surface rendering (a) and a horizontal section (b) of a polychlorovinyl tube tied in a bundle. The NMR images were obtained using the spin echo technique.

residual dipolar spin–spin coupling.^{236,237} Chemical shift anisotropy was used as the basis of image contrast in a study of the ordering of pre-stressed polytetrafluoroethylene²³⁸ and in monitoring the propagation of mechanical stress during crack growth in the material.¹⁸⁸ The density of cross-links between polymer chains can be determined *via* swelling of the materials in solvents.^{1,2}

The relaxation times T_2 and $T_{1\rho}$ are sensitive to slow molecular motions and suitable for studying changes in the mechanical properties of polymers and elastomers including vulcanisation and ageing.^{10,188} The results of real-time monitoring of vulcanisation of butadiene–styrene rubber without filler and with carbon black additive have been reported.^{10,11,188} Co-vulcanisation of composite materials has been studied.¹⁰ A study of oxidative ageing of butadiene–styrene and natural rubbers at elevated temperatures²³⁹ revealed the formation of a rigid ‘crust’ on the surface of the samples. The ‘crust’ was shown to thicken with time.^{10,188} It was separated from the unmodified material by a narrow region characterised by increased molecular mobility due to the polymer chain scission. The influence of external conditions and chemical composition of materials on the ageing and solvent transport in aged rubbers has been studied.²⁴⁰

Mechanical ageing can be due to crystallisation induced by mechanical stress or to additional cross-linking or scission of molecular chains upon an increase in temperature. Mechanical ageing has been studied taking samples cut from a tyre as examples.¹⁰ Inhomogeneous vulcanisation can induce early degradation of rubber items under the operating conditions. NMR images of swollen items reveal distinctions in the degree of vulcanisation between the damaged and normal regions.¹⁸⁸ NMR imaging also permits detection and studies of the properties of boundary regions at the interfaces between different types of rubbers upon vulcanisation.²⁴¹ A number of studies of rubber items characterised by the presence of an interface between the butadiene–styrene and natural rubbers have been carried out.

Knowledge of the distribution of mechanical stress and strain in polymeric and elastomeric items under the operating conditions is of great importance. NMR imaging provides a means for studying the changes in the molecular mobility and orientation of the molecular chains. For ‘soft’ materials this information can be obtained by directly measuring the molecular displacements.² In addition, the spin relaxation times, chemical shift anisotropy, quadrupole splittings and multiquantum coherence are sensitive to stress and deformation. The morphology of cold-drawn polycarbonate was studied^{188,242} using the effective relaxation time T_2 related to the local mobility of polymer chains as contrast agent. Measurements of the effective relaxation time T_1 permitted the determination of the mechanical stress distribution in a glass-supported tripropylene glycol diacrylate film 0.9 mm thick. It was also shown that the stress substantially increases as the distance from the film region under study to the support decreases.²³⁵ Crack growth in polymer samples was studied by inducing tensile stress and monitoring the morphology and mechanical stress near the tip of the growing crack.²⁴³

The fact that many spin interactions are anisotropic can be useful for studying the deformation and stress anisotropy. Quadrupole splittings in the ^2H NMR spectra are very sensitive to alignment of the molecular chains as a result of changes in the degree of averaging of anisotropic interactions. The samples can be deuterated either during the preparation of materials or by swelling in deuterated solvents or oligomers. The latter approach was used for studying mechanical stress in strained natural rubber.^{10,244} Creation of two-quantum coherence^{10,237} of single quadrupole nuclei or interacting nuclei with spin 1/2 also offers some advantages.

Studies of the properties of various materials under dynamic load conditions are of great value. In contrast to conventional techniques, MRI allows spatially resolved studies of the properties of various materials and, in particular, mapping the temperature distribution over the sample. For instance, the relaxation time T_1

of butadiene–styrene rubber exponentially decreases with an increase in temperature, while the relaxation time T_2 is proportional to the local temperature.^{10, 188, 245} An NMR probe was designed to carry out experiments under dynamic load conditions (compression or shear deformation) with frequencies ranging between 1 and 20 Hz. Experiments with a cylindrical sample at different load frequencies and different amounts of filler in the rubber revealed an increase in the temperature by 20 degrees and inhomogeneous temperature distribution over the cross-section of the sample.

Studies of polystyrene after bending strain or impact load^{188, 227} and acquisition of a 3D NMR image of extruded polycarbonate can serve as examples in the case of rigid materials.²⁴⁶ The study of polyethylene revealed nanometre-size transient regions between the amorphous and crystalline domains.²⁴¹ Spatial inhomogeneity of the distribution of crystalline and amorphous domains in polymeric materials was established by combining MRI data and spectral information obtained from ^{13}C NMR measurements.²⁴⁷ NMR imaging was also employed to study the damaged regions in low density polyethylene upon electrical breakdown and the dendritic microvoid structures created by electrical breakdown.²⁴¹ It was found that the breakdown zone is characterised by a decrease in the size of crystalline domains and by an increase in the size of amorphous domains as a

result of rapid local heating followed by cooling. ^1H and ^{27}Al NMR imaging was used to study solid propellants.¹⁸⁸

* * *

In conclusion mention may be made of a number of reviews, monographs and books concerning the problems considered in this review. They are concerned with basic MRI principles^{189, 248–250} and applications of the technique in various fields.^{251–260} Another group of references are devoted to MRI studies of porous materials^{252–254, 261} including fluid transport in porous media,^{262, 263} problems of application of NMR and MRI in chemical technology and catalysis,^{264–266} principles and examples of solid-state MRI applications^{192, 210, 256, 267, 268} and NMR studies of noble gases.²⁶⁹

This review has been written with the financial support by the Russian Foundation for Basic Research (Project Nos 02-03-32770 and 00-15-97450) and the Siberian Branch of the Russian Academy of Sciences (the ‘Integration’ Programme Project No. 46).

VII. Supplement

Table S.1 presents additional information on the MRI studies considered in this review.

Table S.1. Applications of NMR imaging techniques.

Field /T	Nucleus	Object, process	Technique	Dimension	Spatial resolution characteristics ^a	Recording time	Ref.
—	^1H	polypropylene block at 300 and 330 K	spin echo	2D	128×128 , a slice 5 mm thick	3.5 min	4
—	^1H	polymerisation of MMA + substituted peroxodisulfate (0.2%) in a mould at 60 °C	the same	2D	128×256 , a slice 4.5 mm thick	1 min	4
—	^1H	vulcanisation of a composite polymeric material reinforced with carbon fibre	"	2D	128×128 , a slice 5 mm thick	1 min	4
6.34	^1H	water or water + MnSO_4 in a cross-linked poly(methacrylic acid) gel	"	2D	a slice 2 mm thick	—	6
2.35	^1H	copolymerisation of methacrylamide with N,N' -methylenebisacrylamide + 10% ammonium persulfate + tetramethylethylenediamine at 25 and 35 °C	"	2D	—	—	7
4.7	^1H	epoxy resin reinforced with carbon fibres	"	2D	128×128 , a slice 1 mm thick	64 s	8
2	^1H , ^{19}F	methacrylic acid + benzoyl peroxide + N,N -dimethylaniline + 1,4-dibromotetrafluoroethylene	"	1D	256; 0.4 mm	5 s	12
2.9	^1H	photoinduced polymerisation of a resin containing methacrylic monomers	spin echo + STRAFI	1D, 3D	54 μm (1D); $128 \times 128 \times 128$, (100 μm) ³ (3D)	—	13
4.7	^1H	photoinduced polymerisation of hexamethylene dimethacrylate + benzyl dimethyl ketal	spin echo	2D	256×256 , (20 μm) ² , a slice 300 or 500 μm thick	—	14
—	^1H	1,6-hexanediol dimethacrylate + benzyl dimethyl ketal	the same	2D	256×128 or 256×256 ; from (11 μm) ² to $39 \times 78 \mu\text{m}$, a slice 300 μm to 1.7 mm thick	—	15
3	^1H	irradiated polymer gel	"	2D	128×128 or 256×256 (234 μm) ² or (195 μm) ² , a slice 1 mm thick	6.4 min or 6 h 49 min	16

Institute of Problems of Chemical Physics of the Russian Academy of Sciences

This issue of the journal 'Russian Chemical Reviews' is fully composed of papers contributed by staff researchers of the Institute of Problems of Chemical Physics of the Russian Academy of Sciences (IPCP RAS), one of the leading research institutes of the Division of Chemistry and Materials Science of the RAS. In 1956, Academician N N Semenov, the former director of the Institute of Chemical Physics (ICP) of the USSR Academy of Sciences and a Nobel Prize Winner, and F I Dubovitsky, Corresponding Member of the USSR Academy of Sciences, set up an affiliated branch of ICP in the village of Chernogolovka (Noginsk Region near Moscow) with the primary goal to carry out large-scale research in combustion and explosion processes. In 1972, the affiliated branch was rearranged into a section of ICP and in 1991 the section was reorganised into the Chernogolovka Affiliation of ICP (presently, IPCP RAS).

The main lines of research pursued at IPCP RAS are as follows:

- general problems of chemical physics;
- structures and compositions of molecules and solids; kinetics and mechanisms of complex chemical reactions;
- physical chemistry of combustion and explosion;
- preparation and modification of polymers;
- biological processes and systems.

Noteworthy, all these studies have a common basis, *viz.*, study of kinetics and mechanisms of diverse chemical and biological conversions.

The Institute has at its disposal a unique experimental base: proving grounds; specialised reinforced premises for large-scale studies of fast processes; chemical, technological and microbiological pilot plants; a vivarium; cryogenic equipment; a multi-access analytical centre for experimental support of investigations in the framework of projects of the Russian Foundation for Basic Research (RFBR) and state-sponsored research programmes of the Russian Ministry for Industry, Science and Technology.

The computer centre of IPCP is equipped with the most up-to-date computing system RM 600 E60/E20 (Siemens, FRG) which is integrated into the computer network of the Chernogolovka Research Centre and provides facilities for other research institutes of the RAS residing in Chernogolovka as well as for Moscow State University (MSU), Moscow Institute for Physics and Technology (MIPT), Moscow Engineering and Physical Institute and many other research and educational institutions in Moscow, Kazan, Rostov-on-Don, Ivanovo and other cities. The establishment of a high-capacity computer centre at IPCP has made it possible to state new fundamental tasks:

- design of software tools for numerical simulation of development of hydrodynamic instability;
- development of an 'individual particles' technique for description of high-energy pulsed processes;
- study of phase transitions in organic crystals;
- quantum-chemical studies of mechanisms of chemical conversions in organic compounds.

Researchers at IPCP have developed new generations of software complexes based on the use of massively parallel technologies which allows one to reduce the computation time 10–20-fold and to carry out direct simulation of fire- and explosive-hazardous events at chemical and nuclear units.

The staff of the Institute consists of more than 800 researchers including 109 D.Sci. and 322 Ph.D's. A department of the MIPT is functioning successfully on the mode of IPCP. An affiliated branch of the Department of Chemistry of MSU was established in IPCP in 1995 owing to the joint efforts of IPCP RAS and the Department of Chemistry of MSU. The Moscow Regional Affiliation of MSU, which includes departments of chemistry, physics and geology, has been functioning at IPCP since 1997. The Institute provides degree research facilities to students of senior courses of MSU, MIPT and other higher educational establishments; postgraduate students prepare their doctoral theses on the

basis of the Institute. IPCP has three expert councils for Ph.D. and doctoral theses; the post-graduate courses offer research facilities in 16 scientific disciplines.

In recent years, the interest of talented young scientists in scientific research has increased considerably owing to the organisation in the Chernogolovka Research Centre of a continuous educational system: school–college–postgraduate courses. At present, 30 students of IPCP are carrying out diploma works and over 30 people are postgraduate students.

The Institute carries out research in the framework of various projects supported by the RFBR (about 100 research projects annually), the European Union (INTAS), the International Science and Technology Centre (ISTC) as well as in the framework of Federal purpose-oriented programmes and RF President's Grants for leading scientific schools and collaborates with more than 50 universities and institutions in Russia and abroad.

Such a broad range of research, which encompasses virtually all main areas of chemical physics, is reflected in the present structure of IPCP. The Institute has ten sections: combustion and explosion; kinetics of chemical and biological processes; kinetics and catalysis; extremal states of substances; polymers and composite materials; structures of substances; photochemistry; functional inorganic materials; chemical technology; mathematics. In-depth fundamental studies carried out at IPCP have provided results of fundamental importance in all these areas.

Methods for exact calculation of complex surfaces of potential energy and dynamics of elementary processes have been developed. The quantum theory of molecular rearrangements has been devised. The rate constants for the main elementary reactions occurring in gas, liquid and solid phases have been established both theoretically and experimentally. The mechanisms of action of metalloenzymes have been investigated. These data served as a basis for the construction of purely chemical systems for photocatalytic liberation of hydrogen and oxygen from water, oxidation of methane and catalytic reduction of hydrogen under mild conditions.

The mechanism of combustion of condensed compounds has been investigated and its general theory is developed. Some methods of control over combustion have been proposed. The regularities of heterogeneous and filtrational combustion have been analysed.

In-depth studies into various aggregate states of substances and chemical and phase conversions at high pressures and temperatures under intense shock and detonation waves have been carried out. The thermal properties of dense plasma characterised by strong interparticle interactions as well as thermodynamic and conducting properties of gaseous and liquid hydrogen under conditions of multiple shock-wave loading have been investigated. The ability of hydrogen, helium and xenon to pass to a highly conducting (metallic) state has been established. The transition of metals (particularly, of lithium and sodium) into dielectric states at high dynamic pressures has been detailed. The electrical resistance of fullerite C₆₀ under dynamic conditions has been measured for the first time. It has been established that the temperature dependence of resistance of shock-loaded fullerite is reversible and typical of semiconductors.

In-depth studies are carried out at IPCP within the framework of a general problem: molecular structure–solid structure–physical and chemical properties of materials. This resulted in the preparation and investigation of a vast variety of superconductors, metals, photochromic materials, superionics, materials with a broad range of useful mechanical, electrical and optical characteristics, nanomaterials and fullerenes.

Chemical modification of various classes of antitumour cytostatics by incorporation of fragments of iminoxyl radicals (bio-antioxidants) has resulted in the development of novel classes of drugs manifesting a broad range of antitumour activities as well as membrane protectors and antioxidants.

Adequate nitrosyl models of active [Fe–S] centres of non-heme proteins, a novel class of promising medicinal drugs, have

been obtained for the first time. Some new methods for the synthesis of these conjugates, which contain simultaneously two biochemical functional groups, *viz.*, the –NO group (radio- or chemosensitiser) and the –SR group (antibacterial and anti-inflammatory agents, enzyme inhibitors, antimetabolites), have been developed.

The Institute combines fundamental research with the solution of applied practical tasks and is actively engaged in the development and commercialisation of advanced technologies and processes. The German company 'Linde' has purchased the Institute's license for highly selective synthesis of higher linear α -alkenes based on controlled dimerisation and oligomerisation of ethylene and started the construction of several plants utilising this technology in Saudi Arabia. A process for pilot-plant production of poly- α -alkene bases for synthetic lubricants has been developed by IPCP in collaboration with the petrochemical company 'Petroleum Industry of Serbia'. This technology has served as the basis for the construction of the first plant in the Russian Federation for the production of synthetic motor oils in the town of Nizhnekamsk (Tatarstan).

The Russian–Chinese Joint Venture 'Sychuan Mianyang Lier' has been established for industrial realisation of a technology for preparation of pyridine-type pesticides developed by IPCP RAS in collaboration with the Chinese Academy of Physical Engineering. In 1997, the production of 3,6-dichloropicolinic acid and Lier (which represents an analogue of Lontrel) was set in operation at the Mianyang plant belonging to the Company.

In-depth studies of non-equilibrium filtration combustion processes have led to the development of environmentally safe technologies and equipment for processing industrial and domestic wastes and low-grade combustible fuels aimed at production of thermal and electric energy. Commercial plants for processing quenching oils (JSC 'Electrostaltazhsmash', Electrostal', Moscow Region) and household wastes (Lappeenranta, Finland) have been set up. The assembly of an incineration plant is near completion in Moscow.

Active engagement of IPCP RAS in the activities connected with commercialisation of its own achievements has led to the establishment, in 2001, with the assistance of the Academy of National Economy at the Government of RF and the British Council, of a new section, *viz.*, a Centre for commercialisation, which is aimed at performing technological audits, legal regulation and market research. The experts at the British Council render permanent support for the newly established Centre in organising training seminars on technological audits. This undertaking has received further support. At the end of 2002, it was decided to establish an Innovation-Technological Centre of the RAS on the basis of the Chernogolovka Research Centre in order to meet the need for qualified personnel for innovation spheres. The agreement on its establishment has been made between the Russian Academy of Sciences, MSU, the Government of the Moscow Region and the Academy of National Economy of the RF Government. One of the main provisions of this agreement is education of specialists and acquisition of professional skills and knowledge in the field of technological management, which includes commercialisation of new developments, estimation of commercial potentials of novel technologies, attraction of investments and advancement of novel technologies and scientific and technological products in the market.

The Institute takes an active part in international and domestic scientific-and-industrial exhibitions. In the past five years, IPCP researchers participated in 61 exhibitions, such as the International Industrial Fair in Hannover (FRG), Salon of Innovations, Novel Technologies and Inventions at Pittsburg (USA), and domestic exhibitions 'Khimekspo' and 'Ekspogorod'. Many of them won prizes at popular international exhibitions ('Innovations: Novel Materials and Chemical Products', 'Science and Scientific Instruments', 'Salon of Industrial Property 'Archimed') and the national exhibition 'Technologies from Russia'. The developments of the Institute were highly appraised

by the Jury of the 51st Salon 'Brussels: Eureka-2002' where they were awarded three gold, one silver and one bronze medals.

Every year, researchers of IPCP publish about 350 papers in domestic and foreign journals and make about 400 reports at national and international conferences. In the past five years, 34 monographs of IPCP researchers came out of such highly reputed publishing houses as Gordon and Breach, Elsevier, Springer, Kluwer Academic, Nauka, Khimiya, *etc.* The Institute publishes books of collected papers on diverse problems of chemical physics, physical chemistry, combustion and explosion, chemical kinetics, physics and chemistry of polymers. The Institute owns more than 60 patents for advanced developments and technologies; of those, 30 patents were granted in the last five years.

The Institute supports the organisation of numerous national and international scientific conferences and symposia devoted to combustion and explosion, chemistry and physicochemistry of oligomers, physical and chemical characteristics of elementary chemical processes, crystal chemistry and catalysis.

Several researchers of IPCP were awarded the honorary title 'Honoured Scientist of Russia'. Among other rewards granted to IPCP members in the new millennium are the Government Prize of RF for innovative activity, RF prizes for young scientists for outstanding achievements in science and technology and the European Academy prizes for young Russian scientists. In 2002, Academician V E Fortov was awarded a prestigious prize of the Max Planck Society for a series of experimental and theoretical investigations on the properties of various substances under extremal conditions.

The reviews published in this issue do not cover the whole range of investigations carried out at IPCP; many of the research subjects are intended for consideration by the physical community only.

As was mentioned previously, one of the most actively developed lines of research at IPCP is chemical physics of the formation and modification of polymers, namely, the kinetics of the formation and destruction of polymers, macromolecular design, interphase events occurring in polymers and composite materials; design and investigation of polymers and composite materials possessing unique optical, electrical and magnetic properties, structural theory of macromolecules and phase formation in polymeric materials; physical methods for studies of polymeric materials, *etc.* This line of research is detailed in the review by G V Korolev 'Current trends in investigations into the micro-heterogeneous mechanism of three-dimensional radical polymerisation' and the review by D P Kiryukhin and I M Barkalov 'Chain chemical reactions at low temperatures'.

Yet another important trend which combines different lines of research carried out at IPCP is related to the study of kinetics,

mechanisms and elementary acts of chemical reactions. Of particular interest is the study of short-lived intermediate species involved in these reactions. The review by E Ya Misochko, A V Akimov and I U Goldshleger 'Modern applications of matrix isolation technique to investigation of radical species generated in atom-molecular chemical reactions' describes one of the most efficient in contemporary chemical physics techniques for the study of transient products and its application to concrete systems. Special attention is given to the analysis of conditions for the stabilisation of radical intermediates generated in cryochemical reactions and combined applications of various spectroscopic techniques.

The fundamental line of research aimed at activation of hydrocarbons by transition-metal complexes is led by Academician A E Shilov. Some aspects of this problem have been considered in the review by V D Makhaev 'Structure of methane complexes according to the data of experimental and theoretical investigations', which is devoted to the analysis of relationships between the nature of the central metal atom and the ligands and coordination of methane within complexes with neutral atoms, ions and molecular fragments and the comparative study of structural regularities of methane and tetrahydroborate complexes.

The kinetics and mechanisms of thermal decomposition of high-energy compounds, their chemical stability and application safety have long been studied by F I Dubovitsky, Corresponding Member of RAS. The results of long-term exploratory works aimed at the synthesis of novel representatives of high-energy compounds of the triazine series and their analogues are presented in the review by A V Shastin, T I Godovikova and B L Korsunskii 'Nitro derivatives of 1,3,5-triazine: synthesis and properties'. This is the first attempt to systematise the published data on novel 1,3,5-triazine derivatives as high-energy and biologically active substances and reagents for organic synthesis. The ability of trinitromethyl groups of 1,3,5-triazine derivatives to undergo nucleophilic substitution presents unquestionable interest for the understanding of mechanisms of nucleophilic aromatic substitution in heterocyclic compounds.

These are only a few trends of research being carried out at IPCP. In one of the next issues of Russian Chemical Reviews we shall continue to get you acquainted with the results of our investigations. For more detailed information see our web-site (<http://www.icp.ac.ru>).

Abstract. Data on the kinetics and mechanism of the three-dimensional radical polymerisation of multifunctional vinyl monomers (oligomers) containing two (or more) double bonds are generalised and analysed. The history of this field of research is briefly outlined. The characteristic feature of the mechanism of three-dimensional radical polymerisation, *i.e.*, microheterogeneity, is considered. Special attention is focused on recent advances (last decade) in studies of three-dimensional radical polymerisation associated with the development of new techniques (fiber-optic techniques, information technologies, *etc.*). Consideration is given to methodological aspects of kinetic experiments in highly cross-linked reaction media in which three-dimensional radical polymerisation proceeds. The bibliography includes 223 references.

I. Introduction

In 1977, rigorous proof of the specific mechanism of radical polymerisation of multifunctional monomers (oligomers) was reported for the first time.¹ In the last 25 years, this mechanism found considerable supporting evidence. Presently, this mechanism is called microheterogeneous. The hypothesis about the microheterogeneous character of the formation of highly cross-linked polymer networks (three-dimensional polymerisation) was advanced long before 1977 and was rather clearly formulated by Howink as early as 1934.² Later on, this idea was developed by Kozlov,^{3,4} Galacher and Bertelheim,⁵ Korolev *et al.*,^{6,7} Notley,⁸ Bobalec *et al.*,⁹ and Dušek.¹⁰

First attempts to refine the model of microheterogeneous radical polymerisation were undertaken using the three-dimensional radical polymerisation (TRP) of phenol–formaldehyde resins as an example.^{3,4} In 1962, the knowledge of the mechanism of radical polymerisation was substantially improved due to the application of light scattering to the investigation of the nucleation and evolution of microheterogeneity (microgel particles) in

the course of the polymerisation of unsaturated esters.⁵ In the same year, an hypothesis was proposed about the formation of discrete microgel particles, which serve as autonomous microreactors in the course of the polymerisation of multifunctional methacrylic esters.⁶ In such autonomous microreactors, polymerisation proceeds much more rapidly than in the remaining bulk of the reaction system due to the local gel effect. In addition, important details of the TRP mechanism were revealed.⁸ In 1964, the microheterogeneous mechanism was postulated also for three-dimensional polyesterification of non-radical three-dimensional polymerisation processes.⁹ In 1970, the mechanism of TRP involving microheterogeneity was formulated on the basis of new experimental data.⁷ In 1971, microsineresis was observed¹⁰ in the course of formation of highly cross-linked macromolecular structures.

However, only long-term studies of model objects, *viz.*, oligoester acrylates (OEA) belonging to a new class of unsaturated oligomers whose chemical structures were varied in a desired mode,[†] with the use of original procedures[‡] culminated in 1977 with experimental evidence for the microheterogeneous mechanism of radical polymerisation. Hence, the above hypothesis not only became a proven concept but also was detailed. This provided a model suitable for quantitative calculations. The results of these calculations were reported in the study.¹¹

The present review surveys the most important stages of investigation into three-dimensional radical polymerisation of multifunctional oligomers, which is one of the most important fields of polymer science. Considerable progress made in this field recently in response to the requirements of modern technology is associated mainly with advances made due to the discovery of microheterogeneity as the main characteristic feature of the mechanism of TRP. Prospects of further progress are based on the possibilities of modern computer modelling and the discovery of new phenomena in the kinetics of radical polymerisation (living chains, kinetically active associates).

[†] The compounds were synthesised by A A Berlin and co-workers in the N N Semenov Institute of Chemical Physics of the Russian Academy of Sciences.

[‡] Procedures specially designed for kinetic, structural and physical measurements during TRP were developed by G V Korolev and co-workers in the N N Semenov Institute of Chemical Physics of the Russian Academy of Sciences.

II. Characteristic features of three-dimensional radical polymerisation

Three-dimensional radical polymerisation can involve many practically important classes of unsaturated multifunctional compounds, *viz.*, oligoester acrylates and maleates (for example, maleate–styrene resins), compositions based on allylic compounds, divinylbenzene and its derivatives. Oligoester acrylates are used as construction materials in the aircraft industry (as fiber glasses), paint-and-varnish materials and hermetics, stomatological materials (fillings, protection varnishes, materials for prosthetics) and modern liquid-crystalline systems. Since maleate–styrene resins contain a volatile toxic component (styrene), these polymers are of limited utility. Other classes of polyunsaturated compounds are of even more limited use. For example, divinylbenzene is used primarily in the synthesis of polymeric substrates for ion-exchange resins.

The TRP polymers are infusible and insoluble. These valuable properties are common to all polymers formed by any type of three-dimensional polymerisation, including non-radical polymers (for example, polycondensation of epoxide or phenol–formaldehyde resins). The advantages of TRP are both high polymerisation rates at rather low temperatures and the fact that various specific (associated with the chain nature of the process) highly efficient methods are available, which allow one to influence the TRP rate just in the course of radical polymerisation. These methods are: (1) the use of initiators (organic peroxides, azodinitriles, *etc.* at concentrations of 10^{-3} – 10^{-2} mol litre $^{-1}$), which enable one to reach very high TRP rates (10^{-2} – 10^{-3} mol litre $^{-1}$ s $^{-1}$) at moderate temperatures (300–350 K); (2) the use of inhibitors (stable free radicals, quinones, haloids, nitro compounds, *etc.* at concentrations of 10^{-4} – 10^{-2} mol litre $^{-1}$), which allow one to suppress TRP within a predetermined period of time τ (induction period) in order to prevent premature spontaneous polymerisation, particularly, in the course of technological processes; (3) the use of external sources of initiation (light or radiation), which enables one to start or terminate the TRP process at any temperatures (including below room temperature) at any instant of time and to control the TRP rate within any limits by decreasing or increasing the irradiation intensity. In the last-mentioned case, it is possible to reach high rates such that highly reactive monomers (for example, oligoester acrylates) are virtually instantaneously cured into thin films, which is of considerable importance, for instance, in solving the problem of freezing of liquid-crystalline structures.

Three-dimensional radical polymerisation can involve only unsaturated compounds (monomers, oligomers) whose molecules contain two or more double bonds. Only in this case does polymerisation afford linear chain structures (primary carbon chains) bearing one (if the starting monomer contains two multiple bonds per molecule) or more (if the number of multiple bonds is larger than two) double bonds that remain intact per unit (pendant vinyl groups), which serve as centres of branching and cross-linking of carbon chains to form a network. Further polymerisation of these vinyl groups gives rise to secondary structures (first branched structures and then three-dimensional networks) in which carbon chains are cross-linked to each other by cross-bonds, the starting molecules located between the vinyl groups (oligomeric blocks) serving as such cross-links. Generally, the latter are heteroatomic chains consisting of two or more carbon atoms and two or more heteroatoms (oxygen, nitrogen, sulfur, phosphorus, *etc.*).

Figure 1 shows successive stages of TRP exemplified by monomers containing two vinyl groups each. Apparently, the final structure is a macromolecular three-dimensional network. Hence, polymerisation of such polyfunctional compounds is called three-dimensional polymerisation. Network junctions are of the utmost importance as characteristics of highly cross-linked macromolecular structures, because it is the junction mobility that controls the relaxation properties of polymeric materials, which,

Figure 1. Successive stages of TRP of monomers containing two vinyl groups each; (a) the initial state, (b) primary (non-branched) polymer chain containing pendant double bonds, (c) fragment of the network with an incomplete structure (conversion < 1), (d) fragment of the final network (conversion is ~ 1); (1) vinyl groups, (2) oligomeric blocks, (3) secondary or tertiary carbon atoms containing substituents H or R, R_i is the radical of the initiator.

in turn, determine their main physical–mechanical characteristics. It can be seen that TRP gives rise to trifunctional junctions. Two or three interjunction chains per junction are very short rigid carbon chains $-\text{CH}_2-$, whereas the third heterochain (best suited for constructing a cross-linked structure) is longer and more flexible due to the presence of heteroatoms (in particular, oxygen). In the worst situation, this chain is also rigid, for example, in monomers of divinylbenzene, whose molecule contains the rigid aromatic $-\text{C}_6\text{H}_4-$ fragment and is devoid of heteroatoms.

The above-described topological feature is typical of polymer networks formed in TRP. Other types of polymerisation, for example, non-radical three-dimensional polymerisation (polycondensation) of compounds devoid of double bonds, afford products in which two short carbon chains are absent, because the latter can be generated only through the radical-initiated cleavage of multiple bonds. Catalytic hardening of diepoxides gives rise not to $-\text{CH}_2-$ but to $-\text{OCH}_2-$ heterochains, which, being also short, are much more flexible. Hence, macromolecular networks formed in the course of TRP, all other factors being the same, should be characterised by rigid structures and low relaxation ability. In certain cases, this is an advantage, whereas in other cases this is a drawback. Networks can be rather easily modified by copolymerisation with the use of comonomers, which contain only one double bond per molecule and are able to alternate under given conditions (copolymerisation constants for the monomers r_1 and r_2 are lower than unity). In this case, short interjunction carbon chains are elongated, but the volume concentration of the network junctions simultaneously decreases.

Three-dimensional radical polymerisation is a specific process. Thus, a homogeneous reaction system is transformed into a microheterogeneous system (microgel, nanodispersion) consisting of cross-linked polymer particles, which are rather weakly linked to each other by crossing chains, virtually from the very beginning of the polymerisation. These particles serve as autonomous microreactors in which further polymerisation proceeds. The particles remain discrete upon the completion of the polymerisation process. This is responsible for the specific morphology of TRP products as a nanodispersion of highly cross-linked particles (grains) separated by interlayers of a poorly cross-linked (defect) polymer (Fig. 2).

Figure 2. Morphology of TRP products as highly cross-linked particles separated by interlayers of a lowly cross-linked polymer.

The above-mentioned features complicate the TRP process. Therefore, the elucidation of the mechanism of TRP called for the development of a special methodology and new theoretical research in the field of radical polymerisation. As a result, TRP was classified as a special case of radical polymerisation, which could not be interpreted within the framework of the commonly accepted notions.

The basic research into the TRP mechanism was completed in 1977,¹ when the microheterogeneous model was proposed. These new concepts were experimentally supported by a series of systematic studies of the kinetics and mechanism of curing of oligoester acrylates. The latter proved to be very convenient model compounds for such studies, because the procedure for their synthesis enables one to vary the chemical composition and the length of oligomeric blocks over wide ranges in a desired fashion, while the terminal groups (methacryl or acryl), which are able to undergo polymerisation, remain intact.

Below are given the chemical formulae of several types of oligoester acrylates, which served as the basic compounds for revealing the fundamental features and mechanism of TRP.

Oligoesters containing unsaturated terminal groups, which are able to undergo TRP, can be described by the general formula

where the substituents R^1 , R^2 and R^3 correspond to saturated dicarboxylic acids, polyols and unsaturated monocarboxylic acids, respectively; $n = 0, 1, 2, \dots$ (preferentially, $n \leq 2$). For oligomers of the first type, $\text{R}^2(\text{OH})_2$ is generally a diol $[(\text{CH}_2)_m(\text{OH})_2]$, $m = 1, \dots, 10$ and $\text{R}^3\text{CO}_2\text{H}$ is generally acrylic or methacrylic acid. Phthalic, adipic, sebacic, thiodivaleric and carbonic (used as COCl_2) acids can serve as $\text{R}^1(\text{CO}_2\text{H})_2$. In the case of carbonic acid, the oligoester fragment of molecule **1** includes not only ester groups $[-\text{C}(\text{O})\text{O}-]$ but also carbonate groups $[-\text{OC}(\text{O})\text{O}-]$ possessing specific properties. Hence, oligoester acrylates of this type are considered as a special class and are called oligocarbonate (meth)acrylates.¹² For this type of oligoester acrylates, the functionality in the TRP process (f) determined by the number of terminal groups (multiple bonds) in the molecule, which can be involved in polymerisation, is equal to two.

Oligoester acrylates of the second type described by formula **1** contain polyol $\text{R}^{2'}(\text{OH})_m$, where $m > 2$ (generally, glycerol with $m = 3$ or pentaerythritol, xylitol with $m > 3$) instead of diol $\text{R}^2(\text{OH})_2$. For such oligoester acrylates, the functionality in TRP is 3 (or larger). Correspondingly, the volume-averaged concentration of the macromolecular network junctions in the polymer increases (compared to oligoester acrylates of the first type).

Different reactions resulting in the introduction of various fragments, such as

the urethane groups, the symmetrical triazine ring, phosphorus-containing groups and metals, into compounds **1**,¹¹ give rise to oligoester acrylates of the third type.

III. Methodological basis of three-dimensional radical polymerisation

Beginning in 1960, systematic studies on the synthesis of various oligoester acrylates with variable structures were carried out by researchers under the supervision of A A Berlin. The results of these studies not only stimulated fundamental investigation but also gave impetus to the development of new (and also to the improvement of known) experimental techniques for studying the kinetics and mechanism of TRP (including structure–physical studies of polymerisates). The necessity of developing such techniques was dictated by the fact that conventional methods (gravimetry, dilatometry, molecular-mass distribution measurements, *etc.*) are inefficient in studies of TRP due to cross-linking of the reaction system in the early stages of polymerisation and the insolubility of the polymer formed.

Calorimetry,^{13–25} spectroscopy,^{13, 23, 26–34} densitometry¹³ and other kinetic methods^{13, 24, 35–57} proved to be most efficient in studies of the kinetics and mechanism of TRP as well as of the structure–physical features of highly cross-linked polymers.

1. Calorimetry

High-precision isothermal microcalorimetry using Calvet calorimeters finds wide application. Studies with the use of DSC non-isothermal calorimeters followed by complex mathematical treatment of experimental data give less reliable results. High heats of polymerisation ($\Delta H = 42–92 \text{ kJ mol}^{-1}$) are virtually independent of the conversion. Hence, only the velocity of heat evolution dQ/dt in the course of polymerisation can be continuously recorded with high accuracy by identifying this velocity with the polymerisation rate

$$W = -\frac{d[M]}{dt} \equiv \frac{dQ}{dt}.$$

The difference between the initial and running concentrations of the monomer $[M_0] - [M_t]$ is equal to the instantaneous quantity of liberated heat Q divided by ΔH of the monomer. In the case of copolymerisation, when

$$[M] = \sum_i M_i$$

and

$$\Delta H = \sum_i H_i,$$

the application of calorimetry to kinetic measurements is limited to azeotropic systems characterised by constant compositions of the monomer mixture and copolymer in the course of copolymerisation. For example, copolymerisation of the compound M_1 containing reactive styrene groups with the compound M_2 containing the methacryl groups in a molar ratio $[M_1]:[M_2] \simeq 1$ afforded a copolymer consisting of alternating units (because the copolymerisation constants correspond to the condition $r_1 \simeq r_2 < 1$), whose composition is independent of the conversion. In this case, the molar heat of copolymerisation can be calculated by averaging the heats of homopolymerisation of both monomers

$$\Delta H = 0.5(\Delta H_1 + \Delta H_2).$$

Then

$$[M] = [M_1] + [M_2] = \frac{2Q}{\Delta H_1 + \Delta H_2}$$

and

$$[M_1] = [M_2].$$

Most data on the TRP kinetics published in 1960–2003 were obtained by calorimetric methods.

Considerable progress has been made in the calorimetry of TRP, particularly in studies of photochemically initiated fast processes. The use of high-precision quick-response photocalorimeters, for example, a DSC-7 differential scanning calorimeter, Perkin-Elmer, Norwalk and CT,¹⁵ photocalorimeters¹⁵ equipped with a monochromatic photoaccessory, allows one to perform measurements in a second-scale range and, consequently, to record the kinetics of very fast TRP processes not only in the steady-state mode (during photoinitiation) but also in the post-effect mode (after termination of photoinitiation) at any stage of polymerisation (especially, at high conversions). Such a combination of steady- and non-steady-state kinetic measurements is necessary for estimating the rate constants of elementary stages of chain propagation and termination (k_p and k_t , respectively) as functions of the conversion (C). The results of such calculations are used as components of the database for macromolecular design.

It should be noted that the parameters $k_p = f(C)$ and $k_t = \varphi(C)$ for TRP (for oligoester acrylates) were experimentally measured for the first time in the 1960s.^{13, 24, 25}

2. IR spectroscopy

For kinetic studies of TRP, second in importance to calorimetry is the IR spectroscopic method of the determination of the instantaneous concentration of double bonds. In the Real-Time Infrared (RTIR) version, this method (1430, Perkin-Elmer, Norwalk and CR spectrometers) proved to be even faster than the photocalorimetric method. It enables one to solve the same problems of the stationary and non-stationary kinetics in an even shorter time. For example, the instantaneous concentrations of double bonds in acrylates were measured very rapidly (20 spectra per second)⁸ from the peak at 811 cm^{-1} .²⁶ The main source of errors in IR spectroscopy as applied to TRP is associated with the distortion of the spectral shape, which increases as the conversion increases due to cross-linking of the matrix. The latter is tantamount to a change in the calibration in the course of transformation. Generally, this problem can be solved to a greater or lesser extent on the basis of choosing spectral lines which show the least changes with increasing conversion.

3. Densitometry

Densitometric methods of kinetic measurements, particularly those on the basis of flotation and titration, proved to be convenient under the conditions of TRP. Densitometric methods are based on an increase in the density of polymerisation systems (from the density of the monomer up to that of the polymer) with increasing conversion. The difference between these values is 10%–20% of the density of the starting system. The density increases linearly with conversion. The deviations from linearity may appear only at high conversions in the case of very dense networks and high rates of TRP. Under these conditions, physical processes of structural relaxation may lag compared to the chemical addition reaction accompanying the contraction. Evidently, this complication is also inherent in dilatometry, which is based on measurements of the contraction of a polymerisation system in the course of TRP.²⁴

§In the plenary paper (*Photopolymerisation of functionalised oligomers*) presented at the International Conference on Chemistry and Physical Chemistry of Oligomers (September 9–14, 2002, Moscow–Chernogolovka), C Decker reported that this number could be increased to 50 spectra per second.

4. Other methods of kinetic measurements

Such methods as gravimetry, chemical analysis (determination of the concentration of double bonds),³⁵ dilatometry and some other techniques are employed with advantage and give excellent results in studies of radical polymerisation. However, substantial modifications of these methods were required to use them in the investigation of TRP. The first two methods deal with monomers isolated from reaction systems, and it is necessary to modify procedures for isolation, because conventional precipitation of the polymer cannot be performed due to cross-linking, while extraction may appear to be incomplete due to the presence of pendant double bonds. Hence, isolation should be preceded by the stage of de-cross-linking³⁶ (a very cumbersome and insufficiently selective process of destroying interchain cross-links, for example, by hydrolysis if cross-links contain ester or other bonds subjected to destruction by hydrolysis). The classical version of dilatometry is unsuitable for studies of TRP, because the system loses flowability in the early stages of polymerisation (at a conversion of less than 1%). Specially designed dilatometers are used, among which are long thin glass tubes (2–3 mm in diameter and 500–1000 mm in height), elastic dilatometers, etc. A very complicated differential dilatometric apparatus²⁴ equipped with two elastic cells and a high-precision detector of displacements proved to be most successful. This apparatus was used for performing the first non-stationary kinetic measurements of TRP processes and determining the dependences $k_p = f(C)$ and $k_t = \varphi(C)$.^{13, 25}

In recent years, specific methods in which the TRP process was monitored by indirect evidence associated with an increase in the viscosity, freezing of the molecular mobility of components of the reaction system, for example, of the unconsumed monomer (NMR spectroscopy^{37, 38}) or the addition of compounds, which are specially introduced as a molecular probe (fluorescence methods^{40–43}), have also gained acceptance. Compounds, which can undergo isomerisation in a TRP system, are also used as molecular probes.⁴⁴ If the activation volume in polymerisation is rather large, the isomerisation rate can serve as a measure of the free volume in the isomerisation system and, consequently, as an indirect characteristic of the conversion.

The use of isomerisable compounds, such as azobenzene and stilbene, as photochromic probes made it possible not only to observe an increase in the conversion in the course of TRP but also to judge the character of the free volume distribution in the system as well as to identify the microheterogeneous structure of the polymer network formed.⁴⁴

Methods based on light scattering are of particular importance in studies of the mechanism of TRP, because they allow one to observe the evolution of the structural microheterogeneity in the course of TRP.^{11, 45–53} The sizes of strongly branched macromolecules and microgels in the pre-gel state can be estimated with static and dynamic light scattering.^{20, 22, 54}

5. ESR method

Since free radicals $R^\bullet$ in cross-linked reaction media have long lifetimes (τ_R), the concentrations of $R^\bullet$ can be directly measured by ESR.^{11–13, 45, 50, 57–70} The use of ESR proved to be particularly efficient in the following fields of investigation: studies of the kinetics of accumulation^{11, 13, 45, 61, 62} and decay^{11–13, 45, 63} of free radicals and structure–physical studies.^{11, 45, 50, 65–70}

a. Studies of the kinetics of accumulation of free radicals in a non-stationary mode

In the case of the thermal decomposition of initiators (organic peroxides) in partially cured oligoester acrylates (30%–70% conversion), the temperatures of the process can be chosen in such a way that the kinetics of accumulation of $R^\bullet$ can be recorded by ESR over 10–20 min. For a non-stationary mode, this kinetics can be described by the following classical formula:

$$[R^\bullet] = \sqrt{\frac{W_i}{k_t}} \operatorname{th}(\sqrt{W_i k_t} t).$$

At short times

$$t \leq \frac{0.3}{\sqrt{W_i k_t}}$$

this formula is approximated by the equation

$$[R^*] \simeq W_i t,$$

at long times

$$t > \frac{1}{\sqrt{W_i k_t}}$$

this formula is approximated by the equation

$$[R^*] \simeq \sqrt{\frac{W_i}{k_t}},$$

which allows one to calculate W_i and k_t from the experimental data. The initiator and temperature can be chosen in such a way that once the stationary value of $[R^*]$ is attained, $[R^*]$ begins to slowly (at long times) decrease due to consumption of the initiator. Then, knowing the kinetics of this decrease, the rate constant of thermal decomposition of the initiator k_d can also be calculated. In this case, the efficiency of initiation can be estimated as

$$f = \frac{k_i}{k_d} = \frac{W_i}{[I]k_d},$$

where $[I]$ is the concentration of the initiator and k_i is the rate constant of initiation determined by the equation

$$W_i = k_i [I].$$

Therefore, this method enables one to determine k_i , k_d , k_t and f for TRP at high conversions and, correspondingly, to estimate the influence of cross-linking on chain initiation and termination. In the case of organic peroxides, k_t and f for oligoester acrylates decrease by factors of 10^6 – 10^7 and 25–50, respectively, as the conversion increases from 0% to 70%–90%. In the case of azonitriles as initiators, these values decrease by factors of 250–500.^{11, 13, 45, 61, 62}

b. Study of the kinetics of termination of accumulated free radicals

In studies of the kinetics of termination of accumulated (trapped) free radicals, photochemical or radiation initiation is used to prevent the undesirable thermal generation of R^* in the course of ESR measurements. Studies by ESR revealed important characteristic features. First, it was found that the kinetics of R^* death is described by the following complex equation:

$$[R^*] = f(t),$$

whose curve has bends at points $t_1, t_2, \dots, t_i$ ($i = 2-4$). In intervals between the bends, the kinetics are adequately described by the classical equation

$$-\frac{d[R^*]}{dt} = (k_t)_i [R^*]^2,$$

where $k_{t1} > k_{t2} > \dots > k_{ti}$. Second, the numerical value of k_{t1} correlates with the conversion and depends on the nature of the starting cross-linking monomer (oligomer). The factors controlling the flexibility of oligomeric blocks are of primary importance in these correlations. In a macromolecular network, the oligomeric blocks serve as interjunction chains, which link long carbon chains (*i.e.*, serve as interchain cross-links). The most important factors are the length of the oligomeric block and the presence of interatomic bonds characterised by low rotational barriers (for example, the replacement of the C–C groups by C–O–C leads to an increase in flexibility). Analysis of the termination kinetics of trapped R^* not only makes it possible to examine the mechanism of TRP but also enables one to obtain structure–physical information. Thus, bends in the $[R^*] = f(t)$ curves are indicative

of the microheterogeneity of a highly cross-linked polymeric matrix. The numerical values of k_{t1} serve as a measure of relaxation of a cross-linked structure at the molecular level.^{11–13, 45, 63}

c. Synchronic comparison of the $[R^*] = f_1(t)$ and $W = f_2(t)$ kinetic curves measured continuously

The polymerisation rate

$$W = f_2(t)$$

can be measured by any continuous method (preferentially, by high-precision kinetic calorimetry). Since

$$W = k_p [R^*] [M],$$

the current concentration of free radicals serving as chain carriers in the reaction system can be calculated from the instantaneous rate of TRP and the instantaneous concentration of the $[M]$ monomer according to the formula

$$[R^*]_2 = \frac{W}{k_p [M]}.$$

The concentration $[R^*]_2$ can be underestimated to any extent as compared to $[R^*]_1$ determined by ESR, because $[R^*]_2$ is the concentration of only those radicals, that are involved in chain propagation at a particular moment

If some radicals lose the ability to be involved in the reaction (for example, due to immobilisation in a highly cross-linked polymeric matrix), a synchronic comparison of the results of ESR measurements of $[R^*]_1$ with the results of calculations using kinetic data on $[R^*]_2$ makes it possible to determine the proportion of the radicals that lose activity

$$\gamma_R = \frac{[R^*]_1 - [R^*]_2}{[R^*]_1},$$

in a broad range of conversions and, consequently, to reveal the characteristic features of the changes in γ_R in the course of TRP. In the case of dimethacrylates, γ_R increases sharply once a certain (critical) conversion is attained. At moderate temperatures (20–70 °C), depending on the flexibility of the methacrylate molecules, this value varies from 10% (for very rigid molecules) to 50% (for very flexible molecules). The critical conversion increases as the temperature is raised.^{11, 13, 45}

d. Structure–physical studies by ESR

In studies of TRP products using paramagnetic probing with stable iminoxyl radicals externally introduced by vapour sorption,⁶⁵ two types of ESR spectra, *viz.*, narrow (2945.2–3024.8 A m^{−1}) and broad (5412.8–5651.6 A m^{−1}), are superimposed. This fact is interpreted as the manifestation of the microheterogeneity of TRP products. Thus, the narrow signal corresponds to defect microregions with a loose network (with a low concentration of junctions) and, correspondingly, with a high mobility of probe molecules (correlation time $\tau_c \ll 10^{-7}$ s), while the broad signal corresponds to microregions with low molecular mobility ($\tau_c \geq 10^{-7}$ s). When varying the temperature over a broad range (from −195 to +150 °C), the temperature range $\Delta T = T_2 - T_1$ (transition region) was found in which the intensity of the narrow signal increased at the expense of the intensity of the broad signal up to the complete disappearance of the latter at the upper limit ΔT (at T_2). Only the narrow signal was observed above T_2 . By contrast, only the broad signal was observed below T_1 . The state corresponding to the broad signal was interpreted as the glassy state, the state corresponding to the narrow signal was considered as the high-elasticity state, and ΔT was assigned to the α -transition region. Within the framework of this interpretation, the ratio between the intensities of the narrow (I_1) and broad (I_2) signals in the region of their superposition (ΔT)

characterises the ratio between the total microvolumes in the highly elastic and glassy states

$$\frac{I_1}{I_2} = \frac{\sum_{i=1}^m \Delta V_i}{\sum_{i=1}^n \Delta V_i},$$

where ΔV_i is the volume of the i th microregion, m , $(n - m)$ and n are the numbers of highly elastic and glassy microregions and their sum, respectively, and $\sum_{i=1}^n \Delta V_i$ is the total volume of the system.

Evidently, a smooth change in I_1/I_2 in a very broad range of ΔT (several tens degrees) can occur only if a microheterogeneous system consists of a large set of subsystems (microregions ΔV_i) including n different types of ΔV_i , each being characterised by its own (local) glass transition temperature T_{gi} , which successively changes in the series $\Delta V_1, \Delta V_2, \dots, \Delta V_n$. For example, $T_{g1} > T_{g2} > \dots > T_{gn}$. If n is rather large, a change in I_1/I_2 is smooth (without jumps). Apparently, the value of ΔT corresponds to the difference $T_{g1} - T_{gn}$ and, consequently, characterises the degree of microheterogeneity of TRP products (n is the number of subsystems ΔV_i , which differ by T_{gi} ; ΔV_i with higher degrees of cross-linking have higher local temperatures T_{gi}).

For oligoester acrylates,⁶⁵ ΔT values were estimated and their evolution in the course of TRP was traced. It was found that the degree of microheterogeneity characterised by the parameter ΔT increases with increasing conversion but only to a certain limit reached at $C \simeq 50\%$.

Other applications of ESR to structure–physical studies of TRP products, including radiation and diffusion probing, were described in the monographs^{11,45} and original publications.^{50,66–69}

A simple method was proposed for the identification of the structural heterogeneity of highly cross-linked methyl methacrylate–ethylene glycol dimethacrylate (EGDMA) copolymers.⁷⁰ The radicals accumulated in the polymer network were used to study the permeation of oxygen molecules by ESR. It was found that the permeability coefficient is maximum at the EGDMA concentration of ~ 70 mass %, which indicates that the porosity of the network increases with increasing concentration and reaches a maximum at the above-mentioned concentration of EGDMA.

This method can be considered as diffusion probing with oxygen molecules, which enables one to identify very small microheterogeneities.

6. NMR method

Nuclear magnetic resonance has proved to be an efficient method for studying chemical structures, molecular mobility and intermolecular interactions in high-molecular-weight compounds. However, this method is of limited use for studying TRP products because of their insolubility and non-fusibility. Of the other NMR techniques that are available, pulse NMR, broad-line NMR, and high-resolution cross-polarisation magic-angle spinning ¹³C NMR spectroscopic methods appeared to be the most efficient.^{37,38,43,45,59,71–73}

Studies of oligoester acrylates by pulse NMR demonstrated⁷¹ that the kinetics of the magnetisation decay includes at least two modes (fast and slow), whose contributions can be rather precisely separated due to a large difference in their relaxation times. Analysis of the kinetics of the magnetisation decay for a series of samples with different conversions led to the conclusion that a polymerisation system is microheterogeneous starting from low conversions up to completion of TRP.

Broad-line NMR spectroscopy is generally used for revealing the temperature dependence of the second moment of NMR lines in a broad temperature range. Analysis of this dependence allows one to judge the presence of relaxation transitions and to estimate

the corresponding activation energies. Investigation of a model series of oligoester acrylates with specified variations in the structure revealed fundamental characteristic features.^{45,72} High-resolution cross-polarisation magic-angle spinning ¹³C NMR spectroscopic studies of an analogous series of oligoester acrylates provided data on the configurations of the units in a polymer network and on the structural microheterogeneity manifested in broadening of spectral lines.

7. Physical-mechanical and thermomechanical methods

Upon deformation (ε) of TRP products in the mode of uniaxial compression with low rates ($\dot{\varepsilon} = 10^{-4} - 10^{-3} \text{ s}^{-1}$), profiles of deformation curves can be recorded in the range of $0 \leq \varepsilon \leq 0.5$ including the region of the transition from the Hook to the forced elastic deformation. Analysis of the profiles of deformation curves in this transition region allows one to draw justified conclusions about the structural features of highly cross-linked polymers, including their microheterogeneity. Thermomechanical curves $\varepsilon = f(T)$ in the region of the α transition are also suitable for an analogous analysis.

In the case of oligoester acrylates, physical-mechanical and thermomechanical measurements were carried out on a high-precision apparatus⁷⁴ specially designed for studying mini-samples ($\sim 0.1 \text{ g}$). These measurements were performed on a large number of various oligoester acrylates, including polymers, which can be synthesised only in small amounts and exclusively in laboratory conditions.

Physical-mechanical measurement in the dynamic mode have also been successfully employed in studies of the structures of TRP products. For this purpose, relaxation time spectra have been analysed. It was found that the degree of microheterogeneity of the structure correlates with the width of the spectra in a certain frequency region.⁷⁵

8. Application of pulsed radiation in non-stationary kinetic studies of three-dimensional radical polymerisation

A new promising method for determining the rate constants of elementary steps of the polymer chain growth is based on the use of pulsed coherent radiation (laser as a source) for photoinduced polymerisation followed by the analysis of molecular-mass distribution of the polymer formed (gel chromatography).^{76,77}

For TRP, this method can be used only in the early stages of polymerisation until the gel point is reached and the strongly branched polymer is still able to dissolve in chromatographic eluents.

Nevertheless, measurements of k_p even in this very limited conversion range ($C \leq 1\%$ in block polymerisation, $C \leq 10\%$ in solution) are of great importance, because they allow one to judge the effect of the degree of branching of growing polymer chains on their reactivity, which is one of the fundamental problems of TRP.

9. Complex techniques

Three-dimensional radical polymerisation involves a chemical transformation (radical polymerisation) and a series of competitive physical transformations (aggregation, microsineresis, *etc.*), which actively influence the chemical process. Hence, it is best to study TRP using complex techniques, which enable one to perform both kinetic measurements and follow the structural evolution in the course of polymerisation or reveal the structural features of the final polymeric products.^{11,15,20–23,34,35,39,43,45,48,50,53,54,66–69,78–86}

Advances in studies of the TRP mechanism and its main characteristic feature, *viz.*, microheterogeneity, are associated primarily with the development and use of a methodological complex, which involves more than ten kinetic and structure–physical methods.^{11,45,53} For example, in order for the structure–physical and kinetic information to be obtained directly in the course of polymerisation, the following combined approaches were developed: spectroturbidimetry in combination with calorimetry, the use of calorimeter–dielcometer, molecular labels and

IR spectroscopic monitoring of the kinetics of three-dimensional copolymerisation.^{48, 78–82} In some cases, not only known procedures were combined but also original techniques were developed. Among these methods are the detection of the local redistribution of an initiator using radiation probing in combination with diffusion probing with paramagnetic NO molecules.^{11, 45, 50, 66–69}

Studies of TRP by complex methods are being extensively developed.^{15, 20–23, 34, 35, 39, 43, 54, 83–86}

IV. Kinetic features of three-dimensional radical polymerisation

1. Characteristic features of polymerisation in a cross-linked polymerisation system at high conversion

All TRP processes follow the same scheme. The initial polymerisation rate W_0 is not constant even in a very narrow conversion range $0\% < C < 5\%$ and it increases virtually from the very beginning with increasing C . At a certain value of $C = C_{\max}$, the rate reaches maximum $W_{\max}$ followed by sharp autoretardation of TRP up to complete termination at $C = C_{\lim} < 100\%$. Apparently, both autoacceleration at the first stage of TRP at $0 < C \leq C_{\max}$ and autoretardation at the second stage at $C_{\max} < C \leq C_{\lim}$ should be interpreted within the framework of the diffusion kinetics. As the diffusion mobility of the reagents is frozen by the cross-linked structure formed in the reaction medium, first faster elementary steps (chain termination, k_t) and then slower elementary steps (propagation, k_p) become diffusion-controlled. Because of this, first autoacceleration takes place due to a decrease in effective k_t followed by autoretardation due to a decrease in effective k_p .

An analogy can be drawn with the well known gel effect, which takes place in usual linear bulk polymerisation of some monomers [for example, of methyl methacrylate (MMA)] and also gives rise to autoacceleration–autoretardation, because it has the same physical causes, *viz.*, freezing of diffusion mobility of the reagents to the level at which the elementary steps become diffusion-controlled, and their effective rate constants decrease as the diffusion hindrance increases. The only difference is the mechanism of freezing of diffusion mobility, which leads to substantial quantitative differences for TRP, both processes being qualitatively analogous.

In linear polymerisation, double bonds remain only in the monomers up to the end of the polymerisation process. Hence, the diffusion control over the processes involving monomer molecules (chain propagation) takes place only at very deep stages of polymerisation, when the polymer–monomer mixture begins to transform into the glassy state. In TRP, the starting molecules contain two or more double bonds. The addition of one of these bonds to the growing cross-linked network gives rise to pendant double bonds with substantially limited mobility. Hence, not only chain termination but also chain growth in TRP becomes diffusion-controlled even at low conversions. As a result, autoacceleration slows down. A comparison of autoacceleration for MMA and dimethacrylates (DMA) shows that the $W_{\max}/W_0$ ratio for MMA is 10–20 times larger than that for DMA, whereas dW/dC in the region characterised by the highest level of autoacceleration is 100–200 times larger than the corresponding value for DMA and dW/dC sharply increases with increasing conversion (for DMA, dW/dC is nearly constant throughout the autoacceleration region $0 < C < C_{\max}$).

The specific mechanism of freezing of the diffusion mobility in TRP is manifested also in specific kinetic features related to the correlation between the reactivity of the initial molecules and their physical (conformational) properties (length of the molecule, rotational barriers of the atomic groups). These characteristic features were analysed for a large number of TRP objects involving oligoester acrylates, because the method for their synthesis allows one to vary the molecular structure over a very wide range. It should be noted that only one particular parameter (for example, the length) can be varied, all other parameters (the

nature of the groups capable of undergoing polymerisation, the nature of the groups responsible for the internal rotation barriers and, finally, the flexibility) being unchanged. By contrast, the internal rotational barriers can be varied, all other parameters being constant. The reactivity of TRP monomers, which is characterised by the parameters W , $W_{\max}$, $C_{\max}$, and $C_{\lim}$ (where W is instantaneous polymerisation rate in the range $W_0 < W < W_{\max}$) at $T = \text{const}$, was found to increase with increasing length of oligomer blocks of the starting molecules and increasing flexibility, which is characterised by barriers to internal rotation provided that the nature of reaction centers (double bonds) is unaltered. The dependence of the above-mentioned physical (conformational) properties of the initial molecules on the reactivity becomes sharper with increasing conversion, the parameters $W_{\max}$, $C_{\max}$ and, particularly, $C_{\lim}$, being most sensitive.

The kinetic features of TRP are illustrated in Figs 3–7. The reactivity is expressed in terms of the reduced rate $W/[M]$ ($[M]$ is the instantaneous concentration of the monomer, which was measured using a specially designed high-speed kinetic calorimeter (Fig. 3) and a high-precision DAK-1-1 kinetic Calvet calorimeter (Figs 4–7)). The parameters associated with the nature of the monomers (oligomers), *viz.*, the length of the chain linking the terminal methacryl groups (oligomeric block) and internal rotation barriers of the atomic groups of the oligomeric block, control the mobility of cross-linking chains of macromolecular networks formed in the course of TRP. It is these oligomeric blocks that become one of three cross-linking chains with trifunctional junctions once both methacryl groups of dimethacrylate are involved in the reaction. Since two other cross-linking carbon chains are very short and rigid, it is the third chain that provides junction relaxation controlling the molecular mobility of a highly cross-linked reaction medium. Curves 1, 2, 4 and 5 in Fig. 3 correspond to analogous (with the same set of rotation barriers) DMA with successively increasing length of the oligomeric block. The reactivity sharply increases in the same order, particularly, at deep stages of transformation, so that the maximum conversion for DMA with the shortest oligomeric block $C_{\lim} \rightarrow 40\%$ (curve 1), whereas autoretardation in the case of DMA with rather long chains (curves 4 and 5) virtually disappears and $C_{\lim} \rightarrow 100\%$. Curves 3 and 4 correspond to DMA, which have

Figure 3. Kinetics of polymerisation of related molecules of different length (1, 2, 4, 5) and internal rotational barriers of molecules of comparable length (2, 3). $T = 70^\circ\text{C}$, benzoyl peroxide (1 mass %) as the initiator.

The following reagents were subjected to TRP: $M-(\text{CH}_2)_n-M$, $n = 4$ (BM; curve 1), $n = 10$ (DM; curve 2); $M(\text{CH}_2)_2\text{O}(\text{CH}_2)_2\text{O}(\text{CH}_2)_2M$ (TGM-3; curve 3); $M[(\text{CH}_2)_2\text{O}(\text{CH}_2)_2\text{O}(\text{C})-Z-\text{C}(\text{O})\text{O}]_n(\text{CH}_2)_2$. $\text{O}(\text{CH}_2)_2M$, $n = 1$ (decandiol dimethacrylate orthophthalate, DMP-1; curve 4), $n = 2$ (DMP-2; curve 5). Here and in Figs 4–7, M is the $\text{CH}_2 = \text{C}(\text{CH}_3)\text{C}(\text{O})\text{O}$ group and Z is the fragment of orthophthalate.

Figure 4. Kinetics of copolymerisation of the molecules of different types; (1) homopolymerisation of TGM-3, (2) homopolymerisation of DMP-8, (3) copolymerisation of TGM-3 and DMP-8 in a mass ratio of 1:1; (4) homopolymerisation of GMP-9 $M(CH_2CH_2O)_3(O)C-Z-C(O).(OCH_2CH_2)_3M$ serving as a model of a copolymerisation system with respect to the number of double bonds. $T = 50^\circ C$, dicyclohexyl peroxycarbonate (CPC) as the initiator, $[CPC] = 1$ mass %.

oligomeric blocks of similar lengths but differ by the set of internal rotational barriers. In decanediol dimethacrylate (DM, curve 2), only two ester groups are rather weakly hindered. In triethyleneglycol dimethacrylate (TGM-3, curve 3), not only rotations of the ester groups but also those of the ether bonds are weakly hindered and, as a result, the reactivity in the later stages of TRP increases.

Figure 4 shows the data on the dependence of TRP on non-trivial factors, which are also associated with the physical properties of the reaction medium. It appeared that the reactivities of binary systems of dimethacrylates of different length are not intermediate between the reactivities of each component but are higher than both of them (!) (*cf.* curves 1, 2 and 3). Curve 4 corresponds to dimethacrylate, which was specially chosen in such a way that the length of its oligomeric block was equal to the average length in the binary system (the nominal volume concentrations of the junctions of the macromolecular network, which were equal to the concentration of the double bonds in the starting mixture, were also equalised). As can be seen from curve 4, in this case the reactivity has an intermediate value and the unusual effect typical of mixtures of molecules of different length disappears.

The influence of external factors, which are not associated with the nature of the starting oligomers, *viz.*, dilution of the reaction mixture with inert solvents, addition of inhibitors and surfactants, is illustrated in Figs 5–7. It can be seen that good solvents (from the viewpoint of thermodynamic affinity) enhance the reactivity, whereas bad solvents (heptane) decrease the reactivity. Apparently, it is associated with the fact that the chain growth is diffusion-controlled even in the early stages of polymerisation due to microheterogeneity. Hence, good solvents hinder microheterogenisation of the reaction mixture, whereas bad solvents facilitate chain aggregation and, consequently, increase microheterogenisation.

Figure 6a presents the kinetic dependences reflecting the influence of a rather strong inhibitor (X), *viz.*, benzoquinone, for which the rate constant of the linear chain termination is ~ 4 times as large as that of chain growth. Due to this difference in the rate constants, X is completely consumed in the early stages of TRP. The concentration of X was varied, the concentration of the initiator for each [X] being chosen so that the reactivity in the initial stages of TRP remained the same (see curves 1–3 at $C < 20\%$). A considerable increase in the difference in the reactivity as C increases cannot be explained without considering the microheterogeneous character of TRP. Actually, the microheterogenisation in the presence of X proceeds in such a way that the higher is the concentration of X, the larger is the number of

Figure 5. Effect of inert solvents on the kinetics of TRP using TGM-3 as an example.

The concentration of TGM-3 in a solution (vol.%): 100 (1), 80 (2), 60 (3), 50 (4), 40 (5), 90 (6), 80 (7), 70 (8), 30 (9), 40 (10). $T = 40^\circ C$, $[CPC] = 2.6 \times 10^{-3}$ mol litre $^{-1}$; the solvent: (2–5) benzene, (6–9) heptane, (10) acetonitrile.

Figure 6. Effect of the structural defects, which are generated upon termination of growing polymer chains by inhibitors, on the kinetics of TRP.

(a) polymerisation of GMP-9 at a fixed molar ratio initiator (CPC)/inhibitor (benzoquinone) = 1:1; increasing absolute concentrations of the initiator and inhibitor (mass %): (1) 2, (2) 4, (3) 6; $T = 35^\circ C$; (b) polymerisation of TGM-3 in the presence of inhibitors (trinitrotoluene, TNT), which act throughout the TRP process; $T = 60^\circ C$, dinitrile of azoisobutyric acid (AIBN) as the initiator, $[AIBN] = 0.02$ mol litre $^{-1}$; $[TNT] = 5 \times 10^{-3}$ (1), 3×10^{-2} mol litre $^{-1}$ (2).

autonomous microreactors (N) simultaneously acting in the reaction system^{11,45}

$$N_{\text{lim}} = \frac{(k_X[X])^2}{(f-1)k_p^2[M]_0}$$

Figure 7. Kinetics of polymerisation of TGM-3 in a solution containing stabilising additives.

Additives: (1–3) acetonitrile, 40% TGM-3; (4–6) heptane, 30% TGM-3; $T = 40^\circ\text{C}$, $[\text{CPC}] = 2.6 \times 10^{-3} \text{ mol litre}^{-1}$. The additive and its concentration (mass %): (1, 6) without an additive; (2) colloxylin, 0.1; (3) linoleic acid, 0.2; (4) polyisoprene, 0.4; (5) surfactant, 0.5.

This is consistent with the arrangement of curves 1–3. Thus, the higher is the concentration $[X]$, the higher is the reactivity.

The dependences shown in Fig. 6*b* illustrate the influence of the inhibitors of another type with rather low constants k_X ($k_X < k_p$), which act throughout the process rather than only at the initial stages of TRP. In this case, quadratic chain termination $R + R$ controlled by diffusion due to large sizes of R (macro-radicals, some of which are already bound to the network) is changed for linear chain termination $R + X$ involving small (mobile) molecules X , the latter process being diffusion-controlled to a much lesser extent. Hence, at a particular concentration of X (curve 2), the kinetics typical of TRP (autoacceleration–maximum–autoretardation) are transformed in such a way that the stage of autoacceleration completely disappears and the stage of autoretardation is shifted to very high C .

The results of experiments on the suppression of microheterogenisation by adding surfactants are presented in Fig. 7. These compounds prevent aggregation, which is the initial stage of the formation of microheterogeneous (microgel) particles. Besides, within the framework of the microheterogeneous mechanism, autoretardation at deep stages of TRP is also interpreted as being a result of aggregation of microgel particles.^{11,45} Three types of surfactants were used and the autoretardation stage was completely suppressed in all cases.

Therefore, the kinetic characteristic features at the later stages of TRP are determined by the conformational properties of the starting multifunctional monomers (oligomers), such as the length of the molecule and internal rotational barriers, and the reaction medium (diluent, surfactants, additives of inhibitors), which influence the aggregation of polymer chains and microgel particles as well as the length of primary polymer chains (inhibitors with $k_X > k_p$) and the character of chain termination (inhibitors with $k_X < k_p$). In the initial stages of TRP (initial rate W_0), the reactivity of the system at $C \rightarrow 0$ (non-cross-linked system) depends on other factors.

2. Early stages of three-dimensional radical polymerisation

At a very low conversion ($C < 5\%$), the reactivity of oligomers characterised by W_0 depends, generally, on the viscosity of the reaction system. The higher is the viscosity, the larger is

W_0 .^{11,13,45,87,88} As in the case of the reactivity at a high conversion, the physical properties (those, which control the level of intermolecular interactions in the reaction system) of the starting oligomers rather than their conformational properties have a dominant role, *i.e.*, the presence of centres of strong intermolecular interactions, which can form hydrogen dipole–dipole and other labile bonds, is of importance. Cooperative hydrocarbon groups characterised by very weak dispersion interactions can also serve as such centres [for example, the methylene groups $-(\text{CH}_2)_n-$ at $n > 4$ are involved in intermolecular interactions with the energy $E > 17 \text{ kJ mol}^{-1}$ comparable to the energy of hydrogen bonds and the phenyl groups are involved in intermolecular interactions with $E = 29–33.5 \text{ kJ mol}^{-1}$]. Generally, it is the ability of starting oligomers to form intermolecular interactions that controls the viscosity of the reaction system at low conversions. The viscosity exerts a trivial effect on W_0 , *viz.*, chain termination in the TRP process is diffusion-controlled even at $C \rightarrow 0$, and the diffusion depends on the viscosity. The higher is the viscosity, the lower is the effective constant k_t and, consequently, the larger is W_0 . A correlation between W_0 and the viscosity was found for a large number of compounds involved in TRP.

However, an anomalous reactivity was sometimes observed in the early stages of TRP.^{11,45,89,90} In some cases, for example, the rate constant of chain growth (measured by a non-stationary kinetic method in the region of $C < 5\%$) sharply decreases in the presence of very small additives of inert compounds, including the polymer formed. In other cases, the viscosity has an anomalous effect on W_0 , and W_0 increases rather than decreases as the viscosity decreases (for example, upon dilution with an inert solvent).⁹¹ These anomalies provide evidence in favour of the existence of yet another specific feature of TRP processes associated with the involvement of polyfunctional molecules, which differ from usual monomers by a rather large size. These molecules are prone to the formation of associates. The lifetime (τ) of labile associates, particularly, if molecules contain centres of strong intermolecular interactions (generally, several centres, taking into account the large size of the molecules), often reaches $\tau_{ph} \approx 3 \times 10^{-3} \text{ s}$, which is comparable to the characteristic time of the chain propagation ($\tau_{ch} \leq 10^{-4} \text{ s}$; the indices *ph* and *ch* denote ‘physical’ and ‘chemical’, respectively). Evidently, if $\tau_{ph} > \tau_{ch}$ and the degree of association of the starting oligomers is rather high, the chain growth takes place in an associated reaction medium. In this case, the packing (mutual orientation) of the molecules in the associate (if it is regular and characterised by the correlation time $\tau_0 > \tau_{ch}$) can be either favourable or unfavourable for growth

because all reactions of the addition of free radicals at the double bonds are sterically strictly controlled (as evidenced by very low steric factors $10^{-3}–10^{-5} \ll 1$). An anomalous change in W_0 is due to the presence of associates with either a favourable molecular packing (associate-plus) or an unfavourable molecular packing (W_0 increases with dilution; associate-minus). Recently, using polymerisation of specially chosen model compounds, which can form associates of both types (plus and minus), not only the existence of such associates and their effect on the kinetics of polymerisation processes have been proved but also the quantitative model of polymer chain growth in regular associates has been proposed.^{92–102} The average length of sequences of molecules oriented in a like manner in the absence of perturbing agents (several tens of molecules can be involved in such a sequence) were calculated from the kinetic data on the influence of small additives of comonomers incorporated into the associate as agents interrupting the above sequence.

Recently, processes for the formation of associates in a medium containing groups capable of being involved in strong intermolecular interactions (acrylates and methacrylates) were examined by molecular mechanics and molecular dynamics.^{101–104} These methods are based on the fundamental laws of

physics. Hence, the results of calculations by these methods are as convincing as the results of direct experiments and one can say about computer experiments. This is all the more important because the interpretation of the kinetic anomalies^{92–95} was made possible based on the hypothesis of the existence of associates with a regular molecular packing (*i.e.*, molecules oriented in a particular way) in a medium of acrylates and methacrylates undergoing polymerisation. In other words, this hypothesis assumes the existence of associates with a pronounced long-range order. However, direct experimental methods for the detection of such associates, *i.e.*, methods necessary for verification of the correctness of this hypothesis, are lacking. In this case, the results of computer simulation (experiment) are evidently of great importance. Let us consider these results in more detail.

The kinetic anomalies,^{89–106} which are presumably related to the formation of associates, are particularly pronounced in the polymerisation of higher alkyl acrylates (HAA) and higher alkyl methacrylates (HAM),^{92–95,100} which can be considered as models of monomers (oligomers) containing centres of strong intermolecular interactions. In the case of HAA, the kinetic anomalies are interpreted by postulating the formation of associates in which the mutual orientation of the molecules is favourable for chain growth (precursor). In the case of HAM, the formation of associates with the orientation of the molecules unfavourable for chain growth is postulated (anti-precursor). The correctness of these hypotheses was strongly supported by the results of experiments^{93,95,100} on the influence of small additives (one molecule per 100 molecules of the main monomer) on the rate of polymerisation of comonomers possessing the same ability to undergo polymerisation *via* double bonds (the acryl group for HAA and the methacryl group for HAM) but containing alkyl substituents of different length. A very strong negative effect of such additives in the case of HAA was interpreted by assuming that the comonomer molecules are readily incorporated into the pre-associate but simultaneously disturb the positional (or) orientational order due to the difference in the size of alkyl fragments. As a result, due to an unfavourable orientation of the double bonds, the molecules of additives terminate the polymer chain growth developed within the precursor. Based on these concepts, the computational apparatus was devised, which made it possible to evaluate the average number of molecules in the precursor (this number increases from 10 to 40 as n in the alkyl fragment $-(CH_2)_n-$ increases from 4 to 12) and the ratio between the rate constants of the chain growth within and outside the associate (from 50 to 200 in the same range of changes in n). The most probable reason for an increase in these parameters is the increase in the energy of intermolecular interactions in the homological series of HAA due to cooperation of weak dispersion interactions in alkyl fragments to form a centre of strong intermolecular interactions and, correspondingly, an enhancement of stability of the precursor.

The positive effect of very small additives of related comonomers observed in the case of HAM was interpreted as an effect of degradation (or a decrease in stability) of anti-precursors by molecules incorporated into the associates with a different positional or orientational packing.

The correctness of these hypotheses was confirmed by computer simulation,^{101–104} as evidenced by the following results. It was demonstrated that higher alkyl acrylates and alkyl methacrylates, starting from butyl esters, can form regular associates, in which the ester molecules (or their hydrocarbon fragments, ester groups and double bonds) are mutually positionally and orientationally ordered (Fig. 8). These regular associates were related to kinetically active associates, whose existence was postulated in the interpretation of the kinetic anomalies occurring in HAA and HAM polymerisation.

The double bonds in the HAA and HAM molecules are ordered both within associates and with respect to the double bonds of the adjacent associates. The order of the double bonds within the associates is virtually identical to that in associates of

Figure 8. Monomolecular sectional view of the medium layer of a regular associate of NA (a) and NMA (b) in polymerisation of HAA and HAM.

nonyl acrylate (NA), nonyl methacrylate (NMA) and other alkyl acrylates and alkyl methacrylates (see Fig. 8), whereas the inter-associate order of the double bonds in alkyl acrylates and alkyl methacrylates, including NA and NMA, is substantially different (Table 1).

It is believed that it is these characteristic features of the interassociate order of the double bonds of associated molecules that are favourable for polymerisation of NA and other higher alkyl acrylates and, by contrast, are unfavourable for polymerisation of NMA and other higher alkyl methacrylates. Apparently, these factors control the addition of polymeric radicals at the double bonds of the monomers. It was found that the incorporation of additive molecules into associates not only changes the positional order of the double bonds in the sites of localisation of the additive molecules by increasing the distance between the carbon atoms at the double bonds to 0.6–0.9 nm but also changes the molecular dynamics of all other associates. Molecular dynamics simulation of the thermal motion of molecules in regular associates of HAA and HAM showed that the inclusion of the molecules of BA or ethylhexyl acrylate (EHA) [BMA or ethylhexyl methacrylate (EHMA)] into regular NA (NMA) associates leads to their destabilisation (Fig. 9) by shifting

Table 1. Average distances between the carbon atoms at double bonds (δ) and the angle characterising the mutual orientation of the double bonds (θ) in the adjacent molecules in associates of alkyl (meth)acrylates (δ_a , θ_a) and between associates (δ_m , θ_m).

Associates	δ_a /nm	θ_a /deg	δ_m /nm	θ_m /deg
n-Alkyl acrylates				
BA	0.352	3	0.392	81
NA	0.343	1	0.365	88
DcA	0.340	1	0.358	89
CA	0.403	0	0.379	92
n-Alkyl methacrylates				
BMA	0.348	3	0.675	177
NMA	0.378	1	0.684	183
DcMA	0.358	1	0.624	182
CMA	0.392	1	0.648	182

Note. The distances δ and the angle θ in the models were determined with an accuracy of ± 0.001 nm and $\pm 2^\circ$, respectively; BA is butyl acrylate, DcA is decyl acrylate, CA is cetyl acrylate, BMA is butyl methacrylate, DcMA is decyl methacrylate, CMA is cetyl methacrylate.

the dissociate $\rightleftharpoons$ associate equilibrium toward the non-associated monomers. For n-alkyl acrylates, this should lead to a decrease in the concentration of precursors and to a corresponding decrease in the polymerisation rate. In the case of HAM, the inclusion of the above-mentioned molecules should decrease the concentration of anti-precursors and increase the polymerisation rate.

The results of computer simulation of fluoroalkyl (meth)acrylates also confirmed the existence of rather stable structures influencing the kinetics of polymerisation processes.

The hypothesis,¹⁰⁵ which was proposed in the 1950s after the discovery of the kinetic anomalies in polymerisation of the monomers crystallised in the phase transition region, was then extended to the high-temperature region far from the phase transition due to the discovery of new kinetic anomalies.^{89–91,106} Its computational apparatus was devised on the basis of experiments on specially chosen model monomers and their mixture.^{93–95,100} This hypothesis can be considered to be reliable as applied to TRP.

In conclusion, let us note the brave attempt¹⁰⁷ to represent the associated structure of a reaction medium as pseudopolymer chains with a limited lifetime τ_{ph} (blinking chains), whose units are linked *via* intermolecular interactions. For example, these chains can appear upon binding of alcohol molecules to form linear associates through hydrogen bonds.^{108–110} It is assumed that the behaviour of blinking chains is somewhat analogous to

Figure 9. Temperature dependence of the distances between the double bonds (δ_a) in associates.
(1) BA, (2) NA + BA, (3) NA.

that of usual macromolecules formed by covalent bonds. Hence, these chains can be described using the concepts and approaches developed in the physics of polymers, including scaling approaches. For chemical reactions proceeding in such a pseudo-polymer medium, the relations were found in which the reaction order and other parameters reflect the characteristic features associated with the polymer statistics rather than with the laws of chemical kinetics.

V. Three-dimensional radical polymerisation as a tool of macromolecular design

In recent years, researchers involved in different fields of fundamental science (chemists, physicists, mathematicians), specialists in computer simulation and engineers have focussed their efforts on the macromolecular design, *viz.*, the chemical construction of macromolecules and the target synthesis of macromolecules with predicted structures and properties. In the area of highly cross-linked polymers formed by TRP, the macromolecular design is based on data from fundamental science, which made it possible to reveal the characteristic features of the kinetics and mechanism of TRP, whose distinguishing feature is the microheterogeneity. To use these data as an efficient tool of macromolecular design, it is necessary to transform them into mathematical (computer) models of TRP. Such models of TRP can be divided into two groups.

The first group of models developed in the period from 1977 to 1983 is based on the maximum simplified concepts.^{1,11,45} Microgel particles acting as autonomous microreactors are approximated by spheres of the average radius r . It is assumed that the polymerisation process is localised in the peripheral layer of this sphere (with the thickness h , which remains unchanged with conversion). The calculated estimates showed that the number of microreactors remains virtually constant in the course of the polymerisation, so that the conversion increases due to an increase in r . When r reaches the value at which the spheres come into contact with each other, their loose peripheral layers acting as efficient reactors partially overlap with each other and their cores, which consist of highly cross-linked polymers with the maximum conversion (and, hence, which cannot interpenetrate), are packed to form a tetragonal or (which is less probable) hexagonal structure. In this stage, the polymerisation process is localised (reaction zone) in cavities of the structure composed of spheres (more precisely, in the inner near-surface layer of these cavities with the thickness h). It is assumed that at a rather high conversion, these cavities are spherical (of the average radius r'). Evidently, r' decreases in the course of further transformation. Within the framework of this model (percolation model), the rate constants of all elementary steps (initiation, propagation, termination) do not vary with conversion, because the conditions in the reaction zone (in loose near-surface layers above the dense highly cross-linked polymer) remain unchanged during polymerisation and only the total volume of the reaction zone changes (first it increases until the spheres come into contact with each other and then decreases). Correspondingly, the overall (experimentally observed) reduced polymerisation rate $W/[M]$ first increases (autoacceleration) and then decreases (autoretardation). In this case, both stages can be described by the following simple mathematical expressions:

autoacceleration

$$W = W_0 \left(1 - \frac{C}{C_{lim}}\right) + W_r (4\pi N)^{1/3} h \left(\frac{3C}{C_{lim}}\right)^{2/3}, \quad (1)$$

where W_0 and W_r are the polymerisation rates in the starting reaction mixture and spherical layers with the thickness h , respectively, C is the instantaneous conversion, C_{lim} is the limiting conversion, N is the concentration of spherical microreactors (microgel particles, grains);

autoretardation

$$W = W_0 \left(1 - \frac{C}{C_{\text{lim}}}\right) + W_r (4\pi N)^{1/3} h^{2/3} \left(1 - \frac{C}{C_{\text{lim}}}\right)^{2/3}. \quad (2)$$

The region between autoacceleration and autoretardation cannot be described by such simple expressions.

The number of microreactors (microgel particles) formed in the reaction system reaches a constant value N_{lim} in the early stages of TRP (at $C < 1\%$). This parameter depends on both the kinetic parameters and reaction conditions.

In the absence of inhibitors,

$$N_{\text{lim}} = \frac{W_i k_t}{(f-1)k_p^2 [M]_0}, \quad (3)$$

where W_i is the initiation rate, f is the functionality and $[M]_0$ is the initial concentration of the monomer.

In the presence of the inhibitor X

$$N_{\text{lim}} = \frac{(k_X [X])^2}{(f-1)k_p^2 [M]_0}, \quad (4)$$

where k_X is the rate constant for the trapping of radicals as chain carriers.

Equations (1)–(4) indicate the manner in which the morphology of the polymer can be controlled. For example, a coarse-grained structure can be transformed into a fine-grained structure by increasing W_i or (and) adding additives X. The main advantage of this model is that it accounts for the microheterogeneous character of TRP.

Another group of mathematical (predominantly, computer) models deals with more complex equations.^{111–120} Generally, it is assumed that k_p and k_t depend on the conversion. The character of the dependences is established on the basis of the corresponding concepts of molecular physics. Some of the physical constants remain unknown and serve as fitting parameters in the further comparison of the results of calculations with experimental data. From the applied viewpoint, this semiempirical theory has certain advantages. Thus, the above-mentioned equations are suitable for planning macromolecular design (but they are of limited use due to the empirical origin of the parameters). In the best-developed model, the rate constants of elementary steps are described by the following equations:¹¹⁸

$$k_p = \frac{k_{p0}}{1 + \exp[A_p(1/v - 1/v_{cp})]},$$

$$k_t = \frac{k_{t0}}{1 + \{R_d k_p [M]/k_{t0} + \exp[-A_t(1/v - 1/v_t)]\}^{-1}}.$$

Here, k_{p0} is the true kinetic rate constant, *i.e.*, k_p in the absence of diffusion control; A is the parameter determining how fast the diffusion-controlled kinetic constant decreases with increasing diffusion hindrance; v is the average partial free volume of the system; v_{cp} is the critical free volume for the chain propagation reaction determined as the value of v at which $k_p = (1/2)k_{p0}$; $R_d k_p [M]$ is the component accounting for the contribution of the reaction-diffusion mechanism; $[M]$ is the instantaneous concentration of double bonds and R_d is the parameter characterising the reaction diffusion.

To calculate the partial free volume at a particular conversion, it is necessary to know the following six characteristics of the material: the densities of the monomer and polymer (ρ_m and ρ_p , respectively), their glass transition temperatures (T_{gm} and T_{gp} , respectively) and the differences between the expansion coefficients in the high-elasticity and glassy states (α_m and α_p).

The parameter R_d was evaluated¹²¹ from the results of non-stationary experiments (post effect) as follows:

$$R_d = \frac{k_t}{k_p [M]}.$$

VI. Critical conversion in three-dimensional polymerisation

The theory of polymer-network formation is one of the most important lines of investigation into the TRP mechanism. This theory has been developed in the studies of Dušek and co-workers,^{10, 115, 122–143} Kloosterboer,^{144–146} Boots and co-workers,^{113, 145–147} Macosko and co-workers,^{148–152} Lee and co-workers,^{153–156} Hamielec and co-workers,^{157–163} Chomppf and co-workers¹⁶⁴ and Okay and co-workers.^{114, 165–170} The results of these studies were generalised and analysed in the reviews.^{120, 170, 171}

Some concepts of the theory of network formation are based on the Flory–Stockmayer model of polymerisation processes (for example, of stepwise reactions). Attempts to apply these concepts to TRP-type chain polymerisation processes were based on doubtful assumptions and rough approximations. Recently, it has been demonstrated^{172–178} that calculations of the critical conversion α_c (gel point) for TRP with the use of the Flory–Stockmayer equations gave incorrect results even if these equations were specially adapted to this process. The equations, which work well for polycondensation (stepwise process), differ substantially from those derived in the studies^{172–178} specially for TRP (chain process). Expressions relating α_c to the kinetic parameters of TRP stages (initiation, propagation, quadratic and linear chain termination and chain transfer) were deduced in the studies.^{172–178} The problem was solved by the moments method followed by the generalisation of the numerical solutions in the form of equations. The starting model was based on the scheme of radical polymerisation including stationary-state conditions as the only assumption.

The critical conversion α_c in the formation of cross-linked polymers, which characterises the transition of the system from the flowable state to the state with the equilibrium modulus of elasticity, is an important parameter of the system both from the technological and theoretical standpoints.^{179, 180} The formation of an insoluble gel in technological processes complicates the preparation of polymers. By contrast, the relation between the critical conversion, on the one hand, and the structural and kinetic parameters of the process, on the other hand, enables one to prepare cross-linked polymers with required physical-mechanical characteristics. Theoretically, the gel point determines the fluidity threshold in the polymer system formed and, hence, it is important to reveal the dependence of this value on the kinetics of the process and structural characteristics of the product.

The problem of the determination of the critical conversion was solved by Flory and Stockmayer¹⁸¹ for polycondensation reactions of the type

which give rise to bonds between the functional groups A and B. The reactions can either be accompanied by elimination of by-products or proceed without the formation of the latter, groups A and B being either different or identical. If the number of functional groups per molecule of the starting reagents is larger than two, branched and cross-linked polymers can be generated. At a particular degree of conversion, higher-order (starting from the second) moments of the molecular-mass distribution of macromolecules approach infinity. This degree of conversion is called critical. The experimental critical conversions are determined from the results of viscosimetric measurements (the viscosity approaches infinity) or relaxation measurements (the appearance of the equilibrium modulus of elasticity). In recent years, the determination of the gel point on the basis of the frequency dependence of the relaxation modulus have gained wide acceptance.¹⁸² It is believed that the critical conversion corresponds to the equality of $G'(\omega)$ and $G''(\omega)$.

The critical conversion and the structure of the network depend on the character of the functional-group distribution for

the starting reagents,¹⁸³ which can be expressed in terms of the average ($\bar{f}_n$) and weighted average ($\bar{f}_w$) functionalities^{179, 183}

$$\bar{f}_n = \frac{\sum_i im_i}{\sum_i m_i}, \quad \bar{f}_w = \frac{\sum_i i^2 m_i}{\sum_i im_i}$$

where m_i are the concentrations of the starting reagents bearing i functional groups.

For polycondensation with related functional groups, it was found that

$$\alpha_c(\bar{f}_w - 1) = 1. \quad (6)$$

In the case of functional groups of different nature

$$\alpha_c^2 r (\bar{f}_{aw} - 1)(\bar{f}_{bw} - 1) = 1, \quad (7)$$

where r is the ratio between the concentrations of the interacting functional groups,

$$r = \frac{\sum_i im_{ai}}{\sum_j m_{bj}} < 1,$$

the indices a and b correspond to different types of functional groups.

The cross-linking of polymer chains is a special case. Generally, the critical conditions are expressed as follows:

$$\alpha_c(\bar{P}_w - 1) = 1, \quad (8)$$

where $\bar{P}_w$ is the weighted average degree of polymerisation of macromolecules subjected to cross-linking. It is implicitly assumed that the cross-linking can involve any unit of the polymer chain.

Equations (6)–(8) were derived by both the statistical method and kinetic calculations.^{179, 180} These equations were also supported by the experimental data. The prerequisite to their applicability is the absence of intramolecular reactions.

The three-dimensional polymerisation, which can be represented by the scheme

(M is the monomer, R_i is the active chain, the index i denotes the number of units in the chain), is generally described by Eqn (8), in which the critical branching proposed by Flory and Stockmayer^{181, 184} is used as α_c . The relation between α_c and the conversion was established by solving the kinetic equations of the consumption of the functional groups of monomers.¹⁸⁵ Hence, calculations were based on probabilistic considerations, which are of limited usefulness in the case of polymerisation.^{179, 180} The procedure for kinetic calculations of the gel point was developed in the studies.^{1, 11, 45, 180, 186–189}

In the studies,^{186–188} the gel point was calculated assuming

$$\frac{dN}{dt} = 0.$$

Evidently, these calculations should overestimate values, because, as in polycondensation, the second moments of the molecular-mass distribution (and, consequently, the functional-group distribution) approach infinity at lower conversions than the 'zero' concentration of polymer chains.^{179–181}

The correct requirement for the infinity of the second moment of the molecular-mass distribution was used in the studies.^{1, 11, 45, 180, 189} The following equations were derived:

$$\alpha_c = \frac{(k_t W_i)^{1/2}}{(n-1)k_p[M]_0}$$

and

$$\alpha_c = \frac{\{(k_t + k_t^1)[R] + k_m[M]\}^2}{k_p[M]\{(3k_t + k_t^1)[R] + 2k_m[M]\}}.$$

In these cases, the chain length was determined from the following kinetic parameters of the polymerisation process: the initiation rates W_i ; the rate constant of chain propagation (k_p), the rate constants of chain termination by disproportionation (k_t^1) and recombination (k_t) and the rate constant of chain transfer to the monomer (k_m); the functionality of the monomer (n). It should be noted that in the latter case, the conversion with respect to the monomer rather than with respect to the functional groups was considered as the degree of conversion. Besides, it was noted that the equations in the above-given form can be deduced only for special conditions.

The above-mentioned equations were not confirmed experimentally. However, their validity was not questioned by researchers, because it is known that these conditions are not realised in the case of three-dimensional polymerisation.^{1, 11, 45, 179, 180} Thus, intramolecular cyclisation proceeds rather vigorously due to fast chain growth by the radical mechanism and because of a low concentration of the chains in the early stages of TRP.^{179, 190} It is believed that repeated cross-linking within the same pair of chains (formation of multiple junctions and ladder macromolecular structures) also decreases the effective concentration of interchain cross-links thus increasing the critical conversion. Hence, the radical polymerisation can be considered as a typical microheterogeneous process.^{1, 11, 20, 45, 117, 168}

At the same time, polymerisation and polycondensation are radically different from the kinetic viewpoint.¹⁷⁹ A comparison of Eqns (5) and (9) shows that two functional groups are consumed in the course of the former reaction, whereas only one group is consumed in the latter case (in this reaction, the concentration of active centres remains unchanged). Hence, one functional group per monomer molecule is sufficient to prepare a polymer chain by polymerisation. In the polycondensation reaction of a monofunctional monomer, the chain is terminated. This fact casts doubt on whether the approaches, which were developed for studying polycondensation, can be extended to an investigation of polymerisation processes.

The study of living three-dimensional radical polymerisation demonstrated¹⁹¹ that Eqn (8) is not fulfilled in this case as well,¹⁹² although cyclisation is of little importance and the microheterogeneous character of the process is not manifested.^{192, 193}

This fact served as the basis for stating the problem, whose solution revealed the critical conditions (gel point) for TRP. The analysis carried out in a number of studies^{172–178} demonstrated that the critical conversion is related to the kinetic conditions of polymerisation in a complex way. Depending on the ratio between the rates of initiation and termination of a material chain, the gel point is determined by only one of the following parameters: (1) initiation rate, (2) termination rate. The former situation takes place if chain branching can occur, *i.e.*, at a high concentration of a multifunctional monomer, the process being substantially influenced by the kinetics of accumulation of active centres. In the latter case, the length of the material chain is of importance, because the number of pendant functional groups (probable branching points) per polymer chain is a controlling factor at a low concentration of the multifunctional monomer. However, the weighted average functionality of the starting monomer mixture is, on the whole, the governing factor.

The results of the solution of this problem are given in Table 2 in the form of equations for α_c in different processes. The criteria conditions limit the field of application of each equation. It should be emphasised that these equations are not analytical but were derived by generalising numerical solutions.

It is evident that the equations listed in Table 2 differ from all solutions obtained with the use of the Flory–Stockmayer theory. As mentioned above, an experimental comparison is hampered by side processes of the formation of small rings, which have a strong effect on α_c (shift toward higher values). However, under partic-

Table 2. Equations for critical conversion α_c .

Process	Φ_{22} small	Φ_{22} large	Criteria conditions
Living polymerisation, instantaneous initiation	$\frac{\alpha_c^2 \Phi_{22}}{I_0} \approx 1$	$\frac{\alpha_c^2 \Phi_{22}}{I_0} \approx 1$	$\frac{k_i}{k_p} > \sqrt{I_0 \Phi_{22}}$
The same + chain transfer	$\alpha_c \approx \frac{1}{2} \frac{k_X X_0}{k_p \Phi_{22}}$	$\frac{\alpha_c^2 \Phi_{22}}{I_0} \approx 1$	$\Phi_{22} > \frac{(k_X X_0)^2}{k_p^2 I_0}$
Living polymerisation, slow initiation	$\frac{\alpha_c^2 \Phi_{22} k_p}{W_i} \approx 1$	$\frac{\alpha_c^3 \Phi_{22}^2 k_p}{W_i} \approx 1$	$\frac{k_i}{k_p} > \sqrt{I_0 \Phi_{22}}$
The same + chain transfer	$\alpha_c \approx \frac{1}{2} \frac{k_X X_0}{k_p \Phi_{22}}$	$\frac{\alpha_c^3 \Phi_{22}^2 k_p}{W_i} \approx 1$	$\Phi_{22} > \frac{(k_X X_0)^3}{k_p^2 k_i I_0}$
Slow initiation, chain termination by recombination	$\alpha_c \approx 0.33 \frac{\sqrt{k_i W_i}}{k_p \Phi_{22}}$	$\frac{\alpha_c^3 \Phi_{22}^2}{W_i} \approx 1$	$\Phi_{22} > \frac{\sqrt{k_i^3 W_i}}{k_p^2}$
Slow initiation, linear chain termination	$\alpha_c \approx \frac{1}{2} \frac{k_{tY} Y_0}{k_p \Phi_{22}(0)}$	—	—
Replacement effect, chain termination through disproportionation	$\alpha_c = \frac{\sqrt{k_i W_i}}{k_{p2} \Phi_{22}}$	—	$\frac{k_{p1} \Phi_{22}}{\sqrt{k_i W_i}} < \frac{k_t}{k_{p2}}$

Note. Φ_{22} is the second moment of the functionality distribution for the starting reaction mixture (at $t = 0$); $\Phi_{22} \equiv \Phi_{22}(0) = \sum i(i-1)m_i$, where m_i is the initial concentration of i functional monomers (oligomers); W_i is the initiation rate; I_0 , Y_0 and X_0 are the initial concentrations of the initiator, inhibitor and agent of chain transfer, respectively; k_i , k_p , k_t , k_{tY} and k_X are the rate constants of initiation, propagation, quadratic and linear termination and transfer of the chain, respectively; k_{p1} and k_{p2} are the rate constants of propagation for free and pendant double bonds in the processes in which the reactivities of the starting molecules containing two double bonds change after the one of these double bond has reacted; $\varepsilon = k_{p2}/k_{p1}$.

ular conditions (for example, if the probability of cyclisation is low), it is nevertheless reasonable to perform such a comparison.

The results obtained with the use of these equations and equations based on the Flory–Stockmayer theory were compared with the results of experiments performed under conditions in which internal cyclisation is suppressed.^{176, 178} Two examples of such a minimisation are considered below.

Inhibited polymerisation of dimethacrylates. Radical polymerisation of triethyleneglycol dimethacrylate initiated by dicyclohexyl peroxydicarbonate in the presence of large amounts of inhibitors (benzoquinone or TNT) was carried out in cylindrical evacuated sealed tubes (250 mm in height and 3–3.5 mm in diameter). The conversion was detected from the contraction (shift of the meniscus was followed with an accuracy of 0.1 mm; the total shift at the instant of gel formation in the inhibition range under examination was 3–10 mm). The gel point was detected from the loss of flowability. A comparison with other methods showed that this approach gives a rather accurate estimate of the critical conversion.¹⁹²

In the region of the longest lengths of growing polymer chains (at the smallest parameters $k_{tY} Y$), there is a large discrepancy (several orders of magnitude) between the calculated and experimental critical conversions, but then these values converge as the chain length decreases ($k_{tY} Y$ increases), and the best agreement is attained with the use of the equation

$$\alpha_c = \frac{1}{2} \frac{k_{tY} Y_0}{k_p \Phi_{22}(0)}, \quad (10)$$

where k_{tY} is the rate constant of linear chain termination involving molecules of this inhibitor, Y_0 is the starting concentration of the inhibitor (at $t = 0$).

Calculations were also carried out with the use of the Flory–Stockmayer formula

$$\alpha_c = \frac{1}{\rho(\bar{P}_w - 1)}, \quad (11)$$

where ρ is the molar fraction of the cross-linking agent, $\bar{P}_w$ is the weighted average degree of polymerisation of primary polymer chains, *i.e.*, chains which can be generated in the absence of a cross-linking agent at the instant corresponding to the gel point. This value was determined by gel permeation chromatography at degrees of conversion lower than α_c followed by extrapolation to zero conversion.

Since the experimental values of α_c are overestimated primarily due to cyclisation¹⁷⁹ (interchain cross-linking of pendant double bonds), it is believed that the probability of cyclisation decreases as the length of the growing polymer chain decreases and $k_{tY} Y$ increases. Hence, a comparison with the experiment at the largest values of $k_{tY} Y$ demonstrated that Eqn (10) is most precise. At the same time, this result indicates that the above-described calculations gave the correct estimate of the critical conversion not only in the range of parameters where Eqn (10) is valid, but also in the range where all relations presented in Table 2 are true.

This is all the more important because the discrepancy between the experimental and calculated values of α_c is often¹⁹⁴ considered as a test for estimating the percentage of cyclic structures in polymer networks, α_c being calculated with the use of the Flory–Stockmayer formula (8). Evidently, the use of the relations presented in Table 2 enables one to eliminate erroneous conclusions.

The experimental and calculated values of α_c for the inhibited polymerisation of triethyleneglycol dimethacrylate are given in Table 3.

Table 3. Experimental and calculated α_c for inhibited polymerisation of triethyleneglycol dimethacrylate (the molar initiator : inhibitor ratio is 2, dicyclohexyl peroxydicarbonate as the initiator).

Concentration of inhibitor /mol litre ⁻¹	$k_{tY} Y_0$ /s ⁻¹	Experiment	Calculations by Eqn (11)	Calculations by Eqn (10)

^a $k_{tY} \approx 10^2$ litre mol⁻¹ s⁻¹. ^b $k_{tY} \approx 2 \times 10^3$ litre mol⁻¹ s⁻¹, $k_p \approx 350$ litre mol⁻¹ s⁻¹ (see Ref. 204), $[M]_0 \approx 4$ mol litre⁻¹, $\Phi_{22}(0) \sim 8$ mol litre⁻¹. ^c The kinetics of polymerisation were recorded by high-precision calorimetry; initiation rates $10^7 W_i$ (mol litre⁻¹ s⁻¹) are given in parentheses.

Copolymerisation of divinylbenzene with styrene. It was expected¹⁹⁵ that the probability of cyclisation would decrease to a negligibly small value and the polymer network would have an ideal structure with decreasing concentration of divinylbenzene (*m*-DVB) used as a polyfunctional agent in the initial comonomer mixture. Verification of this conclusion was searched for in the agreement between the calculated [according to Eqn (11)] and experimental values of α_c .

The criteria condition for estimating α_c at chosen kinetic constants dictates the choice of the equation

$$\alpha_c \approx 0.33 \frac{\sqrt{k_t W_i}}{k_p \Phi_{22}}, \quad (12)$$

which was used in calculations. The results are given in Table 4.

Table 4. Experimental and calculated α_c for copolymerisation of *m*-DVB with styrene.

[<i>m</i> -DVB] (mol.%)	$10^3 \bar{P}_w$	$\Phi_{22}(0)$	Experi- ment	Calcula- tions by Eqn (11)	Calcula- tions by Eqn (12)
1	1.19	0.154	0.215	0.0425	0.032
0.5	0.79	0.077	0.333	0.133	0.065
0.25	0.74	0.039	0.488	0.271	0.128
0.17	0.67	0.026	0.549	0.435	0.192

Note. Block copolymerisation initiated by AIBN (4×10^{-2} mol litre⁻¹) at 60 °C, $W_i = 4 \times 10^{-7}$ mol litre⁻¹ s⁻¹, $k_p = 200$ litre mol⁻¹ s⁻¹, $k_t = 10^7$ litre mol⁻¹ s⁻¹, $\Phi_{22} = 15.4$ mol litre⁻¹ for pure *m*-DVB.

Analysis of the data in Table 4 casts doubt on the conclusion¹⁹⁵ that an ideal network is attained at low concentrations of *m*-DVB (the last row in the table). The conclusion about the attainment of an ideal-network state upon copolymerisation of dimethacrylates with monomethacrylates¹⁹⁶ is also in doubt. In this case, agreement between the experimental values of α_c and those calculated by Eqn (11) was observed at an even lower concentration (0.03 mol.%) of the bifunctional component (dimethacrylate). Calculations according to Eqn (12) gave lower α_c in this case as well. Consequently, contrary to the conclusions drawn in the study,¹⁹⁶ the contribution of cyclic structures is rather high. This contribution is also essential, if the length of primary chains can be decreased by several orders of magnitude due to an extensive chain transfer in the course of the polymerisation process,¹⁹⁶ although there is a tendency for cyclisation to be suppressed. For example, the ratio of the experimental critical conversion in the polymerisation of dimethacrylates to the calculated value decreases from 100 (at $\bar{P}_w = 1000$ in the absence of a chain transfer agent) to 13 ($\bar{P}_w = 142$) and then to 7–8 ($\bar{P}_w = 64$) in the presence of highly efficient chain transfer agents (dodecanethiols). In the case of diallylic monomers, which serve as active chain transfer agents, this ratio decreases to 5.2–5.5 at the smallest values $\bar{P}_w = 39$ –49. This tendency is manifested not only upon a decrease in the chain length but also upon an increase in its rigidity.¹⁹⁷

In the case of the above-considered inhibited polymerisation of dimethacrylates (see Table 3), the agreement between the calculated and experimental values of α_c is observed at $\bar{P}_w$ of less than 10. Apparently, this is the main reason for the fact that the contribution of cyclisation is close to zero, *i.e.*, an ideal structure of the network is attained.

VII. Living three-dimensional radical polymerisation as a tool of macromolecular design

The discovery of living radical polymerisation (in the 1980s), reliable evidence for its occurrence in particular polymerisation

processes obtained in 1993 and subsequent rapid progress in studies in this field of polymer science led to the development of a new tool of macromolecular design, *viz.*, living TRP.[†] It appeared that living chain TRP radically changes the kinetic characteristic features, mechanism and structure (both topological and morphological) of the polymer formed. Correspondingly, the properties of the polymer material (physical-mechanical, sorption, thermomechanical, *etc.*) are sharply changed due to the transformation of the detailed mechanism of polymer chain growth, *viz.*, the instantaneous chain growth of macromolecules (taking place in the case of usual TRP) is transformed into a slow stepwise process. The term 'instantaneous' is used in reference to processes satisfying the condition $\tau \ll t$ (where τ is the interval from the onset of the growing chain to its death due to quadratic or linear termination, t is the polymerisation time). The term 'slow' is taken to mean that the process meets the condition $\tau \geq t$. As a result of this transformation, the main factor responsible for the appearance of microheterogeneity is eliminated. Since it is the microheterogeneity that determines the main specific features of TRP, elimination (even partial) of the above factor leads to radical changes. From this viewpoint, living TRP as a tool of macromolecular design is considerably superior to usual TRP in efficiency.

Using dimethacrylates and their copolymers as examples,^{198–200} it was established that the transformation of usual TRP into living TRP leads to a sharp change in the properties, *viz.*, the molecular mobility increases and, correspondingly, the properties controlled by molecular mobility change. The modulus of elasticity decreases (both in the glassy and high-elasticity states at $T > T_g$). The glass transition temperature decreases by 20–40 °C. The rate of diffusion of the solvents and their equilibrium sorption increase. The temperature dependence of the rate constant of the quadratic termination of free radicals stabilised in a polymer matrix follows an alternative law (the character of the function changes); in this case, the radicals are generated by irradiation of the polymer with γ radiation (⁶⁰Co source) within the framework of the special techniques used in structure–physical investigation called radiation probing.⁴⁵

The properties of the polymerisates prepared in the living chain and usual modes (according to the results of a studies^{198–200}) are given in Table 5. Polymerisates of the typical reagent of TRP, *viz.*, triethyleneglycol dimethacrylate (TGM-3), with the conversion $C = 0.80 \pm 0.02$ were prepared in the presence of AIBN as the initiator at 90 °C. To perform the living chain polymerisation, CuBr₂ and tetramethylthiuram disulfide were added to the initiator. The latter new agent of living radical polymerisation proposed in the study²⁰⁰ provides a virtually complete transformation of usual TRP into the living chain mode at a particular component ratio.

In addition, Table 5 gives the characteristics of highly cross-linked macromolecular structures formed upon copolymerisation of triethyleneglycol dimethacrylate (TGM-3) with styrene (copolymerisation constants $r_1 \approx r_2 \approx 0.5$, equimolar mixtures, alternation of the units) in the presence of initiators (peroxides) at 125 °C. A benzoyl peroxide–2,2',6,6'-tetramethylpiperidin-1-oxyl system (nearly equimolar ratio) was used as the agent of living TRP. This system, which has been intended only for reaction mixtures containing no less than 50 mol.% of styrene, was used with advantage.¹⁹¹

Living TRP is an efficient tool of macromolecular design for preparing highly cross-linked macromolecular structures with high molecular mobility (which are used, for example, in gel chromatography or for the preparation of materials with enhanced relaxation). Apparently, these changes in the properties are associated with either the absence or low concentration of high cross-linked regions ('grains') in living cross-linked polymers.

[†]The history of this discovery, the stages of development, analysis of the state-of-the-art of this scientific field and prospects in this area of investigation have been surveyed in the review.¹⁹¹

Table 5. Characteristics of usual and living TRP using homo- and copolymerisation as examples.

Parameter	Homopolymerisation		Copolymerisation	
	usual ^a	living ^b	usual ^c	living ^c
E /MPa	2122	1328	$\frac{1652}{1314}$	$\frac{1486}{403}$
σ ($\varepsilon = 10\%$) /MPa	104	58.9	$\frac{77.1}{52.3}$	$\frac{62.8}{17.0}$
W_g (%) during one hour	1.24×10^{-3}	0.42	$\frac{0.14}{1.38}$	$\frac{0.22}{2.00}$
S (%)	< 1	16.5	$\frac{15}{35}$	$\frac{38}{46}$
T_g /°C			$\frac{138}{-}$	$\frac{96}{-}$
$E_g(T > T_g)$ /MPa			$\frac{43.6}{-}$	$\frac{10.7}{-}$

Note. Physical-mechanical tests were carried out in the mode of uniaxial compression at 25 °C (glassy state) with a deformation rate $\dot{\varepsilon} = 10^{-4} \text{ s}^{-1}$; E is the modulus of elasticity, σ is stress on deformation $\varepsilon = 10\%$; W_g and S are the diffusion rate and sorption of benzene vapour, respectively, at 25 °C for 24 h. Free radicals (methacryl) were generated in polymer matrices with the initial conversion $C \simeq 80\%$ under the action of ^{60}Co γ radiation (dose was 2 Mrad).

The temperature dependence of the rate constant of recombination: ^a linear; ^b non-linear; ^c parameters at $C = 0.85 \pm 0.02$ and $C = 0.78 \pm 0.02$ are given above and below the bar, respectively.

This new tool has gained acceptance only recently,^{192, 193, 198–202} because both theoretical and, in particular, experimental bases of living TRP are not sufficiently advanced. Although living radical polymerisation has been studied extensively, only $\sim 3\%$ of more than 400 studies published up to the year 2000 inclusive were devoted to living TRP.

Problems associated with living chain TRP are due, primarily, to two factors. First, information on the behaviour of agents of living radical polymerisation under conditions of highly cross-linked reaction media is scarce. It can be assumed that the diffusion hindrance and specific phenomena, such as microsyneresis and microredistribution of components of initiating systems, influence elementary steps of reversible trapping of radicals serving as chain carriers, which is the essence of the mechanism of living radical polymerisation. Second, (meth)acrylates are most commonly used in TRP, whereas the action of many agents of living radical polymerisation is limited to styrene, its derivatives and styrene-containing reaction mixtures. Hence, there is a need to search for new agents or adapt the available agents to conditions of TRP. The problem is that most of agents suitable for TRP of (meth)acrylates contain copper, iron, cobalt and other variable valence metal halides as basic components, which are insoluble or poorly soluble in cross-linked reaction media.

Living TRP was examined in the study.²⁰³ Using polyethylenglycol dimethacrylates as examples, it was demonstrated that the methyl α -bromophenylacetate–Cu(I)Br–1,1,4,7,10,10-hexamethyltriethylenetetramine system can serve as an efficient agent of living TRP of methacrylates starting with 70 °C. A comparison of the kinetic characteristic features of polymerisation, the critical conversions (gel points), molecular-mass characteristics of sol fractions and the kinetics of accumulation of stabilised radicals serving as chain carriers for usual and living TRP demonstrated that autoacceleration–maximum rate–autoretardation kinetic curves typical of usual TRP are transformed into curves with a maximum rate at small conversion ($C \rightarrow 0$) if the living-chain mode is used. Subsequently, the rate decreases more rapidly than

one would expect (assuming the first-order reaction with respect to the monomer), *i.e.*, the process shows evidence of autoretardation. The characteristic kinetic evidence for the living chain mode, *viz.*, the linear time dependence of $\ln([M]_0/[M])$ ($[M]_0$ and $[M]$ are the initial and instantaneous concentrations of the monomer, respectively), is true only up to the conversion $C \simeq 40\%$. This gives grounds to assume that the later stages of TRP ($C > 40\%$) proceed in the usual fashion (due to the influence of a highly cross-linked macromolecular structure of the reaction medium). In living chain polymerisation, the critical conversion was shifted from $< 1\%$ to $\geq 5\%$, which is consistent with other experimental data¹⁹⁸ and the new theory of gel formation.^{172–178} Analysis of TRP by gel chromatography showed that a sol fraction in the course of usual TRP consists of a pure monomer in all stages of the polymerisation process starting with $C \rightarrow 0$ and up to $C > 50\%$, which is consistent with the microheterogeneous mechanism of TRP (see Section II). On going to the living chain mechanism, M_n of the sol fraction linearly increases with conversion (the characteristic feature of living radical polymerisation¹⁹¹) to a critical value and then slightly decreases in the range $10\% \leq C \leq 40\%$ (from $M_n = 8000$ as a maximum at $C = 10\%$ to $M_n = 6000$ at $C = 40\%$). In the above-mentioned C region, the M_w/M_n ratio remains equal to ~ 2.5 .

Presumably, the data from ESR measurements can be used for obtaining quantitative estimates. However, this was not done in the study.²⁰³ It was found that the kinetics of accumulation of the free methacryl radicals $[R'] = f(t)$, where t is the polymerisation time, is described by curves with a maximum $[R']_{\max}$ attained at $C \simeq 50\%$ both for usual and living TRP. When the temperature changes from 70 to 90 °C, $[R']_{\max}$ decreases by a factor of 3.5 and by more than an order of magnitude in the case of usual and living TRP, respectively. However, quantitative estimates are of most interest. These estimates can be made by comparing the data on the reduced polymerisation rates

$$\frac{W}{[M]} \equiv W',$$

where $[M]$ is the instantaneous concentration of the monomer with $[R']$ at the same t . Actually, taking into account that

$$W = k_p[R'] [M],$$

the instantaneous rate constant of chain propagation can be represented as follows:

$$k_p = \frac{W'}{[R']},$$

where $[R']$ is the concentration of radicals as chain carriers which can add molecules M . The concentration of the $[R']_{\Sigma}$ radicals measured by ESR includes not only $[R']$ but also the dead methacryl radicals immobilisation in a highly cross-linked structure in microregions with frozen mobilities of both R' and M .^{11, 13, 63} Hence, it can be written that

$$k_p \geq \frac{W'}{[R']_{\Sigma}},$$

i.e., using $[R']_{\Sigma}$ measured by ESR instead of the unknown concentration $[R']$, the lower limit can be estimated as

$$k_p \equiv k'_p \quad \left(k_p \geq k'_p = \frac{W'}{[R']_{\Sigma}} \right).$$

The k'_p constants thus estimated from the published experimental data²⁰³ are given below. In the case of usual TRP performed at 70 °C, k'_p decreases from 9800 to 380 litre $\text{mol}^{-1} \text{ s}^{-1}$ in the range of $55\% \leq C \leq 75\%$. In the case of living TRP at the same temperature and in the same C range, k'_p is in the range of 60–70 litre $\text{mol}^{-1} \text{ s}^{-1}$. If the data obtained in the study²⁰³ are considered to be reliable, this result is unexpected. It is known²⁵ that in the course of usual TRP, k_p decreases (see Ref. 204) from 300–500 at $C \rightarrow 0$ to < 10 litre $\text{mol}^{-1} \text{ s}^{-1}$ at

$C > 50\%$. Since $k_p > k'_p$, $k_p > 9800$ (!?) at $C = 55\%$. For living polymerisation at 70°C , $k'_p = 60-70$ ($k_p > 60-70$) seems to be normal as related to the results of the study,²⁵ because the molecular mobility of a cross-linked macromolecular medium increases in going from TRP to living chain polymerisation. However, the results of the study²⁰³ of living TRP at higher temperatures also gave unexpected results. At $C \geq 50\%$, k'_p is in the range of 250–500 at 80°C ($k_p > 250-500$, which is inconsistent with the prediction) as the conversion increases to the limiting values. At 90°C , $k'_p = 1500-3000$ (!!).

To summarise, studies of living TRP are at their infancy.¹⁷²⁻¹⁷⁷ Hence, the use of TRP as an efficient tool of macromolecular design of highly cross-linked polymer structures can only hold promise for the (hopefully close) future.

VIII. Conclusion

In the late 1950s–early 1960s, TRP attracted considerable attention due to the development of a new class of unsaturated polyester resins, *viz.*, polyester acrylates, which were later called oligoester acrylates. Extensive systematic studies on the basis of a large number of oligoester acrylates in combination with the development of new experimental techniques enabled researchers first to reveal the main kinetic features of TRP and then to discover its main distinguishing feature, *viz.*, microheterogeneity. Later on, the presence of microheterogeneity was repeatedly confirmed by both experiments and calculations. These results were generalised in the monograph.¹¹ In more recent studies of TRP, new original procedures were developed^{45, 49-51} for the investigation of the microheterogeneity and these procedures were applied to molecular design. These studies were surveyed in the monograph.⁴⁵

Beginning in 1990s, interest in TRP has quickened all over the world resulting in a more than tenfold increase in the number of publications. This is associated with the development of new technological approaches, for example, in rapidly progressing materials science (construction of materials for information storage, biomaterials, fiber-optic coatings, *etc.*). It is TRP that has proved to be best suited for solving new technological problems owing to its distinguishing features, among which are the possibilities of performing reactions in the superfast mode at any (including low) temperatures, control of the process by initiation (including easily controlled sources of photochemical initiation), *etc.* Besides, the discovery of living radical polymerisation has opened up new opportunities for macromolecular design.

The following modern trends in studies of TRP should be noted. Fundamental studies of the kinetics and mechanism of TRP are carried out with the use of new experimental possibilities associated with the development of reliable fast-acting efficient methods for kinetic studies, such as fast-response calorimetry, spectroscopy, *etc.* It should be noted that no radically new data on the kinetic characteristics and mechanism of TRP have been obtained since 1977.^{1, 11} Both the correlations between the kinetics and conformational properties of the starting multifunctional monomers and microheterogeneity as the principal features of TRP, which have been described and discussed earlier in the study¹ and monographs,^{11, 13} were confirmed in many studies of a large number of materials with the use of modern techniques. Three-dimensional radical polymerisation was investigated primarily using two classes of monomers, *viz.*, divinylbenzene and its derivatives (including copolymerisation with styrene), on the one hand, and multifunctional (di-, tri-, tetra-) methacrylates and acrylates, on the other hand. The quantitative identification of cyclisation and a decrease in the reactivity of the pendant vinyl group in the course of TRP are major achievements of studies of the first group of compounds (divinylbenzene).^{151, 168, 169, 194}

In studies of compounds belonging to the second group (acrylates and methacrylates), considerable efforts have recently focused on the examination of superfast modes of TRP under

conditions of photochemical initiation. It was found that at high photoinitiation rates, the initiating radicals R_i serve as main partners in the quadratic chain termination $R + R_i \rightarrow$ death reactions (where R_i is a radical of small size due to which it is highly mobile in a cross-linked medium; R is a polymeric low-mobile chain carrier). This fact radically changes the TRP process. Thus, autoacceleration disappears and the reaction rate order with respect to initiation decreases from 0.5 (normal) to ~ 0 (anomaly).

It should be noted that considerable efforts in the studies of both groups of compounds have been directed to computer simulation of TRP.¹¹¹⁻¹²⁰ This direction of investigation is progressing rapidly, which is of great importance for extending the possibilities of macromolecular design.

Of special note are the development of procedures for performing living radical polymerisation involving both the adaptation of the known agents of living TRP to complex conditions of cross-linked media and the construction of new agents specially designed for TRP. Prominence is given to detailed studies of the kinetics and mechanism of living TRP.

Applied studies are carried out primarily in the field of materials science. These studies are aimed at using cross-linked polymers for producing materials for microelectronics and information storage systems, polymers for paint-and-varnish coatings, films and packings, biomaterials, materials for aspherical lenses, polymeric carriers for control drug delivery, fiber-optic coatings, ultraviolet curable adhesives, dental materials, abrasive-resistant coatings, polymeric hosts for luminophores and liquid-crystalline structures. The properties of TRP products and fields of application of these products were considered in the studies.²⁰⁵⁻²²²

Problems of three-dimensional radical copolymerisation are beyond the scope of the present review and will be surveyed in the future.

In conclusion, it should be noted once again that there are two radically different approaches to the interpretation of the dependence of the reduced polymerisation rate on the conversion within the framework of the microheterogeneous mechanism (microheterogeneous model) of TRP. One approach is based on the assumption that elementary steps of TRP (chain initiation, propagation and termination) are diffusion-controlled. Hence, their effective rate constants depend on the conversion and they change in the course of polymerisation. The functions $k = f(C)$ depend on the choice of a physical model for the diffusion control of elementary steps (according to Smolukhovskii, within the framework of the free volume theory or on the basis of the reaction-diffusion model). This approach does not explicitly take into consideration the microheterogeneity of the reaction medium and does not radically differ from the known theories for the gel effect developed for linear polymerisation of usual (monofunctional) vinyl monomers in high-viscous media.²²³ The trivial kinetic features of TRP (autocatalysis in the early stages, auto-retardation at high conversions, the dependence of $W/[M]$ on the initiation rate at fixed C) and the results of non-stationary kinetic measurements of elementary (actually, effective) rate constants of chain growth and termination are in satisfactory agreement with the results obtained with the use of models relying on the correlation between the diffusion-controlled rate constants and the state of the reaction medium determined by the conversion.

However, TRP involves unusual processes and phenomena (which are discussed in the present review and have been described and analysed in detail in the monograph⁴⁵), which cannot be interpreted on the basis of homogeneous models with the constants $k = f(C)$. This gave impetus to the development of the microheterogeneous model of TRP. The simplest version of this model involves two types of local microreactors in which polymerisation processes occur, *viz.*, microreactors with a high-viscous reaction medium (peripheral layers of microgel particles) and microreactors with a reaction medium consisting of the virtually pure starting monomer (oligomers). Because of this, the microheterogeneous model deals with only $(k)_0 = f(C = 0)$ and

$(k)_g = f(C = C_g)$, where the index g denotes the gel, instead of the rate constants $k = f(C)$ changing continuously in the course of TRP (homogeneous model). Hence, the rate constants of the elementary stages of TRP (chain initiation, propagation and termination), $(k)_0$ and $(k)_g$, in the case of the microheterogeneous model are independent of the depth of polymerisation. The occurrence of autoacceleration in the early stages and autodeceleration in the later stages of TRP (interpreted within the framework of the homogeneous model as a result of the dependence of k on the conversion) is associated first with an increase (at conversions lower than the critical value) and then with a decrease (at conversions higher than the critical value) of the total volume of microreactors of the first type (microgel particles).

Apparently, both models (homogeneous and microheterogeneous) are limiting cases of TRP. In actuality, the microheterogeneity of TRP is most pronounced for oligomers with short and(or) rigid oligomeric blocks in polymerisation with low (no higher than 10^{-7} mol litre $^{-1}$ s $^{-1}$) initiation rates. For oligomers with long and(or) flexible oligomeric blocks or upon polymerisation with very high initiation rates (higher than 10^{-6} – 10^{-5} mol litre $^{-1}$ s $^{-1}$), the microheterogeneity is less pronounced. In recent experiments on living chain TRP, sources of the appearance of microheterogeneity in copolymerisation with the specially chosen comonomers as well as in polymerisation under conditions leading to the formation of very short chains (inhibition, chain transfer, catalytic chain transfer) were eliminated to an extent that the homogeneous model of radical polymerisation became quite suitable.

This review has been written with financial support of the Russian Foundation for Basic Research (Project No. 01-03-33227).

VI. Conclusion	230

Abstract. The review generalises results of studies on chain cryochemical polymerisation and copolymerisation, oxidation, chlorination and hydrobromination of saturated hydrocarbons and alkenes in the crystalline and glassy state. Chain chemical reactions that occur at liquid helium temperature with a measurable, temperature-independent rate are considered; high-intensity autowave modes of low-temperature reactions in solid phase are discussed. The bibliography includes 111 references.

I. Introduction

Chain chemical reactions were discovered and their study was started at the beginning of the 20th century. The term ‘chain reaction’ appeared in 1913 when Bodenstein was studying the reaction of hydrogen with chlorine. The application of the chain reaction theory turned out to be exceptionally fruitful for understanding the kinetics and mechanisms of many processes, including natural ones. Chain processes that had originally been discovered in the gas phase were later observed in liquid and solid phases. A fundamental contribution to the development of the quantitative theory of chain processes was made by Academician N N Semenov and his disciples, and also by Professor S Hinshelwood (Semenov and Hinshelwood were awarded the Nobel prize in chemistry for these works in 1956). Chain reactions were classified into the following basic types: non-branched, branched and degenerate branched; furthermore, the following steps of a chain process were distinguished: chain initiation, chain growth, chain branching and chain termination. The history of the creation and development of the theory of chain reactions is described in detail in the monograph by Emanuel *et al.*¹

Until recently, the obstacles to studies on chemical reactions at low and ultralow temperatures (4.2–77 K) were the traditional theory of the chemical reaction mechanism. The requirement that an activation barrier has to be overcome in each elementary event postulated by this theory precludes any noticeable chemical transformations in the vicinity of absolute zero temperature. The

thousand-year experience of the mankind showed that cooling prevents any complex chemical transformations.

The classical picture of the elementary event of a chemical reaction is based on the following postulates: (1) the activation energy barrier is necessary to be overcome in order to start a reaction between reactants; (2) the reactants get the energy they need to overcome the activation barrier from intermolecular interactions; (3) the time required for the reactants to accumulate this energy (the characteristic time of an elementary event) is determined by the temperature of the environment. It is easy to show that these postulates totally exclude the possibility for a chain chemical reaction to occur near absolute zero. However, a considerable fraction of matter in the Universe exists in the cold of the cosmic space. It is hard to believe that this matter has been scattering since the Big Bang without undergoing any chemical evolution.

The natural chemical transformations in solids only become noticeable on a geological time scale; they also involve liquid and gas phases, mechanical destruction, as well as high pressures and temperatures. The combustion of solid fuels, explosions and sintering processes were always considered as reactions occurring at interfaces between a solid and a gas or liquid. It should be noted that it is most thermodynamically favourable to perform the majority of important industrial processes, *e.g.*, synthesis of ammonia from nitrogen and hydrogen, at the lowest possible temperatures. Low-temperature synthesis is also preferable because, for complex chemical processes, only those of the possible transformation channels ‘survive’ which have the lowest activation energy.

In the 1930s, polymerisation of crystalline monomers was reported.^{2–4} It was found, for example, that transparent trioxane undergoes polymerisation in the presence of formaldehyde vapour to give polyoxymethylene fibres oriented along one of the crystallographic axes. The formation of polymers was observed^{3,4} upon freezing of acetaldehyde (m.p. 150 K). This was a step to the low-temperature synthesis. It was found that chain reactions can occur in solid matter even at low temperatures, although this is forbidden.

The concept that chain chemical reactions are impossible near absolute zero was discarded after a low-temperature threshold of the rate of a chemical reaction had been revealed experimentally in studies on the polymerisation mechanism of solid formaldehyde at 4–100 K.^{5–7} Subsequently, the low-temperature reaction rate threshold was found to exist for many chain and non-chain chemical processes.⁸ It was found that certain chemical reactions can occur with a measurable temperature-independent rate at

liquid helium temperature. Just after the low-temperature reaction rate threshold had been discovered, it was suggested that the mechanism of this phenomenon could be interpreted within the framework of the molecular tunnelling concept. Later, this idea was developed with intramolecular oscillations taken into account.^{8–12}

The scope of studies on chain cryochemical reactions expanded considerably after the discovery of transformations in autowave modes that occur upon local brittle destruction of solid samples subjected to radiolysis or photolysis at 4.2–77 K.^{13–15} When a sufficiently extended sample undergoes local brittle destruction, a chemical reaction starts on the newly formed surface. The temperature or density gradients that appear during the reaction create stresses that favour subsequent layer-by-layer destruction of the solid sample. Owing to this positive feedback, an autowave of the chemical transformation spreads along the sample, *i.e.*, a kind of mechanoenergetic chain is realised.^{13–15} The autowave mode is observed for many reactions (chlorination of hydrocarbons, hydrobromination of alkenes, polymerisation) in the temperature range 4–77 K. This concept allowed us to put forward new ideas regarding the mechanisms of the ‘cold’ chemical evolution of matter in the Universe.¹⁵

In the present work, we generalise experimental data of studies on chain cryochemical processes that have led to the discovery of the low-temperature threshold of the chemical reaction rate and also the autowave and self-oscillating modes of low-temperature transformations. Consideration of general trends of the evolution in this field of chemistry is certainly interesting; however, our review pays the most attention to studies performed over the last years.

II. Chain reactions in crystals

1. Polymerisation of solid formaldehyde

In the 1960s, studies on the solid-phase polymerisation were developed intensely. However, most of these studies were phenomenological, and the theoretical conclusions and hypotheses were rather speculative than based on experimental results. Initially, it was assumed¹⁶ that the strict orientation of monomer molecules in the crystal can predefine the regularity of chains of the macromolecules formed, and hence the ‘precursors’ of reactants in the crystal will favour the realisation of unusually fast chemical transformation mechanisms. As early as in 1960, N N Semenov proposed the energy chain mechanism for the solid-phase polymerisation.¹⁶ The idea was that the energy evolved in each elementary event of the polymer chain growth does not dissipate as heat, but is consumed for overcoming the activation barrier in the next event. A variant of such collective interaction is the exciton movement along the chain of monomer molecules in the crystal. In this case, the polymer chain growth will occur at a rate equal to the exciton propagation rate.¹⁷

The reader can find vast experimental data collected to date in a number of reviews.^{18–22} Let us outline the main conclusions of studies carried out during that period. When a polymer is formed, the mean distances between the fragments of the monomer crystal lattice change (*i.e.*, the intermolecular distances are replaced by the lengths of chemical bonds). Two extreme cases are possible: (1) the monomer crystal structure defines the structure of the resulting polymer (diacetylene derivatives, trioxane); (2) the polymer is formed as a separate phase in extended defects of the crystal lattice, which leads to subsequent destruction of the monomer crystal (acrylamide). In addition, many intermediate cases exist.

It is hard to imagine that the decay of the growing macroradicals can occur by recombination or disproportionation in a crystal where the translational movement is quite limited. The previously developed ideas of ‘polychronous kinetics’ were found to be also applicable when considering the polymerisation in a crystal.^{23,24} As the polymer chain grows in a solid, the access of the monomer to the active site is hampered and kinetic inhibition of

the process occurs; this is called polymer chain ‘freezing’ (the opposite process is called ‘revival’).

The main results of studies on the radiation-induced polymerisation of solid formaldehyde at 5–150 K were described by Kiryukhin.²⁵ The dependences of the formaldehyde polymerisation rate (m.p. 155 K) and the radiation-chemical yield of the polymer [$G(-M)$] on temperature were studied in the temperature range 4.2–140 K. It was found that these dependences become weaker as the temperature is decreased, and are no more observed in the range 5–20 K (Fig. 1). Even at 5–20 K, polymerisation occurs with high radiation-chemical yield $G(-M) = 1000$ which is typical of chain processes.[†] This is the first experimental proof of the existence of long polymeric chains formed upon conversions in the vicinity of absolute zero temperature (~ 1000 monomer units at 4.2 K). The non-steady-state process kinetics was studied and the elementary polymerisation rate constants were determined. In the temperature range 80–140 K, the time required for the chain to lengthen by one unit increases with a decrease in temperature according to the Arrhenius law, with an activation energy of ~ 10 kJ mol⁻¹, and no longer depends on temperature upon deeper cooling, *i.e.*, a low-temperature threshold of the chain chemical reaction is observed.⁷ The formaldehyde polymerisation is a typical chemical reaction: a number of planar triangular molecules of the monomer are transformed to a long $-CH_2-O-CH_2-O-$ chain; obviously, the formation of chemical bonds in the macromolecules being formed should increase considerably the density of the compound.

Figure 1. Temperature dependences of the rate (w) and radiation-chemical yield [$G(-M)$] of formaldehyde polymerisation under γ -irradiation.²⁵

Studies of low-temperature photoinitiated solid-phase formaldehyde polymerisation were also carried out. It was reported^{26,27} that a polymeric phase was formed in crystalline and amorphous formaldehyde containing an additive of β -naphthol as a result of photoinitiation at temperatures above 20 K. Low-temperature transformations in amorphous formaldehyde–chlorine mixtures were studied.^{28–30} Photolysis of chlorine under these conditions was carried out by an excimer laser ($\lambda = 308$ nm) or an arc mercury lamp ($\lambda = 365$ nm). In the temperature range 10–77 K, the formation of oligomers containing 5–7 monomeric units was observed. At temperatures above 90 K, the chain length increased twofold. These values are much lower than those of the polymer formed upon radiolysis of crystalline formaldehyde (chain length 10^3 – 10^6); this is probably due to the molecular disorder in the amorphous compound.

[†] The radiation-chemical yield of active sites (g) that initiate polymerisation is usually 1 (per 100 eV of absorbed energy); in this case, $G(-M)$ equals the kinetic length (ν) of the polymeric chains: $\nu = G(-M)/g = 1000$.

Polymerisation of crystalline acetaldehyde (the nearest homologue of formaldehyde) and glyoxal (the simplest dialdehyde) occurs with much lower rates; at $T < 77$ K, no long polymeric chains are formed from these monomers.^{25,31} Subsequent search for cryochemical chain reactions involved two-component polycrystalline systems.^{32–37}

2. Solid-phase hydrobromination and chlorination of ethylene

The photochemical hydrobromination of alkenes at temperatures above 77 K has been reported in detail.^{32,33} A detailed study of the kinetics and mechanism of radiation hydrobromination of ethylene in the temperature range 4.2–90 K revealed long kinetic transformation chains in the low-temperature range ($\nu \approx 300$ chain units at 20 K).^{34,35} This process is yet another example of a low-temperature rate threshold of a chain chemical reaction. The elementary events of chain growth in hydrobromination and deuterobromination were compared in the following systems: C_2H_4-HBr , C_2H_4-DBr , C_2D_4-HBr and C_2D_4-DBr . This made it possible to determine more precisely the chain growth mechanism in the hydrobromination of ethylene at ultralow temperatures. It was found that it is the approach of heavy species (including intermolecular oscillations) rather than the tunnelling transfer of the hydrogen atom that limits the rate of the low-temperature chain growth.

A method to obtain reactive cryocrystals was reported; the activation-free growth of chains ~ 300 units long at 17–45 K was studied for ethylene photochlorination as an example.³⁶ The role of the spatial packing of reactants in solid-phase chain chemical reactions at ultralow temperatures was considered by Misochko.³⁷ Three limiting cases were discussed: (1) growth of one-dimensional chains along a specific direction in a mixed crystal with alternating arrangement of reactants; (2) chain growth in a random binary mixture of reactants; (3) chain growth with long-range migration of 'hot' atoms. In the first case, where the products formed in the reaction gradually replace the reactants in the lattice sites without any considerable displacement of the neighbouring molecules, chains up to ~ 300 units long can grow. In the second case, the mean chain length is determined by the number of molecules in the first coordination sphere which are accessible to any reactive species. The chain growth ends in the stabilisation of radicals; the mean chain length is 3–7 units. If chain growth involves 'hot' atoms, the latter can migrate to a far distance from the cage and thus increase the efficient number of sites that separate successive chain units.

Thus, data on the radiation-induced formaldehyde polymerisation and ethylene hydrobromination and on the ethylene photochlorination in crystalline state have shown that chain processes can occur at temperatures near absolute zero. These experiments promoted theoretical studies aimed at the development of the concept of the elementary event of a chemical reaction in a solid.^{8,12,36–41}

3. Low-temperature oxidation

Studies on the gas-phase and liquid-phase oxidation of various compounds have contributed markedly to the development of the chain reaction theory.¹ In particular, the possibility, in principle, of radiation-induced oxidation of sulfur dioxide with molecular oxygen under low temperature conditions (at 77 K and in the post-radiation effect mode, *i.e.*, upon heating of a pre-radiated system) was shown experimentally.⁴² The radiation-induced oxidation of SO_2 is of interest in the context of decontamination of gaseous industrial exhausts and the possibility of obtaining sulfuric acid. Therefore, it is important to evaluate the efficiency of the non-traditional environmentally safe method for the SO_3 synthesis at low temperatures where undesirable admixtures can be frozen-out. Studies of the low-temperature oxidation of sulfur dioxide showed that the basic process occurs by a chain mechanism during γ -irradiation at 77 K; the initial radiation-chemical yield is 30. The optimum starting molar ratio $SO_2:O_2$ which

provides the maximum conversion of sulfur dioxide is 1 : 4. In the post-radiation mode, the conversion is no greater than 1%.

4. Low-temperature radiation-induced conversions of hydrogen cyanide and cyanogen bromide

Hydrogen cyanide (prussic acid) is a compound that is rather common in the outer space: HCN molecules have been detected in comets, in protoplanet formations, in giant clouds of interstellar dust and in other galactical structures. In principle, the HCN molecule may be regarded as the basis of pre-biological chemical evolution, since hydrogen cyanide is a precursor of purines, pyrimidines and amino acids.^{43–47} Stahler⁴⁸ suggested that the chain length of azapolyene macromolecules formed upon HCN polymerisation may be used as a kind of clock to determine the age of interstellar clouds. Other astrophysical aspects of the chemical conversions of hydrogen cyanide are also being developed intensely.^{49,50}

It seemed interesting to study the chemical behaviour of this simple molecule under conditions that are close to those in outer space (low temperatures and radiation) and the role it plays in the 'cold' chemical evolution of the Universe. Below we present the results of experiments carried out in a number of studies.^{51–54}

Cooling of liquid HCN to 77 K converts it to the crystalline state. On heating of hydrogen cyanide cooled to 77 K, a 'crystal-crystal' phase transition occurs (248 K) followed by melting (260 K). The heat of melting of HCN is 8.4 ± 0.4 kJ mol⁻¹.

When solid HCN undergoes radiolysis (with doses of 1–800 kGy) at 77 K, the active sites of radical and radical ion nature are stabilised in the crystal.⁵⁴ On subsequent heating of the system, a brown polymer ($-HC=N-)_n$, which contains conjugated double bonds, and crystals of the tetramer (1,2-diaminomaleonitrile) are formed in the solid phase. At low temperatures, the polymerisation rates of crystalline HCN are low, and chain polymerisation at 77 K under γ -radiation is not observed. A polymer is formed at temperatures near the melting point of the monomer.

The ESR spectrum of the polymer represents a singlet typical of polyconjugated systems. Within the framework of the suggested radical transformation scheme,⁵⁴ the brown colour of the polymer may be explained by the formation of the $-HC=N-HC=N-$ conjugation chain. The formation of needle-like crystals of 1,2-diaminomaleonitrile (tetramer of hydrogen cyanide) may be⁵³ due to the formation of an intermediate biradical, *viz.*, aminocyanocarbene; dimerisation of the latter results in the tetramer. The fact that 1,2-diaminomaleonitrile is formed under conditions that are close to those in outer space (low temperatures and radiation) seems very important to us, since this compound may play a key role in pre-biological organic synthesis because its hydrolysis directly gives an amino acid.

Crystalline cyanogen bromide does not contain $N\cdots H$ hydrogen bonds typical of crystalline HCN. It was of interest to compare the ability of this compound and hydrogen cyanide to undergo cryopolymerisation. Polymerisation of BrCN following radiolysis at 77 K occurs upon unfreezing in the temperature range 220–230 K and near the monomer melting point (324 K).⁵⁵ The heats of melting of BrCN (11.6 kJ mol⁻¹) and of polymerisation (86.0 ± 2.0 kJ mol⁻¹) have been determined. The dependence of the polymer yield from cyanogen bromide on the pre-irradiation dose has an unusual shape with an extremum. At doses in the range 0–900 kGy, the polymer yield increases monotonically to reach a maximum value of $\sim 9\%$ at 900 kGy. A subsequent increase in the irradiation dose decreases the yield to $\sim 4\%$ at 1200 kGy; at higher doses, the yield remains nearly constant up to a dose of 2000 kGy. It is assumed⁵⁵ that the suppression of the polymerisation of cyanogen bromide at high pre-irradiation doses results from the progressive degradation of the matrix structure. Such radiation-induced degradation may increase rather strongly the molecular mobility near the monomer melting point. As a result, the rate of polymer chain termination may increase, which would result in degeneration of the chain

process and hence decrease the polymer yield. Thus, the absence of intermolecular chains with strong N...H hydrogen bonds in crystalline cyanogen bromide predetermines a difference in the dynamics of the cryopolymerisation of BrCN and HCN and decreases the radiation resistance of BrCN.

5. Cryopolymerisation of ketene

Work on the mechanism of cryochemical chain reactions involved studies on the radiation-induced polymerisation of carbonyl-containing compounds (formaldehyde, acetaldehyde, glyoxal, *etc.*).²⁵ Ketene ($\text{H}_2\text{C}=\text{C}=\text{O}$) is of considerable interest for studying the features of the low-temperature polymerisation of such compounds. Since the ketene molecule contains cumulated hetero-chain double bonds, its linear polymerisation may occur by three different pathways to give a polyketone, a polyacetal or a polyester.

Polyketones are formed in the presence of cationic catalysts (*e.g.*, AlBr_3) at -60°C ,⁵⁶ whereas polyesters and polyacetals are formed with anionic catalysts (AlEt_3).⁵⁷ Radical initiators do not cause ketene polymerisation.

In addition to soluble linear macromolecules, polymerisation can give insoluble cross-linked structures, since each ketene molecule contains two double bonds.

On cooling to 77 K, ketene is completely converted to the crystalline state. When such a sample is heated, the calorimetric curve displays only an endothermic peak, which corresponds to the melting of crystalline ketene at 140 K (Fig. 2, curve 1). The heat of melting of ketene determined from calorimetric measurements is $4.0 \pm 0.4 \text{ kJ mol}^{-1}$.

Figure 2. Calorimetric curves of ketene unfreezing;²⁵ (1) non-irradiated sample; (2) sample exposed to γ -irradiation with a dose of 300 kGy (here and in Figs 4 and 5, W is the heat evolution rate).

Heating of crystalline ketene pre- γ -irradiated at 77 K results in the solid-phase polymerisation of the monomer, which starts near the melting point and occurs near the melting point, as well. An increase in the pre-irradiation dose decreases the measured temperature of the beginning of polymerisation. For example, at a dose of 300 kGy, the temperature of the beginning of the reaction is about 30 K lower than the melting point of the monomer (Fig. 2, curve 2). The polymer yield increases with an increase in the pre-irradiation dose and reaches 17% at a dose of 350 kGy.

The thermal effect of ketene polymerisation in this reaction mode as determined from the comparison of the gravimetric yield of the polymer with data from calorimetric measurements is $18.1 \pm 1.8 \text{ kJ mol}^{-1}$. The resulting polymer is yellow; on heating to room temperature, it gradually turns dark-orange. It is partially soluble in ethyl methyl ketone. The ratio between the soluble and insoluble polymer fractions depends on the time of exposure of the sample at room temperature. For example, the solubility of the polymer obtained after pre-irradiation of the monomer with a dose of 350 kGy is 85%. If a sealed tube containing this polymer and non-consumed monomer is kept for 20–30 min at $\sim 20^\circ\text{C}$,

the soluble polymer fraction decreases to 60%. Hence, post-polymerisation of ketene gives a partially cross-linked polymer; this polymer undergoes additional structuring at room temperature in the presence of the monomer, and the proportion of the cross-linked fraction in it increases. This indicates that the polymer retains double bonds which are involved in cross-linking of the macromolecules.

Analysis of the IR spectra of the polymer (the ratio of the band intensities characterising the $\text{C}=\text{C}$ and $\text{C}=\text{O}$ bonds in the regions of 1600 and 1720 cm^{-1} , respectively) suggests that ketene polymerisation mainly involves cleavage of the $\text{C}=\text{O}$ bonds.

The preferential cleavage of $\text{C}=\text{O}$ bonds during the post-radiation polymerisation of ketene is additionally evidenced by the measured thermal effect of the reaction, which is 18 kJ mol^{-1} . This is close to the thermal effect of polymerisation⁵⁸ occurring with the cleavage of $\text{C}=\text{O}$ double bonds [the experimentally determined heat of polymerisation of acetaldehyde is 10.5 kJ mol^{-1} and that of glyoxal is 21.0 kJ mol^{-1} (see Ref. 25)]. The thermal effects of polymerisation involving the cleavage of $\text{C}=\text{C}$ bonds are much higher, *viz.*, about $50\text{--}80 \text{ kJ mol}^{-1}$.

The cross-linking of the polymer on its storage at room temperature probably occurs through $\text{C}=\text{O}$ bonds, since the IR band intensities corresponding to the stretching vibrations of these bonds decrease during this process.

Thus, the low-temperature post-radiation polymerisation of crystalline ketene mainly involves the cleavage of $\text{C}=\text{O}$ bonds to give a polyester. The retention of $\text{C}=\text{O}$ bonds enables the cross-linking of the polymer.

6. Carbon suboxide

Unusual features were observed in the low-temperature polymerisation of carbon suboxide (tricarbon dioxide) C_3O_2 (m.p. 160 K).^{59,60} Calorimetric measurements showed that no radiation-induced polymerisation of solid C_3O_2 with measurable yields in the temperature range 77–160 K could be detected. Similarly, no polymerisation of the monomer was observed in the radiolysis of liquid carbon suboxide. However, it was found that heating of C_3O_2 samples which have been exposed to preliminary γ -irradiation at 77 K resulted in efficient post-polymerisation. The calorimetric curve of unfreezing of samples pre-exposed to radiolysis shows that the heat evolution due to the polymerisation of C_3O_2 is observed starting from the melting point of the monomer. In the temperature range 180–260 K, polymerisation occurs with a very low rate; its rate increases significantly upon subsequent heating, reaches a maximum and then decreases as the monomer is consumed. Probably, radiolysis of crystalline carbon suboxide at 77 K and subsequent heating produce oligomeric active sites (containing 3–5 monomer units); the probability of their decay is low both in the solid and liquid phases. It is these sites that are responsible for the efficient liquid-phase post-radiation polymerisation of C_3O_2 . The chain growth in this reaction occurs by the cationic mechanism.^{25,60}

Yet another interesting feature of the post-polymerisation of carbon suboxide is the auto-acceleration of the process at constant temperature. The post-polymerisation of C_3O_2 was studied calorimetrically (Fig. 3) at 297 K .⁵⁹ At this temperature, the process rate first increases with time, *i.e.*, auto-acceleration of the reaction is observed, and then decreases to zero because the monomer is exhausted. This phenomenon is unusual because the number of active sites 'preformed' during preliminary irradiation can only decrease. Probably, the most likely reason for the auto-acceleration is branching of the chain reaction in an elementary event of monomer addition. Without specifying the particular branching mechanism, let us note that the specific features of the electron structure of the C_3O_2 molecule allow us to speak of both physical and energetic branching. Anyway, the issue of the auto-acceleration mechanism remains open as yet.

Figure 3. Variation of the post-polymerisation rate (w) of C_3O_2 at 297 K with time; the pre-irradiation dose is 10 kGy.⁵⁹

7. Cryocopolymerisation of dienes and α -alkenes with sulfur dioxide

Certain dienes, such as butadiene, isoprene and 2,3-dimethylbutadiene, efficiently copolymerise with sulfur dioxide to give copolymers with the 1:1 composition.⁶¹ Two main mechanisms of the formation of alternating copolymers are possible in such two-component systems. One of them is based on the assumption that two monomers are added sequentially. The alternation of monomer units is due to the considerably higher rate constants of the cross-growth of chains in comparison with the addition constants for each of the monomers. The other mechanism assumes that the copolymer is formed by the mutual addition of binary charge-transfer complexes, which are formed upon mixing of the monomers. The results of studies on the alternating copolymerisation were reported by Golubev⁶² for a broad range of such systems.

A specific feature of alternating copolymerisation is that copolymers with the 1:1 composition are formed, no matter what the composition of the original monomer mixture. However, the reaction has specific features at low temperatures, which not always comply with the common concept of liquid-phase processes. In fact, solid-phase chemical transformations and copolymerisation in particular depend considerably on the complex phase state of the solid reactant mixture, and are sometimes determined by this composition.²² As a rule, radiolysis of solid organic mixtures at 77 K results only in the accumulation of stabilised active sites, which are released from the traps upon subsequent heating of the system in the absence of irradiation and initiate the chain chemical transformations. When the system melts, all the growing active sites usually decay, and the polymerisation processes stop. Thus, both phase transitions and chain copolymerisation occur in the temperature range from 77 K to the melting point region of the multicomponent system.²¹

Experimental results obtained by Kichigina *et al.*⁶³ indicate that the phase composition of an isoprene- SO_2 system affects both the copolymer composition and the dynamics of post-radiation copolymerisation. On sufficiently rapid cooling of a liquid solution of these monomers to 77 K, the system vitrifies; however, it can also be obtained in polycrystalline state upon 'annealing'. The eutectic mixture formed in the system is not equimolar. If isoprene is copolymerised with SO_2 in the post-radiation effect mode at these low temperatures and with an excess of one of the monomers, the isoprene and SO_2 molecules are incorporated in the chain not in strict sequence but with violated alternation of units in the copolymer, as deduced from the results of elemental analysis and the heats of polymerisation.

The processes of post-radiation copolymerisation of a number of dienes and alkenes (ethylene, but-1-ene, cyclopentene, hex-1-ene, oct-1-ene, *etc.*) with sulfur dioxide, occurring both on heating of samples irradiated at 77 K and spontaneously (upon mutual dissolution of the compounds) were compared.⁶⁴ It was concluded that the possibility of the formation of donor-acceptor complexes of SO_2 with a monomer is not a sufficient condition, as it is

necessary that the structure and composition of the resulting complex favour subsequent polymerisation. A vivid example is provided by comparison of the following two-component systems: cyclopentene- SO_2 and cyclohexene- SO_2 . Spontaneous polymerisation is only observed in mixtures of cyclopentene with SO_2 ; neither spontaneous nor radiation-induced polymerisation is observed in the case of cyclohexene.

8. Quenched high-pressure phases

The radiation-induced polymerisation of crystalline acrylamide starts in areas containing extended defects and occurs at interfaces between the amorphous polymer and the crystalline monomer. In the eutectic mixture acrylamide-water, the chain polymerisation in the quenched high pressure phase was found to be hindered very strongly when the samples that had been exposed to radiolysis at 77 K were heated.⁶⁵ The most likely reason for the inhibition of this process is the small size of eutectical acrylamide crystals, the contacts between which are disturbed as the metastable ice phase passes into the equilibrium phase, with the accompanying sharp increase in the volume of the system and its strong dispersion. In fact, if the sample under study represents monomer microcrystals that have virtually no contacts between each other (which hinders strongly the transfer of the growing polymer chain from one crystal to another) and the linear size of these crystals does not exceed 100 molecules (the length of polymer chains is ~ 100 units), the polymerisation in such a sample will be hampered strongly in comparison with a monolithic sample (at equal concentrations of active sites). The estimated size of such crystals is $\sim 0.1 \mu m$.

III. Chain reactions in glasses

Amorphous bodies feature only short-range ordering where only the mutual arrangement of a few molecules is correlated. Owing to the absence of long-range order, amorphous bodies are isotropic, *i.e.*, their macroscopic properties do not depend on direction. At temperatures above the melting point, the compound is in a thermodynamically stable liquid state, while on cooling below the melting point it is transformed to another equilibrium state, *i.e.*, a crystal. However, sufficiently fast cooling can give a liquid in a non-equilibrium supercooled state; its subsequent cooling below the glass transition point (T_g) results in yet another non-equilibrium solid amorphous state, which is commonly referred to as glass. In fact, the transition from the supercooled liquid state to the glassy state occurs within a narrow temperature range. The glass-transition point is not a thermodynamic characteristics of a compound and may vary widely depending on conditions of the sample preparation and the measurement procedure used. Species in a glass are only capable of oscillation and small-scale rotational movement. The translational mobility typical of liquids is lost almost completely.

In our subsequent discussion, the following fact is very important: both the transition from the supercooled liquid state to the glassy state and the reverse transition (called devitrification) are accompanied by an abrupt change in the properties of the compound, such as viscosity, elastic modulus, thermal expansion factor, *etc.* Certainly, the most impressive phenomenon is the huge jump of viscosity (by 10–12 orders of magnitude) in the narrow glass-transition range.⁶⁶ From the chemical viewpoint, this means that the molecular mobility, which defines the dynamics of a chemical conversion, changes abruptly in this region. The nature of the chemical process should change considerably when the glass softening region is passed owing to the abrupt change in the mobilities of the reactants (in this case, the mobilities of molecules change stepwise on increasing or decreasing the temperature by only a few degrees).

Radiolysis of glassy matrices gives rise to reactive radical or ionic species which are stabilised in more or less deep traps and which may preserve reactivities for a long time. The absence of molecular mobility in the glass prevents mutual recombination of such stabilised radicals. When the matrix is heated and the glass

passes to the supercooled liquid state (devitrification), the translational mobility increases abruptly and, as a consequence, recombination of the accumulated radicals occurs. In the systems where the radicals released upon devitrification can initiate a chain reaction, efficient chain radical processes are realised (see below).

Polymerisation reactions (radical, ionic, copolymerisation, graft polymerisation) occurring quite intensely upon devitrification of glassy matrices that have undergone radiolysis at 77 K are described in detail in a review by Barkalov and Kiryukhin.⁶⁶

1. Chlorination during matrix devitrification

Specific features of low-temperature radiation-induced chlorination in glassy matrices were studied in a system butyl chloride–molecular chlorine ($T_g = 100$ K). The reaction was studied (i) directly under γ -irradiation and (ii) in the post-radiation effect mode on heating of pre-irradiated samples.^{67,68}

The radiation-induced chlorination of butyl chloride, in both the glassy and supercooled liquid state near the devitrification point (98–107 K), is characterised by a long life time (τ) of active sites (~ 1500 s). As the temperature is increased, the chain growth rate in the supercooled liquid reaches a maximum at 114 K; when the system passes to a thermodynamically stable liquid and the viscosity of the medium decreases, the probability of chain termination increases ($\tau < 100$ s). This decreases the overall rate of the process in the temperature range 115–150 K.

When glassy solutions of chlorine in butyl chloride pre-exposed to γ -irradiation at 77 K are heated in a calorimeter, heat evolution is observed because of chlorination. As the pre-irradiation dose is increased, the heat evolution due to chlorination is detected at progressively lower temperatures. After irradiation with a dose of 100 kGy, the reaction starts at 80 K.

The ESR spectra recorded during the irradiation of the system at 77 K manifest two types of paramagnetic centres, *viz.*, alkyl radicals ($R_A^\bullet$) and Cl_2^- species. The most likely mechanism of the formation of the $R_A^\bullet$ radical involves the dissociative capture of a slow electron:

The formation of Cl_2^- species probably results from direct electron addition:

The chain chlorination in the temperature range 90–110 K occurs by the classical mechanism:

The behaviour of the Cl^- species formed upon radiolysis is quite unusual: in the presence of these species, chlorine atoms are captured from the chain at 80–100 K according to the reaction:

As a consequence, the efficiency of the low-temperature radiation-induced chlorination decreases. It is this that differs radiation-induced chlorination from photochemical chlorination. In fact, photolysis does not produce Cl^- species, and at equal concentrations of alkyl active sites $R_A^\bullet$ the process occurs more intensely in those samples which have undergone photolysis.

Measurements of the rate of the process directly during γ -irradiation and in the post-effect mode (on heating of pre-irradiated samples) gave the following rate constant for the limiting step of chain growth [reaction (4)] in the temperature range 98–114 K:^{67,68}

$$k_4 = 10^{12} \exp\left(-\frac{25000}{RT}\right) \text{ litre mol}^{-1} \text{ s}.$$

Thus, the chain reaction of chlorination of chloroparaffins (both in the glassy and supercooled liquid state near the devitrification region) features long life times of active sites. With an increase in temperature, the chain growth rate reaches a maximum in the supercooled liquid; when the system passes to the thermodynamically stable state and the viscosity of the medium decreases, the probability of chain termination increases. Hence, similarly to polymerisation processes,⁶⁶ the suppression of chain termination reactions and simultaneous provision of efficient chain growth (this is the mode which is automatically realised near the devitrification region) makes it possible to increase considerably the overall reaction rate.

2. Hydrobromination of alkenes

The solid-phase hydrobromination of ethylene occurs in an equimolar crystalline complex. Mozhaev *et al.*⁶⁹ studied low-temperature radiation-induced hydrobromination of alkanes (for allyl chloride as an example) in the glassy state.

On cooling to 77 K, an allyl chloride–HBr system passes to the glassy state ($T_g = 88$ K) for all the reagent ratios used (1:1, 10:1 and 60:1). Spontaneous hydrobromination in this system occurs only in the liquid state (in the temperature range 182–220 K); for the allyl chloride:HBr ratio = 1:1, the conversion is 50% in this temperature range. The degree of conversion was determined calorimetrically. Complete conversion of HBr in thermoactivated hydrobromination occurs only in the presence of an excess of allyl chloride. For example, complete conversion of hydrogen bromide is observed in the allyl chloride–HBr system with 10:1 composition. The thermal effect of the reaction (ΔH) determined in a series of experiments is 71.4 ± 2.0 kJ mol⁻¹. This value is in good agreement with the thermal effect of ethylene hydrobromination and the calculated ΔH value.³⁴

Hydrobromination in the allyl chloride–HBr system can give either 2-bromo-1-chloropropane (addition in accordance with the Markownikoff rule) or 3-bromo-1-chloropropane (anti-Markownikoff addition). The difference between the thermal effects of these two reaction pathways is determined by the different strengths of C–H bonds in the methyl and methylene groups. In fact, the strengths of the C–Br bonds in 1-bromopropane and 2-bromopropane are the same,⁶⁹ whereas the energies of the C–H bonds in propane at the C(1) and C(2) atoms are 412 and 395 kJ mol⁻¹, respectively.

Thus, the thermal effect of the Markownikoff addition of bromine is 17 kJ mol⁻¹ higher than that of the anti-Markownikoff addition. Hence, the experimentally measured thermal effect of spontaneous hydrobromination of allyl chloride (which is the same as that of the hydrobromination of ethylene) corresponds to the Markownikoff addition of HBr to give 2-bromo-1-chloropropane.

During radiolysis of the allyl chloride–HBr system (⁶⁰Co γ -irradiation) at 77 K, active sites are stabilised in the matrix; they initiate efficient chain hydrobromination when the sample is unfrozen. This reaction occurs when the molecular mobility increases abruptly, *viz.*, in the devitrification region of the system (in the temperature range 87–95 K). The degree of conversion depends on the pre-irradiation dose; for example, it increases from 12% to 25% as the dose is increased from 1.5 to 20 kGy. A decrease in the HBr concentration in the original mixture increases the degree of conversion. In allyl chloride–HBr systems with 20:1 and 60:1 compositions that have been pre- γ -irradiated with a dose of 10 kGy, complete HBr conversion is observed. Naturally, no spontaneous addition occurs on heating of such samples to 200 K. The thermal effect of the post-radiation reaction (ΔH) determined in a series of experiments⁶⁹ is 55.4 ± 2.0 kJ mol⁻¹. Hence, the post-radiation addition of HBr to allyl chloride results in 3-bromo-1-chloropropane (anti-Markownikoff addition); the thermal effect of the reaction coincides with the calculated⁶⁹ ΔH value.

3. Hydrobromination of allene

Chain addition at low temperatures has also been studied for the first representative of hydrocarbons containing cumulated C=C bonds, *viz.*, allene ($\text{H}_2\text{C}=\text{C}=\text{CH}_2$).⁷⁰

On stirring the allene–HBr equimolar mixture at ≤ 190 K followed by freezing to 77 K, the system passes to the glassy state ($T_g \approx 80$ K). Unlike the equimolar mixture, samples with allene–HBr molar ratios of 1:5, 1:2 or 5:1 pass to the crystalline state upon stirring and cooling to 77 K. An eutectic mixture is formed in the case of the allene–HBr molar ratio of 1:2, and the calorimetric curve shows only the melting of the eutectics around ~ 120 K. In the other reaction mixtures containing a larger excess of one of the components, melting of the excess component is observed as well. Subsequent heating of samples results in spontaneous hydrobromination; calorimetric curves show exothermic reactions at a temperature of ≥ 170 K. The hydrobromination rate increases with an increase in the HBr content in the mixture. The maximum reaction rates in mixtures with allene–HBr molar ratios of 1:2 and 1:5 are observed at 260 and 230 K, respectively.

Spontaneous hydrobromination of allene in this temperature range obeys the Markownikoff rule. In all the systems studied, 2-bromopropene [$\text{MeC}(\text{Br})=\text{CH}_2$] is the major reaction product, irrespective of the original ratio of the reactants. Analysis of absorption IR spectra of the reaction products allows two conclusions to be made. First, spontaneous hydrobromination of allene results in the cleavage of only one C=C bond, since the IR spectrum of the reaction products displays absorption bands near 1650 cm^{-1} , which correspond to the stretching vibrations of the C=C bond. Second, the absorption IR spectra of 2-bromopropene, unlike those of allyl bromide, contain bands originating from the presence of a methyl group in the regions of 800 cm^{-1} (skeleton C–Me vibrations) and $\sim 1380\text{ cm}^{-1}$ (symmetric deformation vibrations of the C–H bond in the methyl group).

The yield of the allene spontaneous hydrobromination product (the reaction occurs in the dark; the heating rate is $\sim 1\text{ deg min}^{-1}$) depends on the original molar ratio of the reactants: it is $\sim 25\%$ (allene:HBr = 1:1) or $\sim 60\%$ (allene:HBr = 1:2 or 1:5). The thermal effect of the reaction (ΔH) determined in a series of experiments⁷⁰ was $70.0 \pm 0.7\text{ kJ mol}^{-1}$.

It should be noted that the conclusion that only one C=C bond is cleaved in the allene molecule during spontaneous hydrobromination under these reaction conditions is confirmed experimentally. Studies of the reaction of allyl bromide (3-bromopropene) and 2-bromopropene with HBr showed that no spontaneous hydrobromination of these compounds occurs in the temperature range 77–290 K.⁷⁰

Studies of the radiation-induced hydrobromination of allene were carried out for the same systems (with the molar ratios allene:HBr = 1:1, 1:2, 5:1) that have been used in studies of the spontaneous reaction. When the allene–HBr equimolar mixture pre-exposed to γ -irradiation with a dose of 2 kGy at 77 K was heated, intense heat evolution due to hydrobromination was observed in the temperature range of system devitrification (82–90 K).

When the allene–HBr system pre-exposed to γ -irradiation at 77 K with 1:2 molar ratio of the reactants was heated, hydrobromination was detected in the temperature ranges 85–95 K and 105–110 K. Subsequent heating results in melting of the remaining eutectic mixture.

If an excess of allene is originally present in the system (molar ratio allene:HBr = 5:1), post-radiation hydrobromination is observed in the temperature range 90–115 K. Subsequent heating of the sample results in melting of the excess allene. It should be noted that the heat of melting of the excess allene remains the same in both systems, *viz.*, intact and subjected to radiolysis. Hence, hydrobromination involves only the amount of allene which corresponds to its content in the eutectic mixture.

Thus, the post-radiation hydrobromination of allene, unlike spontaneous hydrobromination, occurs at much lower temper-

atures (80–120 K). Analysis of hydrobromination products in allene–HBr systems (with original molar ratios of the reactants 1:1, 1:2 and 5:1) makes it possible to conclude that one allene C=C bond is cleaved in the first step, and subsequent hydrobromination involves the cleavage of the second C=C bond. The post-radiation hydrobromination of allene at low temperatures occurs as the anti-Markownikoff addition to give allyl bromide and also a product of more extensive hydrobromination of allene, *viz.*, 1,3-dibromopropane. The absorption IR spectrum of the reaction products is a superposition of two spectra, *i.e.*, those of allyl bromide and 1,3-dibromopropane.

Since the boiling points of allyl bromide and 1,3-dibromopropane differ considerably (344 and 439 K, respectively), it is easy to separate these products. It was found that if the composition of the original mixture is 1:1, then the overall product yield is $\sim 50\%$, while the yield of 1,3-dibromopropane is $\sim 14\%$; if the allene:HBr ratio is 1:2, the overall yield is 70%, while the yield of 1,3-dibromopropane is $\sim 50\%$. The IR spectra of the reaction products that were isolated match completely the spectra of allyl bromide and 1,3-dibromopropane recorded previously.

Thus, the hydrobromination of allene in the temperature range 80–120 K during unfreezing of the allene–HBr system pre-exposed to radiolysis at 77 K occurs as the anti-Markownikoff addition, irrespective of the original ratio of the reactants. In the first stage, allyl bromide is formed; it then undergoes hydrobromination to give 1,3-dibromopropane. The content of allyl bromide and 1,3-dibromopropane in the reaction products depends on the original composition of the reaction mixture and on the pre-irradiation dose.

4. Cryopolymerisation of epichlorohydrin

Epichlorohydrin (ECH) passes to the glassy state on cooling to 77 K at a rate of $50\text{--}100\text{ deg min}^{-1}$. The calorimetric heating curve for ECH (Fig. 4, curve 1) displays the transition from the glassy state to the supercooled liquid state ($T_g = 130\text{ K}$), crystallisation in the temperature range 150–170 K and melting of the monomer (at 210 K).⁷¹ The heat of melting of ECH determined from these calorimetric measurements is $10.0 \pm 0.5\text{ kJ mol}^{-1}$.

Preliminary γ -irradiation of ECH at 77 K followed by heating results in polymerisation of the monomer.⁷¹ The most intense polymerisation is observed in the devitrification region (see Fig. 4, curves 2, 3). As the pre-irradiation dose is increased, the post-polymerisation of ECH during heating is detected calorimetrically at progressively lower temperatures. At sufficiently high pre-irradiation doses ($> 300\text{ kGy}$), the calorimetric curve shows that the polymerisation rate first increases with an increase in temperature, then decreases slightly and eventually increases abruptly in the glass softening region (see Fig. 4, curve 3). This pattern is probably a consequence of the kinetic non-uniformity of the growing active sites. The ‘freezing’ and ‘revival’ of growing polymer chains during solid-phase polymerisation,²³ the decay

Figure 4. Calorimetric curves of epichlorohydrin heating;²⁵ non-irradiated sample (1); samples exposed to γ -irradiation with doses of 57 kGy (2) and 310 kGy (3). The irradiation was carried out at 77 K.

of stabilised active sites and a number of other processes may be interpreted within the framework of the 'polychronous kinetics' concept.²⁴ In the glass softening temperature range, where the molecular mobility increases abruptly, the post-polymerisation of ECH (like that of the majority of other monomers) occurs efficiently.

In order to elucidate the specific features of the reaction mechanism, Kichigina *et al.*⁷¹ studied the effect of certain additives (pyridine, hydroquinone, ethanol) on the post-polymerisation of ECH. The addition of ~4% pyridine (a typical inhibitor of cationic polymerisation) to the system suppressed completely the ECH post-polymerisation. On the other hand, the addition of hydroquinone (a typical inhibitor of radical polymerisation) did not affect the ECH post-polymerisation. The yield of the polymer from samples containing hydroquinone was almost the same as in the case of pure ECH. Hence, the post-radiation polymerisation of ECH in the temperature range 85–150 K occurs according to the cationic mechanism. It is of note that a polymer is also formed in the region of the system devitrification during the radiation polymerisation of ECH in a glassy matrix of dichloromethane, which is a typical solvent for cationic polymerisation.

Ethanol was found to exert an unusual effect on the post-radiation polymerisation of ECH. The addition of ethanol (to a concentration of 5%) does not virtually affect the post-polymerisation in the temperature range 77–120 K and suppresses strongly the polymerisation in the devitrification region (130–150 K). Ethanol is a weaker inhibitor of cationic polymerisation than pyridine. This is probably the reason why it suppresses the ECH polymerisation in this way. At low temperatures, far from the devitrification region where the matrix is sufficiently rigid, ethanol does not affect polymerisation. In the devitrification region, where softening of the matrix occurs with an abrupt decrease in the viscosity and hence an increase in molecular mobility, ethanol suppresses the cationic polymerisation of ECH. In this case, the yield of the polymer is 5% for the irradiation dose of 150 kGy (for the pure monomer, the yield of the polymer is 12% for the same irradiation dose).

The dynamics of the post-radiation polymerisation of crystalline ECH differs considerably from that of the glassy monomer. Crystalline ECH is obtained by 'annealing' a sample in a calorimeter: glassy ECH is heated to the pre-melting region and then frozen to 77 K.⁷¹ Unlike the glassy monomer, insignificant heat evolution associated with polymerisation is only observed in the pre-melting region for the crystalline sample pre-exposed to radiolysis. At equal pre-irradiation doses at 77 K (170 kGy), the yield of the polymer from crystalline ECH is 3%, while that from glassy ECH is 12%.

It is well known that the epoxide ring is highly resistant against high-energy ionising radiation.^{72,73} Efficient chain polymerisation of ethylene oxide could be carried out only by heating a glassy solution of the monomer in butyl chloride pre-exposed to radiolysis at 77 K.⁷⁴ In the case of ECH, post-polymerisation during devitrification makes it possible to carry out the reaction without the use of glass-forming solvents, since the monomer itself readily passes to the glassy state on cooling to 77 K. This analogy may be extended. As shown previously,⁷⁵ heating of a pre-irradiated glassy ethylene oxide–hydrogen cyanide mixture results in their copolymerisation. It was found that a solution of HCN in ECH (molar ratio 1 : 3) passes to the glassy state on cooling to 77 K (the glass softening temperature is ~130 K). Cooling of this solution pre-irradiated at temperatures in the glass softening region results in copolymerisation of ECH with HCN. The brown reaction product is soluble in ECH. Its IR spectrum displays a band near 1680 cm⁻¹ characteristic of the stretching vibrations of the C=N bond, which indicates that HCN molecules are involved in the copolymer.

5. Polymerisation of ketene in glassy matrices

Solutions of ketene (25 mol.%) in butyl chloride pass to the glassy state on cooling to 77 K (Fig. 5a, curve 1).⁷⁶ Heating of this

Figure 5. Calorimetric curves of the unfreezing of ketene solutions in butyl chloride (25 mol.%) (a) and in diethyl ether (33 mol.%) (b);⁷⁶ non-irradiated solutions (1, 1'); solutions γ -irradiated with doses of 250 kGy (2) and 330 kGy (2').

glassy system pre- γ -irradiated at 77 K results in ketene polymerisation in the devitrification temperature range ($T_g = 95$ K) (see Fig. 5a, curve 2). Subsequent heating results in crystallisation, which (due to the presence of the polymer) is shifted to a higher temperature range with respect to the crystallisation of a non-irradiated sample; in addition, melting of the mixture occurs (see Fig. 5a).

The dependence of the yield of the polymer on the pre-irradiation dose is shown in Fig. 6. In the case of ketene polymerisation in a glassy butyl chloride matrix, the yield of the polymer reached the limit of ~20% at a dose of 50 kGy (see Fig. 6, curve 2). The resulting polymer is yellow; it is partially soluble in ethyl methyl ketone. Its solubility increases with an increase in the pre-irradiation dose: the soluble polymer fraction is 10% at a dose of 10 kGy and 75% at 250 kGy. The polymer was isolated without exposure at room temperature.⁷⁶

Figure 6. Dependence of the yield (Y) of the ketene polymerisation product on the dose (D) of preliminary γ -irradiation;⁷⁶ (1) ketene, (2) solution of ketene (25 mol.%) in butyl chloride, (3) solution of ketene (33 mol.%) in diethyl ether.

The specific heat of ketene polymerisation in a glassy matrix of butyl chloride differs considerably from the heat of polymerisation of crystalline ketene. The mean specific heat of ketene polymerisation in the devitrification region of the system determined in a series of experiments is $74 \pm 3 \text{ kJ mol}^{-1}$, which is almost fourfold larger than the specific heat of polymerisation obtained for crystalline ketene.

The IR spectrum of polyketene resulting from the reaction in the ketene–butyl chloride system also differs considerably from that of the polymerisation product of crystalline ketene. The former contains an intense absorption band characteristic of the stretching vibrations of the C=O bond and a weak band corresponding to the C=C bond. The absorption IR spectra and the specific heat of ketene polymerisation (which is close to the heat of cleavage of the C=C bond) suggest that the cryopolymerisation of a glassy solution of ketene in butyl chloride predominantly occurs with the cleavage of C=C bonds.

It should be noted that previous studies of low-temperature post-radiation polymerisation of various monomers (cyclopentadiene,⁷⁷ ethylene oxide,⁷⁸ acetaldehyde⁷⁹) in a butyl chloride glass-forming matrix pointed to a cationic reaction mechanism. It is likely that the cryopolymerisation of ketene in butyl chloride also occurs by the cationic mechanism with the cleavage of the C=C bond.

Post-radiation cryopolymerisation of a solution of ketene (33 mol.%) in diethyl ether was studied.⁷⁶ On cooling to 77 K, this solution, like the ketene–butyl chloride system, passes to the glassy state. The calorimetric curve of heating displays devitrification of the system ($T_g = 100 \text{ K}$), crystallisation (110–120 K) and melting of the mixture (150 K) (see Fig. 5*b*, curve 1').

After γ -irradiation at 77 K followed by heating of the irradiated sample, as in the ketene–butyl chloride system, the calorimetric curve displays ketene polymerisation in the devitrification temperature range (see Fig. 5*b*, curve 2'). However, unlike the ketene–butyl chloride system, the formation of a polymer in the devitrification region of the ketene–diethyl ether system shifts crystallisation to a lower temperature range (105–110 K). Post-polymerisation of ketene occurs not only in the devitrification temperature range but also during subsequent heating near the melting point of the system (see Fig. 5*b*, curve 2').

The yield of the polymer increases almost linearly with an increase in the pre-radiation dose to 200 kGy and equals $\sim 35\%$ at a dose of 400 kGy (see Fig. 6, curve 3). The isolated polymer was yellow; it was completely soluble in ethyl methyl ketone.

The IR spectrum of the ketene polymerisation product formed in this system is virtually completely the same as that of the polymer obtained by cryopolymerisation of crystalline ketene. The specific heat of ketene polymerisation in a diethyl ether glassy matrix is $21 \pm 2 \text{ kJ mol}^{-1}$, which is close to the specific heat of polymerisation of pure ketene. These data suggest that, as for pure ketene, its polymerisation in a diethyl ether matrix probably occurs by an anionic mechanism involving the preferential cleavage of C=O bonds and formation of a polyester.

Analysis of experimental data⁷⁶ demonstrates clearly that the low-temperature post-radiation polymerisation of ketene can occur by both the anionic and cationic mechanism depending on the conditions of the process. Using solvents typical of cationic (butyl chloride) or anionic polymerisation (diethyl ether) as the glass-forming matrix, it is possible to govern the predominant reaction pathway.

6. Cryoozonolysis of perfluoroalkenes

Cryochemical methods have favoured a considerable progress in the studies on perfluoroalkenes. First, it became possible to conduct experiments with pure ozone (which was isolated by low-temperature rectification). Second, the use of low-temperature kinetic calorimetry⁸⁰ made it possible to follow the temperature and rate parameters of chemical processes involved in the cryoozonolysis of perfluoroalkenes.

The low-temperature ozonolysis of neat tetrafluoroethylene (TFE) and hexafluoropropylene (HFP) in the absence of oxygen was studied.^{81,82} It was found that for equimolar perfluoroalkene:O₃ ratios and at low temperatures (140–230 K) ozone adds quantitatively to the double bond to give the corresponding ozonides. The cryoozonolysis products are stable up to temperatures of 250–290 K. They decompose at higher temperatures; however, the ozonide from TFE is more stable than the ozonide from HFP. The resulting decomposition products of TFE and HFP ozonides initiate the polymerisation of TFE and a number of other monomers.⁸³

The previously developed technique to prepare samples and perform experiments, which prevents the reaction from occurring in uncontrolled explosive mode, allowed the low-temperature ozonolysis of some other perfluoroalkenes, *e.g.*, perfluoro-4-methylpent-2-ene (HFP dimer, or DHFP) and perfluoro-2,4-dimethyl-3-ethylpent-2-ene (HFP trimer, or THFP) to be studied as well.^{83,84}

On cooling to 77 K, the HFP dimer passes to the glassy state ($T_g = 110 \text{ K}$). On cooling the sample containing equimolar amounts of DHFP and O₃, an exothermic reaction of ozone with DHFP occurs starting from $\sim 210 \text{ K}$. The cryoozonolysis rate increases with an increase in temperature to reach a maximum near ~ 240 – 250 K . The overall activation energy of the reaction in the temperature range 210–240 K is $90 \pm 5 \text{ kJ mol}^{-1}$. On further increase in temperature, the rate of the process decreases because the reactants are depleted. The thermal effect of DHFP ozonolysis determined in a series of calorimetric measurements is $505 \pm 5 \text{ kJ mol}^{-1}$.

As with TFE and HFP, the ozonolysis of DHFP at low temperatures according to the well-known three-step Criegee mechanism⁸⁵ gives the corresponding carbonyl-containing compounds and the DHFP ozonide. Initially, the reaction of ozone with DHFP gives the so-called molozonide

This ozonide is unstable and decomposes quickly to a bipolar ion $-\text{FC}^+ - \text{O} - \text{O}^-$ $\leftrightarrow$ $-\text{FC}^+ = \text{O} - \text{O}^-$ and a carbonyl compound $-\text{FC} = \text{O}$ $\leftrightarrow$ $-\text{FC} = \text{O}$. The resulting intermediates readily reassemble in a different manner to give a more stable ozonide

Like TFE and HFP ozonides, DHFP ozonide initiates polymerisation of a number of monomers, *e.g.*, TFE, methyl methacrylate, acrylonitrile, and also copolymerisation of tetrafluoroethylene with hexafluoropropylene. It should be noted that the use of the ozonides obtained for the initiation of the polymerisation of fluoromonomers has important advantages over the use of other initiators.⁸⁶ DHFP ozonide is non-explosive and storage-stable. The use of perfluoroosonides makes it possible to polymerise TFE under atmospheric pressure and at room temperature with technologically acceptable rates. In principle, such initiators allow continuous polymerisation of fluoromonomers in the gas phase to be performed. The equipment required for the process is simplified considerably because gaseous TFE is used under ordinary pressure; furthermore, the synthesis becomes much more environmentally safe, because no emulsions or water are used.

IV. Autowave processes

In our discussion of the mechanism of an elementary act of a chemical reaction at temperatures near absolute zero (radiation-induced and photochemical polymerisation of formaldehyde, photochlorination of ethylene in a spatially ordered crystalline structure, radiation-induced hydrobromination of ethylene,

etc.^{25–33}), we did not touch upon the mechanism of the chemical transformation chain. However, in addition to the obscure issue of the mechanism of overcoming the activation barrier, yet another important problem remained open, *viz.*, that of the mechanism of the displacement of reagents in an elementary act of attachment of monomeric unit. It should be reminded that in the formation of a macromolecule each van der Waals distance between the monomers in a crystal decreases to the lengths of chemical bonds as a result of the reaction.

The consideration of the mechanochemical aspect of the radiation cryochemistry of solids was stimulated by the discovery of the chain reaction initiation upon local sample destruction.⁸⁷

When destruction of a solid occurs, the mechanical energy of its elastic deformation is concentrated in the vicinity of the newly formed surface. It is well known that upon such energy transformation, the properties of substances on the newly formed surface change considerably in comparison with their bulk properties.^{88,89} Brittle destruction is accompanied by a number of physicochemical phenomena: emission of electrons and ions, luminescence, generation of radicals, sharp acceleration of transfer processes on the split surfaces.^{90–92} It seemed logical that the transition of the reaction from the homogeneous mode to the considerably heterogeneous mode by performing brittle destruction of the sample would 'switch on' the non-equilibrium mechanism of energy transfer to active sites previously stabilised in the solid matrix, and initiate chemical transformations at low temperatures.

Let us consider yet another circumstance that prompted the researchers to reconsider the generally accepted concepts. In the studies performed before, both the kinetic models that describe solid-phase radiation-chemical transformations and the experimental techniques were based on the assumptions about the system uniformity and homogeneity of the chemical reaction. This stage was quite logical, as it is difficult to reveal and study specific features of non-uniform chemical transformation modes by calorimetric and spectroscopic techniques that deal with integral signals. There have always been doubts as to the applicability of zero-dimensional kinetic models in the radiation chemistry of solids, since it is well known that an irradiated sample is never homogeneous on the microscopic scale. The main results obtained at this step of the studies were generalised in a number of reviews.^{13–15}

Polymerisation and copolymerisation are the most interesting processes during which it is possible to observe low-temperature transformation autowaves. Their principal difference from previously studied chain reactions of chlorination and hydrobromination of hydrocarbons is that polymerisation produces long material chains. It is reasonable to expect that this predetermines certain features of the reaction, *e.g.*, an increase in the life time of active polymerisation sites due to the limited molecular mobility in the network formed by a polymeric product. Furthermore, the formation of long polymeric chains under low and ultralow temperature conditions is of undoubted interest for the explanation of the processes of 'cold' chemical evolution of matter in the Universe.

1. Polymerisation autowave of crystalline acetaldehyde

The propagation of the polymerisation front in solid radiolysed acetaldehyde at comparatively high temperatures (117–147 K) close to the monomer melting point (150 K) was observed by thermography and by shooting a film.⁹³ This phenomenon was interpreted within the framework of the classical thermal mechanism of burning. The propagation rate of the reaction front was 1–3 cm s⁻¹ at the temperatures specified above and upon pre-irradiation with doses of 5–100 kGy. Using just one heat transfer equation and a number of assumptions, Pshezhetskii and Tupikov⁹³ calculated the time required to add one monomeric unit to a polymeric chain (10⁻⁸ s). The kinetics of this reaction has been studied in detail by the calorimetric method in a slow temperature scanning mode and directly under γ -irradiation in the absence of

noticeable sample overheating.²⁵ The rate constant of chain growth in the crystalline monomer was determined at 130–140 K:

$$k \approx 3 \times 10^{17} \exp\left(-\frac{46000}{RT}\right) \text{ litre mol}^{-1} \text{ s}^{-1};$$

it was found that the time required for the addition of one monomer unit is as short as 0.1–0.01 s. In view of this, a question appeared whether the theory of burning was rightfully used⁹³ to describe the process of the layer-by-layer propagation of the polymerisation front.

The development of the concept of autowave processes stimulated Kichigina *et al.*⁹⁴ to analyse specific features of the polymerisation of crystalline acetaldehyde on a new qualitative level. This reaction is of particular interest owing to two factors. First, the discovery of the autowave mode during the polymerisation of acetaldehyde would allow one to state that a cryochemical wave is possible in a one-component system. Second, the thermal effect of this reaction is virtually an order of magnitude lower than those of systems studied previously.

The main concepts regarding the mechanochemical feedback in the autowave process^{13–15} were confirmed by a study of this system. The polymerisation wave, which appears as a result of local brittle destruction of crystalline pre-radiolysed acetaldehyde in the temperature range 4.2–77 K, was observed in bulk (cylindrical) and thin-film samples immersed in a nitrogen or helium bath.⁹⁴

The principal features of the structure of the running polymerisation fronts in acetaldehyde are similar to those found for other cryochemical reactions (Fig. 7). These include an indistinctly expressed stage of inert heating and the abrupt reaction 'turn-on' at considerably lower temperatures than in the case of thermoactivated processes. However, unlike the systems studied before, more time is required for the temperature decrease after the polymerisation front has passed. The characteristic time of this decrease is 2–3 times longer than the thermal inertia of the system. Hence, the polymerisation reaction is not 'turned off' after the wave front has passed, and part of the polymer is formed behind the front.

Figure 7. Time and spatial scanning of characteristic temperature profiles of the propagation waves of acetaldehyde polymerisation at 77 K (a) and 4.2 K (b).⁹⁴

The γ -irradiation dose is 700 kGy; the wave propagation rates are 26 (a) and 4 mm s⁻¹ (b).

When the front passes through a sample immersed into a helium bath, the maximum temperature in the polymerisation front does not exceed 130 K, which is much lower than the monomer melting temperature (150 K). Thus, this system may be used to analyse the changes in the structure and phase state of a crystalline sample caused by the passage of a cryopolymerisation mechanochemical wave through the sample. According to the concept developed in a series of studies,^{13–15} the front of a chemical reaction is a mechanical dispersion zone that moves

through a solid reagent. The cinegrams obtained by Kichigina *et al.*⁹⁴ for the polymerisation of acetaldehyde show that a polycrystalline sample becomes transparent after the wave has passed. It may be assumed that, as the polymerisation wave passes, amorphisation of polycrystalline acetaldehyde occurs due to both the formation of an amorphous polymer phase and mechanical dispersion.⁹⁴

This assumption was checked by the calorimetric method, which allows determination of the ratio of amorphous and glassy phases in a solid matrix, based on changes in the thermal effect of melting. In order to perform this analysis, a cylindrical sample of acetaldehyde through which an autowave has passed in liquid helium was transferred to a liquid nitrogen bath and then cut into several parts at different heights. Each of the parts was placed in a separate calorimeter at 77 K and its calorimetric curve of unfreezing was recorded. It was found that the crystalline phase was absent in the entire sample after the wave has passed. The calorimetric experiments only manifested a jump of the thermal capacity which accompanies devitrification, whereas the thermal effect of melting was not observed. However, if the process is carried out not in the autowave mode but by slow heating of the entire sample in a calorimeter (without brittle destruction that initiates an autowave), then the nonconsumed monomer maintains its crystallinity. This confirms that the passage of a mechanochemical wave through a crystalline sample results in its amorphisation.

The autowave propagation rate depends on the pre-irradiation dose. For samples immersed into liquid nitrogen, the propagation rate of the polymerisation autowave increases linearly with an increase in the irradiation dose up to 1200 kGy. It was logical to assume that the increase in the wave propagation rate resulted from the accumulation of active sites. However, active sites (radical ions and radicals) are accumulated linearly during the radiolysis of polycrystalline acetaldehyde at 77 K as the irradiation dose increases to 50 kGy; after that, the process slows down and ceases completely at doses above 650 kGy.

The increase in the wave propagation rate with an increase in the irradiation dose may be explained as follows. The low-temperature radiolysis of acetaldehyde gives rise to methane and carbon monoxide, which exist in a condensed state at 77 K. When the reaction front passes, these radiolysis products turn into gases (the melting points of CH₄ and CO are 111 and 81 K, respectively). The gases evolved can facilitate brittle dispersion of the sample and thus accelerate the movement of the running transformation front.⁹⁴

2. Acetaldehyde polymerisation autowave in a glassy matrix

Pure acetaldehyde could not be transformed to the glassy state even by fast cooling. Solutions of acetaldehyde (up to 30 mass %) in butyl chloride are completely transformed to the glassy state on cooling. As the content of acetaldehyde in the original solution is increased (> 30 mass %), a crystalline phase appears in samples cooled to 77 K (the cooling rate is ~150 K min⁻¹). Such samples are mixtures of a glassy and crystalline phases.

On slow cooling (in a calorimeter) of the acetaldehyde–butyl chloride system radiolysed at 77 K, efficient polymerisation of the monomer occurs in the devitrification region. Convincing proof of the cationic mechanism of the post-polymerisation of acetaldehyde in a glassy butyl chloride matrix has been obtained.²⁵

An autowave polymerisation mode initiated by local brittle destruction was realised in a glassy acetaldehyde–butyl chloride system pre-irradiated at 77 K.⁹⁵ It is interesting to compare the characteristics of the cryopolymerisation waves for crystalline and glassy acetaldehyde samples. The main parameters of the autowave polymerisation process are qualitatively the same in polycrystalline and glassy matrices, but differences are observed as well.

The maximum temperature at the running wave front in a glassy system is 110–130 K; in the case of crystalline acetaldehyde, it may reach 150 K. The critical dose of pre-irradiation, *i.e.*,

the dose starting from which autowave propagation of the process is ensured, is 60 kGy for the glassy system, whereas in the crystalline monomer, it is above 300 kGy.⁷⁹

There is a minimum threshold concentration of acetaldehyde in the original solution that still supports the autowave mode. In fact, the reaction cannot be run in autowave propagation mode in samples containing less than 20 mass % of acetaldehyde at a pre-irradiation dose of 300 kGy.

It is reasonable to relate the observed differences between the cryopolymerisation waves in the crystalline and glassy acetaldehyde with differences in the reaction mechanisms (ionic mechanism in glass and radical mechanism in crystal) and in the strength characteristics of the systems in question. It should be reminded that the devitrification temperature of the acetaldehyde–butyl chloride system ($T_g = 95$ K) is much lower than the melting point of crystalline acetaldehyde (150 K).

Thus, while autowave modes have previously been observed for reactions that were believed to involve radical processes, the acetaldehyde–butyl chloride system features a polymerisation autowave which occurs by a cationic mechanism.

3. Cyclopentadiene cryopolymerisation autowave

It has been shown previously⁷⁷ that the post-radiation polymerisation of cyclopentadiene vitrified in a butyl chloride matrix occurs by a cationic mechanism in the devitrification temperature range of the system ($T_g = 97$ K). These results gave grounds for the search for autowave modes in this system. The local brittle destruction of a cyclopentadiene sample in a glassy butyl chloride matrix pre-radiolysed at 77 K initiates polymerisation that propagates through the sample as an autowave.⁹⁶ As in other autowave processes, this reaction ‘switches on’ at 77 K, and the temperature at the wave front quickly reaches a maximum value. However, considerable time is required for the decrease in temperature after the front has passed, just as in the case of the acetaldehyde cryopolymerisation wave. The polymerisation is not ‘turned off’ after the wave front has passed, and part of the polymer is formed behind the front. The mean degree of conversion calculated from the adiabatic heating at the reaction wave front is ~25%, whereas the yield of the polymer determined gravimetrically is ~55%.

Thus, unlike the autowave processes that give low-molecular-mass products (chlorination and hydrobromination), considerable additional conversion occurs behind the wave front in the case of polymerisation. It may be assumed that the low degree of conversion, *e.g.*, in the butyl chloride–chlorine system, is due to the heating of the wave front to the devitrification temperature, where the molecular mobility increases abruptly; this results in the efficient decay of active sites due to recombination. On the contrary, the limited molecular mobilities of active sites during the polymerisation increase the life time of these sites and hence the degree of conversion.

The velocity of the cyclopentadiene polymerisation autowave increases linearly with an increase in the pre-irradiation dose up to 1200 kGy. Most likely, this behaviour of the wave rate does not result from the dynamics of the accumulation of cationic active sites, since their concentration ceases to increase at much lower doses. It has been shown in special experiments that the radiolysis of the cyclopentadiene–butyl chloride system at 77 K produces a gas mixture with an overall radiation yield of ~1 molecule per 100 eV of absorbed energy.⁹⁶ The fraction of hydrogen in this mixture is ~75%. The passage of the polymerisation wave through a sample (heating to 110–130 K occurs at the wave front) results in intense evolution of dissolved and frozen gases from the glass and their transfer to the gas phase. The pressure of the gas micro-bubbles may favour the brittle destruction of the system. An increase in the pre-irradiation dose increases the quantity of evolved gases almost linearly; hence, brittle destruction should be facilitated. Analysis of the cinegrams of the reaction propagation through the sample confirms this assumption qualitatively.

At high pre-irradiation doses, strong swelling of a sample upon passage of the polymerisation wave is observed; as a result, its volume increases almost twofold after the process has ended. At low pre-irradiation doses and hence smaller amounts of gaseous radiolysis products, no swelling of the sample occurs upon passage of the wave.

Depending on the autowave 'startup' conditions, the character of the autowave process may differ considerably. For the same pre-irradiation doses, the propagation rate of the polymerisation wave initiated in the lower part of the sample is much higher than if the wave is initiated in the upper part. It is of note that if the wave is initiated in the lower part of the sample, the temperature profile of the running wave is steeper. This fact can also be explained by the role of radiolytic gases. When the polymerisation wave propagates from above downwards, the gaseous products can exit to the evacuated space above the sample. However, if the reaction is initiated in the bottom part of the sample, the gases evolved at the wave front have no free way to exit; as a result, the disjoining pressure of the gases increases and accelerates the front movement.

Yet another reason for the linear increase in the wave propagation rate with an increase in the pre-irradiation dose is possible.⁹⁷ Part of the irradiation energy absorbed during the low-temperature radiolysis can be accumulated by means of lattice deformations and formation of metastable phases. Under certain conditions, this accumulated energy will facilitate the brittle destruction of the system. When the wave is launched in the top part of the sample, there are conditions for its 'relief'; however, when it is launched in the bottom part of the sample, 'relief' is hindered considerably owing to the permanent solid 'plug' created by the top part of the sample. In the latter case, the deformation energy accumulated during radiolysis is spent more efficiently, which accelerates the movement of the wave.

The IR spectra of the polymer isolated after the passage of the polymerisation wave coincide completely with the spectra of the product obtained in the post-radiation polymerisation mode during devitrification. However, the conversion of the monomer is much higher if polymerisation is carried out in the autowave mode. The maximum yield of the polymer is 20% for post-polymerisation during devitrification (at a pre-irradiation dose of 50–500 kGy) and from 30% at a dose of 100 kGy to 55% at a dose of 1200 kGy in the autowave mode. The molecular mass of polycyclopentadiene obtained in the autowave mode decreases from 10^6 to 10^4 with an increase in the pre-irradiation dose, but it is by almost an order of magnitude higher than the molecular mass of the polymer formed upon post-radiation polymerisation during devitrification.⁷⁷ This difference may result from the fact that polymerisation in the autowave mode commences at lower temperatures (almost at 77 K) than thermally activated post-polymerisation ($T_g = 97$ K).

It should be noted that the 'explosive' polymerisation of cyclopentadiene was observed in films obtained from molecular beams of the monomer and TiCl_4 as a catalyst, after pricking the film with a metal needle at 77 K.^{98,99} In these experiments, the reaction propagated through the sample at high rate. The highest propagation rates of cryochemical reactions initiated by local brittle destruction of samples pre-radiolysed at 77 K were achieved by Kiryukhin *et al.*¹⁰⁰ These facts suggest that such cryochemical processes may involve a detonation mechanism. It is possible that the 'gas-free detonation' mechanism is realised in this case. According to this mechanism, the shock wave appears and is then supported by the system owing to changes in the density of the compound during the conversion.¹⁰⁰ A model of an autowave process that occurs due to appearance of a density gradient in the reacting layer upon formation of reaction products was suggested.^{101–103} These calculations allowed evaluation of the size of the fragmentation grain of the reactant matrix. The resulting value (~ 10 μm) agrees well with experimental data for autowave modes of cryochemical transformations in thin-film samples.

4. Autowave of acetaldehyde–HCN cryocopolymerisation

The autowave mode has also been realised for cryocopolymerisation.¹⁰⁴ On cooling to 77 K, an HCN–acetaldehyde mixture containing 25 mol.% of hydrogen cyanide passes to the glassy state. Its devitrification temperature (transition to the supercooled liquid state) is 90 K, the crystallisation temperature is 110–115 K, and the melting point is 140 K. The local brittle destruction of such a sample pre-radiolysed at 77 K gives rise to an autowave of copolymerisation of acetaldehyde with HCN. The copolymerisation wave front rapidly propagates over the entire sample from the top downwards (this may be observed visually by the changes in the sample colour). The maximum temperature at the wave front increases from 125 K at an irradiation dose of 15 kGy to 148 K at a dose of 140 kGy; the yield of the copolymer increases similarly.

The dependence of the propagation rate of the cryocopolymerisation autowave front on the pre-irradiation dose was found to be unusual (Fig. 8, curve 2). It should first be noted that, as in the systems studied previously in which the autowave low-temperature transformation mode was observed, the acetaldehyde–HCN system features a critical dose of preliminary γ -irradiation below which autowave cryocopolymerisation is not initiated. In this case, the threshold γ -irradiation dose is ~ 15 kGy. The propagation rate of the acetaldehyde–HCN copolymerisation wave front increases with an increase in the pre-irradiation dose to ~ 8 cm s^{-1} at 100 kGy. If the irradiation dose is increased, the propagation rate of the copolymerisation wave front decreases.¹⁰⁴

Figure 8. Dependence of the yield (Y) of the copolymer (1) and the rate (v) of the copolymerisation propagation wave front (2) on the pre-irradiation dose (D).¹⁰⁴

The open squares show the values for the reaction in the thermoactivated post-radiation effect mode.¹⁰⁵

The model of the autowave phenomena studied is based on a concept of the existence of a positive feedback between (i) the heat evolved in an exothermic reaction and (ii) destruction of the matrix. As follows from this concept, the chemical reactivity of a radiolysed system is determined not only by the concentration of active sites but also by the potential mechanical energy accumulated in the sample and the strength parameters of the matrix. In fact, autowave transformation modes have been realised at 4.2 K whereas the thermally activated mode requires much higher temperatures for these reactions to occur (near the melting point or the system devitrification temperature). The linear relationship between the propagation rate of the transformation wave and the concentration of the active sites accumulated during radiolysis is violated considerably. It was assumed¹⁰⁴ that the slowing down of the acetaldehyde–HCN copolymerisation propagation wave at doses above 100 kGy results from changes in the accumulating properties of this matrix during the radiolysis.

After the passage of the copolymerisation wave at 77 K, the sample was unfrozen to room temperature and the copolymerisa-

tion yield was determined.^{105, 106} On increasing the pre-irradiation dose, the copolymerisation yield increases to reach a maximum value of 45%–50% (see Fig. 8, curve 1). Figure 8 also shows the dependences of the yield of the copolymer on the irradiation dose during thermally activated post-polymerisation.^{105, 106} During slow unfreezing of a pre-irradiated acetaldehyde–HCN system in a calorimeter, post-polymerisation occurs in the devitrification temperature range. The dependences of the yield of the copolymer on the irradiation dose are similar for both reaction modes.

The copolymer obtained in the autowave mode is colourless; it is completely soluble in ethyl methyl ketone, and its molecular mass decreases with an increase in the pre-irradiation dose.¹⁰⁵ On the contrary, the content of nitrogen in the copolymer increases with an increase in the pre-irradiation dose (Table 1). Based on these experimental results and the data on the yield of the copolymer at different irradiation doses, it is possible to calculate the mean number of HCN and acetaldehyde molecules in one polymeric macromolecule and the concentration of polymeric chains in the system during the reaction. The calculated values are listed in Table 1.¹⁰⁴ It is of note that the number of macromolecules formed increases monotonically with an increase in the pre-irradiation dose; this number is larger than that of the initiating active sites accumulated during pre-radiolysis, especially at high doses.^{107–109} These data are evidence of the existence of chain transfer.

Table 1. Characteristics of acetaldehyde–hydrogen cyanide copolymers.¹⁰⁴

Pre-irradiation dose /kGy	Molecular mass	Nitrogen content (mol.%)	Mean number of units in a macromolecule		Number of macromolecules, $10^{-19} A / g^{-1}$
			HCN units	MeCHO units	
15	13 500	0.8	2.4	306	1.2
40	9 000	1.28	2.6	204	2.6
50	7 800	1.59	2.8	176	3.2
90	5 000	3.95	4.5	111	5.6
140	4 000	—	—	—	7.8
200	2 200	—	—	—	13.3
220	2 200	18.6	9.1	34	14.8

The principal difference between the autowave polymerisation mode described above and classical liquid-phase processes is that in the former case the reaction initiation rate at the wave front quickly attains a maximum value (in approximately 0.1 s) and then decreases (the active sites accumulated during irradiation are consumed during the process). The observed characteristics of copolymerisation are evidently due to this feature of the process kinetics.

It should be noted that autowave copolymerisation does not give cross-linked insoluble fractions formed as a result of a thermally activated reaction (slow heating of pre-irradiated samples) at different acetaldehyde : HCN starting ratios.

A scheme of thermally activated copolymerisation of acetaldehyde and HCN was suggested, which involved a combination of two mechanisms (cationic and radical).¹⁰⁶ At low pre-irradiation doses, the copolymer is mostly formed by the cationic mechanism. As the pre-irradiation dose is increased, the radical mechanism starts to predominate, and the fraction of HCN in the copolymer increases. Taking into account that the characteristics of the copolymers obtained in different reaction modes (autowave and thermoactivated) are similar, it may be assumed that a similar mechanism is realised in the autowave cryocopolymerisation of acetaldehyde with HCN.

V. Cosmochemical aspects of low-temperature reactions

It is very likely that a very long period of chemical evolution of compounds preceded the origination of living matter and its subsequent biological evolution. This pre-biological development provided ‘building materials’ for the creation and development of living substance: the formation and accumulation of progressively more complex molecular structures, *viz.*, amino acids, nucleotides, polysaccharides, *etc.*, that could subsequently be utilised as a basis for building the main elements of the living cell in the process of biological evolution.

It is hard to imagine, based on the generally accepted concepts about the dynamics of chemical transformations, that a sufficient amount of the ‘building material’ could have been formed in a specific place over any period when favourable physical conditions existed on the Earth (temperatures within 250–450 K, pressure within 1–1000 bar, virtual absence of radiation fields). Probably, the main obstacle was that there had never existed a sufficiently long time interval during which the required conditions were maintained. Previously, the idea was put forward that the cosmic time and space scales may be used to describe the pre-biological evolution process (see, *e.g.*, the monograph by Zigel’¹¹⁰). However, the common concepts about the dynamics of chemical transformations hampered the development of this idea. The impossibility of chemical reactions at temperatures near absolute zero had to be doubted after it had been established experimentally that chain polymerisation of solid formaldehyde can occur at temperatures within 4–100 K. Later, low-temperature chain processes were also observed for a number of other chemical transformations.

The autowave cryopolymerisation processes considered above demonstrate that macromolecules can be formed under conditions similar to those in outer space, *i.e.*, at low temperatures and in weak radiation fields. It is quite rightful to apply the ideas considered in the present review to the explanation of the processes of ‘cold’ chemical evolution in the Universe, *i.e.*, formation of progressively more complex molecules from elements under conditions of interstellar dust and cold planets.

Since the time of their origination in the ‘big bang’,^{110, 111} the matter in the Universe may have passed through a number of cycles involving strong heating. The end of any such cycle may have served as a starting point for the subsequent chemical evolution of matter. Certainly, matter only existed as chemical elements during any heating cycle. Subsequent cosmic processes resulted in a more or less fast temperature decrease almost to absolute zero. The formation of molecules from elements and their subsequent complication could only occur during such cooling. For example, molecular gases were formed: hydrogen, oxygen, nitrogen, carbon monoxide. If these gases froze on interstellar dust particles, then, according to the classical concept, their subsequent chemical transformations were quite doubtful, even on the cosmic time scale. On the other hand, ‘oceans’ of ammonia and methane have been discovered on many outer planets and their satellites. In addition, the interstellar space also contains large amounts of these gases and water.

We can attempt to describe the formation of such compounds as ammonia and methane from a frozen mixture of elements that originally existed on the surface of cold planets and their satellites in the following way. The thermal stress in the solid planet cover was a means for its continuous destruction. The multiple brittle destruction events of the frozen element mixture pre-activated by radiation may have resulted in the chemical binding of the components. This scenario may have been realised in interstellar clouds, *i.e.*, huge suspensions of dust grains in a gas. It is believed^{8, 48} that space dust particles contain silica or graphite nuclei coated with a ‘coat’ of ‘dirty ice’, *viz.*, a mixture of frozen gases.

The next stage of chemical evolution, during which solid ammonia and hydrocarbons were transformed to the simplest

amines due to the positive feedback between brittle destruction and chemical reactions on the freshly formed surface, is also quite believable. The fact that long polymeric chains are formed upon brittle destruction under conditions of cosmic cold may be regarded as proven experimentally for the polymerisation of formaldehyde and acetaldehyde.

The information presented above is also of interest in relation to other cosmochemical problems. Hydrogen cyanide is a widespread molecular compound in outer space, specifically, in huge clouds of interstellar dust, in comets and in other galactic structures. The HCN molecule is generally considered to be the basis for further chemical evolution, because its transformations provide a direct route to proteins and other large molecules. The chemical behaviour of this simple molecule under conditions that are close to those in outer space (low temperatures and radiation) and the role it plays in the 'cold' chemical evolution of the Universe are of considerable interest for researchers.

VI. Conclusion

Studies on the cryochemical reactions in crystals have made it possible to observe experimentally chain processes at temperatures near absolute zero. These results, which are beyond the scope of the classical concepts of chemical kinetics, have stimulated studies on the mechanisms of 'non-Arrhenius' elementary events of chemical transformations.^{8, 12, 35–41} However, there are not so many reactions that occur by the chain mechanism at $T < 77$ K: radiation-induced polymerisation and photopolymerisation of formaldehyde^{5, 25, 27, 30} and acetaldehyde;^{25, 31} photochlorination of ethylene in a spatially ordered structure,³⁶ radiation-induced hydrobromination of ethylene,^{34, 35} and others.^{20–22, 26}

The next step important in principle which favoured the expansion of studies at low temperatures involved the discovery and investigation of the autowave modes of chemical transformations initiated by local brittle destruction of solid samples at 4.2–77 K.^{13–15, 87} Results of recent studies suggest that autowave processes are rather widespread in the cryochemical transformations of solids. Autowave modes of cryochemical transformations have been observed for polymerisation and copolymerisation, chlorination and hydrobromination of saturated and unsaturated hydrocarbons.²⁵ The realisation of high chemical transformation rates at such low temperatures is also very attractive.¹⁰⁰ The results obtained open up new approaches to the explanation of the mechanism of chain cryochemical reactions; these approaches take the potential energy accumulated by a solid and the high reactivity of surfaces formed upon brittle destruction in an autowave transformation mode into account.

If a chemical reaction is carried out during matrix devitrification, transformations of the reactants can be studied at temperatures much lower than the melting points of these compounds.²⁵ Obviously, a chain reaction in a crystal lattice is hindered owing to the low translational mobility of the reactants and the necessity of destruction of the lattice. On the other hand, the selection of an appropriate vitrifying matrix makes it possible to perform a reaction at very low temperatures.^{22, 66} The interest in such low-temperature chemical processes is due to the fact that, as the temperature is decreased, selection from among the possible reaction pathways occurs: those reactions that have the lowest activation energy 'survive'.

Thus, a decrease in the reaction temperature should increase the selectivity of the process. Furthermore, the entropy factors that are so important in the thermodynamics of chemical reactions become less important at lower temperatures; therefore, the equilibria of transformations are shifted in favour of exothermic reactions, even if the latter give rise to highly ordered systems.

The data presented in this review are of interest because they can help explain the 'cold' chemical evolution of matter in the Universe.

Abstract. The potential of using the translational mobility of hydrogen, oxygen and fluorine atoms in the crystals and solid matrices of inert gases for initiating solid-phase cryochemical reactions and for investigating the stabilised intermediate particles generated in these reactions is discussed. The main spectroscopic methods used to study the stabilised particles are considered. Particular emphasis is placed on elucidation of the spectroscopic characteristics required for reliable identification and determination of the structure of new reactive intermediates. Methodological approaches to the solution of this problem are discussed. Examples of successful implementation of these approaches by various research groups are given. The bibliography includes 205 references.

I. Introduction

Atom–molecular chemical reactions play an important role in various chemical and biological processes. Therefore, considerable attention has been given to applied studies of and basic research into such reactions. Experimental determination of the rate constants for most of the practically important atom–molecular reactions in the gas phase dates back to the latter half of the 20th century. However, the mechanisms of cleavage and formation of new chemical bonds in this type of reactions cannot always be described at the molecular level due to the lack of information on the dynamics of the reacting systems in the vicinity of the transition state.

A particular avenue of research in the field of modern chemical physics is the investigation of the dynamics of atom–molecular chemical reactions in which the formation of end products is preceded by binding the reactants into a long-lived (compared to the period of intramolecular vibrations) intermediate complex.

Of particular interest are the investigations of intermediate species (radical intermediates) involved in these reactions. This is due to a noticeable and sometimes even determining effect of these species on the ratio of the reaction products and on the energy distribution over their internal degrees of freedom. Experimental kinetic data as well as quantum-chemical calculations on this type of reactions in the gas phase indicate the possibility for a variety of reactive intermediates to exist. Nevertheless, spectroscopic information on the intermediate species of most of the reactions in question is unavailable as yet. Detection of such intermediates in the gas phase is a rather complicated problem since the intermediate products usually have short lifetimes because of high collision energies of reactants in the reactions occurring under normal conditions.

Traditionally, information on the reaction dynamics of elementary processes in the gas phase has been obtained using the molecular beam technique which allows measurements of the energy and angular distributions of products formed in the atom + molecule collision reactions. However, these experiments provide indirect information on the reactive intermediates, since the behaviour of the reacting system in the vicinity of the transition state is reconstructed from the data on the state of the end reaction products. Improved experimental techniques combining supersonic cooling of gas jets and spectroscopic methods with high temporal resolution^{1,2} are based on the concept of studying the chemical dynamics of a system with a temporal resolution that is better (shorter) than the characteristic times of intramolecular motions. This permits obtaining information on the potential energy surface (PES) of reactions in the vicinity of the transition state. However, these methods are applicable to a narrow range of objects due to the requirement of high sensitivity and temporal resolution imposed on the measurements carried out under conditions when the system is 'frozen' in configuration on the femtosecond time scale.

Another approach to the investigation of short-lived intermediates in the gas phase involves freezing of reactive intermedi-

ates at cryogenic temperatures. In the simplest version of this technique products of a gas-phase reaction are trapped and frozen in a matrix consisting of a large excess of inert gas. The use of inert gases as solid matrices for spectroscopic investigations of radical species was proposed in the studies of research groups headed by Pimentel and Porter in 1954.^{3,4} These studies marked the beginning of intensive development of the matrix isolation technique. The vast majority of species trapped in the matrices of inert gases exhibit no translational mobility at temperatures up to the melting (sublimation) temperature of the crystal of inert gas. This allows accumulation of sufficiently high concentrations of radicals and their detection by continuous-wave spectroscopic techniques. It is these methods that were employed to obtain spectroscopic data for most of the known free radicals; this information is generalised and systematised on a regular basis.⁵ An essential drawback of the technique is the interaction between the species under study and the crystalline environment, which inevitably causes changes in their spectroscopic characteristics. Therefore, molecular beam spectroscopy provides more accurate information on subtle features of the molecular structure and properties of reactive intermediates. Nevertheless, versatility and the possibility of using continuous-wave spectroscopic equipment for detecting new molecules and obtaining primary characteristics of their structures make the matrix isolation technique a basic experimental method of research in such fields of science as chemical physics and molecular spectroscopy.

During the last 50 years the concept of matrix isolation of radical species developed in two main directions, namely, search for new conditions for generation of reactive intermediates and the use of various spectroscopic methods for their studies. These research avenues have been reviewed.^{6–8} In the mid-1960s, Milligan and Jacox proposed⁹ that, would the atoms of light elements (*e.g.*, hydrogen) have sufficiently high translational mobility in low-temperature matrices, the reactive intermediates could be stabilised by generating them *in situ* in the reactions of the mobile atoms with molecules of the other reactant trapped in the inert matrices.

Indeed, at ultralow temperatures (≤ 50 K) the solid matrix acts as an inert chemical microreactor which permits fast relaxation of the excess energy of the reaction and prevents the reaction products from flying apart. The matrix also provides ideal conditions for stabilisation of the reactive intermediates characterised by short lifetimes in the gas phase. To illustrate their hypothesis, Milligan and Jacox carried out spectroscopic studies of the products of photolysis of HI molecules in dilute Ar/HI/O₂ solid mixtures and first determined the vibrational frequencies of the HO₂ radical. They assumed that this radical is produced in the reaction of the migrating photogenerated hydrogen atom with oxygen molecule trapped in the inert matrix,

Obtaining new experimental data on the mobility of various atoms in cryogenic crystals and solid matrices in the last decade gave an impetus to further development of this concept. Since the early 1990s a large number of studies on the conditions for generation of atoms in solid matrices by photolysis of trapped molecules have been reported. It was established that in some cases the ‘cage effect’, which precludes photodissociation of molecules in solids, is insignificant and generation of atoms in inert matrices can occur with quantum yields close to unity. A large number of studies provide only qualitative data which permits ambiguous interpretation from the standpoint of physical mechanisms. Nevertheless, they point to the possibility for particular atoms to migrate over rather long distances in the crystals and matrices of inert gases. The results obtained were generalised in a review¹⁰ which also concerns possible mechanisms of translational mobility of atoms at ultralow temperatures, namely,

migration and thermalisation of a translationally excited ‘hot’ atom generated upon photodissociation of precursor molecule as well as thermal and photostimulated diffusion of atoms.

In this review we discuss the potentialities of using mobile atoms in cryogenic solid matrices for generation and investigation of reactive intermediates. The data on the mobility of various atoms are presented, methodological approaches aimed at solving the problem posed are outlined and some examples of their practical implementation are given.

We will consider reactions with participation of reactive atoms of only three elements, that is, hydrogen, fluorine and oxygen, involved in various practically important processes. The relatively simple electronic structure of these atoms facilitates analysis of the various elementary processes they are involved in. Two different [from the standpoint of their chemical reactions in solid matrices (crystals) of inert gases] types of mobile atoms considered in this review are translationally excited ‘hot’ atoms and diffusing thermalised atoms.

To generate reactive intermediates in a solid-phase chemical reaction in crystals at ultralow temperatures, the following conditions should be met:

- the molecules of reactant and photolytic precursor of atoms must be initially isolated in the sample;
- the atom must be mobile to migrate in the solid matrix;
- the energy of the atom must be high enough to overcome the barrier to reaction.

This shows the interrelation between matrix isolation techniques and preparative-scale cryochemistry. They have much in common from the standpoint of methodology but are mutually excluding in their basic formulations, namely, matrix isolation implies the absence of chemical transformations while the subject of cryochemistry is specific features of chemical reactions at ultralow temperatures.^{11,12}

In this review cryochemical reactions of mobile atoms are treated as a means of generation of reactive intermediates while spectroscopic methods of investigation are considered as experimental techniques for studying matrix-isolated particles. This concept predetermines the issues that have attracted primary attention in this review. First of all, investigations of chemical transformations require relevant kinetic measurements to establish the principal reaction channels in the reacting system and to identify the primary and subsequent reactions. Carrying out spectroscopic measurements, one should choose spectroscopic characteristics necessary for reliable identification of particles. This is of particular importance in studies of novel open-shell species that were not observed earlier by other experimental methods.

Isotope substitution has been traditionally employed in analysis of vibrational and EPR spectra. Until recently, in most cases analysis of the spectra of isotopomers with the same stoichiometry served as the only objective argument when identifying new stabilised particles and establishing their structure. Improvement of computer hardware and development of new methods of quantum-chemical calculations in the last 10–15 years brought about radical changes in the procedure for identification and characterisation of trapped intermediates. Experimental data on the structure of most reactive intermediates are scarce, which precludes evaluation of the reliability and accuracy of calculations. It should be noted that quantum-chemical calculations should be treated as a kind of prediction until confirmation by corresponding experimental data. However, the use of modern methods of quantum-chemical calculations permits reliable identification of new chemical compounds based on comparison of the calculated and experimental spectroscopic data. In this review particular emphasis has been placed on joint use of experimental (both spectroscopic and kinetic) data and the results of quantum-chemical calculations of reactive intermediates.

II. Low-temperature spectroscopy of matrix-isolated species as a tool for investigations of reactive intermediates

1. Vibrational spectroscopy

The absorption IR spectroscopy is the most widely used method of investigation of matrix-isolated particles. Using this technique implies that the interaction of impurity particles with the lattice of inert gas is weak and has only little effect on the structure and vibrational dynamics of the species under study. The relative matrix shifts of vibrational frequencies (ratio of the frequency difference between the molecular vibration in the solid matrix and in the gas phase to the vibrational frequency in the gas phase) of various molecules and radicals have been analysed.¹³ For most molecules the matrix shifts were found to lie between -2% and 2% (Fig. 1). The matrix shift histogram presented is centred at $\sim 0.5\%$ while the dispersion is at most 1% . The magnitude and sign of the matrix shift are related to the character of intermolecular interactions between the particle and environment. In some cases one should take into account the dynamic effects in addition to static guest–host interactions. Modern computational approaches to determination of matrix shifts have been documented.^{14, 15}

Figure 1. Relative matrix shifts (m) of vibrational frequencies of intermediates isolated in argon matrices.¹³

Head-Gordon *et al.*¹⁶ reported comparative analysis of the accuracy of calculations of vibrational frequencies for various molecular compounds using the most widely used *ab initio* computational methods (in the harmonic approximation). The accuracy of B3LYP density functional calculations of fundamental frequencies was shown to be comparable with that of the frequency calculations by the CCSD(T) method. For instance, the frequencies obtained from B3LYP/cc-pVDZ calculations deviate from the corresponding frequencies measured in the gas phase by $\sim 5\%$ on the average, while the relative error of CCSD(T)/cc-pVDZ calculations can be as high as 1.5% . At the same time, all computational methods employed give a rather wide scatter of deviation values (dispersion of the deviations from the experimental values amounts to $10\%–12\%$). The most complicated problems are associated with calculations of the vibrational frequencies of light atoms (in particular, hydrogen atom) in polyatomic molecules.

The potentialities of IR spectroscopy are extended with improvement of corresponding equipment. Currently, the technique permits reliable detection of molecular compounds under study at concentrations that are low enough to provide conditions for spatial isolation of these species in a solid matrix. A conventional procedure for preparation of solid samples of an inert gas, containing trapped impurity molecules, involves condensation of

the gas molecular beams *in vacuo* on a substrate cooled to helium temperatures. Thin films of inert gas thus obtained have a polycrystal morphology and are characterised by the presence of nonequilibrium defects and a large specific surface. Usually, such films are called ‘solid matrices’; however, one should keep in mind a basic difference between these films and crystals grown under equilibrium conditions. It is nonequilibrium conditions for condensation and low concentrations of impurity particles that allow trapping of virtually any particle in the matrix without their association. Long-range order in the vicinity of the small impurity molecules trapped in a solid matrix corresponds, as a rule, to substitutional impurity or to interstitial impurity occupying the O_h site in the face-centred cubic (f.c.c.) lattice of inert gas.¹⁴ An impurity trapped in a solid matrix is considered isolated if its nearest environment contains no analogous particle. If the trapped molecules are randomly distributed over the substitutional sites of a f.c.c. crystal lattice, the probability, p , for a particular molecule to be spatially isolated is given by the following expression,

$$p \approx 1 - zx_m,$$

where $z = 12$ is the number of atoms in the first coordination sphere of the impurity molecule and x_m is the relative concentration of impurity particles ($x_m = [m]/[Ar]$). To consider a total of 99% of impurity particles isolated, their concentration x_m should be less than 10^{-3} . In real experiments the number of trapped dimers and higher clusters of impurity molecules much exceeds the statistical average. This is usually explained by limited mobility of the molecules on the surface of the growing film during condensation and by their interaction in the gas mixture. If only van der Waals intermolecular interactions occur, the fraction of clusters amounts, as a rule, to $1\%–5\%$ of the total number of trapped molecules at $x_m \approx 5 \times 10^{-4}$. If the molecules are capable of forming hydrogen-bonded clusters (*e.g.*, NH_3 and HCN , see Refs 17–19), this proportion increases to $10\%–20\%$.

The sensitivity of IR spectroscopic measurements in the conventional spectral range ($400–4000\text{ cm}^{-1}$) under conditions of matrix isolation of the particles under study can be estimated based on the characteristic values of the integrated intensity ($B \approx 10^7\text{ cm mol}^{-1}$) and spectral halfwidth ($\Delta \approx 3\text{ cm}^{-1}$) of absorption bands. At optical densities $D > 2 \times 10^{-3}$, these values correspond to a measurable number of particles, $N > 5 \times 10^{14}\text{ cm}^{-2}$. In this case, assuming that the thickness of the matrix film is $\sim 100\text{ }\mu\text{m}$, the average relative concentration of the particles to be recorded is greater than 10^{-6} . These values allow measurements of the IR spectra using low concentrations (sufficient for spatial isolation) of reactant molecules. Usually, the relative concentrations of impurity molecules are of the order of $10^{-3}–10^{-4}$. This permits both reliable detection of weak bands in the IR spectrum (with the integrated absorption coefficient of about $10^5–10^6\text{ cm mol}^{-1}$) and measurements of changes in the concentrations of initial reactants in the course of chemical transformations with an error of at most 0.5% .

IR spectroscopy allows detection of different types of particles (molecules, radicals, ions, molecular complexes). Therefore, this method is a universal tool for kinetic measurements. The potential of the technique, as applied to differentiation between particular bands in the IR spectrum of products of the reactions of mobile atoms based on the results of kinetic measurements, was demonstrated taking reactions of fluorine atoms with CO molecules in solid argon at 20 K as examples.^{20, 21} In this case, where only one reactant (fluorine atom) is mobile in the matrix, the principal channels of consumption of the reactants are as follows: recombination of diffusing fluorine atoms

primary reaction of fluorine atoms

secondary reaction of fluorine atoms

The experimentally observed changes in the band intensities in the IR spectrum of the reactant molecule (CO) and reaction products correspond to this simple kinetic scheme. Namely, in the initial stage, the intensities of the bands of the molecular product (F_2CO) increase quadratically with respect to the increase in the intensities of the bands of FCO^* radicals and those of the consumption of the molecular reactant. This allows one to distinguish between the IR bands of the primary and secondary products of the reactions of the mobile atoms. One can also measure the absolute intensities of the bands by comparing the increase in the band intensity and the corresponding decrease in the intensities of the bands of the reactant molecules. Taking into account the mass balance equation for the CO group,

$$\Delta[\text{CO}] = \Delta[\text{FCO}^*] + \Delta[\text{F}_2\text{CO}] \quad (3)$$

one gets a linear relation between the product band intensities, A_{FCO^*} and $A_{\text{F}_2\text{CO}}$, normalised to the corresponding decrease in the intensity of the band of the molecular reactant, ΔA_{CO}

$$\frac{A_{\text{FCO}^*}}{\Delta A_{\text{CO}}} = -\beta_1 \frac{A_{\text{F}_2\text{CO}}}{\Delta A_{\text{CO}}} + \beta_2, \quad (4)$$

where β_1 and β_2 are the ratios of the integrated intensities of the bands

$$\beta_1 = \frac{B_{\text{FCO}^*}}{B_{\text{F}_2\text{CO}}}, \quad \beta_2 = \frac{B_{\text{FCO}^*}}{B_{\text{CO}}}. \quad (5)$$

Since the ratio of the concentrations of the primary and secondary reaction products varies in the course of transformations, the relative absorption coefficients for the products and reactant, $B_{\text{FCO}^*}/B_{\text{CO}}$ and $B_{\text{F}_2\text{CO}}/B_{\text{CO}}$, can be determined from the linear dependence of the relative intensities of the product bands in Eqn (4). Experiments showed²⁰ that the band intensities of the

molecular product (F_2CO) thus obtained are in agreement with those determined earlier by other methods and that the band intensities of the radical product (FCO^*) are in reasonable agreement with the results of corresponding quantum-chemical calculations.

Despite high sensitivity and versatility of IR spectroscopy, identification of radical intermediates and determination of their structure faces some problems. For instance, if we deal with condensation of reaction products from the gas phase, the IR bands of different products cannot always be reliably distinguished and identified. As mentioned above, carrying out solid-phase reactions eliminates this problem. Another type of severe problem is associated with the fact that the vibrational frequencies measured by IR spectroscopy are dynamic characteristics of molecular compounds. Therefore, in some cases determination of the molecular structure based on the vibrational spectra only is complicated and additional information is required. This is of particular importance in studies of loosely bound molecular complexes or various isomers and conformers of trapped intermediates. Registration of characteristic low-frequency vibrations ($\nu \leq 300 \text{ cm}^{-1}$) of loosely bound complexes using conventional instruments is also difficult. Moreover, both static deformations of the structure and dynamic lattice effects predetermine large shifts of the vibrational frequencies of complexes.

When studying various isomers of the same stoichiometry, one should take into account minor changes in the vibrational dynamics of different isomers, especially if changes in position of the hydrogen atom are concerned. In this case changes in the characteristic vibrational frequencies are comparable with the accuracy of calculations. Therefore, identification of a particular isomer of a stabilised radical by comparing the experimental and calculated vibrational spectra is complicated.

As an example, Table 1 lists the geometric parameters, vibrational frequencies and isotropic hyperfine coupling constants (IHFC) of structural isomers of the $2\text{-C}_2\text{H}_2\text{F}^*$ radical generated in the reaction of a mobile fluorine atom with a C_2H_2 molecule in

Table 1. Calculated and experimental vibrational frequencies and isotropic hyperfine coupling constants of structural isomers of $2\text{-C}_2\text{H}_2\text{F}^*$ radical. Calculations were carried out by the B3LYP/6-311++G(3df,2p) method.

^a The data were taken from Ref. 22; the vibrational frequencies were calculated in the harmonic approximation. ^b The vibrational frequencies were taken from Ref. 23 and the IHFC constants were taken from Ref. 24. ^c Only absolute values of IHFC constants were measured experimentally.

solid argon²² as well as the results of an earlier study²³ in which the 2-C₂H₂F[•] radicals were stabilised by condensation of reaction products in gas discharge. Analysis of the vibrational dynamics in the model structure of the *trans*-2-C₂H₂F[•] isomer suggested²³ that the radical stabilised corresponds to this isomer. However, as can be seen in Table 1, the vibrational frequencies of the *trans*-2-C₂H₂F[•] and *cis*-2-C₂H₂F[•] isomers calculated by modern quantum-chemical methods are close and the experimental IR spectra cannot be assigned to a particular isomer even taking into account the results of analogous measurements for the deuterated analogue (2-C₂D₂F[•]). Comparison of the spectra of the radicals^{22,23} reveals close values of all vibrational frequencies (to an accuracy of $\pm 15\text{ cm}^{-1}$), except for the relatively weak bending vibration $\text{H}\beta\text{CC}$, for which the frequency difference is 52 cm^{-1} . However, the reason for such a large difference is still to be clarified (this can be different matrix shifts due to a different manner of arrangement of the radical in the lattice, or these are different isomers, or incorrect assignment of the weak IR band!). Moreover, identification of another structural isomer, 1-C₂H₂F[•], faces analogous problems since the patterns of the vibrational spectra of all three particles are similar and exhibit no characteristic distinctive features (see Table 1). Unambiguous establishment of the structure of radical intermediates in the two above-mentioned cases can be made only by joint use of vibrational and EPR spectroscopy.^{22,25}

2. EPR spectroscopy

Electron paramagnetic resonance is widely used in various applications of the matrix isolation technique as well as in cryochemical and radiation chemistry studies. Some key aspects of the use of this method in studies of matrix-isolated reactive intermediates are considered below.

High spectral resolution and sensitivity of the EPR technique under conditions of generation of radical intermediates in solid-phase reactions of mobile atoms with isolated reactant molecules are due to the following factors: perfect isolation of the radicals stabilised and the absence of radical pairs in the nearest environment (this eliminates the dipole–dipole interaction between radicals), the absence of super-HFC on the matrix nuclei due to zero nuclear spins of argon and neon atoms (and the ⁴He and parahydrogen molecules), and fast (incoherent) rotation of radicals in the lattice, which averages anisotropic magnetic interactions.

These factors are due to both the procedure for generation of radicals and the properties of the inert matrices. Under conditions of ideal matrix isolation of the radicals the widths of individual components of the hyperfine structure (HFS) are at most 0.1 mT in solid argon and at most 0.01 mT in solid p-H₂. Therefore, the spectral resolution under these conditions is no worse than in liquids²⁶ and much better than in organic crystals and glasses.²⁷ The spectroscopic parameters of ethyl radicals measured in different media are listed in Table 2. As can be seen, the intrinsic widths

of the lines in the spectra of radicals stabilised in solid parahydrogen or argon is comparable with the linewidths in the EPR spectra recorded in the liquid phase.^{28–33}

A feature of small polyatomic molecules is rotation in solid matrices and crystals at ultralow temperatures. Depending on the species size and on site occupied by the particles in the crystal lattice, both free rotation (with population of nonzero rotational quantum states) and rotational diffusion (incoherent rotation) characterised by the rotational correlation time, τ_c , can occur. Fast incoherent rotation of radicals in the lattice causes averaging of anisotropic interactions, thus providing high resolution of the hyperfine structure and the possibility of determining the absolute values of the IHFC constants if they exceed 0.1 mT.

As an example illustrating the influence of various factors on the resolution of the EPR spectra of trapped radicals, Fig. 2 presents the spectra of the 2-C₂H₂F[•] radicals generated in the solid-phase reaction $\text{F} + \text{C}_2\text{H}_2$. Spectrum 1 was obtained in an argon matrix with high concentration of C₂H₂, while spectrum 2 was recorded in a krypton matrix containing magnetic nuclei (the nuclear spin of ⁸³Kr atom is 9/2). In the former case most of the reactant molecules (C₂H₂) exist as dimers and more complex associates. This leads to stabilisation of the radicals bound in complexes with the neighbouring C₂H₂ molecules. The radical–molecule interaction in these complexes stabilises the structure formed and hinders rotation of the radical. Probably, that is why no resolved hyperfine structure of these radicals in photolysed mixtures $\text{Ar}:\text{F}_2:\text{C}_2\text{H}_2(\text{C}_2\text{D}_2) = 200:1:1$ was recorded earlier.³⁴ A hyperfine splitting of 0.25 mT on the α -proton of the 2-C₂H₂F[•] radical was first observed under conditions of perfect isolation of the radicals generated in the reactions of

Figure 2. EPR spectra of 2-C₂H₂F[•] radicals produced by photolysis at 15 K and subsequent annealing of the samples at 25 K.²²

The spectra were recorded at 30 K; shown are the HFS of 2-C₂H₂F[•] and FO₂[•] radicals. Sample composition: $\text{Ar}:\text{F}_2:\text{C}_2\text{H}_2 = 300:1:1$ (1), $\text{Kr}:\text{F}_2:\text{C}_2\text{H}_2 = 3000:1:1$ (2) and $\text{Ar}:\text{F}_2:\text{C}_2\text{H}_2 = 3000:1:1$ (3).

^a Calculated using the formula $a = \frac{2A_{\perp} + A_{\parallel}}{3}$.

mobile atoms in solid argon (see spectrum 3 in Fig. 2). Experiments with heavier isotopomers of acetylene (C_2D_2 and C_2HD) allowed assignment of a complete set of IHFC constants of this type of radicals.²² Analogously, frozen van der Waals complexes $\text{FCO}^{\bullet}\cdots(\text{CO})_n$ were produced in the samples with relative concentrations of the reactant molecules, $[\text{CO}] > 10^{-3}$ (see Refs 35 and 36). The EPR spectra of $\text{FCO}^{\bullet}$ radicals at 4.2 K provide a classical example of the EPR spectra of frozen radicals with strong anisotropy of the constants of HFC with the fluorine atom. Recently,³⁷ it was found that anisotropic spectra of the $\text{FCO}^{\bullet}$ radicals (they are similar to the spectra reported earlier^{34,35}) in photolysed $\text{Ar}/\text{F}_2/\text{CO}$ samples with a high concentration of the molecular reactant ($[\text{CO}] > 5 \times 10^{-3}$) remain unchanged up to 30 K. However, the shape of the EPR spectra of $\text{FCO}^{\bullet}$ radicals in the samples with much lower concentration of the reactant molecules ($[\text{CO}] < 10^{-3}$) changes dramatically upon temperature variation.

The EPR spectrum of $\text{FCO}^{\bullet}$ radicals is presented in Figure 3. This is a superposition of an anisotropic spectrum, which varies only slightly with temperature, and a spectrum whose pattern closely resembles that of an isotropic spectrum. The linewidths in the latter spectrum drastically decrease as the temperature increases at $T > 13$ K. The samples with the relative concentration of the reactant molecules of less than 10^{-4} are characterised by a virtual absence of radicals exhibiting anisotropic spectra at high temperatures. The time τ_c of the isolated radicals, estimated from changes in the linewidths under conditions of fast incoherent rotation, is $\sim 10^{-9}$ s at 30 K. Averaging of the anisotropy due to fast rotation of radicals in inert matrices at ultralow temperatures was also pointed out in other studies (*e.g.*, Refs 38 and 39). These examples demonstrate that under perfect isolation conditions, the anisotropy of magnetic interactions of not only small radicals (*e.g.*, $\text{FCO}^{\bullet}$) but also larger structures, (*e.g.*, $\text{C}_2\text{H}_2\text{F}^{\bullet}$) is averaged due to fast rotation of the species in the lattice.

Figure 3. EPR spectra of $\text{FCO}^{\bullet}$ radicals in $\text{Ar}:\text{F}_2:\text{CO} = 300:1:1$ (a) and $\text{Ar}:\text{F}_2:\text{CO} = 3000:1:1$ (b) recorded at 15 (1), 22.5 (2) and 35 K (3).³⁷ The components of the HFC tensor are labelled X, Y and Z and the isotropic line is labelled 'iso'.

Figure 4. EPR spectrum of $p\text{-H}_2:\text{C}_2\text{H}_5\text{I} = 5000:1$ sample after UV photolysis at 4.7 K.²⁸

The intense signal at the centre of the spectrum (asterisked) is due to the presence of paramagnetic particles in the quartz ampoule. Shown are the calculated positions of the components of the anisotropic spectrum of ethyl radicals with A' , A'' , E' and E'' symmetry. Vertical lines and triangles denote positions of the components in the spectrum of ethyl radicals in which the C—C bond is respectively perpendicular and parallel to the direction of the external magnetic field.

Kumada *et al.*²⁸ reported the EPR spectra of $\text{C}_2\text{H}_5^{\bullet}$ radicals isolated in solid parahydrogen (Fig. 4). High spectral resolution achieved in this study (< 0.01 mT) allowed both determination of the anisotropic components of the HFC tensor in the absence of rotation of the whole radical and distinguishing between the spectral lines corresponding to different rotational states of the methyl group. The rotational energy level splitting in solid parahydrogen (5.3 ± 0.7 K) determined from temperature-induced variations of the line intensities was found to be close to that measured earlier by IR spectroscopy in the gas phase. Resolved EPR spectra of 2-fluoroethyl radicals can be recorded in solid argon under conditions of perfect isolation (Fig. 5).⁴⁰ Fast (incoherent) internal rotation and the dependence of the IHFC constants on the angle of rotation of the CH_2 group around the CH_2F fragment is responsible for a sharp temperature dependence of the EPR linewidths in the temperature range from 20 to 35 K. Anisotropy of the HFC tensor of the fluorine atom is retained upon warming up the system; therefore, changes in the spectral pattern are due to internal rotation of the CH_2 group only. Variation of the angle of rotation causes modulation of the HFC, thus leading to temperature-induced line broadening. The energy barrier, E_a , to internal rotation was estimated from the Arrhenius dependence of the linewidth at $\approx 920\text{--}1050$ J mol⁻¹,

Figure 5. EPR spectrum of $2\text{-C}_2\text{H}_4\text{F}^{\bullet}$ radicals generated in reactions of diffusing fluorine atoms with C_2H_4 molecules and isolated in solid argon.⁴⁰

which is close to the barrier height calculated⁴¹ for a free radical in the gas phase. However, this value is much smaller than that measured in viscous liquids ($\sim 4000 \text{ J mol}^{-1}$).⁴²

The aforesaid indicates that perfect isolation of radical species in inert matrices containing no magnetic nuclei permits both determination of the principal HFC parameters and characterisation of internal rotation of molecular fragments and atomic groups in the absence of rotation of the whole radical.

The experimentally measured IHFC constants provide a reliable structure-sensitive parameter suitable for identification of new radical intermediates. Their structures can be determined by comparing the experimental values of spectroscopic characteristics with the corresponding values calculated using modern quantum-chemical methods. This approach was substantiated^{43–45} when analysing the experimental data and results of quantum-chemical calculations of different types of radicals. These investigations have demonstrated the practical applicability of density functional calculations to the studies of the interrelation between structure and spectroscopic characteristics. The IHFC constants are determined by the distribution of the unpaired electron density over the corresponding magnetic nuclei in the molecular structure. Therefore, these characteristics are rather sensitive to the changes in the electron wave function on the magnetic nuclei. The error in calculations of the IHFC constants using modern methods is usually at most 10%.⁴⁴ The vibrational frequencies can be calculated with better accuracy; however, they are much less sensitive to changes in the electronic structure. This is of crucial importance for the identification of reactive intermediates and for the determination of their structure in at least two critical situations. The first case concerns identification of a particular isomer of the stabilised intermediate. A typical example is provided by the *cis*- and *trans*-isomers of the $2\text{-C}_2\text{H}_2\text{F}^\bullet$ radical. The vibrational spectra of these isomers were discussed above. As can be seen from Table 1, the values of the IHFC constants of the radicals stabilised in solid argon correspond to *cis*- $2\text{-C}_2\text{H}_2\text{F}^\bullet$ rather than *trans*- $2\text{-C}_2\text{H}_2\text{F}^\bullet$, as was reported earlier.^{24,34} In this case both the chemical intuition (assignment of the experimental EPR spectrum was based on the assumption of analogy between the electron density distributions in the $2\text{-C}_2\text{H}_2\text{F}^\bullet$ and $\text{C}_2\text{H}_3^\bullet$ radicals and on the predicted thermodynamic properties of the *cis*- and *trans*-isomers) and vibrational analysis²³ led to erroneous conclusions. This was first pointed out by Barone *et al.*⁴³ Reliable identification of the other structural conformer, $1\text{-C}_2\text{H}_2\text{F}^\bullet$ radical, is possible only based on measurements of the IHFC constants. Insertion of a fluorine atom at the α -position causes a twofold increase in the IHFC constant a_F (and simultaneous increase in the IHFC constants on protons) compared to the corresponding constants of the isomers of the $2\text{-C}_2\text{H}_2\text{F}^\bullet$ radical.

Another practically important problem is to determine the structure of weakly bound radical – molecular complexes. It has been shown^{46,47} (for detailed analysis, see below) that reaction products of hydrogen abstraction from RH molecules can be stabilised in matrices in the form of radical – molecular complexes $\text{R}^\bullet \cdots \text{HF}$. Taking into account the spectral resolution that can be achieved in the experiments with inert matrices, the EPR technique seems to be promising for the investigation of the structure of such intermediates. If the radical and the molecule in a complex are separated by at most 0.3 nm and the individual components of the HFS are no wider than 0.1 mT, the EPR spectra exhibit a resolved hyperfine structure corresponding to interactions of the unpaired electron of the radical with the magnetic nuclei of the other molecule (nuclear spin of the H and F atoms of the HF molecule is $1/2$). The constants of magnetic interactions are rather sensitive to the distances and orientation of fragments in complexes; this permits their structure and sometimes the type and characteristic times of hindered internal motions of the fragments in the complex to be determined reliably.

3. Optical spectroscopy and photoinduced transformations of stabilised reactive intermediates

The main fields of application of the optical studies of cryogenic matrices involve spectroscopy of electronically excited states, photoinitiation of chemical transformations in the complexes comprised of molecular reactants, generation of radical species in the photodissociation of isolated molecules and photoinduced intramolecular conversion of isolated species as well as photo-stimulated translational mobility of atoms.

The electronic and vibronic transitions in the condensed phase are strongly affected by the environment, even if the molecular species under study are isolated in inert matrices. For this reason, spectroscopic investigations of matrix-isolated particles are to a greater extent focussed on the studies of the mechanisms of relaxation of excitation energy in the solid phase (see review⁴⁸) rather than spectroscopic characterisation of excited states. Besides, instrumental problems due to strong scattering of the visible and UV light by crystalline matrix films, as well as the effects of nonradiative relaxation in the matrices reduce the sensitivity of absorption spectroscopy and limit the use of the laser-induced fluorescence (LIF) technique in these studies. Most spectroscopic data on the excited states of radical species were obtained in the gas-phase LIF and laser-induced magnetic resonance studies (these methods are characterised by high sensitivity and the possibility of carrying out experiments with spectral and temporal resolution). Detailed investigations of the $\text{OH}^\bullet$ (see Ref. 49), $\text{CN}^\bullet$ (see Refs 50 and 51) and $\text{ClO}_2^\bullet$ (see Refs 52–54) radicals were performed, and considerable attention has been given to the studies of perturbations of the lower electronic states by the crystalline environment and of the dynamics of relaxation processes in solid matrices.

Photoinduced transformations in molecular complexes is an interesting branch of cryochemistry. The key feature of these investigations is to preliminarily prepare molecular complexes of reactants in the matrix. Further chemical reactions in the complexes are initiated by photo-excitation of one of the reactants. In most cases these studies are limited to identification of reaction products and determination of the relative yields of the principal reaction channels.⁵⁵ Description of chemical transformations on the molecular level taking into account the dynamics of molecular rearrangements and the energy relaxation in the lattice is a rather complicated task. Some approaches to the molecular dynamics simulation of these transformations using semiempirical methods of calculations of the PES of corresponding reactions have been reviewed by Raff.⁵⁶ If the initial reactants are closed-shell species chemical transformations within the matrix cage will also result in the molecular products. To trap the radical intermediates, the radical fragment of the reacting system should escape the reaction cage and then be trapped outside it. For instance, photodissociation of a complex of a diatomic molecule (AB) with a reactant (M) can yield radical adducts or radical – molecular complexes, if one of the atoms is stabilised outside the reaction cage:

However, different research groups (see, *e.g.*, Refs 57–59) reported that photolysis of halogen molecules bound into a complex with the molecules of the other reactant results mainly in the molecular products and that the yield of radical pairs in the reactions (6a) and (6b) is negligible. These results were expected for the complexes containing molecules of heavy halogens (Cl, Br and I). At the same time, the reaction channels (6a) and (6b) can be significant for the complexes with HI (HBr) or F_2 molecules due to weakening of the cage effect for the hydrogen and fluorine atoms compared to the heavy halogen atoms.⁶⁰

Photolysis of isolated molecules in cryogenic matrices is a conventional method of generation of stabilised radicals. Spectro-

scopic data for the radical species thus produced served as the basis for further studies of these objects (see, *e.g.*, Ref. 6). At the same time the cage effect precluding spatial separation of the photodissociation products, the formation of tight radical pairs as well as photolysis of primary products of photodecomposition reduce the efficiency of generation of stabilised radicals and make the interpretation of the spectroscopic and kinetic data more difficult.

Another method for generation of new matrix-isolated particles involves photo-excitation of an isolated particle followed by intramolecular rearrangements. In contrast to the gas phase, photo-excitation to the dissociative absorption band under conditions of the crystalline environment, which impedes spatial separation of the photodissociation fragments, can cause stabilisation of various structural conformers of the same stoichiometry. In most of such studies the molecules were matrix isolated using conventional techniques (see, *e.g.*, Refs 61 and 62). Despite the fact that this procedure for generation of new molecular species has found a rather wide application, there are only a few examples of generation of radical species in this manner. Methodological difficulties in such studies are associated with the necessity of obtaining sufficiently high concentrations of radicals in the absence of other products.

Electronically excited halogen – Rg complexes (Rg is the atom of inert gas) have been traditionally used as a working substance for gas lasers. Basic research into the optical properties of halogen atoms in the solid matrices and crystals of inert gases^{63,64} was mainly stimulated by the idea of creation of solid-state excimer lasers. It was found that in most cases the effects of multibody interactions in crystals preclude radiative deactivation of diatomic exciplexes. For instance, the energy of electronic excitation of an ArF complex in solid argon is close to that determined in the gas phase (Fig. 6). However, the excited state undergoes fast relaxation (during $\sim 10^{-13}$ s) into a more stable triatomic exciplex (Ar_2^+F^-) (see Ref. 65). Radiative deactivation of diatomic exciplexes in solid krypton is also preceded by the formation of triatomic excited states, *e.g.*, $(\text{Kr}_2)^+\text{F}^-$ (see Ref. 66). Since exciplexes are characterised by electron transfer from the halogen atom to the atoms of the inert gas, the equilibrium distances in such structures are much shorter than the van der Waals interatomic distances in the ground electronic state. As a result, radiative deactivation of an electronic excitation causes transformation of a large portion of the exciplex energy (1 to 2 eV) into the kinetic energy of the atoms of the dissociating particle (see Fig. 6). This brings about a unique phenomenon, namely, photo-induced migration of ‘hot’ fluorine atoms in the crystals of inert gases.^{65,66} For instance, experiments on photogeneration of fluorine atoms in argon crystals showed that excitation to the ArF exciplex absorption band with light at $\lambda = 193$ nm upon continuous irradiation of the samples leads to bimolecular recombination of fluorine atoms

The average migration length of a ‘hot’ F* atom with an initial kinetic energy of ~ 0.7 eV was estimated at ~ 7 nm.⁶⁶ An analogous effect of photoinduced migration was also observed for the oxygen atoms isolated in solid krypton or xenon.^{67–69} Studies of continuous photolysis of xenon or krypton crystals containing stabilised $\text{O}(^3\text{P})$ atoms with light at $\lambda = 248$ nm showed that radiative deactivation of charge-transfer Rg^+O^- exciplexes induces migration of the atomic oxygen in the crystal and, finally, loss of the oxygen atoms by a bimolecular mechanism

Photoinduced migration of reactive atoms in the crystals of inert gases opens up unique prospects for practical implementation of chemical reactions involving these atoms at ultralow temperatures. This is possible if two conditions are met. First, the atom must possess the ability to migrate in the crystal. Second, it must have an excess kinetic energy required to overcome a reaction barrier. Methodologically, there is a feature which complicates a correct interpretation of the results of such experiments. To make atoms mobile, the sample should be irradiated with UV light at a wavelength of about 200 nm. This can cause photoinduced conversions of both the reactant molecules and the primary products of the reactions of the mobile atoms. Nevertheless, this effect can be insignificant since diatomic exciplexes are, as a rule, characterised by extremely large absorption cross sections ($\sim 10^{-16} - 10^{-17}$ cm², see Ref. 66).

III. Translational mobility of hydrogen, fluorine and oxygen atoms in the crystals and solid matrices of inert gases

1. Translationally excited ‘hot’ atoms produced by photodissociation of isolated molecules

Photodissociation dynamics of small molecules in the crystals of inert gases have been well studied experimentally. Efficient photodecomposition of an isolated precursor can be achieved if the kinetic energy of one reactant (in this case, the atom) is high enough to overcome the lattice barrier which precludes spatial separation of the dissociation products. Possible mechanisms of photodissociation of a number of small molecules, accompanied by generation of H, F and O atoms in the crystals of inert gases, have been considered in detail by Apkaryan and Schwentner.¹⁰ Fundamental difficulties which arise when simulating such processes include the necessity of taking into account the effects of multibody interactions at short distances, which make the pair atom – atom potentials non-additive. Nevertheless, the results of the molecular dynamics simulation are in reasonable agreement with the available experimental data.

The dynamics of ‘hot’ atoms in the crystal is controlled by the following factors. The $\text{F}(^2\text{P})$ and $\text{O}(^1\text{D})$ atoms are characterised by relatively short effective interaction ranges in the crystals of inert gases. If such atoms occupy octahedral interstitial sites (O_h) of the f.c.c. crystal lattice, they interact with adjacent lattice atoms (Ar, Kr or Xe) in the attraction region of the pair interaction potentials $U(r)$. At the same time the repulsive part of the interaction potentials at short distances determines the optimum trajectory of the motion of the atom to an adjacent O_h site through the edge of a face of the octahedron.^{70,71} Since the masses of the F and O atoms are comparable with those of the atoms of the argon lattice, the energy of a translationally excited ‘hot’ atom efficiently dissipates by collisions with the lattice atoms. Therefore, efficient escape of the atoms from the cage and spatial separation of the photodissociation products require that the bond cleaved in the photolytic precursor be oriented towards a face of the cell. In this case the atom can migrate in the crystal in a ballistic regime, thus avoiding direct collisions with the lattice atoms.⁷²

Figure 6. Scheme of excitation and deactivation of ArF exciplex in solid argon.⁶⁵

Quite different are the dynamics of photolytically generated hydrogen atoms. The effective radius of the interaction between the $\text{H}(^2\text{S})$ atom and Ar, Kr and Xe atoms is comparable with the interatomic distances in the lattice. Therefore, the $\text{H}(^2\text{S})$ atom interacts with adjacent lattice atoms only in the repulsive region of the pair interaction potentials and the optimum trajectory of the motion of the atom between interstices passes through the centres of the triangular faces of the f.c.c. crystal lattice.⁷³ It is believed¹⁰ that this predetermines another (compared to the F and O atoms) trajectory of the escape of the 'hot' atom from the reactant cage. In addition, due to the small mass the hydrogen atom loses a small portion of the kinetic energy by collisions with the lattice atoms. Therefore, the requirements on the orientation of the photolytic precursor in the lattice are not so severe as in the case of the $\text{F}(^2\text{P})$ or $\text{O}(^1\text{D})$ atoms. In this case the trajectory of motion of the 'hot' hydrogen atom during thermalisation should be close to the diffusion trajectory.

2. Thermally activated diffusion of atoms

Thermally activated mobility of H, O and F atoms in the crystals and matrices of inert gases has been reported by different research groups. The available literature data suggest that fluorine atoms possess extremely high translational mobility in the crystals of argon and krypton. The diffusion coefficients of hydrogen and oxygen atoms have been determined under conditions providing efficient recombination of the atoms, corresponding to typical kinetics of bimolecular reactions. Detailed consideration of these studies is given below.

IV. Chemical reactions involving hydrogen atoms

Hydrogen atoms isolated in cryogenic matrices have been the subject of intensive physicochemical studies using the matrix isolation technique. These investigations were mainly focussed on the problems of creation of high-energy systems, studies of quantum motions of light atoms and on specific features of multibody interactions in the condensed phase. After establishment of the fact that accumulation of high concentrations of stabilised hydrogen atoms in the solid phase is limited due to involvement of these atoms in chemical reactions, the emphasis was placed on the investigation of mechanisms of photoinduced generation of the atoms and subsequent chemical processes with their participation in low-temperature crystals and matrices.

1. Photogeneration of hydrogen atoms

EPR is a very sensitive method for detection of hydrogen atoms in inert matrices. It was found that the lines of the hydrogen doublet in the EPR spectra in solid matrices exhibit a multiplet structure, which is due to the presence of several possible atomic sites in the crystal lattice. Analysis of distortions of the HFC and g -factor tensors by the crystal field showed that photogenerated hydrogen atoms are mainly stabilised in the interstitial sites (O_h and T_d) and to a lesser extent in the substitutional sites.^{74–78}

The HBr and HI molecules are convenient photolytic precursors for generation of hydrogen atoms in the solid phase. In the early studies (see, *e.g.*, Ref. 6) photolysis of these molecules was used to produce hydrogen atoms that entered into reactions with various reactants. Spectroscopic data for the radical species $\text{HO}_2^\bullet$, $\text{PHCO}^\bullet$, $\text{H}_2\text{NO}^\bullet$, *etc.* were first obtained using this experimental technique. It was shown⁷⁹ that 'hot' hydrogen atoms produced by photodissociation of HBr in solid xenon are stabilised at rather long distances (up to 10 nm!) from the dissociation site. This conclusion was drawn based on the study of the kinetics of HBr consumption and accumulation of bromine atoms during continuous photolysis of HBr with light at a wavelength of 248 or 193 nm. It was found that the kinetic dependences obey a second-order law due to reactions of the 'hot' atoms (characterised by long migration length) with the distant HBr molecules

This conclusion was confirmed in a study carried out using the EPR and LIF techniques and molecular dynamics simulation.⁷⁸ It was established that only a fraction of photogenerated H atoms is stabilised in the Xe and Kr matrices. Other H atoms either enter into reactions (8) or recombine during thermalisation

A quite different situation was shown to occur in solid argon where hydrogen atoms are trapped near the dissociation site. Therefore, nearly 100% of the precursor molecules are converted into trapped hydrogen atoms. The molecular dynamics simulation of thermalisation of a 'hot' atom showed that the hydrogen atom with an initial excess energy of 2.5 eV can move from the parent cage over long distances (up to 4 nm in solid krypton). In view of these results, one should expect that reactions of photogenerated 'hot' hydrogen atoms with various molecules should be efficient in solid krypton and xenon.

2. Thermally activated diffusion of hydrogen atoms

Consumption of hydrogen atoms during temperature annealing of solid Rg matrices was reported by different authors.^{80–84} It was found that consumption of hydrogen atoms in Kr and Xe matrices at $T > 30$ K obeys a second-order kinetic law, which corresponds to bimolecular recombination. Loss of H atoms in solid argon at temperatures above 12 K was observed. However, analysis of the kinetic dependencies of the loss of H atoms suggested⁸⁴ predominance of geminate recombination

of the atoms produced during low-temperature photolysis of HBr molecules.

The available literature data allow one to assume that solid matrices of inert gases (Ar, Kr and Xe) can serve as convenient media for studying the interactions of hydrogen atoms with small concentrations of various dopants. Chemical reactions of hydrogen atoms involving cleavage of molecular bonds are, as a rule, characterised by rather high activation barriers ($\geq 6–8$ kJ mol^{−1}). At ultralow temperatures, such thermally activated reactions must occur very slowly and therefore the use of photogenerated 'hot' atoms to produce reaction products seems to be more promising than the reactions of diffusing 'cold' atoms. At the same time stabilisation of a long-lived pre-reaction complex $\text{H} \cdots \text{M}$ formed by collision of the mobile atom with the isolated molecule in the absence of efficient thermal activation of chemical reactions provides the possibility of studying the interactions in the stage where the reactants approach each other.

Studies of tunnelling reactions of hydrogen exchange with hydrogen isotopes in solid hydrogen^{85–87} were also carried out in solid argon where the bound state of reactants was first detected by EPR.^{88,89} Stable complexes of reactants were formed as a result of diffusion of the H and D atoms at temperatures above 17 K. In particular, the atoms diffusing in solid Ar/HD mixtures form pre-reaction complexes upon collisions with the HD molecules. Among subsequent exchange reactions,

a tunnelling transition resulting in complexes of the products is possible only in reaction (9a). This allows one to expect stabilisation of two complexes, $\text{H} \cdots \text{HD}$ and $\text{H} \cdots \text{D}_2$, in this system. Their EPR spectra (Fig. 7) exhibit a resolved HFS on the doublet lines of the H atoms due to the interaction of the unpaired electron of the atom with the magnetic nuclei of the molecules in the complexes $\text{H} \cdots \text{HD}$ and $\text{H} \cdots \text{o-D}_2$. Besides, the hyperfine splitting on the hydrogen atom in the complex ($a_\text{H} = 51.18$ mT) differs from the characteristic a_H values of the atoms trapped in solid

Figure 7. EPR spectra of van der Waals complexes $\text{H}'\cdots\text{HD}$ and $\text{H}'\cdots\text{D}_2$ formed in an argon matrix at 20 K.⁸⁹

The intense line denoted by H_s is due to hydrogen atoms stabilised in the substitutional site O_h . Shown are the characteristic splittings for individual complexes.

argon ($a_{\text{H}} = 50.73, 51.42$ and 51.54 mT for the substitutional site and the O_h and T_d interstitial sites, respectively).

The spectra of complexes $\text{H}'\cdots\text{H}_2$ generated analogously in Ar/ H_2 mixtures exhibit no super-HFS since the more stable parahydrogen molecule has a zero nuclear magnetic moment in the ground rotational state. Nevertheless, the formation of this complex was detected by the appearance of the hydrogen doublet with $a_{\text{H}} = 51.18$ mT. Specific features of the EPR spectra, such as narrow isotropic HFS lines and equal values of the constants of super-HFC with both atoms of the H_2 , HD and o- D_2 molecules (with allowance for correction for different gyromagnetic ratios, $\mu_{\text{H}}/\mu_{\text{D}} = 6.5$) were attributed to fast internal rotation in the complex. Quantum-chemical QCISD/aug-cc-pvqz calculations of hyperfine interactions in the complex showed that the experimental superhyperfine splitting $a_{\text{H}}' = 0.386$ mT corresponds to a distance of 0.245 nm between the atom and the geometric centre of the molecule.⁸⁹ This is much shorter than the value calculated earlier for free van der Waals complex $\text{H}'\cdots\text{H}_2$ on the PES of the H_3 system (0.34 nm). These data are in agreement with the results of investigations of tunnelling reactions of H atoms in solid hydrogen (H_2 , D_2 and HD), according to which the distances between the reactants in the crystalline environment are shortened.⁹⁰

3. Formation of chemical bonds with atoms of inert gases

A unique feature of heavy atoms of inert gases (xenon and krypton) is their ability to form chemical bonds with other atoms or molecular fragments that are efficient electron acceptors. This is due to a relatively low ionisation energy of the closed-shell atoms. This type of stable compounds can be exemplified by XeF_2 and XeF_4 which were first synthesised more than three decades ago.^{91,92} Data on binding xenon atoms into chemical compounds with fluorine and oxygen atoms have been generalised in some reviews (see, e.g., Refs 93–95).

Quantum-chemical calculations predict that the formation of weak chemical bonds with the light atoms of inert gases is possible.⁹⁶ Such chemical compounds can be stabilised only at ultralow temperatures. Therefore, the crystals of inert gases, which interact with free atoms under these conditions, are, strictly

speaking, not chemically inert. For instance, the XeCl_2 and KrF_2 molecules were first synthesised and characterised under matrix isolation conditions.^{97–99}

Convincing proofs of the possibility for chemical bonds with the atoms of inert gases were provided by researchers from Finland who detected a number of new chemical compounds, namely, $\text{H}-\text{Xe}-\text{H}$, $\text{H}-\text{Xe}-\text{Y}$ and $\text{H}-\text{Kr}-\text{Y}$ (Y is the halogen atom or a CN^* or OH^* radical). These compounds are formed in the reactions of diffusing hydrogen atoms in the solid matrices of xenon and krypton.^{100–102} Studies of these reactions have been reviewed.^{103,104} It is believed that neutral molecules $\text{H}-\text{Rg}-\text{Y}$ are formed as a result of the interaction of two close-lying diabatic PES corresponding to the interaction between neutral and charged fragments (Fig. 8). The low-lying bound state $^1\Sigma^+$ is treated as an ion pair $(\text{HRg})^+ \text{Y}^-$ in which the covalently bound fragment $(\text{HRg})^+$ is involved in electrostatic interaction with the negatively charged fragment Y^- . Based on this model, a molecular structure with ionic bond, $(\text{HXe})^+ \text{Cl}^-$, was predicted by semiempirical quantum-chemical calculations even in 1988.¹⁰⁵ The structure $\text{H}-\text{Xe}-\text{H}$ is treated analogously, that is, as a resonance hybrid between $(\text{HXe})^+ \text{H}^-$ and $\text{H}-(\text{XeH})^+$. Quantum-chemical calculations predict a linear geometry of $\text{H}-\text{Rg}-\text{Y}$ and the molecular energies lying between 38 and 135 kJ mol^{-1} relative to the energy of dissociation into neutral atoms. Global potential minima of such systems correspond to neutral HY molecules and Rg atoms. Because of the ionic type of chemical bonding the molecules $\text{H}-\text{Rg}-\text{Y}$ are characterised by high IR band intensities and by an extremely large dipole moment of the electronic transition $\text{A}^1\Sigma \leftarrow \text{X}^1\Sigma$ between two close-lying electronic states.^{106,107} Therefore, such particles are mostly studied by IR and optical spectroscopy. Table 3 lists the experimental and calculated frequencies of the $\text{H}-\text{Rg}$ stretching vibrations as well as the calculated bond lengths for a number of compounds.

Figure 8. Scheme illustrating the nature of the chemical bond in HRgY molecules. Diabatic PES for the ionic $[(\text{HRg})^+ + \text{Y}^-]$ and neutral ($\text{H} + \text{Rg} + \text{Y}$) states of the system are shown by solid lines.¹⁰³ The abscissa is the sum of the $\text{H}-\text{Rg}$ and $\text{Rg}-\text{Y}$ distances in the linear configuration HRgY .

It was also found that HXeOH and HXeH stabilised in solid xenon dissociate over $\sim 10^3$ s at temperatures of 54 and 66 K, respectively.¹⁰⁷ Thermal decomposition was explained by decay of metastable states upon activation of bending vibrations

and

However, no formation of H_2O and H_2 molecules that would provide confirmation of the existence of such a dissociation channel was observed. The energy of IR quantum necessary to decompose a compound by multilevel IR excitation or the long-

wavelength edge in the electronic absorption spectra are used as the upper limit of the binding energies. The H – Rg – Y particles have rather large intrinsic dipole moments; hence, polarisation interactions between them and the surrounding atoms can strongly affect the spectroscopic and energy characteristics of the intermediate. Therefore, the problem of stability of both free and matrix isolated particles is still to be clarified. Currently, the H – Rg – Y particles have been the subject of intensive research^{107–109} and one can expect to obtain new data on these interesting objects by the time of publication of this review.

The procedure for generation of the H – Rg – Y particles employed in the above-mentioned studies included (i) preparation of thin films of inert gas, containing a controlled amount of HY molecules (e.g., HI, HCl or HCN), (ii) low-temperature photolysis of the impurity molecules, resulting in the formation of spatially separated radical pairs $\text{H}^\bullet \cdots \text{Y}^\bullet$ and (iii) annealing of the matrix up to the temperatures at which thermally activated diffusion of hydrogen atoms is possible. The results of a joint study by IR, optical and EPR spectroscopy showed that the kinetics of loss of the hydrogen atoms correlates with the kinetics of formation of the H – Xe – H and H – Xe – Y molecules.^{83, 107} In the course of the reactions the loss of the stabilised radicals $\text{Y}^\bullet$ amounts to 40%, and virtually no recombination of the molecules of the photolytic precursor HY occurred. With allowance for these facts it was concluded that the three-body interactions $\text{H} + \text{Rg} + \text{H}$ and $\text{H} + \text{Rg} + \text{Y}$, which are responsible for stabilisation of the xenon- and krypton-containing compounds, are the principal channels of loss of the diffusing atoms. Detailed quantitative balance for the reactions of the diffusing atoms has not been determined as yet; however, the results of kinetic measurements suggest that high-energy processes of direct recombination of the radicals,

are inefficient under such conditions due to stabilisation of triatomic intermediates H – Rg – Y.

Quantum-chemical calculations of the PES of a free HRgY particle (in the ground electronic state $^1\Sigma^+$) showed that the reaction can follow two routes as the hydrogen atom approaches the RgY fragment. If the angle of attack, H – Rg – Y, is larger than 90° and the H – Rg distance is shorter than 0.4 nm, the system tends to reach an intermediate bound state with a linear configuration H – Rg – Y. In contrast, if the angle of attack is smaller than 90° , the system tends to arrive at a global minimum corresponding to recombination $\text{H}^\bullet + \text{Y}^\bullet$ (see Refs 103 and 104).

**Figure 9.** The O_h , T_d and D_2 interstitial sites occupied by hydrogen atom in the f.c.c. crystal lattice of an inert gas.

Impurity particle $\text{Y}^\bullet$ occupies the substitutional site. Roman numerals I – IV and VI denote the atoms in the first to fourth and in the sixth coordination spheres of the crystal surrounding the impurity $\text{Y}^\bullet$.

Realisation of a particular reaction channel in the crystal is determined by the trajectory of the motion of the hydrogen atom in the vicinity of the trapped impurity (heavy fragment $\text{Y}^\bullet$). Diffusion of hydrogen atoms in the f.c.c. crystal lattice of inert gas has been traditionally treated as random jumps between octahedral interstitial sites O_h , which occur in such a way that in the intermediate states the H atom is located at the tetrahedral site T_d (Fig. 9). If a heavy fragment of primary photodissociation ($\text{Y}^\bullet$) occupies a lattice site, recombination $\text{H}^\bullet + \text{Y}^\bullet$ should occur when the H atom arrives at a tetrahedral T_d (I) or octahedral site O_h (I) adjacent to the fragment $\text{Y}^\bullet$. The formation of a bound species H – Rg – Y must occur with participation of an Rg(I) atom (one of the twelve lattice atoms in the first coordination sphere of the $\text{Y}^\bullet$ species). Linear structure H – Rg(I) – Y can be formed if the hydrogen atom occupies the interstitial site D_2 . There are several T_d and O_h (II) sites outside the first coordination sphere of the $\text{Y}^\bullet$ fragment (see Fig. 9). Jumping between them, the hydrogen atom arrives at the attraction region on the PES of the triatomic system H – Rg(I) – Y and becomes bound into the intermediate H – Rg(I) – Y. As a consequence, its recombination with the fragment $\text{Y}^\bullet$ is now impossible. If the H atom arrives at other tetrahedral sites T_d surrounding the first coordination sphere of the fragment $\text{Y}^\bullet$, the H – Rg₂(I) – Y configurations comprised of adjacent atoms are formed.

It is known that cations of the type $(\text{HRg}_2)^+$ can be stabilised in low-temperature matrices. Therefore, analogous ionic bonds $(\text{H} - \text{Rg}_2)^+ - \text{Y}^-$ can also be formed in such T_d configurations and these T_d sites can be considered as saddle points for binding the H atom into a more stable linear configuration H – Rg(I) – Y. In this case all trajectories of the H atom, which lead to recombination of fragments, are blocked by the interactions responsible for stabilisation of the intermediate. This treatment demonstrates the necessity of taking into account multibody interactions to gain a deeper insight into the mechanisms of the reactions of diffusing hydrogen atoms with isolated impurity $\text{Y}^\bullet$.

The synthesis of a compound called hydrido argon fluoride, H – Ar – F, in solid argon has been reported.¹¹⁰ Changes in the vibrational frequencies of the stabilised intermediate upon isotope substitutions $\text{H} \rightarrow \text{D}$ and $^{40}\text{Ar} \rightarrow ^{36}\text{Ar}$ are thought to be the most important argument in favour of the formation of the H – Ar and F – Ar bonds. According to quantum-chemical calculations carried out at the CCSD(T)/aug-cc-pVQZ level of theory (see Ref. 111), the energy of HArF is 14.7 kJ mol^{-1} relative to the energy of dissociation into neutral atoms while the barrier to

dissociation is 17.2 kJ mol^{-1} . In addition, calculations predicted a high stability of the intermediate towards internal conversion into neutral systems corresponding to the global potential minimum

Such a conversion can occur involving the bending vibration. The calculated barrier to reaction along the coordinate of the $\text{H}-\text{Ar}-\text{F}$ bending vibration was $\sim 96.4 \text{ kJ mol}^{-1}$.

Taking into account successful stabilisation of chemical compounds $\text{H}-\text{Rg}-\text{Y}$ (see above), one can suggest that the use of experimental methods employed for the synthesis of such compounds will allow detection of new compounds with the atoms of inert gases including light Rg atoms. Calculations predict that the reaction barriers responsible for the intrinsic stability of such intermediates are at most $10\text{--}15 \text{ kJ mol}^{-1}$; therefore, stabilisation of these particles requires operation at temperatures below 20 K . Bondybey *et al.*¹⁰⁸ succeeded in using solid neon for stabilisation of intermediate particles ($\text{H}-\text{Kr}-\text{Br}$) under conditions where thermal diffusion of hydrogen atoms unfreezes at temperatures below 10 K . Low-density solid media (*e.g.*, impurity–helium solid phase, which is stable at temperatures below 10 K) can also be considered as solid matrices suitable for stabilisation of loosely bound compounds of various atoms with the atoms of inert gases.^{112, 113} The morphology of such structures is not known with certainty; however, Boltnev *et al.*¹¹⁴ have demonstrated the possibility of doping solid phases of composition $\text{Rg}(\text{He})_n$ ($\text{Rg} = \text{Ne}, \text{Ar}, \text{Kr}, \text{Xe}; n > 10$) with reactive species.

V. Chemical reactions involving fluorine atoms

Chemical reactions with participation of fluorine atoms have been the subject of intensive basic and applied research.^{115, 116} These reactions are characterised by high exothermicity and low energy barriers (usually, the gas-phase barriers are at most 8 kJ mol^{-1}), which predetermines high reaction rates and the formation of excited products. The matrix isolation technique has been traditionally used for detection and studies of the products of such reactions. Comprehensive reviews of investigations in this field carried out to the late 1980s have been reported by Jacox.^{6, 117} Because of this we will concern ourselves with more recent studies.

1. Translational mobility of fluorine atoms

The unique properties of fluorine atoms produced by photodissociation of F_2 molecules isolated in solid argon or krypton matrices have been reported in the early 1990s. Experiments⁶⁶ showed that the quantum yield of photodissociation of F_2 is close to unity, if the excess energy per atom,

$$\Delta E = \frac{h\nu - D_e(\text{F}_2)}{2},$$

where D_e is the dissociation energy of the F_2 molecule, exceeds 1 eV . As can be seen from Fig. 10, at $\Delta E > 1 \text{ eV}$ the cage effect is insignificant and the efficiency of photodissociation of F_2 in solid argon is close to the efficiency of the corresponding gas-phase process. Photodissociation of F_2 in solid matrices is basically different from the photodissociation of the molecules containing heavy halogens (Cl_2 , ICl , Br_2), since in the latter case the quantum yield is at most 10^{-5} at moderate excess energies ($< 3 \text{ eV}$).^{118–120} The thermalisation length of a ‘hot’ atom F was estimated at $3\text{--}8 \text{ nm}$.⁶⁶

The possibility for a long-range migration of ‘hot’ fluorine atoms to occur was also confirmed by other researchers,¹²¹ though estimates of the thermalisation length were smaller. Using the molecular dynamics simulation, it was shown⁷² that migration of a ‘hot’ atom in the crystal occurs as ballistic motion (*i.e.*, the trajectory of the fluorine atom passes through the lattice interstices) until the first strong collision with the lattice atom. This is due to efficient dissipation of the energy of the ‘hot’ fluorine atom

Figure 10. Quantum yield of photodissociation of F_2 molecules isolated in solid argon as a function of excess photon energy.⁶⁶ The arrows denote the characteristic wavelengths of photolysing radiation.

in the interaction with the argon atoms. Yet another feature of the fluorine atoms is that their diffusion mobility unfreezes at temperatures much below the melting (sublimation) temperature of the crystal. Consumption of the fluorine atoms produced by photolysis of F_2 in the crystals of argon and krypton is illustrated in Fig. 11. At concentrations of the order of 10^{17} cm^{-3} , the lifetime of the F atoms stabilised in argon is nearly 10^3 s at 20 K . Kinetic measurements revealed the absence of geminate recombination of the atoms produced by photodissociation of one F_2 molecule.⁶⁶ In the course of diffusion the atoms migrate in the crystal over long distances and the kinetics of loss of the atoms corresponds to bulk recombination

$$\frac{d[\text{F}]}{dt} = -k_d[\text{F}]^2, \quad (12)$$

where $[\text{F}]$ is the volume average of the concentration of the atoms.

Figure 11. Temperature dependence of the concentration of fluorine atoms (c_F) in argon (1) and krypton (2) crystals.⁶⁶ Heating of samples from 10 K at a rate of $\sim 0.5 \text{ K min}^{-1}$.

2. Reactions of photogenerated ‘hot’ fluorine atoms

As photogenerated ‘hot’ atoms escape the parent cage, they can react with distant molecules of the other reactant. The formation of stabilised radicals generated by low-temperature photolysis of solid $\text{Rg}/\text{F}_2/\text{M}$ mixtures was established in the early studies (see, *e.g.*, Refs 33, 35, 122, 123). However, no reaction channels responsible for the formation of such products were found. The point is that the radical species can be produced both in the interaction of the migrating atom with the isolated impurity molecule, $\text{F} + \text{M}$, and by photolysis of F_2 contained in heterodimers $[\text{F}_2 \cdots \text{M}]$, if the photogenerated atom escapes the cage [see reactions (6a) and (6b)]. However, in a series of studies^{58, 124, 125} it

was shown that photolysis of heterodimers $[F_2 \cdots M]$ results in predominant formation of molecular (closed-shell) products. Therefore, the emphasis was placed on studies of hydrogen-bonded molecular complexes generated in photoinduced reactions

In our joint investigations carried out in collaboration with Prof. C Wight (University of Utah, USA) we succeeded in distinguishing between the reaction channels associated with the formation of molecular and radical products in such systems.^{20, 21} Figure 12 presents the kinetic curves of consumption of the reactants and of accumulation of the products during photolysis of Ar/F₂/CO mixtures prepared using a conventional matrix isolation technique. Exponential fit of the kinetic curves of consumption of the CO molecules and binary complexes $[F_2 \cdots CO]$ in the course of continuous photolysis shows a nearly twofold difference in the rates of the processes. The rate of accumulation of the F₂CO molecules equals the rate of consumption of the $[F_2 \cdots CO]$ complexes, whereas an increase in the concentration of the FCO[•] radicals correlates with consumption of isolated CO molecules. Spectral and kinetic studies of the reactants and reaction products revealed two principal reaction channels with participation of photogenerated fluorine atoms:

(1) reaction in the complex of reactants

(2) reaction of a 'hot' F* atom with an isolated CO molecule

Analysis of changes in the band intensities in the IR spectra of the reactants and reaction products showed that the mass balance for consumption of complexes $[F_2 \cdots CO]$ and accumulation of F₂CO is kept constant within the limits of experimental error ($\pm 10\%$). This means that photolysis of complexes of the reactants causes no exit of the fluorine atoms from the reaction cage; rather, they react with the neighbouring CO molecule. Only $\sim 3\%$ of the CO molecules in the samples of composition Ar:F₂:CO =

1000:1:1 undergo conversion into the FCO[•] radicals following reaction (16). The proportion of binary complexes $[F_2 \cdots CO]$, which produce the F₂CO molecules in reaction (14), is $\sim 7\% - 10\%$ of the total amount of CO molecules. Thus, the amount of molecular products of the cage reaction exceeds the amount of radicals generated in the reactions of the migrating 'hot' fluorine atoms by a factor of 2 to 3. This product ratio remains unchanged for the samples of various compositions (at x_{F_2} and $x_{CO} < 10^{-3}$), since the amounts of the radical products and $[F_2 \cdots CO]$ complexes vary in proportion to the concentrations of F₂ and CO in the sample. Analogous measurements were also carried out in argon crystals doped with F₂ and CO molecules.²¹ The principal channels of the reactions of photogenerated atoms in the crystal and in the argon matrix were found to be similar. However, a basic difference between them is that the yield of radicals in reaction (16) in the crystal was 10 to 15 times higher than in the matrix at equal initial concentrations of the reactants in the samples.

The ratio of the amount of radicals produced to the initial amount of F₂ molecules in the sample was used^{20, 21} as a measure of the efficiency of reaction (16) between the migrating F* atoms and the isolated molecules. If the relative concentration of the molecules of the second reactant, x_m , is less than 10^{-2} , this ratio increases in proportion to x_m for all the systems studied

$$\frac{[R]}{[F_2]_0} = Kx_m, \quad (17)$$

where K is the coefficient characterising the yield of stabilised radicals in the reactions of photogenerated fluorine atoms with impurity molecules in the solid argon matrix.

The coefficient K determined from the concentration dependencies for reactions of F* atoms with CO molecules in an argon matrix was found to be 27 ± 8 . Analogous measurements in argon crystals gave a much larger value, 340 ± 120 . Even with allowance for the error of measurements the efficiency of the reaction of 'hot' fluorine atoms in argon crystal is more than an order of magnitude higher than in the matrix.

The coefficient K characterises the number of lattice atoms which are 'surveyed' by two migrating, photogenerated fluorine atoms (in order to react with impurity molecule). This value must depend on both the mean thermalisation length, $\langle l \rangle$, and the reaction cross-section, σ_m . The reaction of the thermalised atom with the nearest environment should also be taken into account. If migration occurs in the ballistic regime up to the first strong collision followed by thermalisation⁷² (provided a uniform distribution of reactants over the sample), the yield of radicals can be evaluated from the simple expression

$$\frac{[R]}{[F_2]_0} = (2\sigma_m \langle l \rangle N_0 + 2Z)x_m, \quad (18)$$

where N_0 is the density of atoms in the argon crystal and $Z = 6$ is the coordination number for the O_h interstitial site in the crystal.

According to Eqn (18), the maximum value, $K(\text{matrix}) \simeq 50$, corresponds to a mean thermalisation length of the atom of $\langle l \rangle \simeq 1.5$ nm, or nearly three lattice constants of the argon crystal. A higher yield of radicals in the crystal can be due to a much larger $\langle l \rangle$ value compared to the matrix. The mean thermalisation length in the crystal estimated from the experimental $K(\text{crystal})$ value is as long as 17 nm. Expression (18), as applied to the atomic dynamics in the solid phase, is not rigorous since the atom moves in the crystal field and continuously loses its energy. Therefore, these $\langle l \rangle$ values should be treated as estimates. Nevertheless, they are in agreement with the results of earlier studies in which different scales for migration of 'hot' atoms in argon crystals and in solid matrices were obtained.^{66, 121} The relatively low reactivity of such atoms in the matrix can be rationalised by shortening of the thermalisation length due to the small size of crystallites and to high concentration of defects. Taking into

Figure 12. Kinetic curves of consumption of CO molecules (1) and $[F_2 \cdots CO]$ binary complexes (2) and those of accumulation of reaction products for FCO[•] radicals (3) and F₂CO molecules (4) during continuous photolysis of a ternary sample (Ar:F₂:CO = 2000:1:1) with light ($\lambda = 355$ nm) at 16 K.²⁰

The experimental band intensities were normalised to their values after 215 min of photolysis. The curves denote exponential fits to the experimental data.

account the mass ratio of the F and Ar atoms, one can suggest that the fluorine atom with an initial energy of ~ 1 eV must undergo thermalisation after 1–3 successive collisions with the lattice atoms. Without considerable loss of energy the ‘hot’ atom can migrate in the crystal only by moving along specific trajectories passing through the interstices of the crystal lattice, thus avoiding strong collisions with the lattice atoms. Only in this case can the migration length of a ‘hot’ atom be as long as ~ 10 nm,⁷² the lattice defects being a ‘heat sink’ for the excess energy of the atom, thus accelerating its thermalisation in the matrix.

Table 4 lists the K values measured in an argon matrix for the reactions of ‘hot’ fluorine atoms with various molecules. The most efficient is the interaction of such atoms with small diatomic molecules; the interaction with large molecules (*e.g.*, C_2H_2 or C_2H_4) is 2 to 3 times less efficient. Hydrogen abstraction reactions are characterised by the smallest K values. In contrast to nearly barrierless reactions of addition to diatomic molecules O_2 , CO , NO (energy barriers to these reactions in the gas phase are at most 2 kJ mol⁻¹), the barriers to hydrogen abstraction from NH_3 , CH_3 and H_2 molecules in the gas phase vary from 4 to 7.5 kJ mol⁻¹. An important factor, which also reduces the probability for the ‘hot’ atom to react, is high stereospecificity of the hydrogen abstraction reactions in which the atom must attack the molecule along the C–H bond (collinear collision).

Table 4. Values of K coefficient in formula (17).

Reaction	Products	K	Measuring technique

3. Reactions of diffusing fluorine atoms

Thermally activated chemical reactions in thin argon films doped with fluorine atoms and molecules of the second reactant have long been observed (see Refs 6 and 117). Transformations observed were explained by unfreezing of the local mobility of the atoms at high temperatures. More recent studies revealed a key feature of the diffusing atoms, namely, the absence of geminate recombination of photogenerated atoms and the ability of such atoms to diffuse over long distances in crystals and argon matrices.^{65,66} In this case chemical reactions of mobile atoms are limited to their bulk recombination [see Eqn (2a)]. Assuming a uniform distribution of molecules throughout the sample, the kinetics of processes can be described using the volume averaged concentrations of reactants and the rate constants for bimolecular reactions (2a) and (2b). In the framework of this approach the efficiency of reactions of diffusing atoms can be characterised by the ratio of the concentration of radicals produced to the initial concentration of atoms¹²⁶

$$\frac{[R]_{\max}}{[F]_0} \cong \frac{k_r}{k_d} \frac{[x_m]_0}{[F]_0} \ln \left(1 + \frac{k_d}{k_r} \frac{[F]_0}{[x_m]_0} \right), \quad (19)$$

which is in turn determined by the ratio of the initial concentrations of the reactants, $[F]_0/[x_m]_0$, and by the ratio of the rate constant for reaction (2b) to the rate constant for recombination of atoms (2a), k_r/k_d . The k_r/k_d ratios for various reactions are

Table 5. The k_r/k_d ratios for reactions of thermal fluorine atoms in an argon matrix at 26 K. (The recombination constant of F atoms is $\sim 2 \times 10^{-21}$ cm³ s⁻¹ at 26 K.)

Reaction	k_r/k_d	Measuring technique
F + CO	0.4–0.6 0.35–0.45 0.45–0.6	IR spectroscopy EPR IR spectroscopy in crystal
F + O ₂	0.6–0.8 0.5–0.65	IR spectroscopy EPR
F + C ₂ H ₄	0.2–0.3 0.15–0.25	IR spectroscopy EPR
F + NH ₃	0.02–0.03	"
F + CH ₄	0.001–0.002	"
F + H ₂	0.0003–0.001	"

listed in Table 5. As can be seen, the values of this parameter vary by three orders of magnitude. The O₂ and CO molecules are the most efficient scavengers of diffusing atoms. The rate constants for the reactions with these molecules are close to the rate constant for recombination of the atoms. The smallest k_r/k_d values were obtained for the reactions of hydrogen abstraction from the CH₄ and H₂ molecules.

An example illustrating the efficiency of stabilisation of the reactive intermediate in the matrix is provided by the interaction F + C₂H₄, resulting in addition of fluorine at the double bond of ethylene and the formation of a vibrationally excited radical

In the gas phase the radical dissociates in $\sim 10^{-9}$ s (see Ref. 127)

Stabilisation of 2-C₂H₄F[•] in the matrix requires transfer of an energy of ~ 60 kJ mol⁻¹ into the matrix, the transfer time being shorter than the dissociation time. In contrast to the gas-phase reaction, the reaction of diffusing fluorine atoms in solid argon results in stabilised intermediate as the major product.^{39,128,129}

p is the reaction channel probability.

High resolution of the HFS in the EPR spectra of isolated radicals 2-C₂H₄F[•] allowed detailed analysis of the spectra and determination of the character of internal motions in the stabilised radical. Eight vibrational frequencies of this radical were first determined by IR spectroscopy.¹²⁹

New reactive intermediates generated in solid-phase reactions of mobile fluorine atoms are considered below.

4. Radical – molecular complexes R[•]---HF

According to published data obtained from studies in the gas phase and from quantum-chemical calculations, most hydrogen abstraction reactions

occur in a collinear complex where the fluorine atom attacks the reactant molecule along the R–H bond.^{130,131} No bound intermediate states of such reactions were observed earlier, though the possibility for them to exist in the vicinity of the transition state both in the product and the reactant valleys was discussed in the literature. Different ways of trapping the products of chemical

reactions (22) in low-temperature matrices have been considered.¹¹⁷ It was pointed out that stabilisation of the bound state of products, $R^{\bullet} \cdots HF$, can be achieved only if the solid-phase reaction is carried out. Information on such complexes provided by IR spectroscopy is insufficient. High-frequency vibrations of radicals change only slightly upon binding into complexes, while the frequencies of characteristic intermolecular vibrations in the complexes appear in the region below 300 cm^{-1} and are unavailable for conventional measuring techniques. The frequency shift of the HF stretching vibration (difference between the frequency in complex and the vibrational frequency of isolated HF molecule) can be indicative of binding the molecule into complex. However, it provides only qualitative information on the binding energy of the complex.

The possibility of stabilisation of pre-reaction complexes $F \cdots RH$ was shown taking low-temperature co-condensation of fluorine atoms and CH_3X ($X = Cl, Br, I$) molecules in excess of argon as an example. The processes with participation of these reactants, occurring in the solid matrix, can be schematically depicted as follows:¹³²

Complexes $H_3CX \cdots F$ are the major products. Weak additional satellite IR bands characterised by small frequency shifts relative to the intense bands of isolated CH_3X molecules were assigned to the pre-reaction complexes $F \cdots HCH_2X$. No reactions with participation of CH_3X in the ground electronic state were observed; however, photolysis of the samples by visible light ($\lambda > 420\text{ nm}$) led to disappearance of complexes $F \cdots HCH_2X$ and production of complexes $H_2XC' \cdots HF$. The experimental HF vibrational frequencies in a number of related radical – molecular complexes isolated in a solid argon matrix are listed in Table 6. This seems to be the only spectroscopic characteristic of intermediates obtained under such experimental conditions by IR spectroscopy.

Table 6. HF stretching vibration frequencies (cm^{-1}) of complexes $R^{\bullet} \cdots HF$ and $M \cdots HF$ trapped in a solid argon matrix. (The stretching vibration frequency of HF molecule trapped in a solid argon matrix is 3916 cm^{-1}).

Complexes	Frequency	Ref.
$NC^{\bullet} \cdots HF$	3753	133
$HC_2^{\bullet} \cdots HF$	3756	133
$H_2FC^{\bullet} \cdots HF$	3854	134
$H_3C^{\bullet} \cdots HF$	3764	24, 135
$H_2N^{\bullet} \cdots HF$	3267	47
$HF \cdots HF$	3825	136
$HCN \cdots HF$	3626	137
$H_3N \cdots HF$	3041	138

A radical – molecular complex $H_3C^{\bullet} \cdots HF$ was stabilised in solid argon and identified by IR spectroscopy as an intermediate of the reaction $F + CH_4$.¹³⁵ Experiments with isotope substitution of the reactants ($CH_4 \rightarrow CD_4$) permitted the determination of the HF vibrational frequency (3764 cm^{-1}) and the frequency of the CH_3 out-of-plane vibration (664 cm^{-1}) in the complex. Both vibrations in the complex are characterised by rather large

frequency shifts relative to the frequencies of the corresponding vibrations of isolated HF molecule and $CH_3^{\bullet}$ radical (3916 and 619 cm^{-1} , respectively).

The assignment of these frequencies to complexes $H_3C^{\bullet} \cdots HF$ generated in the reactions of diffusing fluorine atoms with CH_4 molecules in solid argon was confirmed in more recent IR and EPR studies.^{24, 126}

Using the EPR technique it was found that reactions of ‘hot’ fluorine atoms with isolated CH_4 molecules result in isolated radicals $CH_3^{\bullet}$ as the major product (quartet of HFS lines with the splitting $a_H = 2.3\text{ mT}$). The reactions of diffusing fluorine atoms give a product characterised by a sixteen-component EPR spectrum. Each component of the HFS of radical $CH_3^{\bullet}$ is additionally split into four components due to interaction between the unpaired electron and the magnetic nuclei of the HF molecule ($a_F = 1.6\text{ mT}$, $a_H \leq 0.2\text{ mT}$). The structure of free complex $H_3C^{\bullet} \cdots HF$ corresponding to the bound state on the PES in the product valley has been calculated.²⁵

According to calculations, the complex has a collinear configuration of C_{3v} symmetry and a binding energy of $\sim 8.4\text{ kJ mol}^{-1}$. The frequency of intermolecular vibration in the complex is 125 cm^{-1} while the frequency of the H–F vibration in the complex is $\sim 130\text{ cm}^{-1}$ lower than in the free molecule. The calculated IHFC constants of the complex are in good agreement with the experimental values. The IHFC constants of the F and H atoms dramatically decrease upon small variations of orientation of the HF molecule relative to the equilibrium configuration. Therefore, it was concluded that most of the reaction products are stabilised in the form of collinear complex $H_3C^{\bullet} \cdots HF$. This lattice-stabilised complex of reaction products retains the symmetry of the transition state of the reaction.

Gas-phase chemical reaction

has been the subject of numerous studies aimed at investigating the reaction dynamics in elementary chemical processes (see, *e.g.*, Refs 139–141). Quantum-chemical calculations¹⁴² predicted a collinear configuration of complex $H^{\bullet} \cdots HF$ in the output channel of the reaction. The authors¹⁴² pointed out that the presence of such a bound state in the product valley affects the angular and energy distribution of the end reaction products. Complex H_2F produced in the reactions of diffusing fluorine atoms with H_2 molecules was first studied experimentally in solid argon by EPR spectroscopy.¹⁴³ Two bound configurations of the complex were shown to exist. Their relative concentrations vary in the temperature range from 10 to 30 K due to hindered internal rotation of the HF molecule. Temperature dependence of the shape of the EPR spectra was described using a model with allowance for exchange between the energetically inequivalent configurations of the complexes $A \rightarrow B$ and $B \rightarrow A$. The IHFC on ^{19}F and ^1H nuclei of the HF molecule were found to be $a_F = 3.2$ and $a_H < 0.1\text{ mT}$ for complex A and $a_F = 0.5$ and $a_H \approx 0.4\text{ mT}$ for complex B. Complex B appears to be more stable, since its contribution to the EPR spectrum increases as the temperature decreases.

Figure 13 presents the isolines of the constants of IHFC with the nuclei of fluorine atoms of the HF molecule calculated for different configurations of the complex. The experimental IHFC a_F and a_H of complex B are consistent with collinear configura-

Figure 13. Isolines of IHFC constants on the ^{19}F nucleus in radical–molecular complex $\text{H}'\cdots\text{HF}$ obtained from B3LYP/aug-cc-pVTZ calculations.

The regions corresponding to the measured IHFC constants are labelled A and B; -0.46 (1), -0.05 (2), 0.27 (3), 0.75 (4), 1.82 (5), 2.33 (6), 2.70 (7), 2.83 (8), 2.92 (9), 3.16 (10), 3.44 (11), 4.07 (12), 4.39 (13), 4.49 (14), 4.70 (15) and 4.71 (16).

tion $\text{H}'\cdots\text{HF}$ with a $r_{\text{HH}'}$ distance of 0.22 nm, which corresponds to a local minimum in the product valley on the PES of the reaction.¹⁴² The nature of the second configuration of the complex (A) is still unknown. The experimental IHFC constants of this complex are in agreement with the calculated IHFC constants for a bent configuration $\text{H}'\cdots\text{H}-\text{F}$ characterised by the angle $\theta \approx 100^\circ$ and the distance $r_{\text{HH}'} = 0.24$ nm. We were unable to find in the literature reliable computational data that would help to decide between the presence or absence of the bound state on the PES in this region of geometric parameters of the system.

Interest in gas-phase reaction

was due to attempts at implementing the process in gas lasers to create an inverse population of rovibrational states of HF molecules. However, no inverse population could be created despite the high exothermicity of the reaction.^{144, 145} The existence of a strongly bound complex in the output channel of the reaction was predicted theoretically and discussed in the literature based on indirect gas-phase kinetic data.¹⁴⁶ Complex $\text{H}_2\text{N}'\cdots\text{HF}$ was first stabilised in solid argon as a product of reactions of mobile fluorine atoms with NH_3 molecules.^{46, 47, 147} Table 7 lists the spectroscopic characteristics of the complex, obtained by EPR and IR spectroscopy as well as the results of quantum-chemical calculations, which predict that the free complex has a planar structure of C_{2v} symmetry

The $\text{N}\cdots\text{H}'$ binding energy in the complex is 51.5 kJ mol^{-1} . Comparison of the experimental and calculated vibrational frequencies and IHFC constants reveals good agreement between them. The calculated binding energy of the complex is comparable with those of strongly bound hydrogen-bonded molecular complexes (*e.g.*, $\text{H}_3\text{N}\cdots\text{HF}$). This conclusion is confirmed by the IR spectrum of the complex: a large shift of the HF vibrational frequency and intense librations with frequencies lying between ~ 800 and 900 cm^{-1} (see Table 7) are characteristic of the

Table 7. Calculated and experimental vibrational frequencies and IHFC constants of radical–molecular complex $\text{H}_2\text{N}'\cdots\text{HF}$.⁴⁷

Parameter (vibration)	Calculated ^a	Experimental

complexes with the binding energies of $\sim 50\text{--}70 \text{ kJ mol}^{-1}$. According to quantum-chemical calculations, even small distortions of the geometry of the complex must cause significant changes in the IHFC constants. Taking into account the results of geometry optimisation and the arrangement of the complex at the substitutional site of the argon lattice, it was concluded that the geometry of the complex stabilised in solid argon is similar to that calculated for free complex (Fig. 14).

Figure 14. Arrangement and equilibrium geometry of radical–molecular complex $\text{H}_2\text{N}'\cdots\text{HF}$ in the argon crystal lattice.⁴⁷ Shown are twelve nearest Ar atoms.

5. Radical $\text{F}_2\text{NO}^\bullet$

Fox *et al.*^{148, 149} postulated the formation of a radical species $\text{F}_2\text{NO}^\bullet$ in the synthesis of F_3NO molecules

Vibrationally excited radical $\text{F}_2\text{NO}^\bullet$ was considered¹⁵⁰ as an intermediate species in other chemical reactions, *e.g.*,

$$\Delta H_0^\circ \approx -277 \text{ kJ mol}^{-1}.$$

Attempts at detecting this species experimentally in the elementary reactions (25)–(27) failed. The EPR spectra of radical $\text{F}_2\text{NO}^\bullet$ were obtained in the experiments on radiolysis of solid F_3NO .¹⁵¹ This species was stabilised in solid argon (radical was generated in successive reactions of diffusing fluorine atoms with isolated NO molecule).^{152, 153} IR and EPR spectroscopic studies revealed that in the temperature range 17–35 K the radical $\text{F}_2\text{NO}^\bullet$ exists in dynamic equilibrium with the pre-reaction complex $\text{F} \cdots \text{FNO}$

At high temperatures, the equilibrium is shifted to the right, while at low temperatures it is shifted to the left. The enthalpy and entropy of direct reaction (28) determined using a linear approximation of the temperature dependence of the experimental equilibrium constant are respectively

$$\begin{aligned} \Delta H &= 1240 \pm 180 \text{ J mol}^{-1}, \\ \Delta S &= 62 \pm 10 \text{ J mol}^{-1} \text{ K}^{-1} \end{aligned} \quad (30)$$

per mole of reactants isolated in solid argon. This indicates that the formation of the second N–F bond in radical $\text{F}_2\text{NO}^\bullet$ in the solid-phase reaction is an endothermic process. At the same time the formation of this radical is accompanied by a substantial increase in entropy. It is the large positive entropy of reaction (29) that plays a key role in stabilisation of a high equilibrium concentration of radicals upon warm-up of the system when $T\Delta S > \Delta H$. Radicals $\text{F}_2\text{NO}^\bullet$ can also be detected at $T < 20 \text{ K}$, since the characteristic time of their dissociation at these temperatures exceeds 10 h.

A feature of the electronic structure of radical $\text{F}_2\text{NO}^\bullet$ is that it is characterised by low energy of the N–F bond and a rather high N–F stretching vibration frequency ($> 700 \text{ cm}^{-1}$). Because of this, reasonable agreement between the calculated and experimental vibrational frequencies can be obtained only using computational methods with correct inclusion of configuration interactions [QCISD(T)].¹⁵³ According to calculations, the N–F bond dissociation energy is merely $\sim 10 \text{ kJ mol}^{-1}$. However, the formation of $\text{F}_2\text{NO}^\bullet$ in solid-phase reaction (29) is endothermic (by 1.2 kJ mol^{-1}). Direct comparison of these two values is impossible, since the initial reactant in the solid-phase reaction was the bound complex $\text{F} \cdots \text{FNO}$, whereas the bond dissociation energy was calculated relative to the noninteracting reactants F and FNO. In addition, one should take into account the interaction of the reactants with the atoms of the argon lattice, which must be different for complex $\text{F} \cdots \text{FNO}$ and radical $\text{F}_2\text{NO}^\bullet$.

6. Complex $\text{FO} \cdots \text{O}_2$

Asymmetric chlorine trioxide $\text{ClO}_3^\bullet$ was postulated^{154, 155} as a reactive intermediate and unstable product of photodecomposition of ozone by chlorine. However, it is impossible to draw unambiguous conclusions about the stability of such intermediates based on the results of quantum-chemical calculations.¹⁵⁶ The assumption of the existence of a bound particle FO_3 was never made in the experimental and theoretical studies of fluorine oxides $\text{FO}^\bullet$, $\text{FOO}^\bullet$, FOF , OFO and FOOF . It was found that a product of the reaction $\text{F} + \text{O}_3$ in photolysed solid $\text{Ar}/\text{F}_2/\text{O}_3$ mixtures is characterised by two intense IR bands at 968 and 1522 cm^{-1} in the region of the vibrational frequencies of FO and O_2 , respectively.¹⁵⁷ In the experiments with ^{18}O -enriched ozone these bands were assigned to the F–O and O–O vibrations of reactive intermediate $\text{F} \cdots \text{O} \cdots \text{O} \cdots \text{O}$. Based on the results of kinetic measurements and spectroscopic data, it was concluded that reactions of translationally excited and diffusing fluorine atoms with O_3 molecules result in a highly reactive complex $\text{FO} \cdots \text{O}_2$. However, at present the results of quantum-chemical calculations

prevent us from drawing unambiguous conclusions about the nature of chemical bonding and the geometry of the complex.

7. Structural isomers of $[\text{HFCN}]^\bullet$

The possibility of the existence of two structural isomers in radical systems containing the CN group (*e.g.*, $\text{H}_2\text{C}=\text{N}^\bullet$ and $\text{HC}^\bullet=\text{NH}$, $\text{F}_2\text{C}=\text{N}^\bullet$ and $\text{FC}^\bullet=\text{NF}$, $\text{HFC}=\text{N}^\bullet$ and $\text{FC}^\bullet=\text{NH}$) was predicted by numerous quantum-chemical calculations.^{158–160} However, detailed experimental studies were carried out only for π -radicals $\text{H}_2\text{C}=\text{N}^\bullet$ and $\text{F}_2\text{C}=\text{N}^\bullet$ (see, *e.g.*, Refs 161–165). Therefore, quantum-chemical calculations of the structure and properties of such types of radicals are well substantiated experimentally. Until recently, almost no data on free σ -radicals $\text{HC}^\bullet=\text{NH}$, $\text{FC}^\bullet=\text{NF}$, $\text{FC}^\bullet=\text{NH}$ were available. It was assumed^{162, 163, 166} that radicals $\text{HC}^\bullet=\text{NH}$ and $\text{FC}^\bullet=\text{NF}$ can be the secondary products of photolysis of solid mixtures $\text{Ar}/\text{HI}/\text{HCN}$ and $\text{Ar}/\text{trans-N}_2\text{F}_2/\text{FCN}$. The band at 886 cm^{-1} in the IR spectrum was assigned to radical $\text{HC}^\bullet=\text{NH}$ while the band at 1053 cm^{-1} was assigned to radical $\text{FC}^\bullet=\text{NF}$. This assignment is tentative, since it is to a great extent based on the experience and professional intuition of researchers.

Recent EPR and IR spectroscopic studies^{167, 168} allowed the conditions for stabilisation of radical conformers $\text{HFC}=\text{N}^\bullet$ and $\text{FC}^\bullet=\text{NH}$ in solid argon to be determined for the first time. It was shown that a π -radical is generated in the reaction of diffusing fluorine atoms

while radical $\text{FC}^\bullet=\text{NH}$ is produced in the solid matrix as a result of photoinduced conversion of stabilised radical $\text{HFC}=\text{N}^\bullet$

Selective excitation to the absorption band of the $\tilde{\text{X}}^2\text{A}' \rightarrow \tilde{\text{A}}^2\text{A}''$ electronic transition of radical $\text{HFC}=\text{N}^\bullet$ causes a complete conversion of this species into the other structural isomer. The resolved EPR spectra of both structural isomers are shown in Fig. 15. Based on the results of kinetic measurements and analysis of the absorption and fluorescence spectra of

Figure 15. EPR spectra of $\text{HFC}=\text{N}^\bullet$ (a) and $\text{FC}^\bullet=\text{NH}$ (b) radicals stabilised in solid argon at 35 K.¹⁶⁹

The radical was produced in the reactions of diffusing fluorine atoms with HCN molecules (a); the radical was generated by photolysis of trapped $\text{HFC}=\text{N}^\bullet$ radicals with light at $\lambda = 450\text{--}490 \text{ nm}$ (b). Shown are the HFS of the spectra of the radicals.

HFC=N* and DFC=N*, it was concluded that irreversible reaction (32) is due to intramolecular tunnelling of hydrogen atoms on the PES of the electronically excited state.^{169,170} The structure of these species was determined by comparing the calculated and experimental spectroscopic characteristics (a complete set of vibrational frequencies and IHFC constants).

VI. Chemical reactions involving oxygen atoms

Chemical reactions with participation of oxygen atoms in cryogenic matrices were mostly investigated in order to study the elementary processes initiated by photolysis of ozone molecules. In particular, it was found that the O₃ molecule is an efficient photolytic precursor for generation of oxygen atoms. In the text below we will consider the following aspects of these studies: the behaviour of photogenerated oxygen atoms in inert matrices, photochemical reactions in isolated molecular complexes [O₃–M] and chemical transformations initiated by photolysis of ozone in solid O₃ and O₂.

1. Oxygen atoms in solid matrices and crystals of inert gases

Photolytic generation of oxygen atoms in solid matrices has been studied in the course of photodissociation of isolated molecules O₃, O₂ and N₂O. In the gas phase excitation of O₃ molecules by light to the Hartley absorption band, X¹A₁ → 1¹B₂, causes generation of a singlet oxygen atom with a quantum yield of 0.9

Another dissociation channel, with a quantum yield of 0.1,

arises due to interception of the excited term 1¹B₂ with the dissociative term that correlates with the ground state of the ozone molecule. UV-Photolysis of ozone in solid argon occurs with a low quantum yield (~10^{−1}–10^{−3}) due to a strong cage effect.^{171–173} The quantum yield of photolysis of ozone monomers in solid argon as a function of temperature is presented Figure 16. A dramatic weakening of the cage effect with an increase in temperature was rationalised by an increase in the amplitude of the O₃ librations at the lattice site.¹⁷¹ The quantum yield of photolysis of ozone in solid xenon is close to unity. However, nearly 80% of the stabilised atoms recombine with the neighbouring oxygen molecules after warm-up to 30–40 K.¹⁷⁴ Other atoms react with distant dioxygen molecules or undergo bulk recombination. By analysing the kinetics of geminate recombination

it was concluded¹⁷⁴ that the thermalisation length of ‘hot’ oxygen atoms (~0.2 nm) is comparable with the binding distance between the diffusing atom and the dioxygen molecule. The weak influence of the cage effect on photodissociation of ozone was rationalised by the fact that the effective radius of the interaction R_g–O(¹D) is much smaller than that of the interaction R_g–O(³P).^{71,175} Therefore, ozone molecules are considered as

convenient photolytic precursors for generation of reactive oxygen atoms, O(¹D), in low-temperature matrices.^{173,176,177} For instance, the formation of N₂O in the photolysis of ozone molecules in solid nitrogen¹⁷⁷ is energetically possible only in the reaction of a singlet atom with an N₂ molecule

Another channel of O₃ photolysis causes stabilisation of the O(³P) atom outside the reaction cage

The mass-balance equation for the reaction products showed¹⁷⁷ that the formation of one N₂O molecule in reaction (34a) ‘costs’ a total of fifteen dissociated O₃ molecules. The fact that the N₂O molecules are formed only in complexes with O₂ unequivocally indicates that reaction (34a) occurs with participation of the N₂ molecules surrounding the ozone molecule and that the oxygen atoms outside the parent cage do not react with distant nitrogen molecules. At the same time a value of 0.7 was reported¹⁷⁶ for the quantum yield of O₃ photodissociation in a solid nitrogen matrix at 10 K. Taking into account the results obtained by Schriver-Mazzuoli *et al.*,¹⁷⁷ this means that the main process is exit of the ‘hot’ atom from the cage followed by stabilisation of the O(³P) atom [reaction (34b)]. If the atom does not escape the parent cage, either the O + O₂ recombination or ‘concerted’ reaction (34a) with participation of the oxygen atom and O₂ and N₂ molecules occur. Therefore, the efficiency of reaction (34a) should be compared with that of the competing reaction of inverse recombination to the cage. Comparison of the data reported in Refs 176 and 177 suggests that the ratio of yields of these reactions is ~1 : 6.

In the example just considered the reaction involved the O(¹D) atom located within the parent cage. Chemical reactions of photogenerated atoms O(¹D) outside the cage were discovered in studies of photolysis of ternary mixtures Ar/O₃/hydrocarbon.^{178,179} In particular, it was shown that the main channel of the reaction of the O(¹D) atom with methane and methanol molecules is insertion of this atom into the C–H bond, which causes stabilisation of the reactive intermediates:

These results supported the effect of insertion of the oxygen atom into the C–H bond, which was reported earlier.^{180,181} The results of recent studies of the O + CH₄ interaction in molecular beams and analysis of its dynamics in the framework of the Rice–Ramsperger–Kassel–Markus (RRKM) statistical theory showed that the end products (mostly CH₃ + OH and CH₂O + H) are formed after dissociation of vibrationally excited intermediate (CH₃OH)* characterised by a lifetime of ~10^{−11} s. Direct reaction of hydrogen abstraction contributes insignificantly to the balance of end products (see, *e.g.*, Ref. 182).

The problem of distinguishing the reaction channels associated with the oxygen atoms generated by photolysis of O₃ molecules consists in that the van der Waals complexes of ozone with other molecules are, as a rule, characterised by small frequency shifts in the IR spectra. Therefore, discrimination between the reaction products formed by photolysis of binary complexes [O₃–M] and the products of reactions of migrating ‘hot’ atoms with distant molecules is not necessarily successful. The best results were obtained in studies of ozone photolysis in charge-transfer complexes. A correlation was found between consumption of the photolysed [O₃---M] complexes and the formation of the products of photolysis. As a rule, such reactions are completed with transfer of oxygen atom from the photoexcited O₃ molecule to the partner in the complex

Figure 16. Quantum yield (Φ) of photolysis of ozone monomers in solid argon as a function of temperature.¹⁷¹

Table 8. Primary products of photoinitiated reactions in [O₃---M] complexes isolated in solid argon.

Complex	Photoinitiation wavelength range /nm	Product	Ref.
[O ₃ ---H ₂ O]	266	H ₂ O ₂	183
[O ₃ ---Cl ₂]	800–360	ClClO	184

[O ₃ ---H ₂ O ₂]	266	H ₂ O ₃	194

Table 8 lists the data on the products of photoinduced reactions (36). Reliable distinction between the reaction channels was reported recently¹⁹³ in a study of photolytic reactions of O₃ with SO₂ molecules. Using spectral and kinetic methods, they distinguished between the reactions of photogenerated O(¹D) atoms with distant SO₂ molecules and transformations in the photolysed complexes [O₃---SO₂]. The only product detected was a symmetric oxide SO₃. Besides, experiments with the ¹⁶O → ¹⁸O isotope substitution revealed an efficient exchange of oxygen atoms between the reactants

Taking into account the results obtained, the authors suggested the existence of vibrationally excited asymmetric isomer (OSO₂)^{*} as reactive intermediate.

Among five structural isomers of SO₃ predicted by quantum-chemical calculations,⁶¹ the above-mentioned isomer is less stable than symmetric SO₃ (the energy difference is 230 kJ mol⁻¹). The conclusion¹⁹³ that the excited intermediate does not correspond to the symmetric structure of the most stable isomer (*D*_{3h} symmetry) was based on the assumption that the isotope composition of the products of reactions (37a) and (37b) does not correspond to the structure of the (SO₃)^{*} intermediate containing three equivalent oxygen atoms.

At present, the available experimental data on the mobility of thermalised oxygen atoms in the solid cryogenic matrices and crystals are inadequate to correctly describe diffusion of such atoms even phenomenologically. The kinetics of thermally induced loss of oxygen atoms in a solid xenon matrix in the temperature range 30–40 K^{69,195,196} was described by two rate constants corresponding to the diffusion coefficients of 1.4 × 10⁻¹⁵ and 5.4 × 10⁻¹⁸ cm² s⁻¹ at 32 K. Thermal diffusion of oxygen atoms in the crystals of krypton and xenon was also studied.⁶⁸ The loss of the O atoms was described by three activation barriers assuming the existence of three types of atomic sites in the crystal lattice. Calculations of the mobility of oxygen atoms in a xenon crystal, carried out in the framework of the

transition state theory using various types of pair potentials for the interaction of the O(³P) atom with the atoms of the crystal, gave somewhat contradictory results. For instance, the diffusion coefficients reported by Guo and Thompson¹⁹⁷ are three to five orders of magnitude higher than those calculated by Ford *et al.*,¹⁹⁸ whereas the corresponding experimental values^{68,69} lie between them. These discrepancies can be understood if we take into account the fact that the barriers to diffusion are determined by the short-range terms of the pair interaction potentials and that thermally activated processes occurring at ultralow temperature are very sensitive to the height of the activation barrier. In addition, differences in morphology between the matrices and crystalline samples predetermine a wide scatter of the activation barriers.

Another phenomenological model of thermally activated mobility of atomic oxygen was proposed by Danilychev and Apkaryan^{68,71} who postulated that the oxygen atom in the ground state, O(³P), in the crystal is immobile. It was also assumed that thermally induced intersystem crossing O(³P) → O(¹D), which occurs with participation of the lattice phonons, is followed by migration of the atom across the singlet PES O(¹D)–(Xe)_n until recrossing and stabilisation in the crystal. According to calculations,⁷¹ O–(Xe)_n intersystem crossing is possible in crystalline xenon. Bringing forward arguments in support of this diffusion mechanism, it was emphasised that the length of thermally activated migration appears to be comparable with the migration length of the O(¹D) atoms generated by photoexcitation of stabilised atoms. Nevertheless, the possibility for this diffusion mechanism to occur is still a moot question (see review¹⁰). The multiplicity of diffusing atoms can be experimentally determined by following their reactions with impurity molecules, which proceed involving the singlet atoms only. Earlier, such reactions were observed for ‘hot’ O(¹D) atoms generated in the photodissociation of ozone molecules in solid argon (see, *e.g.*, Refs 173 and 178).

2. Chemical transformations initiated by photolysis of ozone in solid oxygen and ozone matrices

Photodecomposition of ozone upon UV photolysis to the Hartley absorption band in the gas phase occurs with a quantum yield of ~4.¹⁹⁹ Both products of primary photodissociation [see Eqn (33)] participate in further reactions to give a total of six oxygen molecules

Photolysis of thin films of pure ozone at 10 K occurs with a quantum yield of 2.0 ± 0.3 (see Ref. 171). This means that photodecomposition of ozone in the solid phase involves two successive stages, namely, photodissociation (33) characterised by a quantum yield close to unity and the reaction of one photodecomposition product with the O₃ molecule. Among the three feasible secondary reactions (38)–(40), reaction (38) with participation of the O(¹D) atom seems to be the most probable,¹⁷¹ since the activation barriers to the other two reactions in the gas phase are rather high (> 15 kJ mol⁻¹). Analogous transformations were found in the case of UV photolysis of ozone dimers isolated in solid argon¹⁷¹

The results obtained by Schriver-Mazzuoli *et al.*²⁰⁰ supported high efficiency of photolysis of the [O₃---O₃] dimers in solid argon. However, based on the kinetic data, they proposed another mechanism of loss of the dimers which leads to stabilisation of the oxygen atom

The main difficulty distinguishing between the reaction channels (41) and (42) is that only consumption of the ozone molecules was studied by IR spectroscopy.^{171,200} In this case kinetic measurements cannot provide a means for reliable determination of the product ratios for reactions (41) and (42). The results of IR spectroscopic investigations can be essentially supplemented by carrying out experiments with isotope substitution in the molecules of initial reactants. For instance, photolysis of ozone molecules in solid oxygen was studied using the isotope substitution of oxygen atoms.²⁰¹ The main idea of this experimental strategy was to trap the ¹⁸O-enriched ozone molecules in the solid oxygen matrix containing the ¹⁶O atoms only. Figure 17 illustrates the evolution of the IR spectrum of ozone in the region of the ν_3 vibration during continuous photolysis with light at a wavelength of 693 nm to the Chappuis absorption band. Changes in the spectrum show that the number of the O₃ molecules remains constant during long-term irradiation. However, the isotope composition of ozone molecules changes radically, namely, the ¹⁸O₃(18-18-18) molecules are replaced by the ¹⁶O₃(16-16-16) molecules during photolysis. Kinetic analysis showed that the atom produced upon photodissociation of O₃ is added to the neighbouring O₂ molecule to give an O₃ molecule with altered isotope composition. Subsequent photolysis of products of these reactions causes further transfer of the ¹⁸O atoms in the O₂ molecules and, correspondingly, enrichment of the ozone molecules with the ¹⁶O isotope

In fact this reaction mechanism describes a photoinduced chemical migration of ozone molecules in solid oxygen. The use of isotope substitution allowed reliable establishment of reaction channels in the case where the reactants and products are comprised of oxygen atoms only.²⁰¹

Figure 17. Evolution of the IR spectrum of ozone in the region of the ν_3 vibration during continuous photolysis of a ¹⁸O₃: ¹⁶O₂ = 1:4000 sample with light ($\lambda = 693$ nm).²⁰¹

VII. Conclusion

The results of experimental and theoretical investigations considered in this review show that chemical reactions of mobile atoms, which occur in an inert crystalline environment at ultralow temperature, cause stabilisation of free radicals and radical–molecular complexes (short-lived intermediate particles in the gas phase). The use of mobile atoms for generation of reactive intermediates permitted obtaining spectroscopic data on new metastable molecular structures which were not observed by other methods. This type of reaction is characterised by a rather high extent of conversion of the initial reactants, which makes it possible to detect matrix-isolated products of primary reactions. Stabilisation of a particular type of isolated particles is due to high selectivity of cryochemical reactions. This permits detection of matrix-isolated products of primary reactions using conventional methods of low-temperature spectroscopy. Joint use of the IR, optical and EPR spectroscopy allows reliable identification of products and establishment of their structure by comparing the measured spectroscopic characteristics with the results of quantum-chemical calculations.

The use of mobile atoms for cryochemical synthesis of new compounds is not limited to the atoms of three elements and their reactions considered in this review. In particular, of considerable interest is the use of photostimulated mobility of the rare-earth metal atoms and transition metal atoms. The results of such studies carried out before 1999 were generalised in a monograph.²⁰² Experimental approaches to low-temperature synthesis of particles containing various metal atoms and clusters have been reviewed.²⁰³

The fact that international conferences on the chemistry and physics of matrix-isolated species and on low-temperature chemistry are held on a regular basis (in particular, the last two conferences were held in Poland²⁰⁴ and Finland²⁰⁵) points out that this review is topical. When preparing the manuscript, the authors of this review used not only original communications but also information obtained in discussions, which is useful for refinement of researchers' views of particular (including moot) questions.

This review has been written with financial support from the Russian Foundation for Basic Research (Project No. 01-03-33171).

V. Some structural features of methane complexes	273
VI. Supplement	275

Abstract. The results of experimental and theoretical studies of the structures of methane complexes with neutral metal atoms, metal ions M^+ and molecular fragments ML_n are considered and generalised. The influence of the charge and electronic configuration of the central atom and the nature of stabilising ligands L on the mode of coordination of methane in the complexes is analysed. The data from theoretical calculations of the structures of methane complexes are compared with the results of structural studies of some classes of model compounds, namely, borane complexes $M(CO)_5 \cdot BH_3L$ ($M = Cr, Mo, W$) and tetrahydroborate complexes $ML_n(BH_4)_m$ containing BH_4^- anions as ligands. Some rules determining the mode of methane coordination in the complexes are elucidated and assumptions concerning the dependence of the mode of methane coordination on the electronic configuration of the central atom are made. The bibliography includes 173 references.

I. Introduction

The development of methods for mild selective catalytic functionalisation of saturated hydrocarbons (alkanes) is a highly important problem having great potential in organometallic chemistry. As D R H Barton said figuratively,¹ the solution of this problem is the dearest chemists' wish of the last few decades, as desired and unattainable as the Holy Grail for medieval knights. The key stage in alkane functionalisation is the activation of the chemically inert C–H or C–C bonds by metal complexes. Experimental data on the reactions of metal complexes with hydrocarbons have been considered in detail in a number of reviews and monographs (see, for example, Refs 2–12).

Numerous spectroscopic and kinetic data indicate that the addition of metal complexes to C–H bonds in saturated hydrocarbons as well as the reverse elimination of alkanes give intermediate alkane complexes of the corresponding metals containing one or several alkane molecules.^{13–15} The existence of such complexes is now beyond doubt. Some of them have been detected by spectroscopy [for example, $M(CO)_5(\text{alkane})$ complexes, where $M = Cr, Mo, W$].³ Recently, the intermediate formation of alkane

complexes has been observed directly by femtosecond IR spectroscopy during activation of the C–H bonds in alkanes both in low-temperature matrices¹⁶ and in solutions at usual temperatures.¹⁷ The first example of direct NMR monitoring of the formation of an alkane complex of a transition metal, $CpRe(CO)_2(C_5H_{10}\text{-cyclo})$, in solution at -80°C was reported.¹⁸ Similar methane complexes have not been detected experimentally in solutions.⁵

Those involved in experimental investigations of the structures of metal complexes with alkanes are faced with considerable difficulties because these complexes have not been isolated in a pure state. The existing data on these structures were mainly deduced from the results of quantum-chemical calculations.

Methane complexes attract particular attention of researchers because methane is the most naturally abundant hydrocarbon widely applied as an energy carrier and is promising as a cheap, readily available potential raw material for the chemical industry. Catalytic reforming of methane to methanol has been mentioned recently among the ten most important goals of catalysis.¹⁹ Meanwhile, methane is the least reactive hydrocarbon; therefore, its functionalisation is a particularly difficult task.

Of great theoretical interest are items concerning the modes of methane coordination in metal complexes and factors dictating the predominance of one or another coordination mode. A large number of publications have been devoted to the structures of methane complexes with neutral metal atoms, metal ions M^+ and molecular fragments ML_n . According to quantum-chemical calculations, there exist a diversity of possible modes of methane coordination and the difference between the energies of various structures is slight, which is indicative of structurally non-rigid compounds. Therefore, determination of the most stable structure is ambiguous and depends on the particular system (complex) as well as on the calculation method and the basis set of functions used. This ambiguity is inherent in the calculations for any of the three modes of methane complexes, *i.e.*, those with neutral metal atoms, cations and molecular fragments. The lack of uniqueness of calculation results hampers elucidation of the regular structural features of methane complexes. In this connection, there appears to be a need to compare the theoretical data for methane complexes with experimental data obtained for complexes of some species structurally similar and isoelectronic to methane.

This review considers the results of experimental and theoretical studies of the structures of methane complexes with neutral metal atoms, cations M^+ and molecular fragments ML_n . The effects of the charge and the electronic configuration of the central atom and the nature of the stabilising ligands L on the mode of methane coordination in the complexes are analysed. The calcu-

Received 19 December 2002

Uspekhi Khimii 72 (3) 287–310 (2003); translated by Z P Bobkova

lated data on the structures of methane complexes are compared with the results of structural investigations of some classes of model compounds — borane complexes $M(\text{CO})_5 \cdot \text{BH}_3\text{L}$ ($M = \text{Cr}, \text{Mo}, \text{W}$) and tetrahydroborate complexes $\text{ML}_n(\text{BH}_4)_m$ in which the ligands are represented by the BH_4^- anions isoelectronic to methane and resembling methane in geometry. Some features determining the mode of methane coordination in the complexes are elucidated and suggestions concerning the dependence of the methane coordination mode on the electronic configuration of the central atom are made. The review covers papers published up to 2001 inclusively and some publications of 2002.

The following designations are used for the modes of methane coordination in the complexes. Compounds in which methane is linked to the central metal atom through one hydrogen bridge $[\text{MHCH}_3 \text{ (A)}, \text{ the } M-\text{H}_b-\text{C} \text{ angle is } \sim 180^\circ, \text{ the } \text{CH}_4 \text{ tetrahedron is coordinated by a vertex}]$ are designated as η^1 -complexes (Fig. 1). Compounds where methane is bound to the central atom by two $[\text{MH}_2\text{CH}_2 \text{ (B)}, \text{ the } \text{CH}_4 \text{ tetrahedron is coordinated by an edge}]$ or three $[\text{MH}_3\text{CH} \text{ (C)}, \text{ the } M-\text{C}-\text{H}_t \text{ angle is } \sim 180^\circ, \text{ the } \text{CH}_4 \text{ is coordinated by a face}]$ hydrogen bridges are designated as η^2 - and η^3 -complexes, respectively. Compounds with one bent hydrogen bridge $[\text{MHCH}_3 \text{ (D and E)}, \text{ the } M-\text{H}_b-\text{C} \text{ angle is much smaller than } 180^\circ]$ are referred to as η_2^1 - and η_3^1 -complexes. The complexes **D** and **E** are often designated in the literature by $\eta^2\text{-C,H}$; however, this designation does not provide a strict description of the structure, because these complexes can be formed upon distortion of either the η^2 - or η^3 -structure. Therefore, for more exact descriptions of the structures of these complexes, here we call them η_2^1 and η_3^1 .

Figure 1. Types of methane coordination in the complexes; η^1 is mono-, η^2 is bi-, and η^3 is tridentate coordination of methane; η_2^1 and η_3^1 are intermediate modes of coordination; H_b and H_t are bridging and terminal hydrogen atoms, respectively.

The accepted notation for the quantum-chemical methods and the software used is given in the Supplement.

II. Methane complexes with neutral metal atoms

The data on the structures of methane complexes with neutral metal atoms are relatively scarce. The formation of the $\text{Co}(\text{CH}_4)$ complex was detected experimentally by IR spectroscopy upon irradiation of the CH_3CoH complex with light with $\lambda > 400 \text{ nm}$ in a low-temperature argon matrix. This reaction is reversible; on exposure to UV radiation, the $\text{Co}(\text{CH}_4)$ complex is converted again into CH_3CoH . After the formation of the $\text{Co}(\text{CH}_4)$ complex, the triply degenerate absorption band of methane $\nu_4(\text{f}_2)$ located at 1305.3 cm^{-1} was split into two peaks. This allowed the authors to suggest that this complex has C_{3v} symmetry. The most likely coordination of methane in this complex is tridentate — $\text{Co}(\eta^3\text{-CH}_4)$.²⁰

Similar complexes have also been obtained for iron atoms in a methane matrix.²¹ Molecular orbital calculations using the effective Hamiltonian proposed by Anderson (see Ref. 22 and references therein) have shown that Fe atoms in the ground state

($^5\text{D}, 3\text{d}^6 4\text{s}^2$) are able to form complexes with methane. A tridentate coordination of methane is most probable for these complexes. The energy of the $\text{Fe}-\text{C}$ bond is 11 kcal mol^{-1} and the $\text{Fe}-\text{C}$ distance is $3.4 \text{ \AA}$. The oxidative addition of methane to an iron atom is hampered due to the mutual repulsion of the closed electron shells of the methane $\text{C}-\text{H}$ bonds and the 4s electrons of iron atoms.²²

Experimental studies showed that none of the neutral atoms of 3d metals in the ground state reacts with alkanes in the gas phase at 300 K. In the case of 4d-metal atoms, only palladium atoms in the ground state ($^1\text{S}, 4\text{d}^{10}$) form complexes with higher alkanes with a binding energy of not less than 8 kcal mol^{-1} (see Ref. 23). However, a palladium complex with methane is not formed under these conditions, which points to a lower energy of the $\text{Pd}-\text{C}$ bond. The results of *ab initio* self-consistent field (SCF)²⁴ calculations of the interaction between a palladium atom and methane, which were carried out using the minimum basis set of gaussian orbitals (LCGO) before the relevant experiments, are at variance with experimental data.²³ According to calculations,²⁴ the palladium atom forms a methane complex with monodentate coordination of the methane ligand, $\text{Pd}(\eta^1\text{-CH}_4)$; the bond energy is $7\text{--}8 \text{ kcal mol}^{-1}$.

In a series of publications,^{25–30} Blomberg and coworkers studied theoretically the activation of the $\text{C}-\text{H}$ bonds in methane by 3d-, 4d- and 5d-metal atoms.† A modified coupled pair functional (MCPF) study of the reaction of methane with 4d metals ranging from yttrium to palladium showed²⁷ that only palladium in the ground state ($^1\text{S}, 4\text{d}^{10}$) is able to be complexed with methane to give a $\text{Pd}(\eta^2\text{-CH}_4)$ type complex. The stabilisation energy of this complex with respect to the initial reactants is 4 kcal mol^{-1} . Ruthenium and rhodium form complexes with methane only in the low-spin excited state ($^3\text{F}, 4\text{d}^7 5\text{s}^1$ and $^2\text{D}, 4\text{d}^9$, respectively), the stabilisation energies of these complexes relative to the excited metal atoms being 12 and 9 kcal mol^{-1} , respectively. It was noted²⁷ that the potential energy surface (PES) minima corresponding to metal complexes with methane can also be found for other 4d-metal atoms, but the metal...carbon distances in these complexes are very long (stabilisation energies do not exceed 2 kcal mol^{-1}). A MCPF study of the interaction of rhodium and niobium atoms with methane showed that rhodium in the low-spin excited state ($^2\text{D}, 4\text{d}^9$) is inserted almost without a barrier into a $\text{C}-\text{H}$ bond of methane to give the HRhCH_3 complex.³¹ The $\text{Rh}(\eta^2\text{-CH}_4)$ complex is formed as an intermediate. Unlike rhodium, niobium does not react with methane.²⁶

Experimental and theoretical investigations of the reactions of alkanes with transition metal atoms in the ground electronic state have shown that rhodium and palladium‡ are the only 4d metals able to react with ethane and higher alkanes at 300 K.²⁸

According to experimental results, among the transition 5d metals in the ground electronic state, only neutral platinum atoms can activate methane in the gas phase at 300 K.²⁹ The results of theoretical investigations [using the density functional theory (DFT) with Becke's exchange functional and the Lee–Yang–Parr correlation functional (B3LYP) with parametrised configuration interactions (PCI-80) and *ab initio* calculations]³⁰ of the activation of methane $\text{C}-\text{H}$ bonds by transition 3d-, 4d- and 5d-metal atoms are consistent with experimental data. The calculations showed that platinum and rhodium atoms are capable of activating the $\text{C}-\text{H}$ bonds in methane but only platinum can participate in the further formation of the $\text{Pt}=\text{CH}_2$ carbene, which is needed for experimental monitoring of the reaction.²⁹

† It is noteworthy that calculations of the $\text{M}-\text{C}$ bond energies for all metals were carried out using the geometric parameters optimised for the rhodium complex $\text{Rh}(\eta^2\text{-CH}_4)$, i.e., the influence of the electronic configuration of the central atom on the mode of coordination of the methane ligand was not taken into account.

‡ Palladium is unique due to its ability to form η^2 -complexes with linear alkanes (except for methane), while rhodium is able to dehydrate higher alkanes (but not methane).

Experimental and theoretical (MCPF technique) research of gas-phase reactions of iridium and platinum with n-alkanes C_nH_{2n+2} ($n = 3, 4$) demonstrated that the potential barrier to the reaction between a platinum atom and propane or butane does not exceed $1-2 \text{ kcal mol}^{-1}$, while iridium atoms are inert towards these alkanes.²⁹ Thus, the chemical behaviour of atomic iridium in the gas phase differs appreciably from the behaviour of iridium complexes in solutions; many of these complexes are able to react with alkanes.⁵

Density functional theory calculations in the PCI-80 approximation have shown³⁰ that the inertness of iridium atoms is due to the great promotion energy between the chemically inert ground state ($5d^7 6s^2$) and the excited state ($5d^8 6s^1$). In the excited state the iridium atom reacts with methane to give a molecular adduct with a bond energy of 2 kcal mol^{-1} . Attempts to calculate the geometric parameters of the complex formed by the iridium atom with methane by *ab initio* SCF methods in the MCPF approximation and by the second-order Møller–Plesset perturbation theory (MP2) have not met with success.

The platinum atom in the ground state ($5d^9 6s^1$) forms a weak complex with methane (the Pt–C distance is 3.61 Å , the bond energy is $2.1 \text{ kcal mol}^{-1}$).³⁰ The mode of coordination of methane in this complex was not indicated. In the case of the low-spin excited state of platinum ($1S, 5d^{10}$), MP2 calculations predict the formation of an η^2 -complex with a Pt–C distance of 2.38 Å and a binding energy of $19.1 \text{ kcal mol}^{-1}$. However, when the geometry of the singlet $Pt(\eta^2\text{-CH}_4)$ complex was optimised by more effective methods, no minimum was found on the PES.³⁰

The activation of methane by 5d-metal atoms (Re, Os, Ir and Pt) has been studied by *ab initio* methods using the relativistic effective core potentials (RECP) and taking into account electron correlation.³² It was found that rhenium atoms in the ground state ($6S, 5d^5 6s^2$) are highly inert with respect to methane, compared with other transition 5d metals, due to the presence of a half-filled 5d shell. Osmium in the ground state ($5D, 5d^6 6s^2$) is also inert toward methane; however, the energy barrier to the reaction is much lower for osmium than for rhenium. Iridium atoms in the excited state ($2P$), like platinum atoms in the ground ($3D, 5d^9 6s^1$) and low-spin ($1S, 5d^{10}$) states, are inserted into the C–H bond of methane to give $HMCH_3$ complexes.

III. Methane complexes with bare metal ions

It was found in 1979 that transition metal cations (Ti^+ , Fe^+ , Co^+ , Ni^+) are able to react with alkanes (butane and isobutane) in the gas phase.³³ This discovery has triggered intensive research into gas-phase reactions of transition metal cations M^+ with alkanes and the carbene complexes MCH_2^+ with hydrogen, which is still being continued. The purpose of the researches mentioned above is to elucidate the mechanism of activation of the H–H, C–H, and C–C bonds by metal cations. According to the obtained results, metal ions are markedly more reactive toward alkanes than neutral atoms. A typical gas-phase reaction of metal ions not stabilised by ligands is the dehydrogenation of alkanes C_nH_{2n+2} ($n \geq 2$). Methane dehydrogenation has been much less studied. None of the 3d transition metal ions in the ground state is able to perform exothermic dehydrogenation of methane. Of the 4d-metal ions, only Zr^+ exhibits capacity for methane dehydrogenation in the ground state. As regards 5d-metal ions, the fast successive reactions

have been observed for Ta^+ , W^+ , Os^+ , Ir^+ , and Pt^+ (iridium and platinum atoms are most reactive in this reaction); La^+ , Hf^+ , Re^+ and Au^+ ions did not dehydrogenate methane under similar conditions.³⁴ The reactivity of these ions depends on both the electronic configuration and the spin state.

Meanwhile, many ions of both transition and non-transition metals are able to form ion–molecular complexes $M(CH_4)_n^+$ with methane. The properties of these complexes, resulting from association of metal cations with one or more CH_4 molecules, have been studied experimentally using various methods, in particular, electron impact, photoionisation, photoelectron-photoion coincidence spectroscopy, standard or quadrupole mass spectrometry, *etc.* The $Mg(CH_4)^+$, $V(CH_4)^+$, $Fe(CH_4)^+$, $Co(CH_4)_n^+$ ($n = 1-4$), and $Pt(CH_4)_n^+$ ($n = 1, 2$) complexes have been studied experimentally. Under multicollision conditions at 300 K and a helium pressure of 0.75 mmHg, 3d-metal ions react with methane to form complexes with the composition $M(CH_4)_n^+$ [$M = Sc^+$ ($n = 1-3$), Ti^+ ($n = 1-5$), V^+ ($n = 1-4$), Cr^+ ($n = 1, 2$), Fe^+ ($n = 1-3$), Co^+ ($n = 1-3$), Ni^+ ($n = 1, 2$), Cu^+ ($n = 1, 2$), and Zn^+ ($n = 1$)], the structures of which have not been determined.³⁵ According to experimental results,³⁵ the energy of methane binding in these complexes exceeds 10 kcal mol^{-1} . An exception is the manganese ion, which does not form complexes with methane under these conditions.

The alkane complexes of alkali metal cations (sodium and potassium), which are similar in size to transition metal ions, have not been observed experimentally. This attests to an important role of d orbitals in the stabilisation of metal complexes of alkanes. The geometric parameters and bond energies of complexes formed by methane with lithium, sodium, magnesium, scandium, titanium, vanadium, chromium, iron, cobalt, copper, 4d metals, tantalum, iridium and platinum were calculated by quantum-chemical methods. Some of the results of experimental and theoretical investigations of the ion–molecular $M(CH_4)^+$ complexes are considered below.

1. Non-transition metal ions

The interaction of methane with the lithium cation has been studied theoretically.³⁶⁻³⁸ The geometry of the $Li(CH_4)^+$ complex was optimised by the restricted Hartree–Fock (RHF) method using the SKBJ effective core potential (relativistic compact effective core potential and the Stevens, Basch, Krauss and Jasien shared-exponent basis set). The complex $Li(\eta^3\text{-CH}_4)^+$ with C_{3v} symmetry was found to correspond to the minimum on the PES. The ion–ligand interaction in this complex was assumed to be mainly of the ion–dipole nature.³⁶

The potential energy surface of the $Li(CH_4)^+$ complex was studied within the framework of the *ab initio* Hartree–Fock method.³⁷ The tridentate coordination of methane in the $Li(\eta^3\text{-CH}_4)^+$ complex with a binding energy of $8.2 \text{ kcal mol}^{-1}$ was found to be energetically the most favourable. The researchers believe³⁷ that this binding energy is large enough to enable the existence of this ion in an isolated state in molecular beams or inert matrices. The potential barrier to the transition from the η^3 - to η^2 -complex is low ($0.5 \text{ kcal mol}^{-1}$), indicating structural non-rigidity of the $Li(CH_4)^+$ complex. Analysis of the Mulliken populations showed that the Li^+ cation perturbs only slightly the electron density of the CH_4 ligand. The electron density (expressed in fractions of the electron charge) on hydrogen atoms decreases upon coordination by 0.06 (H_b) and 0.13 e (H_i), and that on the C atom increases by 0.17 e. The overlap populations $Q(Li-H_b)$ and $Q(Li-C)$ are fairly low (0.03 and 0.16 e, respectively), pointing to weak covalent interaction of the Li^+ ion with the ligand. It should be noted that in the study cited,³⁷ the calculations were carried out in the approximation of a rigid tetrahedral CH_4 core with a fixed C–H distance (1.096 Å).

Charkin *et al.*³⁸ used the *ab initio* QCISD(T)/6-31G**//MP2/6-31G* + ZPE(MP2/6-31G*) calculation methods⁸ to represent

§ Here QCISD(T) means the single and double quadratic configuration interaction with an estimation of triple excitations by a perturbation method; 6-31G** is the Pople basis set extended by d- and p-polarisation functions with the 1s-AO being approximated by six and the 2s, 2p-AO, by four gaussian type functions grouped in the (3,1) form; ZPE is the zero-point energy.

fragments of the potential energy surfaces for the $\text{Li}(\text{CH}_4)^+$ and $\text{Na}(\text{CH}_4)^+$ ion–molecular complexes in the vicinity of formation of mono-, bi- and tridentate structures. It was found that the global minimum on the $\text{M}(\text{CH}_4)^+$ PES ($\text{M} = \text{Li}, \text{Na}$) corresponds to a tridentate structure, whereas a bidentate structure is matched by a maximum connecting the two nearest minima in the potential curve. The calculated energies for cation elimination from $\text{M}(\text{CH}_4)^+$ complexes ($\text{M} = \text{Li}, \text{Na}$) do not exceed 10–12 kcal mol⁻¹. However, they are sufficiently high to ensure the existence of these complexes in the isolated state or in inert matrices. The $\text{Li}(\eta^2\text{-CH}_4)^+$ and $\text{Li}(\eta^1\text{-CH}_4)^+$ complexes are 1.6 and 6.5 kcal mol⁻¹ less stable than $\text{Li}(\eta^3\text{-CH}_4)^+$, while the corresponding complexes $\text{Na}(\eta^2\text{-CH}_4)^+$ and $\text{Na}(\eta^1\text{-CH}_4)^+$ are 0.6 and 3.4 kcal mol⁻¹ less stable than $\text{Na}(\eta^3\text{-CH}_4)^+$.

For the $\text{Mg}(\text{CH}_4)^+$ complex, the geometric parameters and the energies of binding of the Mg^+ ion in the ground and excited electronic states to the methane ligand were calculated theoretically. The tridentate coordination of methane to form $\text{Mg}(\eta^3\text{-CH}_4)^+$ was found to be energetically the most favourable for the Mg^+ ion in the ground state ($^2\text{S}, 3\text{s}^1$); the same geometric configuration corresponds to a minimum on the system PES. The $\text{Mg}-\text{CH}_4$ binding energy in this complex is 4.0–7.6 kcal mol⁻¹ (see Ref. 39). The Mg^+ and CH_4 species in this complex are weakly bound by electrostatic forces. The methane ligand differs slightly from non-coordinated methane in geometric parameters, in particular, the $\text{H}-\text{C}-\text{H}$ angles change by about 0.5° and the $\text{C}-\text{H}$ distances, by less than 0.01 Å. Analysis showed that in the case of the Mg^+ ion, η^3 -coordination is preferred for methane over η^2 - or η^1 -coordination, as this decreases the repulsion between the 3s^1 electron of the magnesium ion and the $\text{C}-\text{H}$ bond electrons of the methane molecule. This results in a shorter $\text{M}-\text{C}$ bond and, hence, enhances the electrostatic interaction between the species. When the Mg^+ s electron passes to the $\text{p}\pi$ orbital of the complex, the methane ligand in $\text{Mg}(\text{CH}_4)^+$ retains the η^3 -coordination, while upon transition of the s electron to the $\text{p}\pi$ orbital, the coordination of the methane ligand changes to a bidentate one. The structure of the $\text{Mg}(\text{CH}_4)^+$ complex has been studied experimentally using photoelectron spectroscopy with a reflectron time-of-flight mass spectrometer.⁴⁰ The results of calculations³⁹ are in good agreement with the experimental data.

2. Transition metal ions

Mass-spectrometric studies of the interaction of the Sc^+ ion with alkanes in the gas phase have shown unique properties of this ion compared to other 3d-metal ions. With butane or higher alkanes, this ion forms $\text{Sc}(\text{C}_n\text{H}_{2n+2})_m^+$ complexes (presumably, dialkyl-scandium ions), which have not been detected for other 3d-metal ions.⁴¹ The reaction of Sc^+ with methane has been studied theoretically.^{42,43} The $\text{Sc}^+ + \text{CH}_4$ and $\text{ScCH}_2^+ + \text{H}_2$ reactions were investigated by the complete active space self-consistent field (CASSCF) method and by the multideterminant configuration interaction method with single and double excitations using the wave function obtained by CASSCF (MR-SDCI-CASSCF).⁴² The Sc^+ ion in the ground state ($^3\text{D}, 3\text{d}^1 4\text{s}^1$) reacts with methane to form the $\text{Sc}(\eta^3\text{-CH}_4)^+$ complex with a tridentate methane coordination and with an $\text{Sc}-\text{CH}_4$ binding energy of 15.1 kcal mol⁻¹. After the formation of this complex, the reaction is terminated due to the high energy barrier to its conversion into other isomeric complexes. In the case of the Sc^+ ion in the first excited state ($^1\text{D}, 3\text{d}^1 4\text{s}^1$), the bidentate coordination of methane is preferred. The stabilisation energy relative to the reactants is 13.3 kcal mol⁻¹ (the stabilisation energy with respect to the ground state of the Sc^+ ion is 5 kcal mol⁻¹).⁴² The reaction of methane with the Sc^+ cation was also studied by the density functional approach in the B3LYP approximation.⁴³ It was found that the Sc^+ cation both in the ground ($^3\text{D}, 3\text{d}^1 4\text{s}^1$) and the first excited state ($^1\text{D}, 3\text{d}^1 4\text{s}^1$) forms tridentate methane complexes $\text{Sc}(\eta^3\text{-CH}_4)^+$ due to the ion–dipole interaction. The $\text{Sc}-\text{CH}_4$ bond energies in these complexes are 15.7 and 8.4 kcal mol⁻¹, respectively (relative to the starting reactants).

A mass-spectrometric study⁴⁴ of the reaction of titanium ions with excess methane in the gas phase at 300 K has shown that under these conditions, the Ti^+ ion in the ground state ($^4\text{F}, 3\text{d}^2 4\text{s}^1$) is able to add up to three methane molecules. The binding energy for the first two methane molecules is ~17 kcal mol⁻¹, while that for the third molecule is 6.6 kcal mol⁻¹ (see Ref. 44). After the addition of two methane molecules, activation of $\text{C}-\text{H}$ bonds starts to compete with the addition reaction; in this case, the gas phase contains simultaneously the $\text{Ti}(\text{CH}_4)_3^+$, $(\text{CH}_4)_2\text{Ti}(\text{H})$, $(\text{CH}_3)^+$ and $(\text{CH}_4)_2\text{Ti}^+=\text{CH}_2$ ions. In the researchers' opinion,⁴⁴ the increase in the methane binding energy in the insertion products with respect to its binding energy in the corresponding $\text{Ti}(\text{CH}_4)_n^+$ complexes is the driving force of activation. The discovered reaction mechanism was called 'cluster-assisted σ -bond activation'.

The reaction of the excited titanium ion $\text{Ti}^+(^2\text{F}, 3\text{d}^2 4\text{s}^1)$ with CH_4 has been studied by the MP2/6-31G** method taking account of electron correlation and using the Hay–Wadt effective core potentials.⁴⁵ It was found that the first stage represents the formation of the intermediate $\text{Ti}(\text{CH}_4)^+$ complex, which is followed by hydrogen migration from methane to Ti^+ giving rise to an insertion product, HTiCH_3^+ . The calculation showed that the tridentate (η^3 , C_{3v}) coordination of methane with a binding energy of 73.1 kcal mol⁻¹ is most favourable for the $\text{Ti}^+(^2\text{F}, 3\text{d}^2 4\text{s}^1)$ ion. The $\text{Ti}(\eta^3\text{-CH}_4)^+$ complex corresponds to a deep energy minimum on the PES with respect to the starting reactants and to the transition state of the oxidative addition.⁴⁵

More recent calculations⁴⁶ by the DFT method in the B3LYP approximation also confirm the predominance of the tridentate coordination of methane to the excited $\text{Ti}^+(^2\text{F}, 3\text{d}^2 4\text{s}^1)$ ion; however, according to these results, the binding energy of methane to the titanium ion is only 21.81 kcal mol⁻¹ relative to the reactants (8.89 kcal mol⁻¹ with respect to the ground state of the Ti^+ ion). The reaction of methane with the Ti^+ ion in the ground state ($^4\text{F}, 3\text{d}^2 4\text{s}^1$) also yields the $\text{Ti}(\eta^3\text{-CH}_4)^+$ complex,⁴⁶ the $\text{Ti}-\text{CH}_4$ bond energy (22.21 kcal mol⁻¹) being roughly equal to that in a similar complex with the excited $\text{Ti}^+(^2\text{F}, 3\text{d}^2 4\text{s}^1)$ ion. These data are more consistent with the results of experimental studies⁴⁴ than the data obtained earlier.⁴⁵

Study of the gas-phase reaction between vanadium ions and methane by mass spectrometry⁴⁷ has shown that V^+ ions in the ground quintet state ($^5\text{D}, 3\text{d}^4$) do not react with methane. Transition of the V^+ ion into the triplet excited state ($^3\text{F}, 3\text{d}^3 4\text{s}^1$) results in a substantial increase in its reactivity. The weakly bound $\text{V}(\text{CH}_4)^+$ complex was prepared by ultrasonic expansion of the vanadium ion plasma generated by laser radiation with the use of helium containing 1% of methane as the carrier gas. The isolated $\text{V}(\text{CH}_4)^+$ ion was studied by resonance single-photon photodissociation spectroscopy.⁴⁸ The $3\text{d}^4 \rightarrow 3\text{d}^3 4\text{s}^1$ electron transition corresponding to the excitation of the central metal atom in the electrostatically bound $\text{V}(\text{CH}_4)^+$ complex was observed in this experiment. The binding energy between the V^+ ion in the ground state ($^5\text{D}, 3\text{d}^4$) and methane is ~15 kcal mol⁻¹. This differs little from the calculated Nb–C bond energy (11.8 kcal mol⁻¹) in the $\text{Nb}(\eta^2\text{-CH}_4)^+$ complex.⁴⁹ However, the researchers note that C_{2v} symmetry cannot be reliably ascribed to the $\text{V}(\text{CH}_4)^+$ complex in the ground state without full analysis of the rotation spectrum. The binding energy between the excited $\text{V}^+(3\text{d}^3 4\text{s}^1)$ ion and methane amounts to 8.3 kcal mol⁻¹. The decrease in the V^+-CH_4 binding energy taking place as vanadium passes from the ground state to the excited state is assumed⁴⁸ to be due to the mutual repulsion of the electron in the 4s shell of the excited ion and the electrons of the methane ligand.

The results of density functional calculations in the B3LYP approximation for the $\text{V}(\text{CH}_4)^+$ complex are consistent with the assumed bidentate coordination of methane by the V^+ ion in the ground state ($^5\text{D}, 3\text{d}^4$). The calculated energy of the bond between methane and V^+ in this complex (15.09 kcal mol⁻¹) is in good agreement with the experimental value (~15 kcal mol⁻¹). The

excited vanadium ion $V^+(^3F, 3d^3 4s^1)$ was found⁴⁶ to form a complex with tridentate coordination of the methane ligand.

Ab initio quantum-chemical calculations with allowance for electron correlation (MCPF method) of the insertion of single-charged 4d-metal ions into a methane C–H bond have shown⁴⁹ that all these ions are capable of forming complexes with methane, the ion–ligand binding energy being lower for ions with an outer s shell or d^5 shell than for d^4 , d^7 , d^8 and d^9 ions.⁴⁹ It should be noted that these calculations were carried out for a fixed η^2 -geometry of methane complexes, *i.e.*, the influence of the electronic configuration of a particular ion on the geometry of the complex was neglected.⁴⁹ As far as we know, experimental data concerning the binding energies in the methane complexes with 4d-metal ions are missing.

The activation of the methane C–H bonds by the Ta^+ cation observed experimentally in the gas phase^{2, 50, 51} has been studied by the density functional approach in the B3LYP approximation.⁵² This process was found to consist of several steps. The first step is the formation of the $Ta(CH_4)^+$ complex with electrostatic binding; this is followed by Ta^+ insertion into the C–H bond to give the dihydride $H_2TaCH_2^+$. A slightly distorted η^3 -coordination of methane is preferred for the Ta^+ ion in the ground state ($^5F, 5d^3 6s^1$); the $Ta^+–CH_4$ binding energy is 12 kcal mol^{−1}. The interaction between Ta^+ and methane is mainly electrostatic. The methane ligand almost retains the geometry of the free molecule (the length of one C–H_b bridging bond is increased by 0.003 Å). The Ta^+ ion does not lie on the C–H_t axis but is shifted somewhat toward one of the H_b atoms (the Ta–C–H_{tb} angle equals 73.02°).⁵²

Recent results obtained by density functional calculations in the B3LYP approximation for the reaction of methane with the Cr^+ ion in the ground ($^6S, 3d^5$) and excited ($^4D, 3d^4 4s^1$) states attest to a tridentate methane coordination in the resulting complexes.⁴⁶ The binding energies between methane and chromium ions in the ground and excited states are equal to 13.1 and 29.31 kcal mol^{−1}, respectively, relative to the reactants.

The reaction of methane with the Fe^+ ion (in the gas phase) has been studied in more detail.^{53–56} The ion–ligand binding energy for the $Fe(CH_4)^+$ complex was determined experimentally and calculated theoretically. The collision-induced dissociation (CID) of $Fe(CH_4)_n^+$ ions ($n = 1–4$) was studied by mass spectrometry.⁵³ The dissociation energy of the $Fe(CH_4)^+$ complex was found to be 13.7 ± 0.8 kcal mol^{−1}. These results prompted the conclusion that the Fe^+ ion in $Fe(CH_4)^+$ has a sextet ground state ($^6D, 3d^6 4s^1$).⁵³ In a mass-spectrometric investigation⁵⁴ of the $FeCH_2^+ + D_2$ and $Fe^+(^6D, ^4F) + CD_4$ reactions, the bond dissociation energy was found to be $D_0(Fe^+–CH_4) = 13.62$ kcal mol^{−1}; this is consistent with the value $D_e(Fe^+–CH_4) = 13 \pm 1$ kcal mol^{−1}, determined by the MCPF calculations.⁵⁴

The CASSCF and MR-SDCI-CASSCF methods were employed to study the PES of the $FeCH_2^+ + H_2$ reaction; the formation of the ion–molecular $Fe(CH_4)^+$ complex was established.⁵⁵ The $Fe(CH_4)^+$ complex with a binding energy of ~ 16 kcal mol^{−1} is stable with respect to dissociation into $Fe^+(^6D, 3d^6 4s^1)$ and CH_4 . The back reaction, $Fe^+ + CH_4$, gives only one product, $Fe(CH_4)^+$, at moderate temperatures. The calculations showed that the structures with C_{2v} (η^2) and C_{3v} (η^3) symmetry for $Fe(CH_4)^+$ are almost degenerate (the energy difference between these two complexes is equal to 0.05–0.17 kcal mol^{−1}). Thus, $Fe(CH_4)^+$ can be considered to be a structurally non-rigid system in which the Fe^+ ion is almost free to migrate around the CH_4 molecule giving structures with the symmetry

The main forces that stabilise the $Fe(CH_4)^+$ complex are the dispersion interaction and the 'ion-induced dipole' interaction. Study of the back reaction $Fe^+ + CH_4$ demonstrated that Fe^+ in the ground state ($^6D, 3d^6 4s^1$) forms the ion–molecular $Fe(CH_4)^+$ complex in the sextet state ($^6A_2$) with a binding energy of

15.5 kcal mol^{−1}, which does not participate in subsequent transformations.

The structure in which methane is coordinated to Fe^+ by only one hydrogen atom (η^1) is energetically less favorable than the η^2 - or η^3 -structures.⁵⁵ More recent calculations⁵⁶ by the DFT method in the B3LYP approximation point to a η^2 -coordination of methane in the $Fe(CH_4)^+$ complex; however, the values for the $Fe^+–CH_4$ binding energy obtained in this study do not correspond to experimental results.

Of all the methane–bare metal ion systems studied in the gas phase, the $CH_4–Co^+$ system has been studied in most detail.^{57–62} The temperature-dependent equilibria of gas-phase reactions were investigated by mass spectrometry; the ion–ligand binding energies in the $Co(CH_4)_n^+$ complexes ($n = 1–4$) were determined. In the case of $Co(CH_4)^+$, the dissociation energy is equal to 22.9 ± 0.7 kcal mol^{−1} (see Ref. 57).

According to MCPF calculations with electron correlation,⁵⁸ methane is coordinated by the Co^+ ion through two or three hydrogen atoms, the complex with η^2 -coordination being 1.3 kcal mol^{−1} more stable than the complex with η^3 -coordination. The dissociation energy of the $Co(\eta^2-CH_4)^+$ complex found by these calculations is 21.4 kcal mol^{−1}. The Co^+ ion in this complex has a d^8 electron configuration. The researchers noted a substantial change in the methane geometry in the η^2 -complex compared to free methane, in particular, the C–H_b bond lengths increase by 0.016 Å and the Co–H_b–C angle increases by 10.3°. The C–H_t bond lengths change slightly. This change in the methane geometry diminishes the energy of the complex by 2.9 kcal mol^{−1}. In the η^3 -complex, the methane geometry changes to a lesser extent; consequently, the bond strength increases by only 1.1 kcal mol^{−1} (see Ref. 58). In the researchers' opinion,⁵⁸ the strength of the $Co^+–CH_4$ bond is mainly determined by the charge-induced polarisation. However, if the contribution of only this effect is taken into account, the η^3 -conformation should be somewhat more stable than the η^2 -conformation (18.2 and 17.7 kcal mol^{−1}, respectively). When other factors such as electron repulsion according to the Pauli principle, charge transfer from methane to Co^+ , and polarisation of metal non-bonding orbitals are also taken into account, the order of stability for these two conformations is reversed.⁵⁸

The mechanism of the reaction

has been studied by the CASSCF and MR-SDCI-CASSCF methods.^{59, 60} It was found that cleavage of the H–H bond is the first to occur; this is followed by the formation of the ion–molecular $Co(CH_4)^+$ complex with a stabilisation energy of 19–22 kcal mol^{−1}. The back reaction $Co^+ + CH_4$ gives only one product, $Co(CH_4)^+$, at moderate temperatures. The researchers calculated the metal–ligand binding energies in the $Co(CH_4)^+$ complexes with C_{2v} and C_{3v} symmetry. The C–H_b and C–H_t bond lengths are nearly equal in the complexes with both types of symmetry, whereas the Co–H_b bond is much longer in the C_{3v} than in the C_{2v} structure. The calculations using the Hay–Wadt effective potential have shown that the two structures are nearly degenerate and it is difficult to choose which of them is more favourable. However, the calculations by the above-mentioned methods in the SKBJ approximation have shown that the C_{2v} structure is much more favourable (by 6.5 kcal mol^{−1}) than the C_{3v} -symmetric structure. The η^1 -structure in which Co^+ is coordinated to one hydrogen atom is 15–16 kcal mol^{−1} less favourable than η^2 - or η^3 -structures.^{59, 60}

The energies of successive elimination of the ligands from the $Co(CH_4)_n^+$ ($n = 1–4$) complexes have been determined both experimentally and theoretically.⁶¹ Study of the collision-induced dissociation of $Co(CH_4)_n^+$ complexes gave a dissociation energy of the Co–CH₄⁺ bond $D_0(Co–CH_4)^+ = 21.45 \pm 1.38$ kcal mol^{−1}, which is close to the value found previously.⁵⁷ These results are in good agreement with the results of *ab initio* calculations (MCPF method), which gave the value $D_e(Co–CH_4)^+ = 21.45$ kcal

mol^{-1} . According to calculations,⁶¹ the methane ligands in the $\text{Co}(\eta^2\text{-CH}_4)_n^+$ complexes ($n = 1-4$) are bound electrostatically to the Co^+ ion in the ground state ($^3\text{F}, 3\text{d}^8$). The structures with η^3 -coordination of the methane ligand are energetically somewhat less favourable.⁶¹

Study of the reactions

$\text{M} = \text{Co}, \text{Rh}$

by the density functional method with Becke's exchange potential and Perdew's correlation potential (B3P86)⁶² led to the conclusion that the reaction $\text{CoCH}_2^+ + \text{H}_2$ proceeds by a four-centre mechanism in the triplet state. In the complex formed upon the addition of hydrogen, methane is coordinated to cobalt in the bidentate manner. According to these calculations, the $\text{Co}(\eta^2\text{-CH}_4)^+$ complex corresponds to a global minimum on the PES, and its dissociation to give Co^+ and CH_4 requires $22.4 \text{ kcal mol}^{-1}$.

The reaction of Rh^+ with CH_4 was studied by guided-ion beams mass spectrometry (GIBMS).⁶³ This endothermic reaction was found to give ionic products, RhH^+ and RhCH_x^+ ($x = 0-3$). For low energies of the reactants, methane dehydrogenation is the predominant process

However, direct experimental data on the mechanism of the $\text{Rh}^+ + \text{CH}_4$ reaction are missing because the method used is unable to disclose mechanistic details. Therefore, considerable attention was devoted to quantum-chemical studies of methane activation by the Rh^+ ion.^{49, 60, 62, 64, 65} The PES of the reaction

was studied by the CASSCF and MR-SDCI-CASSCF methods.^{60, 64}

It was found that the first stage of the reaction gives the ion-molecular $(\text{H}_2)\text{RhCH}_2^+$ complex, which is then converted into HRhCH_3^+ upon cleavage of the $\text{H}-\text{H}$ bond. The latter complex rearranges into $\text{Rh}(\eta^2\text{-CH}_4)^+$, probably, without a barrier. This complex is more stable than the products of its dissociation, $\text{Rh}^+(^3\text{F})$ and CH_4 , by $16.8 \text{ kcal mol}^{-1}$. The $\text{Rh}(\text{CH}_4)^+$ structures with η^2 - and η^3 -coordination of methane differ little in energy but the C_{2v} -symmetric structure is more stable. The $\text{C}-\text{H}_\text{b}$ bond lengths in $\text{Rh}(\eta^2\text{-CH}_4)^+$ are longer than $\text{C}-\text{H}_\text{t}$ by $0.01-0.02 \text{ \AA}$.^{60, 64} Modified coupled pair functional calculations⁴⁹ also demonstrated that the η^2 -coordination of methane in the $\text{Rh}(\text{CH}_4)^+$ complex is most favourable (the $\text{Rh}-\text{CH}_4$ binding energy is $\sim 13 \text{ kcal mol}^{-1}$).⁴⁹

The potential energy surface of reaction (2) has been studied by the DFT approach in the B3P86 approximation.⁶² The Rh^+ cation occurs in the ground state $^3\text{F}, 4\text{d}^8$, and the initial steps of the $\text{RhCH}_2^+ + \text{H}_2$ reaction take place on a triplet potential surface. It was found that the HRhCH_3^+ intermediate formed in this reaction is unstable and rearranges without a barrier into $\text{Rh}(\eta^2\text{-CH}_4)^+$. The final complex corresponds to an absolute minimum on the PES with respect to any other critical point of the PES for both the triplet and singlet states of the Rh^+ ion. Dissociation of the $\text{Rh}(\eta^2\text{-CH}_4)^+$ complex to give Rh^+ and CH_4 requires $13.9 \text{ kcal mol}^{-1}$ (see Ref. 62). The researchers cited⁶² note that the results of PES calculations they obtained for this reaction are in good agreement with experimental data, unlike the results obtained in another study.⁶⁴

The potential energy surface for endothermic reaction (1) was studied by the density functional approach in the B3LYP approximation using the Hay-Wadt effective potential and by the MCPF method in the PCI-80 approximation.⁶⁵ The first stage gives the $\text{Rh}(\text{CH}_4)^+$ complex with electrostatic binding. The triplet state of this complex is more stable than the ground states of the reactants by 14.2 (PCI-80) or $11.5 \text{ kcal mol}^{-1}$ (B3LYP). The calculated⁶⁵ values for the $\text{Rh}-\text{CH}_4$ binding energy in $\text{Rh}(\text{CH}_4)^+$ are consistent with the results of calculations carried

out by other researchers.^{62, 64} However, in Ref. 65 considering the $\text{Rh}(\text{CH}_4)^+$ molecular complex with C_s symmetry, methane was assumed to have a distorted η^3 -coordination, which was found to be more stable than the η^2 -coordination by $0.9 \text{ kcal mol}^{-1}$. Meanwhile, the latter was proposed as the coordination of choice in the other two studies.^{62, 64}

It has been noted above that the Ir^+ ion is most efficient, among transition metal ions, in the gas-phase methane dehydrogenation.³⁴ A theoretical investigation [Hartree-Fock method with singly and doubly excited configurations (HFSD)]⁶⁶ of the reaction profile for

has shown that the reaction of the Ir^+ ion in the ground state ($^5\text{F}, 5\text{d}^7 6\text{s}^1$) with methane yields initially an ion-molecular complex $\text{Ir}(\eta^2\text{-CH}_4)^+$ with weak binding. However, due to the intersection of PES for the triplet and quintet states, the spin state of iridium changes, which results in the formation of a triplet ion-molecular complex $\text{Ir}(\eta^2\text{-CH}_4)^+$ with stronger bonds ($^3\text{B}_2, \text{C}_{2v}$). The stabilisation energy of this complex with respect to the ground states of the reactants [$\text{Ir}^+(^5\text{F}, 5\text{d}^7 6\text{s}^1) + \text{CH}_4$] amounts to $20.4 \text{ kcal mol}^{-1}$. The energy of the triplet η^3 -complex ($^3\text{E}, \text{C}_{3v}$) is 4 kcal mol^{-1} higher than the energy of the η^2 -complex.⁶⁶

The CASSCF and MR-SDCI-CASSCF methods were used⁶⁰ to study the PES of the reaction

Unlike the exothermic reactions of the carbene complexes of cobalt and rhodium with hydrogen, this reaction with iridium is endothermic. The $\text{Ir}(\text{CH}_4)^+(^3\text{A}_2)$ complex is ~ 15.7 (26.4) kcal mol^{-1} more stable than the products of its dissociation, $\text{Ir}^+(^5\text{F}, 5\text{d}^7 6\text{s}^1)$ and CH_4 . The structures of $\text{Ir}(\text{CH}_4)^+$ with C_{2v} and C_{3v} symmetry are rather similar in energy. The back reaction $\text{Ir}^+ + \text{CH}_4$ yields initially the $\text{Ir}(\text{CH}_4)^+$ complex and then the HIrCH_3^+ methyl hydride complex and the $(\text{H})_2\text{IrCH}_2^+$ bis(hydrido)carbene complex.⁶⁰

The Pt^+ cation is only slightly inferior to Ir^+ regarding the efficiency of methane dehydrogenation.³⁴ Several studies dealing with reactions of methane with this cation have been reported.⁶⁷⁻⁷⁰ One publication presents a theoretical and experimental (guided ion beam tandem mass spectrometry, GIBTMS) study of the activation of methane by the Pt^+ ion.⁶⁷ The dehydrogenation of CH_4 by thermalised Pt^+ cations ($\text{Pt}^+ + \text{CH}_4 \longrightarrow \text{PtCH}_2^+ + \text{H}_2$) proceeds on a doublet PES of the ground state of the ion. The reaction is reversible under conditions of ion-cyclotron mass spectrometry (FTICR-MS). The insertion of the Pt^+ cation in the ground state ($^2\text{D}, 5\text{d}^9$) into the methane $\text{C}-\text{H}$ bond occurs *via* the formation of the $\text{Pt}(\eta^3\text{-CH}_4)^+$ complex, which is transformed with a negligibly low activation barrier ($1.3 \text{ kcal mol}^{-1}$) to give the methyl hydride HPtCH_3^+ complex. This complex corresponds to a global energy minimum on the PES. The $\text{Pt}(\eta^2\text{-CH}_4)^+$ and $\text{Pt}(\eta^3\text{-CH}_4)^+$ complexes are transition states; they are matched by saddle points on the reaction PES. According to calculations,⁶⁷ the ion-ligand binding energy in the $\text{Pt}(\eta^3\text{-CH}_4)^+$ complex is equal to $28.3 \text{ kcal mol}^{-1}$. In the researchers' opinion,⁶⁷ no structures of this type have been considered previously in theoretical investigations of $\text{M}(\text{CH}_4)^+$ complexes.

An experimental and theoretical study of the oxidation of methane by oxygen in the presence of the Pt^+ cation as the catalyst has been reported.⁶⁸ The first step of the process is the formation of electrostatically bound complex $\text{Pt}(\eta^3\text{-CH}_4)^+$ with C_s symmetry. The ion-ligand binding energy is equal to 19.2 (B3LYP) and $25.4 \text{ kcal mol}^{-1}$ (PCI-80). Calculations⁶⁸ using a fuller basis set than those reported in the publication discussed above⁶⁷ also showed the presence of a C_{2v} -symmetric structure very close in energy to the C_s structure. Unfortunately, no energetic or geometric parameters for the $\text{Pt}(\eta^2\text{-CH}_4)^+$ complex are given in the publication.⁶⁸

The reactions of argon complexes of platinum ions PtAr_m^+ ($m = 1-6$) with CH_4 and CD_4 were studied experimentally by the FTICR-MS method and theoretically by the density functional approach in the B3LYP approximation.⁶⁹ The PtAr_m^+ complexes ($m = 2-6$) enter into ligand exchange reactions in which up to four argon atoms can be replaced by methane molecules. Conversely, the bare Pt^+ ion and the PtAr^+ complex react with methane to give PtCH_2^+ . The intermediate formation of the $\text{Pt}(\text{CH}_4)^+$ complexes in the $\text{Pt}^+ + \text{CH}_4$ and $\text{PtAr}^+ + \text{CH}_4$ reactions is confirmed by peaks of these complexes observed experimentally in the mass spectra. It was noted⁶⁹ that the results of calculations of the geometric and energetic parameters of the $\text{Pt}(\text{CH}_4)^+$ complexes with predominating 'ion-induced dipole' interaction depend appreciably on the basis set chosen. As expected, the geometric parameters of these complexes calculated using polarisation functions and without these functions are substantially different.⁶⁹

The results of a combined experimental (GIBMS) and theoretical (DFT/B3LYP) investigation of the $\text{Pt}^+ + \text{CH}_4$ and $\text{PtCH}_2^+ + \text{H}_2$ reactions and collision-induced dissociation of $\text{Pt}(\text{CH}_4)^+$ upon the reaction with xenon have been reported.⁷⁰ For the $\text{Pt}^+ + \text{CH}_4$ system, it was found that the only process observed at low temperatures is effective exothermic dehydrogenation of methane giving rise to $\text{PtCH}_2^+ + \text{H}_2$. The reaction starts with the formation of the $\text{Pt}(\text{CH}_4)^+$ complex due to the 'ion-induced dipole' interaction. The depth of the potential well for the $\text{Pt}(\text{CH}_4)^+$ adduct with respect to the reactants is $\sim 20 \text{ kcal mol}^{-1}$ (0.9 eV). The geometric parameters of the $\text{Pt}(\text{CH}_4)^+$ complex were not reported.

A number of publications⁷¹⁻⁷⁴ report a theoretical study of the methane adduct with the Cu^+ cation with the filled d-electron shell. This adduct is of interest because it involves interaction of two species having filled electron shells, namely, the Cu^+ ion with a formal d^{10} configuration and a fully saturated hydrocarbon (CH_4). The *ab initio* SCF method with different basis sets was used⁷¹ to calculate the geometry and the relative energetic characteristics for various structures of $\text{Cu}(\text{CH}_4)^+$. This complex was shown to be stable against unimolecular decomposition. It was suggested that it can exist in the isolated state in inert matrices. At the given theoretical level, the tridentate coordination of the CH_4 molecule, characterised by a $\text{Cu}-\text{CH}_4$ binding energy of $9.8 \text{ kcal mol}^{-1}$, was shown to be the most favourable for the $\text{Cu}(\text{CH}_4)^+$ ion. The complexes with bi- and monodentate types of coordination of methane are higher in energy than the η^3 -complex

by 3.8 and 5 kcal mol^{-1} , respectively. At moderately high temperatures, the Cu^+ cation can migrate quasi-freely around the methane molecule.⁷¹

The electronic structure and the geometric parameters of the $\text{Cu}(\text{CH}_4)^+$ adduct were also calculated by the SCF method in the approximation of linear combination of gaussian orbitals (LCGO-SCF) and by the MP2 method.⁷² The $\text{Cu}(\text{CH}_4)^+$ complex was found to be stable with respect to the reactants. The metal-ligand binding is mainly due to electrostatic interactions. The geometry optimisation for $\text{Cu}(\text{CH}_4)^+$ resulted in a C_{3v} -symmetric structure with a rotation axis. In the $\text{Cu}(\eta^3\text{-CH}_4)^+$ complex, the Cu, C and H_i atoms are located on the rotation axis, while the other three hydrogen atoms are arranged to form an 'umbrella' pointing towards the copper ion. The dissociation energy of this complex is $9.3 \text{ kcal mol}^{-1}$ (SCF) or $16.6 \text{ kcal mol}^{-1}$ (MP2).⁷²

The full optimisation of the complex geometry at the SCF level with the use of analytical methods to calculate the first and second derivatives (the GRADSCF method) has also led to an η^3 -structure.⁷³ It was noted that metal-ligand binding in $\text{Cu}(\text{CH}_4)^+$ is mainly electrostatic; therefore, it is not surprising that the geometric structure of the methane ligand differs little from the structure of free methane. The C-H distances in methane change by not more than $0.01 \text{ \AA}$ upon complexation. Other geometric parameters of the complex were not reported. The energy of the $\text{Cu}-\text{CH}_4$ bond for this structure determined by MCPF calculations is equal to $14.8 \text{ kcal mol}^{-1}$. It was suggested⁷³ that this value is understated by $\sim 5 \text{ kcal mol}^{-1}$ due to the limited basis set and incomplete allowance made for the correlation interaction.

In another study,⁷⁴ where the geometry of $\text{Cu}(\text{CH}_4)^+$ was optimised by the MP2 method with fuller basis sets, a structure with bidentate coordination was found to be most stable; in particular, more stable than the η^3 -structure by $0.3-1.2 \text{ kcal mol}^{-1}$. Comparison of these results⁷⁴ with the results of earlier calculations⁷¹⁻⁷³ provides the conclusion that with the extension of the basis set and more perfect allowance for the electron correlation for the Cu^+ (d^{10}) ion, the η^2 -coordination of methane to Cu^+ would prove to be preferred. The researchers believe that the electrostatic interaction promotes η^3 -coordination to the Cu^+ ion, whereas the dative interaction is favourable for the formation of the η^2 -complex.⁷⁴

The dissociation energies of the $\text{M}(\text{CH}_4)^+$ complexes determined experimentally and the calculated geometric parameters

IV. Methane complexes with the molecular fragments ML_n

Complexes of many transition metals are able to react with saturated hydrocarbons under certain conditions in solutions, thus activating the C—H bonds. The activation of alkanes can follow different mechanisms. Complexes containing metals in high oxidation states with a d⁰ electron configuration tend to undergo cycloaddition of alkanes to a single or multiple metal—ligand bond (σ-bond metathesis and 1,2-addition, respectively). Transition metal complexes with a dⁿ electron configuration of the metal are prone to enter into electrophilic substitution or oxidative addition of alkane to the central atom of the complex.^{2–12} The activation of alkanes by complexes of platinum group metals, especially rhodium and iridium, has been studied most comprehensively. Presumably, complexes with alkane molecules as ligands are formed as intermediates in these reactions.^{13–18}

Apart from experimental studies, considerable attention has been devoted to the theoretical investigation of the mechanisms of these reactions, in particular, by quantum-chemical methods.

1. Complexes with the d⁰ electron configuration of the complex-forming ion

It was found experimentally that organometallic compounds of early transition metals (lanthanides, actinides) in higher oxidation states are able to activate the C—H bonds in alkanes according to the mechanism of σ-bond metathesis. The first example of this type of reaction was described by Patricia Watson in 1983.⁷⁵

M = Y, Lu; Cp* = η⁵-C₅Me₅.

Subsequently, other similar systems have been found and studied in detail.^{11,76–79} Metathesis of σ-bonds is highly selective with respect to the sterically least hindered C—H bonds at the primary carbon atom. The selectivity is so high that it is possible to use cyclohexane as an inert solvent to study these reactions.^{5,7}

A number of publications^{80–82} have been devoted to quantum-chemical investigations of the mechanism of σ-bond metathesis. The activation of the H—H and C—H bonds in the

$X_2LuCH_3 + H_2$ and $X_2LuCH_3 + CH_4$ systems was studied by the density functional approach with different potentials.⁸⁰

In this study, the Cp_2^*Lu fragment of the $Cp_2^*LuCH_3$ complex used in experiments, was modelled by the Cl_2Lu species. It was found that both reactions involve the formation of a highly ordered four-centre transition state with a negative activation entropy. The weakly bound methane adduct $Cl_2LuH(\eta_3^1-CH_4)$ with a binding energy of $1.96 \text{ kcal mol}^{-1}$ with respect to the final products, Cl_2LuH and CH_4 , is formed as the intermediate compound in hydrogenolysis.

The exchange reaction

has a high activation barrier and proceeds *via* the adduct $Cl_2Lu(CH_3)(\eta_1^1-CH_4)$, which is $4.64 \text{ kcal mol}^{-1}$ less stable than the initial reactants (Cl_2LuCH_3 and CH_4). The methane fragments in the η_3^1 and η_2^1 adducts are distorted only slightly compared to free methane.

The density functional approach in the B3P86 approximation has been used⁸¹ to study the energy profiles of hydrogenolysis and methyl-group exchange for the Cp_2ScCH_3 complex.

After the initial formation of the Cp_2ScCH_3 adduct with H_2 , the energetic profile of hydrogenolysis leads, *via* a transition state, to the $Cp_2ScH(\eta_3^1-CH_4)$ adduct. The methane ligand in this complex has a distorted tridentate coordination. The bridging C–H_b bonds (1.14 and 1.11 Å) are elongated compared to the C–H bonds in free methane. The binding energy of methane in the $Cp_2ScH(\eta_3^1-CH_4)$ complex is $4.78 \text{ kcal mol}^{-1}$ relative to the products (Cp_2ScH and CH_4). The exchange by methyl groups proceeds *via* the adduct $Cp_2Sc(CH_3)(\eta^2-CH_4)$ with a binding energy of $5.97 \text{ kcal mol}^{-1}$. Comparison of the hydrogenolysis and methyl exchange processes for scandium and lutetium complexes shows that the replacement of hydrogen in X_2M-Y ($M = Sc, Lu$; $X = Cp, Cl$; $Y = H, CH_3$) by a bulkier CH_3 group entails a change in the mode of coordination of the methane ligand from the tridentate (or distorted tridentate) coordination found in the $X_2MH(CH_4)$ complex to a bidentate one in the $X_2M(CH_3)(CH_4)$ complex. This replacement also results in a longer M–CH₄ bond, apparently, due to steric factors (the geometric parameters of the complexes were optimised without non-local corrections).

The activation of methane by model compounds Cl_2LnZ ($Z = H, CH_3$) has been studied for the whole lanthanide row⁸² by the density functional method using the hybrid B3PW91 functional. These compounds were assumed to be rather good models for bis(pentamethylcyclopentadienyl) complexes Cp_2^*LnZ . The obtained results appear to cast doubt on the possibility of intermediate formation of the $Cp_2^*LnZ(CH_4)$ complexes in these reactions. The researchers believe that the process of methane activation can be represented in this case as proton transfer between two anionic groups coordinated to Ln atoms.

It is well-known that Ziegler–Natta catalysts and metallocene catalysts for polymerisation of α -olefins can react with methane and that methane can be used to terminate the growth of polymer chains to control the molecular mass of polymers.⁸³ To elucidate the mechanism of methane activation by metallocene catalysts, the PES for model reactions between methane and $Cp_2M(CH_3)^+$ cations ($M = Ti, Zr$) (σ -bond metathesis) have been studied in detail by the density functional method in the generalised gradient approximation (GGA) using the Perdew, Burke and Ernzerhof (PBE) density functional.^{84,85} The calculations showed that the first stage gives the intermediate σ -complex $Cp_2M(CH_3)$.

$(\eta^2-CH_4)^+$. The complexation energy for the zirconium cation is $9.4 \text{ kcal mol}^{-1}$ and that for the titanium cation is $4.2 \text{ kcal mol}^{-1}$. It was noted that the free energies of complexation (ΔG_{298}) at room temperature are positive with respect to the initial components due to a great entropy contribution; they are $1.5 \text{ kcal mol}^{-1}$ for zirconium and $8.3 \text{ kcal mol}^{-1}$ for titanium.

The reactions of $Cp_2MCH_3^+$ cations with H_2 result directly in the $Cp_2MH(\eta^2-CH_4)^+$ σ -complexes without an activation barrier. The back reaction $Cp_2MH^+ + CH_4$ also includes the intermediate formation of $Cp_2MH(\eta^2-CH_4)^+$ in which the electrons of two C–H_b bridging bonds are involved in binding of the CH_4 molecule to the central metal atom.

Density functional theory calculations in the PBE approximation for the model reaction

$M = Ti(IV), Zr(IV)$; $R = Me, Et, Pr^n, Pr^i$

showed that the reaction of $Cp_2MCH_3^+$ with alkanes proceeds *via* the stage of formation of $Cp_2M(RH)(CH_3)^+$ complexes, which are subsequently isomerised into $Cp_2MR(CH_4)^+$.⁸⁶ The energy of the M–CH₄ bond in the $Cp_2MR(CH_4)^+$ complexes decreases on passing from $R = Me$ to $R = Et, Pr^n$ or Pr^i . This sequence of variation of the bond energy was attributed to the influence of steric factors. In the case of isopropyl ligands, the minima corresponding to the $Cp_2MPri(CH_4)^+$ complexes ($M = Ti, Zr$) could not be found on the PES, as these complexes undergo barrier-free dissociation to give methane and $Cp_2M(Pr^i)^+$. In zirconium complexes, methane is coordinated according to the η^2 mode; in the case of the titanium ion, which is smaller in diameter, according to the η_2^1 mode ($R = Pr^n, Pr^i$), apparently, also due to steric factors. The geometric parameters of methane ligands in these complexes were not reported.⁸⁶

Yet another type of complexes formed by high-valence transition metals able to activate the C–H bonds in alkanes includes compounds with metal–ligand multiple bonds. It has been found experimentally that the imido complexes $L_nM=NR$ formed by transition d^0 metals ($M = Ti, Zr, Ta, V, W$) are able to activate various hydrocarbons including methane.^{87–94} The reaction results in alkane ($R'H$) addition to the highly polarised $M^{\delta+}=N^{\delta-}$ double bond of the complex giving rise to $L_nM(R')(NHR)$. The addition of alkanes to the $M^{\delta+}=N^{\delta-}$ multiple bonds, like the metathesis of σ -bonds, is distinguished by a high degree of selectivity with respect to the primary C–H bonds. It was suggested that high polarity of the metal–imide ligand bond is important for this reaction, as it promotes the subsequent cleavage of the activated C–H bond in the alkane.⁸⁷ Data obtained by isotope labelling are consistent with the intermediate formation of alkane complexes assumed for these reactions.^{91,93,94}

A series of publications have been devoted to theoretical investigation of the mechanism of methane addition to the $M=NR$ multiple bonds.^{36,95–100}

The activation of methane by the imido complexes $H_2M=NH$ ($M = Ti, Zr, Hf$) has been studied *ab initio* (RHF, MP2) methods.⁹⁵ Methane is coordinated by the metal in the η^3 mode to give the $H_2M(=NH)(\eta^3-CH_4)$ charge transfer complex. The hydrogen atoms bound to the metal occur in an eclipsed conformation relative to the $H_2M=NH$ complex. In this complex, the activated C–H bond lies in the same plane as the $M=N$ bond. The geometric parameters of fragments in the $H_2M(=NH)(\eta^3-CH_4)$ complexes are virtually identical to those calculated for free reactants. The calculation results support the hypothesis of an important role of the highly polar $M=N$ bond in this reaction and demonstrate that the formation of the alkane complex increases the polarity of the $C^{\delta-}-H^{\delta+}$ bond. In the free methane molecule, the charge on the carbon atom is $-0.24 e$, while that on the hydrogen atoms is $+0.06 e$. On complexation, the polarity of the C–H bonds increases and the charge on carbon becomes equal to $-0.48 \pm 0.02 e$, and that on hydrogen is $+0.15 \pm 0.01 e$. Due to the reaction, the negatively charged

methyl group is transferred to the central metal atom and the positively charged hydrogen atom migrates to the imide nitrogen atom carrying a negative charge. Thus, the overall process can be regarded as proton transfer between two anionic centres. The calculated energy barriers to the elimination of methane from the $H_2M(CH_3)(NH_2)$ complexes ($M = Ti, Zr, Hf$) are in good agreement with the values found experimentally regarding both the absolute magnitude and the pattern of variation of the magnitude depending on the nature of the central atom.

The structures of methane complexes with monoimides of Group IV metals, bisimides of Group V metals, and trisimides of Group VI metals with a d^0 electron configuration and the $M-CH_4$ binding energies in these compounds have been determined by RHF and MP2 calculations.⁹⁶ It was found that methane adducts with pyramidal bisimides $(NH_2)M(=NH)_2$ ($M = Nb, Ta$) and trisimides $M(=NH)_3$ ($M = Mo, W$) are characterised by rather high bond enthalpies (11–16 kcal mol⁻¹), comparable to those for dihydrogen complexes (Kubas complexes). Meanwhile, the enthalpy of binding of the methane ligand to Group IV metal monoimides is much lower. The coordination of methane is accompanied by the transfer of 0.1–0.3 e from methane to the central metal atom, which results in elongation and polarisation of the $C^{\delta-}-H^{\delta+}$ bond. These data are indicative of the important role of the methane adduct in the subsequent cleavage of the C–H bond.

The charges on the central metal atoms (Z) in the starting imido complexes have been calculated.⁹⁶ According to this calculation, the enthalpy of the $M-CH_4$ bond in Group IV–VI metal imido complexes varies in proportion to the variation of the Z/r^2 ratio, where r is the $M-C$ distance (Table 2). In our opinion, this correlation implies a predominant contribution of electrostatic interaction to the formation of the methane–imido complex bond. In the case of imido complexes of metals with a d^2 electron configuration, no correlation of this type is found; they cannot form adducts with methane due to repulsion between the free electron pair in the metal d orbital and the electrons of the C–H σ -bond.

Table 2. Dependence of the stabilisation enthalpy of methane complexes with metal imides on the charge on the central metal atom and the $M-C$ distance (from the data of Ref. 96).

Complex	Electronic state of M	$M-C$ / Å	$Z(M)^a$	Z/r^2	H_{add} (see ^b)
$Ti(OH)_2(=NH)(\eta^1_2-CH_4)$	d^0	2.84	+1.36	0.169	6.6
$Ti(NH_2)_2(=NH)(\eta^1_2-CH_4)$	d^0	3.10	+1.08	0.112	4.4
$Zr(NH_2)_2(=NH)(\eta^1_2-CH_4)$	d^0	3.05	+1.62	0.174	6.3
$Nb(NH_2)(=NH)_2(\eta^2-CH_4)$	d^0	2.84	+1.48	0.183	11.1
$Ta(NH_2)(=NH)_2(\eta^2-CH_4)$	d^0	2.79	+1.55	0.199	13.6
$Mo(=NH)_3(\eta^1_2-CH_4)$	d^0	2.77	+1.2	0.19	13.7
$W(=NH)_3(\eta^1_2-CH_4)$	d^0	2.72	+1.48	0.224	15.6

$Os(=NH)_3(CH_4)$	d^2	—	+1.19	—	<0

^a Calculated (Mulliken) charges on the metal atoms in the reactants.

^b In kcal mol⁻¹.

The mechanism of methane activation by Group V metal bisimido complexes has been studied.⁹⁸ Methane adducts with the $(NH_2)M(=NH)_2$ complexes ($M = V, Nb, Ta$) have C_s symmetry; one C–H bond of the methane ligand is arranged above the bisector of the $N=M-N$ angle. The geometric parameters of the fragments in the adducts differ little from those of free molecules. In the Group V metal adducts, methane is considered to be coordinated by an edge, because the $M-H_b$ distances for the two bridging hydrogen atoms are nearly equivalent. The complexes formed by Group V metals, $M(NH_2)(=NH)_2(\eta^2-CH_4)$, differ in the mode of methane coordination from similar complexes derived from Group IV and VI metals, which should rather

be regarded as monodentate complexes with a bent $M-H-C$ bridge, $M(NH_2)_2(=NH)(\eta^1_2-CH_4)$ ($M = Ti, Zr, Hf$) and $M(=NH)_3(\eta^1_2-CH_4)$ ($M = Mo, W$), because in this case, the lengths of the $M-H_b$ bonds for two bridging H atoms markedly (by more than 0.2 Å) differ from each other.

The activation of methane by the trisimido complexes formed by d^0 metals, $M(=NH)_3$ ($M = Mo, W$), $Ta(=NH)_3^-$, $M(=NH)_3^+$ ($M = Tc, Re$), and d^2 metals, $Tc(=NH)_3^-$, $Os(=NH)_3$, has been studied by RHF calculations with the effective core potential and by molecular mechanics.³⁶ It was found that the energy of methane binding to imido complexes is more sensitive to the type of electronic configuration of the central atom (d^0 or d^2) than to the nature of the metal or the charge of the complex. According to calculations, methane reacts with d^0 -metal complexes irrespective of their charge (neutral, anionic, or cationic) but does not react with d^2 -metal imides.

In the complexes formed by d^0 metals, the energy of binding of methane to the metal increases on passing from anionic to neutral and cationic complexes in the series $Ta(=NH)_3^- < W(=NH)_3 < Re(=NH)_3^+$, being equal to 8.3, 15.6 and 26.3 kcal mol⁻¹, respectively. The methane binding energy increases on passing from Group III metal amides to Group IV metal monoimides, Group V metal bisimides, and Group VI metal trisimides

It was suggested that complexes of alkanes with $M(=NAr)_3^+$ ($M = Tc, Re$) can be sufficiently stable to be studied experimentally.

The changes in the geometry of the reactants upon complexation are insignificant. The angle between the C–H_b bridging bonds somewhat increases, from 109.5° (in free methane) to 113° [in the anionic complex of tantalum $Ta(=NH)_3^-$] and to 119° [in the cationic complex of rhenium $Re(=H)_3^+$]. The lengths of uncoordinated C–H bonds are similar to the C–H bond lengths in free methane. The length of the C–H_b bridging bond increases with an increase in the $M-CH_4$ binding energy from 1.10 (in the anionic tantalum complex) to 1.14 Å (in the cationic rhenium complex).^{36,98}

The above theoretical data dealing with the activation of methane C–H bonds by two types of complexes based on metal ions in high oxidation states with a formal d^0 electron configuration (cyclopentadienyl complexes of Group III, IV metals and Group IV–VI metal imides) show that methane is coordinated in these compounds *via* either a face (η^3 and η^1_3 modes of coordination) or an edge (η^2 and η^1_2 modes of coordination). The mode of methane coordination is appreciably affected by steric (the size of stabilising ligands) and electronic factors (high polarity of the metal–ligand bond). The activation of methane C–H bonds by complexes of this type can be represented as proton transfer between two anionic centres in the coordination sphere of a highly charged d^0 metal.

2. Complexes with a d^n electron configuration of the complexing ion

A much larger number of papers have been devoted to methane activation by complexes formed by transition metals with d^n electron configurations. Sixteen-electron molybdenum and tungsten metallocenes Cp_2M (d^4 configuration) are well-known to be highly reactive intermediates which readily enter into oxidative addition reactions to give 18-electron derivatives. In particular, these complexes are able to activate the C–H bonds of alkanes. The reactions of methane with metallocene derivatives of molybdenum and tungsten have been studied by the density functional method in the B3P86 and B3LYP/LANL2DZ approximations.^{101–103}

Study of the intramolecular hydrogen exchange in the $Cp_2W(CH_3)H$ and $[CH_2(C_5H_4)_2]W(CH_3)H$ complexes showed that in both cases, hydrogen exchange proceeds *via* the intermediate formation of the methane complex with η^1_2 -coordination of

methane. In these complexes, two C–H bonds of the methane ligand pointing toward the tungsten atom are located in the equatorial plane of the metallocene fragment.¹⁰¹

Density functional theory calculations in the B3LYP approximation were used to study the oxidative addition of methane to molybdenum and tungsten 16-electron $[n]$ -metallocenophanes.¹⁰² According to the results of calculations, these $[n]$ -metallocenophanes react with methane to form σ -complexes with a binding energy of 1.3–7.6 kcal mol^{−1}. In these σ -complexes, methane is bound to the central metal atom according to the η_2^1 type, the bridging C–H_b bonds being located in the equatorial plane of the metallocene fragment.¹⁰²

Poli and coworkers¹⁰³ have studied the addition of methane to various types of metallocenes formed by Group VI metals, namely, Cp₂M, [CH₂(C₃H₄)₂]M, and Cp₂⁺M (M = Mo, W), by density functional theory calculations in the B3LYP/LANL2DZ approximation. It was found that these compounds in the singlet excited state form asymmetric η^1 -complexes with methane, in which the M–H_b–C hydrogen bridge is situated in the equatorial plane of the metallocene fragment. The C–H_b bridging bond is much longer than the other C–H bonds of the methane ligand, whose average length is 1.088 Å. This elongation is more pronounced in tungsten complexes (1.138–1.156 Å) than in molybdenum complexes (1.122–1.126 Å), indicating that the M–CH₄ interaction is stronger in the case of tungsten. The W...H_b distance is 0.1 Å shorter than Mo...H_b. The binding energy of methane in cyclopentadienyl and *ansa*-metallocene complexes is equal to 3.4–6 kcal mol^{−1} relative to the excited (singlet) state of the corresponding metallocenes. The reaction of Cp₂⁺M with methane is energetically unfavourable even for the singlet state of these complexes due to the influence of steric factors.¹⁰³

To elucidate the reason for the experimentally observed difference between the reactivities of the Cp*W(NO)(CH₂Bu)₂ and Cp*Mo(NO)(CH₂Bu)₂ complexes towards alkanes,¹⁰⁴ the reactions of model compounds CpM(NO)(=CH₂) (M = W, Mo) were studied by density functional theory calculations in the B3LYP/LANL2DZ approximation.¹⁰⁵ It was found that the reaction of methane with the model compound CpW(NO)(=CH₂) is more exothermic and has a lower activation barrier than the reaction with CpMo(NO)(=CH₂). The calculations attest to the formation of intermediate CpM(NO)(=CH₂)(CH₄) complexes for both molybdenum and tungsten. The methane ligands in both complexes are coordinated according to the η_2^1 pattern, one M...H_b bridging bond being 0.4 Å shorter than the other. One of the C–H_b bonds in the methane ligand is somewhat elongated (1.119 Å for Mo and 1.12 Å for W) compared to the other C–H bonds (each ≤ 1.10 Å). In addition, the H–C–H angle between the two hydrogen atoms directed toward the metal is also increased to 116.5° for Mo and to 117.2° for W. The energy of methane binding in the complexes is 6.5 (for Mo) and 7.7 kcal mol^{−1} (for W). The CpM(NO)(=CH₂)(CH₄) complexes can participate in two competing processes, namely, activation of the C–H bonds to give CpM(NO)(CH₃)₂ and dissociation with the loss of methane. The calculations showed that for the tungsten complex, the heights of the energy barriers to both reactions are almost equal, whereas in the case of the molybdenum complex, the formation of CpM(NO)(CH₃)₂ is energetically rather unfavourable.¹⁰⁵

Fast time-resolved infrared spectroscopy (TRIS) has been used to study the reactions of a number of alkanes and fluoroalkanes with the 16-electron species W(CO)₅ in the gas phase.¹⁰⁶ It was found that W(CO)₅ is reversibly complexed with unsubstituted alkanes, except for CH₄. The binding energies of alkanes in the complexes are in the range 7–11 kcal mol^{−1}; they increase with an increase in the alkane size. Since no complex with CH₄ was detected experimentally, it was concluded¹⁰⁶ that the binding energy in this complex is less than 5 kcal mol^{−1}.

For comparison with experimental data, the energies of binding of alkanes to W(CO)₅ were found by *ab initio* calculations using various basis sets and methods for taking into account the

electron correlation.¹⁰⁷ The Hartree–Fock (HF) optimisation of the geometric parameters of the W(CO)₅(RH) complexes showed that the η_2^1 -coordination is energetically the most favourable for methane, although two transition states with η_3^1 and η^2 modes of coordination do not differ much from it in energy. When the geometry of W(CO)₅(CH₄) was optimised by the MP2 methods, all three structures were found to correspond to energy minima, the energy difference between them being less than 1 kcal mol^{−1} and the order of their stability being dependent on the basis set and the calculation method used. Excellent agreement with experimental data was attained only when the MP2 binding energies in the largest basis set were corrected for the basis set superposition error (BSSE), the zero point energy (ZPE), and the temperature; the difference between the results of MP2 and QCISD calculations was also taken into account.¹⁰⁷

In a recent publication,¹⁸ the alkane complex CpRe(CO)₂·(C₅H₁₀-cyclo) was observed directly by NMR spectroscopy in a solution at −80 °C. According to NMR data, the cyclopentane ligand in this complex is bound to rhenium according to the η^2 or η_2^1 pattern.¹⁸ Unfortunately, to the best of our knowledge, no theoretical calculations of a similar rhenium complex with methane have been reported.

The oxidative addition of methane to model 14-electron complexes, *cis*- and *trans*-[OsCl₂(PH₃)₂], was studied theoretically by the RHF method with subsequent correction for electron correlation by the MP2 and the density functional theory techniques. It was concluded that isomeric σ -complexes can be formed, namely, *cis*- and *trans*-[OsCl₂(PH₃)₂(η^2 -CH₄)].¹⁰⁸ According to the calculations, the complex of methane with *cis*-[OsCl₂(PH₃)₂] is much more stable than that with *trans*-[OsCl₂(PH₃)₂]. Oxidative addition giving rise to OsCl₂(PH₃)₂(CH₃)(H) was found to be energetically favourable for the *trans*-[OsCl₂(PH₃)₂(η^2 -CH₄)] complex.

The coordination of methane by the Cp₂M complexes (M = Ti–Ni) was studied by semiempirical SCF MO LCAO calculations in the INDO (intermediate neglect of differential overlap) valence approximation using the unrestricted Hartree–Fock (UHF) formalism.¹⁰⁹ The results of calculations attest to the possible formation of weak complexes of methane with these metallocenes. In the researchers' opinion,¹⁰⁹ the coordination of a methane molecule by titanium, vanadium, manganese or nickel derivatives is likely to be accompanied by oxidative addition resulting in Cp₂M(H)(CH₃). In all of these complexes, methane is coordinated according to the η_2^1 pattern. It should be noted that the calculation method used leads to an unusually great value for the length of the C–H_b bridging bond (1.2–1.35 Å) in these complexes compared to the values obtained by other researchers (1.11–1.16 Å). The unusually high bond energies of methane in the complexes with ferrocene, cobaltocene and nickelocene (14–21 kcal mol^{−1}) also raise doubts.

A number of papers are devoted to the theoretical investigation of carbonylation of alkanes with carbonyl chloride rhodium complexes Rh(PR₃)₂Cl(CO), which was discovered experimentally and studied by Sakakura and Tanaka.¹¹⁰ An *ab initio* investigation of the PES for the oxidative addition of methane to the model 14-electron RhCl(PH₃)₂ complex has shown¹¹¹ that the reaction proceeds *via* the formation of the *trans*-[RhCl(PH₃)₂(η^2 -CH₄)] complex and a three-centre transition state. According to these calculations, the bond energy of methane in RhCl(PH₃)₂(η^2 -CH₄) is 16.7–17.2 kcal mol^{−1}. However, a repeated (MP2) study of this system carried out by the same researchers¹¹² gave somewhat different results. The authors noted that C–H-bond activation proceeds *via* the *trans*-[RhCl(PH₃)₂(η_2^1 -CH₄)] complex with C_s symmetry rather than *via* the *trans*-[RhCl(PH₃)₂(η^2 -CH₄)] complex, as they had established previously. One Rh...H_b distance in the η_2^1 complex is much shorter than the other (by 0.4 Å). Both C–H_b bridging bonds are elongated relative to the C–H bonds in free methane, although to different extents. The energy of methane binding in this complex is 13.7 kcal mol^{−1}. The energy of the structure with C_{2v} symmetry is

higher by 0.1 kcal mol⁻¹ than the energy of the *C_s*-symmetric structure. The former is not an equilibrium structure but a transition state between two *C_s* structures. The Rh–C distances are nearly equal for both structures (~2.53 Å). The C–H_b bond length in the *C_{2v}* structure is 1.119 Å. According to more recent density functional theory calculations,¹¹³ the activation of methane by the RhCl(PH₃)₂ complex proceeds *via* a η²-adduct with *C_{2v}* symmetry, RhCl(PH₃)₂(η²-CH₄). The stabilisation energy of the *cis*-isomer with respect to the reactants is 6.4 kcal mol⁻¹, while that of the *trans*-isomer is 13.9 kcal mol⁻¹. Comparison of the results of two publications^{112, 113} concerning the structures of the RhCl(PH₃)₂(CH₄) complex determined using different calculation techniques attests to a higher stability of the *trans*-isomer [the bond energies are similar, 13.7 (Ref. 112) and 13.9 kcal mol⁻¹ (Ref. 113)] relative to the *cis*-isomer. However, the modes of methane coordination found in the two studies are dissimilar.

The intermediate complexes formed in the reactions of methane with rhodium compounds, RhCl(CO), RhH(CO) and RhH(NH₃), have been studied theoretically.¹¹⁴ The presence of a ground or low-lying singlet state of the central metal atom was found to favour the formation of a stable methane complex, while the presence of a ground or low-lying triplet state contributes to the decrease in the energy barrier to oxidative addition. The geometric parameters of methane complexes were found by SCF and MP2 calculations. In these complexes, methane was assumed to have a distorted η³-coordination¹¹⁴ with one of the three Rh–H_b bonds being substantially shorter than the other bonds. This difference increases in the sequence RhCl(CO)(CH₄)–RhH(CO)(CH₄)–RhH(NH₃)(CH₄).

Numerous experimental data have been obtained indicating that the 16-electron intermediates Cp*ML (M = Rh, Ir; L = PR₃, CO) are able to activate C–H bonds in alkanes according to the oxidative addition mechanism (see a review¹¹⁵ and references therein). This initiated several theoretical studies dealing with methane interaction with the CpMX fragments (M = Co, Rh, Ir; X = CO, CH₂, PH₃, SH₂).^{116–119} Ziegler *et al.*¹¹⁶ used the density functional method to find out that a σ-adduct of methane with CpMX (M = Rh, Ir; X = CO, PH₃) is formed in an early step. The energy of formation of the adduct varies from 5.7–6.9 kcal mol⁻¹ for rhodium complexes to 12.2–14.1 kcal mol⁻¹ for iridium complexes. In the CpRh(CO)(CH₄) complex, methane is coordinated to rhodium in the η¹ mode (the Rh–H_b–C angle is close to 180°). The C–H_b bond (1.15 Å) is somewhat longer than the C–H_t bonds (1.09 Å).¹¹⁶

Song and Hall¹¹⁷ studied the oxidative addition of methane to CpRh(CO) by the RHF and MP2 methods. The reaction PES was found to contain two local energy minima, one corresponding to the CpRh(CO)(CH₄) complex and the other, to the oxidative addition product, CpRh(CO)(CH₃)(H). The methane binding energy in CpRh(CO)(CH₄) is 2.2 (RHF) or 14.8 kcal mol⁻¹ (MP2). The experimental value for the binding energy of alkanes in such complexes was estimated to be ~10 kcal mol⁻¹ (see Ref. 120). According to Song and Hall,¹¹⁷ the methane ligand in the CpRh(CO)(CH₄) intermediate is coordinated in the η¹ mode (the Rh–H_b–C fragment is markedly bent, the corresponding angle being 114.9°). The C–H_b bond is somewhat elongated (1.128 Å) with respect to the C–H bonds in free methane.¹¹⁷

Musaev and Morokuma,¹¹⁸ who studied the PES of the CpRh(CO) + CH₄ reaction by the MP2 method with the effective Hay–Wadt potential for the Rh atom and with different basis sets, have found that the first step of the reaction gives CpRh(CO)(η¹-CH₄) (the Rh–H_b–C angle is 179.3°) with a stabilisation energy of 7.7 kcal mol⁻¹ with respect to the reactants. The formation energies of the structures with two or three bridging hydrogen atoms are only 1 kcal mol⁻¹ higher than the energy of the monodentate structure but they do not correspond to local minima on the PES and, hence, they rearrange spontaneously to a monodentate complex. The C–H_b bridging bond in the methane ligand is 0.02 Å longer than the C–H_t bonds. The

charge on the bridging hydrogen atom changes under the influence of the electronically unsaturated rhodium atom from +0.12 e in free CH₄ to –0.13 e in CpRh(CO)(η¹-CH₄).

More recently,¹¹⁹ the reactions of the 16-electron complexes CpM(CO) (M = Ru⁺, Os⁺, Rh, Ir, Pd⁺, Pt⁺) with methane have been studied by the MP2, MP4SDTQ (fourth-order Møller–Plesset perturbation theory with single, double, triple and quadruple excitations) and by the density functional method in the B3LYP approximation. Each of these complexes was found to form the compounds CpM(CO)(CH₄) with η²- or slightly distorted η²-coordination of methane. The equilibrium geometries of the intermediate methane complexes were determined without any symmetry restrictions by the MP2 method with the LANL1DZ basis set and by the density functional method in the B3LYP approximation. It was found that the central atoms with a high electron density (Ru⁺, Os⁺) or with a large atomic mass (Pd⁺, Pt⁺) readily enter into oxidative addition reactions with methane, while electronically unsaturated light central metal atoms tend to undergo reductive elimination reactions to give C–H bonds.¹¹⁹ The results of calculations attest to η¹-coordination of CH₄ in the CpRh(CO)(CH₄) complex and they are in better agreement with the data obtained by Song and Hall¹¹⁷ than with Ziegler's¹¹⁶ and Musaev and Morokuma's results.¹¹⁸

The binding energies of methane in the complexes with CpML (M = Co, Rh, Ir; L = CO, CH₂, SH₂, PH₃) have been determined in terms of the perturbation theory in the PCI-80 approximation and by the density functional method in the B3LYPB approximation.^{121, 122}

The mechanism of activation of methane C–H bonds by coordinatively unsaturated rhodium and iridium complexes CpM(PH₃)(CH₃)⁺ has been studied by the MP2 method with the LANL2DZ basis set and the QCISD method.¹²³ The iridium complex tends to undergo oxidative addition, whereas in the case of rhodium, σ-bond metathesis with a four-centre transition state is a more probable mechanism. The CpM(PH₃)(CH₃)(η¹-CH₄)⁺ complexes (the M–CH₄ binding energy is 9.5 kcal mol⁻¹ for Rh and 7.09 kcal mol⁻¹ for Ir) are formed intermediately in these reactions.

A number of studies^{124–127} have been devoted to experimental and theoretical investigations of the reactions of alkanes with pyrazolylborate rhodium complexes.

Experimental data^{124, 125} indicate that alkane σ-complexes are involved in the reductive elimination of alkanes from the pyrazolylborate rhodium complexes Tp'Rh(L)(R)(H) [Tp' is tris(3,5-dimethylpyrazolyl)borate, L = CNCH₂Bu⁺; R = CH₃, CH₂D, CD₃]. The results of a study of the photoinitiated activation of alkanes by the Tp'Rh(CO)₂ complexes by fast time-resolved infrared spectroscopy point to successive formation of two different complexes along the pathway to the oxidative addition product, Tp'Rh(CO)(R)(H).¹²⁶ To elucidate the nature of these complexes, density functional theory calculations in the B3P86 and LANL2DZ approximations were carried out for the PES of the reaction between the model TpRh(CO) compound [Tp is tris(pyrazolyl)borate] and methane.¹²⁷ Two minima corresponding to the (η³-Tp)Rh(CO)(η¹-CH₄) and (η²-Tp)Rh(CO)(η¹-CH₄) complexes were found on the PES. Parameters of the methane–rhodium bonds (bond length and energy) in these complexes are substantially different, which is consistent with the results of experimental studies.

Generally, different calculation methods give different results concerning the mode of coordination of the methane ligand in rhodium complexes. Structures with one linear (η¹-coordination) or bent (η²- or η³-coordination) Rh–H_b–C bridge or with two bridges (η²-coordination) are presumably formed.

Parallel supercomputer calculations have been performed to study the methane activation by 14-electron $\text{Ir}(\text{PH}_3)_2\text{X}$ fragments ($\text{X} = \text{H}, \text{Cl}$).¹²⁸ This study demonstrated that the formation of σ -complexes with an η^2 -coordination of methane is energetically the most favourable for $\text{Ir}(\text{PH}_3)_2\text{H}$. The geometric parameters of the products were determined by the RHF method. The energy of the complex with η^2 -coordinated methane is only $0.1 \text{ kcal mol}^{-1}$ lower than the energy of the transition state with η^2 -coordination. In the author's opinion, the $\text{Ir}(\text{PH}_3)_2(\text{H})(\text{CH}_4)$ methane adduct should exhibit structural non-rigidity at ambient temperatures. The replacement of hydrogen by chlorine in $\text{Ir}(\text{PH}_3)_2\text{X}$ results in a substantial decrease in the $\text{Ir}\cdots\text{C}$ and $\text{Ir}\cdots\text{H}$ distances and an increase in the stabilisation energy of the $\text{Ir}(\text{PH}_3)_2\text{Cl}(\eta^1\text{-CH}_4)$ complex.

Strout *et al.*¹²⁹ carried out a density functional theory study (B3LYP approximations) of the mechanism of the low-temperature activation of C–H bonds in alkanes by the cationic iridium complex $\text{Cp}^*\text{Ir}(\text{PMe}_3)(\text{CH}_3)^+$ in perfluoropyridine. Earlier, this reaction was found experimentally.¹³⁰ This reaction is formally similar to the metathesis of σ -bonds typical of electron-deficient complexes of early transition metals. Therefore, it was suggested in the experimental study¹³⁰ that this reaction was a new example of σ -bond metathesis involving a complex of a late transition metal. Since the two possible mechanisms (oxidative addition or σ -bond metathesis) cannot be distinguished experimentally, it was of interest to perform a theoretical study of this system. Quantum-chemical calculations for the model $\text{CpIr}(\text{PH}_3)(\text{CH}_3)^+ - \text{CH}_4$ system showed the intermediate formation of the $\text{CpIr}(\text{PH}_3) \cdot (\text{CH}_3)(\eta^1\text{-CH}_4)^+$ complex in which methane is weakly bound to iridium by the bent $\text{Ir}-\text{H}_b-\text{C}$ bridge (the $\text{Ir}-\text{H}_b-\text{C}$ angle is 134°). The results of density functional theory calculations of the coordination mode of methane in this complex¹²⁹ are consistent with the results obtained by the MP2 method with the LAND2DZ basis set.¹²³ According to the calculations, the low-temperature reaction of $\text{CpIr}(\text{PH}_3)(\text{CH}_3)^+$ with CH_4 occurs as oxidative addition of methane to the central metal atom. The pathway involving a four-centre transition state (metathesis of σ -bonds) is energetically unfavourable.

Thus, the results obtained by various methods point to the η^2 -coordination of the methane ligand as energetically the most favourable for all the iridium complexes studied, namely, $\text{CpIr}(\text{CO})(\text{CH}_4)$, $\text{Ir}(\text{PH}_3)_2(\text{H})(\text{CH}_4)$, $\text{Ir}(\text{PH}_3)_2\text{Cl}(\text{CH}_4)$ and $\text{CpIr}(\text{PH}_3)(\text{CH}_3)(\text{CH}_4)^+$.

Density functional theory calculations have been carried out¹³¹ to study the mechanism of the recently discovered dehydrogenation of alkanes by the $[\eta^3\text{-C}_6\text{H}_3(\text{CH}_2\text{P}^i\text{Bu}^t)_2\text{-1,3}]\text{IrH}_2$ complex.¹³² It was shown that the formation of a σ -complex with methane is endothermic in this case.¹³¹

The energy characteristics and the mechanism of oxidative addition of methane to the zerovalent 14-electron $\text{Ni}(\text{PH}_3)_2$ fragment has been studied by the RHF method.¹³³ It was shown that the formation of the $\text{Ni}(\text{PH}_3)_2(\text{CH}_4)$ σ -complex is energetically favourable and that the pseudo-tetrahedral η^2 -coordination of the methane ligand with two hydrogen atoms pointing towards the nickel atom is the most stable.

The MP2 and the density functional (B3LYP) approaches were used to study the PES for two model systems — CH_4 –*trans*- $[\text{PdCl}_2(\text{PH}_3)_2]$ and CH_4 –*trans*- $[\text{PtCl}_2(\text{PH}_3)_2]$.¹³⁴ According to the results,¹³⁴ the palladium and, especially, platinum complexes $\text{MCl}_2(\text{PH}_3)_2$ ($\text{M} = \text{Pd}, \text{Pt}$) are more active in stepwise methane activation according to the oxidative addition pattern with preliminary forced abstraction of the phosphine ligand than in the metathesis of the C–H and M–Cl bonds. The 14-electron $\text{MCl}_2(\text{PH}_3)$ fragments resulting from the removal of one phosphine ligand react with methane to give the σ -complexes $\text{MCl}_2(\text{PH}_3)(\eta^2\text{-CH}_4)$.

The elementary steps of the recently described¹³⁵ activation of methane by a cationic platinum(II) complex with a bidentate N-donor ligand $[N,N,N',N']$ -tetramethylethylenediamine (tmeda)]

have been studied by the density functional technique in the B3P86 approximation.¹³⁶ The theoretical results are consistent with the mechanism comprising the formation of a σ -complex and subsequent oxidative addition. In the model σ -complex $[(\text{en})\text{Pt}(\text{CH}_3)(\text{CH}_4)]^+$ (en is ethylenediamine), methane is bound according to the η^2 type. The C–H_b bridging bond is elongated by $0.08 \text{ \AA}$ compared to the C–H bonds in free methane. The energy of the $\text{Pt}-\text{CH}_4$ bond amounts to $21.9 \text{ kcal mol}^{-1}$. In order to compare the calculated bond energy with that obtained experimentally (for the reaction in solution), the energy of methane solvation by the solvent has to be subtracted from the calculated value.

Calculations by the MP4SDQ method for the reaction of $(\text{PH}_3)_2\text{Pt}$ with CH_4 indicate the formation of the $(\text{PH}_3)_2\text{Pt}(\eta^2\text{-CH}_4)$ complex having C_{2v} symmetry and a very small stabilisation energy ($0.6 \text{ kcal mol}^{-1}$).¹³⁷ In line with the small stabilisation energy, the geometric parameters of the methane fragment in this complex change only slightly with respect to those in free methane.

The reductive elimination of methane from a model complex of divalent platinum, $(\text{PH}_3)_2\text{Pt}(\text{H})(\text{CH}_3)$, has been investigated by the density functional approach in the B3LYP approximation.¹³⁸ Unlike the results cited above,¹³⁷ the results of these calculations showed that the process includes the formation of the $(\text{PH}_3)_2\text{Pt}(\eta^1\text{-CH}_4)$ σ -complex with a straight bridge (the $\text{Pt}-\text{H}_b-\text{C}$ angle is close to 180°). The length of the C–H_b bond directed towards the metal is virtually the same as the lengths of the other three C–H_i bonds. The stabilisation energy of this complex with respect to free reactants is close to zero.

The reductive elimination of methane from the $(\text{PH}_3)_2\text{Pt}(\text{H}) \cdot (\text{CH}_3)$ complex gives the σ -complex $(\text{PH}_3)_2\text{Pt}(\eta^2\text{-CH}_4)$ as an intermediate in which two C–H bonds of the methane ligand undergo equally strong interactions with the platinum atom (the corresponding $\text{Pt}-\text{H}$ bonds are 2.065 and $2.066 \text{ \AA}$). Both these bonds are almost $1 \text{ \AA}$ shorter than the $\text{Pt}-\text{H}$ agostic bond in $(\text{PH}_3)_2\text{Pt}(\eta^1\text{-CH}_4)$, which is indicative of a stronger binding of methane in this complex. Indeed, the enthalpy of methane binding in $(\text{PH}_3)_2\text{Pt}(\eta^2\text{-CH}_4)$ is $10.8 \text{ kcal mol}^{-1}$, whereas this value for $(\text{PH}_3)_2\text{Pt}(\eta^1\text{-CH}_4)$ is negligibly small. The reductive elimination of methane from *trans*- $[(\text{PH}_3)_2\text{PtCl}_2(\text{H})(\text{CH}_3)]$ proceeds *via* the complex *trans*- $[(\text{PH}_3)_2\text{PtCl}_2(\eta^2\text{-CH}_4)]$ (C_{2v} symmetry) in which the enthalpy of methane binding is equal to $3.6 \text{ kcal mol}^{-1}$.

The reductive elimination of methane from the cationic *cis*- $[(\text{PH}_3)_2\text{PtCl}(\text{H})(\text{CH}_3)]^+$ complex yields *cis*- $[(\text{PH}_3)_2\text{PtCl}(\eta^2\text{-CH}_4)]^+$ in which the lengths of the two $\text{Pt}-\text{H}_b$ bonds are different. The enthalpy of methane binding in *cis*- $[(\text{PH}_3)_2\text{PtCl}(\eta^2\text{-CH}_4)]^+$ is $9.5 \text{ kcal mol}^{-1}$, which is much higher than that in *cis*- $[(\text{PH}_3)_2\text{PtCl}_2(\eta^2\text{-CH}_4)]$. Apparently, the stronger binding of methane in $(\text{PH}_3)_2\text{PtCl}(\eta^2\text{-CH}_4)^+$ is due to the fact that methane is attached to the positively charged $(\text{PH}_3)_2\text{PtCl}^+$ fragment, unlike the neutral $(\text{PH}_3)_2\text{PtCl}_2$ fragment in the other complex.¹³⁸

The results of calculations of geometric parameters of the $\text{ML}_n(\text{CH}_4)$ complexes and the binding energies of the methane ligand in these complexes are listed in Table 3, and the modes of coordination of the CH_4 ligand in these complexes, depending on the nature of the complexing ion, are shown in Fig. 3.

The results of calculations considered above demonstrate that in methane complexes with ML_n molecular fragments whose central atoms have a d^n electron configuration, the methane ligand is typically coordinated along the edge (η^2 and η^1_2 modes of coordination). The η^2 -coordination where one bridging bond is much shorter than the other is found most often. A somewhat less frequently encountered mode of methane coordination to the metal is η^2 -coordination due to two bridging hydrogen atoms, which results in elongation of the C–H_b bonds compared to those

Table 3. Data of calculation of the geometric structure and the bond energy for the $ML_n(CH_4)$ complexes containing stabilising ligands.

Figure 3. Dependence of the modes of coordination of the CH_4 ligands in the complexes $\text{ML}_n(\text{CH}_4)$ on the nature of the complexing ion.

in free methane. Examples of methane coordination along a face (η^3 and η_3^1) by d^n -ion complexes are rare; this mode of coordination was mentioned only in one study.¹¹⁴ The η^1 -coordination of methane (by a tetrahedron vertex) is equally unusual.^{116, 118}

V. Some structural features of methane complexes

The data considered above demonstrate that the results of quantum-chemical calculations of methane complexes with neutral metal atoms, metal ions and molecular fragments ML_n predict a diversity of modes of methane coordination in these complexes and small energy differences between various structures, which is typical of structurally non-rigid compounds. In complexes with neutral atoms or metal ions without stabilising ligands, η^2 and η^3 modes of coordination are energetically preferred for methane. No complexes with linear η^1 -coordination have been found for these species. In rare cases, calculations predict the η_3^1 -coordination of methane as the most stable [for example, in $\text{Rh}(\eta_3^1\text{-CH}_4)^+$ and $\text{Pt}(\eta_3^1\text{-CH}_4)^+$];^{65, 67} however, the use of other calculation methods or higher-level theories shows that for Rh^+ and Pt^+ complexes, too, η^2 -coordination is the most stable.^{62, 68}

Complexes with η^3 -coordination of methane are mainly typical of non-transition metal ions M^+ and for transition metal ions of the beginning of the row (Li^+ , Mg^+ , Sc^+ , Ti^+ , Cr^+ , Ta^+), while transition metal ions of the end of the row (Co^+ , Rh^+ , Ir^+ , Cu^+) tend to form complexes with η^2 -coordination of methane. The $\text{Fe}(\text{CH}_4)^+$ structures with C_{2v} (η^2) and C_{3v} (η^3) symmetry are nearly degenerate, the energy difference between them being 0.05–0.17 kcal mol^{−1} (see Ref. 55).

The results of calculations of the geometric structure of $\text{Mg}(\text{CH}_4)^+$ and $\text{V}(\text{CH}_4)^+$ show that it depends appreciably on the electronic state of the central atom.^{39, 46} The energy of binding of the methane ligand to the metal increases on passing from non-transition to transition metals. For neutral metal atoms in the ground state, the energy of methane binding in the complexes is relatively low, as a rule, less than 4 kcal mol^{−1} (see, for example, Ref. 29). Of transition metal ions in the ground state, the lowest binding energy of the methane ligand was found for Mn^+ and Zn^+ (~10 kcal mol^{−1}),³⁵ while the highest energy was found for the Pt^+ ion (~30 kcal mol^{−1}).⁶⁹

Some discussion has been devoted to the dependence of the mode of methane coordination on the nature of the complexing ion. According to Yoshizawa,⁵⁶ η^2 -coordination is most probable for low-spin states of ions and η^3 -coordination is most likely for high-spin ions. Bauschlicher and coworkers,⁷⁴ while considering the structure of the $\text{Cu}(\text{CH}_4)^+$ complex, suggested that electrostatic interaction is favourable for the formation of a η^3 -structure, and dative interaction promotes η^2 -coordination.

Other modes of coordination are typical of methane complexes with ML_n molecular fragments. Only a few examples of complexes where η^3 -coordination of methane should be preferred according to calculations are known [derivatives of d^0 ions:

Cl_2LuH ,⁸⁰ $\text{H}_2\text{M}=\text{NH}$ ($\text{M} = \text{Ti}, \text{Zr}, \text{Hf}$)⁹⁵]. Complexes with η_3^1 -coordination of the methane ligand are also represented by single examples [RhHCl , $\text{RhH}(\text{CO})$, $\text{RhH}(\text{NH}_3)$]¹¹⁴. It is noteworthy that η_3^1 -coordination of methane has not been found for platinum complexes containing stabilising ligands, whereas this mode of coordination has been reported⁶⁷ to be preferred for complexes of the Pt^+ ion without ligands. In most cases, calculations point to monodentate methane coordination with a bent $\text{M}-\text{H}-\text{C}$ bridge (η_2^1 -coordination) as the most energetically favourable for complexes with ML_n molecular fragments. η^2 -Coordination is also often found for these complexes (however, not as often as η_2^1). In both cases, methane is coordinated to the metal by the tetrahedron edge. The difference between these modes of coordination is that in the case of η_2^1 -coordination, two bridging $\text{M}-\text{H}_b$ bonds have markedly different lengths. The energy of methane binding is much lower in complexes containing stabilising ligands than in complexes with bare ions; in most cases, the former does not exceed 10 kcal mol^{−1}.

It is obvious that this difference in the structures and binding energies between complexes with bare ions and with ML_n molecular fragments is due to the stabilising ligands. In particular, a substantial influence of steric factors on the structure of methane complexes has been noted in an early publication¹³⁹ devoted to this problem and in a number of subsequent studies.^{81, 86}

It should be noted that the results of calculations of the geometric structures of methane complexes obtained by different researchers differ markedly from one another. Quantum-chemical calculations point to an insignificant energy difference between complexes that differ only in the mode of methane coordination. Therefore, determination of the most stable structure is ambiguous and depends on both the system under study (the complex) and the calculation methods and basis sets used.¹⁰⁷ This ambiguity is observed both for complexes containing stabilising ligands and for complexes formed by bare ions.

Currently it is impossible to verify experimentally the calculation results for methane complexes, because, unlike complexes formed by molecular N_2 or H_2 , which have been isolated in the crystalline state, no metal complexes with an alkane molecule as a ligand have been isolated so far. In view of the ambiguity of calculation results and the impossibility of their experimental verification, it would be useful to compare the results of calculations of the structures of methane complexes with experimental data for some existing systems that resemble methane complexes in electronic and geometric structures.

Several systems have been proposed to model various steps of alkane activation. For example, structural data for alkyl complexes with intramolecular $\text{C}-\text{H}\cdots\text{M}$ agostic bonds were used by Crabtree *et al.*¹⁴⁰ to model the trajectory of addition of the $\text{C}-\text{H}$ bond to the central atom. However, this model does not allow one to identify the mode of methane coordination in the complexes.

Recently, adducts of metal carbonyls with phosphine and amine boranes, $\text{M}(\text{CO})_4\cdot\text{H}_3\text{BL}$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$; $\text{L} = \text{PMe}_3$,

PPh_3 , NMe_3), have been considered as structural models of methane complexes.^{141, 142} Presumably, these complexes are fairly important as model systems because H_3BL molecules are isoelectronic to methane and, like methane, they are electrically neutral. According to X-ray diffraction data, the borane ligand in the considered complexes is attached to the metal according to the η^3 pattern through one bent hydrogen bridge.¹⁴¹ This mode of coordination is apparently due to steric reasons because it allows the bulky substituent L in the borane ligand to be located far from the $\text{M}(\text{CO})_4$ fragment. According to NMR data, the three hydrogen atoms of the borane ligands are equivalent in solutions; this is indicative of structural non-rigidity of the complexes on the NMR time scale. Examples of η^2 -complexes formed by boranes are also known.¹⁴³

The η^1 -coordination of phosphine or amine boranes to Group VI metal carbonyls, found experimentally, is not quite consistent with the results of calculations for $\text{M}(\text{CO})_5 \cdot \text{CH}_4$, according to which the η^2 -coordination of methane is preferred for these complexes from the energy standpoint.¹⁰⁷ The data presented in this review demonstrate (see Tables 1 and 3) that η^1 -coordination is unusual for methane and seldom corresponds to an energy minimum. Apparently, this difference between the two systems being compared is due to steric factors, in particular, the presence of bulky substituents L in phosphine or amine boranes and the absence of such groups in the methane molecule. Unfortunately, the scope of applicability of this model is limited due to the limited selection of stabilising ligands (mainly, these are carbonyl or phosphine ligands) and complexing ions (Group VI–VIII metals). The number of structurally studied complexes of this type is small. Therefore, this model does not permit a systematic investigation of the dependence of the structure of complexes on the nature of the ligands and the complexing metal. It is also evident that due to steric factors, these complexes are not quite suitable for the modelling of methane complexes.

It has been assumed repeatedly that tetrahydroborates of various metals, whose structures have been studied rather extensively, could serve as structural models of methane complexes.^{144, 145} Indeed, the BH_4^- anion is isoelectronic to the methane molecule. The BH_4^- and CH_4 species are very similar in size and geometry (tetrahedron), which is rather important in view of the considerable influence of the steric factor on the mode of coordination of these ligands. The BH_4^- anion forms a rather large number of complexes, sufficiently stable to be studied experimentally, with metal ions of almost all Groups (with diverse modes of ligand coordination). However, the use of these compounds as models for comparison with methane complexes was precluded by the lack of knowledge of particular factors determining the structural and dynamic properties of tetrahydroborates themselves.

Recently, some previously unknown features of the structures of tetrahydroborate complexes have been elucidated.¹⁴⁶ It was shown that tetrahydroborate complexes can be subdivided into two large groups which differ appreciably in the structural (the mode of coordination of the tetrahydroborate ligand) and dynamic (structural rigidity or non-rigidity) properties.¹⁴⁶ The main factor determining the difference between the structures and dynamic properties of tetrahydroborate complexes is the difference between the electronic configurations of the central metal atom.

Derivatives of transition metals in high oxidation states [as a rule, these are Group III and IV metals having no outer d electrons — d^0 -electron configuration or d^1 -configuration in the case of Ti(III) complexes] and alkali and alkaline earth metals tend to form structurally non-rigid complexes with tridentate BH_4 ligands. Other modes of coordination (η^2 and η^1) in these complexes usually arise due to the presence of stabilising ligands (e.g., as a result of steric hindrance), i.e., they are forced.¹⁴⁷

Tetrahydroborate complexes of monovalent metals with the s^1 configuration have not been isolated in a pure state and no structural data for these compounds are available. However,

gas-phase studies have shown that the tetrahydroborate ligand in the monovalent calcium complex $\text{Ca}(\text{BH}_4)$ is coordinated according to the η^3 type (C_{3v} symmetry).¹⁴⁸ These data are consistent with the results of *ab initio* calculations.¹⁴⁹

Tetrahydroborate η^3 -complexes with d^2 – d^{10} central metal atoms are unknown. Even in the absence of steric hindrance, the BH_4 ligand in these complexes is coordinated according to the η^2 type (in a few cases, according to the η^1 type).

The data presented in this review demonstrate that a similar pattern of dependence of the structure of complexes on the electronic configuration of the central atom is also observed for methane complexes with neutral metal atoms and bare metal ions. Indeed, according to quantum-chemical calculations, a tridentate methane coordination is assumed for $\text{Li}^+(1s^2)$, $\text{Na}^+(2p^6)$, $\text{Mg}^+(3s^1)$, $\text{Sc}^+(3d^1 4s^1)$, $\text{Ti}^+(3d^2 4s^1)$, $\text{V}^+(3d^3 4s^1)$, $\text{Ta}^+(5d^3 6s^1)$, $\text{Cr}^+(4d, 3d^3 4s^1)$, $\text{Fe}^+(3d^6 4s^1)$, $\text{Fe}^0(3d^6 4s^2)$ and $\text{Co}^0(3d^7 4s^2)$ ions having no d electrons in the outer shell. In the case of d^n ions ($n = 2$ – 10) and neutral atoms with a d^n -type shell — $\text{Nb}^+(5d, 4d^4)$, $\text{Co}^+(3f, 3d^8)$, $\text{Rh}^+(3f, 4d^8)$, $\text{Ir}^+(3f, 5d^8)$, $\text{Cu}^+(1s, 3d^{10})$, $\text{Rh}^0(2d, 4d^9)$, $\text{Pd}^0(1s, 4d^{10})$ and $\text{Pt}^0(1s, 5d^{10})$ — a bidentate methane coordination predominates. Due to the scarcity of experimental data and the results of calculations of methane complexes with multicharged M^{n+} ions, it is impossible to draw any general conclusions concerning their structure. However, the dependence of the mode of methane coordination on the electronic configuration of the complexing ion, observed for single-charged ions M^+ , might also hold for multicharged ions M^{n+} .

Similar regularities, that is, the tendency for the formation of η^3 -complexes for d^0 ions and $\eta^2(\eta^1)$ -complexes for d^n -ion derivatives, are also observed for complexes containing stabilising ligands. However, in this case, the mode of methane coordination is determined not only by the electronic configuration of the central metal atom but also by the electronic and steric properties of the ligands. Thus the bidentate coordination of the methane ligand in the complexes formed by d^0 ions, in particular, $\text{Cp}_2\text{Sc}(\text{CH}_3)(\eta^2\text{-CH}_4)^{81}$ and $\text{Cp}_2\text{MR}(\eta^2\text{-CH}_4)^+$ ($\text{M} = \text{Ti}, \text{Zr}$; $\text{R} = \text{CH}_3, \text{C}_2\text{H}_5, \text{C}_3\text{H}_7$),⁸⁶ corresponds to the coordination of the BH_4 groups in similar tetrahydroborates, namely, $\text{Cp}_2\text{Sc}(\eta^2\text{-BH}_4)$, $\text{Cp}_2\text{Ti}(\eta^2\text{-BH}_4)$ and $\text{Cp}_2\text{Zr}(\eta^2\text{-BH}_4)_2$, where this mode of coordination is due to the influence of steric factors.¹⁴⁷

There are only a few exceptions to this regularity. The results of calculations predict a tridentate coordination of methane to the Cr^+ ion in the ground ($6s, 3d^5$) state⁴⁶ and η^3 -coordination to the $\text{Pt}^+(2d, 5d^9)$ ion,⁶⁷ instead of the expected η^2 -coordination. Currently, it is impossible to find out whether this discrepancy in the calculation results is caused by the difference in the coordination properties of methane and the tetrahydroborate anion or is related to inaccuracy of the calculation techniques. An extension of the basis set and the use of higher-level theory for these calculations might bring the calculated data in correspondence with those we predict in terms of the tetrahydroborate model, as was the case for the $\text{Cu}^+(1s, 3d^{10})$ ion.

Unfortunately, direct comparison of the structure of methane complexes with similar tetrahydroborate complexes can seldom be carried out. The prevalence of monodentate coordination for methane complexes can be explained by the lower strength of the bond between the methane ligand and the metal compared to that in the case of tetrahydroborate; this makes methane more susceptible to the influence of the ligands.

In our opinion, the analogy found in the dependences of the mode of coordination of methane and the tetrahydroborate anion on the electronic configuration of the central atom for these two types of complexes is not accidental. This is due, apparently, to high accuracy of modern quantum-chemical calculations, which often allow one to predict properly the relative stabilities of various conformations of methane complexes, and to the existence of some common features in the structures of complexes formed by tetrahedral species, BH_4^- and CH_4 .

Probably, the discovered dependence of the structure of the BH_4^- and CH_4 complexes on the nature of the central metal atom is related to the difference between the coordination properties of d^0 and d^n ions, well-known in coordination chemistry.¹⁵⁰ The d^0 -metal ions tend to undergo ion–ion or ion–dipole electrostatic interactions with formation of weak complexes, while d^n -metal ions are more prone to covalent interactions to give strong metal–ligand bonds. Thus, these two types of complexes differ in the nature of the metal–ligand interaction. The results of studies of the electronic structure of the methane ligand in complexes formed by d^0 and d^n ions are in line with this assumption.

In d^0 -ion complexes $[\text{Cl}_2\text{LuH}]$,⁸⁰ $[\text{Cl}_2\text{LnZ}]$ ($Z = \text{H}, \text{CH}_3$),⁸² $\text{H}_2\text{M} = \text{NH}$ ($\text{M} = \text{Ti}, \text{Zr}, \text{Hf}$)⁹⁵, methane coordination is accompanied by an increase in the negative charge on the carbon atom and the positive charge on the bridging hydrogen atoms ($\text{C}^{\delta-} - \text{H}_b^{\delta+}$). Therefore, metathesis of σ -bonds in the series of lanthanide complexes and methane addition to imide complexes can be interpreted as hydrogen transfer between two anionic CH_3 groups in the coordination sphere of the positively charged central atom.^{82, 96} When methane reacts with $\text{CpRh}(\text{CO})$, polarisation of the $\text{C}-\text{H}$ bonds switches to the opposite one: $\text{C}^{\delta+} - \text{H}_b^{\delta-}$ (see Ref. 118). Unfortunately, data on $\text{C}-\text{H}$ bond polarisation in other d^n -ion complexes are missing, but one can assume that polarisation of the methane $\text{C}-\text{H}$ bonds in these complexes would be similar to that found in $\text{CpRh}(\text{CO})(\text{CH}_4)$. Apparently, the difference in the polarisation of $\text{C}-\text{H}$ bonds of the methane ligand is responsible for the different mechanisms of activation of these bonds by d^0 - and d^n -ion complexes, namely, proton transfer between two carbanions for d^0 -ion complexes and oxidative addition of the hydride ion and the carbocation for d^n complexes.

The observed dependence of the ligand denticity on the nature of the complexing ion can be explained qualitatively in the following way. In the case of spherically symmetrical ions with an $s(s^1, s^2)$ or s^2p^6 outer electronic shell where the ion–ion or ion–dipole interaction predominates, the highest bond energy is provided by the shortest distance between the components, which is attained in the case of η^3 -coordination. As noted above, this entails only a slight change in the geometric parameters of the methane ligand. In the case of d^n ions, the predominant contribution is made by directional covalent interaction with one or two $\text{E}-\text{H}$ bonds of the EH_4 species ($\text{E} = \text{B}, \text{C}$), resulting in η^2 - or η^2_2 -coordination, higher bond energy and more pronounced distortion of the ligand geometry.

It should be noted that the differences between the properties of d^0 and d^n transition metal complexes can also be followed in systems with intramolecular $\text{M}\cdots\text{H}-\text{C}$ agostic bonds. Indeed, the figure, reported previously,¹⁴⁰ which describes the dependence of the $\text{M}\cdots\text{H}-\text{C}$ angle (α) in complexes with an agostic bond on the radius r_{bp} ($r_{\text{bp}} = d_{\text{bp}} - r_{\text{M}}$, where d_{bp} is the distance from the metal to the electron pair of the $\text{C}-\text{H}$ agostic bond, r_{M} is the covalent radius of the metal, and bp is the bonding pair), shows that any point for d^0 complexes lies below the curve characteristic of d^n complexes (Fig. 4).

Thus, of all the structural models of methane complexes considered above, the tetrahydroborate model describes most adequately the available results of structural studies of methane complexes. In terms of this model, one is not only able to make assumptions concerning the influence of the electronic configuration of the central atom on the mode of coordination of the methane ligand but can also attack the problem of the possible difference between structural properties of $\text{M}\cdots\text{C}-\text{H}$ agostic bonds in d^0 and d^n transition metal complexes.

One may hope that further studies of the structure of tetrahydroborate complexes would throw light on some structural features of methane complexes. For instance, information concerning monodentate tetrahydroborate complexes, little studied at present, could be useful for the understanding of factors that determine the prevalence of η^2_1 methane coordination in the complexes containing stabilising ligands. Systematic research

Figure 4. Dependence of the $\text{M}\cdots\text{H}-\text{C}$ angle in complexes with agostic bonds on the radius r_{bp} (according to Ref. 140).

The light dots are the $\text{M}\cdots\text{H}-\text{C}$ angles in d^n -complexes and the dark dots correspond to d^0 -complexes.

into structurally rigid tetrahydroborates could be helpful in the search for compounds that would hold methane most firmly in the coordination sphere.

* * *

The considered experimental and theoretical data on the structures of complexes containing methane as a ligand and comparison of these data with the structural information concerning tetrahydroborate complexes provide the following conclusions:

— methane as a ligand is characterised by diverse modes of coordination to central metal atoms. The mode of coordination of the methane ligand depends appreciably on the electronic configuration of the central metal atom and the nature of stabilising ligands;

— neutral atoms M^0 and bare ions M^+ tend to form $\text{M}(\eta^2\text{-CH}_4)^+$ or $\text{M}(\eta^3\text{-CH}_4)^+$ complexes. The geometry of these complexes is determined by the electronic configuration of the central atom: ions and neutral atoms with either s or s^2p^6 outer shell form complexes with tridentate coordination of methane. In the case of d^n ions ($n = 2-10$), bidentate methane coordination predominates. Apparently, similar regularities are to be expected for multicharged M^{n+} ions;

— for ML_n fragments containing stabilising L ligands, calculations point to a similar dependence of the structure of methane complexes on the electronic configuration of the central atom (η^3 -complexes are formed for derivatives of d^0 ions and are not formed for complexes of d^n ions). However, the presence of stabilising ligands results in η^2 and η^2_1 modes of methane coordination becoming more energetically favourable for these complexes, apparently, due to the electronic and steric influence of the ligands. Factors determining the preference of the η^2_1 methane coordination over η^2 -coordination have not yet been elucidated.

The author is grateful to Ph.D.'s Z K Nikitina and T S Zyubina for interest in the work and useful discussion.

VI. Supplement

Below we present the accepted abbreviations for calculation techniques and software

SCF — self-consistent field method;

LCGO — linear combination of gaussian orbitals;

MCPF — modified coupled pair functional method;

DFT — density functional theory;

PCI-80 — parametrised configuration interaction method with an 80% parameter (in the general case, PCI-X);¹⁵¹

RECP — relativistic effective core potential;

B3LYP — Becke's gradient-corrected three-parameter non-local exchange functional^{152, 153} and Lee–Yang–Parr gradient-corrected non-local correlation functional;¹⁵⁴

B3P86 — Becke's gradient-corrected three-parameter non-local exchange functional combined with Perdew's gradient-corrected correlation functional;¹⁵⁵

B3PW91 — the same with the Perdew *et al.* correlation functional;¹⁵⁶

RHF — restricted Hartree–Fock method;

UHF — unrestricted Hartree–Fock method;

HFSD — Hartree–Fock method with singly and doubly excited configurations;

SKBJ — relativistic compact effective core potential and the Stevens, Basch, Krauss and Jasien shared-exponent basis set;¹⁵⁷

DZVP — a basis set proposed by Wimmer and coworkers;¹⁵⁸

6-31G — Pople basis set with the 1s-AO being approximated by six and the 2s,2p-AO, by four gaussian functions grouped in (3,1); 6-31G** — the 6-31G basis set extended by d- and p-polarisation functions;

6-31G+ — the 6-31G basis set extended by diffusive functions;

QCI — quadratic configuration interaction method;

QCISD — single and double quadratic configuration interaction method;

QCISD(T) — the same with an estimation of triple excitations by a perturbation method;

MP2(3,4) — second- (third-, fourth) order Møller–Plesset perturbation theory;

MP4SDTQ — fourth-order Møller–Plesset perturbation theory with single, double, triple and quadruple excitations;

CASSCF — complete active space self-consistent field method;

MR-SDCI-CASSCF — multideterminant configuration interaction method with single and double excitations using the wave function obtained by CASSCF;

GRADSCF — a vectorised SCF method with the first and second derivatives;

SCF-CI — self-consistent field configuration interaction method;

SCF-SDCI — self-consistent field with single and double configuration interactions;

CCSD(T) — coupled-cluster theory with singles and doubles and non-iterative estimation of triple excitations;

GGA — generalised gradient approximation;¹⁵⁹

PBE — Perdew, Burke and Ernzerhof density functional;¹⁵⁹

INDO — intermediate neglect of differential overlap;

SBK — relativistic compact effective potential and the Stevens, Basch and Krauss basis set;¹⁶⁰

LANL1DZ, LANL2DZ — effective core potentials and basis sets developed by Hay and Wadt at the Los-Alamos National Laboratory;^{161–163}

GVB (General Valence Bond) — a quantum-chemical program package developed at the California Institute of Technology under the direction of W A Goddard III;

GAMESS (General Atomic and Molecular Electronic Structure System) — a quantum-chemical program package (M Dupuis, D Spangler, J Wendolowski. NRCC Software Catalog. Vol. 1, Program No. QG01);¹⁶⁴

GAMESS-UK — a quantum-chemical program package (F M Guest, P Fantucci, R J Harison, J Kendrick, J H Van Lenthe, K Schoeffel, P Sherwood. CFS Ltd., Darenbury, UK, 1993);

GAUSSIAN80–98 — various versions of a quantum-chemical program package developed by the GAUSSIAN corporation (Gaussian Inc., Pittsburgh, PA, 1998);

MOLECULE-SWEDEN — a quantum-chemical program package (J Almlof, C W Bauschlicher Jr., M R A Blomberg, D P Chong, A Heiberg, S R Langhoff, P-A Malmqvist, A P Rendell, B O Roos, P E M Siegbahn, P R Taylor);

MOLPRO — a quantum-chemical program package developed at the Sussex University;^{165–168}

Dgauss — a quantum-chemical program package;¹⁶⁹

STOCKHOLM — a quantum-chemical program package for general purposes (P E M Siegbahn, M R A Blomberg, L G M Petersson, B O Roos, J Almlof);

A-MOL — a program system developed by Baerends *et al.*¹⁷⁰ and vectorised by Ravenek;¹⁷¹

Laikov — is the program package developed by Laikov;¹⁷²

ADF — the Amsterdam density functional program system;¹⁷³

Jaguar 4.0 — a quantum-chemical program package of the Schrödinger corporation (Schrödinger Inc., Portland, Oregon, 1991–2000);

MELD — a quantum-chemical program package (E R Davidson, L E McMurchie, S T Elbert, S R Langhoff, D Rawlings, D Feller. Computer Centre Library Program No 030).

Nitro derivatives of 1,3,5-triazine: synthesis and properties

A V Shastin, T I Godovikova, B L Korsunskii

Contents

I. Introduction	279
II. Nitro-1,3,5-triazines	279
III. Nitramino-1,3,5-triazines	281
IV. Nitromethyl-, dinitromethyl- and trinitromethyl-1,3,5-triazine derivatives	282

Abstract. The published data on nitro derivatives of 1,3,5-triazine, belonging to the class of high-energy substances, have been systematised for the first time. The properties of *C*-nitrotriazines, nitraminotriazines and nitroalkyltriazines are considered. The data on the synthesis of previously unknown trisubstituted 1,3,5-triazines containing various functional groups including trinitromethyl groups are generalised. The bibliography includes 69 references.

I. Introduction

1,3,5-Triazines are known for about 200 years.¹ They are used as herbicides, pesticides, coupling reagents in the peptide synthesis, modifiers, antioxidants, thermal stabilisers, antipyrenes, bleaching agents, dyes and base compounds for combinatorial libraries.^{1–6} Melamine–formaldehyde resins have found broad application.⁷ It was shown that 1,3,5-triazines encounter in some natural objects, such as meteorites and algae.^{8,9} However, despite the great body of the published data on substituted 1,3,5-triazines,^{1,7,9,10} information on nitro-, nitramino- and nitro(poly-nitro)methyl 1,3,5-triazine derivatives is scattered in the literature.

The aim of the present review is to generalise and systematise the published data on nitro derivatives of 1,3,5-triazines which present special interest as high-energy compounds. Some of these compounds have been synthesised as explosives or components of explosive mixtures; therefore, special emphasis in their description is given to their explosive properties and sensitivity to shock, friction, etc.

II. Nitro-1,3,5-triazines

There are several approaches to the synthesis of nitro-1,3,5-triazines, viz.:

- (1) electrophilic nitration of the triazine ring;
- (2) nucleophilic substitution of the nitrite ion for the halogen atom or other good leaving groups (nucleophilic nitration);
- (3) oxidation of amino, nitroso, hydroxyamino or azido groups;
- (4) cyclotrimerisation of nitriles containing a nitro group;
- (5) nitration of heterocyclic organometallic compounds.

1. Electrophilic nitration

Electrophilic nitration of 1,3,5-triazine (**1**) has been described relatively recently.¹¹ In contrast to nitration of aromatic compounds, that of heteroaromatic compounds containing several nitrogen atoms is significantly inhibited due to the acceptor effect of the nitrogen atoms present in the ring (the nitration rate decreases 10⁶-fold upon substitution of C=N for one C=C fragment).¹² Moreover, nitration in acidic media creates additional difficulties due to easier protonation of nitrogen-containing heterocycles in comparison with aromatic rings, which also reduces the nitration rate. In general, direct nitration of six-membered azines is used only if the heterocycle contains some activating groups (e.g., amino or hydroxy groups) or *N*-oxide groups. However, no more than two nitro groups can be incorporated simultaneously irrespective of the nature of the heterocycle.¹³ Nitration of unsubstituted triazines with nitric anhydride (Scheme 1) occurs as a conjugate addition of nitronium nitrate to the N=C bond, which affords isomeric *N*-nitronitroxyhexahydro-1,3,5-triazines, viz., 1,3,5-trinitro-*cis*-2,4,6-trinitroxyhexahydrotriazine (**2a**) and 1,3,5-trinitro-*trans*-2,4,6-trinitroxyhexahydrotriazine (**2b**).¹¹ In this case, nitration proceeds similarly to the known halogenation reactions of the triazine ring and affords perhalogenohexahydrotriazines.¹⁴ The structures of the compounds obtained were established¹¹ based on the analysis of the NMR spectra of the reaction mixture and the composition of their methanolysis products **3a** and **3b** (yields 14% and 10%, respectively). Nitronitroxyhexahydro-1,3,5-triazines **2a,b** themselves could not be isolated because of their low stability (according to the NMR spectroscopic data, they are rather stable at temperatures below 0 °C and decompose at nearly the same rates at 20 °C). Presumably,¹¹ dinitramide (**4**) is the final decomposition product of these compounds (see Scheme 1). This is formed as a result of retro-[2+2+2]cycloaddition of hexahydrotriazines **2a,b** and formation of transient imidoyl nitrate which is further rearranged into *N,N*-dinitroformamide to give dinitramide **4**. The reaction products **3a,b** represent methoxy-substituted analogues of hexogen.

Scheme 1

2. Nucleophilic nitration

Nucleophilic nitration is not virtually applied to aromatic compounds because of the high mobility of the aromatic nitro group and the ambident nature of the nitrite ion.¹⁵ Nevertheless, alkali metal nitrites were used as efficient nucleophiles for the replacement of halogen atoms in 1-halogeno-4-nitro-, 1-halogeno-4,6-dinitro- and 1-chloro-2,4,6-trinitrobenzenes under conditions of phase transfer catalysis (solid phase – liquid) in the presence of 18-crown-6 ether.¹⁶ Nucleophilic nitration of some halogen-substituted pyridazinones also gives acceptable yields.¹⁷ It is not therefore surprising that nucleophilic nitration of cyanuric chloride (6) with silver nitrite was the first, albeit unsuccessful, attempt to synthesise 2,4,6-trinitro-1,3,5-triazine (5).¹⁸ A similar reaction of 4,6-dimethoxy-2-chloro-1,3,5-triazine with potassium nitrite was unsuccessful also.¹⁹

3. Oxidation of nitrogen-containing groups

Oxidation of exocyclic nitrogen-containing groups is a convenient method for the synthesis of nitroazines.¹³ Few mononitro-1,3,5-triazines 7 were prepared by photochemical oxidation of azido-1,3,5-triazines 8 in the presence of oxygen²⁰ (similar to oxidation of azidopyrimidines²¹) or by ozonisation of the corresponding hydroxyaminotriazines 9 or nitrosotriazines 10, e.g., the bisdimethylamino-substituted derivative 10a.^{22,23} The yields of mononitrotriazines 7 are 15%–50%. Photooxidation includes the formation of a transient triplet nitrene. Ozonisation is very sensitive to the electronic properties of the substituents in the triazine ring; thus the reaction is only successful if one or two dialkylamino groups are present in the ring.

a: $\text{R}^1 = \text{R}^2 = \text{NMe}_2$ (29%); b: $\text{R}^1 = \text{OMe}$, $\text{R}^2 = \text{NMe}_2$ (15%).

a: $\text{R}^1 = \text{R}^2 = \text{NMe}_2$ (28%); b: $\text{R}^1 = \text{OMe}$, $\text{R}^2 = \text{NMe}_2$ (30%); c: $\text{R}^1 = \text{R}^2 = \text{N}(\text{CH}_2)_5$ (50%); d: $\text{R}^1 = \text{R}^2 = \text{OMe}$ (0%).

However, this method cannot be used for the introduction of several nitro groups into the triazine ring. The oxidation of hydroxyaminotriazines 9a,c with manganese oxide in chloroform gives only nitrosotriazines 10a,b and their condensation products with the starting hydroxylamines 11a,b.²⁴ The oxidation of 2-hydroxyamino-4,6-dimethoxy-1,3,5-triazine (9d) under identical conditions resulted in the formation of solutions with the greenish colour typical of nitrosoazines, but the attempts to isolate the corresponding triazine or to identify its adduct with aniline failed. 2-Anilino-4,6-dimethoxy-1,3,5-triazine formed as a result of substitution of aniline for a mobile nitroso group was the only compound identified.²⁴

Compounds	R^1, R^2	Yield of 10 (%)	Yield of 11 (%)
9a, 10a, 11a	NMe_2	35	0
9c, 10b, 11b	$\text{N}(\text{CH}_2)_5$	30	30

4. Cyclotrimerisation

The trimerisation of hypothetical nitrocyanogen into 2,4,6-trinitro-1,3,5-triazine (**5**) is discussed in a study²⁵ devoted to the energy characteristics of trinitrotriazine as a representative of a novel class of high-energy compounds of the general formula $C_nN_{2n}O_{2n}$.

This scheme looks rather attractive: according to the calculations [*ab initio* calculations with optimisation of geometrical parameters using the HF/6-31G* and MBPT(2)/6-31G* basis sets and the ACES II software], the trimerisation of hypothetical nitrocyanogen can be energetically favourable: $\Delta E = -70.2 \text{ kcal mol}^{-1}$ as calculated by MBPT(2). However, it has been shown²⁶ that the reaction of HCN with NO_2BF_4 in nitromethane, tetrahydrothiophene 1,1-dioxide or in the absence of a solvent is not accompanied by trimerisation of the intermediate, structurally similar and less sterically hindered neutral $\text{CN}-\text{NO}_2$.

In the calculated trinitrotriazine structure with the symmetry C_3 corresponding to the minimum energy, the aromatic triazine ring is planar and the nitro groups are rotated 40° to the ring plane. Such a spatial arrangement of the nitro groups compensates for their conjugation with the ring and the mutual repulsion of the negatively charged oxygen atoms and the nitrogen atoms of the triazine ring (the minimum value corresponds to the angle 90°). The length of the C–N bond in the triazine ring is equal to 1.331 Å, the NCN angle is equal to 128.4° (according to the electron diffraction spectroscopy data, the length of the C–N bond in unsubstituted 1,3,5-triazine is 1.338 Å, while the NCN angle is equal to 126.2°). The standard enthalpy of formation (ΔH_f°), the heat of explosive degradation (ΔE_r) and specific impulse (I_{sp}) of compound **5** were calculated to be equal to $\Delta H_f^\circ = 46 \text{ kcal mol}^{-1}$, $\Delta E_r = 304 \text{ kcal mol}^{-1}$, I_{sp} is 269 s at ambient pressure and 294 s in vacuum. These characteristics are similar to the corresponding values for hexogen, but the calculated density (ρ_0) of trinitrotriazine **5** is higher (1.82 and 2.1 g cm^{-3} for hexogen and compound **5**, respectively).²⁷ Korkin and Bartlett²⁵ expect to prepare trinitrotriazine **5** using an original scheme which includes trimerisation of nitrocyanogen. The following characteristics of compound **5** have been calculated²⁸ (for comparison, the corresponding parameters for hexanitrobenzene are given in parentheses): detonation rate (D), 9530 (9413) m s^{-1} ; $\Delta H_f^\circ = 18$ (36) kcal mol^{-1} , $\rho_0 = 1.973$ (1.973) g cm^{-3} .

5. Nitration of organometallic compounds

Nitration of 1,3,5-triazine stannyl derivatives is yet another, hitherto non-explored method for the synthesis of nitro-substituted triazines. Recently, this approach has been used in the synthesis of 2-nitro derivatives from 2-trimethylstannylated benzo[*b*]furan, benzo[*b*]thiophene, substituted indoles and 2-, 3- and 4-trimethylstannylpyridines under the action of tetranitromethane or dinitrogen tetroxide (in the case of 3- and 4-trimethylstannylpyridines, the yields did not exceed 2%).²⁹

Thus, 2,4,6-trinitro-1,3,5-triazine, a heterocyclic analogue of one of the most potent explosives, *viz.*, hexanitrobenzene,³⁰ could not be prepared so far.

III. Nitramino-1,3,5-triazines

Both substituted and unsubstituted nitramines based on heterocyclic compounds are usually prepared by nitration of the corresponding amines, sometimes with preliminary protection of the NH_2 group. Primary and secondary (*i.e.*, containing the NHNO_2 and NRNO_2 groups, respectively) nitramines of the 1,3,5-triazine series are documented. Numerous attempts at the

synthesis of 2,4,6-tris(nitramino)-1,3,5-triazine (**12**), which is the first member of this series, failed.^{31,32}

It was shown³³ that nitration of melamine (**13**) gives dinitroammeline (**14a**) in 44%–52% yield. Presumably, the transient compound **12** formed in this reaction is hydrolysed to dinitroammeline with the loss of a nitramino group, which is typical of nitramino derivatives of six-membered heterocycles.³² It is of note that nitration of triacetylmelamine at higher temperatures yields nitroammelide (**14b**). The feasibility of dinitroammeline as a high-energy compound is being investigated.^{33,34} Dinitroammeline rapidly decomposes on heating to 228°C , while nitroammelide decomposes at 248°C and slowly sublimates at 200°C (1 Torr).

Melamine salts with nitramide and nitric acid are considered to be promising candidates for high-energy compounds.³⁵

The data on substituted nitraminotriazines, *i.e.*, triazines containing secondary nitramino groups as substituents, are more numerous. Thus the synthesis and properties of 2,4,6-tris(methylnitramino)-1,3,5-triazine (**15**) have been described.³⁶ This compound is prepared by nitration of a complex of 2,4,6-tris(methylamino)-1,3,5-triazine with oxalic acid (**16**) with acetyl nitrate (40°C , 5 h) (the yield of the product **15** is 72%).

According to derivatography data, triazine **15** decomposes at 210°C . This compound has the following characteristics (for comparison, some parameters of tetryl are given in parentheses): single crystal density (ρ_m), 1.67 g cm^{-3} , $\Delta H_f^\circ = 275.1$ (33.9) kJ mol^{-1} , friction sensitivity > 36 (36), impact sensitivity, 12.5 (6.5–12.5),[†] detonation rate, 7228 m s^{-1} at the charge density of $\rho = 1.53 \text{ g cm}^{-3}$ (7575 m s^{-1} at $\rho = 1.71 \text{ g cm}^{-3}$).³⁶

The nitration of such melamine derivatives as 2,4,6-triaziridino-1,3,5-triazine (**17a**) and 2,4,6-tris(methylaziridino)-1,3,5-

[†] There are many ways for expressing the sensitivity of explosives. As a rule, this is determined as a ratio of the number of explosions of a standard amount of a substance for a given number of trials to the total number of trials at a given mass and load fall height. In this case, they represent relative values.³⁶ In the Russian literature, the sensitivity is traditionally expressed on a per cent basis; the mass and load fall height separated by an oblique stroke are given in parentheses: $x\%$ ($M \text{ kg}/N \text{ cm}$).

triazine (**17b**) with N_2O_5 in dichloromethane at $0-5^\circ\text{C}$ (the molar ratio **17**: N_2O_5 is 1.0:3.3) afforded nitramines **18a,b** (yields 95% and 78%, respectively).³⁷ The nitration of 2,4,6-triazetidino-1,3,5-triazine (**19**) under analogous conditions yields a mixture of products which contains nitramine nitrate **20** (60%) and non-identified compounds.³⁸

$\text{R}^1 = \text{H}$ (**a**), Me (**b**); $\text{R}^2 = \text{CH}_2\text{CHR}^1\text{ONO}_2$.

$\text{R} = (\text{CH}_2)_3\text{ONO}_2$.

Some characteristics of triazine **18a** (its commercial name is 'Tris-X') have been reported:³⁹ m.p. = $68-69^\circ\text{C}$, $\rho_m = 1.73\text{ g cm}^{-3}$ (data from X-ray diffraction analysis), impact sensitivity, 57, detonation rate, 8700 m s^{-1} . The latter value suggests that compound **18a** is a high-energy low-melting explosive despite its relatively low density.

2,4,6-Tris(picrylnitramino)-1,3,5-triazine (**21**) gave 2,4,6-tris(picrylnitramino)-1,3,5-triazine (**22**) in 95% yield.⁴⁰

$\text{R} = 2,4,6-(\text{NO}_2)_3\text{C}_6\text{H}_2$.

Unlike nitramines **18a,b**, which dissociate at $177-197^\circ\text{C}$, compound **22** is unstable: this slowly decomposes at 0°C and rapidly decomposes at 100°C .³⁹

Synthesis of 2-azido-4,6-bis(ethylnitramino)-1,3,5-triazine (**23**) from 2-azido-4,6-bis(ethylamino)-1,3,5-triazine (**24**) has been described.⁴¹ The characteristics of compound **23** obtained in 20% yield are as follows: m.p. = $40-41^\circ\text{C}$, $\rho_m = 1.375\text{ g cm}^{-3}$, $\Delta H_f = 540.2\text{ kJ mol}^{-1}$, initial decomposition temperature, 207°C . Presumably,⁴¹ elimination of nitrogen from the azido group is the initial step in the decomposition of azidotriazine **23**.

The use of *tert*-butyl protection in the nitration of bistrinitromethyl-substituted triazine **25a** and subsequent removal of the protective group in the *tert*-butylnitraminotriazine **26** formed with

trifluoroacetic acid has enabled the preparation of nitraminotriazine **27**,⁴² which possesses low thermal stability.

Attempts at direct nitration of unprotected aminotriazine **25b** and introduction of the trimethylsilyl protective group (compound **25c**) were ineffective: the amino group of triazine underwent oxidative hydroxylation. 2-Hydroxy-4,6-bis(trinitromethyl)-1,3,5-triazine (**28**) formed in this reaction was isolated and characterised as *tert*-butylammonium salt **29** (for the synthesis of trinitromethyl-substituted aminotriazines see Section IV.1).

IV. Nitromethyl-, dinitromethyl- and trinitromethyl-1,3,5-triazine derivatives

The synthesis of these 1,3,5-triazine derivatives includes nucleophilic substitution, nitration, destructive nitration and cyclotrimmerisation.

1. Nitromethyl derivatives

The attempts to synthesise 2,4,6-tris(nitromethyl)-1,3,5-triazine (**30a**), the first representative of nitromethyl-substituted 1,3,5-triazines, by nucleophilic substitution of the chlorine atom in 2,4,6-tris(chloromethyl)-1,3,5-triazine were unsuccessful.⁴³

Compound **30a** could be synthesised⁴³ starting from 2,4,6-tris[di(*tert*-butoxycarbonyl)methylidene]hexahydro-1,3,5-triazine (**31**). 2,4,6-Tris(nitromethyl)-1,3,5-triazine (**30a**) represents a solid yellow-coloured substance (decomposition temperature is 155°C). According to NMR spectroscopic data (acetone- d_6), it

exists in solution exclusively in a nitromethyl form (the potential tautomer **30b** was not found).⁴³

A convenient method for the synthesis of substituted 2-amino-4,6-bis(nitromethyl)-1,3,5-triazines **33** based on 2,4,6-tris[di(*tert*-butoxycarbonyl)nitromethyl]-1,3,5-triazine (**32**) has been developed.^{44, 45}

$R^1, R^2 = \text{H, Alk.}$

As can be seen from the scheme, the bulky di(*tert*-butoxycarbonyl)nitromethyl group in triazine **32** acts as a pseudo-halogen. It is noteworthy that reactions involving compounds of the type **34** (triazine, pyrimidine and pyrazine derivatives) are documented,⁴⁶ where the nitro group plays the role of a leaving group. Such a

$R = \text{Me, Et.}$

substitution proceeds by a mechanism which involves the initial formation of a radical pair.

Apparently, substitution of di(*tert*-butoxycarbonyl)nitromethyl group (rather than the nitro group) in triazine **32** is due to both the high electrophilicity of the triazine ring and the shielding of the nitro group with bulky *tert*-butoxycarbonyl substituents.

To the best of our knowledge, no methods for the synthesis of nitromethyl-1,3,5-triazines based on destructive nitration or cyclisation of the corresponding nitroacetonitriles have been reported so far.

2. Dinitromethyl derivatives

The known methods for the synthesis of dinitromethyltriazine derivatives are based on cyclotrimerisation of dinitrochloroacetonitrile (**35a**) under conditions of acidic and basic catalyses⁴³ and cyclotrimerisation of fluorodinitroacetonitrile⁴⁷ (**35b**) in methanol at 60 °C and 0.8 GPa. It is assumed⁴⁷ that the target 2,4,6-tris(dinitrofluoromethyl)-1,3,5-triazine (**36**) is formed but is converted into the corresponding mono- and dialkoxy derivatives **37** and **38** under the reaction conditions. These compounds could not be isolated in a pure state and their existence was judged from the respective transformation products, mass and NMR spectra. According to mass spectrometry data, the yields of the target triazines **37** and **38** were 45% and 19%, respectively, along with non-identified products.

The attempts at trimerisation of dinitrochloroacetonitrile (**35a**) in basic and acidic media were unsuccessful.⁴³ Two approaches were used, *viz.*, preparation of the corresponding imidate hydrochloride and *in situ* treatment with anhydrous sodium acetate at 0 °C and trimerisation of the nitrile with chlorosulfonic acid. Both methods gave negative results: a vigorous reaction with heating and evolution of nitrogen oxides occurred when the reaction product of the nitrile with ethanol was treated with sodium acetate; no trimerisation occurred in the presence of chlorosulfonic acid.

The known method for the synthesis of dinitromethyl derivatives from oximes of aromatic and heteroaromatic carbonyl compounds^{48–51} was not applied to triazine derivatives, although the synthesis of 1,3,5-triazine-2,4,6-tricarboxaldehyde trioxime had been reported.⁵² The authors of the review are unaware of the attempts to use dinitromethane salts for the synthesis of dinitromethyltriazine derivatives, although this method is applied in the case of halogenobenzenes activated by nitro groups.⁵³ 1,3,5-Triazines containing a dinitromethyl group together with amino and hydroxyl(oxo) groups have been described, but their synthesis has not been detailed.^{54, 55} Acidification of potassium salts of 2,4-diamino-6-dinitromethyl-1,3,5-triazine (**39a**),

Table 1. Physicochemical and explosive characteristics of compounds **40a–c**.^{54, 55}

Parameter	40a	40b	40c
Single crystal density ρ_m / kg m ⁻³	1880	1910	2020
Initial temperature of intense decomposition T_d / °C	265	253	170

2-amino-6-dinitromethyl-4-oxodihydro-1,3,5-triazine (**39b**) and the dipotassium salt of 2-hydroxy-6-dinitromethyl-4-oxodihydro-1,3,5-triazine (**39c**) afforded dinitromethyl-substituted triazines **40a–c** in the zwitter-ionic (**40a,b**) or dioxotetrahydro-triazine form (**40c**).^{54, 55} The compounds synthesised possess high energy and high density and represent low-sensitivity explosives (Table 1).

Salts of dinitromethyl-1,3,5-triazine derivatives (**41**) prepared by reduction of the corresponding C-trinitromethyltriazines **42** with conventional reducing agents were used in the synthesis of functionalised dinitromethyl-1,3,5-triazines.⁵⁶ It was shown that under conditions of acid catalysis formaldehyde enters into the Henry reaction with the salts **41** to give (2-hydroxy-1,1-dinitroethyl)-1,3,5-triazine derivatives **43** (Scheme 2). The same authors performed the alkylation of the salts **41** with methyl iodide in aprotic solvents to the corresponding dinitroethyl derivatives **44** (yields 70%–90%). Salts of C-dinitromethyl-1,3,5-triazine derivatives **41** enter into the Michael reaction with various derivatives of acrylic acid, particularly with methyl acrylate and acrylonitrile, to give 4-(2-R¹-4-R²-1,3,5-triazin-6-yl)-4,4-dinitrobutyric acid derivatives **45**. The halogenation of the salts **41** proceeds differently depending on the halogen used. Chloro- and bromodinitromethyl-1,3,5-triazine derivatives **46** are formed in good yields (80%–95%) in reactions with chlorine and bromine; fluorination gives a complex mixture of products.

Red is a reducing agent; M = Na, K, NH₄ etc.; R¹, R² = OAlk, OAr, NH₂, NHAik, NAlk₂, N₃ etc.; R³ = CO₂H, CO₂Me, CN, COMe; Hal = Cl, Br.

The oxidation of the salts **41** with potassium permanganate in an aqueous medium yields the carboxylic acid salts **47**; depending on the substituents in the triazine ring, their acidification gives either the carboxylic acids **48a** (R¹ and R² are the alkoxy groups), or the zwitter-ionic compounds **48b** (if at least one of the substituents represents an amino group). This can be attributed to the differences in the basicities of dialkoxy- and alkoxyamino-triazines. The interest in the synthesis of dinitromethyl-1,3,5-triazines is due to the fact that these compounds manifest diverse biological activities including the cytotoxic (antitumour) activity.^{57, 58} It was shown that the level of the cytotoxic effects of the most active synthetic compounds is commensurate with that of clinically important 1,3,5-triazines;⁵⁷ the highest activity ($GI_{50} = 10\text{--}80\text{ }\mu\text{mol litre}^{-1}$) is manifested by some representatives of C-(2-hydroxy-1,1-dinitroethyl)-1,3,5-triazines (**43**: R¹ = R² = OMe; R¹ = C(NO₂)₂CH₂OH, R² = NMe₂).[‡]

[‡] GI_{50} is the concentration of the tested substance which causes 50% inhibition of growth of tumour cell cultures under standard conditions *in vitro* (this methodology was developed at the National Cancer Institute).

M = Na, K, NH₄ etc.; R¹ = NH₂, NAlk, NAlk₂, OAlk;
R² = OAlk, R¹.

Reactions of the salts of the dinitromethyl-1,3,5-triazine derivatives **41** with nitrogen dioxide in organic solvents afford furoxanes **49**.⁵⁶

M = Na, K, NH₄ etc.; R¹ = R² = OMe, NMe₂.

3. Trinitromethyl derivatives

Trinitromethyl-1,3,5-triazine derivatives are synthesised by methods developed by Khmel'nitskii for aromatic and heteroaromatic compounds containing trinitromethyl groups.^{48–51, 59} 2,4,6-Tris-(trinitromethyl)-1,3,5-triazine (**50**) presents the greatest interest among other 1,3,5-triazines both in the academic and practical aspects; however, numerous attempts at its synthesis did not give any positive results until recently.⁶⁰ This compound could be obtained only after the synthesis of 2,4,6-tris(dicarboxymethyl)-1,3,5-triazine (**51a**),⁶⁰ which presumably exists in the ylidene form **51b**. Its destructive nitration with a mixture of sulfuric and nitric acids results in tris(trinitromethyl)triazine **50**.

2,4,6-Tris(trinitromethyl)-1,3,5-triazine (**50**) is a colourless crystalline substance, which is stable infinitely at room temperature (in the absence of water vapour). Its pycnometric density is equal to 1.91 g cm⁻³, m.p. = 91–92 °C (with decomposition), ΔH_f = 93 kcal kg⁻¹, impact sensitivity is 90% (2 kg/20 cm),

α = 1.5. The hydrolytic stability of this compound is rather low: after dissolution in aqueous dioxane, the hydroxy group is substituted for one trinitromethyl group to give a stable dioxane complex **52**.

The following characteristics of the complex **52** have been determined: decomposition temperature, 150–152 °C, impact sensitivity, 90% (2 kg/20 cm), ρ_m = 1.764 g cm⁻³ (X-ray diffraction data).⁶⁰

Reaction of compound **50** with nucleophiles can occur with the substitution of one, two or three trinitromethyl groups (Scheme 3).^{61,62} Thus reaction with ammonia or amines gives the monoamino derivatives **53a–c**; treatment of triazine **50** with an excess of ammonia gives the diamino derivative **54**.

Scheme 3

53: R¹ = R² = H (**a**), Me (**b**); R¹ = H, R² = Ph (**c**).

The use of various azide ion sources has enabled the synthesis of mono- and diazido derivatives **55** and **56**, respectively.⁶³

Under certain conditions,⁴³ nitration of the hexaoic acid **51a** yields, along with 2,4,6-tris(trinitromethyl)-1,3,5-triazine (**50**), the

dinitromethyl derivative, 2-dinitromethyl-4,6-bis(trinitromethyl)-1,3,5-triazine **57**, which exists in the dinitromethyl form.

Compound **57** is thermally and hydrolytically unstable. Attempts have been undertaken to reduce 2,4,6-tris(trinitromethyl)-1,3,5-triazine and to perform selective nitration of 2,4,6-tris(nitromethyl)-1,3,5-triazine;⁴³ however, no reducing agent could be found that did not cause nucleophilic substitution of the trinitromethyl group.

It was found⁶⁴ that substitution of phenols for the C(NO₂)₃ group in the bis(trinitromethyl)-1,3,5-triazine derivatives **53b,d** in the presence of a base occurs in a selective manner and results in 4-aryloxy-2-dimethyl(diethyl)amino-6-trinitromethyl-1,3,5-triazines **58a–v**.

53: R¹ = R² = Me (**b**), Et (**d**);

58: R¹ = R² = Me: R³ = *o*-Me (**a**), *m*-Me (**b**), *p*-Me (**c**), *o*-NO₂ (**d**), *m*-NO₂ (**e**), *p*-NO₂ (**f**), *o*-Cl (**g**), *m*-Cl (**h**), *p*-Cl (**i**), *o*-OMe (**j**), *m*-OMe (**k**), *p*-OMe (**l**), *o*-CO₂Me (**m**), *m*-CO₂Me (**n**), *p*-CO₂Me (**o**); R¹ = R² = Et: R³ = *o*-Me (**p**), *p*-OMe (**q**), *m*-CO₂Me (**r**), *p*-NO₂ (**s**), *o*-Cl (**t**), 2,4-(NO₂)₂ (**u**), H (**v**).

The substituted 1,3,5-triazines **59** and **60** containing trinitromethyl and fluorodinitromethyl groups linked to the triazine ring through the aminomethyl or oxymethyl bridge have been described.^{65–67}

Compound **59** has the following characteristics:⁶⁵ detonation rate, 7700 m s^{−1} at ρ = 1.54 g cm^{−3}, impact sensitivity, 50% (2 kg/20 cm). For compound **60**, m.p. = 76–77 °C, ρ_m = 1.795 g cm^{−3};⁶⁶ however, its synthesis has not been

detailed. 1,3,5-Triazines containing both trinitro(fluorodinitro)-methyl and 2,2,2-trinitro(2-fluoro-2,2-dinitro)-ethoxy groups are reported;⁶⁸ some physicochemical and thermodynamic characteristics of these compounds are given, but the methods for their synthesis are omitted.⁶⁸ These include 6-amino-2,4-bis(2-fluoro-2,2-dinitro-ethoxy)-1,3,5-triazine (**61**), 6-hydroxy-2,4-bis(2-fluoro-2,2-dinitroethoxy)-1,3,5-triazine (**62**), tri-2,4-bis(2-fluoro-2,2-dinitroethoxy)-1,3,5-triazine (**63**), 6-amino-4-trinitromethyl-2-(2-fluoro-2,2-dinitroethoxy)-1,3,5-triazine (**64**), [4,6-bis(fluorodinitromethyl)-1,3,5-triazin-2-yl]amine (**65**) and [6-trinitromethyl-4-(fluoro-dinitromethyl)-1,3,5-triazin-2-yl]amine (**66**).

R = OCH₂CF(NO₂)₂.

Compound	M.p. /°C	ρ _m /g cm ^{−3}	Compound	M.p. /°C	ρ _m /g cm ^{−3}
61	91–92 (with decomposition)	1.78	64	94–95	1.84
62	144–145	1.89	65	109–111	1.86
63	113–114	1.82	66	73–75	1.83

* * *

Some nitro-substituted 1,3,5-triazines considered in this review (e.g., nitramino-1,3,5-triazines, trinitromethyl-1,3,5-triazines) belong to the class of high-energy compounds and present potential as explosives or components of explosive mixtures. Many of them are promising chemical reagents for the synthesis of novel representatives of 1,3,5-triazines, such as trinitromethyl-1,3,5-triazines and nitromethyl-1,3,5-triazines. All nitro-substituted triazines can be used as NO donors;⁶⁹ some dinitromethyl-substituted 1,3,5-triazines were found to manifest high cytotoxic activity.^{57, 58} An interesting feature of trinitromethyl-1,3,5-triazines is the ease of substitution of various nucleophiles for the trinitromethyl group. Since the major part of these compounds has been obtained relatively recently, in-depth investigation of 1,3,5-triazine nitro derivatives is a topical matter.

Abstract. This review is the first attempt to generalise, in a descriptive-conceptual form, material-synthesising and material-affecting combustion and explosion processes and relevant physicochemical, technological and materials science problems with special emphasis on their practical (technological and industrial) applications. The bibliography includes 127 references.

I. Introduction

Combustion and explosion are physicochemical processes where transformations of substances are accompanied by intense release of energy and exchange of heat and mass with the environment. These processes, which have been known since ancient times, have made a significant contribution to the technological progress and ensured high level of development of modern civilisation. Combustion and explosion processes can be implemented in miscellaneous media, *viz.*, gaseous, condensed and multiphase (homogeneous, heterogeneous, organic, inorganic, *etc.*) and are therefore widely spread in nature and technology.

Combustion and explosion processes have both common and distinctive features. Common to both processes are high energy and nonlinearity, while distinctive features include the nature of their effects, self-propagation mechanisms, characteristic time scales and approaches to their theoretical description (Table 1).

It is noteworthy that common features prevail over distinctions. It is not therefore surprising that studies in the field of combustion and explosion are being developed in the framework of a single problem as can be judged from the establishment of the Integrated Scientific Council on Combustion and Explosion at the Presidium of the Russian Academy of Sciences, the journal 'Combustion, Explosion and Shock Waves', joint symposia on combustion and explosion, *etc.*

Combustion and explosion processes are described in terms of a specially developed scientific methodology based on the analysis

of feedforwards and feedbacks of exothermic reactions and transport processes. This methodology was used for the description of numerous specific phenomena and effects typical of these processes. It is the existence of a particular scientific methodology that allowed consideration of combustion and explosion as an independent area of knowledge.

The place of the combustion and explosion science in the family of related scientific disciplines some of which are concerned with the studies of chemical reactions, while others deal with transport processes, is shown in Fig. 1.

As regards the uniqueness of the scientific methodology and the range of their practical applications, combustion and explosion processes are unrivalled. Some areas of practical applications of these processes are shown in Fig. 2.

Figure 1. The position of combustion and explosion science in the family of related scientific disciplines.

Received 20 September 2002

Uspekhi Khimii 72 (4) 323–345 (2003); translated by R L Birnova

[†] This review has been written on the basis of the report presented by the author at the All-Russian Conference 'Combustion and explosion in physical chemistry and technology of inorganic materials' (Moscow, June 24–27, 2002).

Table 1. Some common and distinctive features of combustion and explosion processes.

Process	Nature of effect	Mechanism of self-propagation	Characteristic time scale	Areas of knowledge used for theoretical description of the process
Combustion	heat	heat transmission, diffusion	milliseconds and more	chemical kinetics + theory of heat and mass exchange
Explosion	gas-dynamic	shock compression	microseconds	chemical thermodynamics + gas dynamics

**Figure 2.** Practical applications of combustion and explosion processes.

A tremendous contribution to the chemistry of combustion and explosion has been made by Soviet (Russian) scientific schools.

— The school of N N Semenov laid the foundations of the modern theory of combustion and explosion. Its brilliant representatives Ya B Zeldovich, D A Frank-Kamenetsky, A F Belyaev, *etc.*, have won international recognition for their studies in the field of combustion and explosion.^{1–6}

— The schools of M A Lavrent'ev and M A Sadovsky developed the gas-dynamic principles of the explosion theory and substantiated the practical aspects of detonation effects (*e.g.*, surface shots, material processing by explosion, *etc.*) on various substances.

— The schools of B P Zhukov and V S Shpak worked out problems of combustion of solid propellants.

Solid flame combustion (SFC) and self-propagating high-temperature synthesis (SHS) have been developed especially intensively. Studies in these areas were initiated and developed for a long time only in the USSR; however, researches and developments in the field of SHS are currently under way in 47 countries as can be judged from the ever increasing number of publications (totalling ~ 10 000 at a rate of about 2 articles per day). The largest research centres dealing with in-depth studies of SHS are situated in Russia [Institute of Structural Macrokinetics and Materials Science of the Russian Academy of Sciences (ISMAN), SHS Research-and-Educational Centre of the Moscow Institute of Steel and Alloys and ISMAN, Department of Structural Macrokinetics of the Tomsk Research Centre of the Siberian Branch of the Russian Academy of Sciences, Samara State Technological University, Altai State Technological University], USA (University of Notre Dame, Northwestern University, University of California at Davis, Colorado School of Mines), Japan (Ryukoku University, Osaka University, Tokyo Institute of Technology), China (Wuhan University, Beijing University of Science and Technology, Harbin Institute of Technology), France (Montpellier University) and Israel (Israeli Institute of Technology). A significant contribution to SHS has been made by

specialised international symposia and the 'International Journal of Self-Propagating High-Temperature Synthesis'.

This review considers only those combustion and explosion processes which are aimed at the development of materials with predetermined properties, namely, the synthesis of novel materials or imparting novel properties to the existing materials by virtue of their processing. The former approach entails material-synthesising combustion and detonation processes, while the latter is confined to material processing.

In considering miscellaneous material-synthesising processes, special attention will be given to combustion and explosion products as subjects for the synthesis and mechanisms of transformation of the starting elements in combustion and detonation waves (chemical reactions, phase transitions, structure formation of final products, *etc.*) and theoretical aspects of combustion and explosion. The main emphasis in the analysis of material processing will be laid on processing of materials by combustion and explosion, effects of high temperatures and high pressures on materials and interactions of processed materials with the green mixture.

II. Material-synthesising technological combustion and explosion processes

Material-synthesising processes include:

- classical technologies, *e.g.*, blast-furnace processes, out-of-furnace metallurgy, incomplete combustion of hydrocarbons, *etc.*;
- self-propagating high-temperature synthesis (primary and advanced SHS);
- processes carried out in shock and detonation waves.

1. Classical processes. Out-of-furnace metallurgy

Some examples of classical processes aimed at the preparation of novel materials by combustion and explosion are given in Table 2. Although these technologies are out of date and are being

Table 2. Classical processes of industrial combustion.

Process	Combustion regime	Raw materials	Final product
Blast furnace process	filtration	coke, ore, additives, air	cast iron
Out-of-furnace metallothermy	liquid flame	ground ore or metal oxides	ferroalloys and reinforcers or reduced metals
Combustion of rich hydro-carbon-air mixtures	condensation	gaseous or liquid hydrocarbons, air	industrial carbon (soot)

developed at a very slow pace, they still find application as industrially useful processes.

Out-of-furnace metallothermy,⁷ *i.e.*, a redox process carried out in powder mixtures of metal oxides and reducing metals in a combustion mode, is one of the most well-developed and well-studied classical processes. It was first implemented by N N Beketov and, later, by V M Goldschmidt as early as the 19th century; however, the first theoretical combustion research into metallothermic compositions (thermites) were carried out by A F Belyaev and L D Komkova as late as 1950.⁸ The fundamental of out-of-furnace metallothermy has been detailed in the well-known book.⁷

The chemical scheme of an out-of-furnace metallothermic process can be presented as follows:

where M_mO_n is the oxide of the metal to be reduced, M' is the reducing metal and Q is the heat of combustion. If the heat of combustion is high, the combustion proceeds in a wave mode. Al (aluminothermy), Mg (magnesiothermy), Ca (calciothermy) and Si (silicothermy) are generally used as reducing metals. Out-of-furnace metallothermy is used for joining metals and alloys. The most significant achievements have been attained in the production of ferroalloy ingots, hardeners and rare metals.

Special attention in the development of out-of-furnace metallothermic processes should be given to aggregate states of the final and by-products. A chart of the aggregate states of two combustion products [a reduced metal (P_1) and a reducing metal oxide (P_2)], which is based on thermodynamic calculations, is shown in Fig. 3.³ The two coordinates, $T_{ad}/T_m(P_1)$ and $T_{ad}/T_m(P_2)$, reflect the correlation between the combustion and melting temperatures of the reduced metal and the reducing metal oxide. Here, T_{ad} is the adiabatic combustion temperature of the metallothermic mixture; $T_m(P_1)$ and $T_m(P_2)$ are the melting temperatures of the reduced metal and the reducing metal oxide, respectively.

There are four adiabatic combustion zones differing in the aggregate states of a metal to be reduced and a reducing metal, *viz.*, zone I, solid metal and solid oxide; zone II, solid metal and liquid oxide; zone III, liquid metal and liquid oxide and zone IV, liquid metal and solid oxide. As can be seen from Fig. 3, the theoretical points are localised in all the four zones.

Of particular interest is zone III where a heterogeneous molten mass consisting of liquid metal oxide and drops of a liquid metal is formed. The drops sediment in the gravitational field of the Earth to produce an ingot. Such a phase separation allows easy isolation of the final product.

The combustion temperatures of the aforementioned systems depend on the pressure of an external gas, which suppresses

Figure 3. Aggregate states of combustion products prepared by out-of-furnace metallothermy. The pressure of the ambient gas is 0.1 MPa. Reducing metal: (1) aluminium, (2) magnesium, (3) silicon, (4) calcium. For description of zones I–IV see text.

gasification in the combustion. The dependences of the combustion temperatures on the gas pressure for some metallothermic systems are shown in Fig. 4.

Contamination of final products with reducing metals is the main disadvantage of out-of-furnace metallothermy.

Reduction of impurity content in the out-of-furnace ingots is a difficult task. Studies aimed at governing the chemical composition of Nb ingots prepared by aluminothermic reduction of Nb_2O_5 in the presence of Mg have been undertaken at ISMAN. In these studies green mixtures with the variable compositions and densities and variations of external gas pressures and of gravitational effects were used as the most modern methods for controlling the composition. The purest specimen of niobium obtained by this method contained 1.6 mass % Al, 0.04 mass % Mg and 0.74 mass % O. These results corroborate the conclusion by Yelyutin⁹ that out-of-furnace metallothermy and refinement can be used for the preparation of pure metals.

Recently, Freidin *et al.*¹⁰ have developed a method for the synthesis and refinement of molten products in a single technological step. To this end, a refining additive was mixed with a small

Figure 4. Dependence of combustion temperatures of various metallothermic compositions on ambient gas pressure (P). (1) $MoO_3 + 2 Al$, (2) $CrO_3 + 2 Al$, (3) $WO_3 + 2 Al$, (4) $V_2O_5 + 5 Ca$, (5) $2 WO_3 + 3 Si$, (6) $Ta_2O_5 + 5 Mg$.

portion of the green mixture and placed under the bulk of the green mixture which gradually converted into a melt. The melt passed through the layer with the refining additive thus undergoing purification and crystallised. The ingots thus prepared contained lesser amounts of impurities. This approach proved to be especially efficient in the aluminothermic synthesis of phosphide copper¹¹ and high-purity iron (total content of impurities did not exceed 0.01%). The feasibility of this approach in the synthesis of a broad range of metallothermic products presents interest. The most recent achievements in this area have been documented.^{12, 13}

2. Solid-flame combustion and self-propagating high-temperature synthesis

Solid-flame combustion (SFC) is a self-sustained chemical wave process which yields fully or predominantly solid products (materials). The following types of SFC are known:

- gasless (solid-phase, liquid-phase, multiphase) combustion;
- infiltration combustion (with spontaneous or forced infiltration);
- condensation combustion (*e.g.*, of gases and condensed systems).

The phenomenon of SFC was discovered by Merzhanov *et al.*¹⁴ and registered in the USSR Register of State Inventions and Discoveries under No. 287 in 1967. It was found that slow self-inhibited solid-phase reactions may be concentrated in definite zones following local initiation and proceed thereafter at fast rates commensurate with the propagation rate of the combustion wave. This unique phenomenon and the products formed immediately evoked keen interest from investigators. This discovery was preceded by studies on 'ignition' of metallothermic mixtures (Beketov and Goldschmidt, around 1900) and combustion of thermites (Belyaev and Komkova, 1950)⁸ and copper acetylenide (Borovinskaya and Merzhanov, 1966)⁸ and by development of a gasless combustion model (Maksimov, Merzhanov and Shkiro, 1965).¹⁵ However, none of SFC processes could be implemented without a thorough knowledge of modern combustion theory.

Titanium monoboride was the first compound prepared by SFC.

The snapshots illustrating the formation of TiB from solid elements are shown in Fig. 5 which has become widely popular. These frames depict the main stages of the combustion process, *i.e.*, initiation (ignition), propagation of the combustion front and cooling of the solid product. Depending on the operational

Figure 5. Frames of an SHS process; (a) initiation ($t = 0$), (b, c) propagation of the combustion front [$t = 0.1$ s (b) and 2.7 s (c)], (d) cooling ($t = 4$ s).

conditions, the solid formed may represent a substance, a material or an end product.

The synthesis of compounds by SFC has got the name of self-propagating high-temperature synthesis (SHS). SHS is used for obtaining chemical compounds with predetermined compositions, structures and properties.

SHS is usually subdivided into primary and advanced SHS. This classification reflects the rapid progress in this area, which has changed the very concept of this synthesis.

Under primary SHS is understood the combustion of 'solid + solid' and 'solid + gas' systems and the formation of high-melting (refractory) materials (carbides, borides, nitrides, silicides, *etc.*) by direct synthesis, *i.e.*, based on the exclusive use of chemical elements as the starting reactants. Advanced SHS includes all possible combustion modes and yields valuable solid products and materials.

The fundamental tasks of primary SHS are as follows:

- studies of regularities and mechanisms of combustion;
- mathematical simulation of combustion;
- establishment of a relationship between the product composition and operational conditions (combustion);
- optimisation of operational conditions for the preparation of single-phase compounds.

3. Primary SHS

Although the build-up period of primary SHS was relatively short (1967–1972), it was marked for fundamental discoveries.^{16–21}

First, the nature of solid-flame combustion was elucidated. Until that time, it was unclear how slow solid-phase reactions leading to solid products could occur in fast regimes, such as combustion. To rationalise this phenomenon, one had to abandon the equilibrium flame propagation theory proposed by Ya B Zeldovich and D A Frank-Kamenetsky.²² According to this theory, the width of the reaction zone in the combustion wave is much narrower than that of the preheating zone and can often be neglected.[¶]

However, in the solid-flame processes the reaction zone is significantly wider than that of the preheating zone due to strong self-inhibition of the combustion reaction[†] (the non-equilibrium theory). Moreover, the reaction zone may even involve the afterburning subzone, which does not influence wave velocity. The concept of broad reaction zones¹⁹ has subsequently become very popular. In terms of the non-equilibrium flame propagation theory, the SFC wave has a multizone structure and comprises three main zones, *viz.*, the preheating (preheating) zone ($T_0 - T_f$), the zone where the major heat is evolved, which determines the combustion rate ($T_f - T_*$), and the afterburning zone ($T_* - T_f$). Here, T_0 is the initial temperature, T_f is the temperature of the combustion front separating the preheating zone and the reaction zone (the inflection point on the temperature curve) and T_* is the temperature determining the combustion rate (Fig. 6). These fundamental concepts underlie the novel, non-equilibrium flame propagation theory.²³

According to this theory, the wave velocity U in broad zones is determined by the temperature T_* ($T_f < T_* < T_{ad}$) which reflects the incompleteness of conversion of the substance ($\eta_* < 1$)

$$U^2 = A \frac{T_*^2}{\eta_*} \exp\left(-\frac{E_a}{RT_*}\right),$$

where A is the value determined by the reaction rate and heat transfer constants, η_* is the degree of conversion at temperature T_* and E_a is the activation energy.

¶ This concept has been used in nearly all theoretical studies on flame propagation.

† The term 'self-inhibition' implies that the rate of combustion decreases drastically as the substances are burnt out. In the case of classical processes of flame propagation in gases, this effect is small.

Figure 6. A schematic diagram of the structure of a solid-flame combustion wave (1), depth of conversion (2) and heat release rate in combustion (3).

Yet another important result is related to the elucidation of the infiltration combustion mechanism of ‘solid — one-component gas’ systems. Here it is necessary to distinguish between the gas inside and outside pores of a sample (internal and external reactants). At relatively low pressures, the propagation of the combustion wave is provided by infiltration of the external gas through the pores of the solid sample. Studies of combustion of zirconium in nitrogen¹⁷ have established two limiting modes: the layer-by-layer mode (Fig. 7a) and the surface (Fig. 7b) mode. The interconversion of these two processes has been studied (Fig. 7c). It was shown that the combustion mode is unambiguously described by the criterion π equal to the ratio of the characteristic times of infiltration (t_f) and the reaction occurring in the wave (t_r):

$$\pi = \frac{t_f}{t_r} \sim \frac{Ud}{P_0},$$

where d is the diameter of the sample and P_0 is the pressure of the ambient gas.

Figure 7. Layer-by-layer (a) and surface combustion (b) in ‘porous solid — gas’ systems and some regularities of their interconversions (c); m_c , nitrogen content in the centre of the sample, $\bar{m}$, average nitrogen content in the sample.

The infiltration (surface) combustion mode meets the criterion $\pi \gg 1$. In this case, the reaction is fast and the gas has no time to penetrate inside the sample; therefore, the combustion occurs only in the surface layers. The kinetic (layer-by-layer) combustion mode meets the criterion $\pi \ll 1$.

The development of infiltration concepts has provided a clue to uniform combustion of hybrid systems. The very first results in this area have stimulated numerous experimental and theoretical studies which culminated in the development of a general theory of infiltration combustion.²⁴

Yet another important event is the discovery of combustion spin waves.¹⁸ Under certain conditions, flame propagation occurs in an unstable mode, as a result of which the combustion centre begins to move along the sample by a spiral path rather than as a flat layer. A non-steady-state two-dimensional flame propagation model has been developed in order to elucidate the nature of this phenomenon.^{25,26} The frames (a) and computer simulation (b) of spin combustion are shown in Fig. 8. As can be seen (Fig. 8a), the combustion centre appears from the rear of the sample, moves in the lateral direction and disappears. The computer version was obtained after solution of the simplest two-dimensional non-steady-state problem of a transition to the post-ignition flame propagation mode:

$$\begin{cases} c\rho \frac{\partial T}{\partial t} = \lambda \left(\frac{\partial^2 T}{\partial x^2} + \frac{1}{x^2} \frac{\partial^2 T}{\partial \varphi^2} \right) \rho Q \frac{\partial \eta}{\partial t} - \alpha_t (T - T_0) \\ \frac{\partial \eta}{\partial t} = k_0 (1 - \eta) \exp \left(-\frac{E_a}{RT} \right) \end{cases}$$

Figure 8. Snapshots of spin combustion of hafnium in a nitrogen — argon mixture (a) and visualisation of solutions of equations describing the spin waves (b).

Table 3. Examples of compounds prepared by primary SHS.

Compound	Metal content (mass %)		Non-metal content (mass %)		Lattice type	Unit cell parameters /Å	Micro-hardness /kg mm ⁻²
	total	free	total	free			
Titanium carbide	80.0	< 10 ⁻³	19.8	9 × 10 ⁻²	cubic NaCl	<i>a</i> = 4.323	2900
Zirconium carbide	88.2	< 10 ⁻³	11.4	< 10 ⁻²	"	<i>a</i> = 4.686	3040
Niobium nitride	86.9	< 10 ⁻³	13.0	—	"	<i>a</i> = 4.385	1670
Titanium nitride	77.6	< 10 ⁻³	21.4	—	"	<i>a</i> = 4.240	1800
Tantalum nitride	91.8	—	7.5	—	"	<i>a</i> = 4.323	3200
Boron nitride	43.8 ^a	0.2 ^a	55.7	—	hexagonal	<i>a</i> = 3.331, <i>c</i> = 3.518	—
Titanium diboride	68.6	—	31.0	10 ⁻¹	"	<i>a</i> = 2.619, <i>c</i> = 3.230	3500
Hafnium diboride	89.0	—	10.7	< 10 ⁻²	"	<i>a</i> = 3.134, <i>c</i> = 3.467	2890

^a Boron content is indicated.

with the following initial and boundary conditions:

$$\begin{aligned}
 &t = 0, x > 0: T = T_0, \eta = 0, \\
 &t > 0, x = 0: \begin{cases} T = T_{\text{ign}}, \text{ at } t \leq t_{\text{ign}} \\ \frac{\partial T}{\partial x} = 0, \text{ at } t > t_{\text{ign}} \end{cases} \\
 &t > 0, x = x_0: \frac{\partial T}{\partial x} = 0.
 \end{aligned}$$

Here, *c*, *ρ* and *λ* are the heat capacity, density and heat conductivity of the sample, respectively; *x* and *φ* are the integral and angular coordinates; *Q*, *E_a* and *k₀* are the thermal effect, activation energy and a preexponential factor, respectively; *α_t* is the heat exchange coefficient and *T_{ign}* and *t_{ign}* are the ignition temperature and the delay time, respectively.

An analysis of the calculated dependences *T(x, t)* and *η(x, t)* and the instantaneous linear combustion rate *dx/dt* at the point $(\partial\eta/\partial t)_{\text{max}}$ has shown that, depending on the parameters, the post-ignition process occurs in either a steady-state combustion mode or a spin, self-oscillating or chaotic (non-steady-state) mode. It should be noted that all the three unstable combustion modes, *viz.*, self-oscillating, spin and chaotic, can be realised in the same system for different parameters of the green mixture and under different operational conditions.

The discovery of spin waves gave impetus to the appearance of a huge number of publications and the spin wave has become a very popular subject of investigation in nonlinear dynamics.

However, the main result in the first stage of SHS development was associated with the synthesis of novel materials. A simple methodological scheme has been developed which included:

- elucidation of parameters determining the chemical and phase compositions of combustion products;
- analysis of their relationships;
- optimisation of conditions for the synthesis of homogeneous products.

Some examples of compounds obtained by SHS in the early stages of development of the method¹⁶ are given in Table 3.

As can be seen, SHS enables the synthesis of chemical compounds of very high quality. This circumstance has played a crucial role in the development of the SHS method as a whole.

Self-propagating high-temperature synthesis is a multiparametric process which is controlled by many mechanisms. This means that its optimisation presents a problem, but once optimum conditions have been established, one can obtain products exceeding in quality the products prepared with the use of low-parametric processes, *e.g.*, furnace synthesis.

Hence, primary SHS is a bright chapter in the history of solid-flame combustion.

4. Advanced SHS

A significant advance in the field of SHS has been made in the past 35 years after the discovery of the phenomenon of solid flame. These achievements include:

- considerable expansion of the raw material base for SHS, *i.e.*, the range of compounds applicable for SHS;
- further development of combustion chemistry, structural macrokinetics, nonlinear dynamics, three-dimensional simulation;
- elucidation of effects of physical fields on SHS;
- development of technologies and facilities (equipment) for SHS;
- calculation of technological and economic efficiencies of SHS;
- synthesis of various valuable SHS products;
- pilot-plant and large-scale production of SHS products;
- commercialisation and marketing;
- a search for novel SHS processes.

Here we outline only some general trends in the development of SHS and refer all those who are interested in this branch of chemistry to some recent reviews^{27–46} and papers.^{47–51}

The infrastructure of advanced SHS is shown in Fig. 9. It comprises three main areas where SHS studies are under way. However, these investigations differ in their intensities. Thus the fundamental principles of SHS are rather well-developed, while industrialisation and commercialisation aspects of SHS are the least explored. This is not surprising, since SHS has been following the route from science to technology.

5. Transformations in shock and detonation waves

Studies of chemical and physicochemical transformations of substances in shock and detonation waves under the action of waves with inherent high pressures, high temperatures and shear deformations are important areas of research which have considerable technological significance.

Two types of processes initiated by shock and detonation waves are shown in Fig. 10. In the former case, the necessary conditions for the transformation of a substance are generated by external factors; in the latter case, they are created by self-propagating detonation processes.

Both types of processes are used for the preparation of superstrong materials (*e.g.*, cutting diamonds and wurtzite-like BN).^{52–54} Studies of transformations of substances in shock and detonation waves have posed the question about their localisation: in the wave proper (over microseconds) or after passage of the wave front (*e.g.*, at residual temperatures 300–500 °C). Studies of transformations of various systems, *e.g.*, Al + Fe₂O₃, Sn + S, Sn + Te, Al + S, Zr + 2S, *etc.*, in shock waves carried out by S S Batsanov⁵⁵ have shown that in these systems the synthesis occurs directly in the shock wave and is over within 10⁻⁷–10⁻⁶ s.

Figure 9. The infrastructure of SHS.

Figure 10. Chemical synthesis and physicochemical conversions in shock and detonation waves.

Numerous papers devoted to transformations of substances in shock waves have been published. For specialists in detonation techniques, their practical implementation presents no problem. The simplest approach consists in mixing of a tested substance or a sample with an 'explosive', formation of a blasting charge and initiation of explosion in a blasting chamber. An analysis of solid particles gathered after detonation gives some information about the explosion-induced transformations.⁵⁶

Transformation of substances in the detonation wave is a new trend in the chemistry of combustion and explosion. In this case, we deal with shock-driven SHS where self-propagation of the wave is initiated by shock compression rather than heat transmission. Obviously, such processes can be realised only if transformation of substances is accompanied by an increase in the volume, *e.g.*, due to concomitant evolution of gas. This can be achieved by adding gas-evolving inert additives to the green mixture. This technological approach is used for the preparation of a broad range of SHS products.

Apparently, SHS was first discovered by I P Borovinskaya²¹ at the dawn of SHS studies, more exactly, in experiments with combustion of a boron powder in liquid nitrogen in a sealed vessel. If nitrogen was taken in excess, SHS was accompanied by explosion. Interestingly, all the vessels split in two in the same place. This finding led the author to conclude that combustion passes into explosion. Later, special experiments aimed at initiating detonation confirmed the possibility of detonation in such systems. Unfortunately, at that and subsequent times these works did not receive proper attention.

Some new data on SHS in shock and detonation waves have been described.^{57, 58}

6. On thermal explosion

The interest in thermal explosion as a technological process for the synthesis of novel inorganic materials has increased considerably in recent years.^{59, 60} Whereas the combustion wave is initiated in some particular locus artificially, in thermal explosion the external source warms up the whole mass of the green mixture and ignition occurs spontaneously as a result of self-acceleration of the reaction. Where and how such ignition occurs and how transformation of substances proceeds under conditions of thermal explosion are these questions critical for conducting SHS syntheses.

Critical conditions and induction period are the most important characteristics of thermal explosion. Critical conditions are those in which the reaction passes from a slow (non-isothermic) mode to a detonation mode; the induction period is the explosion delay time. In other words, investigators are interested in whether and when the explosion takes place. Such a statement of the problem is aimed at the solution of safety problems.

The use of thermal explosion for the preparation of materials has posed some new questions: how does explosion develop in the post-induction period? what are the transformation modes? how does explosion affect thermal and concentration quasi-homogeneities? And so on.

The first explicit answers to these questions were given in a theoretical paper devoted to SHS.⁶¹ We studied thermal explosion in both induction and post-induction periods up to complete conversion of the reactants. It was concluded that the process depends essentially on the ratio of internal heat transfer and external heat emission, the so-called Bio criterion (*Bi*)

$$Bi = \frac{\alpha r}{\lambda},$$

where α is the heat emission coefficient from the surface of a sample, r is the characteristic size of the sample and λ is the thermal conductivity of the green mixture.

At nearly all values of Bi (with the exception of the ideal case where $Bi = 0$), the temperature and concentration fields in the sample are nonuniform. Ignition takes place at a point where the temperature in the induction period is the highest and is accompanied by rapid elevation of temperature. The reaction spreads further from the spontaneous ignition site in the form of a combustion wave causing layer-by-layer transformation of the reacting charge into the reaction product.

There are two modes of combustion wave propagation. One of them is characterised by higher values of Bi and consists in the transmission of heat from high-temperature products to initial reactants by a classical flame propagation mechanism. In the other mode, the process is controlled by the temperature gradient generated in the induction period. In the latter case, the wave propagation is apparent being unrelated to the heat transfer mechanism and is initiated by sequential (layer-by-layer) adiabatic self-ignition of the green mixture. The second mode is realised at very low Bi values ($Bi \ll 1$).

Theoretical studies^{62–64} are devoted to a detailed analysis of the nature and mechanisms of thermal explosion in the post-induction period. The results of these studies correlate with the aforementioned concepts which have considerable methodological significance. In current literature, thermal explosion was often opposed to SHS under the *a priori* assumption that thermal explosion represents three-dimensional combustion of the green mixture. It was found, however, that at $Bi \neq 0$ thermal explosion comprises a stage corresponding to the self-propagating process involving up to 80% of the reacting green mixture. After publication of the work,⁴⁸ two SHS modes came to be argued: artificial initiation of SHS and spontaneous (although local) initiation.

Until recently, there have been no experiments aimed at the application of thermal explosion to material-forming processes. The ideas developed in theoretical studies have long remained unclaimed which can be attributed to the difficulties in the implementation of SHS because of significant fluctuations in temperature, temperature gradients and characteristic time scales in a single technological process. Notwithstanding, recently such publications did appear (for a review see Ref. 60). It was shown that the synthesis of materials by thermal explosion is more applicable to those reactions that are not sufficiently exothermic where local ignition fails to induce further propagation of the combustion wave due to heat losses.

It was shown^{65,66} that thermal explosion in specially designed moulds and SHS compaction of the reaction product gives useful (from the standpoint of materials science) results.

Unfortunately, all the works aimed at the synthesis of materials by thermal explosion are carried out with no relation to macrokinetic concepts and studies which leads to a significant impoverishment of experimental data.

III. Material-affecting combustion and detonation processes

Processing of materials by combustion includes all kinds of flame coating: gas-thermal spraying (gas flames), aluminothermic welding ('liquid' flames), induction welding (microwave-induced thermal explosion) and condensation coating (chain flames). This category also includes remelting of reject or waste intermetallic articles and welding of components by electrothermal explosion.

In combustion and explosion processes, processable material is loaded into the reaction chamber together with the green mixture. The position of the green mixture relative to the processable material can be different: (1) the processable material

is inside the green mixture; (2) the processable material and the green mixture are spatially apart but are in contact with one another and (3) the processable material and the green mixture are spatially apart and do not contact.

1. Material-affecting combustion

Combustion-induced material-affecting is carried out at high temperatures generated upon burning of the charge.

Aluminothermic welding, *i.e.*, coating of moulded hard alloys onto flat steel surfaces, is the most popular procedure.²⁷ The principle of this method is very simple and consists of the following. A layer of an aluminothermic green mixture able to form a 'hard' alloy is applied onto a steel plate (Fig. 11 *a*). After combustion of the mixture, a heterogeneous melt consisting of the 'hard' alloy and liquid alumina is formed on the surface of the plate. Under the action of gravitational forces, the melt stratifies in such a way that the lower layer adjacent to the steel base consists of the hard alloy and the upper layer consists of alumina. The latter performs an accessory function by protecting the hard alloy from oxidation by atmospheric oxygen. Thermal and chemical interactions of the 'hard' alloy with the steel plate result in a broad gradient intermediate layer (Fig. 11 *b*). After crystallisation of all layers, the oxide layer peels off leaving a steel part coated with the hard alloy.

The distribution of concentrations of chemical elements and microhardness as a function of the distance from the alloy (the molten layer) to the base are shown in Figs 12 and 13. The

Figure 11. Application of a moulded coating onto a steel base (SHS welding); (a) prior to processing by combustion, (b) after processing.

Figure 12. Distribution of chemical elements in a layer welded onto a steel plate (x is the layer height). Composition of the green mixture: $\text{TiO}_2 + \text{CrO}_3 + \text{NiO} + \text{Al}$.

Figure 13. Distribution of microhardness according to Rockwell, the hardness scale A (HRA) in a welded layer.
The starting mixture: (1) Cr–Ti–C–B–Ni, (2) Cr–Ti–C–Ni, (3) Cr–C–Ni, (4) Cr–C–Fe.

presence of a distinct, broad (from 0.5 to 1.5 mm) intermediate zone is an obvious advantage of SHS welding, since it eliminates adhesion owing to the high degree of binding between the coating and the base.

Aluminothermic welding allows application of relatively 'thick' (> 0.5 mm) layers. Thinner layers are coated by induction SHS welding. This process is technologically similar to that described above, except that the charge layer is smaller and the process is implemented in a high-frequency electromagnetic field.⁶⁷ Numerous green mixture compositions aimed at the solution of miscellaneous practical tasks have been developed.

Electrothermal welding is yet another example of a material-affecting SHS.^{68–70} In this process, the conducting green mixture (welding compound) composed of chemical elements is loaded into a gap between the parts to be welded which also play the role of electrodes. When electric current is passed through the electrodes, the green mixture is heated to self-ignition. The parameters are chosen so that the thermal-explosion product is formed in the melt. This interacts with the submolten layers of the parts to be welded and forms a fairly strong welding joint after crystallisation. The strength of the welding joint can be increased, if the melt is extruded from the gap prior to crystallisation with a simultaneous decrease in its thickness.

This approach was used for welding refractory parts of Nb, Ta, W, Mo and C to one another and between themselves. One of the most recent developments is welding of a hard alloy BK8 to the 40X steel.⁷⁰ A micrograph of a thin section of the welding joint is shown in Fig. 14. The Zr + Ni green mixture was used as the welding material.

The Zr + Ni green mixture ensures high strength of the welding joint: the break occurs in the hard alloy but not in the joint. Such a high breaking strength cannot be provided by conventional brass plating.

Figure 14. SHS welding. A micrograph of a longitudinal section of the solid alloy BK8 and the steel 40X.

Characteristics of the welding joints produced by SHS and traditional fusion are given in the table below.

Welding material	Flexural strength /MPa	Fracture surface
Ti + Ni	400–600 (welding)	welding joint
Zr + Ni	600–800 (welding)	hard alloy
Brass plating	200 (soldering)	welding joint

SHS welding is used for thermal bonding of refractory materials where conventional electric welding is of little effect.

2. Material-affecting explosion

A crucial role in material-affecting explosion is played by detonation energy which produces high pressure. Under the impact of high pressure, the processable material undergoes plastic deformation. Simultaneous action of pressure and temperature on the processable material induces physicochemical transformations.

All detonation effects on processable materials are subdivided into mechanical and structural. The former includes crushing, dispersion (brittle fracture), pressing, calibration, punching and cutting (plastic destruction); the latter includes reinforcement of metals (workhardening), compaction of metal powders (controlled structure formation) and welding (bonding) of metals.

Explosion-induced welding is the most popular and technologically efficient procedure. A welding scheme of two plates is shown in Fig. 15. After welding, the flat surfaces of both plates acquire a wave-like shape. Pictures of typical welding joints are shown in Fig. 16. Interestingly, the cross-sections of welding joints of homogeneous metals manifest a purely sinusoidal shape (Fig. 16a), whereas the S-shape of the welding joints of heteroge-

Figure 18. Detonation cutting: cumulative charges (a) and slit items (b).

neous (or, more exactly, heterodense) metals is distorted due to the appearance of higher harmonics, which change the wave profile. This phenomenon was described in detail by Gordoplov.⁷¹ Wave formation is a useful process, since it increases the strength of the welding joint.

Pictures of some items prepared by explosion-induced welding are shown in Fig. 17.[‡] The most common practical task relates to the production of bimetallic rolled stock from billets obtained by explosion-induced welding.

Cutting of metals by explosion is also a highly efficient process. It is opposite to welding and is based on the use of cumulative jet streams generated by cumulative green mixtures. Significant progress in this field has been attained by a research team headed by V V Kalashnikov at the Samara State Technological University.⁷² Photographs of cumulative charges and items processed by this technology are shown in Fig. 18. Detonation is also used for cutting metals with thicknesses of 1 cm and more.

IV. Combustion and explosion in physical chemistry of inorganic materials

The physicochemical aspects of combustion and explosion science are sufficiently well-studied as can be evidenced from numerous publications (particularly, those devoted to combustion)[§] which have made a significant contribution to the development of high-temperature physical chemistry.

However, the boundaries of combustion and explosion as an independent trend of research in physical chemistry have not been adequately outlined. It remains to note that the science of combustion and explosion studies chemical and physicochemical transformations which occur spontaneously (after initiation) under non-isobaric and/or non-isothermal conditions, in a non-steady-state mode, have low characteristic times and yield (exclusively or predominantly) solid products.

The latter circumstance is of particular importance, since this review is devoted to materials.

[‡] These pictures were made by Yu A Gordoplov in 1978, they were presented in a Report of the United Institute of Chemical Physics of the Academy of Sciences of the USSR.

[§] A more prominent role in the explosion theory is ascribed to gas-dynamic factors.

Let us consider briefly some recent trends in physical chemistry of inorganic materials related to combustion and explosion processes.

1. On the chemistry of combustion and explosion

Study of the chemical mechanisms is one of the main areas of research in combustion and explosion science, which is sometimes referred to as the chemistry of combustion and explosion. Its main goals are as follows:

- determination of intermediate and final stages in combustion and detonation waves;
- development of methods for the isolation of intermediate products;
- characterisation of final products and its relationship to operational regimes.

Let us consider the formation of yttrium–barium cuprate possessing superconducting properties in a combustion wave as an example. This synthesis is a very ‘capricious’ process, since the final compound is thermally unstable, easily loses oxygen and, as a consequence, its superconducting properties. Traditionally, it is prepared by furnace synthesis using the reaction:

It was recommended⁷³ to perform this synthesis from a mixture containing copper, barium peroxide and yttrium oxide powders.

Although combustion of this mixture is easily initiated, the preparation of a high-quality product demands optimisation of conditions of synthesis. To meet this goal, the mechanism of this reaction in the combustion wave was studied. The formation and consumption of intermediate products and the formation of the final product were studied using different techniques. The reaction mechanism is as follows:⁷⁴

The final stage represents a phase transition from a non-superconducting tetragonal phase to the superconducting orthorhombic phase with an insignificant overoxidation of the cuprate formed. The knowledge of this mechanism has made it possible to develop a technology for synthesising of a high-quality product with remarkable superconducting properties.⁷⁴ Some characteristics of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ powders synthesised in the combustion wave (grade SHS samples) and by furnace synthesis (other samples) are given in Table 4 (see Ref. 75). A comparative study of these powders was carried out by the US company ‘Super Conco’. As can be seen from the Table, the SHS-J2 powder prepared by SHS is by far the best.

2. Kinetics of chemical reactions at high temperatures

Whereas the knowledge of chemical mechanisms of reactions occurring in a combustion wave helps control the quality of final products, kinetic studies are necessary for elucidation of mechanisms of self-propagation of the combustion wave. In the latter case, the main interest is focused on the kinetics of heat evolution.

Table 4. Comparative characteristics of powders of the high-temperature superconductor $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ prepared by the furnace method and SHS.

Sample	Content of oxygen ^a (a.u.)	Transition temperature /K	Y_{123} orthorhombic phase content (%)	Main impurities	Average particle size / μm
SC5-S	6.92	93.5	98	CuO	40.0
SC-P	6.87	93.5	99	CuO	8.2
SC5-6.5	6.88	90.5	97	BaCuO_2	6.8
SC5-7	6.85	92.5	99	CuO	5.7
CPS A-1203	6.85	92.0	99	BaCuO_2	3.0
SSC 03-0065	6.89	92.0	99	—	6.5
SHS-J1	6.90	92.0	97	CuO	9.0
SHS-J2	6.92	93.5	99	—	8.0

^aOxygen content was determined by iodometry.

It should be noted that the kinetic aspects of explosion science are not sufficiently developed (here, thermodynamic and gas-dynamic interests 'dominate'). In contrast, in combustion science these aspects constitute an independent and well-developed area of research. Direct kinetic studies are hardly possible due to high reaction rates and high temperatures; therefore, kinetic information is derived from the very combustion experiments using indirect methods. Determination of effective activation energy, E_{eff} (see Refs 76 and 77) using the formula:

$$U^2 = AT_{\text{ad}}^2 \exp\left(-\frac{E_{\text{eff}}}{RT_{\text{ad}}}\right)$$

is an example of such an approach.

A method for processing temperature profiles in the combustion wave aimed at determination of the heat evolution rate $\dot{q}$ (dq/dt) as a function of the temperature T and the amount of evolved heat q , has been developed.⁷⁸ It is reduced to the solution of the kinetic equation:

$$\dot{\eta} = f(T, \eta), \quad \eta = \frac{q}{Q},$$

where $\dot{\eta}$ is the reaction rate. Correct determination of the initial stages of transformations of various substances by this method is difficult: it provides reliable kinetic information only at more advanced stages of the conversion. Nevertheless, direct kinetic studies of chemical reactions in the temperature range close to that of the combustion wave were carried out for one class of reactions, *viz.*, high-temperature reactions of metals with gases. The method in question represents electrothermography for kinetic studies.^{79, 80}

The principle of the method is simple and well-known. A system of two reactants, *viz.*, a thin filament made of the tested metal and a gas, is considered. The metal filament is heated by electric current and thus plays the role of a reactant and a high temperature source. The advantage of this method^{79, 80} is that it employs an optical or electrical monitoring system and heat evolution compensation for maintaining the constant temperature of the filament by attenuation of the electrical power. This procedure allows recording time dependences of heat evolution rates at different constant temperatures. The process can easily be stopped by switching off the current (the cooling is complete within fractions of a second); the kinetics of growth of diffused layers is deduced from metallographic analysis of filament sections. The electrographic method was used to study the kinetics of reaction of some transition metals (Groups IV and V of the Periodic Table) with nitrogen, oxygen, hydrogen, silane and some hydrocarbons.

The dependences of heat evolution rates on the growth time and the width of the tantalum nitride film (product) for the

**Figure 19.** Kinetics of heat evolution in the high-temperature nitrogenation of tantalum.

$T/^{\circ}\text{C}$: (1) 2210, (2) 2300, (3) 2610, (4) 2700, (5) 2850, (6) 2970.

**Figure 20.** Kinetics of product layer growth (d) during high-temperature nitrogenation of tantalum.

$T/^{\circ}\text{C}$: (1) 2420, (2) 2570, (3) 2650, (4) 2750, (5) 2840, (6) 2930.

reaction of tantalum with nitrogen are shown in Figs 19 and 20.^{81, 82} An analysis of experimental results revealed that this process is described by a kinetic equation:

$$\dot{q} = 8.6 \times 10^{-2} \exp\left(-\frac{40\,800}{R}\right) q^{-1} \text{ (kcal}^2 \text{ cm}^{-4} \text{ s}^{-1}\text{)},$$

which reflects the parabolic oxidation law. Note that these results were obtained in a high-temperature range [2210–2970 $^{\circ}\text{C}$ (!)].

Interesting studies of reactions of metals with complex gases (hydrocarbons, silane, *etc.*) have been carried out by Kharatyan *et al.*^{83–85} In these multistep processes, decomposition of the gas on the surface of the filament and the formation of a solid film (carbon, silicon) were followed by the interaction of the latter with the metal by a diffusion mechanism.

3. Thermochemistry and thermodynamic calculations

An important line of investigations includes quantitation of the amount of heat evolved during reactions of chemical elements in a combustion mode. These data enable easy determination of the heats of formation of various compounds with allowance for incomplete burning and impurities. The heats of formation of some high-melting materials prepared by SHS (carbides, silicides, borides) have been determined.⁸⁶ Direct measurement of heats of formation in a combustion mode gives more accurate results than the conventional method based on combustion of tested substances and the starting reactants in oxygen or fluorine. In the classical method, the values of the heats of formation represent a small difference of large numbers, which is a potential source of errors.

For carbides and silicides, which are readily burnt in oxygen or fluorine, the scatter in the values of heats of formation obtained by different authors is small. The values of the heats of formation obtained by direct measurement of the amount of the heat evolved in SHS are in good agreement with the literature data.

Borides are more stable compounds and their combustion is often incomplete, hence the scatter in the values of heats of formation cited in the literature. For these compounds, the direct measurements are more important in principle. The heats of formation of titanium-, zirconium-, hafnium- and other metal borides obtained by both methods are listed in Table 5.

Table 5. Heats of formation of metal borides.

Reaction	Heat of formation /kcal mol ⁻¹

^a Published data.

An important role in thermodynamic studies is ascribed to calculations of adiabatic temperatures and equilibrium compositions of combustion and detonation products. However, in the case of detonation processes such calculations are complicated due to the lack of reliable information about equations of state at high pressures and temperatures. As regards combustion and especially SHS, these processes are sufficiently well documented. There are two approaches to thermodynamic calculations.

In the first (approximate) approach, combustion temperature is determined under the assumption that the compositions of the products are known.⁴⁴ The calculations are made according to the equation:

$$\int_{T_0}^{T_{ad}} c(T) dT = (Q - \sum_{i=0}^n L_{ph}^i) - \mu_{ph} L_{ph},$$

where c is the thermal capacity of the product, Q is the heat of formation at T_0 , L_{ph}^i are the heats of phase transitions at $T_{ph}^i < T_{ad}$, n is the number of phase transitions at $T_0 < T_{ph} < T_{ad}$, L_{ph} and μ_{ph} are the heats of phase transitions and the content of the high-temperature phase in the combustion product at $T_{ph} = T_{ad}$, respectively. At $T_{ph} > T_{ad}$ $\mu_{ph} = 0$, at $T_{ph} < T_{ad}$ $\mu_{ph} = 1$.

This method was used⁸⁷ for the calculation of T_{ad} for many self-propagating high-temperature reactions which yield a single product. The data obtained shed more light on the combustion mechanisms of many specific systems.

In the general case, the calculations are performed using a complete procedure which allows simultaneous determination of T_{ad} and equilibrium compositions of reaction products at T_{ad} . Originally, this approach was used in combustion studies of propellants, but after some modifications it was extended to material-synthesising combustion processes.

The first calculation of this kind was performed for direct synthesis of iron from iron oxide by reduction with methane.⁸⁸ A three-dimensional diagram of the combustion products is shown in Fig. 21 (the hatched area corresponds to the formation of reduced iron as a single condensed product).

Numerous thermodynamic calculations have now been performed. A special ISMAN-TERMO programme and a database

Figure 21. A triple diagram of combustion products in the $\text{Fe}_2\text{O}_3 + \text{CH}_4 + \text{O}_2$ system.

of adiabatic combustion temperatures of binary and ternary systems have been developed by the researchers of ISMAN.

4. Physicochemical effects in the mechanisms of combustion and detonation

Material-synthesising combustion and explosion are associated with evolution and transfer of heat (combustion) or a release of energy and shock-driven compression (detonation). As a rule, these processes are accompanied by various (mostly, physicochemical) effects and involve phase transitions. Their analysis falls also under the scope of physical chemistry of inorganic materials.

Let us consider several examples. Combustion of powder mixtures of low-melting metals (Ti, Zr) with more refractory non-metals (C, B) is accompanied by a very important effect termed 'capillary spreading'.⁸⁹ The mechanism of this effect is as follows. Prior to reaction with a non-metal in the precombustion zone, the metal reactant melts and spreads over the surface of refractory non-metal particles. Since the sizes of carbon and boron particles are usually 2–3 orders of magnitude smaller than those of the metal particles, the above-mentioned process results in spontaneous homogenisation of the green mixture, which increases the reaction rate and, correspondingly, the combustion rate. The experimental values of the combustion rates of the Ti + C systems are 10–15 cm s⁻¹. Such high rates for processes occurring in the condensed phase can be attributed exclusively to a significant increase in the reactivity of the green mixture.

Phase transitions (e.g., melting) have a significant effect on the structure of the combustion wave. The temperature profile of the combustion wave is distorted due to phase transitions, these induce the appearance of isothermal plateaus on the temperature curve and a shift of the combustion zone, which determines the wave velocity, from the high- to the low-temperature zone (see, e.g., Ref. 23).

Let us consider another example of a detonation process associated with physicochemical transformations in shock waves. After investigators of detonation have learnt to preserve the integrity of samples exposed to the shock wave, their attention came to be focused on the nature of changes caused by detonation. First of all, they posed themselves the question: where do phase transitions take place: in the shock wave proper (for an order of microseconds) or after passage of the wave at high residual temperatures? An answer to this question came after successful attempts to record the shock adiabat (the compression curve). The distortions in the smooth curve (shock adiabat) testified to physicochemical transformations in the shock wave. The shock

Figure 22. A shock adiabat of boron nitride.

adiabat for boron nitride shown in Fig. 22⁹⁰ provides an illustrative example of a phase transition from the hexagonal phase of BN to the wurtzite-like phase at increasing pressures.

At present, shock adiabats have been established for a broad range of compounds and are used for elucidation of shock compression mechanisms.

V. On the theory and mathematical simulation

Theoretical studies into material-synthesising combustion and detonation processes were largely concentrated on solid-flame combustion and made use of classical approaches developed in the flame propagation theory by Ya B Zeldovich for gases and further extended with account of formation of solid products (see, *e.g.*, Refs 6 and 35 and references cited therein). High thermal capacities, possible phase transitions of solid products and solid reactants and the lack of diffusion-driven transfer of products are the main factors responsible for the immense complexity of flame propagation modes.

Let us consider some key aspects.

As a rule, the information on the structure and velocity of the combustion wave is obtained through the solution of the simplest steady-state flame propagation equations:

$$\lambda \frac{d^2 T}{dx^2} - c\rho U \frac{dT}{dx} + Q\rho\varphi(T, \eta) = 0$$

(heat conduction equation),

$$U \frac{d\eta}{dx} = \varphi(T, \eta)$$

(kinetics equation)

where x is the linear coordinate of the combustion wave and $\varphi(T, \eta)$ is the kinetic function for the boundary conditions:

$$x = -\infty, T = T_0, \eta = 0$$

and

$$x = +\infty, \frac{dT}{dx} = \frac{d\eta}{dx} = 0.$$

The linear transfer of the reaction product was neglected in the solution of these equations; material-synthesising processes (*i.e.*, solid-phase reactions yielding solid products) were described by

the 'non-classical' kinetic functions $\varphi(\eta)$.[†] The following kinetic functions were employed in the very first theoretical studies:^{6, 19}

$$\varphi(\eta) = \exp(-m\eta)\eta^{-n},$$

where m and n are the constants.

More advanced theoretical studies took into account various features of evolution and transmission of heat in different systems, such as melting and formation of molten layers, transfer of mass and heat by infiltration after impregnation of initial porous green mixtures with the melt, multistep character of reactions, *etc.*^{91–93}

Description of flame propagation processes in hybrid 'porous body–gas' systems is a more complicated task. At relatively low gas pressures, solid reactants do not contact with one another and the transformation of the solid demands the delivery of a gaseous reactant to the combustion zone. Usually, this situation is analysed for one-component gases which are fully consumed upon reaction. This assumption suggests that their transport proceeds in a purely infiltration mode (if another gas is present, allowance is made for diffusion).

Numerous studies on filtration combustion modes have been carried out. One-dimensional filtration was found to occur in cylindrical samples with gas-impermeable lateral surfaces and open edges. The results of one-dimensional combustion studies have been generalised.⁹⁴ A theoretical analysis of more complex filtration regimes, *e.g.*, combustion with lateral filtration leading to limiting surface and layer-by-layer modes and high-pressure combustion, has been carried out.^{95, 96}

Of substantial interest are material-synthesising combustion implemented in non-steady-state modes (in unstable regions, in particular). Studies by Ya B Zeldovich have shown that the enthalpies of condensed systems in combustion waves exceed those of the starting reactants (at initial temperatures) or final products (at combustion temperatures) which are equal. The excess of enthalpy is the reason for the instability of the wave propagation. In the case of gas-releasing systems, such as explosives, instability leads to extinction of the process. Owing to their high thermal capacity, the condensed products prevent extinction and wave propagation continues, however, in a complex or abnormal mode. The existence of one-, two- and three-dimensional non-steady-state modes reflects the complex nature of spatiotemporal instability.

In the case of one-dimensional instability, the smooth (nearly flat) combustion front characteristic of steady-state modes is preserved, and only time instability is observed. In this case, we deal with the so-called self-oscillations where the instantaneous value of the combustion front velocity fluctuates around a certain mean value (the so-called harmonic or relaxation oscillations, Fig. 23). Figure 23 shows curves for the time changes in the instantaneous front velocity in dimensionless coordinates for different limiting stability loss values (α_{st}).

A novel mode of combustion has been established in model studies of two-dimensional instability of a hollow cylinder with account of temperature distribution and degree of conversion along the height and circumference of the cylinder with no allowance for the radial direction.¹⁸ Here we deal with the aforementioned spin wave where the reaction is concentrated in a centre moving along the sample by a spiral path. After a certain period of time, the velocity of the centre becomes constant indicating spatial instability, but temporal stability remains. Such regimes are usually described within the framework of a thin cylindrical shell model with allowance for longitudinal and tangential (angular) heat exchange components.

[†] The classical kinetic functions for the reactions of the n th-order appears as $\varphi(\eta) = (1 - \eta)^n$.

Figure 23. Self-oscillations of the front velocity as a manifestation of one-dimensional instability (U_{inst} and U_{st} are instantaneous and steady-state combustion velocities, respectively). The structure of pulses at different deviations from the stability limit $\alpha_{\text{st}} = 0.99$ (1), 0.94 (2), 0.82 (3), 0.64 (4), 0.50 (5).

Three-dimensional waves are generated in solid cylindrical samples under the action of a radial heat-exchange component. Such waves propagate in diverse modes which depend upon:

$$\alpha_{\text{st}} = \left(9.1 \frac{c\rho T_{\text{ad}}}{Q} - 2.5 \right) \frac{RT_{\text{ad}}}{E}$$

and

$$r = r_0 \left[\frac{Q}{c} \frac{E}{RT_{\text{ad}}^2} \frac{kT_{\text{ad}}}{a} \right]^{1/2}.$$

The former parameter corresponds to the stability loss limit (the smaller α_{st} the greater the instability), while the latter represents a dimensionless radius of a cylinder, *i.e.*, the ratio of the cylinder radius to the characteristic width of the narrow reaction zone. The smaller α_{st} and the larger r the more complex the instability pattern. Some novel three-dimensional non-steady-state combustion modes, *viz.*, spin waves with self-oscillations of the centre velocities, intermittent spin waves with temperature fluctuations, multipoint periodic waves with recurrent non-steady-state temperature and concentration fields and chaotic waves, have been described.^{97–101} Studies of heat losses to the environment have established several novel regimes of combustion wave propagation described by paraboloid-type functions.

Interestingly, all these previously unknown regimes are described by a classical system of equations which is physico-chemically the simplest, *viz.*, by the heat conduction equation in the cylindrical coordinates:

$$c\rho \frac{\partial T}{\partial t} = \lambda \left(\frac{\partial^2 T}{\partial r^2} + \frac{1}{r} \frac{\partial T}{\partial r} + \frac{1}{r^2} \frac{\partial^2 T}{\partial \varphi^2} + \frac{\partial^2 T}{\partial h^2} \right) + \rho Q \frac{\partial \eta}{\partial t}$$

and the kinetics equation:

$$\frac{\partial \eta}{\partial t} = \begin{cases} k_0(1 - \eta) \exp\left(-\frac{E}{RT}\right) & \text{for } \eta < 1, \\ 0 & \text{for } \eta \geq 1, \end{cases}$$

where r , φ and h are the spatial coordinates (r is the radial, φ is the angular and h is the longitudinal axes of the cylinder) supplemented by the following boundary conditions:

$$t = 0: T = T_0, \eta = 0;$$

$$t > 0: r = r_0, \quad \frac{\partial T}{\partial r} = -\alpha_t(T - T_0);$$

$$h = 0: \frac{\partial T}{\partial h} = 0;$$

$$h = h_0: \begin{cases} T = T_{\text{ign}} & \text{for } t \leq t_{\text{ign}}, \\ \frac{\partial T}{\partial h} = 0 & \text{for } t > t_{\text{ign}}, \end{cases}$$

where T_0 is the ambient temperature and the initial temperature of the sample; T_{ign} is the ignition temperature; α_t is the heat-transfer coefficient from the surface to the environment; r_0 and h_0 are the radius and the height of the cylinder, respectively, and t_{ign} is the duration of the initiating pulse.

The structure of a combustion front for a chaotic regime is shown in Fig. 24.

Figure 24. An example of a chaotic combustion regime in the $\text{Cr}_2\text{O}_3 + \text{Al} + \text{Al}_2\text{O}_3$ system (h , lead of screw thread; A , amplitude); (a) vibrations of the front coordinate relative to the average value, (b) amplitude–frequency spectrum.

All of the foregoing discussions related to processes occurring in mixed systems (powder mixtures). A more complex, but less explored instability pattern is observed in hybrid ‘porous sample – gas’ systems.

Unstable self-excited waves generated in various material-synthesising processes have become an attractive subject of

investigations in nonlinear dynamics. Investigators are contemplating the problem of making these processes more practicable.

VI. Materials science of combustion and explosion products

This important trend of research has a number of specific features, since the conditions of material-synthesising combustion and explosion differ dramatically from those used in ordinary processes, which cannot but reflect on the structures and properties of the final products.

Studies in the field of materials science develop along four main lines (chemical, physical, technical and theoretical).

The chemical materials science studies mechanisms of chemical and structural transformations in the combustion wave, dynamics of formation of the final structures of reaction products and their individual components (phase, crystalline, granular, porous, *etc.*), chemical properties of the reaction products (chemical analysis) and their relationship with conditions and parameters of the corresponding processes. Physical properties of materials and physical material processing fall under the scope of physical materials science. Technological materials science is concerned with the study of operational characteristics and applications of combustion and explosion products in different branches of science and technology. Theoretical materials science deals with structural and macrokinetic simulation and analysis of physical (equilibrium or non-equilibrium) states of reaction products in relation to thermal regimes.

The problem of equilibrium and non-equilibrium character of combustion and explosion products is very interesting and widely debatable. Peremptory and often erroneous judgements exist that the products formed are of non-equilibrium character, since the underlying processes are non-equilibrium. The incorrectness of this statement is due to the ambiguity of its solution, which depends on the criterion S :

$$S = \frac{t_{st}}{t_{tr}}$$

where t_{st} is the characteristic time of structure formation and t_{tr} is the characteristic product cooling time. If $S \ll 1$, the cooling period is long and the product undergoes self-annealing under long-term action of high temperatures, which leads to the formation of an equilibrium product. Synthesis in SHS reactors where the cooling time is 1–1.5 h and structural relaxation is complete is an example of a process for the preparation of equilibrium products.

At $S \gg 1$, the cooling time is short and self-quenching[†] takes place. In this case, non-equilibrium products are formed instead of equilibrium ones.

The structure of the product in the remaining broad intermediate variability domain of parameter S may be very complex.[‡] For example, the equilibrium can be reached for one parameter, *e.g.*, chemical composition of the products, but cannot be reached for other parameters, *e.g.*, crystal phase structure.

Let us consider an interesting example. In 1970, I P Borovinskaya came to obtain an unexpected result in an attempt to synthesise boron nitride by combusting boron in nitrogen under high pressures (~ 300 MPa).²¹ In one of these experiments, the tube broke and rapid release of pressure resulted in hardening of the burnt product. The sample of boron nitride thus obtained appeared to be amorphous. These studies have demonstrated the possibility of obtaining both non-equilibrium and amorphous products by hardening.

[†] Quenching is a rapid (10^3 – 10^4 deg s⁻¹) cooling of a sample and is usually implemented in two modes: in liquid nitrogen and in massive brass blocks for wedge-shaped samples.

[‡] The term 'structure' is very broad and polysemantic. It entails chemical structure, phase state, grain size (in the case of granular structures), *etc.*

Rogachev *et al.*^{102, 103} have described an original procedure for hardening of combustion products using a large copper block with a wedge-shaped cavity filled with a green mixture. Combustion was initiated at the wide base of the wedge and gradually spread deeper into the narrow channel. Increasing heat losses caused the flame to fade at some distance from the wedge base. Layer-by-layer analysis of combustion products made it possible to draw the dependences of chemical and phase compositions, grain size and other reaction parameters as a function of the combustion coordinate, *i.e.*, the distance from the combustion front. These dependences provide indirect (with some errors connected with the hardening time) information about the processes occurring in the combustion zone.

The picture of a combustion process carried out in a wedge-shaped cavity and the micrographs of the granular structures of the samples formed at different distances x from the wedge base are shown in Fig. 25. Figure 26 illustrates the dependence of the mean grain size on the combustion coordinate for TiC, TiB₂, *etc.* Based on the results obtained, it was concluded that after termination of chemical reactions occurring in the combustion wave the system undergoes intense recrystallisation as a result of which the size of the grains increases. The particles formed in the combustion zone have submicron and micron sizes which may increase by orders of magnitude in the course of recrystallisation. This hardening method provides a key to control over the granular structure and, correspondingly, the properties of the materials synthesised.

Studies of dynamics of phase transitions (polymorphous transformations) in the combustion wave are yet another impor-

Figure 25. Combustion in a wedge-shaped gap: a picture (a) and micrographs of product structures taken at different distances from the combustion front (b).

Figure 26. Distribution of grain sizes (r) of combustion products behind the combustion wave front (x is the distance behind the front) for processes of formation of TiC (1), TiB₂ (2), Ti₅Si₃ (3) and TiC + 20%Ni (4).

tant line of research. This required the development of novel techniques for the control over dynamics of phase transitions in all stages: from starting reactants to final products. In addition to hardening, these methods include dynamic X-ray phase analysis based on synchrotron radiation, standard analyses using X-ray tubes and other techniques. The principle of X-ray phase analysis is very simple. The X-ray beam is directed at a definite point on the lateral surface of the sample which is usually flat. When the combustion wave reaches this point, X-ray photographs are taken at definite intervals of time. X-Ray patterns allow the analysis of dynamics of phase transitions and, particularly, of the dynamics of formation of the final products.

Practical implementation of this technique requires the use of X-ray beams of high intensity and rapid shooting of X-ray patterns. The use of synchrotron radiation is the most appropriate to this end. The pioneering studies in this area were carried out on a synchrotron of the Institute for Nuclear Research of the Siberian Branch of the Russian Academy of Sciences by a research team headed by V V Boldyrev.¹⁰⁴ An Ni + Al system used in this study was subsequently employed in other model studies.^{105, 106} A schematic representation of this experiment is shown in Fig. 27; the first dynamic phase formation curves are depicted in Fig. 28.

Figure 27. Dynamic X-ray analysis of SHS; (1) sample, (2) reaction chamber, (3) igniting wire, (4) gas inlet and outlet (He), (5) thermocouple, (6) quartz window, (7) X-ray tube, (8) monochromator, (9) beryllium window, (10) linear detector, (11) interface unit, (12) computer.

Figure 29. A series of dynamic patterns obtained in the combustion of the Ti-C system in air.¹⁰⁹

A simpler design of a laboratory-scale X-ray diffraction analysis on an ordinary diffractometer supplied with a special detector was developed in further studies.^{107, 108} A set of dynamic X-ray patterns obtained by this method is shown in Fig. 29 (see Ref. 109). Their processing made it possible to draw the concentration profiles of the combustion wave (patterns).

Interesting patterns were obtained in the studies of combustion of a titanium powder in air (Fig. 30).¹¹⁰ These diagrams clearly demonstrate that the metal reacts with nitrogen rather than with oxygen to afford an intermediate nitride which undergoes subsequent oxidation to yield titanium oxide (TiO_2) as the final product.

A method for processing patterns was proposed, which provides information about the mechanism of phase formation in the combustion wave.³⁰ The dynamic phase transformation curves are treated in the y - ξ coordinates, where y is the completeness of phase formation and ξ is the dimensionless spatial coordinate:

$$\xi = \frac{U^2 t}{a},$$

where a is the thermoconductivity of the substance.

Figure 30. X-Ray phase diagrams obtained in the combustion of a titanium powder in air; (1) α -Ti + solid solution, (2) β -Ti, (3) TiN_x , (4) $\text{Ti}_3\text{O}_{5-x}\text{N}_x$, (5) $\text{Ti}_6\text{O}_{11-x}\text{N}_x$, (6) TiO_{2-x} , (7) TiO_2 (rutile).

If $0 < \xi < 1$, the structure formation follows the Khaikin–Aldushin–Merzhanov equilibrium mechanism where chemical reactions and structure formation occur simultaneously. At $\xi \gg 1$, the process follows the Borovinskaya non-equilibrium mechanism, *i.e.*, the final product is formed at a sufficiently large distance from the combustion front due to decomposition of unstable intermediate products formed in the combustion wave.^{6, 19, 27} An example of this process is given in Fig. 31.

Figure 31. On the mechanism of structure formation in combustion processes.

To some extent, synchrotron and diffractometric methods are complementary. The former is more suitable for the study of fast burning systems, while the latter is more applicable to slowly

burning systems. However, none of these methods allows identification of the initial stages of phase transitions. Therefore, increasing measurement sensitivity is a currently central methodological task.

A recently published paper¹¹¹ describes the use of the synchrotron method for obtaining information about processes occurring in the detonation wave.

Numerous papers are devoted to a comparison of miscellaneous characteristics of combustion and detonation products to those prepared by conventional methods. This is important from both the scientific and practical point of view, especially for SHS products, because here, like in no other field, their competitiveness with respect to products prepared by conventional methods had to be argued. Some characteristics of AlN powders prepared by SHS and sintered materials therefrom in comparison with particulate materials prepared by furnace synthesis are given in Table 6. Aluminium nitride is a very popular ceramic material which is widely employed in electronics for preparation of microchip boards where quality requirements are especially high. As can be seen from Table 6, the quality of the SHS product exceeds that of the furnace-made analogues in the content of fixed nitrogen and admixed oxygen, but the content of admixed iron in the former is higher. Sintered SHS materials prepared from AlN are also distinguished for high quality.

The next example is related to the synthesis of diamonds. In Table 7, specifications of diamonds prepared by two detonation methods are compared to those synthesised under static conditions at high pressures and temperatures. Diamonds prepared by the three methods differ in grain size (from nanosizes to millimetres) and hence in application fields. All artificial diamonds complement each other rather than compete.

Table 6. Comparative analysis of AlN powders obtained by SHS and by furnace synthesis.

Method	Sample brand ^a	Manufacturer (country)	Impurities (mass %)			Specific surface $S/\text{m}^2 \text{ g}^{-1}$	Mean diameter (d_{50})/ μm	Characteristics of sintered powders		
			N ^b	O	Fe			λ /W K ⁻¹ m ⁻¹	strength /MPa	electric strength /kW m ⁻¹
SHS	SHS-T	ISMAN (RF)	31.5–32.5	1.2–1.5	0.1–0.2	—	—	—	—	—
	SHS-C	ISMAN (RF)	33.5–33.8	0.5–0.8	0.06–0.1	0.6–0.8	<15	—	—	—
	SHS-G	ISMAN (RF)	33.3–33.5	0.7–1.0	0.06–0.1	2.5–3.5	1.0–1.4	160–190	370–390	>20
Furnace	—	RPC 'Reaktiv-Elektron' (RF)	31.0–32.6	0.4–2.9	0.3	—	—	—	—	9.6
	AlNeL [®]	ART (USA)	33.0	1.0	<0.01 (see ^c)	2.0–5.0	—	200	—	10
	CER-ALLOY	Ceradyne (Great Britain)	—	—	—	—	—	120–170	207–280	—
	Grade F	Tokuyama Soda (Japan)	33.6	0.9	0.001	3.2–3.5	1.5	170 ± 10	350	>20

^a Designations: SHS-T, technical grade; SHS-C, pure, conglomerates; SHS-G, pure, ground; ^b stoichiometric content is 34.19 mass %; ^c ppm.

Table 7. Specification of artificial diamonds.

Method for synthesis	Mechanism of formation	Size of crystal grains	Areas of application	Authors
Statical at high pressures and temperatures	phase transition of graphite into diamond in the presence of catalysts	< 5 mm	jewelry, boring/stone-working instrument, polishing tools	V N Bakul', L F Vereshchagin
Detonation-I	phase transition of graphite into diamond in a mixture of an explosive with graphite	0.01–5.00 μm	composite materials with metal/elastomer templates	O N Breusov, A N Dremine <i>et al.</i>
Detonation-II	formation of diamond from carbon present in the explosive	2–4 nm	superfinish polishing, motor oil additives	G V Sakovich, V M Titov <i>et al.</i>

The two detonation methods differ in principle. In one of them, carbon particles are incorporated into the explosive green mixture and diamonds are formed in the detonation wave. In another approach, explosives containing excess carbon (with respect to oxygen balance) are used without additives. Excess carbon atoms are condensed in the detonation wave into small (nanodimensional) particles. Such diamonds virtually represent condensed products of an explosion-induced chemical reaction. This is an example of detonation-driven SHS (see above).

A comparison of various characteristics of products prepared by different methods allows correct choice of a synthetic procedure depending on the practical task.

VII. Material-synthesising and material-affecting combustion and explosion processes in technology and industry

Combustion and explosion processes present substantial practical interest.

Numerous unique technologies based on combustion and explosion processes have been developed; the number of SHS processes alone, which include six technological types, exceeds 30.²⁷

The advantages of combustion and explosion technologies are well known. They include considerable saving of electric energy, simplicity, high productivity, structural and functional diversity of final products, possibility of attaining high quality and optimum parameters, *etc.* Their main disadvantage (especially with regard to material-synthesising processes) is non-versatility. Combustion and explosion can be implemented exclusively in high-energy self-transforming systems. To other drawbacks of these technologies one can add high inflammability and explosibility of high-energy systems used therein. However, in spite of these 'drawbacks' these processes have occupied a prominent place in up-to-date technology.

By virtue of their specific features, combustion and detonation processes are related to the category of alternative (as opposed to conventional) techniques for synthesising inorganic materials. Combustion and explosion can be used in virtually all currently known technological processes. Some examples of conventional technologies and alternative combustion and explosion processes used for synthesising inorganic materials are given in the table below.

Conventional technologies	Combustion and detonation analogues of conventional processes
Furnace and plasma-chemical synthesis of powders	SHS
Synthesis of superhard materials under static conditions	shock wave and detonation synthesis
Sintering, hot-pressing	SHS sintering, STIM technology (STIM stands for synthetic hard instrumental materials)
Plastic metal working	explosive compaction, STIM technology
Flame spraying	powder spraying
CVD processes, diffusional saturation	gas-transport SHS technology
Metallothermic melting of materials, alloys, compounds	SHS metallothermy
Electric arc welding	SHS welding
Electric welding	explosion-induced welding, SHS welding

In choosing a particular technological process, special attention should be given to its efficiency and expected characteristics of final materials. Unfortunately, it does not always work.

There is a large body of evidence on practical applications of materials prepared or processed with the use of combustion and

explosion technologies. Without going into details, we shall confine ourselves to providing a cumulative list of materials (which is far from being complete) and branches of industry where they are employed.

Branch of industry	Materials
Mechanical engineering	abrasives, hard alloys and articles thereof, welded parts including bimetallic rolled stock, superhard materials (diamonds, wurtzite-like BN)
Metallurgy	cast iron; ferro- and foundry alloys including nitrogenated alloys; refractory materials including oxygen-free (nitride) materials; particulate materials for powder metallurgy; moulded high-melting articles including pipes with internal wear-resistant coatings; heat-resistant alloys
Chemical industry	technical-grade carbon; boron and its compounds; pigments; luminophores; fumigants; catalysts; filters for gases and liquids
Electrical and electronic engineering	ceramic (including ferrite) powders; thermal insulators; microcircuit boards; high-temperature heaters; solid conductive lubricants; green mixtures for growing oxide single crystals; powders of high-temperature superconductors
Medicine	storage media and implants

Combustion and explosion products are used successfully in building materials, aircraft industry, *etc.*

Of special importance are industrial applications of combustion and explosion technologies. This includes large-scale production of cast iron and ferroalloys, which have long been known to metallurgy and chemical industry, and some novel SHS technologies carried out in proving grounds and blasting chambers.

Numerous works aimed at assimilation of SHS technologies and organisation of production lines at pilot plants and experimental-industrial enterprises have been carried out at ISMAN together with the Interbranch Research-and-Production Complex (IRPC) 'Termosintez'. Other developments included large-scale production of technical-grade boron (Dal'negorsk), MoSi₂ (Kirovakan), TiC, BN and AlN (Baku), β -Si₃N₄ (Makeevka), ferrites (Razdan), LiNbO₃ (Dzerzhinsk), refractory materials ('Furnone') (Alma-Ata), cutting blades (Nizhny Novgorod), high-temperature ceramic insulators (Samara), nitrogenated ferroalloys (Chusovaya, Izhevsk), titanium alloys (TiC, TiC-Cr₃C₂, TiH₂) (Transcarpathia) and other SHS products (Chernogolovka). Altogether, over 2000 tons of miscellaneous products were manufactured in the last year of existence of the USSR (and, actually, of the IRPC 'Termosintez'). The most recent SHS developments were realised at the fully automated plant 'SHS Ceramicas' (Spain) utilising the ISMAN technology. The production of pipes with internal antiwear coating for transportation of abrasive media (*e.g.*, cement, carbon, minerals, *etc.*) has been set up in China. This production successfully combines the fundamental concepts of the effect of an artificial gravity field on combustion developed by researchers at ISMAN¹¹² with the rich experience of Japanese specialists in the production of large-diameter pipes.^{113, 114} This technology has been introduced at ten Chinese plants with the annual output of 10 000 tons.

Pioneering works aimed at industrial implementation of explosion technologies were undertaken by researchers at the Lavrentyev Institute of Hydrodynamics. Their longstanding efforts have culminated in the establishment of an Engineering-and-Design Institute for Hydraulic Pulse Technology. Its main products include bimetallic (steel-copper, steel-titanium, steel-AO20) preforms. Production of diamond nanopowders in a blasting chamber has been started at the Federal Research-and-

Production Centre 'Altai'. This blasting chamber allows explosion of charges weighing up to 6 kg with frequency of 30 blasts per hour; its productivity is 2.5 tons of refined diamonds per year, which is more than satisfactory for detonation synthesis.

The detonation line installed at the Penza State University and designed for batch production of segnetoelectric materials and articles by explosion-induced compaction of metal powders followed by sintering is also operating with high efficiency. The operational characteristics of these materials have been improved through the formation of fine-grain high-strength structures with well-developed contact surfaces.

The construction of stable explosion chambers has made it possible to enlarge industrial implementation of explosion technologies.

Despite the 'uncommonness' of combustion and explosion technologies, they hold great promise.

VIII. Conclusion

Studies of material-synthesising and material-affecting combustion and explosion are under way. Theorists are working out structural and macrokinetic combustion models which would provide a description not only of characteristics of the combustion wave but also of the structures of final products. Similar problems are being explored in explosion studies aimed at the construction of structural and gas-dynamic detonation models. The first theoretical works in this area were devoted to the solution of three-dimensional combustion problems. Three-dimensional simulation presents interest in principle, since it permits one to follow transformations of substances in the bulk of a burning or detonating body, which cannot be attained by conventional methods.

Many important problems remain to be solved by methodologists. These include studies of structural dynamics of combustion and explosion processes by methods similar to dynamic X-ray diffractometry. Another important task is adequate monitoring of changes in porous structures and microstructures (*e.g.*, grain size) of substances in combustion and detonation waves.

Experimentalists are actively engaged in the study of processes occurring in chemically and physicochemically complex systems. The problem of separation of the primary from the secondary in the totality of processes has been a challenge to investigators at all times.

Some new trends, *viz.*, gas-phase and gas-disperse SHS,^{115, 116} mechanochemical SHS,^{117–121} thermal explosion SHS and high-field-assisted SHS, have emerged relatively recently.^{122–124} Practical implementation of gasless detonation processes is an important task.¹²⁵

Production engineers are concerned with the development of continuous combustion and explosion processes. Some progress has been made in the field of high-energy technologies. However, continuous material-synthesising processes based on combustion and explosion, *e.g.*, production of powders, melts, compacted long-sized items, *etc.*, are still very rare.

This problem is closely connected with utilisation of combustion energy and its transformation into electric energy by conventional methods. Thus, development of energotechnological processes is of interest.¹²⁶ This is topical for continuous processes. Implementation of thermoconjugated modes where one (strongly exothermic) reaction initiates another (weakly exothermic) reaction is especially important for periodic processes.

The use of 'chemical furnaces' is becoming a popular trend in modern research practice.

The major challenge facing designers is in the construction of quasi-adiabatic SHS reactors with large cooling times (of the order of weeks) allowing the synthesis of SHS products in the form of small (of the order of millimetres) crystals. Works on the construction of an SHS attritor for mixing reactants, SHS conducting and grinding the product in one technological step are currently under way. Many practical tasks are related to the

design of special moulds for SHS compaction and tubes for loading and conservation of substances under shock waves, *etc.*

Yet another important trend is a search for novel applications of material-synthesising and material-affecting combustion and explosion technologies.

Recently, the Scientific Council for Combustion and Explosion at the Presidium of the Russian Academy of Sciences has worked out the concept on the development of combustion and explosion processes as a branch of scientific and technological progress. All those who are interested in this problem are referred to the recently published book¹²⁷ which contains sections devoted to materials and technology.

The author is grateful to A E Sytshev, Yu A Gordoplov, V A Veretennikov, A S Rogachev and V I Yuxhvid for their help in selection of the illustrative material and thanks M A Nasonova and I S Zakieva for their assistance in preparation of the manuscript for publication.

Abstract. Data published during the last 15 years on the intercalation of metal and *n*-alkylammonium ions, organic molecules and organometallic complexes in vanadium(V) oxide xerogel are generalised and described systematically. The possible mechanisms of intercalation processes are considered. The possibility of using hybrid materials in electrochemical and optical devices and as precursors for the preparation of anhydrous and nanotubular forms of oxide compounds is discussed. The bibliography includes 159 references.

I. Introduction

In intercalation compounds (insertion compounds), ions or guest molecules are located in the crystallographic vacant sites of such host substances as, for instance, simple or complex oxides, sulfides, *etc.* Basically, these are layered compounds with sandwich-like structure or one-dimensional channel-like substances (tubulenes). Layered compounds possess higher intercalation capacities as compared with tubulenes. Currently, researchers are paying special attention to the intercalation compounds based on vanadium(V) oxide xerogel,¹ which manifests properties of both the original vanadium–oxygen matrix and the intercalated substances. A characteristic feature of these compounds is a quasi-one-dimensional structure and a turbostratic disorder of their layers. Both cations and organic molecules can easily be intercalated into this structure.

This property distinguishes the xerogel under consideration from crystalline V_2O_5 , the three-dimensional lattice of which can be intercalated only by metal ions.² The high intercalation capacity of xerogel is explained by its nature (this is polyvanadium acid, *viz.*, $H_2V_{12}O_{31} \cdot nH_2O$) and is ensured by the negative charge of the vanadium–oxygen layers, which is distributed along the V_2O_5 fibres.³ Intercalation may occur owing to dipole absorption, ion-exchange or redox processes. In all cases, this results in a change in the interlayer distance, which corresponds to the

insertion of one or several layers of an intercalant and does not change the structure of the xerogel itself. Solid solutions in which vanadium is replaced by hexa-, penta- or tetravalent ions can be obtained based on vanadium(V) oxide xerogel. These solid solutions have larger homogeneity regions than anhydrous complex oxides. Such solid solutions can easily be obtained in the form of films, superfine powders and nanocomposites using energy-saving environmentally friendly technologies. That is why they are promising for designing materials for various electrochemical and optical devices,⁴ they can be used in the synthesis of catalysts and as precursors for anhydrous and nanotubular forms of oxide compounds.

Intercalation compounds are usually obtained by a sol–gel method in aqueous, organic or aqueous–organic media. For the large-scale synthesis of $V_2O_5 \cdot nH_2O$ xerogel, a vanadium(V) oxide melt is poured into water, the sol $V_2O_5 \cdot \delta \cdot nH_2O$ obtained is transformed with time into the gel which is dehydrated. By choosing the conditions for dehydration, it is possible to obtain xerogels with different specific surface areas.⁵ An efficient method for the synthesis of intercalation compounds with the general composition $M_xV_{2-y}T_yO_{5+\delta} \cdot H_2O$ (*M* is a mono-, di- or trivalent cation, *T* = Mo, W, Cr, Ti) consists of dissolution of the corresponding oxides, hydrides or metals in hydrogen peroxide followed by decomposition of the peroxide compounds.¹

By passing solutions of alkali metal metavanadates through a cation-exchange resin, a yellow solution of decavanadium acid $H_6V_{10}O_{28}$ is obtained, which becomes dark-red with time and transforms into the stable V_2O_5 gel.⁵ Polymerisation is accompanied by partial ($\sim 1\%$) reduction of V^{5+} to V^{4+} . Intercalation compounds containing cations M^{z+} and different amounts of tetravalent vanadium in particular, can be obtained by hydrolysis of organovanadium compounds⁶ and alkali-metal vanadates.⁷ Intercalation compounds based on vanadium(V) oxide xerogel can possess both mainly ionic or electronic and mixed conductivity.⁵ The ionic component is determined by the mobility of cations M^{z+} and depends on the relative humidity of air, while the electronic component depends on the content of tetravalent vanadium.

In the present review, special attention is given to the studies of the synthesis, structure and physicochemical properties of the intercalation compounds based on vanadium(V) oxide xerogel that have been carried out in recent years. In addition, a new class of these compounds, *viz.*, VO_x -nanotubulenes with intercalated organic substances, is considered.

II. Structure of intercalation compounds

Studies of the structure of intercalation compounds have been carried out on film samples of $V_2O_5 \cdot nH_2O$ xerogel, which is considered to be an insertion product of water molecules in vanadium(V) oxide.⁸ The xerogel has a layered structure, which is deduced from the diffractograms of the $V_2O_5 \cdot nH_2O$ film (Fig. 1). The vanadium–oxygen layers are formed by tangled fibres and connected by water molecules. The interlayer distance (d) depends on the water content and equals 11.57 Å for the composition $V_2O_5 \cdot 1.6H_2O$ (phase I). On heating to 50 °C, this parameter changes only slightly ($d = 11.30 \pm 0.05$ Å). At ~ 100 °C, phase I gradually disappears and phase II ($V_2O_5 \cdot 0.5H_2O$) is formed. The formation of the latter is completed at 250 °C. The diffractograms of phase II also suggest a layered structure, but the interlayer distance equals 8.75 Å in this case. At temperatures above 350 °C, chemically bound water is removed and crystallisation of vanadium(V) oxide occurs. It was found by electronography that the fibres are flat ribbons 1000 Å in length and 100 Å in width (Fig. 2). In the plane of the ribbon, their structure is analogous to that of orthorhombic V_2O_5 and is characterised by the following parameters: $a = 27.0$ and $b = 3.6$ Å. According to the IR spectroscopic analysis, the short-range ordering in $V_2O_5 \cdot nH_2O$ xerogel is similar to that in crystalline oxide. The main absorption bands of IR irradiation for the vanadium(V) oxide xerogel, viz., 1605, 1015, 910, 760 and 530 cm^{-1} , correspond to the following vibrations: $\delta(H-O-H)$, $\nu(V=O)$, $\delta(V-O \cdots H)$, $\delta(V-O-V)$ and $\delta(V-O)$.² Orthorhombic units constituting the ribbons do not lie in the common plane, but rather form a relief structure with an ‘amplitude’ of 2.8 Å. It

was established by neutron and X-ray diffraction that the distance between the basal planes in $V_2O_5 \cdot nH_2O$ changes from 8.8 Å ($n = 0.1-0.5$) to 40 Å ($n = 18.5$ or higher) as the water content (n) increases. For $n \geq 5-6$, the parameter d_{001} increases in a stepwise manner by 3 Å, which corresponds approximately to the thickness of the interstitial water layer. Usual water freezes at the temperatures below 273 K by several degrees to form hexagonal ice crystals. In the xerogel, an interlayer distance of ~ 15 Å, caused by the presence of ordered bilayers of non-freezing water in the range $110 < T < 230$ K, was found by neutron diffraction technique. As the temperature increases to 270 K, the d_{001} value increases to 19 Å and the ordered state of the water layers is violated. The ordering of water in the hydrated layered systems is characteristic of not only $V_2O_5 \cdot nH_2O$ gel but also, for instance, clays.

The structure of the double vanadium–oxygen layer up to now has been controversial. According to one opinion (see, e.g., Ref. 9), it consists of two $VO_{1.5}$ planes, with a distance of 2.8 Å between the planes (Fig. 3). Such a structure is similar to that of the δ -phase of oxide vanadium bronzes of the $M_xV_2O_5$ type ($M = K, NH_4$).² According to another opinion,¹⁰ the V_2O_5 layers are 4.368 Å apart from one another and consist of one $VO_{1.5}$ plane. The axial-distorted tetragonal V_2O_5 pyramid in the $V_2O_5 \cdot nH_2O$ xerogel includes one short vanadyl bond with a length of 1.55–1.58 Å and a nearly planar system formed by four $V-O$ bonds with a length of ~ 1.90 Å.¹¹

Elucidation of the structure of the $V_2O_5 \cdot nH_2O$ xerogel requires the study of the state of its hydrogen–oxygen groups.¹² Two H_3O^+ groups per 6 $V_2O_5 \cdot 1.6H_2O$ molecules have been found. This correlates well with the data on ion exchange, which suggest that polyvanadates of the type $M_2V_{12}O_{31} \cdot nH_2O$ are formed under equilibrium conditions. The number of three-spin systems decreases linearly as the amount of M^+ ions in $V_2O_5 \cdot nH_2O$ increases, thus indicating the exchange of cations of the corresponding metals for these systems. The specimens contain relatively isolated protons as OH groups. Their content in $V_2O_5 \cdot 1.6H_2O$ correlates with the content of tetravalent vana-

The number of pulses

Figure 1. Diffractograms of the $V_2O_5 \cdot nH_2O$ xerogel film (1) and powder (2).

Figure 2. Schematic representation of the layered structure of the $V_2O_5 \cdot nH_2O$ xerogel.⁵

Figure 3. Structural model of the $V_2O_5 \cdot 1.7H_2O$ xerogel.⁹

dium. Comparison of the results obtained in ^1H NMR studies of polyvanadium acids with different compositions allows one to conclude that isolated protons are present in two non-equivalent states and that most of the protons are bound to tetravalent vanadium. Approximately one-half of the OH groups, appeared upon partial dehydration of three-spin systems with reduction of the water content in the xerogel from 1.6 to 1.4 moles, belongs to bridging groups $\text{V}^{5+}-\text{OH}$, which are exchange-active in contrast to the $\text{V}^{4+}-\text{OH}$ groups.

Based on the ^1H NMR data, the structure of the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel can be represented as a result of the interaction of water molecules with coordinatively unsaturated vanadium atoms of the orthorhombic oxide. This process is accompanied by cleavage of $\text{V}-\text{O}-\text{V}$ bonds followed by formation of two bridging OH groups. These bind water molecules to give highly mobile three-spin systems. According to the suggested model (Fig. 4), three types of protons can be distinguished in polyvanadium acid $\text{H}_2\text{V}_{12}\text{O}_{31} \cdot n\text{H}_2\text{O}$ ($\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$): the protons of water molecules coordinated with $\text{V}=\text{O}$ groups belong to the first type (this is a zeolite-type water, which is absorbed reversibly and forms a network of hydrogen bonds); the protons involved in the three-spin systems (H_3O^+) belong to the second type; the protons of bridging hydroxo-groups (OH^-) chemically bound to vanadium atoms, which can be removed as the xerogel structure is destroyed, belong to the third type.

Figure 4. Structural model of the $\text{H}_2\text{V}_{12}\text{O}_{31} \cdot n\text{H}_2\text{O}$ xerogel.

Usually, $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel contains tetravalent vanadium ions which may be present in the vanadium–oxygen layers or in the hydrated $\text{VO}(\text{H}_2\text{O})^{2+}$ ions between the layers.¹³ The presence of V^{4+} ions can easily be detected by ESR¹⁴ and chemical analysis. Their content in the samples depends on the nature of the reducing agent used in the synthesis of the gel and can reach 20 mass %.^{5,15} The study of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ by X-ray photoelectron spectroscopy has revealed¹⁶ that the positions of the V2p-band correspond to binding energies of 517.5 and 516.5 eV for penta- and tetravalent vanadium, respectively. The O1s binding energies are equal to 530.1 for $\text{O}-\text{V}$, 531.6 for the OH groups and ~ 533.2 eV for water molecules.

It should be mentioned that the structural characteristics of vanadium(V) oxide xerogel are similar to those of anhydrous intercalated phases of the $\text{H}_x\text{V}_2\text{O}_5$ and $\text{M}_x\text{V}_2\text{O}_5$ types (see Ref. 2). For instance, $\text{H}_x\text{V}_2\text{O}_5$ ($x \leq 0.5$) has a structure of V_2O_5 with unit cell parameters $a = 11.51$, $b = 3.56$, $c = 4.37$ Å; the IR spectrum of the former compound is analogous to that of V_2O_5 with the exception of the band at 928 cm^{-1} , which is attributed to the OH bond. This band is also present in the spectrum of polyvanadium acid. The unit cell of the β -phase of $\text{M}_x\text{V}_2\text{O}_5$ (the composition of which corresponds to the formula $\text{M}_x\text{V}_{12}\text{O}_{30}$) can adopt four intercalated monovalent ions.

III. Intercalation of cations

Vanadium(V) oxide xerogel exhibits ion-exchange properties.^{12,17} The presence of exchangeable protons in the xerogel can be detected by adding an excess of any alkali metal salt to an aqueous suspension of $\text{H}_2\text{V}_{12}\text{O}_{31} \cdot n\text{H}_2\text{O}$. The following reaction occurs:

The liberating protons are titrated with alkali and the ratio $\text{M}:\text{V}$ is calculated taking into account the amount of the original xerogel. For the monovalent cations, the mean value of this ratio equals 0.17 ± 0.01 , which is in good agreement with the formula of polyvanadium acid. Hydrated polyvanadates with different degrees of replacement of the protons by alkali or alkaline-earth metal ions can be obtained by the ion-exchange method. IR and ^{51}V NMR spectra of such samples are similar to the corresponding spectra of the original polyvanadium acid, thus indicating the unique chemical nature of these compounds. The mean $\log K_{\text{H,M}}$ values at 295 K ($K_{\text{H,M}}$ is the coefficient of the exchange of protons in polyvanadium acid by alkali metal cations or NH_4^+), which depend linearly on the radii of hydrated cations, are given in Table 1. Taking into consideration the ion-exchange coefficients, the cations can be arranged in the following series according to their ability to replace the protons: $\text{La}^{3+} > \text{K}^+ \gg \text{Ba}^{2+} > \text{NH}_4^+ > \text{Ca}^{2+} > \text{Na}^+ \gg \text{Al}^{3+} > \text{Sr}^{2+} > \text{Mg}^{2+} \gg \text{Ni}^{2+} \gg \text{Zn}^{2+} \gg \text{Mn}^{2+} > \text{Cd}^{2+} > \text{H}^+ > \text{Li}^+$ (see Ref. 18).

Table 1. Ion exchange coefficients of the protons of polyvanadium acid for metal cations or NH_4^+ ($T = 295\text{ K}$).¹⁸

NH_4^+	0.99 ± 0.06	Zn^{2+}	0.43 ± 0.03	Al^{3+}	1.60 ± 0.02
Mg^{2+}	0.45 ± 0.11	Cd^{2+}	0.27 ± 0.02	La^{3+}	3.50 ± 0.30

It was estimated by the potentiometric titration method,¹⁹ that the exchange capacity of the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ specimens with respect to the cations of monovalent metals ($\text{M}^+:\text{V}_2\text{O}_5$) is close to 0.3. The rate of exchange $\text{H}^+:\text{M}^+$ is mainly limited by the diffusion of cations at the xerogel–electrolyte solution interface. The values of the diffusion coefficient (D) determined for the alkali metal ions and protons agree well with the data on the selectivity of ion exchange for polyvanadium acid:

Ion	Na^+	K^+	Cs^+	H^+
$10^8 D\text{ cm}^2\text{ s}^{-1}$	5.0 ± 0.4	4.8 ± 0.4	2.1 ± 0.2	1.6 ± 0.2

Upon intercalation of sodium, potassium and cesium monovalent cations into the interlayer space of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel, the interlayer distances become equal to 10.9, 11.0 and 11.1 Å, respectively.

It was found²⁰ that the x value in the formula of xerogel $\text{M}_x^{z+}(\text{V}_2\text{O}_5)^{(0.3-0.4)-} \cdot n\text{H}_2\text{O}$ is mainly determined by the exchange capacity and equals 0.33–0.36, 0.16 and 0.11 for mono-, di- and trivalent cations, respectively. Two types of cations were distinguished: the first type of cations are solvated with one water layer ($d = 10.9\text{--}11.3$ Å), while solvation of the second type of cations takes two water layers ($d = 13.4\text{--}14.2$ Å). For the first type of cations, the charge-to-radius ratio is $z/r < 1.67\text{ e Å}^{-1}$, all of them, except Ba^{2+} , are monovalent ions. For the second type of cations (di- and trivalent ions), $z/r > 1.67\text{ e Å}^{-1}$. Analogous correlation is observed for the parameter characterising the change in the enthalpy upon hydration of the ions: intercalation of the cations is accompanied by the formation of a monolayered hydration shell if $\Delta H > -1465\text{ kJ mol}^{-1}$, while a double hydration layer is formed if $\Delta H < -1465\text{ kJ mol}^{-1}$. The interrelation-

ship between the ionic radii of the intercalated cations and the degree of their hydration has been established. This depends on the number of water molecules associated with the ions during their movement through the solution and equals the amount of water which is determined at temperature below 160 °C. The cations M^{z+} can be arranged in the following order with respect to the degree of hydration: $Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$ and $Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+}$.

Interesting results were obtained²¹ in the studies on the topochemistry and kinetics of the intercalation of polycation $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ (Al_{13}) into $V_2O_5 \cdot nH_2O$ xerogel powders and films. Insertion of this polycation is accompanied by a gradual change in the interlayer distance up to a constant value of 17.5 Å. Obviously, the rate of intercalation is mainly influenced by such geometrical factors as the specific surface area of the xerogel and the length of the possible path of migration of intercalated cations. With the Al_{13} polycation, stable xerogels, based on vanadium(V) oxide, can be obtained by double ion exchange.²¹ In the first stage of the ion-exchange process, $V_2O_5 \cdot nH_2O$ xerogel is involved in the exchange with any mono-, di- or trivalent cation including VO^{2+} . In the second stage, the replacement of M^{z+} in the compounds obtained $M_x^{z+}V_2O_5 \cdot nH_2O$ via $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ occurs. Finally, stable layered materials $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}-V_2O_5$ are formed. If the cations characterised by the ratio $z/r < 1.67 \text{ e Å}^{-1}$ are used in the first step, the xerogel $Al_{13}-V_2O_5$ with $d \approx 15 \text{ Å}$ and a specific surface area $s_0 = 10-30 \text{ m}^2 \text{ g}^{-1}$ is obtained. If VO^{2+} or the ions characterised by $z/r > 1.67 \text{ e Å}^{-1}$ are involved in the ion-exchange process, compounds with $d \approx 18 \text{ Å}$ and a specific surface area $> 80 \text{ m}^2 \text{ g}^{-1}$ are formed. The second type of compounds can be considered as xerogels $Al_{13}-V_2O_5$ with pillared structure, because the specific volume of their micropores amounts to $\sim 0.3 \text{ ml g}^{-1}$, while the distance between the vanadium-oxygen layers is close to 9.4 Å, which corresponds to the diameter of the Al_{13} cation.

Xerogels with a similar pillared structure are formed in the ion-exchange process of polyvanadium acid with clusters $M_6Cl_{18}(OH)_n(H_2O)_m^{(4-n)+}$ ($M = Mo, Nb$).²² For this purpose, an aqueous suspension of $V_2O_5 \cdot nH_2O$ xerogel is mixed with 1.6 M ethanolic solution containing the cluster ion. The compound obtained has an interlayer distance of $\sim 14.3 \text{ Å}$, its specific surface area is $15 \text{ m}^2 \text{ g}^{-1}$.

$V_2O_5 \cdot 1.9H_2O$ obtained by hydrothermal treatment of the xerogel exhibits a high ion-exchange capacity, which is comparable with that of zeolites, and significant selectivity with respect to Cs^+ ion.²³ In the presence of highly concentrated aqueous solutions of salts MCl_z , where $M = Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Ba^{2+}$ and Sr^{2+} ($M^{z+}:Cs^+ = 250$), the xerogel absorbs cesium ions selectively. The selectivity with respect to the cesium cation changes in the following sequence: $Li^+ > Mg^{2+} > K^+ > Na^+ > Ca^{2+} > Sr^{2+} > Ba^{2+}$. The cesium distribution coefficient changes in the same sequence from 226 for Ba to 981 for Li^+ . This selectivity of the xerogel allows one to use it for the extraction of Cs^+ from radioactive solutions.

The ion-exchange properties of xerogel $V_2O_{4.86} \cdot 2.2H_2O$ obtained under hydrothermal conditions have been studied in detail.²⁴ This compound is characterised by a high content of V^{4+} ; the interlayer distance is 14.2 Å. The main exchangeable groups in $V_2O_{4.86} \cdot 2.2H_2O$ are VO^{2+} ions, and the formula of this oxide can therefore be written as $(VO)_{0.10}V_2O_5 \cdot 2.3H_2O$. Compounds $Na_{0.37}V_2O_5 \cdot 1.1H_2O$, $K_{0.32}V_2O_5 \cdot 0.9H_2O$, $Rb_{0.31}V_2O_5 \cdot 0.8H_2O$ and $Cs_{0.28}V_2O_5 \cdot 0.8H_2O$ in which the interlayer distances are close to 11 Å were isolated upon treatment of the initial xerogel with 0.2 M solutions of M_2SO_4 ($M = Na, K, Rb, Cs$). In the case of the exchange reaction involving Li^+ cations, only 20% of the VO^{2+} ions are replaced and compound $Li_{0.12}(VO)_{0.08}V_2O_5 \cdot 2.4H_2O$ is formed. The order of selectivity $Li < Na < K < Rb < Cs$ reported coincides with that for the xerogel obtained under usual conditions.¹⁸ Commonly, the insertion of vanadyl ions between the layers of $V_2O_5 \cdot nH_2O$ xerogel leads to

three phases of compound with the general formula $(VO)_{0.10}V_2O_5 \cdot nH_2O$: phase I ($n = 2.30$, $d = 14.21 \text{ Å}$) is formed at room temperature, phase I- α ($n = 1.12$, $d = 11.64 \text{ Å}$) is formed at 70 °C and phase I- β ($n = 0.45$, $d = 12.21 \text{ Å}$) is formed at 122 °C.²⁵ In these compounds, two V_2O_5 planes and an interstitial plane of VO^{2+} and water molecules can be distinguished; the twin V_2O_5 planes in the layer are situated at a distance of 2.7 Å from each other. Phase transitions are accompanied by transformation of the four interlayer planes present in phase I into two planes in the formation of phase I- α and then into one plane in the formation of phase I- β .

An ion-exchange method was used for the synthesis of precursors of new structures resembling the structures of α -phases of oxide vanadium bronzes.²⁶ Intercalation compounds $Ba_{0.16}V_2O_5 \cdot 1.52H_2O$ ($d = 11.2 \text{ Å}$), $Ni_{0.16}V_2O_5 \cdot 2.47H_2O$ ($d = 13.4 \text{ Å}$), $Fe_{0.11}V_2O_5 \cdot 2.35H_2O$ ($d = 14.1 \text{ Å}$), $Al_{0.11}V_2O_5 \cdot 2.78H_2O$ ($d = 14.2 \text{ Å}$) were obtained by the interaction of $V_2O_5 \cdot nH_2O$ xerogel with aqueous solutions of the corresponding salts. Further thermal treatment at the temperature of crystallisation of the compounds, viz., at 520 (Ba and Ni), 535 (Fe) and 600 °C (Al) leads to the formation of α -phases of $M_xV_2O_5$. The parameters of the unit cells of these compounds do not depend on the nature of the metal M and are equal to $a = 11.43$, $b = 3.55$ and $c = 4.35 \text{ Å}$.

$Al_{0.11}V_2O_{5.15}$ was obtained by an analogous method with thermal treatment at 520 °C for 2 h (see Ref. 27). The specimen contained 1%–2% V^{4+} and had the following unit cell parameters: $a = 11.51$, $b = 3.56$ and $c = 4.38 \text{ Å}$. Upon the interaction of $V_2O_5 \cdot nH_2O$ xerogel with aqueous Ag^+ solutions, β - $Ag_{0.35}V_2O_5$, α - $AgVO_3$ and a new compound, viz., δ - $AgVO_3$, which crystallises in the monoclinic syngony with the unit cell parameters $a = 32.96$, $b = 2.60$, $c = 3.62 \text{ Å}$ and $\beta = 91.88^\circ$, were obtained at different relative silver and vanadium concentrations in the reaction media (see Ref. 28).

Interactions of lanthanide trichlorides with polyvanadium acid in water result in the formation of xerogels of lanthanide polyvanadates.²⁹ After keeping the reaction mixtures for 24 h, the solid phase was filtered out, washed with water and acetone and dried in a vacuum. According to the results of elemental analysis, the following compounds were obtained: $Pr_{0.15}V_2O_5 \cdot 3.7H_2O$, $Nd_{0.11}V_2O_5 \cdot 3.5H_2O$, $Sm_{0.12}V_2O_5 \cdot 2.7H_2O$, $Eu_{0.12}V_2O_5 \cdot 2.1H_2O$, $Ho_{0.13}V_2O_5 \cdot 3.2H_2O$, $Er_{0.13}V_2O_5 \cdot 3.2H_2O$, which may be represented more correctly as the corresponding salts of polyvanadium acid $H_2V_{12}O_{31} \cdot nH_2O$ with incomplete substitution of the lanthanide cations for the protons. The X-ray diffraction studies on these compounds have shown that their structures are less ordered than the structure of $H_2V_{12}O_{31} \cdot nH_2O$. The 001 reflections appear as most intense ones for $Nd_{0.007}V_2O_5 \cdot 1.4H_2O$ ($d = 13.6 \text{ Å}$), $Nd_{0.11}V_2O_5 \cdot 1.7H_2O$ ($d = 14.5 \text{ Å}$) and for $Nd_{0.20}V_2O_5 \cdot 2.0H_2O$ ($d = 14.9 \text{ Å}$), the average size of the xerogel particles is 242 Å. The IR spectra of these substances are similar to each other, but the band at 1010 cm^{-1} corresponding to the vibration of the $V=O$ bond in the initial acid, is displaced to 1032 cm^{-1} for $Nd_{0.20}V_2O_5 \cdot 2.0H_2O$.

Compounds $M_{0.11}V_2O_5 \cdot nH_2O$ ($M = Cr^{3+}, Fe^{3+}$) were obtained by ion exchange for 20 min at room temperature.³⁰ $V_2O_5 \cdot 1.6H_2O$ ($d = 11.60 \text{ Å}$) and a 0.1 M solution of $M(NO_3)_3$ were used as the starting compounds. The interlayer space of the resulting compounds ($d = 14.10$ for $M = Fe^{3+}$, 14.40 Å for $M = Cr^{3+}$) contains two layers of water molecules. It appears to be more correct to call these compounds polyvanadates $M_xV_{12}O_{31} \cdot nH_2O$ as in the case of the intercalation of lanthanides.²⁹ Dehydration of $Cr_{0.11}V_2O_5 \cdot 2.34H_2O$ proceeds in a step-wise manner in the intervals 20–200 °C and 200–350 °C and is finished by the crystallisation of amorphous products of thermolysis at 410 °C accompanied by an exothermic effect. At 520 °C, mixed oxides $M_{0.11}V_2O_{5.16}$ are formed, which give only 001 peaks in the diffractograms of their film samples. Ion exchange is employed for the preparation of xerogels of the polyvanadates $M_2(V_{12}O_{31})_3 \cdot nH_2O$ ($M = Ln, Al, Ga, In$, n changes in the range

$27 \leq n \leq 40$ depending on the air humidity)¹¹ and xerogels of cerium(III) and cerium(IV) polyvanadates with the compositions $\text{Ce}_2(\text{V}_{12}\text{O}_{31})_3 \cdot n\text{H}_2\text{O}$ ($11.0 \leq n \leq 15.0$) and $[\text{Ce}(\text{OH})_2]_x\text{H}_{2-2x} \cdot \text{V}_{12}\text{O}_{31} \cdot n\text{H}_2\text{O}$ ($0.07 \leq x \leq 0.50$ and $11.0 \leq n \leq 27.0$).³¹

Metal ions present in the dispersion medium affect the properties of vanadium(V) oxide gel.³² In the presence of Li^+ , Na^+ , K^+ , Rb^+ , Cs^+ , Mg^{2+} , Ca^{2+} , Ba^{2+} , Al^{3+} , Cr^{3+} and La^{3+} cations, the aggregative stabilities of the hydrosols depend on the amount of metal ions included in the layered structure. The influence of intercalated cations on the absorption of water by $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ has been studied.³³ Lithium cations affect weakly the water absorption. This is explained by their small charge and their ability to form highly hydrated compounds. Intercalated Na^+ , K^+ , Rb^+ , Cs^+ , Mg^{2+} , Ca^{2+} , Sr^{2+} , Ba^{2+} , Al^{3+} , Cr^{3+} and La^{3+} cations exert a dual effect on the water absorption. The hydrophilicities of the cations favour higher absorption of water vapour from air at low relative humidity. At the same time, the energy of the system increases upon intercalation of such cations due to the increase in the interlayer electrostatic charge, which lowers the ability of the layers to move apart.

Intercalation of the NH_3 molecules into $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel has been studied.³⁴ It was found that the first absorbed NH_3 molecules interact with water of the hydrate to form the NH_4^+ ions [according to our data, with the formation of the compound $(\text{NH}_4)_2\text{V}_{12}\text{O}_{31} \cdot n\text{H}_2\text{O}$]. Later on, NH_3 molecules or the NH_4^+ ions, which cannot be detected by IR spectroscopy, were identified on the surface of the xerogel. After the introduction of water vapour in the gas phase containing NH_3 , the topotactic formation of ammonium metavanadate takes place in the 001 plane of the xerogel. In this process, the NH_3 and H_2O molecules occupy the positions between the vanadium–oxygen layers, then dissolution of the hydrate structure occurs followed by crystallisation of NH_4VO_3 .

Intercalation of cations into vanadium oxide xerogel can be carried out with the use of the corresponding organometallic compounds.³⁵ The reaction of $\text{V}_2\text{O}_5 \cdot 0.4\text{H}_2\text{O}$ aerogel with dibutylmagnesium, trimethylaluminium and dimethylzinc in heptane at room temperature gave the corresponding composites, which contained 4 moles of Mg^{2+} , 3.33 moles of Al^{3+} and 2.5 moles of Zn^{2+} per mole of V_2O_5 .

A new type of mixed composites was synthesised based on vanadium(V) oxide xerogel and montmorillonite clay, namely, bentonite. The green-coloured product has the composition $\text{Al}_2\text{O}_3 \cdot 4(\text{SiO}_2)_2 \cdot x(\text{V}_2\text{O}_5) \cdot y\text{H}_2\text{O}$ ($x = 2.7\text{--}3.5$ and $y = 2.6\text{--}3.5$)³⁶ or bentonite $\cdot y\text{V}_2\text{O}_5 \cdot z\text{H}_2\text{O}$ ($y = 1.5\text{--}4.0$ and $z = 5\text{--}12$).³⁷ The composite is promising as a cathode material for chemical current sources: it possesses high conductivity inherent in the vanadium–oxygen xerogel layers and ion-exchange properties characteristic of the laminar clays. The compound has a layered type structure with $d = 12.8$ Å. This value is intermediate between the d values of 10.8 and 15.2 Å, which correspond to the initial substances, viz., $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel and bentonite. According to thermogravimetric analysis,³⁶ dehydration of the composite occurs in discrete steps. In the first step, 2.5 moles of weakly bound water are removed at a temperature below 120 °C. The second step, close to 180 °C, corresponds to the removal of 0.6 moles of stronger bound water. Full dehydration with removal of the remaining 0.4 moles of H_2O occurs at 400 °C. The formation of V–O–Si bonds in the mixed composite was confirmed by a comparative analysis of the IR spectra of the compounds. A new intense absorption band at 835 cm^{-1} appears and vibrations of the V=O and Si–O bonds in the region 1010–1045 cm^{-1} become weaker. Intercalation of the redox-active hexaammineruthenium complex in the interlayer space of the composite bentonite– $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel leads to an increase in its electrochemical response by at least 4 orders of magnitude. It thus follows that the films of the intercalated composite can be used as a material for the preparation of modified electrodes. Moreover, this composite is stable in aqueous solutions, and therefore no special polymeric coatings are needed.

A layered structure of vanadium(V) oxide xerogel is retained upon replacement of vanadium by tetra- and hexavalent ions. The chemistry, thermodynamics and properties of the intercalation compounds $\text{M}_x\text{V}_{2-y}\text{T}_y\text{O}_{5\pm\delta} \cdot n\text{H}_2\text{O}$ (M is proton, an alkali or alkaline-earth metal ion; T = Ti, Mo, W, Cr) have been documented.^{38–48} It was found that even small additives of the element T favour polymerisation of the sol to give stable gels. High intercalation capacity with respect to M^{z+} and thermal stability are characteristic of the intercalation compounds based on such complex vanadium oxides. Depending on the proportion of V to T, the compounds exhibit predominantly the properties of electronic or ionic conductors.

Vanadium-containing intercalation compounds include layered substances of the general formula $\text{VTO}_5 \cdot n\text{H}_2\text{O}$ ($\text{VTO}_4 \cdot n\text{H}_2\text{O}$) and intercalation compounds based on them, $\text{M}_x\text{VTO}_5 \cdot n\text{H}_2\text{O}$ (T = P, As, Nb, S, Mo).⁴⁹ The latter compounds are obtained by redox intercalation of the cations $\text{M} = \text{Li}^+$, Na^+ , K^+ , Rb^+ , Cs^+ , NH_4^+ , Mg^{2+} , Ba^{2+} , Mn^{2+} , Co^{2+} , Ni^{2+} , Fe^{3+} and Zn^{2+} in aqueous and non-aqueous media in the presence of a reducing agent.^{50–53} The reduction of vanadium is mediated by intercalation of a reducing agent followed by reduction of the isolated V^{5+} centres rather than by electron transport through a lattice of $\text{VTO}_5 \cdot 2\text{H}_2\text{O}$. Intercalation of inorganic cations into $\text{VPO}_5 \cdot 2\text{H}_2\text{O}$ disturbs the short-range order, as follows from both the broadening and the decrease in intensity of the diffraction maxima, and lowers the crystallinity of the initial vanadium(V) phosphate. $\text{VO}(\text{HPO}_4) \cdot 0.5\text{H}_2\text{O}$ also has a layered structure. Studies on the intercalation of Zn^{2+} , Ni^{2+} and Pd^{2+} into this compound have shown that the activities of intercalation compounds as catalysts of hydrogenation depend on the method of intercalation.^{54,55}

IV. Intercalation of organic compounds and complex ions

The study of the intercalation of a homologous series of compounds $\text{C}_n\text{H}_{2n+1}\text{N}(\text{CH}_3)_3\text{Br}$ ($n = 1\text{--}18$) and $\text{C}_n\text{H}_{2n+1}\text{NH}_2$ into $\text{V}_2\text{O}_5 \cdot 1.6\text{H}_2\text{O}$ xerogel has revealed⁵ the influence of steric factors on the structure of the complex formed. Depending on the length of the hydrocarbon chain, its orientation with respect to the vanadium–oxygen planes changes: the chain can be parallel ($n < 7$), inclined ($7 \leq n \leq 11$) or perpendicular ($n > 11$) to these planes. The interlayer distance changes correspondingly (Table 2). With the parallel arrangement of alkylammonium ions or alkylamines, the distance between vanadium–oxygen layers does not depend on the length of the alkyl chain and is equal to 12.9 and 12 Å for the compounds of the $\text{RN}(\text{CH}_3)_3\text{Br}$ and RNH_2 types, respectively. On average, the complex compound contains 0.3–0.4 moles of the intercalant per mole of V_2O_5 . These complexes are stable up to 160 °C, at higher temperatures amorphous vanadium(V) oxide is formed, which transforms into orthorhombic V_2O_5 at 400–450 °C. Intercalation of trimethylammonium ions occurs by a cation-exchange mechanism, while in the case of amines, the mechanism is more complex and includes transfer of the electrons between the matrix and the compounds being intercalated.

Table 2. Interlayer distances (Å) for complexes $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O} - \text{C}_n\text{H}_{2n+1}\text{N}(\text{CH}_3)_3\text{Br}$ (I) and $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O} - \text{C}_n\text{H}_{2n+1}\text{NH}_2$ (II).⁵

<i>n</i>	I	II
12	31.1	27.9
13	—	29.4
14	33.5	30.6
15	—	32.1
16	36.5	33.7
18	38.0	36.3

Amine-intercalated layered vanadium(V) oxides of the general formula $V_2O_5(H_2O)(C_nH_{2n+1}NH_2)_2$ ($n = 4, 6, 8$) have been synthesised.⁵⁶ The synthesis was carried out by vigorous stirring of a suspension of $V_2O_5 \cdot 0.6H_2O$ and an n -alkylamine (molar ratio 1:15) at room temperature for 48 h. The compositions of the compounds obtained may be expressed by the formulae $V_2O_5(H_2O)_{1.00}(C_4H_9NH_2)_{1.69}$, $V_2O_5(H_2O)_{1.09}(C_6H_{13}NH_2)_{1.82}$ and $V_2O_5(H_2O)_{1.26}(C_8H_{17}NH_2)_{1.80}$. The compounds possess laminar structures with interlayer distances of $d_{001} = 13.8, 16.4$ and 19.6 Å for butyl-, hexyl- and octylamine, respectively. The study of the ion-exchange properties of amine-intercalated compounds in aqueous 4 M solutions of CH_3COONa and CH_3COOK showed that alkylammonium ions form bilayers between the vanadium–oxygen layers. These ions are easily replaced by Na^+ or K^+ cations, which decreases the interlayer distance to 7.9 and 7.0 Å, respectively, independent of the length of a hydrocarbon substituent. A structural model for vanadium oxide intercalated with octylamine is shown in Fig. 5. On heating of this compound to 200 °C, its structure changes and d_{001} becomes equal to 22 Å. This d_{001} value as well as a layered structure are preserved up to 400 °C. Above 600 °C, a crystalline phase of V_2O_5 is formed.

IR, XPS and ESR studies of the interlayer absorption of ammonia, pyridine (py) and pyrazine into $V_2O_5 \cdot nH_2O$ xerogel have revealed the protonation of the nitrogen-containing bases (B) absorbed in the interlayer space.⁵⁷

Despite partial reduction of pentavalent vanadium upon absorption, the mechanism of intercalation consists mainly of protonation of the base by hydroxonium ions, which compensate the negative charge of the vanadium–oxygen layers (0.2 e per vanadium ion) and/or by water molecules with the formation of OH groups. Treatment of $V_2O_5 \cdot nH_2O$ xerogel with ammonia or pyridine resulted in the disappearance of the hyperfine structure from the ESR spectra. In the IR spectra of the compounds obtained, the absorption band at 975 cm^{-1} appears, which relates to $\nu(V^{4+}=O)$ vibrations. These vibrations contribute much less than the stretching vibrations $V^{5+}=O$ with the maximum absorption at 1020 cm^{-1} . Treatment of $V_2O_5 \cdot 1.5H_2O$ xerogel with ammonia and pyridine affords compounds with the compositions $V_2O_5(NH_4^+)(OH^-) \cdot 0.5H_2O$ and $V_2O_5[(pyH^+)(OH^-)]_{0.3} \cdot 0.6H_2O$ with interlayer distances 10.53 and 13.00 Å, respectively.

Figure 5. Structural model of the vanadium(V) oxide xerogel intercalated with octylamine.

The orientation of the pyH^+ ions is such that the C_2 axis of the heterocycle is perpendicular to the vanadium–oxygen layers.

Molecules of various solvents can easily replace water molecules in the $V_2O_5 \cdot 1.6H_2O$ xerogel;⁵ the interlayer distance changes in this case (Table 3). Mono- or divalent cations solvated by the molecules of organic solvents are also intercalated into the xerogel.⁵ The interlayer distance in the complexes obtained by intercalation of Li^+ , Na^+ , K^+ , Rb^+ , Cs^+ and Mn^{2+} into the xerogel is determined by the nature of the solvent and by the charge-to-effective radius ratio characterising the guest cation (Table 4).

Table 3. Maximum (d_1) and intermediate (d_2 – d_4) interlayer distances (Å) for composites $V_2O_5 \cdot nH_2O$ –organic solvent.⁵

Intercalation of molecules of n -alcohols into $V_2O_5 \cdot nH_2O$ has been considered⁵⁸ as the absorption of alkyl chains containing a different number of carbon atoms and having a polar OH group. It was found that methanol and ethanol molecules are oriented parallel to the vanadium–oxygen layers, while the molecules of alcohols with more than two carbon atoms have a perpendicular orientation. From the character of the alcohol absorption–desorption isotherms it was determined that ~ 0.5 moles of an alcohol are irreversibly intercalated into 1 mole of $V_2O_5 \cdot nH_2O$. These alcohols can be displaced by the action of water vapour followed by evacuation. The interlayer distances in the complexes do not depend on the vapour pressure of the alcohol in the case of alcohols with the number of carbon atoms $n = 2–4$, while in the case of $n > 4$, a noticeable increase in d is observed, which is not proportional to the size of the alcohol molecule. It is obvious that the mechanism of intercalation of n -alcohol molecules differs from that of alkylammonium cations and alkylamines.

The study of the thermal decomposition of complexes $V_2O_5 \cdot nH_2O$ – n -alcohol has revealed⁵⁹ that a layered structure of the matrix is retained up to 100 °C. Upon oxidation of the intercalated alcohol at $200–300$ °C, the vanadium–oxygen framework is destroyed. However, the decomposition products hamper crystallisation of vanadium oxide and the sample remains amorphous up to 550 °C according to X-ray diffraction analysis.

In the case of intercalation of such readily oxidisable organic molecules as aniline,^{60,61} pyrrole⁶² and thiophene,^{5,63} layered composite materials are obtained which contain a conducting polymerised layer in the interlayer space of the xerogel and combine a unique laminar microstructure of the matrix and the properties of a conducting polymer. The formation of these compounds is based on the redox reaction in which a monomer undergoes oxidation and polymerises, while vanadium(V) is partially reduced to a tetravalent state. The complex compound $(\text{C}_6\text{H}_4\text{NH})_{0.44} \cdot \text{V}_2\text{O}_5 \cdot 0.5 \text{H}_2\text{O}$ is a dark-blue colour and retains the layered structure of the xerogel with $d = 13.94 \text{ \AA}$. The conductivity of the compound obtained is higher than that of the original $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel by 4 orders of magnitude and amounts to $\sim 0.5 \Omega^{-1} \text{ cm}^{-1}$ at room temperature. Intercalation of 2,2'-bithiophene affords a black xerogel with the composition $(\text{C}_8\text{H}_4\text{S}_2)_{0.44} \cdot \text{V}_2\text{O}_5 \cdot 0.54 \text{H}_2\text{O}$ possessing metallic lustre, its conductivity amounts to $0.1 \Omega^{-1} \text{ cm}^{-1}$ at room temperature.

Layered intercalation compounds of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel with the cations $(\text{CH}_3)_4\text{N}^+$, $(\text{C}_2\text{H}_5)_4\text{N}^+$ and $\text{C}_6\text{H}_5\text{NH}_3^+$ are synthesised in aqueous solutions of tetramethylammonium, tetraethylammonium and anilinium salts, respectively.⁶⁴ The diffractograms of these compounds are characterised by the very narrow lines of the 00l reflections. The interlayer distances in the compounds synthesised are equal to 12.9, 13.1 and $13.9 \text{ \AA}$, respectively.

An aerogel composite vanadium(V) oxide–polypyrrole (PPyr) is obtained⁶⁵ as a co-polymerisation product of pyrrole and a vanadylalkoxide precursor. Hydrolysis of $\text{VO}(\text{OC}_3\text{H}_7)_3$ in a mixture pyrrole + water + acetone leads to the formation of a monolithic green–black gel, drying of which yields aerogel with a specific surface area of $150\text{--}257 \text{ m}^2 \text{ g}^{-1}$ and a density of $0.1\text{--}0.2 \text{ g cm}^{-3}$. Electroconductivity of this composite decreases with the increase in the content of pyrrole. When V_2O_5 and the colloidal polypyrrole are used as the starting compounds, the latter compound is intercalated into the ribbons of vanadium(V) oxide. This microcomposite gel (the specific surface area is $80\text{--}140 \text{ m}^2 \text{ g}^{-1}$) has an electroconductivity equivalent to that of V_2O_5 .

The microstructure and properties of the aerogel composite $\text{V}_2\text{O}_5\text{--PPyr}$ depend on the method of its synthesis.^{62,66} The composite prepared by dispersion of presynthesised polypyrrole particles into $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ (the matrix) has a nano-dimensional scaly nonhomogeneous structure. 'Post-gel' polymerisation, which includes sequential polymerisation of inorganic and organic phases, improves the microstructure of the hybrid material. The electroconductivity of the preformed specimens with the composition $(\text{PPyr})_{0.35}\text{V}_2\text{O}_5 \cdot 1.8 \text{H}_2\text{O}$ is equal to $(2\text{--}7) \times 10^{-3} \Omega^{-1} \text{ cm}^{-1}$. This value lies in the interval between the conductivities of aerogel $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ ($< 10^{-5} \Omega^{-1} \text{ cm}^{-1}$) and polypyrrole ($5.6 \times 10^{-2} \Omega^{-1} \text{ cm}^{-1}$). The results of a study of the hybrid material by cyclic voltammetry showed that its capacity with respect to reversibly intercalated lithium ion amounts to 1.4 moles of Li per mole of $(\text{PPyr})_{0.35}\text{V}_2\text{O}_5$. The specific discharge capacity of the cathode based on this material is twofold less than that of the cathode prepared from aerogel $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ and is equal to 95 mA h g^{-1} . 'Joint synthesis', consisting of simultaneous spontaneous polymerisation of the organic and inorganic precursors, leads to the formation of the hybrid composite $(\text{PPyr})_{0.8}\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ with nano-dimensional scaly homogeneous microstructure. The intercalation capacity of this material with respect to lithium equals 3.0 moles per mole. Redox intercalation of polypyrrole into the laminar hybrid material bentonite–vanadium(V) oxide xerogel affords a semiconducting ternary composite,⁶⁷ which combines the properties of layered V_2O_5 and the conducting polymer.

Redox-mediated intercalation of aniline and its salts into the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel can be accompanied by their polymerisation.^{61,68} At the molar ratio of anilinium iodide to $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ equal to 4, compound $(\text{C}_6\text{H}_5\text{NH}_3)_{0.4}\text{V}_2\text{O}_5 \cdot 0.4 \text{H}_2\text{O}$ was obtained, while in the case of oxidative polymerisation of aniline, the

Figure 6. Schematic representation of the polymerisation of anilinium in the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel.⁶¹

complex $[(1/n)(\text{C}_6\text{H}_4\text{NH})_n]_{0.4} \cdot \text{V}_2\text{O}_5 \cdot 0.4 \text{H}_2\text{O}$ (Fig. 6) is formed.⁶¹ IR spectra of these substances differ noticeably in frequencies of the stretching vibrations of V–O bonds: the main bands appear at $1000, 750, 496 \text{ cm}^{-1}$ and at $990, 852, 530 \text{ cm}^{-1}$ for the former and the latter compound, respectively. Intercalative intralaminar growth of the polymer in the nanocomposites polyaniline (PAni)– $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ is promoted by molecular oxygen which is activated by vanadium ions. The process results easily in the formation of the monolayers of PAni with the interlayer distance of $5.6 \text{ \AA}$.⁶⁸ Both during and after polymerisation, oxygen plays the role of the electron acceptor.

The study of the hybrid system PAni– $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel with different molar ratios of the components has revealed the formation of two phases, viz., $(\text{C}_6\text{H}_4\text{N})_{0.6}\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ and $(\text{C}_6\text{H}_4\text{N})_{1.2}\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$.⁶⁹ The interlayer distance in the former phase is $14 \text{ \AA}$, which corresponds to the intercalation of one monolayer of PAni into the xerogel. In the latter phase, the interlayer distance is $\sim 20 \text{ \AA}$, which is consistent with intercalation of two monolayers of PAni. On ageing of the nanocomposites $(\text{PAni})_x\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ in air, partial reoxidation of reduced vanadium and further oxidative polymerisation of the oligomers of PAni inside the layers of the xerogel occurs, which leads to elongation of the polymeric chains. The latter conclusion is confirmed by the increase in molecular mass of PAni extracted from aged intercalation compounds as compared to freshly prepared ones. Thermal stability is higher for the aged samples of PAni than for the initial ones. All the samples of $(\text{PAni})_x \cdot \text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ are paramagnetic. Magnetic susceptibility obeys the Curie–Weiss law; the van Fleck contribution does not depend on temperature. Electroconductivity of the freshly prepared hybrid material PAni– $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ depends on the degree of polymerisation of aniline inside the layers of xerogel and is always higher for the aged samples. At room temperature, the electroconductivity is equal to $10^{-6}\text{--}10^{-1} \Omega^{-1} \text{ cm}^{-1}$, while the thermoelectric power has a negative value which changes from -30 to $200 \mu\text{V deg}^{-1}$ depending on the degree of polymerisation.

An analogous composite compound was obtained upon interaction of the emeraldin base with the V_2O_5 sol.⁷⁰ The interlayer distance in the dark-violet composite $(\text{PAni})_{0.65} \cdot \text{V}_2\text{O}_5$ amounts to $13.8 \text{ \AA}$, its electroconductivity is $3 \times 10^{-5} \Omega^{-1} \text{ cm}^{-1}$; this compound is virtually insoluble in most organic solvents. ESR studies have revealed that the electron density is transferred from the lone electron pair on the nitrogen atom of the polymeric chain to V^{5+} .

Dark-green complexes with the compositions $(\text{PAni} \cdot \text{HClO}_4)_{0.52} \cdot \text{V}_2\text{O}_5$ and $(\text{PAni} \cdot \text{HBF}_4)_{0.55} \cdot \text{V}_2\text{O}_5$ containing doped polyaniline have been described.⁷⁰ Their interlayer distances (14.0 and 13.8 Å, respectively) are somewhat larger than for $(\text{PAni})_{0.65} \cdot \text{V}_2\text{O}_5$. It is apparently caused by additional intercalation of the anion-dopant into the layered structure. Due to the presence of doped polymer in the compounds $(\text{PAni} \cdot \text{HClO}_4)_{0.52} \cdot \text{V}_2\text{O}_5$ ($\sigma = 8 \times 10^{-4} \Omega^{-1} \text{ cm}^{-1}$) and $(\text{PAni} \cdot \text{HBF}_4)_{0.55} \cdot \text{V}_2\text{O}_5$ ($\sigma = 9 \times 10^{-4} \Omega^{-1} \text{ cm}^{-1}$), their electroconductivities are higher than those of the non-doped $(\text{PAni})_{0.65} \cdot \text{V}_2\text{O}_5$. The composites synthesised are redox-active in both aqueous acidic and organic aprotic electrolytes. For instance, virtually no destruction of $(\text{PAni})_{0.65} \cdot \text{V}_2\text{O}_5$ occurred upon multiple cycling in 1 M HCl solution in the potential range of 0.2–1.0 V.

A new hybrid material based on a binary polymeric component including poly(2,5-dimercapto-1,3,4-thiadiazole) (PDMcT) and PAni was synthesised.⁷¹ It was reported⁷² that intercalation of the 2,5-dimercapto-1,3,4-thiadiazole (DMcT) dimer leads to its polycondensation with formation of the composite (PDMcT)/ V_2O_5 . Dithiol DMcT is a promising charge-accumulating material. Due to a reversible redox reaction, it polymerises upon oxidation (charge) and depolymerises upon reduction (discharge). It is known that DMcT and PDMcT are not conductors, but their participation in electrochemical processes allows one to increase the efficiency of exploitation of the conducting polymer, *e.g.*, PAni. A hybrid material (PDMcT)/ V_2O_5 is obtained by mixing a methanolic solution of the monomer DMcT with $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ gel in the molar ratio 1 : 2. The reaction mixture is then kept under constant stirring at room temperature for 24 h. The resulting brown precipitate is filtered off, washed with methanol and dried at 50 °C in a vacuum.

Synthesis of a green-coloured composite (PDMcT + PAni)/ V_2O_5 is carried out according to the same scheme with addition of aniline to the reaction mixture in the ratio $\text{V}_2\text{O}_5 : \text{Ani} = 1 : 1$. X-Ray and IR studies on the hybrid material built of a binary polymeric component and $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel confirmed cointercalation of DMcT and Ani with the formation of polymers, *viz.*, PDMcT and PAni, in the V_2O_5 matrix. In the IR spectrum, the band at 1015 cm^{-1} , corresponding to the vibrations of the V = O bond, is displaced to the low-frequency region up to 1000 and 1005 cm^{-1} for PAni/ V_2O_5 and (PDMcT + PAni)/ V_2O_5 , respectively. The interlayer distance in the xerogel increases from 11.79 to 13.83 Å for all the polymer-intercalated specimens. Studies on the electronic structure showed insignificant distortions of octahedral symmetry of VO_6 , which are accompanied by partial reduction of the V^{5+} ions. The specific discharge capacity for the composites polymer/ V_2O_5 is lower than that for the original $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel (205 mA h g^{-1}) and amounts to 200 and 187 mA h g^{-1} for PDMcT/ V_2O_5 and (PDMcT + PAni)/ V_2O_5 , respectively. This effect can probably be associated with a decrease in the vanadium oxidation state. However, the discharge capacity increased by 10% for PDMcT/ V_2O_5 and by 17% for (PDMcT + PAni)/ V_2O_5 after treatment of the specimens in the flow of oxygen at 100 °C for 3 h. Possibly, the enhancement of the electrochemical characteristics occurs due to partial reoxidation of vanadium ions and formation of longer polymeric chains in the interlayer space of the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel. Intercalated PDMcT can be considered as an active additive to PAni, intensifying a reversible process of lithium intercalation–deintercalation.

Intercalation compounds of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel with complexes $\text{M}(\text{bipy})_3^{2+}$ (M = Ru, Ni and Co; bipy is bipyridine) are of interest as photochemical materials and can be used in photocatalysis for decomposition of water.⁷³ The formation of an intercalation compound with the complex is accompanied by an increase in the interlayer distance by ~ 8 Å, which corresponds to intercalation of a monolayer of $\text{M}(\text{bipy})_3^{2+}$ (Table. 5). The content of $\text{M}(\text{bipy})_3^{2+}$ in the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel is somewhat less than the theoretical value (0.2 moles per mole of V_2O_5) and amounts to 0.16, 0.14 and 0.11 moles for M = Ru, Ni and Co, respectively.

Table 5. Compositions and interlayer distances for intercalation compounds $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O} - \text{M}(\text{bipy})_3^{2+}$ (Ref. 73).

$\text{M}(\text{bipy})_3^{2+}$	M : V_2O_5	bipy : M	d_{001} / Å
$\text{Ru}(\text{bipy})_3^{2+}$	0.072	3.1	16.3
	0.12	3.1	17.1
	0.16	3.0	17.3
	0.16	3.2	17.1
$\text{Ni}(\text{bipy})_3^{2+}$	0.14	3.2	17.4
$\text{Co}(\text{bipy})_3^{2+}$	0.11	2.9	16.3

Thermal studies on this composite showed that a layered structure of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel is stabilised upon intercalation of cations.

Xerogel-based nanocomposites with the general formula $(\text{PEO})_x \cdot \text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ were obtained by stirring aqueous solutions of poly(ethylene oxide) (PEO) with vanadium(V) oxide gel followed by slow evaporation of water.⁷⁴ The interlayer distance in the compounds obtained changes from 13.2 to 16.8 Å in the region $x = 0.5 - 1.0$, whereas, at $1 < x < 3$, it changes from 17.6 to 18.3 Å. It was established by means of X-ray diffraction that the composites contain a monolayer or a bilayer of PEO molecules when $x < 1$ and $x \geq 1$, respectively. The PEO chains are close to each other and fill completely the interlayer space of the xerogel by wavy mono- or bilayers.

Complex compounds of $(\text{PEO})_x \cdot \text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ with alkali metal ions are actively studied with the aim of their use as solid electrolytes and as materials with electrochromic properties.⁷⁵ A red composite $(\text{PEO})_x \cdot \text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ has an interlayer distance of 13.2 Å, the chains of PEO are situated linearly in the interlayer space. A single-phase specimen is obtained in the ratio $\text{PEO} : (\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}) < 0.8$. The composite is well moulded to a thin film which is more flexible than that of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$. The film of this specimen absorbs water reversibly, its content changes from 1.6 to 1.8 moles per mole of V_2O_5 . Besides, the film can be involved in redox intercalation according to the reaction

The composite is a dark-blue colour and the interlayer distance 13.0 Å; its electroconductivity is higher than that of the original xerogel.

The $\text{PEO}/\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ films are light-sensitive, they acquire a blue colour upon irradiation with a mercury lamp. These changes in colour are caused by the light-induced reaction in which PEO is oxidised by a pentavalent vanadium. The film of the original $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel is not light-sensitive. IR studies have shown that no structural changes occur on its irradiation. It has been revealed by ESR that the process is only accompanied by the increase in the concentration of V^{4+} centres. Measurements of the magnetic susceptibility have shown a noticeable increase in the magnetic moment which amounted to 0.8 μ_B per formula unit at 300 K. Upon irradiation of the intercalation compound, its conductivity increases by ~ 2 orders of magnitude, while the solubility decreases. A film with the composition $(\text{PEO})_{0.5} \cdot \text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ exhibits semiconducting properties, its conductivity at room temperature equals $10^{-2} \Omega^{-1} \text{ cm}^{-1}$.

By intercalation of such water-soluble polymers as tetraakis(*N*-methyl-4-pyridyl)porphine,⁷⁶ poly(ethylene glycol),⁷⁷ poly(propylene glycol), poly(vinylpyrrolidone), methylcellulose⁷⁸ and poly(4-ethylphenol)⁷⁹ into the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel, ordered nanocomposite materials were obtained, their mechanical, optical and electrical properties can be controlled.

Intercalation of *N*-morpholinoisothiocyanate alone or together with copper ions into vanadium(V) oxide xerogel affords new complex compounds $(\text{C}_5\text{H}_8\text{N}_2\text{OS})_{0.35}\text{H}_2(\text{V}_{12}\text{O}_{31-\delta}) \cdot 8.8 \text{H}_2\text{O}$ and $(\text{C}_5\text{H}_8\text{N}_2\text{OS})_{0.35} \cdot \text{Cu}_{0.2}\text{H}_2(\text{V}_{12}\text{O}_{31-\delta}) \cdot 10.5 \text{H}_2\text{O}$, the inter-

layer distances in which are equal to 11.55 ± 0.05 and 14.30 ± 0.05 Å, respectively.⁸⁰ Intercalation of $C_5H_8N_2OS$ molecules was found to increase thermal stability of the xerogel (from 345 to 370 °C). As the temperature decreases from +50 to –50 °C, the electroresistivity increases sharply for these compounds, and the copper-containing xerogels always possess lower resistivities.

Upon interaction of 3,4-dihydroxyphenylalanine with $V_2O_5 \cdot nH_2O$ gel, a new hybrid material with the composition $(C_8H_9NO_2)_x \cdot V_2O_5 \cdot nH_2O$ was synthesised, which is characterised by a dark-blue colour and metallic lustre.^{81,82} The composite retains the laminar structure of the xerogel at $x < 0.02$, its interlayer distance is ~ 15 Å. A thin-film sample of this material possesses high stability in the electrochemical intercalation–deintercalation of Li^+ and is completely recovered even after 60 oxidation–reduction cycles. It was found that the intercalation of the alanine derivative into the $V_2O_5 \cdot nH_2O$ xerogel lowers the activation energy of conductivity from 0.35 to 0.20 eV.

Compounds of the $V_2O_5 \cdot x(ML_2X) \cdot nH_2O$ type ($M = Fe, Co, L$ is cyclopentadienyl, $X = Cl, Br, I$) were obtained by interaction of 5×10^{-3} M aqueous solution of ML_2X with vanadium(V) oxide xerogel.⁵ The interlayer distance in these compounds depends neither on the water content in the initial xerogel nor on the nature of the anion and amounts to ~ 13.22 Å. For the intercalation compounds with organometallic complexes, the main mechanism of formation consists of the exchange between the cations of the intercalant and the protons of hydrated polyvanadium acid. The formula of the iron-containing compounds was established as $V_2O_5 \cdot 0.4Fe(C_5H_5)_2 \cdot nH_2O$ ($n < 0.5$). Heating of the intercalation compounds in air up to 100 °C results in the loss of absorbed water. The structure of iron- and cobalt-containing complexes remains virtually unchanged up to 200 and 340 °C, respectively. Analysis of the widths of reflections in the diffractograms showed that the coherence length is noticeably increased for these compounds, in particular, for the cobalt-containing ones. Pentadienyl rings are oriented perpendicular to the layers of the basic structure and scaly-like stratifying occurs.

Complexes $V_2O_5 \cdot (H_2O)_{0.6} \cdot [FcH]_{0.27}$, $V_2O_5 \cdot (H_2O)_{0.6} \cdot [FcMe_2]_{0.22}$ and $V_2O_5 \cdot (H_2O)_{0.6} \cdot [FcCH_2NHMe_2^+]_{0.16}$ were obtained by intercalation of the $V_2O_5 \cdot nH_2O$ xerogel with ferrocene, 1,1'-dimethylferrocene or (ferrocenylalkyl)ammonium halides, respectively, using their ethanolic solutions.⁸³ These complex compounds are formed mainly due to a redox reaction between iron and the V^{5+} ions and partly due to an ion exchange. The interlayer distances for the xerogels intercalated with ferrocene or with its alkylamino derivatives are virtually the same (13.2–13.5 Å) (Table 6), which suggests parallel orientation of the alkylammonium cation with respect to the vanadium–oxygen layers (Fig. 7). X-Ray spectroscopic and ESR studies have

Figure 7. Schematic representation of the arrangement of (ferrocenylalkyl)ammonium compounds in the interlayer space of the $V_2O_5 \cdot nH_2O$ xerogel.⁸³

revealed that the Fe^{3+} ions are localised near the V^{4+} ions. Analogous conclusions have been drawn⁸⁴ from the study on the intercalation of diferrocenyl compounds containing bridging alkyl groups $[Fc(CH_2)_nFc; n = 1, 2]$ into the interlayer space of the $V_2O_5 \cdot nH_2O$ xerogel. In this case, intercalation is also caused by a redox reaction between iron and the V^{5+} ions. The guest molecules in $V_2O_5 \cdot (H_2O)_{0.8} \cdot (Fc^+CH_2CH_2Fc^+)_{0.23}$ are oriented nearly parallel to the vanadium–oxygen layers. Orientation of a cobaltocenium ion in the interlayer space of the complex compound $V_2O_5[Co(C_5D_5)_2]_{0.2} \cdot (H_2O)_{0.5}$ has been studied by ^2H NMR.⁸⁵ It was found that the C_5 axes are directed parallel to the vanadium–oxygen framework.

The possibility of intercalation of vanadium(V) oxide xerogel with various macrocyclic compounds as, for instance,

Table 6. Compositions and interlayer distances for intercalation compounds based on the $V_2O_5 \cdot nH_2O$ xerogel.^{83–86}

Intercalation compound	d_{001} / Å	Intercalation compound	d_{001} / Å

where 12C4 is 12-crown-4, 15C5 is 15-crown-5, 18C6 is 18-crown-6, C222 is cryptand-2,2,2, NBnI is benzylammonium iodide, OcI is octylammonium iodide, and TTFRI is *N,N,N*-trimethylmethyliumtetrathiafulvalene iodide, was discussed.^{86–89}

The formation of a hybrid product based on crown ethers proceeds by a complexation mechanism. Cyclic guest molecules interact as the ligands with protons or metal ions (Li^+ , Na^+) localised in the interlayer space of the xerogel with simultaneous partial replacement of water molecules. The compositions and the interlayer distances of the compounds obtained are given in Table 6. IR spectroscopic studies have revealed that the absorption band characterising $\delta(\text{H}-\text{O}-\text{H})$ vibrations is shifted from its position for the initial matrix (1620 cm^{-1}) to 1635 and 1644 cm^{-1} for $18\text{C}6/\text{V}_2\text{O}_5$ and $12\text{C}4/\text{V}_2\text{O}_5$, respectively. This indicates strengthening of the energy of binding between the water molecules and vanadium–oxygen layers in the intercalation compounds. It is obvious that intercalation of macrocyclic compounds into the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel decreases the mobility of the protons and the ionic component of conductivity. Application of hybrid materials based on crown ethers for ion-selective membranes and sensors was proposed.⁸⁹

Intercalation compounds of the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel with tetrathiafulvalene (TTF) and benzidine (Bzd) are of interest as promising novel materials. In essence, they can be assigned to ‘molecular bronzes’. Intercalation proceeds by a charge transfer mechanism. Irreversible intercalation of TTF into the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel in a water–ethanolic solution leads to the formation of a complex compound $(\text{TTF})_x \cdot \text{V}_2\text{O}_5$ ($x < 1.8$)⁹⁰ in which the interlayer distance amounts to $13.7\text{ \AA}$. This compound is insoluble in water, contains a large amount of strongly bound water and up to $\sim 25\%$ of vanadium ions in a tetravalent state. Electronic conductivity of $(\text{TTF})_x \cdot \text{V}_2\text{O}_5$ depends on the stoichiometric composition of these complexes. The conductivity for specimens with $x = 0.17$ and 1.5 is larger than that for V_2O_5 by factors 46 and 15, respectively.

Black flake-like precipitate of compounds $(\text{Bzd})_x \cdot \text{V}_2\text{O}_5$ with a maximum Bzd content ($x = 1$) is formed in an irreversible reaction of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel dispersed in water with an ethanolic solution of Bzd over a few seconds.⁹⁰ In the structurally similar compound $(\text{TTF})_x \cdot \text{V}_2\text{O}_5$, saturation with respect to intercalant is not achieved even at $x = 2.9$. The diffractogram of compound $(\text{Bzd})_x \cdot \text{V}_2\text{O}_5$ was found to contain 001 reflections corresponding to an interlayer distance of $15.6\text{ \AA}$. The benzidine molecules in the xerogel are inclined with respect to the vanadium–oxygen layers. Electronic conductivity of the complex compound $(\text{Bzd})_x \cdot \text{V}_2\text{O}_5$ ($\sigma = 2.8 \times 10^{-6}\text{ }\Omega^{-1}\text{ cm}^{-1}$) differs only slightly from that of the original xerogel.

The conditions for the preparation of intercalation products of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ gel with methyl-, heptyl- and benzylviologens have been described.^{91,92} As a result of ion exchange, the organic components are situated between the layers of the xerogel and orientation of their molecules depends on the type of viologen. With respect to the vanadium–oxygen layers, the molecules intercalated into the interlayer space of the xerogel are parallel (as a monolayer) in the case of methyl- and benzylviologens and perpendicular in the case of heptylviologen.

With intercalation of octyl-, benzyl- and TTF-ammonium iodides,⁸⁶ which is accompanied by a partial reduction of V^{5+} to V^{4+} , the conductivity of the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel increases by 1.5–2 orders of magnitude. The compositions and interlayer

distances for the compounds obtained are given in Table 6. The electroconductivity of the octyl-containing hybrids $\text{V}_2\text{O}_5(\text{Oc})_x \cdot n\text{H}_2\text{O}$ depends on the x value and on the orientation of organic molecules in the interlayer space. At $x \leq 0.2$, the alkyl chains are situated parallel, while, at $x > 0.5$, they are mainly perpendicular to the vanadium–oxygen layers. The electroconductivity of the specimens with transversal geometry of the intercalant is limited by the mobility of charge carriers, *i.e.*, the electrons. Their mobility is associated with overcoming a high potential barrier on moving across the vanadium–oxygen layers. As a consequence, an increase in the interlayer distance leads to decrease in conductivity of the octyl-containing complex.

Mechanical activation of vanadium(V) oxide xerogel accelerates significantly the initial intercalation step as was established⁹³ with an example of *n*-hexadecyltrimethylammonium bromide. The interlayer distance in the compound obtained under equilibrium conditions equals $14.45\text{ \AA}$. This value is very close to the value of quadruplicate diameter of the alkyl chains ($14.52\text{ \AA}$) and is twice as large as the parameter b of the crystal lattice of *n*-hexadecyltrimethylammonium bromide. It thus follows that the latter compound is situated parallel to the layers of the laminar structure of the xerogel.

Photo- and electrophotoreactive nanocomposite materials can be obtained using organic dyes as intercalated substances. The study on the kinetics of intercalation of methylene blue (MB^+) into $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ gel by absorption spectroscopy in the range $500\text{--}800\text{ nm}$ has shown that the driving force of the process is the reduction of methylene blue by the V^{4+} species (see Ref. 94). Interaction of MB^+ with the gel can be described by the following scheme:

Reduction of methylene blue is followed by protonation, reoxidation by oxygen and dimerisation of the dye. The rate constant for the transformation of protonated methylene blue into the dimer is $100\text{ mol litre}^{-1}\text{ s}^{-1}$.

Compounds based on the layered oxides VTO_5 ($\text{T} = \text{P, As, S}$, and others) with a structure of vanadyl phosphate VOPO_4 (Ref. 95) are relative to the above-considered intercalation compounds. In the phases intercalated by pyridine, this coordinates to vanadium and is situated perpendicular to the VTO_5 layers. Reduction of vanadium(V) virtually does not occur and the layers of the original matrix are retained. Cations of relatively large sizes, *e.g.*, ferrocenylalkylammonium, can be intercalated into a layered structure of $\text{VOPO}_4 \cdot \text{H}_2\text{O} \cdot \text{EtOH}$.^{84,96}

The results of the study on the intercalation of $\text{VOPO}_4 \cdot \text{H}_2\text{O} \cdot \text{EtOH}$ with ferrocene and its alkyl derivatives (1,1'-dimethyl-, ethyl-, *n*-butyl-) as well as by cobaltocenium cations, carried out in ethanol, have been reported.⁹⁷ The interlayer distances in the compounds obtained are increased with respect to the interlayer distance of the initial phosphate ($d_{001} = 7.5\text{ \AA}$) and reach $8.8\text{--}10.3\text{ \AA}$. Intercalated molecules of ferrocene and its derivatives were found to be situated perpendicular to the VPO_5 layers.

Layered hydrates of mixed oxides $\text{VAsO}_5 \cdot 3\text{H}_2\text{O}$ and $\text{VPO}_5 \cdot 2\text{H}_2\text{O}$ interact with alkylammonium iodides in an aqueous medium or in organic solvents with formation of compounds with the general formula $(\text{RNH}_3)_x \text{V}_x^{\text{IV}} \text{V}_{1-x}^{\text{V}} \text{TO}_5 \cdot \text{H}_2\text{O}$ ($\text{R} = \text{C}_n\text{H}_{2n+1}$, $n = 3\text{--}8$; $x = 0.4\text{--}0.6$; $\text{T} = \text{As, P}$). It is of note that the parameter d_{001} depends linearly on the number of carbon atoms in the alkyl radical $\text{C}_n\text{H}_{2n+1}$. A layered structure of the initial hydrates of mixed oxides $\text{VTO}_5 \cdot n\text{H}_2\text{O}$ is retained in these intercalation compounds.

Mixtures of aliphatic alcohols ranging from ethanol to *n*-heptanol are intercalated into the lattice of non-hydrated vanadyl sulfate VOSO_4 with the formation of the inclusion compounds.⁹⁸ Intercalation compounds of $\text{VOPO}_4 \cdot n\text{H}_2\text{O}$ with glycerol have been obtained.⁹⁹ These substances are unstable; on keeping in air, glycerol reduces vanadium to a tetravalent state and the specimen changes its colour from yellow to green. Incorporation of the

glycerol molecules into the interlayer space of vanadium(V) phosphates leads to disordered compounds.

The process of intercalation of aniline derivatives into $\text{VOPO}_4 \cdot n\text{H}_2\text{O}$ has been studied.^{100, 101} It was found that their intercalation into the interlayer space of vanadyl phosphate occurs only due to protonation of amino groups or oxidation of the iodide ion accompanied by reduction of V^{5+} to V^{4+} .

V. Nanotubular forms of intercalation compounds

A search for various nano-structured functional materials is accompanied by the development of studies into the synthesis and investigation of properties of non-carbon nanotubes (nanotubulenes, NTs).¹⁰² Vanadium(V) oxide-based nanotubulenes have been synthesised not long ago.¹⁰³ For their preparation, a sol–gel method was found to be effective, which allows one to obtain the xerogel with explicitly pronounced quasi-one-dimensional structure of the layers. By combination of the sol–gel method with hydrothermal treatment in air at 180 °C for 5 h, a nanowire with the composition $\text{V}_2\text{O}_5 \cdot 0.3\text{H}_2\text{O}$ and with a length of several tens of micrometers and a width of several tens of nanometers was synthesised.^{104, 105}

An extensive body of experimental data on the chemistry of intercalation compounds based on the $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel served as a basis for searching new methods for synthesis of nanotubular forms of vanadium(V) oxide. Obviously, the possibility of changing the distance between the vanadium–oxygen layers in the layered structure of the xerogel upon intercalation of molecules of various organic substances in the interlayer space was used in the design of vanadium–oxide NT: in this case, the organic guest molecules act as a template and determine the structure of multi-layered nanotubular composites.

It was suggested^{106–108} that primary amines $\text{C}_n\text{H}_{2n+1}\text{NH}_2$ ($4 \leq n \leq 22$) or diamines $\text{H}_2\text{N}(\text{CH}_2)_n\text{NH}_2$ ($14 \leq n \leq 20$) be used as structure-forming templates. For instance, ethanolic solutions of vanadium(V) triisopropyl oxide ($\text{Pr}^i\text{O})_3\text{VO}$ and an amine taken in the molar ratio 2 : 1, were stirred for 1 h followed by hydrolysis. After ageing of this system for 12–96 h, an orange composite was obtained, which transformed into a black monophasic product after hydrothermal treatment in an autoclave at 180 °C for 2–7 days. The product was isolated in the form of nanotubes with a length of up to 15 μm , an outer diameter of 15–150 nm and an inner diameter of 5–50 nm. The walls of the tubes consisted of 2–30 layers of crystalline vanadium oxide with the amine or diamine molecules intercalated in the space between the layers. The distance between the layers was proportional to the length of alkylamine and changed in the range from 17 to 38 Å. The general formula of these compounds can be written as $\text{VO}_x\text{O}_{y/2} \cdot (\text{C}_n\text{H}_{2n+4}\text{N})_y$. In the case of diamines, the tubes had thicker walls and smaller inner diameters than in the case of amines. The structure of the vanadium–oxygen layers comprised tetrahedra of VO_4 and tetragonal pyramids of VO_5 . The tubes of vanadium oxide remained stable after removal of the amines and were destroyed upon thermal treatment above 250 °C.

Unlike mesoporous metal oxides with laminar structures, the composites under consideration are characterised by a tubular morphology and well-structured walls. According to the published data,¹⁰⁴ the ‘volumes’ of vanadium–oxygen layers are very flexible, they can be stretched in a line and can be involved in numerous exchange reactions. It was reported¹⁰⁹ that the synthesis of NT with the use of vanadium(V) oxychloride and oxide as precursors occurs in two stages. In the first step, VOCl_3 or V_2O_5 was mixed with a primary amine $\text{C}_n\text{H}_{2n+1}\text{NH}_2$ ($11 \leq n \leq 20$) in an inert atmosphere, then hydrolysed in an acetate buffer (pH 7) or in water. The next step consisted of hydrothermal treatment at 180 °C for 7 days. According to data from elemental analysis, the compositions of the NT synthesised from VOCl_3 or V_2O_5 correspond to the general formulae $\text{VO}_{2.45 \pm 0.05} \cdot (\text{C}_n\text{H}_{2n+4}\text{N})_{0.27 \pm 0.01}$ ($11 \leq n \leq 16$) and $\text{VO}_{2.43 \pm 0.03} \cdot (\text{C}_n\text{H}_{2n+4}\text{N})_{0.27 \pm 0.01}$ ($11 \leq n \leq 20$), respectively. Morphological

Table 7. Morphologic characteristics of the vanadium-oxide nanotubulenes (the template is $\text{C}_n\text{H}_{2n+1}\text{NH}_2$).¹⁰⁹

Precursor	<i>n</i>	Outer diameter NT /nm	Inner diameter NT /nm	Number of layers	Length NT / μm
($\text{Pr}^i\text{O})_3\text{VO}$	$4 \leq n \leq 22$	15–150	5–50	2–30	1–15
VOCl_3	11	50–100	15–35	10–20	1.5–5
	16	80–100	20–35	11–14	0.8–1.5
V_2O_5	11	70–140	20–35	9–13	2–12
	12	50–90	15–35	7–13	1–3
	16	70–100	20–45	6–11	1–2
	20	60–90	20–45	6–10	1–3

characteristics of the vanadium oxide NT obtained from different precursors and templates are given in Table 7. It should be mentioned that the ends of the NT obtained by this method are open and characterised by a multi-layer morphology formed by the ‘volumes’ of vanadium–oxygen layers.

Changes in the pH of the V_2O_5 gel by addition of ammonia allows one to synthesise NT with definite structural characteristics.¹¹⁰ In neutral or weakly acidic media, tubes with an interlayer distance proportional to the length of the amine are formed. Nanotubulenes obtained at pH 9–10 have unique wall structures; these are built of the VO_x layers alternating regularly with intercalated molecules of the amine or ammonia (the interlayer distances VO_x – VO_x are equal to 2.0 and 0.9 nm, respectively). Nanotubulenes formed with the use of ammonia are characterised by a significantly larger outer diameter (> 250 nm) and by a smaller length (2–5 μm) as compared with the NT synthesised at pH 4–8. The general formula of the new NT was suggested to be $[(\text{NH}_4)_y\text{VO}_x][(\text{C}_n\text{H}_{2n+1}\text{NH}_3)_z\text{VO}_x]$. An excess amount of the amine in the NT is easily replaced by sodium, potassium, magnesium, calcium, strontium, iron, cobalt, nickel or copper cations.¹¹¹ This method of modification of VO_x -nanotubulenes may become effective for improving properties of the initial composite. This procedure does not change the tubular morphology and only decreases the interlayer distance from 2.8 nm (for $\text{C}_{12}\text{H}_{25}\text{NH}_3\text{VO}_x$) to 0.9–1.2 nm depending on the cation.

A new manganese-containing intercalation compound with tubular morphology with the general composition $\text{Mn}_{0.1}\text{VO}_{2.5+\delta} \cdot n\text{H}_2\text{O}$ was synthesised¹¹² by ion exchange starting from the layered precursor $\text{V}_2\text{O}_5 \cdot \delta(\text{C}_{12}\text{H}_{25}\text{NH}_3)$. For the NT obtained, the section diameter and the length reached 100 nm and 1300 nm, respectively. These NT contained such defects as partial destruction of the layers and their zigzag-like shape. The structure of the layers is tetragonal with unit cell parameters $a = 6.157(3)$ and $c = 10.52(3)$ Å. This compound was assayed as a cathode material in the electrochemical intercalation of lithium. It was found that 0.5 moles of lithium per mole of V_2O_5 are reversibly intercalated into these NT at a potential of ~ 2 V. The specific discharge capacity of the battery amounted to 140 A h kg^{-1} .

It was proposed¹¹³ to use derivatives of *trans*-(1*R*,2*R*)- and *trans*-(1*S*,2*S*)-1,2-diaminocyclohexane as templates in the synthesis of helical chiral VO_x -nanotubulene structures. In the case of the *R,R*-enantiomer, a left-handed helix was always formed, while in the case of *S,S*-enantiomer it was right-handed.

Carbon NT can be used as templates for obtaining nano-structured vanadium oxide.^{114, 115} The synthetic procedure includes covering of a carbon NT with V_2O_5 gel and subsequent removal of carbon by calcination at 700 °C. The carbon NT are pretreated with boiling HNO_3 for 24 h for creation of acidic centres on the surface. The diameters and the lengths of the NT synthesised according to this procedure amounted to 20–55 nm and 2–3 μm , respectively. Electron diffraction studies of the specimens have revealed their orthorhombic structures with unit cell parameters $a = 11.44$, $b = 3.54$ and $c = 4.35$ Å.

Unfortunately, most investigations into the VO_x -nanotubulenes are concerned mainly with synthetic procedures and studies on the morphology of specimens. Only a few publications (see, e.g., Ref. 116) contain data on the physicochemical properties and evaluate the prospects for the application of vanadium-oxide NT as oxidation catalysts,¹¹⁵ a cathode material for reversible lithium batteries^{117–120} and a semiconducting material for the preparation of field-controlled transistors.¹²¹

VI. Applications of intercalation compounds

Most studies on the application of vanadium(V) oxide xerogels have focused on their use in the design of chemical power sources.¹²² Compared to the crystalline vanadium oxides, the xerogels form very mobile layered structures in which various cations and molecules of organic substances can easily be intercalated and deintercalated. The advantages of xerogels include the ion-electronic type of conductivity and the possibility of displacing water molecules by hydrophilic organic solvents. Studies on the cathodic behaviour of superfine powders, films and nanocomposites of the intercalation compounds in the electric power sources with lithium anode merit special attention.^{123–125} In a 1 M solution of LiClO_4 in propylenecarbonate (PC), the exchange of water molecules with molecules of the organic solvent occurs without application of a voltage; this is accompanied by an increase in the interlayer distance up to 21.5 Å. However, the solvent is further displaced by lithium and $\text{Li}_{0.4}\text{V}_2\text{O}_5$ is formed. In the discharge step, the formation of compounds $\text{Li}_{1.1}\text{V}_2\text{O}_5$ and $\text{Li}_{1.6}\text{V}_2\text{O}_5$ was detected. The layered structure of the xerogel is destroyed in the final step of intercalation of Li^+ . The steady-state potential for the film with the composition $\text{V}_2\text{O}_5 \cdot 2.2\text{H}_2\text{O}$ in a 1 M solution of LiClO_4 in PC amounts to 3.20–3.85 V relative to metallic lithium.¹²⁶ The parameter d_{001} of the xerogel $\text{Li}_x\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ changed from 11.6 to 16.7 Å on keeping the specimen in a solution of LiClO_4 , decreased to 10.4 Å ($x = 0.2$) upon cathodic lithiation and then remained constant up to $x = 0.7$ in $\text{Li}_x\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$.

According to the reported data,¹²⁷ intercalation of PC results in compounds $\text{V}_2\text{O}_5 \cdot 0.1\text{H}_2\text{O} \cdot 0.3\text{PC}$ with the parameter $d_{001} = 22.0$ Å, which decreases to 11.0 Å for the ratio $\text{Li}:\text{V} = 0.01$ in the xerogel. Intercalation of Li^+ is accompanied by simultaneous insertion of PC, which weakens the interaction between the protons of the interstitial water and oxygen of the xerogel. Kinetic studies on a compound with the composition $\text{Li}_{0.3+x}\text{V}_2\text{O}_5 \cdot 0.2\text{H}_2\text{O} \cdot \text{PC}$ have revealed¹²⁸ that the chemical diffusion coefficient of lithium ions (D_{Li}) decreases from 10^{-8} to $10^{-9} \text{ cm}^2 \text{ s}^{-1}$ as the x value increases from 0 to 0.2. The above-mentioned values of D_{Li} are higher than the value of $10^{-11} \text{ cm}^2 \text{ s}^{-1}$, characteristic of the crystalline V_2O_5 in the region $0 < x < 1$. As the content of lithium ions increases ($0.2 < x < 1.3$), their mobility decreases and the D_{Li} value becomes equal to $5 \times 10^{-11} \text{ cm}^2 \text{ s}^{-1}$ at $x = 1.3$. Using a chemical or electrochemical method, up to 4 moles of lithium per mole of V_2O_5 can be intercalated. With this material, the specific cell capacity of 1600 W h kg^{-1} can be reached, which is significantly higher than for any other material based on vanadium oxide.¹²⁹

It was mentioned^{130,131} that the degree of intercalation of lithium ions into the films of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogel depends on the morphology of films, which can be modified by adding carbon (in the form of a powder) in the course of the synthesis of the gel. The degree of lithium intercalation is also affected by the electronic conductivity of the xerogel, which can be increased by adding silver (in the form of a powder) or copper to the gel.^{132,133} Thin films with a molar ratio $\text{M}:\text{V} = 0.005–5$ ($\text{M} = \text{Ag}, \text{Cu}$) have been obtained from this type of composite. An increase in the electronic conductivity of the xerogel by 2–3 orders of magnitude was thus achieved. The amount of lithium intercalated into the composite reaches 4 moles per mole of V_2O_5 ; lithium is intercalated reversibly at a very high rate. For $\text{M} = \text{Cu}$, the capacity of

the cathodes does not drop even after 450 charge–discharge cycles.¹³³

Nanocomposites with the compositions $(\text{PPyr})_x\text{V}_2\text{O}_5$ ($x = 0.4–0.9$), $(\text{PAni})_{0.4}\text{V}_2\text{O}_5$ and $(\text{PTh})_x\text{V}_2\text{O}_5$ ($x = 0.3–0.8$, PTh is polythiophene) were tested as cathode materials in lithium power sources.^{63,134} The best characteristics as regards reversibility of the intercalated cations were obtained for the polyaniline-containing composite.^{135–138} Its capacity with respect to Li^+ is 40% higher than that for the original material, viz., $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$. Intercalation of a PAni derivative, namely, poly[*N*-(3-sulfo-propyl)aniline] (PSPAni) resulted in a new composite $(\text{PSPAni})_{0.3} \cdot \text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ exhibiting a specific discharge capacity of cathode equal to 307 A h kg^{-1} and reduction kinetics faster than for the initial xerogel.^{139,140} The electrochemical characteristics of the composites $(\text{C}_6\text{H}_4\text{N})_x\text{V}_2\text{O}_5$ ($x = 0.35–0.40$), annealed in oxygen at 150 °C and treated with hydrogen peroxide to oxidise the reduced vanadium have been reported.¹³⁵ The intercalation of Li^+ remains reversible in the composite even after profound reduction corresponding to intercalation of 3 moles of lithium; the lithium diffusion is deeper than in the case of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$. At a current density of 10 $\mu\text{A cm}^{-2}$, the potential changes over the range from 3.8 to 1.8 V and the specific discharge capacity becomes equal to 370 A h kg^{-1} . On the 15th day after the synthesis, the composite material $(\text{C}_6\text{H}_4\text{N})_{0.6}\text{V}_2\text{O}_5 \cdot 0.3\text{H}_2\text{O}$ not subjected to oxidative treatment had an electroconductivity of $0.09 \Omega^{-1} \text{ cm}^{-1}$ and $d_{001} = 14.14$ Å.¹³⁶ The specific discharge capacity of this compound, equal to 161 A h kg^{-1} , increased to 302 A h kg^{-1} after its annealing in an oxygen atmosphere at 80 °C for 5 h. This value of capacity corresponds to intercalation of 2.7 moles of lithium per mole of the composite material.^{136,141} As the temperature of annealing of the specimen increases, the electrochemical activity of PAni in the composite material decreases.

The use of the nanocomposites PPy–vanadium(V) oxide xerogel as a cathode material for power sources with a lithium anode has been discussed.^{63,66,142} Supercritical dessication of the xerogels (under cryogenic conditions) allows one to obtain materials with a large specific surface area (150–257 $\text{m}^2 \text{ g}^{-1}$) and a density of 0.1–0.2 g cm^{-3} (see Ref. 142). Intercalation of lithium into these composites depends strongly on the concentration of the oxidant [for instance, $\text{Fe}(\text{NO}_3)_3$] used in their synthesis.⁶⁶ For the compound $(\text{PPyr})_{0.8}\text{V}_2\text{O}_5$ obtained without an oxidant, the specific capacity equals 240 A h kg^{-1} upon intercalation of 3 moles of lithium per mole of composite. In the synthesis performed under conditions where $\text{Pyr}:\text{V} = 1$ and $\text{Fe}:\text{V} = 0.05$, the composite obtained had the specific discharge capacity 180 A h kg^{-1} upon intercalation of 2.8 moles of lithium. With an increase in the PPy content to 8.5 moles per mole of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ and the $\text{Fe}:\text{V}$ ratio to 2, the specific capacity of the xerogel decreased to 25 A h kg^{-1} and the amount of intercalated lithium decreased to 1.8 moles.

Hydrated intercalation compounds with the composition $\text{M}_x\text{V}_2\text{O}_5 \cdot \delta \cdot n\text{H}_2\text{O}$, where M is an alkali metal ion, were used in the design of new compact power sources, namely, reserve batteries of bipolar construction with aqueous electrolytes.¹²² Such sources are needed for aerological investigations of the surface atmospheric layers. The process of intercalation of Mg^{2+} , Zn^{2+} and Al^{3+} cations into the vanadium(V) oxide xerogel in both the propylenecarbonate-based and aqueous electrolyte can be used in the design of high-energy batteries. Such power sources will be less dangerous and cheaper than the lithium batteries.

Intercalation compounds based on vanadium(V) oxide xerogel are of interest as solid electrolytes⁷⁵ conducting M^{z+} cations and as electrochromic materials;¹⁴³ they change their colour in the intercalation–deintercalation of protons or lithium ions. Relatively simple technology for obtaining films of these substances allows one to produce electrochromic displays of large area. For instance, the film of polyvanadium acid deposited on the conducting layer of indium and tin oxides changes colour from yellow to green at the voltage ± 1.5 V.¹⁴⁴ The time constant of such an

electrochromic device amounts to 2–20 s depending on the power of the current source; the duration of memory is 20 h, the number of cycles may reach 8×10^4 . The film varies in colour from yellowish-green to grayish-violet according to the amount of intercalated lithium.

$\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ xerogels are of interest as precursors for the synthesis of superfine powders and films of oxide vanadium bronzes^{125, 145–148} and vanadates^{27, 149} used as cathode materials in power sources. The bronze $\text{Na}_{0.33}\text{V}_2\text{O}_5$ with monoclinic syngony was obtained^{150, 151} by annealing the $\text{Na}_{0.33}\text{V}_2\text{O}_5 \cdot 1.6\text{H}_2\text{O}$ xerogel at 550 °C. Electrochemical intercalation of Li^+ and Na^+ ions into the β -phase of $\text{Na}_{0.33}\text{V}_2\text{O}_5$ obtained by the sol–gel method is achieved using solutions of the corresponding salts in PC. This leads to a significantly higher content of these ions as compared with the specimens synthesised by a solid-phase method.¹⁴⁶ In addition, the compound obtained by the sol–gel method possesses the higher (by two orders of magnitude) lithium diffusion coefficient. According to the data from cyclic voltammetry, the β -phase prepared by the sol–gel method has higher electrochemical activity. The oxide vanadium bronze with the composition $\text{Fe}_{0.12}\text{V}_2\text{O}_5$ prepared also by the sol–gel method was recommended as a cathode material in accumulators with a lithium anode. The discharge curve for this source has three plateaux corresponding to total capacity of 3.5 moles of lithium per mole of $\text{Fe}_{0.12}\text{V}_2\text{O}_5$. The specific discharge capacity of the bronze after the 40th cycle amounted to 200 A h kg^{-1} upon cycling in the range 3.8–2.0 V.

Usually, the oxide compounds obtained upon complete dehydration of vanadium xerogels have a large surface and easily undergo intercalation with Li^+ ions. For instance, 0.8 moles of lithium are intercalated into the oxide $\text{Al}_{0.11}\text{V}_2\text{O}_{5.15}$ at a current density of $20 \mu\text{A cm}^{-2}$ with the potential varying in the interval from 3.4 to 3.1 V. The chemical diffusion coefficient for Li^+ in $\text{Li}_x\text{Al}_{0.11}\text{V}_2\text{O}_{5.15}$ equals 10^{-10} – $10^{-11} \text{ cm}^2 \text{ s}^{-1}$. It increases in the interval $0.05 < x < 0.2$ and reaches a maximum at $x = 0.25$, then decreases in the range $0.25 < x < 0.50$ and remains virtually unchanged at $x > 0.50$. The current–voltage curve suggests the possibility of cycling the compound; this is characterised by the three peaks at about 3.35, 3.15 and 2.25 V. Similar studies have been performed on the mixed oxide $\text{Fe}_{0.11}\text{V}_2\text{O}_{5.16}$ (see Ref. 149). Electrochemical intercalation with lithium yielded the compound $\text{Li}_x\text{Fe}_{0.11}\text{V}_2\text{O}_{5.16}$ ($0 < x < 2.4$). As in the case of $\text{Li}_x\text{Al}_{0.11}\text{V}_2\text{O}_{5.15}$, the chemical diffusion coefficient for Li^+ ions depends strongly on x . The Fe^{3+} cations localised in the V_2O_5 octahedra act as stabilisers of the host lattice. As a result, the appearance of phases of the $\text{Li}_x\text{V}_2\text{O}_5$ type upon intercalation of lithium slows down.

Polyvanadate xerogels deposited onto inert plates were used¹⁵² as precursors for obtaining films of oxide vanadium bronzes with the composition $\text{M}_x\text{V}_2\text{O}_5$ ($\text{M} = \text{Na}, \text{Ag}, \text{Ba}$). After annealing at 550 °C of thin layers of compounds $\text{M}_x\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ prepared from $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ by ion exchange in the 0.1 M aqueous solution of MCl, compounds $\text{Na}_{0.33}\text{V}_2\text{O}_5$ and $\text{Ag}_{0.33}\text{V}_2\text{O}_5$ with the β -phase structure of oxide vanadium bronze are formed. The electroconductivity of β -phase films is strongly anisotropic and depends on the nature of the cation M^+ . For $\text{Na}_{0.33}\text{V}_2\text{O}_5$, $\sigma_{\parallel} = 8$ and $\sigma_{\perp} = 4 \times 10^{-2} \Omega^{-1} \text{ cm}^{-1}$ at room temperature, while for $\text{Ag}_{0.33}\text{V}_2\text{O}_5$ the corresponding values are 3 and $1.5 \times 10^{-2} \Omega^{-1} \text{ cm}^{-1}$, respectively. The characteristic times of electron mobility are approximately the same for both these compounds and are equal to 10^{-11} s . The mobilities of Na^+ and Ag^+ ions are characterised by the times $\tau = 5 \times 10^{-12}$ and $\tau = 2 \times 10^{-11} \text{ s}$, and by the activation energies 0.12 and 0.08 eV, respectively. A higher mobility of electrons ($\tau = 10^{-10} \text{ s}$) is observed in the case of $\text{Ba}_{0.16}\text{V}_2\text{O}_5$.

The results of X-ray and thermal studies on the oxide vanadium bronzes with the compositions $\text{Ba}_{0.17}\text{V}_2\text{O}_5$, $\text{Ni}_{0.17}\text{V}_2\text{O}_5$, $\text{Al}_{0.11}\text{V}_2\text{O}_5$ and $\text{Fe}_{0.11}\text{V}_2\text{O}_5$ prepared by the sol–gel method were reported.²⁶ It was noted that, unlike the solid-phase procedure, the sol–gel method allows one to synthesise thin layers of bronzes $\text{M}_x\text{V}_2\text{O}_5$ of the α type with rhombic structures. The

orientation of these layers depends on the nature of the intercalated cation. The layers situated parallel to the support surface can be parallel (Fe^{3+} and Al^{3+}), perpendicular (Ba^{2+}) or either parallel or perpendicular (Ni^{2+}) to the planes of the V_2O_5 layers. With the cesium cation, bronze of a hexagonal syngony with the composition $\text{Cs}_{0.35}\text{V}_2\text{O}_5$ and the unit cell parameters $a = 13.34(1)$ and $c = 3.610(1) \text{ \AA}$ is formed under the same conditions.¹⁵³

From the mixed (as regards the intercalated cation) xerogels, films of oxide vanadium bronzes of the β type, with compositions $\text{Li}_{0.11}\text{Na}_{0.23}\text{V}_2\text{O}_5$, and $\text{Li}_{0.23}\text{Na}_{0.14}\text{V}_2\text{O}_5$ were obtained by an analogous method.¹⁵⁴ Electroconductivities of these bronzes are also strongly anisotropic. At room temperature, $\sigma_{\parallel} = 5.98 \times 10^{-2}$ and $\sigma_{\perp} = 5.48 \times 10^{-5} \Omega^{-1} \text{ cm}^{-1}$ for the first bronze and $\sigma_{\parallel} = 0.138$, $\sigma_{\perp} = 1.08 \times 10^{-4} \Omega^{-1} \text{ cm}^{-1}$ for the second one. The activation energy of the conductivity of the films is close to 0.08 eV at $\sim 100 \text{ K}$ and increases to 0.11 eV as the content of sodium ion decreases.

VII. Conclusion

In recent years, intercalation compounds based on the xerogels of complex and simple vanadium oxides have been the most extensively studied. Different views on the nature of hydrated vanadium(V) oxide existed for a long time but are currently united due to the progress in the studies on the structures of films and the mechanisms of intercalation of cations and organic molecules. In this respect, the results obtained in determining the content and types of the hydrogen–oxygen groups by ^1H NMR are of considerable importance.

The preparation of ordered nano-, meso-, micro- and macrostructures of intercalation compounds is typical of modern experimental research. Synthetic procedures, chemical composition and morphology of the xerogel are usually reported, but the data concerning physicochemical and physical properties are scarce and concern mainly the cathodic behaviour of these substances in chemical power sources. Studies on the electronic structure and the reactivities of the nanocomposites consisting of vanadium–oxygen layers and intercalated organic components are lacking. A new direction for applications of the intercalation compounds is becoming evident, which consists of their use as nanoreactors in the synthesis of polymers⁶¹ or nanotubular carbon structures.¹⁵⁵

New publications dealing with intercalation compounds based on V_2O_5 xerogels have appeared after completion of this review. Studies on the refinement of a bilayer structure of vanadium(V) oxide xerogel are of interest.¹⁵⁶ Investigations into the preparation of bulk¹⁵⁷ and film¹⁵⁸ materials with mesoporous structures have begun. A superlight macroporous crystalline intercalation compound of $\text{V}_2\text{O}_5 \cdot n\text{H}_2\text{O}$ was synthesised that contains intercalated hexadecylamine molecules ($d = 33.4 \text{ \AA}$) with alkyl chains perpendicular to the planes of the vanadium–oxygen layers.¹⁵⁹ All this evidences progress in the studies on the class of compounds under consideration.

The research was financially supported by the Russian Foundation for Basic Research (Project Nos 99-03-39065, 00-15-97418 and 03-03-32104).
