Institute of Physical Chemistry of the Russian Academy of Sciences

This issue of the Journal comprises reviews written by researchers of the Institute of Physical Chemistry of the Russian Academy of Sciences (IPC RAS), one of the leading chemical research establishments of the Russian Academy of Sciences.

In 1929, Academician V A Kistyakovsky, a renowned physicochemist and a specialist in the field of complex colloid-electrochemical problems, was entrusted with the task of organising a colloid-electrochemical laboratory (CELA) under the aegis of the USSR Academy of Sciences. In 1934, the laboratory was granted the status of the Colloid-Electrochemical Institute (CEIN) of the USSR Academy of Sciences. Many prominent scientists, such as Academicians P A Rebinder, A N Frumkin, M M Dubinin, V I Spitsyn, B V Derjaguin, Corresponding Members of RAS G V Akimov, K V Chmutov, A K Pikaev, N A Izgaryshev, S Z Roginsky and Professors A D Gelman, Yu N Golovanov, I L Rozenfeld, N D Tomashev, N E Brezhneva, B A Zaitsev, A T Vagramyan, K M Gorbunova, *etc*., have worked at the Institute at different times. The development of many promising research areas in IPC RAS, such as physicochemical mechanics; physicochemistry of disperse systems and surface forces; sorption and adsorption processes; thin liquid and polymeric layers; corrosion of metals and alloys; electrochemistry and electrocrystallisation; radiochemistry and radiation chemistry as well as chromatography is associated with the names of these distinguished scientists.

At present, the multi-disciplinary fundamental and applied investigations carried out at the Institute are developing along the following lines:

— colloid-surface phenomena and adsorption;

— physicochemistry of nano- and supramolecular systems;

— radiochemistry and chemistry of high energy;

— physicochemical aspects of corrosion, electrochemistry, protective coatings and crystallisation.

The Institute has unique experimental facilities. In 2002, a centre for joint use of physical methods including electron microscopy and X-ray microanalysis, oscillation and electron spectroscopy, positron annihilation, ellipsometry, X-ray diffraction analysis, chromatoionic and mass spectrometry and atomic absorption analysis was organised within the structure of the Institute. The Institute possesses its own corrosion stations for conducting full-scale field tests in Moscow, Zvenigorod, Murmansk and Vladivostok and performs similar tests through a network of stations functioning within the structure of the Tropical Research Centre of RAS and located in different climatic zones of Russia. The Institute has at its disposal complex technological equipment for conducting accelerated tests and possesses a database on atmospheric resistance of various materials with different types of protection created on the basis of long-term observations. Other equipment includes a system for continuous monitoring and computer processing of meteorological data and corrosion parameters of tested materials, a computerised laboratory for static and dynamic autoclave testing of non-strained and mechanically strained materials in aqueous solutions at high temperatures and high pressures, four linear accelerators and four gamma-ray sources.

The Institute has in its structure a research-and-education centre consisting of two main departments (Inorganic, radio- and radiation chemistry and Physicochemistry of surface phenomena and colloid systems) and several research-and-education departments, such as 'Physical chemistry of polymers', 'Physicochemistry of supramolecular systems', 'Physicochemical basis of technology of composite materials', 'Adsorption and adsorbents', 'Chromatography and chromatographic instruments', 'Corrosion and protection of metals', 'Ion-exchange chromatography' and 'Physicochemical mechanics'. Postgraduate courses and four dissertation boards of the Higher Attestation Commission also function at the Institute.

The Institute collaborates successfully with national academies of sciences, universities and research establishments in the USA, Canada, Great Britain, France, FRG, Sweden, Finland, Japan, Korea, Australia and Italy. Researchers of the Institute take an active part in international symposia and conferences; their works are translated and published in many countries of the world. The Institute maintains close ties with large enterprises affiliated to the Ministry for Atomic Energy and the Ministry of Defense of the Russian Federation and some other state-owned institutions and carries out contract work for many manufacturing companies and research centres in France, Germany, USA, India, Korea and other countries.

At present, the Institute comprises proud of several scientific schools with rich traditions and great research experience in all the fields mentioned above.

The staff of the Institute is 920 people including two Academicians and three Corresponding Members of RAS, 70 D.Sci. and 295 Ph.D.'s.

Within the framework of the Programme 'Colloid-surface phenomena and adsorption processes', the Institute carries out in-depth studies on surface forces, stability of colloids and liquid films, adhesion phenomena and physicochemical mechanics of disperse structures and solids and develops theories of gas and vapour adsorption by microporous sorbents.

Some of the most recent achievements of the Institute are as follows: the development of a novel method for measuring parameters of porous structures of adsorbents; the proposal of a methodology for computation of contact angles of aqueous solutions of electrolytes on charged solid surfaces of various degrees of hydrophilicity allowing prediction of the stabilities and thicknesses of wetting films; the development of a new in principle technology for investigations into structure formation and flow processes of concentrated nanodispersed systems; preparation of carbon-based sorbents that allow purification of solutions of organic substances and aqueous media and ultimate purification of drinking water from dioxins and monitoring of the dioxin content in air, water and soil; elaboration of fundamentals of non-linear preparative multicomponent chromatography; development of novel procedures for studying structures of liquids in thin layers. An automatic unit for measuring surface and interphase tensions of liquids and wetting angles under static and dynamic regimes and for determination of critical concentrations of micelle formation developed at the Institute was awarded a diploma and a Gold Medal at the International Exhibition of Innovations, Investigations and Technologies (Brussels, 2001). Yet another development of IPC RAS, *viz.,* a unit for the conversion of a polarised light, was awarded a Silver Medal (Brussels, 2002).

A detailed description of this area of research is given in the reviews by N V Churaev, 'Surface forces and physicochemistry of surface phenomena', and N B Uriev, 'Physicochemical dynamics of disperse systems'.

The fundamental and applied investigations into the structures, phase equilibria, surface and diffusion phenomena in polymeric, polymeric-monomeric and filled systems are carried out within the framework of the Programme 'Physicochemistry of nano- and supramolecular systems' aimed at the elaboration of physicochemical principles for preparation, modification and stabilisation of polymeric coatings, adhesive mixtures and composite binding materials. Strategies for supramolecular design of planar systems are being developed; the effect of dimensional selectivity has been predicted and realised for the first time; two-dimensional polymeric networks with functional molecules and nanoparticles integrated into them have been prepared; the dependence of parameters of nanopores in novel optoelectronic materials based on porous silicon (both before and after oxidation) and artificial opals on the temperature of their processing has been investigated; a theory of colloid interactions of elastic surfaces and a theory of, and a method for, dynamic measurements of forces using atomic-force microscopy have been developed. The principles of the design of a novel class of 'two-dimensional' nanocomposite materials (polymer/metal) have been developed and realised and their feasibility as efficient catalytic systems, which represent elements of planar solid sensors, has been demonstrated.

Physicochemistry of polymers is discussed in the review by A E Chalykh and V K Gerasimov, 'Phase equilibria and phase structures of polymer blends' and physicochemistry of supramolecular systems, in the review by A Yu Tsivadze, 'Supramolecular metal complex systems based on crown-substituted tetrapyrroles'.

As regards physicochemistry of corrosion processes, electrochemistry, protective coatings and crystallisation, studies on kinetics and mechanisms of metal corrosion under natural (atmospheric, marine, subterranean) conditions are currently under way. Also being studied are mechanisms of controlled synthesis and effects of volatile and contact inhibitors of metal corrosion and saturation with hydrogen. A theory of acid resistance, passivity and local violations of the passive state of non-strained and mechanically strained construction alloys is being developed; elaboration of protective coatings against specific corrosion of rocket engine nozzles and thermal-power metallic equipment in the atmosphere of combustion products and in aqueous and gaseous heat carriers as well as studies on multifunctional metallic and composite coatings, hydrogen saturation and hydrogen-induced embrittlement of metals are being carried out.

These studies have led to the development of novel coating technologies for corrosion protection of metals under natural conditions and elaboration of theoretical and practical principles of corrosion-resistant doping of alloys with cathodic additives. Technologies for the production of stainless steels and alloys with optimised compositions, aluminium, copper, nickel, titanium and zirconium, and possessing high corrosion resistance have been developed. A series of novel highly refractory compounds and their heat-conducting compositions with protective (including diamond-like) coatings have been developed. Novel technologies for applying protective and functional galvanic and chemically reduced metallic coatings onto diverse articles have been devised. The mechanism of hydrogen-induced embrittlement upon application of electrolytic coatings has been established and methods for elimination of this defect in aircraft and rocket engineering have been developed. Fundamentals of vapour-phase protection of metals with organic corrosion inhibitors have been elaborated and a new industrial technology for the preparation of protective materials for rocket-and-space engineering has been proposed. A database of the interaction of hydrogen isotopes with thermonuclear reactor materials contacting with plasma has been formed.

This line of research is considered in the review by Yu I Kuznetsov, 'Physicochemical aspects of metal corrosion inhibition in aqueous solutions'.

In the field of theoretical radiochemistry, the following topics are being developed: quantum chemistry of transuranium elements and their derivatives; studies on various valence forms of radioactive elements in aqueous and organic solutions, salt melts, gas and solid phases; redox reactions involving ions of actinides; systematic studies into the synthesis of novel derivatives of radioactive elements, determination of their structures and the most essential properties; elaboration of the scientific basis of extraction and sorption processes for the isolation and purification of radioactive elements, studies of isotope effects in reactions of heavy elements, and physicochemistry of radioactive and irradiated solids.

In the field of applied radiochemistry, the following studies should be mentioned: elaboration of the physicochemical basis for safe disposal of radioactive wastes from nuclear-power energetics, burial of liquid radioactive wastes and safe operation of underground storage pits; development of novel and improvement of existing extractive, sorptive, *etc*., procedures for the isolation of pure radioactive elements; solution of miscellaneous radioecological problems and a search for radioactive sources for medicinal and other applications.

The main investigations in the field of theoretical radiation chemistry include an analysis of primary processes of interactions of the ionising radiation with various substances; studies of fast and superfast reactions in the condensed phase using pulse radiolysis; development of scientific principles for the application

of ionising radiation for modification of various materials; studies on radiation-chemical processes occurring in laser, optoacoustic and superconducting materials and polymeric media and the development of methods for predicting radiation stabilities of various materials and compositions.

The work in the field of applied radiation chemistry is directed to the use of radiation chemistry for solution of environmental problems (*e.g.,* decomposition of toxic substances, *etc.*) and to the development of methods for protecting structural materials from radiation corrosion. Novel radiation-resistant materials and compositions based on them are being developed and advanced radiation-chemical methods for preparation of novel materials for medicine, biotechnology and membrane technology and dosimetric systems for radiation control are being designed.

This line of research is covered in the reviews by N N Krot and M S Grigoriev, 'Cation – cation interactions in crystalline actinide compounds', and B G Ershov, 'Kinetics, mechanisms and intermediates of some radiation-induced reactions in aqueous solutions'.

Needless to say, the size of this issue cannot encompass the whole range of investigations carried out at IPC RAS. Therefore, all those who are interested in more detailed information about the Institute are invited to visit our web-site: http://www.ipc.rssi.ru.

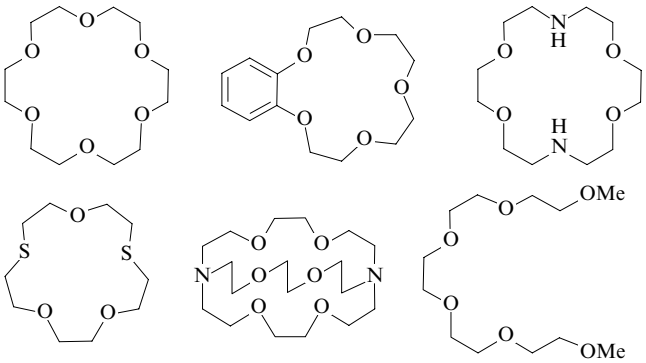
Abstract. The characteristic features of the structures and properties of crown-substituted porphyrinates and phthalocyaninates are considered. Interactions of these compounds with alkali metal salts yield supramolecular ensembles. The factors determining the architecture of such ensembles are described. The bibliography includes 97 references.

I. Introduction

Over many years, the development of coordination chemistry was associated with a search for ligands able to form stable complexes with metal ions. It is polydentate chelate ligands that proved to be these ligands, among which macrocyclic compounds occupy a special place.[1–13] Such macrocyclic ligands as crown ethers, azacrown ethers and thiacrown ethers, cryptands, podands, phthalocyanines, porphyrins and other polyazacyclic compounds have received especially wide acceptance in coordination chemistry.



A Yu Tsivadze Institute of Physical Chemistry, Russian Academy of Sciences, Leninsky prosp. 31, Moscow 119991, Russian Federation. Fax (7-095) 952 53 08. Tel. (7-095) 952 04 62. E-mail: phyche.ac.ru

Natural porphyrins and their synthetic analogues, *viz*., phthalocyanines, which are the most spectacular representatives of polyazacyclic compounds, are related to the class of conformationally rigid macrocyclic ligands. With metal ions in the oxidation state 2+, these ligands form intramolecular planar tetragonal complexes where two protons of the ligand are replaced by metal ions. Formally, the central metal ion in such complexes forms two typically covalent and two typically coordination bonds with the nitrogen atoms of the polyazacycle, which actually become equivalent as a result of complexation.

Metal complexes with crown ethers contain neither typically covalent, nor typically coordination metal—ligand bonds. Crown ethers form surprisingly stable complexes even with ions of alkali metals, which until recently were not considered as metals that form complexes.

In contrast to porphyrins and phthalocyanines, crown ethers represent conformationally flexible ligands. In the free state, the distribution of donor heteroatoms in crown compounds is random; however, after penetration of the cation into the cavity of the macrocycle the latter adopts a crown-shaped conformation. For example, 12-crown-4 (12-C-4) can exist in different conformations depending on the nature of the substituents, solvent, temperature and other factors (Fig. 1).

Flexible crown ligands are specifically adapted to the complexation conditions to yield various types of complexes (Fig. 2). Depending on the sizes of the cations and of the cavities of crown ethers, such complexes are divided into three main types, *viz*., complexes in which the size of a cation is comparable with that of the macrocyclic ligand cavity (complexes of the type **A** or **B**); complexes in which the size of a cation is smaller than that of the crown ligand cavity (compounds **C** or **D**) and complexes in which the size of a cation is larger than that of the macrocyclic ligand cavity (compounds **E** – **G**).

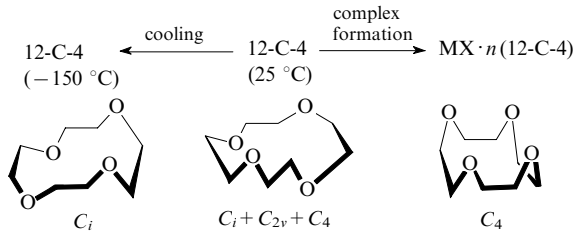

Figure 1. Conformations of 12-crown-4.

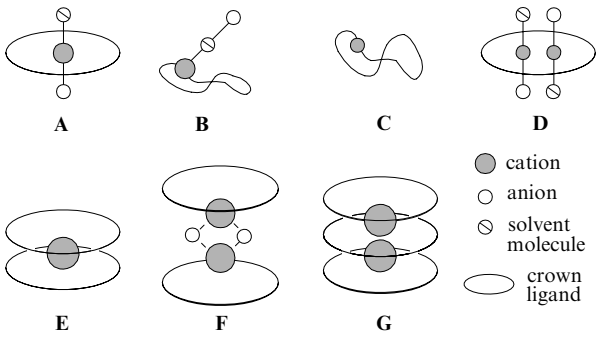

Figure 2. Various types of metal complexes with crown ligands (according to the Punia classification).
A, an encapsulated ion pair (the cation – anion pair remains to be a contact pair, M : L = 1 : 1); **B,** a partly encapsulated ion pair (the cation forms a solvent-separated pair with the anion, M : L = 1 : 1); **C,** enveloping encapsulation (M : L = 1 : 1); **D,** a compound with M : L = 2 : 1; **E,** a sandwich-like compound (M : L = 1 : 2); **F**, dimers linked by bridging ligands (M : L = 1 : 1); **G**, a triple-decker sandwich compound (M : L = 2 : 3).

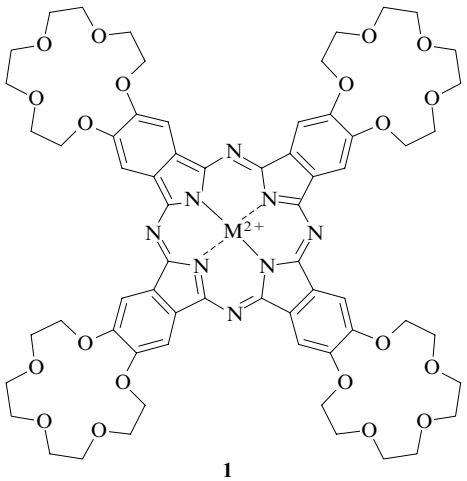
The progress in conformational analysis [6] and, particularly, in spectral conformational analysis † has made it possible to investigate, by the example of a vast (several hundreds) number of complexes, the conformational changes occurring in crown ligands under the influence of diverse factors (*e.g.*, peripheral substituents, metal that represents complexing agent, anions, solvent, *etc.*). This has led to elaboration of a fundamentally new conformational approach to modification of properties of macroheterocyclic compounds based on directed changes in the conformational equilibrium and hence in the complex-forming and ion-selective properties of the crown ligands. Thus an idea appeared to fix, with the help of peripheral substituents, those crown-ether conformations which are especially suitable for selective interactions with the target metal ion. Such a preorganisation of the ligand allows a purposeful choice of crown compounds that bind selectively specific cations.[1–13] At the same time, it should be remembered that rigid fixation of crown ethers deprives them of flexibility, which enables surprisingly effective adaptation to the existing conditions. Therefore, the choice of side substituents should be a reasonable compromise between the rigidity and flexibility of the ligands formed.‡

There are numerous examples of the violation of the Pedersen geometrical correspondence principle [2,3,6,12–15] according to which stable complexes are formed provided the size and shape of the macrocyclic ligand cavity match the size and shape of the complex-forming cation; these can be accounted for by the diversity of the conformational forms of the crown ethers. This principle is violated in those cases where the anion, solvent or intermolecular interactions force the ligand to adopt a conformation where the coordination with a cation (the size of which is larger or smaller than that expected based on the geometrical correspondence principle) is more favourable.

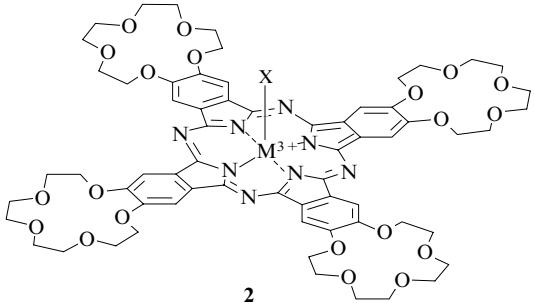
In this case, we deal with dimensional effects characteristic of nanochemistry and nanotechnology. For example, if the size of a metal cation exceeds that of the macrocyclic cavity to such an extent that the cation can by no means occupy the central position in the macrocycle, sandwich-like dimers and trimers (**E** and **G**) are formed; the metal cations in these aggregates are located between the neighbouring crown-ether molecules. The formation of such supramolecular aggregates ensures stability of the complex, but ordered architectures of the molecular ensembles.

The principles of the molecular stereodesign of crown compounds developed allow a purposeful search for highly selective extraction systems for isotope separation. In the choice of a particular system, it is important to know how a concrete crown extractant adapts to specific extraction and reextraction conditions by respective conformational changes. This approach has led to the development of a physicochemical basis of technological processes for the separation of lithium, magnesium, calcium, potassium and boron isotopes.[16]

It is known that porphyrins and phthalocyanines form stable metal complexes possessing unique electrophysical and optical properties;[17–19] however, poor solubility of such complexes in organic solvents and water prevents their wide utilisation. Many problems related to practical realisation of these unique properties of phthalocyaninates could be circumvented through the introduction of peripheral substituents. Some of these substituents ensured the required solubility on the complexes, while others conferred entirely new properties on them. Dimensional effects also play an important role. For example, metal ions with the sizes allowing them to occupy the central position in the macrocycle form monophthalocyaninates (compounds **1**, **2**), whereas bulkier ions (*e.g.,* rare-earth elements) form sandwich-like double- (compound **3**) and triple-decker complexes.



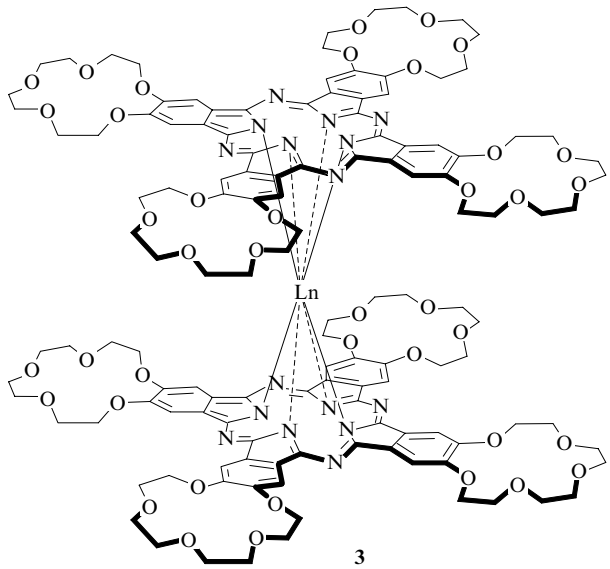
1



2

† Spectral conformational analysis combines oscillation spectroscopy, quantum-chemical calculations and theoretical analysis of normal molecular oscillations.

‡ In the case of porphyrins, nature itself has solved the problem through the selection of appropriate substituents.



3

It is noteworthy that peripheral substituents do not disturb the rigidity of the macrocycle, but influence the mutual arrangement of the phthalocyanine molecules, which, in turn, determines the type of $\pi-\pi$-interactions between the aromatic systems and the formation of supramolecular stacking or liquid crystalline systems. In this respect, crown-ether substituents differ favourably from all other substituents in their ability to provide the required solubility and ordering of complex supramolecular architectural ensembles and to confer novel properties on the phthalocyaninate complexes owing to the formation of additional ion conductivity side channels along with the central semiconducting channel.

A series of crown-substituted phthalocyanines have recently been synthesised which are readily soluble in the majority of solvents and do not form isomeric mixtures like unsubstituted phthalocyanines. Reactions of metal complexes of such tetracrown phthalocyanines with alkali metal salts yield heteronuclear supramolecular aggregates.[20–24] Proneness of crown substituents to form complexes with alkali metals and the tendency of phthalocyanines for stacking interactions of aromatic rings favour the formation of such aggregates.

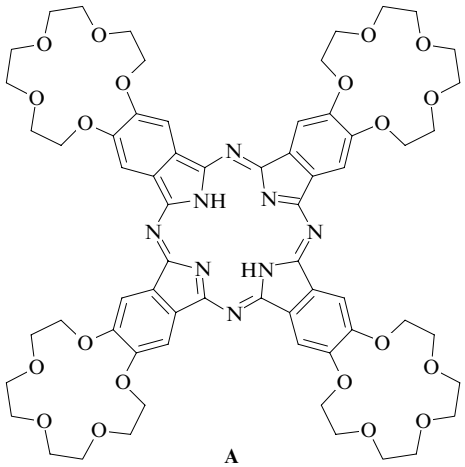
Although porphyrins and phthalocyanines belong to macrocyclic ligands, it was not until the discovery of crown ethers that the remarkable stability of the metal complexes of the former was associated with the macrocyclic effect. Nor did the elucidation of the mechanism of reversible binding of oxygen to hemoglobin lead to the introduction of the term 'supramolecular chemistry', although the non-linear cooperative effect observed thereupon was undoubtedly associated with the formation of supramolecular systems as follows from the sigmoidal shape of the titration curve. The necessity for the introduction of the term 'supramolecular chemistry' arose only in 1978 in the consideration of the unusual selectivity of the complexes formed by alkali metal cations and crown ethers.[1,4,5]

Supramolecular chemistry studies supramolecular systems formed as a result of noncovalent intermolecular interactions.[1–6] The main concepts of supramolecular chemistry are fixation (binding), recognition and coordination. The stability of alkali metal complexes with crown ligands is provided by the recognition of geometrically complementary species and the multiplicity of their interactions due to the increase in the interaction surface. A main goal of supramolecular chemistry is the design of ordered functional units having molecular sizes and that could receive, store, transmit and read information like chemical-and-biological 'machines'[§] responsible for skilful regulation of vital processes in nature.[1]

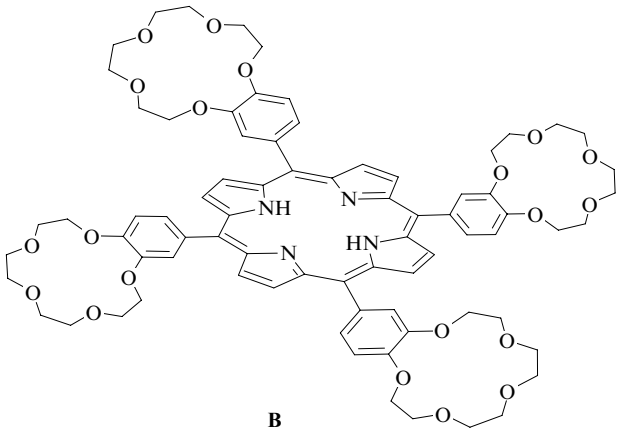
§ Photosynthesis performed by chlorophyll, one of the most typical representatives of natural porphyrins, is an example.

The uniqueness and remarkable efficiency of chemical processes occurring in living organisms have always been a subject of admiration for chemists. The more mysteries of nature that are unravelled by chemists the more new enigmas and undisclosed mechanisms of control over various chemical processes in biological systems emerge. Recently, it has become evident that the unusual controllability and selectivity of vital processes cannot be explained in terms of covalent interactions. The ability to exert flexible control over chemical processes is one of the common features of biological and supramolecular processes realised at the molecular level. The ease of the control over chemical processes mediated by synthetic analogues of macrocyclic natural compounds is reached owing to their selectivity and extreme sensitivity to low-energy influences.

Synthesis of crown-substituted porphyrins and that of phthalocyanines are based on different approaches. This is due to differences in the modes of attachment of crown-ether substituents to porphyrins and phthalocyanines. Thus, crown-ether substituents are fused to phthalocyanines to form a fused tetracyclic system (structure **A**), while these are linked to porphyrins through a C—C bond between the carbon atoms of the benzene ring and the methine group (structure **B**) about which free rotation is possible. These differences are reflected in the supramolecular organisation of these systems.



A



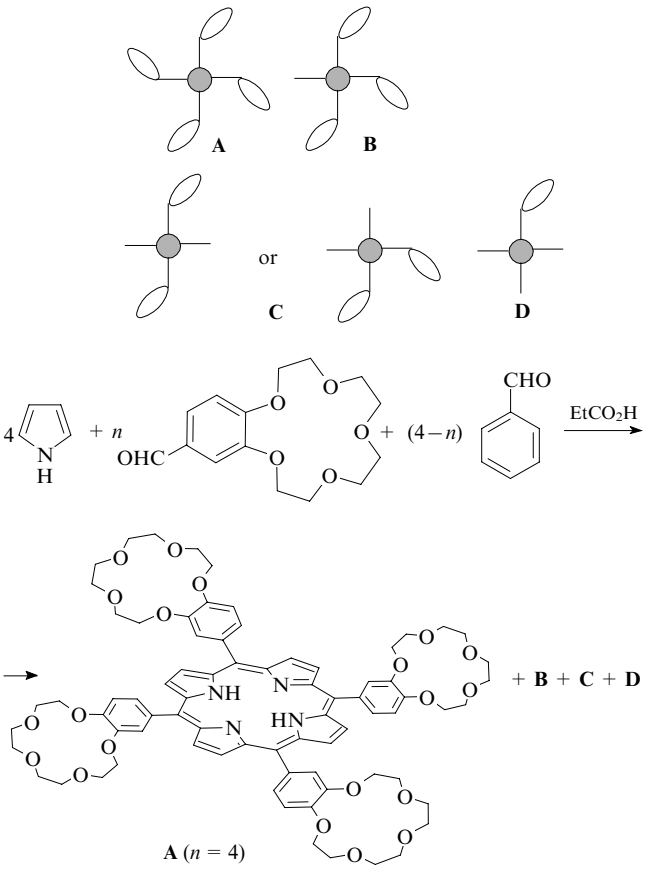
B

II. Crown-substituted porphyrins

Functionalised porphyrins present interest as models for the study of various biological processes, such as heme oxygenation, cytochrome activity and photosynthetic electron transport.[25–29] Thus it was tempting to use porphyrins containing macrocyclic substituents able to recognise cations for the study of sodium-potassium transport across biological membranes. The ionophoric behaviour of such substituted porphyrins can easily be

monitored by following fluorescence changes.¶ The methods for the synthesis of this class of model compounds depend on the nature and position of side substituents. Earlier, substituted pyrroles containing ester, amide or alkyl groups were used for the synthesis of substituted porphyrins;[30–32] however, compounds thus prepared did not possess ionophoric properties. The first attempt to synthesise crown-substituted porphyrins from 4′-formylbenzo-15-crown-5, pyrrole and benzaldehyde (Scheme 1) was undertaken in 1982 by Thanabal and Krishnan.[33] Depending on the ratio of the reactants, tetra- (**A**), tri- (**B**), di- (**C**) or mono-15-crown-5-substituted (**D**) porphyrins were obtained. If the porphyrin molecule is presented as a circle and 15-crown-5 as an ellipse, the resulting compounds will appear as shown in Scheme 1.

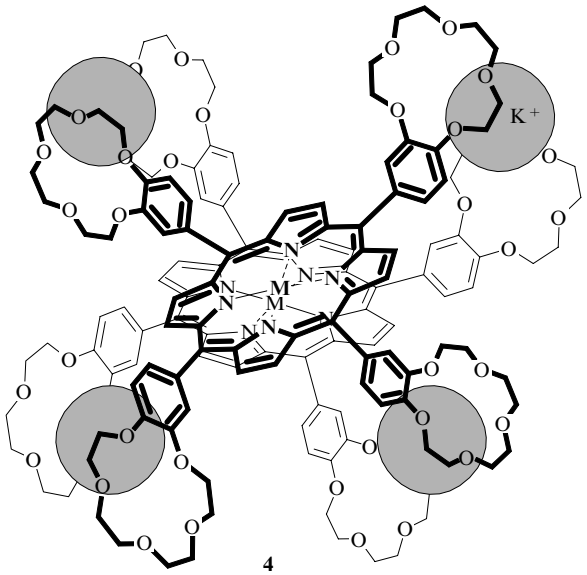
Scheme 1



$n = 1-4$.

Interactions of these crown-substituted porphyrins with metal salts (Co, Cu, Zn) yield chelate compounds. The addition of sodium, magnesium and calcium salts to solutions of tetra- and tricrown-substituted porphyrinates did not cause any changes in the electronic spectra of the complexes, whereas the addition of potassium, ammonium and barium salts resulted in a decrease in their intensities, changes in both Q-bands (broadening and shift by *ca.* 10 nm towards the long wavelength region) (a bathochromic shift) and Soret bands (a hypsochromic shift).†

Such changes can be attributed to specific complexation of crown-substituted porphyrins with these cations. The difference in the behaviour of these cations with respect to crown-substituted porphyrins is due to the formation of M : L = 1 : 1 complexes of benzo-15-crown-5 with sodium, magnesium and calcium cations, whereas potassium, ammonium and barium cations form sandwich complexes with the composition M : L = 1 : 2 (compound **4**). In the latter case, it is dimerisation of the macrocycles induced by a specific behaviour of potassium, ammonium and barium cations that causes changes in their electronic spectra.



M = 2H, Co, Zn, Cu.

The reaction of crown-substituted porphyrins (P) with potassium cations can schematically be presented as:

$$2P + 4K^+ \longrightarrow P_2(K^+)_4.$$

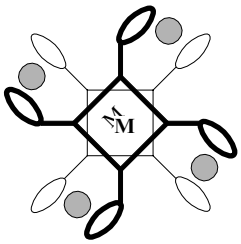
It was suggested [33] that the addition of potassium ions first induces the formation of the dimer P_2, which is followed by complexation, potassium cations filling all the unoccupied positions in the macrocyclic cavities of the peripheral crown-ether substituents. It should be noted that saturation is reached even at very low concentrations of potassium cations (10^{-5} mol litre^{-1}). The stability constant of the complex $P_2(K^+)_4$ is equal to 10^{23} litre^5 mol^{-5}, *i.e.*, it is by several orders of magnitude greater than the corresponding constants of the K^+ complexes with crown ethers.

It was found that the addition of even very small amounts of potassium ions (10^{-5} mol litre^{-1}) to a zinc complex with tetracrown porphyrin ($\sim 10^{-5}$ mol litre^{-1}) in the presence of an excess of sodium ions ($\sim 10^{-2}$ mol litre^{-1}) results in dimerisation as can be evidenced from the significant changes in the electronic absorption spectra of ZnTCP (TCP is tetracrown porphyrin) in ethanol. Such a selectivity of ZnTCP with respect to potassium cations enables its application for quantitation of low concentrations of potassium ions. No such selectivity is observed for ammonium and barium cations: the presence of even very small amounts of sodium ions leads to disaggregation of complexes $P_2(NH_4^+)_4$ and $P_2(Ba^{2+})_4$.

The addition of potassium ions to a CuTCP complex results in significant changes in the ESR spectra due to the formation of $(CuTCP)_2(K^+)_4$ complexes. ESR spectroscopic data suggest that copper ions occupy a position in the centre of the porphyrin ring cavity. The Cu–Cu distance in the dimer reaches ~ 4.20 Å, which is in favour of coaxial symmetry of the complex.[33] The porphyrin rings in the dimer $(CuTCP)_2(K^+)_4$ are turned by 45° relative to one another.

¶ The changes in the porphyrin fluorescence can be conjugated, *e.g*, to the inhibition of oxidative phosphorylation in respiratory mitochondrial systems.

† It is known that Q and Soret bands are extremely sensitive to structural changes.



X-Ray diffraction analysis of a potassium complex $K(B\text{-}15\text{-}C\text{-}5)_2I$ (B-15-C-5 is benzo-15-crown-5) revealed that the crown-ether ligands in this compound are at a distance of ~ 3.8 Å from one another and the plane passing through the oxygen atoms is parallel to the plane of the benzene ring.[34]

The formation of highly ordered systems is yet another specific feature of the tri- and disubstituted copper complexes $(CuTriCP)_2(K^+)_3$ and $(CuDCP)_2(K^+)_2$.[33] However, the Cu—Cu distance in these complexes is greater than that in the corresponding tetrasubstituted complex $(CuTCP)_2(K^+)_4$.

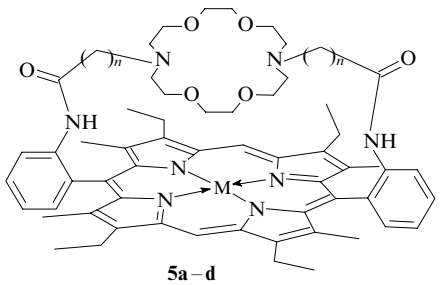
The addition of methanolic solutions of sodium, magnesium and calcium salts to solutions of free tetracrown porphyrin and its ZnTCP complex (5×10^{-5} mol litre^{-1}) in $CHCl_3$ does not bring about changes in their fluorescence spectra, while the addition of potassium salts induces significant changes due to dimerisation. (It is of note that the fluorescence spectra of the complexes appeared to be more sensitive to potassium ions than their absorption spectra). In the case of free tetracrown porphyrin, the dimerisation effect is insignificant.[33]

A detailed analysis of the ESR and optical spectra of a zinc complex with tetracrown porphyrin revealed [35] that the cavities of the porphyrin rings in the dimer are parallel and turned by 23° relative to one another.

Potassium, caesium, ammonium and barium cations induce the formation of porphyrin dimers in the case of vanadyl complexes, the dimerisation constant decreases on going from tetracrown-substituted vanadyl porphyrinate to tri- and disubstituted complexes. The constant of cation-induced dimerisation of vanadyl tetracrown porphyrinate decreases in the following order: $K^+ > Ba^{2+} > Cs^+ \approx NH_4^+$. According to data from ESR spectroscopy, the V—V distance in these dimeric complexes is equal to ~ 4.70 Å.

Magnesium, nickel and manganese(III) complexes with tetracrown porphyrin also yield dimers upon interaction with potassium salts.[36] An electrochemical analysis of redox properties of these metal complexes revealed that the oxidation of the porphyrin ring in dimers occurs at lower anodic potentials than in the corresponding monomers. The electronic absorption and emission spectra of the electrochemically oxidised and reduced states of these dimers were interpreted based on the changes in their electronic structures.[36] The ESR spectra of the oxidised dimeric radical show that the unpaired electron is localised on one of the porphyrin π-systems unlike chlorophyll molecules in bacterial photosynthetic systems.

Synthesis of dioxocyclam- and diaza-18-crown-6-substituted porphyrins (**5a**,**b**) and metal complexes based on them (**5c**,**d**) has been described.[37–39]



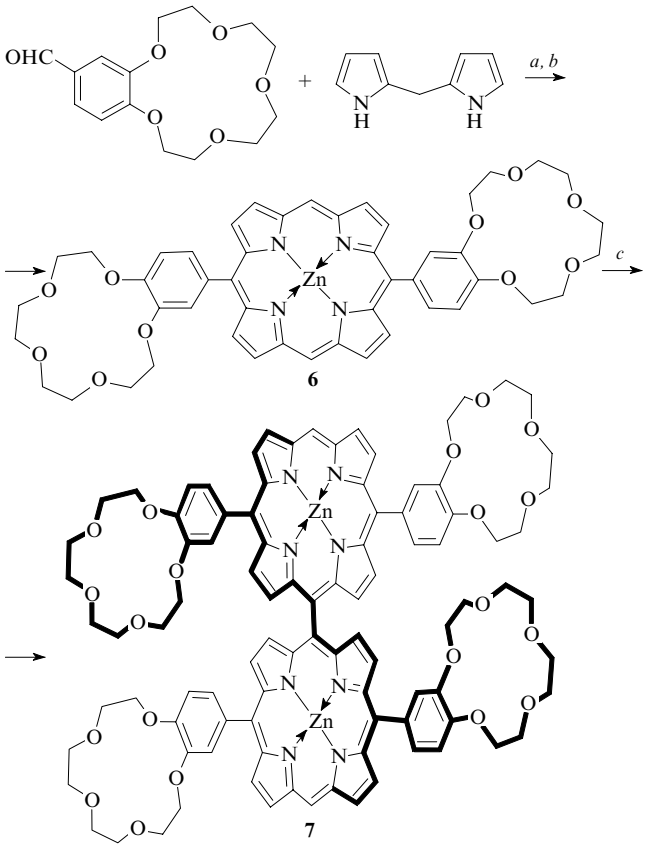
5a–d

5a: M = 2 H, n = 1;
5b: M = 2 H, n = 2;
5c: M = Zn(II), n = 1;
5d: M = Co(II), n = 2.

X-Ray diffraction analysis of compounds **5b** and **5c** [38] confirmed the presence in these compounds of a bridging diaza-18-crown-6 ligand binding two peripheral benzene rings attached to the porphyrin macrocycle. The cavity of diaza-18-crown-6 is coaxial with that of the macrocyclic ring of porphyrin (an analogous position of the rings was observed in a structurally similar 5,15-di(2-alkylamidophenyl)etioporphyrin complex with dioxocyclam [37]). Cobalt and zinc ions enter the cavity of the porphyrin ring. Electrochemical studies of these compounds revealed that cobalt complexes undergo oxidation in an atmosphere of nitrogen. In PhCN, the addition of oxygen is reversible, and irreversible in CH_2Cl_2. Oxidation of the cobalt complex in an atmosphere of carbon monoxide yields a compound in which the cobalt ion is linked to the carbonyl group.

A monomeric zinc complex with bis(benzo-15-crown-5)porphyrin was prepared starting from dipyrrolylmethane, 4′-formylbenzo-15-crown-5 and zinc acetate (Scheme 2).[40] Treatment of the complex **6** with $AgPF_6$ yielded a diporphyrin zinc complex **7** containing two covalently (*meso-meso*) linked porphyrin rings.

Scheme 2



a — $BF_3 \cdot OEt_2$, $CHCl_3$, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone;
b — $Zn(OAc)_2 \cdot 2\,H_2O$, $CHCl_3$ – MeOH;
c — $AgPF_6$, $CHCl_3$ – MeOH – MeCN.

The addition of sodium salts to the monomeric complex **6** in $CHCl_3 - CH_3CN$ (2 : 1) did not cause any changes in the electronic absorption spectra of the complex, whereas the addition of potassium ions caused a shift in the Soret band from 415 to 396 nm (with an isosbestic point at 404 nm) and a decrease in the fluorescence intensity. It was suggested [40] that these changes are due to the formation of a diporphyrin dimer similar to the dimers **4** described above. The changes in the NMR spectrum of the complex **6** following addition of cations K^+ provide additional evidence in favour of formation of a dimer of the type **4**. The addition of a potassium salt to the covalently linked dimeric zinc

complex **7** results in more complicated changes in the electronic absorption spectra.

In the absence of alkali metal ions, the Soret band in the electronic absorption spectrum of compound **7** appears as a doublet at 421 and 453 nm. The splitting of this band is attributed to an exciton interaction. Upon addition of a potassium salt to a solution of the complex **7**, the intensities of the bands at 421 and 453 nm first decrease, and when the concentration of potassium ions reaches 1.0×10^{-5} mol litre^{-1}, the Soret band is shifted towards 423 nm and its intensity increases. These changes are accompanied by an appearance of a shoulder with an isosbestic point at 408 nm on the high-energy side of the Soret band.‡

The fluorescence intensity of the dimer **7** also changes with the concentration of potassium ions. At first, potassium cations ($[K^+] \leqslant 1.0 \times 10^{-5}$ mol litre^{-1}) cause a decrease in the intensity of the fluorescence band; however, the fluorescence increases with increasing concentration of potassium ions. Similar changes in the electronic absorption and fluorescence spectra were observed upon addition of rubidium ions, but not in the case of caesium and sodium ions. These findings are in conflict with the data on the behaviour of the monomeric complex **6** under identical conditions. It may thus be assumed that the intermolecular interactions of the crown-ether fragments of the monomeric (**6**) and dimeric (**7**) zinc complexes with potassium ions have the same character, but the molecular ensembles formed by these complexes differ. Coaxial dimerisation of the monomeric zinc complex upon interaction with potassium ions (the formation of 'face-to-face' dimers) is probable, while self-complementary dimerisation of the covalently bound zinc complex is impossible and linear extended aggregation is more preferable (Fig. 3). The complex character of changes in the electronic absorption and luminescence spectra suggest a multistage equilibrium resulting in the formation of a linear ensemble. The decrease in the fluorescence intensity in the initial step points to the formation of a coaxial diporphyrin, while its subsequent increase may result from interactions of the crown-ether groups of the linear aggregates with alkali metal ions. The polymeric nature of the aggregates is confirmed by light scattering studies: the molecular weight of the aggregate may amount to 10^5, *i.e.,* the linear ensemble is made up of 50 aggregated molecules. It is suggested[40] that the methodology of the supramolecular organisation of porphyrins described above can successfully be used in the design of novel molecular architectural ensembles and new generations of highly efficient materials.

‡ The appearance of a shoulder on the high-energy side of the Soret band is interpreted as the formation of a stacking diporphyrin of the coaxial type (a 'face-to-face' dimer).[40]

III. Crown-substituted monophthalocyaninates

Unlike porphyrins, the pyrrole fragments of phthalocyanines (Pc) forming the macrocyclic cavity are linked by four nitrogen atoms of the azamethine groups. Although these four additional nitrogen atoms are not directly involved in the complexation due to remoteness from the cavity centre, they create quite different

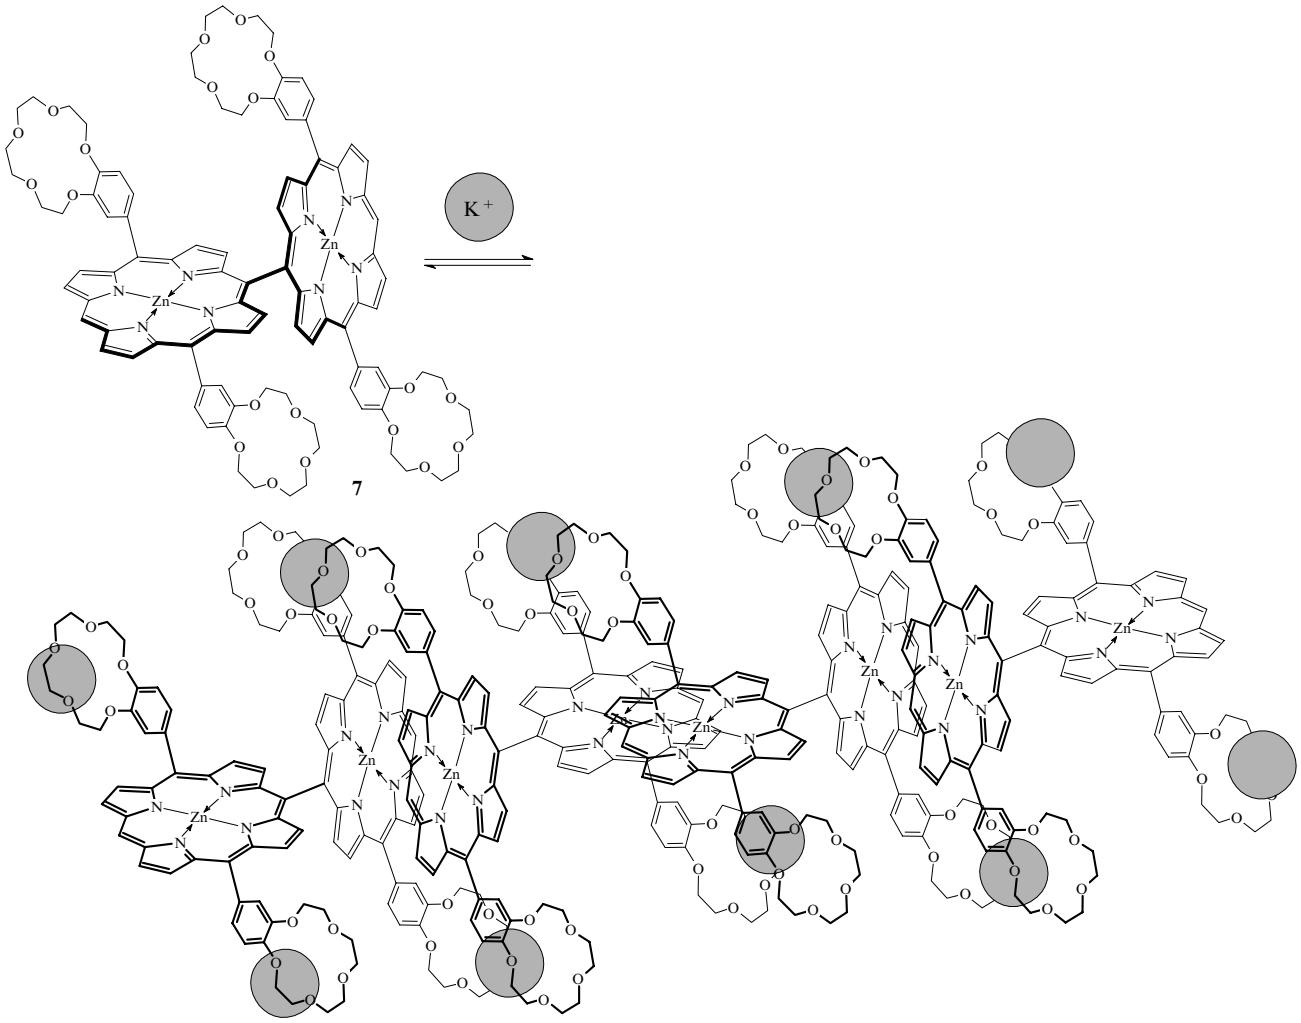


Figure 3. Supramolecular aggregation of dimeric zinc bis(benzo-15-crown-5)porphyrinates **7**.

conditions for the interaction with metal salts. Because of the peculiar electronic structure of the aromatic system, metal phthalocyanines manifest high chemical and thermal stability and possess unique optical, electrical and photochemical properties, which opens up new opportunities for their wide application as semiconductors, catalysts, sensors, pigments and biologically active compounds.

Phthalocyanines are conformationally rigid ligands; therefore, their complexation is accompanied by forced planar-tetragonal coordination of the central metal ion, which ensures high kinetic stability of the corresponding phthalocyaninates.

The first phthalocyanine complex (CuPc) was obtained by accident in 1927 during the synthesis of 1,2-dicyanobenzene from *o*-dibromobenzene and CuCN in pyridine at 200 °C (see Ref. 41). The nitrile-based and urea-based template syntheses of metallophthalocyanines were developed later. The former approach is based on the reaction of phthalonitrile with various metal salts.[42] At present, phthalocyanines are synthesised in different ways, but the template method is still the most popular.

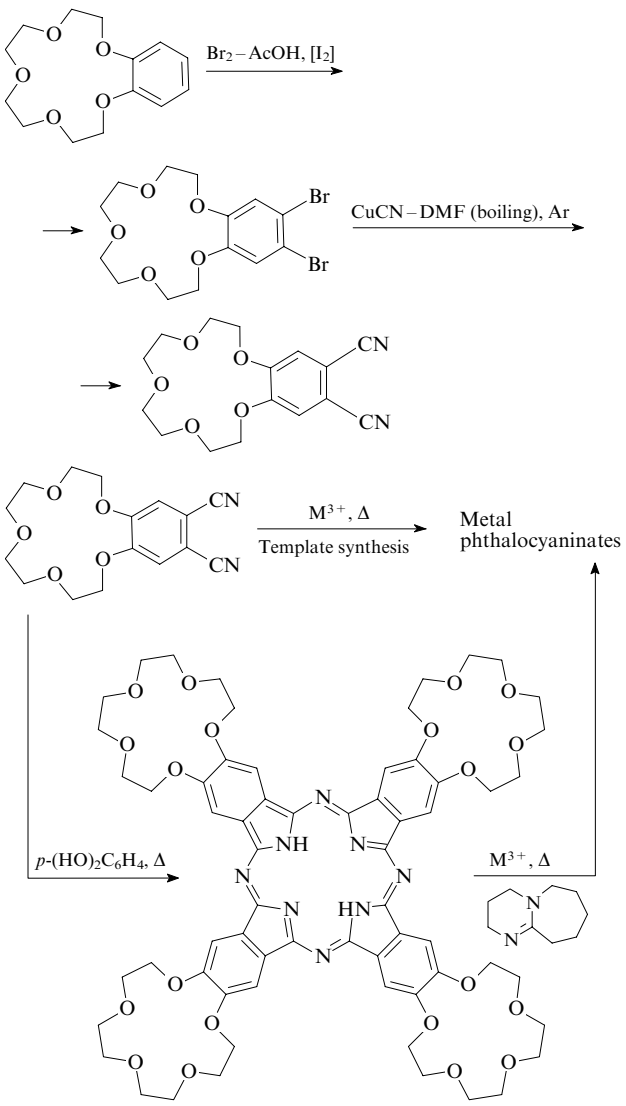
Metallophthalocyanines have limited application due to their poor solubility in organic solvents and water, which prevents the preparation of chemically pure substances and high-quality films based on them. Numerous substituted phthalocyanines have been synthesised in order to improve their solubility. Thus the introduction of bulky substituents (*e.g.*, *tert*-butyl, naphthyl or crown-ether substituents) into the benzene rings of the phthalocyanine molecule increases their solubility in organic solvents,[41,42] whereas sulfation of benzene rings increases the solubility of phthalocyanines in water.

The introduction of a crown-ether fragment into a phthalocyanine molecule as a substituent in the benzene ring of the isoindole fragment not only increases its solubility, but also favours the formation of heterometal complexes upon interaction of phthalocyaninates with alkali and alkaline earth metal salts. Syntheses of such complexes have been described.[20–24,43–46] Tetracrown-substituted phthalocyanines were prepared from benzo-15-crown-5, which was converted into dicyanobenzo-15-crown-5. The latter was used as a starting reagent in the nitrile template synthesis of tetracrown-substituted phthalocyanine (CR-Pc) (Scheme 3).

Interactions of dicyanobenzo-15-crown-5 with divalent metal salts yield chelate complexes M(CR-Pc) [M = Co(II), Ni(II), Zn(II), Cu(II), *etc*.]. With trivalent metals (M = Al), metal complexes are formed with extra ligands occupying an axial position. In contrast to the synthesis of crown-substituted porphyrins where mono-, di-, tri- and tetracrown-substituted derivatives are formed, in the case of phthalocyanines, tetracrown-substituted complexes are always formed as the reaction products. Data from various physicochemical methods have made it possible to postulate a symmetrical structure for the compounds formed. No direct evidence for such symmetry was available until recently due to a lack of X-ray data; however, a comparison of the vibrational spectra of tetracrown-substituted copper phthalocyaninate in a conformationally sensitive region of the IR and Raman spectra (600–1600 nm) (Fig. 4) revealed that these spectra did not coincide either in frequencies, or in relative intensities of the bands over the whole spectral region. This suggests that the IR and Raman spectra of this compound follow the alternative exclusion principle, *viz*., the frequencies that appear in the IR spectra are absent from the Raman spectra and *vice versa*. It is well known that these regularities are characteristic of highly symmetrical compounds.[6] Thus, the symmetrical structure of the above compound was deduced from its vibrational spectra.

An attempt to synthesise an aluminium complex with tetracrown phthalocyanine by the nitrile template method failed.[47] The interaction of aluminium chloride with dicyanobenzo-15-crown-5 (DCB15C5) in quinoline (the nitrile method) at 170 °C was accompanied by degradation of DCB15C5 and the complex was not formed. The yield of the corresponding Al(CR-Pc)(SO_4H) complex (**8**) synthesised from $Al_2(SO_4)_3$ and DCB15C5 in the melt

Scheme 3



was very low due to hydrolysis of the cyano groups. In order to exclude this undesirable effect, the reaction of $Al_2(SO_4)_3$ with DCB15C5 was carried out in urea as in the urea-based version of the template synthesis which is employed for the preparation of

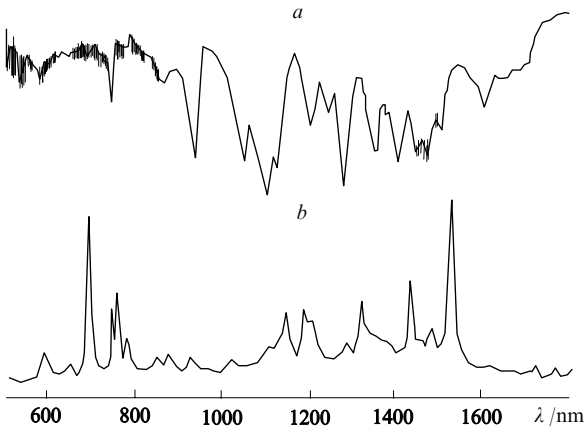


Figure 4. IR- (*a*) and Raman spectra (*b*) of copper tetra(15-crown-5)-phthalocyaninate.

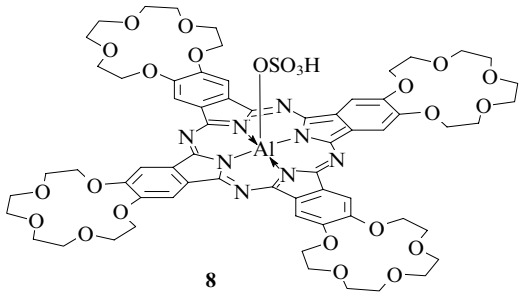
phthalonitriles from phthalimide, phthalic acid or its derivatives and urea. Urea, which decomposes at 130 °C in the presence of a catalyst (ammonium molybdate) with evolution of ammonia, serves as an aminating reagent for the conversion of the phthalic acid derivative into phthalonitrile directly in the course of the synthesis.



8

It was found that the Al(CR-Pc)(SO_4H) complex is soluble in both organic solvents (*e.g.*, chloroform, acetone, pyridine, ethanol, dimethyl sulfoxide, *N*,*N*-dimethylformamide) and in water. The aqueous solution of this complex is stable in neutral and weakly acidic media. At pH > 7, complex **8** is hydrolysed into Al(CR-Pc)OH.

The synthesis of a zinc complex with a crown-substituted phthalocyanine by the nitrile template method is also difficult due to the necessity of prolonged heating of the reagents and relative instability of zinc phthalocyanine complexes.[48] Therefore, the direct method, *viz.*, the reaction of zinc acetate with H_2(CR-Pc), was used for the synthesis of the crown-substituted zinc monophthalocyaninate Zn(CR-Pc).[49] This reaction was carried out either in the presence of an excess of lithium hydroxide in a chloroform–ethanol mixture or in the presence of a stoichiometric amount of BuLi in dimethyl sulfoxide. In the latter case, the yield of the Zn(CR-Pc) complex reached 95%.

Similar problems were observed in the template synthesis of crown-substituted monophthalocyaninates of rare-earth elements (REE). Because of the large radii of lanthanide ions, it is much more difficult to prepare REE monophthalocyaninates than sandwich bisphthalocyaninates.[50–54] An analysis of known methods for the synthesis of crown-substituted REE monophthalocyaninates revealed [55] that the protonated ligand H_2(CR-Pc) is the most suitable starting material. However, reactions of REE acetates with H_2(CR-Pc) occur only in the presence of strong bases, *e.g.*, 1,10-phenanthroline (Phen) and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU).[55] Boiling of lutetium acetate and H_2(CR-Pc) in dichlorobenzene in the presence of an excess of DBU gives crown-substituted lutetium monophthalocyaninate.

$$H_2(\text{CR-Pc}) + Lu(OAc)_3 \xrightarrow[\Delta]{\text{DBU, } o\text{-}Cl_2C_6H_4} Lu(\text{CR-Pc})(\text{DBU})OAc.$$

In the presence of 1,10-phenanthroline, the reaction proceeds in a similar way. In the compound Lu(CR-Pc)$(Phen)_2X$ formed, phenanthroline acts both as the base and the chelating ligand for lutetium ions. Both lutetium complexes possess sufficiently high solubilities in organic solvents of various polarity (*e.g.,* chloroform, dichloromethane, dimethyl sulfoxide, acetone) and in water (the concentration of a saturated aqueous solution of the DBU complex is 1.7×10^{-4} mol litre^{-1}).

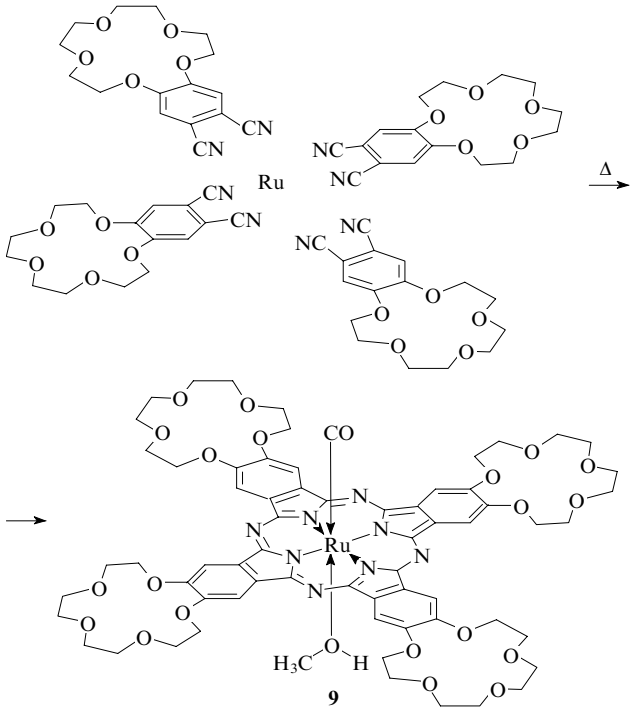
Until recently, data on the synthesis of crown-substituted phthalocyaninates of platinum metals were absent from the literature. At the same time, complexes of platinum metals with such ligands present substantial interest because of the great diversity of coordination properties of both the ligands and the central metal atoms. The synthesis of a complex of ruthenium(II) with tetra(15-crown-5)phthalocyanine has been described.[56]

The template synthesis is mainly used in the preparation of ruthenium complexes with unsubstituted phthalocyanine from phthalonitrile (or cyanobenzamide) and ruthenium trichloride is the main procedure.[57–60] The ruthenium(II) monophthalocyaninate 'PcRu' reacts with various ligands to give complexes with the composition $PcRuL_2$ (L = Py, DMF, DMSO, *etc.*).[60,61] This approach was also used in the synthesis of tetraalkyl-substituted ruthenium phthalocyaninates (yield 95%).[62]

There are still no unambiguous literature data on the structure of the 'PcRu' complex prepared by the template synthesis. Using LAXS and EXAFS methods, Ercolani and co-workers [60,63] have demonstrated that the 'PcRu' complex represents a dimer the length of the Ru–Ru bond in which is equal to 2.40 Å. The molecular formula of this complex can be written as $[(PcRu)_2]_6$. The Ru···Ru distance between the neighbouring dimers (4.30–4.40 Å) exceeds significantly that in the dimer. In the crystal structures of $[(Ru(Py)Pc)_2(\mu\text{-}C)]$ [64] and $(Bu^n_4N)[Ru(CN)(Py)Pc]$,[65] the ruthenium atoms deviate from the plane of the macrocycle by ~0.05 Å. The distance between the neighbouring pyrrole planes, $(Np)_4$,§ is 3.65 Å.[64,65]

The template method was also used for the synthesis of ruthenium tetra(15-crown-5)phthalocyaninate (Scheme 4).[56] It is of note that one complex, Ru(CR-Pc)(CO)CH_3OH (**9**), containing an axial carbonyl group is formed irrespective of the starting ruthenium compound, *viz.*, $RuCl_3 \cdot n H_2O$ or $Ru_3(CO)_{12}$. The formation of a Ru(CR-Pc)(CO)CH_3OH complex was expected in the case of $Ru_3(CO)_{12}$, the formation of a complex with the same composition from $RuCl_3$ was rather unexpected. However, considering that the attachment of CO to the Ru atom occurred in the template synthesis of unsubstituted ruthenium phthalocyanine complexes in an atmosphere of CO with ruthenium chloride as a starting reagent,[66] the formation of a complex of this composition can hardly be called unexpected.

Scheme 4



9

Ru = $RuCl_3 \cdot n H_2O$; $Ru_3(CO)_{12}$.

The IR spectra of two Ru(CR-Pc)(CO)CH_3OH complexes prepared from $RuCl_3$ (α-form) and $Ru_3(CO)_{12}$ (β-form) differ in the region around 1000–1300 cm^{-1} which contains characteristic bands corresponding to ν(COC) of the crown-ether groups. This suggests that crown-ether substituents in the α- and β-forms of Ru(CR-Pc)(CO)CH_3OH have different conformations.[56]

§ $(Np)_4$ is a plane passing through four nitrogen atoms of the pyrrole rings.

It can thus be concluded that Co, Ni, Zn and Cu cations in the oxidation state 2+ form chelate monophthalocyaninate complexes with crown-substituted phthalocyanines, whereas REE and aluminium cations in the oxidation state 3+ and ruthenium cations in the oxidation state 2+ form monophthalocyaninates with various axial ligands.

IV. Supramolecular aggregation of crown-substituted monophthalocyaninates

Crown-substituted metal monophthalocyaninates can form various supramolecular polymeric ensembles by noncovalent interactions. The stability of such ensembles in solution is determined by the multiplicity and dynamism of weak interactions of the $\pi-\pi$-stacking type.[67, 68] These interactions govern packaging of molecules into crystals and, correspondingly, such important characteristics of materials as electron transport. Modification of phthalocyanines by crown-ether substituents creates the necessary prerequisites for preparation of pillar-type structures with C_4, symmetry and high electroconductivity.

Crown-substituted phthalocyanines and their metal complexes form rigid stable coaxial dimers in the presence of alkali and alkaline earth metal ions for which the crown-ether fragments represent chelating ligands. The main prerequisite for the formation of such dimers is a large diameter of the cation which significantly exceeds that of the crown-ether ligand cavity. The formation of heteronuclear supramolecular dimers in the presence of potassium halides or acetate (KX) was studied [20–23, 43–46] using bivalent transition metal complexes (Cu, Ni, Co, Zn) as examples. These studies have demonstrated the possibility of formation of rigid coaxial dimers with the composition $2\,M(CR\text{-}Pc)\cdot 4\,K^+$ (M = Cu, Ni, Co, Zn). It was found also that the aggregation strongly depends on the nature of the solvent and the type of anion.

The electronic absorption spectra, which are highly sensitive to any changes in the complexes in the course of their aggregation, were selected as a tool for dimerisation studies. These spectra are very informative and demonstrate, in the most illustrative way, the characteristic changes in the structure of supramolecular aggregates under the influence of various factors.[20, 21]

In contrast to the aggregation of crown-substituted phthalocyanines, which occurs upon an increase in their concentration in solution and does not result in changes in their absorption spectra, the dimerisation induced by alkali metal cations has well-defined spectral manifestations. Thus it was found that the short-wavelength shift of the major absorption bands (*i.e.*, the Q-band and the Soret band) suggest the formation of rigid coaxial dimers in the system, the so-called H-dimers. The magnitude of the Q-band shifts depends on the distance between the interacting transient dipoles that appear as a result of an electron transfer in the phthalocyanine ligands.

The presence of a Q-band at 670 nm with a half-width of 500 cm^{-1} and a vibrational satellite at 610 nm and of a Soret band around ~ 350 nm with a shoulder in the short-wavelength region is characteristic of electronic absorption spectra of solutions of monophthalocyanines. Absorption around ~ 420 nm, which corresponds to the $n \rightarrow \pi^*$-transition due to the presence of crown-ether substituents, is represented by a broad low-intensity symmetrical band.

In addition to the aforementioned shifts of the major bands, interactions of alkali metal cations with crown-substituted metal phthalocyaninates are accompanied by broadening and a decrease in intensity of Q-bands. For example, the decrease in the intensity of the Q-band of $(15\text{-C-}5)_4$PcCu and $(18\text{-C-}6)_4$PcCu complexes depends on the concentration of the alkali metal salt: the corresponding dependence is linear and reaches a plateau at the stoichiometry 2 : 1 (four cations per two ligands) indicating the formation of the sandwich dimers **10** (Fig. 5).

If the diameter of the alkali metal cation (d_{M^+}) is larger than the size of the cavity of the crown-ether substituent (d_{CR}), highly

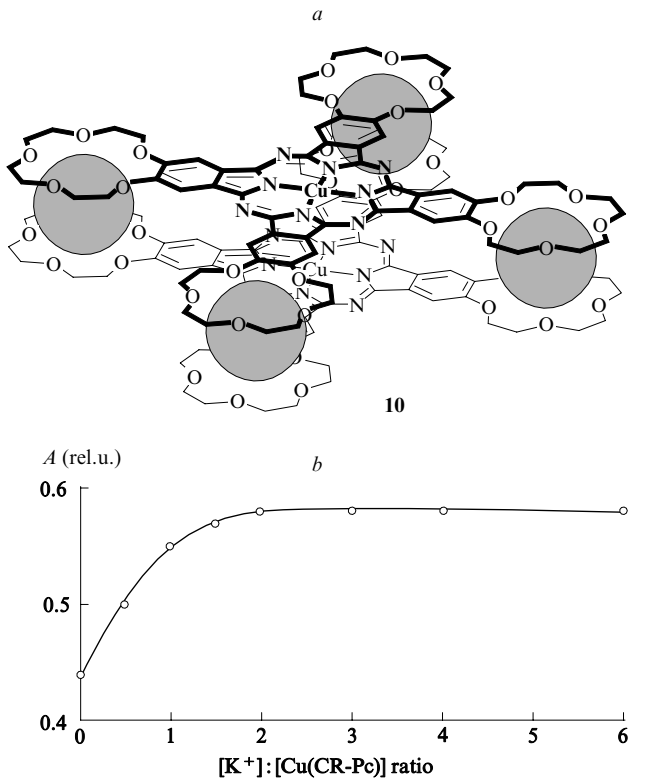


Figure 5. The structure of a sandwich-like supramolecular dimer $K_4[Cu(CR\text{-}Pc)]_2$ (**10**) (*a*) and a spectrophotometric titration curve of the Cu(CR-Pc) complex with potassium thiocyanate (*b*).

symmetrical sandwich complexes with the composition $4\,MX\cdot 2\,M(CR\text{-}Pc)$ are formed, while for $d_{M^+} < d_{CR}$, monophthalocyanine complexes $4\,MX\cdot M(CR\text{-}Pc)$ are formed.

Studies of formation of Co(CR-Pc) complexes with sodium and potassium thiocyanates (Scheme 5) (d_{K^+} = 2.66 Å; d_{Na^+} = 1.94 Å; d_{CR} = 1.7–2.2 Å) by the molar ratio method revealed [69] that the increase in the $[M^+]$: [Co(CR-Pc)] ratio results in changes in the electronic absorption spectra typical of phthalocyanine aggregation, *viz.*, a significant decrease in the intensity of Q-bands up to $[M^+]$: [Co(CR-Pc)] = 2 (nearly twofold for KSCN and threefold for NaSCN) with a simultaneous broadening of the Q-bands characteristic of complex formation and an appearance of an additional absorption band around 626 nm (for M = K) or 737 nm (for M = Na) (Fig. 6). Further increase in the metal : ligand ratio leads to precipitation.

The interaction of sodium thiocyanate with Co(CR-Pc) occurs in two steps.[69] Initially, an increase in the $[Na^+]$: [Co(CR-Pc)]

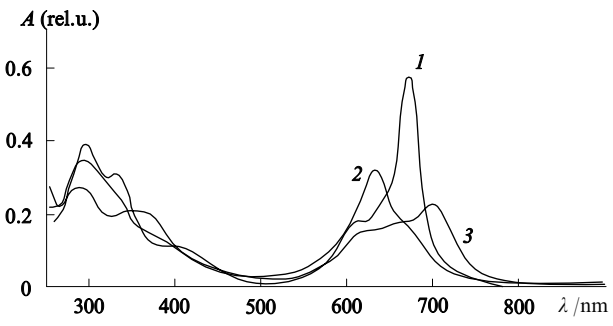

Figure 6. Electronic absorption spectra of Co(CR-Pc) (curve *1*) and its complexes with potassium (curve *2*) and sodium ions (curve *3*) in a chloroform – ethanol mixture (80 : 20, by volume).

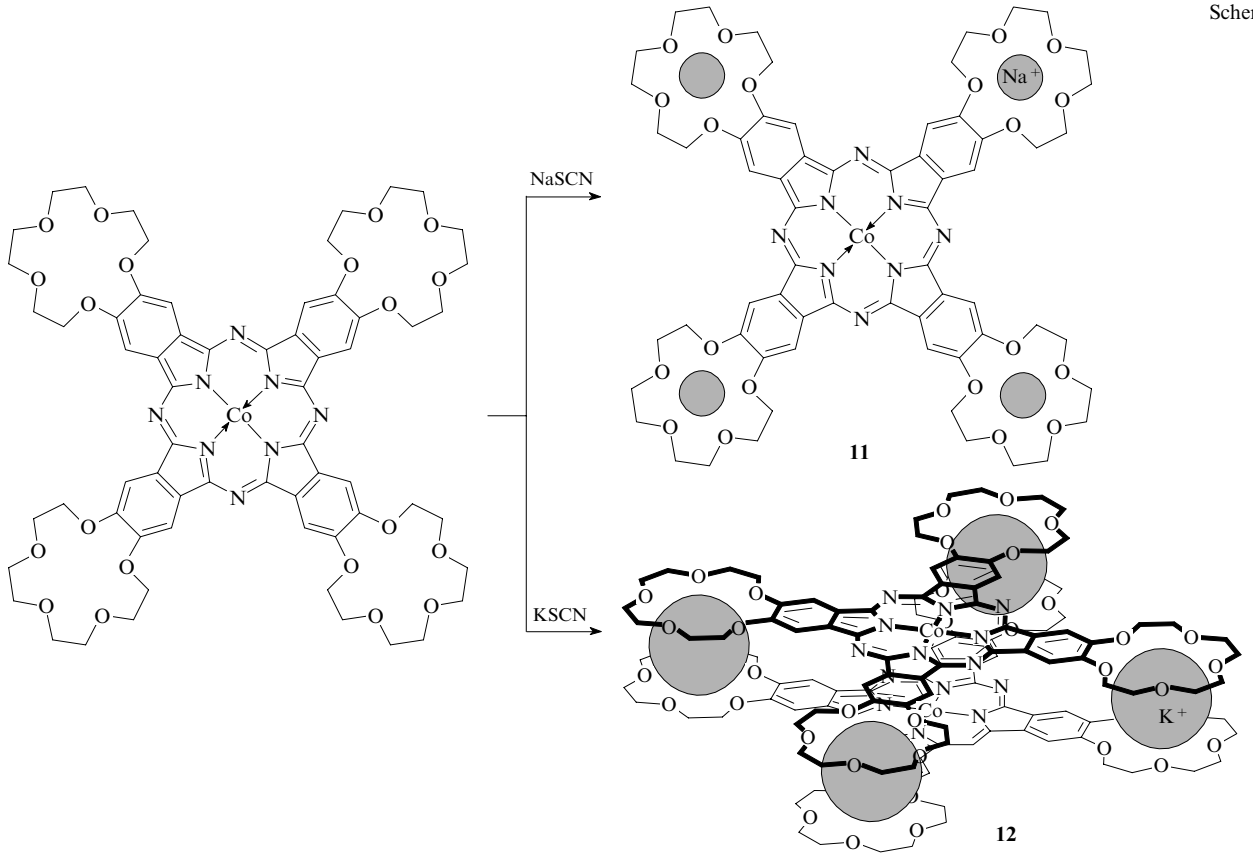
Scheme 5



ratio from 0 to 2 results in a decrease in absorption intensity at 668 nm and an increase at 629 nm. Then in the interval of $[Na^+]:[Co(CR\text{-}Pc)]$ ratios from 2 to 4, the intensity of absorption at 629 nm decreases with a simultaneous increase in the absorption intensity around 700 nm, which suggests the formation of a complex with the composition $4\,NaSCN\cdot Co(CR\text{-}Pc)$ (**11**) (see Fig. 6). At a metal : ligand ratio of 4, the complex is precipitated as a solid phase. The complex with the composition $4\,NaSCN\cdot Co(CR\text{-}Pc)$ is characterised by $\lambda_{max} = 737$ nm and $\varepsilon = 2.90\times10^4$ litre mol^{-1} cm^{-1}, whereas the corresponding parameters for the complex with the composition $4\,KSCN\cdot 2\,Co(CR\text{-}Pc)$ (**12**) established by the molar ratio method are $\lambda_{max} = 626$ nm and $\lambda = 4.28\times10^4$ litre mol^{-1} cm^{-1}. The difference between the λ_{max} equal to 111 nm is sufficient for simultaneous detection of sodium and potassium ions in a solution using the Co(CR-Pc) complex (Figs 6–8). Other known crown-containing phthalocyaninates do not manifest such specific sodium–potassium selectivity.

The form of crown-containing phthalocyaninates present in a solution often plays a crucial role as regards their practical applications. Thus successful application of crown-containing phthalocyaninates as photosensitisers in the photodynamic therapy of malignant tumours requires that these were present in the monomeric form. Contrariwise, the synthesis of liquid crystals demands that soluble crown-containing phthalocyaninates formed the so-called stacks characteristic of unsubstituted phthalocyaninates.[70]

Similar sodium–potassium selectivity was observed for Co(CR-Pc) solutions in chloroform,[69] since the Co(CR-Pc) complex is poorly soluble in water. In order to detect sodium and potassium ions in biological systems with the help of the Co(CR-Pc) complex, it seemed important to characterise the behaviour of the complex in solvents of different polarity and their mixtures with the aim to search for an optimum system where the Co(CR-Pc) complex existed in the monomeric form and manifested sodium–potassium selectivity. It was shown[71] that in a chloroform–ethanol mixture containing $\leqslant 20$ vol.% ethanol

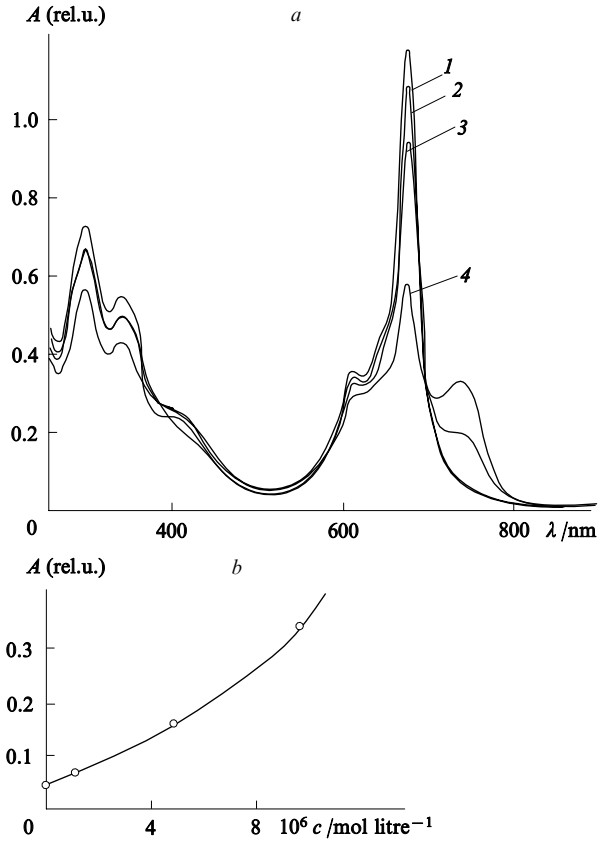


Figure 7. Absorption spectra (*a*) and the calibration curve (*b*) of the $n\,NaSCN\cdot Co(CR\text{-}Pc)$ complex ($n = 0-4$). Concentrations of the Na^+ cations /mol litre^{-1}: (*1*) 0, (*2*) 1×10^{-6}, (*3*) 5×10^{-6}, (*4*) 1×10^{-5} ($\lambda_{max} = 737$ nm).[72]

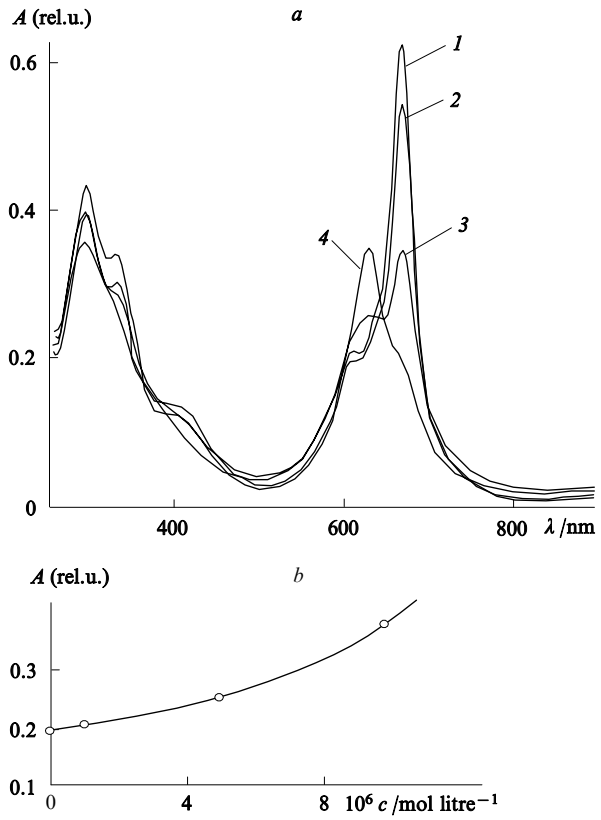

Figure 8. Absorption spectra (*a*) and the calibration curve (*b*) of the nKSCN·Co(CR-Pc) complex ($n = 0-2$). Concentration of the K^+ cations, mol litre^{-1}: (*1*) 0, (*2*) 1×10^{-6}, (*3*) 5×10^{-6}, (*4*) 1×10^{-5} (λ_{max} = 626 nm).[72]

the Co(CR-Pc) complex existed almost completely in the monomeric state. This makes it possible to rule out the effect of the solvent on the interaction of this complex with alkali metal ions. A chloroform–water mixture can be used for the study of biological fluids. However, it cannot be used as a model system because of the limited solubility of water in chloroform.

The kinetics of formation of heteronuclear complexes of Co(CR-Pc) with sodium and potassium cations in a chloroform–ethanol–water mixture was studied in order to apply the effect of differently directed shifts of the Q-band in the absorption spectrum of this compound under the influence of sodium and potassium salts for analytical purposes.[72]

The time dependence of the optical density of the absorption band of Co(CR-Pc) at 626 nm in the presence of an equimolar amount of KSCN suggests that the Co(CR-Pc) complex with potassium is formed at a sufficiently high rate (the equilibrium is reached within 3–5 min). A similar time dependence of the optical density of the absorption band at 737 nm upon addition of NaSCN suggests that the complexation with sodium ions proceeds at a much lower rate than with potassium ions and is complete only after 20–30 min. As a consequence, Co(CR-Pc) complexes with K^+ and Na^+ are formed at different rates, presumably due to differences in their structures, *viz.*, the 'sandwich' complex **12** with K^+ is formed from the starting compounds practically instantaneously, while the formation of the planar sodium complex **11** proceeds through the formation of an intermediate complex with a stoichiometric composition 2M·L. A comparison of the spectral data suggests that both complexes are characterised by a strong dependence of the optical density on the concentration of the metal ions, which enables their application for quantitative determination of Na^+ and K^+ present in a solution simultaneously (Figs 7 and 8).[72]

It is of note that the sodium–potassium selectivity of the Co(CR-Pc) complex is observed only in the case of sodium and potassium thiocyanates and is not manifested in the presence of anions other than NCS^- (*e.g.*, Cl^-, Br^-, I^-, AcO^-). Presumably, ambident thiocyanate ions play a crucial role in the complexation of Co(CR-Pc) with K^+ and Na^+ cations. If sodium ions were located in the centre of the crown-ether cavity, as it normally occurs, to form monomeric complexes, no changes in their electronic spectra would have been observed. In all probability, thiocyanate ions favour the rearrangement of the supramolecular aggregates based on heteronuclear (Co,Na)-monomeric complexes due to the formation of the Co–SCN bonds.

Interactions of alkali metal cations with crown-containing phthalocyaninates of trivalent metal ions with axial ligands occur differently. Thus the Al(CR-Pc)(SO_4H) complex in chloroform interacts with K^+ ions, which is confirmed by a decrease in the intensity of the Q-band; however, the dimer is not formed as can be evidenced from the absence of the corresponding absorption band.[47] This suggests that in contrast to the bivalent metal chelate complexes M(CR-Pc) (M = Cu, Co, Zn, *etc.*), the Al(CR-Pc)(SO_4H) complex does not form 'sandwich' molecules. Apparently, a coordinated extra ligand (SO_4H^-) prevents this process. Even such polar solvents as MeOH and EtOH are incapable to induce the dimerisation of the complex **8**. The electronic absorption spectra indicate that the aluminium complex in chloroform is aggregated to a larger extent than that in the $CHCl_3$–EtOH mixture. Nevertheless, the absorption spectra of the complex **8** depend on the nature of the solvent (Fig. 9).

The aggregation of Al(CR-Pc)(SO_4H) molecules strongly depends on the type of the anion; the corresponding electronic absorption spectra provide an illustrative example (Fig. 10).

As can be seen from Fig. 10, no changes in the Q-band at ~ 691 nm occur upon the interaction of Al(CR-Pc)(SO_4H) with sodium chloride despite the appearance of low-intensity bands at ~ 657 nm characteristic of dimers. The interactions of the complex **8** with sodium bromide and sodium iodide result in the disappearance of the band at ~ 691 nm and an appearance of less intense bands characteristic of aggregated forms around ~ 652 and ~648 nm. However, more significant spectral changes manifested in the appearance of a narrow intense band at ~ 639 nm are observed in the interaction of Al(CR-Pc)(SO_4H) with sodium fluoride: the band intensity is comparable to that at ~ 691 nm. It may thus be concluded that in this case we deal with

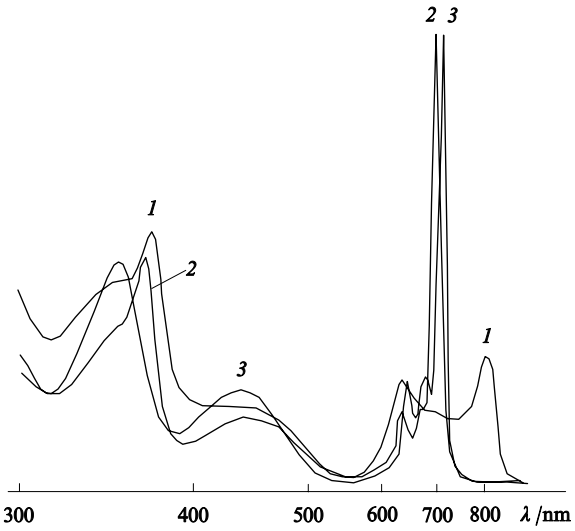

Figure 9. Electronic absorption spectrum of Al(CR-Pc)(SO_4H) in different solvents.

the formation of highly ordered supramolecular ensembles which involve fluoride bridges.

Supramolecular aggregation occurs upon dissolution of Al(CR-Pc)(SO_4H) in water as can be evidenced from significant changes in the electronic absorption (see Fig. 9) and luminescence spectra (Fig. 11). Lowering of the intensity of the luminescence band of complex **8** in water limits its application in the photodynamic therapy of cancer despite its easy solubility in water and normally high quantum yields of luminescence of aluminium phthalocyaninates.

The photodynamic activity of crown-containing phthalocyaninates is manifested in those cases where they are present in aqueous solutions as monomers.[73] However, the majority of crown-containing phthalocyaninates form aggregates in water due to dispersion interactions between aromatic systems.[74] If the charge of the central metal ion is three, a charge-compensating ligand is required for partial separation of the macrocycles, which favours the existence of crown-containing phthalocyaninates in water as monomers.

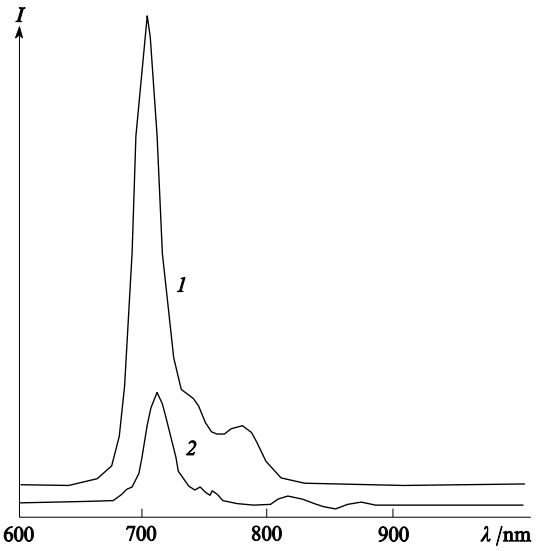

Figure 11. Luminescence spectra of Al(CR-Pc)(SO_4H) solutions in chloroform (λ_{max} = 696 nm) (*1*) and water (λ_{max} = 705 nm) (*2*).

It has been shown[75] that depending on the mutual arrangement of macrocyclic π-aromatic systems in the aggregates their electronic spectra exhibit a short- or a long-wavelength shift of the absorption band in the visible region of the spectrum relative to its position in the corresponding spectrum of the monomer. Aggregates of the first type usually contain a small number of molecules with strong π-interactions between each other. These include, in particular, coaxial dimers also referred to as H-aggregates. In the second type of aggregates termed as J-aggregates, the molecules are strongly displaced relative each other. Here, another type of interaction between electronic π-systems of the molecules results in a long-wavelength shift with a simultaneous narrowing of the absorption band.[75] These changes in the electronic absorption spectra are observed only in aggregates consisting of 4–9 monomers. The mutual arrangement of molecules in such aggregates differs from that in J-dimers which are spectrally indistinguishable from monomers.[75]

A compound with the composition Lu[(15-C-5)$_4$Pc](OAc)$_2\cdot$ 2 Phen, the phenanthroline molecules in which play the role of chelating ligands, has been synthesised[55,76] in order to obtain phthalocyaninates which normally do not form aggregates in aqueous solutions (as is required of preparations used in the photodynamic therapy of cancer). It was suggested[76] that such axial chelate ligands prevent the aggregation. Indeed, this compound was found to exist in aqueous solutions (pH 5.5) in the monomeric state.

Since physiological solutions contain sodium and potassium salts, it is important to elucidate the behaviour of this compound in aqueous solutions containing NaCl and KCl. It was found that NaCl does not induce any aggregation of the Lu(CR-Pc)(OAc)$\cdot$ 2 Phen complex. When the latter is used in the concentration 2×10^{-5} mol litre^{-1} and NaCl is used in the concentrations < 2.0 mol litre^{-1}, no significant changes are observed in the Lu(CR-Pc)(OAc)$\cdot$ 2 Phen complex within the pH range 3.5–9.0 and J-aggregates are formed only upon alkaline hydrolysis.

The interaction of the lutetium complex with potassium chloride in aqueous solutions is accompanied by the formation of H-dimers, however, only if the electrolyte is used in a large excess.

The interaction of the Lu(CR-Pc)(OAc)$\cdot 2\,H_2O$ complex with sodium and potassium acetates was studied using spectrophotometry and ^{1}H NMR spectroscopy.[77] It was found that potassium ions favour the formation of 2[Lu(CR-Pc)(OAc)$\cdot 2\,H_2O$]$\cdot 4\,K^+$ dimers in a $CHCl_3$ – DMSO mixture. It was thus assumed that the

complex represents a coaxial dimer of the 'guest – host' type and has an eclipsed conformation.

The interaction of the ruthenium complex **9** containing CO and CH_3OH molecules as axial ligands with sodium and potassium thiocyanates presents substantial interest. The cation-induced supramolecular aggregation of this complex was studied by electronic absorption spectroscopy (Fig. 12).[78] An analysis of changes in the absorption intensity of the Q-band of the complex **9** *vs.* the $[M^+]:[\mathbf{9}] = n$ ratio revealed that the interactions of the complex **9** with K^+, Rb^+ and Cs^+ thiocyanates yield supramolecular aggregates of the composition $n\mathbf{9}\cdot 2n$MNCS in the form of 'brickwork' (Fig. 13).

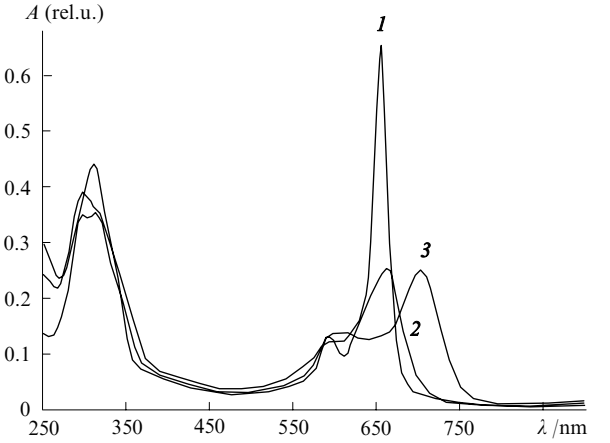

Figure 12. Electronic absorption spectra of (CR-Pc)Ru(CO)(CH_3OH) (**9**) and its complexes with KSCN and NaSCN in $CHCl_3$.
(*1*) **9**, (*2*) **9** + 2 KSCN, (*3*) **9** + 2 NaSCN (after 8 days).

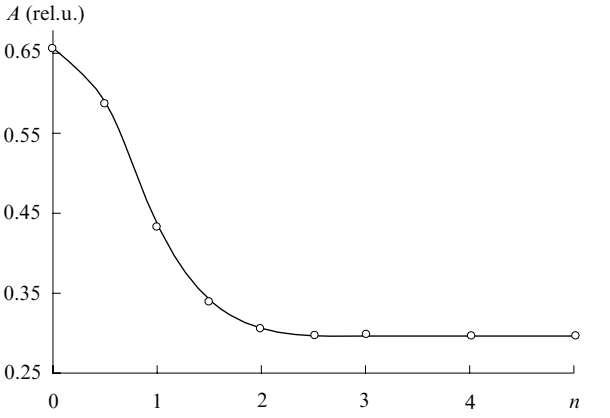

Figure 13. Dependence of the intensity of the absorption Q-band in the electronic absorption spectra of complex **9** in $CHCl_3$ on n ($n = [KSCN]:[\mathbf{9}]$). Similar dependencies are also observed for Rb^+ and Cs^+.

The interaction of the complex **9** with NaSCN is more complicated. In contrast to the cations K^+, Rb^+ and Cs^+, the diameter of the Na^+ cation coincides with the size of the cavity of 15-crown-5, which favours the encapsulation of Na^+ into the crown ether.[6] At the initial moment of time, the interaction of the complex **9** with NaSCN causes a bathochromic shift of the Q-band from 655 to 679 nm, which is followed by more complex reaction kinetics: after 30 min, the Q-band is shifted to 690 nm, after 2 days, to 698 nm, after 4 days, to 701 nm and after 8 days, to 704 nm (see Fig. 12, curve *3*). Such a complex kinetic behaviour and a simultaneous strong shift of the absorption Q-band can be attributed to the formation of a coordination bond between the thiocyanate ions, sodium cations present in the cavities of the crown ethers and ruthenium(II) ions. This can occur upon substitution of the thiocyanate ion for an axially coordinated methanol molecule.

Elucidation of structural specificities of supramolecular aggregates formed upon interaction of the ruthenium complex with sodium thiocyanate required the use of data from vibrational spectra, since it is well known that vibrational frequencies change considerably depending on the mode of coordination of the NCS groups.[79] The NCS^- group can coordinate a metal through a nitrogen or a sulfur atom as well as through a bridging structure. The type of coordination depends on the nature of the metal. The type of bonding of the NCS group in metal complexes is determined on the basis of empirical criteria.[80] Thus the stretching vibration frequencies ν(CN) in N-bonded complexes lie around 2070 cm^{-1} and are lower than those in S-bonded complexes (around 2100 cm^{-1}). The vibration frequencies ν(CN) in the bridged $M-NCS-M'$ complexes lie above 2100 cm^{-1}. The ν(CN) values for thiocyanate alkali metal complexes with crown ethers are usually lower than those for thiocyanate complexes with transition metals.[10, 11, 79] The IR spectra of ruthenium complexes before and after interaction with potassium and sodium thiocyanates are shown in Figs 14 and 15, respectively.

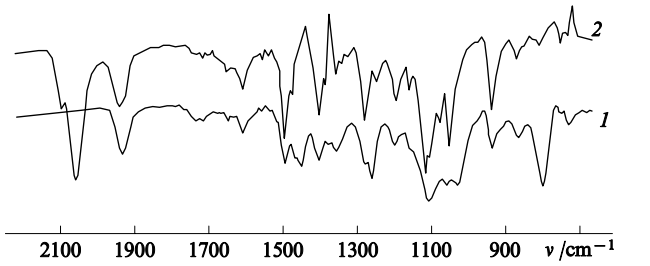

Figure 14. IR spectra of Ru(CR-Pc)(CO)(CH_3OH) (*1*) and its complex with KSCN (*2*).

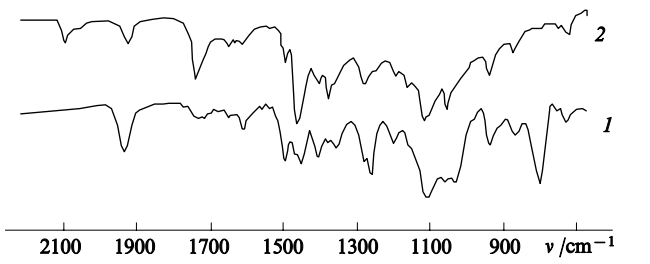

Figure 15. IR spectra of Ru(CR-Pc)(CO)(CH_3OH) (*1*) and its complex with NaSCN (*2*).

The IR spectra of ruthenium crown-containing phthalocyaninates contain all the bands characteristic of metal complexes with crown-containing phthalocyanines. The most intense bands lie around 900 – 1300 cm^{-1}, *i.e.*, in the region where complex stretching-deformation vibrations of the CO, CC and HCH fragments of the crown ether are manifested. It is in this region that the conformational changes associated with the complexation of crown ethers with alkali metals are displayed.[6]

Analysis of the IR spectra of ruthenium phthalocyaninate **9** and its complexes with KSCN and NaSCN allows certain conclusions to be drawn concerning the effect of complexation of alkali metals with crown-substituted ruthenium(II) phthalocyaninate on the conformational state of the crown-ether substituent. The IR spectra of alkali metal complexes with Ru(CR-Pc)(CO).(CH_3OH) in the conformation-sensitive region (900 –

1400 cm^{-1}) differ essentially from the IR spectrum of the original complex, which points to conformational rearrangements in the crown ethers.

Analysis of changes in the IR spectra around 2000–2150 cm^{-1} points also to a strong effect of the nature of the substrate anion on the architecture of the supramolecular ensembles formed. The IR spectrum of the Ru(CR-Pc)(CO)(CH_3OH) complex with potassium thiocyanate contains a stretching vibration band [ν(CN)] at 2060 cm^{-1} (see Fig. 14), which suggests that the NCS group represents an outer-sphere ligand [6, 79] which is not involved in the formation of a supramolecular aggregate. The IR spectrum of the Ru(CR-Pc)(CO)(CH_3OH) complex with sodium thiocyanate contains two stretching vibration bands [ν(CN)] at 2097 cm^{-1} and 2060 cm^{-1} (Fig. 16), which points to coordination of sodium ion with the nitrogen atom of the NCS group. At the same time, the increase in the vibration frequency [ν(CN)] of complex **9** with NaCNS is so significant in comparison with the vibration frequency of the free NCS^- ion and sodium thiocyanate complexes with benzocrown ethers that it may lead to coordination of the sulfur atoms by the ruthenium atom resulting in the formation of bridged complexes.[6, 79] The changes in the IR spectrum of complex **9** with NaSCN (by analogy with the electronic absorption spectra) occurring during several days testify to further rearrangements of the architecture of the aggregate associated with coordination of the NCS group by the ruthenium atom of the macrocycle. This is confirmed by changes in the relative intensities of the absorption bands at 2097 and 2060 cm^{-1}. The band at 2060 cm^{-1} in the IR spectrum of the completely formed supramolecular aggregate is transformed into a shoulder, while the band at 2097 cm^{-1} is transformed into the major band (Fig. 16). This suggests that the NCS^- anion makes the most weighty contribution to the formation of a supramolecular ensemble in the interaction of the Ru(CR-Pc)(CO)(CH_3OH) complex with the NaSCN anion. The hypothetical structures of the supramolecular ensembles formed upon interaction of ruthenium complexes **9** with potassium (*a*) and sodium thiocyanate (*b*), respectively, are shown in Fig. 17.

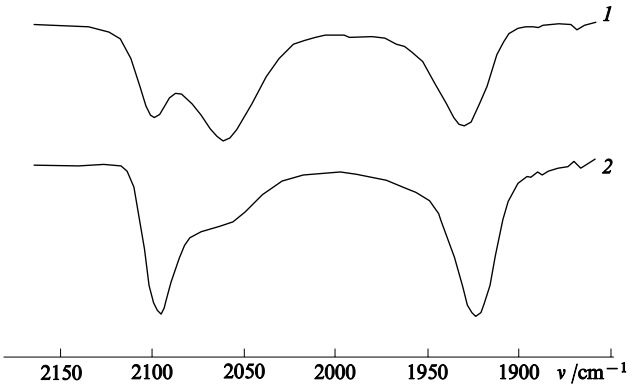

Figure 16. IR spectra of the Ru(CR-Pc)(CO)(CH_3OH) complex with NaSCN around 1900–2150 cm^{-1} recorded after 30 min (*1*) and 8 days (*2*).

V. Sandwich-like double- and triple-decker crown-substituted phthalocyaninates

The size of lanthanide cations exceeds the diameter of the phthalocyanine ligand cavity; therefore, their interactions yield predominantly sandwich-like structures (the so-called double- and triple-decker complexes). Depending on synthetic conditions, differently coloured ('green' and 'blue') forms of REE diphthalocyaninates are formed.

Until recently, the architectures of 'green' and 'blue' forms of diphthalocyaninates were open to discussion. Based on the ESR data for the 'green' form of the diphthalocyaninates $LnPc_2$, the structure of the radical paramagnetic complex was postulated as the most probable.[51–54, 81–83] The 'blue' form was often associated with the protonated diamagnetic structure $HLnPc_2$.[51, 81] Based on data from X-ray diffraction spectroscopy and ESR, it was proposed [84] that the central metal atom is in the oxidation state 4+. According to other authors,[52–54] intramolecular electron transfer is possible in the 'green' form as a result of which the degree of oxidation of the central metal atom changes from Ln^{3+} to Ln^{4+} and a 'blue' form is formed instead.

For the first time, diphthalocyaninates of REE were prepared by fusion of metal acetates with phthalonitrile.[51] Later, it was found [52–54] that this reaction occurs in several steps and depends on the nature of the central metal atom. Monophthalocyanine is formed in the first step of the synthesis of *tert*-butyl-substituted diphthalocyaninates of REE, it is further converted into a 'green' and then into a 'blue' form.

The synthesis of tetra(15-crown-5)-substituted lutetium diphthalocyaninate Lu(CR-Pc)$_2$ was carried out by boiling dicyanobenzo-15-crown-5 as a starting reagent in hexanol for 20 h.[85] A simpler and more convenient method for the template synthesis of a sandwich green form of Lu(CR-Pc)$_2$ has been proposed which consists in the fusion of lutetium acetate with dicyanobenzo-15-crown-5 in a sealed evacuated tube. [86] The optimum conditions for the synthesis of the 'green' and 'blue' forms of crown-substituted lutetium diphthalocyaninates were established by varying the

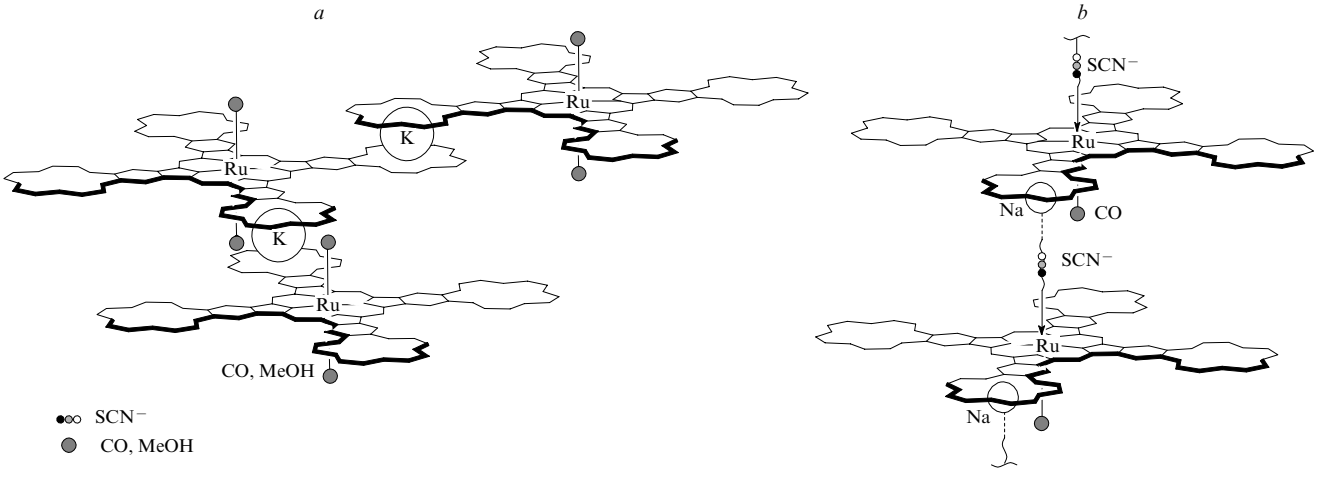

Figure 17. Tentative structures of the supramolecular ensembles based on the Ru(CR-Pc)(CO)(CH_3OH) complexes with KSCN (*a*) and NaSCN (*b*).

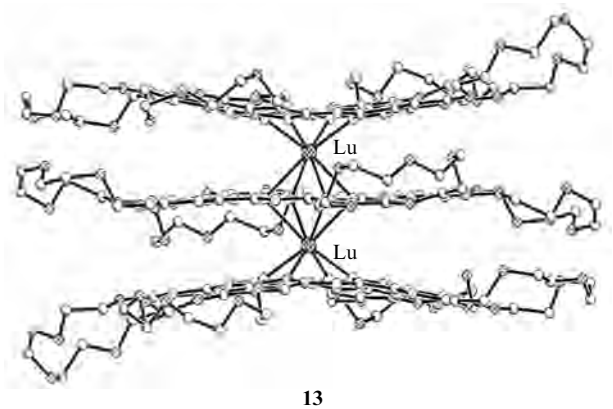
temperature (200 – 290 °C), molar ratios of the reagents (from 1 : 1 to 1 : 8) and reaction time (from 30 min to 5 h).

For a long time, the data on X-day diffraction analysis of crown-substituted metal phthalocyaninates were absent due to significant difficulties in growing of single crystals of this class of compounds. Recently, the molecular crystal structure of the 'blue' form of the $Lu_2(CR\text{-}Pc)_3$ complex (**13**) was established using X-ray diffraction spectroscopy.[87] Prismatic dark-blue crystals were obtained by slow crystallisation of complex **13** from a mixed solvent ($DMSO - CHCl_3$, 2 : 1). This compound was found to have a triple-decker structure (Fig. 18).



13

Figure 18. Structure of the triple-decker complex $Lu_2(CR\text{-}Pc)_3$.

The lutetium atoms in compound **13** are localised between the planes of the phthalocyanine ligands. Two outer phthalocyanine rings have similar orientations with respect to the internal ring which is turned by 43.7° relative to these rings.

The neighbouring macrocycles are not equidistant from the lutetium ion; the distances between the lutetium atoms and the planes of the outer phthalocyanine ligands passing through the donor atoms of the pyrrole ring nitrogens are equal to 1.218 Å, while the corresponding distances from the central ligand are much greater (1.703 Å). This fact agrees with a significant increase in the metal – bridging ligand distance characteristic of all presently known triple-decker molecules with tetrapyrrole macrocyclic ligands.[88,89] The lutetium atom in the double-decker molecule of $LuPc_2$ occupies a practically symmetrical position: for the average metal – ligand distance equal to 1.34 Å, the difference in the distances does not exceed 0.01 Å.[90].

The coordination polyhedron of the lutetium ion represents a distorted tetragonal antiprism. The Lu – Lu distance is 3.406 Å. The Ln – Ln distances in structurally similar Ce_2P_3 (see Ref. 88) and Nd_2Pc_2P[89] complexes (P is porphyrin) exceed the sum of the corresponding lanthanide atomic radii by 0.1 and 0.06 Å, respectively.[91]

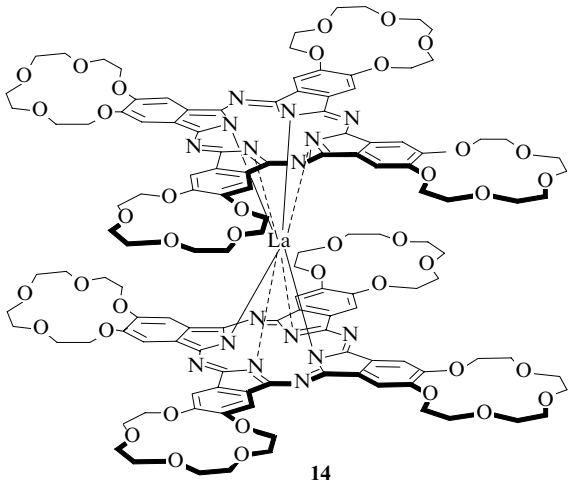
The intramolecular interplanar distance between two neighbouring ligands is 2.923 Å [in $LuPc_2$, the ligands are even closer to one another (2.69 Å)[90]], *i.e.*, the distance between them is less than the van der Waals distance (3.34 Å) between two aromatic systems. Minimisation of the non-bonding interactions is achieved due to a turn of the central macroligand relative to the outer ligands. The atoms in the crown-ether rings protrude above the plane passing through the nitrogen atoms of the pyrrole rings to a greater extent than other atoms constituting the phthalocyanine backbone.

Compound **13** is the first example of a substituted phthalocyanine complex with the established crystal structure.

Double-decker phthalocyaninates of REE are neutral compounds, which represent stable free radicals $[Pc^{2-}M^{3+}Pc^{2-\bullet}]^0$. They undergo reversible redox conversions:

$$\underset{\text{Blue form (anionic)}}{[Pc^{2-}M^{3+}Pc^{2-}]^-} \underset{e}{\overset{-e}{\rightleftharpoons}} \underset{\text{Green form (neutral)}}{[Pc^{2-}M^{3+}Pc^{-\bullet}]^0} \underset{e}{\overset{-e}{\rightleftharpoons}} \underset{\text{Red form (cationic)}}{[Pc^{-\bullet}M^{3+}Pc^{-\bullet}]^+}.$$

The data on double- and triple-decker crown-substituted phthalocyaninates of REE are mainly available for lutetium complexes. Other authors describe the synthesis of double- and triple-decker ytterbium and gadolinium complexes with tetra(15-crown-5)phthalocyanine.[92] $Yb(CR\text{-}Pc)_2$ [but not $Yb_2(CR\text{-}Pc)_3$], $Gd_2(CR\text{-}Pc)_3$ or $Gd(CR\text{-}Pc)_2$ could be prepared by template synthesis,[92] but the yields of the target products were extremely low. Direct interaction of the protonated ligand $H_2(CR\text{-}Pc)$ with ytterbium and gadolinium acetates in the presence of a strong base (DBU) yields the same complexes, *viz.*, $M(CR\text{-}Pc)_2$ and $M_2(CR\text{-}Pc)_3$ [M = Gd, Yb, CR-Pc = (15-C-5)$_4$Pc]. This approach affords sufficiently high yields and a high degree of purity and was also used in the synthesis of the lanthanum complex **14**.[93]



14

$$H_2(CR\text{-}Pc) \xrightarrow{a \text{ or } b} [La(CR\text{-}Pc)_2]^- + [La(CR\text{-}Pc)_2]^0$$

a — $H_2(CR\text{-}Pc) : [La(OAc)_3 \cdot 1.5\,H_2O] : DBU = 1 : 10 : 200$, boiling *o*-dichlorobenzene (b.p. 180 °C), 3 h;
b — $H_2(CR\text{-}Pc) : [La(OAc)_3 \cdot 1.5\,H_2O] : DBU = 1 : 1.5 : 10$, boiling 1-chloronaphthalene (b.p. 250 °C), 2 h.

However, the reaction products represented a radical-neutral form $[(CR\text{-}Pc)^{2-}La^{3+}(CR\text{-}Pc)^{-\bullet}]^0$ and a single-electron-reduced form $[La^{3+}(CR\text{-}Pc)_2^{2-}]^-$; DBU, which is commonly used as a deprotonating reagent in organic synthesis, stabilises the reduced form of crown-substituted lanthanum diphthalocyaninate.

This is the first reaction where a single-electron-reduced form of diphthalocyaninate is prepared in the course of synthesis. The neutral form of the $M(CR\text{-}Pc)_2$ complex represents a stable free radical. Its stability in the case of the terminal elements of the lanthanide series can be attributed to delocalisation of the unpaired electron over two phthalocyanine ligands. In complex **14,** the delocalisation of the electron is much more difficult, since the phthalocyanine rings in this compound are at a much greater distance from one another than, *e.g.*, in the stable complex $[(CR\text{-}Pc)^{2-}Lu^{3+}(CR\text{-}Pc)^{-\bullet}]^0$. For this reason, the electronic state of the two ligands in the $La(CR\text{-}Pc)_2$ complex is levelled off giving rise to the anionic form $[La(CR\text{-}Pc)_2]^-$.

The reaction of $H_2(CR\text{-}Pc)$ with Gd, Yb and Lu acetates in boiling *o*-dichlorobenzene yields the corresponding monophthalocyaninates, whereas boiling of these reagents in chloronaphthalene yields double- and triple-decker complexes. Sandwich-like double-decker lanthanum complexes are formed even upon boiling in *o*-dichlorobenzene. This can be explained by the fact that the larger radius of La (1.061 Å) in comparison with Gd (0.938 Å), Yb (0.858 Å) and Lu (0.848 Å) results in an increase in the

distance between the phthalocyanine ligands, which in turn stabilises the sandwich-like structure of the phthalocyaninate due to the weakening of $\pi-\pi$-interactions.

VI. Supramolecular systems based on double- and triple-decker crown-substituted phthalocyaninates

As mentioned above, crown-substituted metal monophthalocyaninates interact with bulky alkali metal cations to form supramolecular dimers as a result of binding of alkali metal cations to the crown-ether fragments of the neighbouring ligands. The crown-containing phthalocyanine ligands in double- and triple-decker complexes are separated by REE ions which prevent the penetration of alkali metal cations between two neighbouring phthalocyanine fragments of the sandwich complex. However, alkali metals can coordinate with the 'top' and 'bottom' crown-substituted phthalocyanine ligands of the sandwich-like dimers to give pillar-like structures (Scheme 6).

The complexes of 15-crown-5-substituted diphthalocyaninates of REE with alkali metal salts are more stable than the benzo-15-crown-5 itself.[45, 94, 95] The authors point to a positive cooperative effect in the reaction of crown-substituted lutetium diphthalocyaninates with alkali metal cations. This can be explained by the fact that the insertion of the first cation between the two ligands is more difficult in comparison with the insertion of the second and subsequent cations due to prearrangement of the structure. The nature of these positive non-linear cooperative interactions has been studied in detail. The curves of spectrophotometric titration of transition-metal monophthalocyaninates by alkali and alkaline earth metal salts have a common linear shape, whereas the titration curve of octa(18-crown-6)-substituted lutetium diphthalocyaninate by rubidium salts is sigmoidal and resembles that observed in the interaction of hemoglobin with molecular oxygen. This suggests that in this case we deal with a non-linear cooperative effect which is not typical of triple-decker complexes and monophthalocyaninates. Based on the results of light scattering studies, a mechanism for the formation of supramolecular oligomers containing up to 260 building blocks of the $Lu(CR\text{-}Pc)_2$ complex with KSCN has been proposed.[45] Such supramolecular aggregates have pillar-like and tubular shapes where one-dimensional transport of electrons and ions is possible (Fig. 19). It was suggested that these structures can be used in ionic and molecular electronics as well as in the design of new generations of functional materials.[45, 94, 95]

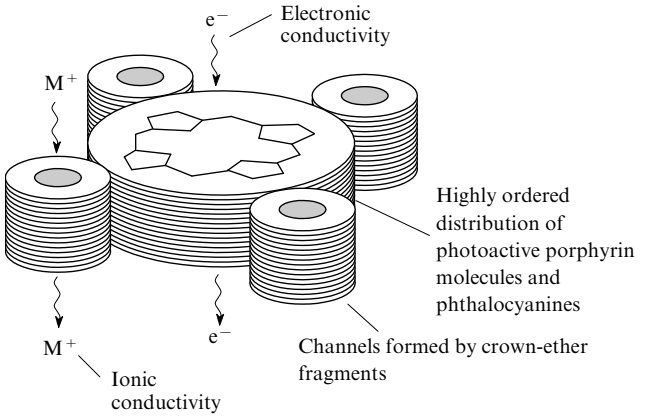


Figure 19. A schematic representation of an ordered supramolecular ensemble based on metal crown phthalocyaninates.

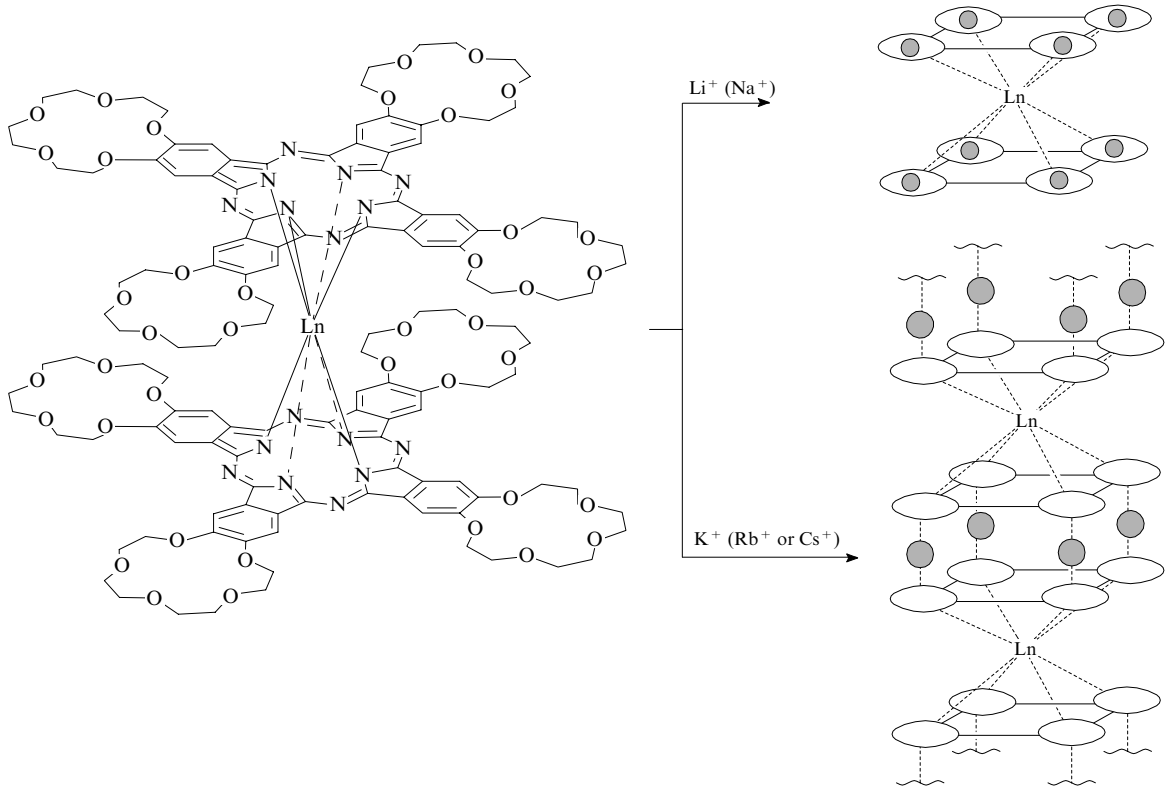
The supramolecular assembly of single-electron-reduced forms of octa(15-crown-5)diphthalocyaninates of the REE series $[Ln(CR\text{-}Pc)_2]^-$ (Ln = Y, Gd, Yb, Lu) has been studied.[96] It was found that the single-electron-reduced form is generated upon dissolution of the radical form in the presence of DBU or by titration of the radical form with DBU in chloroform. The addition of K^+, Rb^+ or Cs^+ thiocyanates to a solution of $[Ln(CR\text{-}Pc)_2]^-$ induces similar spectral changes manifested in a bathochromic shift with a simultaneous decrease in the half-width

Scheme 6



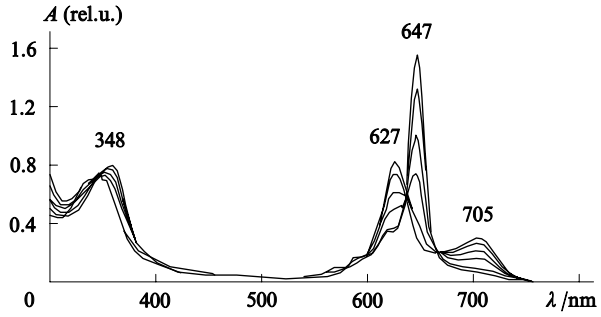


Figure 20. Changes in the electronic absorption spectra of the $[Lu(CR\text{-}Pc)_2]^-$ complex ($c = 6.0 \times 10^{-6}$ mol litre^{-1}) with potassium cations as a function of K^+ concentration.
The concentration of KSCN varied from 0 to 4.8×10^{-5} mol litre^{-1}.

of the Q_1-band (Fig. 20). The splitting of the band of the reduced form also disappears. Analysis of the electronic absorption spectra and spectrophotometric titration curves of the $[Ln(CR\text{-}Pc)_2]^-$ complexes by alkali metal thiocyanates prompted a conclusion about the formation of polymeric coaxial supramolecular aggregates $[(Ln(CR\text{-}Pc)_2)\cdot 4\,MSCN]_n$ ($n > 20$). The radical form of the complex $Lu(CR\text{-}Pc)_2$ interacts differently with potassium and rubidium picrates, whereas the single-electron-reduced form of the complex is arranged into supramolecular 'host–guest' structures on interaction with K^+, Rb^+ and Cs thiocyanates in the same manner. Non-linear cooperative effects are manifested in all the three cases (Fig. 21). No such effect of the anion on the assembly was observed for other potassium salts (acetate, bromide).

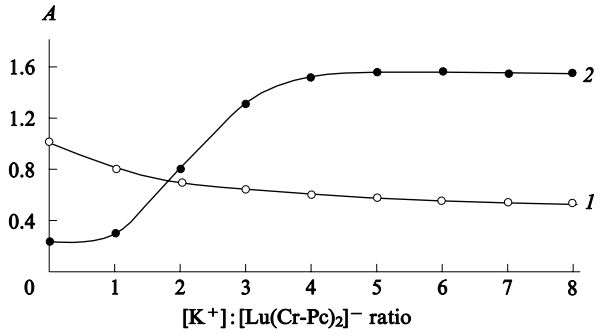

Figure 21. Spectrophotometric titration curves of the $[Lu(CR\text{-}Pc)_2]^-$ complex with potassium cations. The optical densities of the bands at 627 (*1*) and 647 nm (*2*) are given at various $[K^+]:[Lu(CR\text{-}Pc)_2]^-$ ratios. The sigmoidal shape of the titration curve points to a non-linear cooperative effect of the complex formation.

It was shown that interactions of $[La(CR\text{-}Pc)_2]^-$ with cations K^+, Rb^+ and Cs^+ are also accompanied by a non-linear positive cooperative effect (Fig. 22) and yield highly ordered polymeric aggregates.[97] The reduced form of sandwich double-decker crown phthalocyaninates of REE were shown to represent a common sensor for the cations K^+, Rb^+ and Cs^+.

VII. Conclusion

Attachment of crown-ether fragments to porphyrins and phthalocyanines not only improves the inherent properties of crown ethers, porphyrins and phthalocyanines, but also confers novel properties on them. Thus the selectivity of crown-substituted porphyrins and phthalocyanines with respect to alkali metal ions and the stability of the corresponding complexes markedly

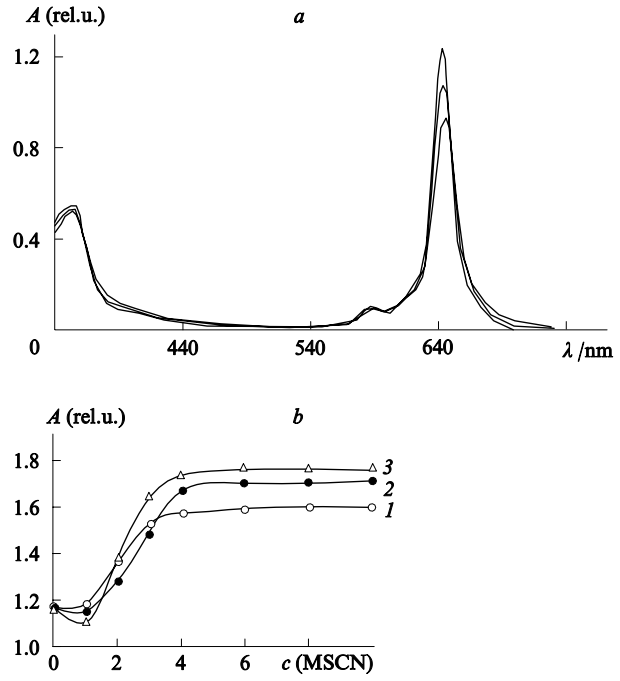

Figure 22. Electronic absorption spectra of the $[La(CR\text{-}Pc)_2]^-$ complex with potassium thiocyanate at different concentrations of K^+ (*a*) and spectrophotometric titration curves (*b*) of the $[La(CR\text{-}Pc)_2]^-$ complex with potassium (*1*), rubidium (*2*) and caesium thiocyanates (*3*).

exceeds the corresponding parameters of crown ethers and their complexes. The solubilities of crown-substituted porphyrins and phthalocyanines are also higher than those of unsubstituted compounds. Some representatives of this class are soluble even in water and thus acquire amphiphilic properties. The ability of crown-substituted porphyrins and phthalocyanines to form heteronuclear supramolecular architectural ensembles upon interaction with alkali metal salts is their characteristic feature.

Crown-ether fragments are linked to porphyrins and phthalocyanines in different fashions. Benzocrown-ether fragments are attached to porphyrins by a C–C bond to produce flexible structures, whereas bonding of crown-ether fragments to phthalocyanines is rigid. In contrast to crown-containing phthalocyanines, porphyrins form tetracrown-substituted analogues along with mono-, di- and tricrown-substituted derivatives. Crown-substituted porphyrins and phthalocyanines differ also in the type of supramolecular heteronuclear architectural ensembles formed upon their interaction with alkali metal salts.

Interactions of potassium, ammonium and barium salts with tetra- and tricrown-substituted porphyrins and metal complexes based on them result in the formation of supramolecular dimers (interactions with sodium, magnesium and calcium salts occur by a different mechanism).

Treatment of the monomeric zinc–bis(benzo-15-crown-5)-porphyrin complex with $AgPF_6$ yields a dimer in which two porphyrin rings are linked by a covalent *meso-meso* bond. Although intermolecular contacts between the neighbouring crown-ether fragments in the monomeric and dimeric zinc complexes interacting with potassium ions are similar, the supramolecular architectural ensembles formed differ from one another. Coaxial ('face-to-face') dimerisation of monomeric zinc complexes is possible upon interaction with potassium ions, whereas linear extended aggregation is more preferable for covalently bonded dimeric zinc complexes.

The nature of the central metal atom in porphyrinates strongly affects the structure of the complexes formed upon their interaction with alkali metal salts. According to the ESR data, the porphyrin rings in the dimeric potassium complex with copper

tetracrown monoporphyrinate are turned by 45° relative to one another, whereas in an analogous zinc complex they are turned by 23°.

The mode of interaction of alkali metal salts with crown-substituted monophthalocyaninates of d-elements differs significantly from that with analogous double- and triple-decker complexes of REE. In the former case, monomeric or dimeric heteronuclear complexes are formed depending on the size of the alkali metal cations; in the latter case, oligomeric supramolecular ensembles are formed.

The stucture of the complexes formed also depends on the nature of the anion. For example, the reaction of the Al(CR-Pc)(SO_4H) complex with sodium chloride is not accompanied by changes in the electronic spectra of the complex, which points to the formation of monomeric heteronuclear complexes. On the other hand, interactions with sodium bromide and iodide afford dimers and the interaction with sodium fluoride yields polymeric supramolecular aggregates.

The optical sodium–potassium selectivity observed in reactions of tetracrown-substituted cobalt monophthalocyaninates with potassium and sodium thiocyanates is manifested in an oppositely directed shift of the Q-band: towards the long-wavelength region (λ_{max} = 737 nm) in the case of sodium thiocyanate and towards the short-wavelength region (λ_{max} = 626 nm) in the case of potassium thiocyanate. The difference in the Q-band shift in the case of a ruthenium complex with tetra(15-crown-5)phthalocyanine is 75 nm. Such a great difference enables the use of this effect for selective photometric measurements of sodium and potassium ions.

The ordered supramolecular aggregates formed upon interaction of sandwich-like phthalocyanine complexes of REE with alkali metals have pillar-like and tubular shapes, where one-dimensional transport of electrons, energy and ions is possible. The electric conductivity of these pillar-like and 'nanotubular' structures strongly depends on the orderliness of the giant supramolecular architectural ensembles formed. It is believed that such ensembles can be used as a starting material in the design of new generations of functional materials for ionic and molecular electronics.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project Nos. 03-03-33160 and 02-03-08013).

II. The influence of electrolytes, surfactants and polymers on the surface forces 28
III. Surface forces in wetting phenomena 32

Abstract. The results of modern theoretical and experimental studies of components of the long-range surface forces which determine the properties of dispersions and wetting liquid films are generalised. The bibliography includes 113 references.

I. Surface forces

During the last 10 – 15 years, numerous studies dealing with the interactions of interfaces through thin liquid films have been carried out as applied to colloids including nanoparticles and asymmetrical systems, *i.e.,* wetting films. This line of research forms the basis for solving a number of engineering problems such as control of the properties of dispersions, wetting, flotation and water treatment and the problems of environmental protection.

The physicochemistry of the surface phenomena considers the components of the surface forces and their change upon modification of the interfaces due to the adsorption of ions, surfactants and polymers including polyelectrolytes.

We shall start the discussion of the state-of-the-art of this field of physicochemical science with consideration of the results of fundamental studies of the surface forces which play the key role when the distances between the interacting particles or surfaces are comparable with the radius of action of these forces.

1. General remarks

Attractive or repulsive forces whose radius of action is much greater than the length of chemical bonds arise between condensed phases separated by a thin gas or liquid interlayer. The physical nature of such long-range forces can be different. They may be due to the electric fields of charged surfaces, fluctuating electromagnetic fields related to the movement of electrons in atoms and molecules, and structural forces arising upon the overlap of the boundary layers of the liquids with a changed structure.[1] The radius of action of these forces has the same order of magnitude as the correlation length in the liquid bulk (usually, this makes several nanometres). For solutions of polymers or surfactants, it is necessary, in addition, to take into account the steric forces which appear when the adsorption layers approach each other and overlap.[2]

Uspekhi Khimii **73** (1) 26 – 38 (2004); translated by Z P Bobkova

The surface forces and the thermodynamic properties of thin liquid interlayers between two planar surfaces of solids are described conventionally by the disjoining pressure (Π), which was introduced by Derjaguin.[3] This value is equal to the difference between the pressure P acting on a planar liquid interlayer with thickness h and the pressure P_0 in the bulk of the same liquid outside the thin interlayer under equilibrium

$$\Pi = P - P_0 . \quad (1)$$

However, it should be borne in mind that the pressure Π does not always 'disjoin' the interlayer; depending on the direction of action of the surface forces, it can also attract the surfaces of different phases.

In the case of wetting films adjoining the gas phase, the P value in expression (1) is atmospheric pressure and the P_0 value characterises the pressure in the bulk region of the meniscus which is in equilibrium with the film.

The disjoining pressure $\Pi(h)$ is a very important thermodynamic parameter of the thin interlayer (film). Let us consider reversible changes in the state of the interlayer taking place upon the change in its thickness by ∂h, while the temperature T, the chemical potentials μ_i of the dissolved substances and the pressure P remain constant. As this takes place, the external forces which are necessary to ensure the equilibrium of the thin film do work equal to the increment of the Gibbs thermodynamic potential ∂G. Thus, it can be written that

$$\Pi(h) = -\left(\frac{\partial G}{\partial h}\right)_{T,P,\mu} . \quad (2)$$

The $\Pi(h)$ dependence which characterises the contribution of various components of the surface forces to the interaction of the surfaces is called the disjoining pressure isotherm. It contains full information on the state of the system at specified temperature, pressure and the composition of the bulk solution.

The surface forces are manifested first of all in disperse systems containing suspended particles that are involved in thermal Brownian motion. Upon the collision of particles, depending on the surface forces that act between them, the system can either remain stable, or alternatively, form weakly bound floccules or stable aggregates. Larger particles settle (or float to the surface) in a gravitational field to give porous precipitates whose structure depends on the forces that act between the particles.

In recent years, in view of a number of practical applications, special attention has been attracted by disperse systems with particle size of the order of several nanometres.

Wetting films, which model asymmetric systems, deserve special attention. These thin liquid films have the condensed

phase on one side and the phase of their own vapour or a different immiscible liquid on the other side.

The theory of several constituents of the surface forces has been developed in relation to a rather simple case of planar interlayers and films. Transition to calculations of the interaction of spherical (or other) particles is done using the Derjaguin approximation based on the integration of the local forces acting between the opposing 'planar elementary sections' of the curved surfaces.[4] For example, in this approximation, the force F that acts between two identical spherical particles with the radius r is given by

$$F = \pi r G(h), \tag{3}$$

where $G(h)$ is the free energy of interaction between planar interlayers with the thickness h,

$$G(h) = \int_h^\infty \Pi(h)\mathrm{d}h\,. \tag{4}$$

However, it should be borne in mind that the scope of applicability of the Derjaguin approximation is limited to interlayer thicknesses much smaller than the particle radius. Therefore, for calculation of the forces and energy for the interaction of particles smaller than 0.1 μm, more complex procedures are employed.[5–9]

2. Dispersion forces

The macroscopic theory of dispersion forces was first developed by Lifshits[10] for the simple case of attraction of identical planar surfaces in vacuum. Subsequently, it was extended to more complex systems in his joint work with Dzyaloshinsky and Pitaevsky.[11] The expression obtained for the disjoining pressure of thin interlayers ($h < 15$ nm) has the following form:

$$\Pi_\mathrm{m} = -\frac{A_{132}}{6\pi h^3}\,, \tag{5a}$$

where

$$A_{132} = \frac{3\hbar}{4\pi}\int_0^\infty \frac{(\varepsilon_1-\varepsilon_3)(\varepsilon_2-\varepsilon_3)}{(\varepsilon_1+\varepsilon_3)(\varepsilon_2+\varepsilon_3)}\mathrm{d}\xi. \tag{5b}$$

Here, the subscripts 1 and 2 refer to the phases that confine the thin film of liquid 3; $\hbar$ is Planck's constant. The frequency dependences of the dielectric constant of the medium $\varepsilon(\mathrm{i}\xi)$ are taken on an imaginary frequency axis.

A qualitatively equivalent solution was obtained earlier by Hamaker[12] in terms of a microscopic approach. Therefore, the constant A_{132} is still called the Hamaker constant, although calculation of this constant from Eqn (5b) gives a markedly different value.

For interlayers with a thickness of $>40-50$ nm, where the electromagnetic retardation effect, first taken into account by Casimir and Polder,[13] is manifested, the disjoining pressure decreases more sharply with an increase in the interlayer thickness h

$$\Pi_\mathrm{m} = -\frac{B}{h^4}\,. \tag{6}$$

In the case of dielectrics, the parameter B depends on the difference between the dielectric constants ε_0 of the interacting bodies and the interlayer separating them and amounts to $\sim 10^{-25}$ J m. For metals, the values of B are higher by approximately an order of magnitude.[1]

To calculate the dispersion forces for the intermediate range of distances, computer programmes are required.[14–17] In this case, the calculation gives the functions $A(h)$ rather than the Hamaker constants, which extends the scope of applicability of Eqn (5a).

Positive A and B values correspond to attractive forces, while negative values imply repulsive forces. The values of these constants and the functions $A(h)$ were reported in monographs[1,2] and in some papers (see, for example, Refs 18–20). In one study,[18] the functions $A(h)$ were calculated using corrected spectral data for water interlayers. Dagastine *et al.*[19] reported the A values for the dispersion attractive forces through water interlayers for a number of solids such as silicon, quartz, diamond, mica, TiO_2, MgO, Al_2O_3, CaF_2, LiF, NaCl, KBr and CdS. The values of A for some other inorganic materials were also documented.[20]

Various methods have been developed for experimental verification of the theory of dispersion forces; the methods make use of model objects such as lens–plane, sphere–sphere and crossed cylinders whose movement towards each other simulates the contact of dispersion particles.

The commercially manufactured instruments (for example, Mark) for direct measurement of the surface forces use glass cylinders crossed at an angle of 90° and coated by mica sheets.[21] The measurements give the dependences of F/R on the shortest distance H between the surfaces of the crossed cylinders with the radius R.

Direct verification of the theory of dispersion forces has been carried out only for the interaction of model bodies in vacuum through interlayers of gases and nonpolar liquids. In the case of aqueous solutions as interlayers, comparison with the theory is hampered because the results of measurements depend not only on the dispersion forces but also on electrostatic and structural forces.

In recent years, atomic force microscopy (AFM) has been used more and more often to study the surface forces. This method allows one to measure the forces between a rounded tip or a small spherical particle (5–10 μm) and a planar surface. The interaction force is found from the deformation of a planar cantilever spring with a test particle attached to the spring end. The number of publications devoted to the use of this method is rapidly increasing. However, it is used most often not merely to verify the theory of dispersion forces but in more complex cases where several components of surface forces act simultaneously, including electrostatic forces, which cover the longest distances.

3. Electrostatic forces

The theory of interaction of charged particles can now be considered as being well developed.[1,2,21] Solutions for the cases of a constant potential (ψ) or a constant charge (σ) of planar surfaces approaching each other have been obtained. Subsequently, the theory has been corrected because, as the surfaces approach each other, the potential-determining ions can be desorbed under the action of the electric field of the opposite surface. This effect, which has been called charge regulation, is often taken into account when analysing the results of direct measurements of electrostatic forces.[22]

The electrostatic repulsion forces between likely charged surfaces are often calculated using the approximation of small surface potentials. The disjoining pressure isotherm has the following form:

$$\Pi_\mathrm{e}(h) = (2\varepsilon\varepsilon_0\kappa^2\psi^2)\exp(-\kappa h), \tag{7}$$

where ε is the dielectric constant of the dispersion medium, ε_0 is the electric constant, κ is the reciprocal Debye radius depending on the ionic strength of the solution.

To pass to the interaction forces between identical particles, relation (1) is used. In the case of small particles where relation (1) is inapplicable, more complex solutions should be used.[5] A strict estimation of the electrostatic interaction requires taking into account other effects, namely, polarisation of the electric double layers (EDL) and the possible redistribution of the surface charge as the particles approach each other. The role of these nonequilibrium phenomena has been considered in a review.[23] The influence of the image forces on the ion distribution near a charged wall and the effects of ion correlation and the finite volume of ions on the electrostatic interaction have been analysed.[24]

However, direct AFM measurements of the electrostatic repulsion forces[25–27] showed that, except for the region of small

distances, rather good agreement is observed between the experimental data and simple solutions of the theory. At least, the calculated ζ-potentials (which are usually equivalent to the surface potentials ψ) are close to the values measured by independent methods. However, it has also been found by AFM [28] that the measured forces depend on the velocity (v) at which the tip moves towards the planar mica surface when $v > 10$ μm s^{-1}. The relaxation times of the EDL were roughly estimated as 5–6 ms. The nature of slow relaxation of the dense part of the EDL has been considered by Dukhin and Liklema.[29] This effect is especially pronounced for high rates of particle movement towards each other, for example, in the case of vigorous stirring or turbulent flow of the dispersion.

In a dispersion consisting of two types of particles which differ in the sign of the ψ-potential, the electrostatic forces become attractive forces, which results in so-called heterocoagulation.[1] If the particle potentials differ only in magnitude, the particles may repel at large distances. The sign of the electrostatic forces changes when they approach each other to the critical distance

$$h_c = \kappa^{-1} \ln \frac{\psi_1}{\psi_2},$$

where ψ_1 and ψ_2 are the potentials of the interlayer surfaces. Coagulation takes place after overcoming a potential barrier formed upon the mutual effect of the electrostatic and dispersion forces.

The publications devoted to the theory of heterocoagulation and the results of experimental studies of the stability of dispersions with a predominantly aqueous dispersion medium have been analysed.[30] The researchers noted an important role of heterocoagulation in the technology of disperse materials.

4. Structural forces

Even the first direct measurements of the forces acting between crossed mica-coated glass threads or cylinders showed that at a distance of $H < 2-3$ nm between the surfaces, the results deviate from the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory, which takes into account only dispersion and electrostatic forces.

This is exemplified in Fig. 1, which shows the results of measurements of the dependence of the repulsive force F/R of molecularly smooth glass surfaces in a 1.1×10^{-2} M aqueous solution of NaCl on the shortest distance H between the surfaces.[31] Small glass plates several micrometers thick cut out of the wall of a rapidly blown bubble were coated with silver from the inside (to obtain the fringe pattern which serves for measuring the interlayer thickness) and attached to the surface of glass cylinders with the radius $R = 1$ cm. The continuous and dashed curves in Fig. 1 correspond to DLVO theory calculations in the constant charge and constant potential approximations, respectively. The experimental points in the region of interlayer thicknesses of $H < 3$ nm lie above the calculated curves, indicating an additional participation of structural repulsion forces. These forces arise upon the overlap of the structurally changed boundary layers of water that exist near the hydrophilic surface of glass. Qualitatively the same results were obtained for solutions of NaCl with other concentrations (10^{-3} and 10^{-1} mol litre^{-1}).[31]

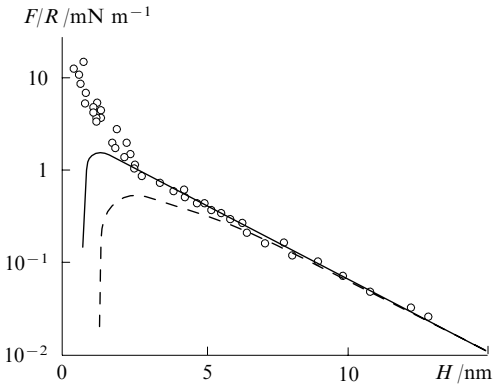

Figure 1. Dependences of the repulsion forces F/R on the distance H between smooth glass surfaces in a 1.1×10^{-2} M aqueous solution of NaCl.[31] For explanation, see the text.

The modified structure of the boundary layers of water was confirmed by a number of independent methods. For instance, recording of the IR spectra of water near the hydrophilic surface with the use of a laser excitation source [32] showed that water dipoles are oriented at a right angle to the surface. If the surface is charged, this orientation extends to 3–5 molecular layers.

It is known that near hydrophilic surfaces, the mobility of water molecules is retarded and the time of dielectric relaxation is an order of magnitude longer than that in the water bulk. Changes in the structure of the boundary layers of water are accompanied by strengthening of intermolecular bonds.[33]

Statistical mechanics calculations have shown that in aqueous solutions of electrolytes, the structural repulsion force between hydrophilic surfaces appears when the interlayer thickness is < 2 nm and increases exponentially as the interlayer becomes thinner.[34]

The experimental isotherms for the structural component of the disjoining pressure for water interlayers between the hydrophilic surfaces are approximated by the exponential dependence

$$\Pi_s(h) = K \exp\left(-\frac{h}{\lambda}\right), \tag{8}$$

where the parameter K describes the magnitude of the forces, and the parameter λ describes the long-range action. The parameters K and λ determined in experiments with thin interlayers of aqueous solutions between various hydrophilic surfaces can be found in monographs.[1, 21, 35]

The first attempts to develop a theory of structural forces were based on the Landau theory of second order phase transitions and the use of the order parameter η. This parameter was defined in such a way that it was zero in the isotropic bulk phase and nonzero (either a positive or a negative value) in the ordered phase. For small interlayer thicknesses, the calculations resulted in expression (8), where λ has the meaning of the correlation length and the parameter K, according to this approach, depends on the degree of surface ordering of water dipoles. The first estimates of these parameters were obtained in experiments with thin interlayers.[1] Subsequently, several versions of this approach have been used, including those taking into account the inhomogeneity of the orientational state of water molecules near the surfaces that confine the interlayer.[36, 37]

In a study devoted to the theory of structural forces,[38] the effects of excluded volume, dipole orientation, and the finite volume of water molecules were taken into account. This theory also predicts an exponential growth of structural forces with a decrease in the interlayer thickness. In addition, it was found that the period of oscillations of structural forces is close to the size of water molecules. The results of calculations are in good agreement with experimental data for a 10^{-3} M aqueous solution of KCl between mica surfaces.[21] The parameters K and λ for interlayers with a thickness of < 3 nm were found to be 3×10^6 N m^{-2} and 1 nm, respectively.

However, it should be borne in mind that the values of the parameters of structural forces presented here were obtained for hydrophilic molecularly smooth surfaces of glass and mica. Real surfaces are chemically heterogeneous and irregular and can be loosened or coated by adsorption layers of surfactants or polymers. Therefore, the quantitative determination of structural forces can only be used as rough estimates.

5. Hydrophobic forces

Some studies have shown that pronounced attractive forces act between the hydrophobic surfaces in water.[1,21,35] Their dependence on the interlayer thickness is described by the same equation (8), but the K values are negative in this case. The hydrophobic surfaces for measurements were usually produced by adsorption of a cationic surfactant or polyelectrolyte on glass or mica. It was found that hydrophobic forces have a greater radius of action than hydrophilic repulsion forces and the range of action increases with an increase in the degree of hydrophobicity of the surfaces. The measured λ values were 1 to 65 nm, depending on the experimental conditions.

The hydrophobic attraction detected in some cases when the distance between the surfaces is up to 100 nm is attenuated with a decrease in H according to a binomial exponential law with $\lambda = 13-15$ nm at long distances and with $\lambda = 1-2$ nm at short distances.

The physical nature of the hydrophobic attractive forces still remains unclear. Once it was assumed that this effect can be attributed, by analogy with the hydrophilic repulsion forces, to the structural changes of the boundary layers of water. Indeed, computations have shown[39,40] that the density of water decreases near a hydrophobic surface, unlike a hydrophilic one. However, the thickness of such boundary layers does not exceed 2–3 nm, which does not suffice to explain the observed long-range action.

It has been shown[41] that a correlation between hydrophobic attraction forces and the contact angles of water can be followed only at small distances. Due to the sharp increase in the attractive forces at short distances, no force oscillations, involved in the case of hydrophilic repulsion, can be detected experimentally.

Apparently, the long-range attraction is related to evolution of bubbles of the gas dissolved in water on the hydrophobic surfaces and the subsequent coalescence of the bubbles[42] or to thermal oscillations of the surfaces of such bubbles.[43,44] The role of the bubbles was confirmed, in particular, by the fact that the hydrophobic attraction forces decrease as water is being degassed.[45–47] Numerous nanobubbles were detected by atomic force microscopy on the quartz surface hydrophobised by octadecyltrichlorosilane.[48] It was concluded that the bubbles are formed before the contact of the tip of the atomic force microscope with the substrate. If the long-range hydrophobic attraction forces are caused by coalescence of the bubbles, their size should be 10–50 nm, which is consistent with experimental observations.

The solvophobic attraction of the surfaces coated by a film of amorphous Teflon with 0.5-nm high surface irregularities was observed not only in water but also in many organic liquids (except for n-alkanes and n-alkanols).[49] The results obtained are in line with the hypothesised formation of submicrometre air bubbles on the interacting surfaces.

The experimental values of the parameters K and λ present in Eqn (8) in the case of the hydrophobic forces for various objects have been summarised in a review.[42]

It can be assumed that the proper hydrophobic attraction exists only in degassed water, *i.e.*, in the absence of gas bubbles. Thus the nature of structural forces can be interpreted from a unified standpoint by relating them to changes in the structure of boundary layers — an increase in the water density and the normal orientation of dipoles in the case of hydrophilic repulsion forces and a density decrease and a tangential orientation of dipoles in the case of hydrophobic attraction forces. In any case, the λ values for hydrophilic and hydrophobic forces are similar and amount to 1–2 nm, which corresponds to the correlation length in the water bulk. This permits inclusion of both types of short-range structural forces in the overall isotherm of the disjoining pressure.

II. The influence of electrolytes, surfactants and polymers on the surface forces

1. Electrolytes

The effect of the electrolyte composition and concentration shows itself through a change in the surface charge as a result of both ion exchange and the change in the Debye radius

$$\kappa^{-1} = (\varepsilon\varepsilon_0 kT)^{1/2} (8\pi z^2 e^2 c)^{-1/2}, \qquad (9)$$

where k is the Boltzmann constant, z is the charge number, e is the charge of an electron, c is the concentration of the solution (in mol cm^{-3}).

It can be seen from Eqn (9) that with an increase in the electrolyte concentration, the Debye radius decreases and, according to Eqn (7), this reduces the range of action of the electrostatic forces. The repulsive forces also decrease, due to the more pronounced influence of the change in the κh in the exponential quantity on the disjoining pressure Π_e. The calculated repulsive forces may increase due to the increase in the charge and the potential ψ of the surfaces, but to only a limited extent, because Eqn (7) was derived with the assumption of small ψ.

Several mechanisms of formation of the surface charge are known. The most important of these are dissociation of the ionogenic surface groups and ion exchange. Therefore, the surface charge is controlled most often by varying the pH, the ionic composition, and the concentration of the solutions.

Usually, the surface charge and potential are determined experimentally. This is done most often using methods based on the measurement of the streaming potential of the solution in a slot or a capillary and on the measurement of the rate of electrophoresis of dispersion particles.

This is exemplified in Fig. 2, which shows the results of measurements of the ζ-potential in 50–150 μm thick planar cells formed by polished glass surfaces.[50] These data provide an idea of the range of possible variation of the surface charge of glass. The calculations were performed using the Smolukhovsky equation with the Dukhin correction for the surface conductivity.

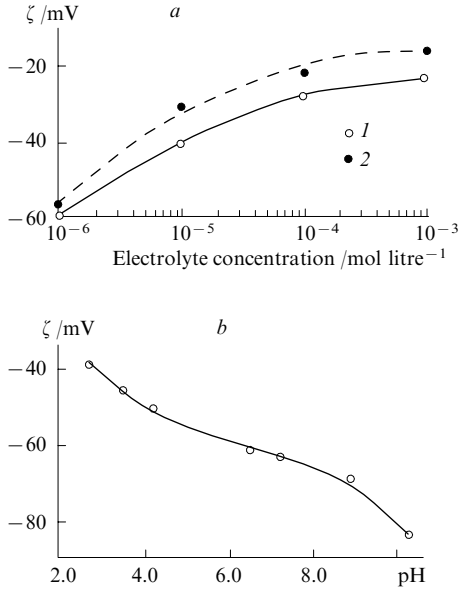

Figure 2. Dependences of the ζ-potential of the surface of glass plates[50] on the concentration of electrolytes (*a*) and on the pH (*b*).
Electrolyte: (*1*) NaCl, (*2*) $AlCl_3$

For quartz capillaries with molecularly smooth surfaces, the absolute values of the ζ-potential are much greater. This confirms the importance of the state of the surfaces, even if they are similar in chemical composition. In addition, the composition of the solution also plays a role. For example, at a constant ionic strength of a 10^{-3} M solution of KCl + HCl (or KOH), the ζ value at pH 10 reaches -140 mV, while at pH 2, it tends to zero.[51]

In the case of high surface potentials ($|\psi| > 100$ mV), electrostatic forces no longer depend on the surface charge and depend only on the electrolyte concentration and the κ^{-1} value.[52]

Atomic force microscopy measurements of the forces of interaction of the TiO_2 particles with a face of a rutile crystal in an electrolyte solution have shown [53] that for electrolyte concentrations of $< 10^{-2}$ mol litre^{-1}, the shielding length κ^{-1} is in good agreement with the value calculated from Eqn (9). At pH 5.6, only dispersion attraction forces corresponding to the Hamaker constant $A = 6 \times 10^{-20}$ J, close to the theoretical value, acted in the isoelectric point.

For spherical polystyrene particles with a diameter of 2 μm, long-range electrostatic repulsion was observed at KCl concentrations smaller than 10^{-2} mol litre^{-1} (see Ref. 54). For a 10^{-3} M solution, the experimental data were in good agreement with those calculated using the Derjaguin approximation (3) and the surface potential $\zeta_1 = 87$ mV was close to a value measured independently (83 mV).

In the interaction of a ZnS sphere of diameter 5 μm with a planar surface of mica with different ζ-potentials (-100 and -90 mV, respectively), the experimental dependence of the repulsive forces on the interlayer thickness was in better agreement with the condition of constant charge.[55] The researchers concluded that the solution of the Poisson – Boltzmann equation should be supplemented by a condition of charge control on both surfaces.

Dependences of the forces of interaction of spherical cellulose particles with a size of 20 – 30 μm on the distance H between them in aqueous solutions of electrolytes have been obtained by AFM.[56] These dependences were used to model some processes of the pulp-and-paper industry. In solutions with low concentrations of KBr (10^{-4} mol litre^{-1}), electrostatic repulsion is the main force at long distances; at $H < 20$ nm, steric repulsion predominates. With an increase in the pH, both forces grow due to an increase in the degree of ionisation of the COOH groups and swelling of cellulose. The observed dynamic effects were attributed to slow establishment of the equilibrium in the polymer – solution system.

Glass and fused quartz can swell in water, which gives rise to a surface gel layer.[57] Therefore, the results of measurements of surface forces can depend on the contact time between the surfaces and water. The diffusion structure of the surface layer can markedly decrease the Hamaker constant and complicate the calculation of electrostatic forces.

The surface roughness can also influence the attractive or repulsive forces. Comparative calculations were carried out for the case of interaction of a rough and a planar surface in a solution of a 1 – 1-electrolyte with ionic strength of 10^{-2} mol litre^{-1}. It was assumed that the ζ-potentials are 25 mV and the Hamaker constant is 10^{-20} J.[58] The roughness was specified by a random distribution of bulges and pits of a hemispherical shape and different radii. Roughness was found to influence substantially the shape of potential curves, especially for short distances between the surfaces. In particular, both the height of the potential barrier and the depth of the potential well can considerably decrease.

By direct microscopic examination,[59] stability of mixed dispersions of silica (SiO_2) and small crystals of NaCl in a saturated salt solution was detected; this cannot be explained in terms of the DLVO theory. The AFM measurements of interaction forces showed that short-range repulsive forces exist between a spherical silica particle and a planar surface of a NaCl crystal in a saturated solution of NaCl, whereas with KCl in place of NaCl, attractive forces appear. These effects were attributed to the action of structural (polar) forces caused by different orientation of the dipoles of water molecules.

2. Surfactants

Adsorption of ionogenic surfactants can change appreciably both the magnitude and the sign of the surface charge. For example, the initial negative charge of the quartz surface is strongly affected by adsorption of a cationic surfactant. Figure 3 shows the dependence of the ζ-potential on the concentration of the cetyltrimethylammonium bromide (CTAB) in a supporting electrolyte solution (5×10^{-4} mol litre^{-1} of NaCl) at pH 6.5 obtained by the streaming potential method. An increase in the content of CTAB results in charge reversal. When the surfactant concentration is close to the critical micelle concentration (CMC) (10^{-3} mol litre^{-1}), ζ-potential increases to $+140$ mV, and the surface charge increases to $+4$ μC cm^{-2} (see Ref. 60). On the basis of the two-layer adsorption theory,[61] it was shown that the adsorption potentials for the first and second layer of CTAB are $15\,kT$ and $11\,kT$, respectively. The curve in Fig. 3, plotted using the equations of this theory, is in satisfactory agreement with experimental data (dots).

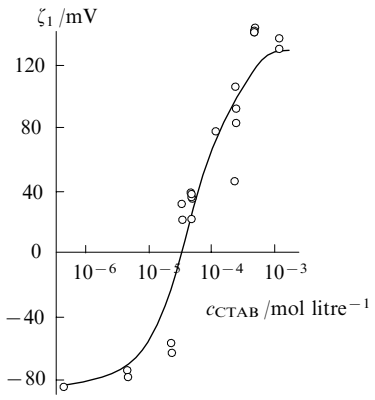

Figure 3. Results of measurements of the ζ_1-potentials of the surface of quartz capillaries for different concentrations of CTAB in a 5×10^{-4} M solution of NaCl (pH 6.5).[60] The curve corresponds to calculations in terms of two-layer adsorption.[61]

The same type of dependence of the surface charge on the surfactant concentration was obtained by direct measurements of the forces of interaction between mica surfaces in CTAB solutions.[62] When the CTAB concentration is low, electrostatic repulsion forces prevail over the dispersion attraction forces; upon neutralisation of the surface charge, the former are replaced by hydrophobic attraction forces.

It has been established [63] that the adsorption mechanism changes at pH 3 where no charged centres remain on the quartz surface. In this case, the bilayer adsorption of the surfactant becomes impossible. Processing of the resulting dependence of the charge on the CTAB concentration in terms of the monolayer adsorption model showed that the adsorption potential is $11\,kT$.

Subsequently, it has been found by AFM [64] that at a CTAB concentration higher than 2 CMC, cylindrical micelles are formed on the mica surface; over a period of 24 h, they are transformed into a planar bilayer structure.

In an alkaline medium, the formation of a second layer on the surface of glass takes place at a CTAB concentration below the CMC and the density of this layer is much lower than the density of the layer on the mica surface. By removing the second layer, it is possible to bring the glass surfaces in a tight hydrophobic contact.[65] The researchers cited suggested that the second layer

consists of separate bunches of surfactant molecules or surface aggregates.

Anionic surfactants influence the charge of the quartz surface into a much lesser extent. After the addition of 5×10^{-5} mol litre^{-1} of sodium dodecyl sulfate to the background solution of NaCl (10^{-4} mol litre^{-1}), the ζ-potential of the quartz surface slightly increased in magnitude (from -125 to -150 mV) and did not change upon further increase in the concentration of sodium dodecyl sulfate in the solution by an order of magnitude.[66]

The adsorption of nonionic surfactants on the hydrophilic surface up to the formation of a full monolayer leads to gradual hydrophobisation of the surface. The formation of the second layer in which the polar groups of the surfactant molecules are directed toward the solution makes the surface hydrophilic again. However, the ζ-potential does not change noticeably; its decrease has been noted only in the case of adsorption of nonionic surfactants whose molecules are capable of forming hydrogen bonds with the surface hydroxy groups.

Note that the influence of surfactant adsorption on the charge and hydrophilicity of the surface, which determine the electrostatic and structural forces, was analysed only for silicate surfaces; however, the key conclusions are valid at a qualitative level for the surfaces of other natural materials, because most of them are negatively charged.

3. Polymers

We shall start with a simpler case of noncharged polymers and then consider polyelectrolytes.

Nikologorskaya *et al.*[67] have employed dynamic light scattering to measure the Brownian diffusion coefficients of the particles of monodisperse silicasols Ludox-SM with the radius $r = 19$ nm and Syton-W50 ($r = 69$ nm) before and after the adsorption of polyethylene oxide (PEO) with a molecular mass of 4×10^4 and estimated the thickness of the adsorbed layers on the basis of the results obtained. At a low electrolyte concentration, the sols were stable due to the action of electrostatic repulsion forces. However, with an increase in the NaCl concentration to 10^{-2} mol litre^{-1} when the Debye radius became smaller than the length of the unfolded PEO molecule, flocculation of the sols took place in the presence of even small amounts of the polymer, as a result of binding of two particles to the same macromolecule (so-called bridging). As the PEO concentration increases and a filled adlayer is formed, the sols become stable once again due to the arising steric repulsion of the particles.

A study of the interaction of mica surfaces in aqueous solutions of ethylhydroxyethylcellulose showed[68] that the adsorbed macromolecules could be easily squeezed out of the interlayer space at 20 °C. This attests to a low adsorption energy. When the temperature was raised to 60 °C, the adsorption of the polymer increased, apparently due to a decrease in the hydrophilicity of the surface, and squeezing out of the molecules became difficult. Upon preliminary hydrophobisation of the mica surface, the adsorption of cellulose sharply increased and long-range steric repulsion was observed.

In aqueous solutions of a triblock copolymer (polyethylene oxide – polytetrahydrofuran – polyethylene oxide) with a molecular mass of 11 900 at a concentration below the CMC, steric repulsion force was detected between the surfaces of quartz spheres; the force increased monotonically as the spheres approached each other.[69] However, after long-term keeping of the spheres in a 10^{-4} % solution of the copolymer, thinning of the interlayer down to 10 nm gave rise to bridging bonds between the surface aggregates of the macromolecules. The steric repulsion was replaced by weak adhesive forces. In an electrolyte solution (NaBr, 0.2 mmol litre^{-1}) without a copolymer, only electrostatic repulsion forces corresponding to a quartz surface potential equal to -75 mV acted between the quartz spheres.

The interaction of mica surfaces in solutions of phospholipid, polyglycerol, and their mixtures in triolein has been studied by the Mark-4 device.[70] Ordering of liquid triglyceride molecules results in the bridging of surfaces and gives rise to two barriers related to structural forces. Conversely, the adsorption of polyglycerol induces the appearance of a steric repulsion barrier at a distance of 12 nm. The adsorption of a phospholipid/polyglycerol mixture on the mica surface results in the formation of complexes, which brings about long-range repulsive forces.

The interaction forces between a spherical particle (15 – 25 μm in diameter) of regenerated cellulose and the planar surface of the same polymer were measured by AFM.[71] The long-range repulsion was due to electrostatic forces corresponding to low potentials of regenerated cellulose surfaces. When the surfaces are brought into contact, adhesive forces are detected between the swelled surface layers of cellulose, which represent a viscoelastic gel. The interaction at short distances is reversible. Upon an increase in the electrolyte concentration, the adhesion strength is enhanced.

If the polymer is not adsorbed on the surfaces that confine the interlayer, attractive forces may arise due to the decrease in the osmotic pressure in the solution film between the particles. This effect was observed experimentally by examining the interaction of a glass sphere with a radius of 38 μm with a glass substrate using an atomic force microscope. Both surfaces were precoated with n-octadecyl alcohol layers. The measurements were carried out in solutions of polydimethylsiloxane in cyclohexane.[72] The distance between the surfaces where the attractive forces are manifested is comparable with the radius of gyration of the polymer macromolecule. When the sphere and the plane are brought to a shorter distance, the steric repulsion forces between the overlapping adlayers of n-octadecanol begin to be detectable.

Costello, Luckham and Tadros[73] studied the interaction forces between the mica surfaces with chemically grafted methyl methacrylate/ethylene oxide copolymer using the method of crossed cylinders. In Fig. 4, the dots correspond to experimental values minus the contribution of the electrostatic repulsion forces. The obtained dependences proved to be fully reversible. The continuous curve was constructed using the de Gennes equation[74]

$$\Pi_{st} = \frac{kT}{l^3}\left[\left(\frac{2L}{h}\right)^{9/4} - \left(\frac{h}{2L}\right)^{3/4}\right], \tag{10}$$

where Π_{st} is the steric repulsion force, l is the average distance between the grafting sites of molecules, L is the thickness of the equilibrium grafted layer of the polymer, h is the thickness of the interlayer between the surfaces.

The first term in the right-hand part of Eqn (10) takes into account the effect of the increasing osmotic pressure caused by accumulation of the polymer in the mutually penetrating layers, while the second term corresponds to the elastic forces that tend to restore the initial linear shape of the macromolecules. As can be seen from Fig. 4, the calculated and experimental results are in good agreement with the assumption that $L = 10$ nm.

For polyethylene oxide adsorbed on the mica surface from aqueous solutions, the steric interaction is not reversible, unlike that for grafted polymers.[75] Figure 5 shows the results of measurements of the interaction of crossed mica cylinders in a 0.1 M background solution of KNO_3. In the absence of the polymer, only weak electrostatic repulsion forces can be detected (curve *I*). After keeping the surfaces for 16 h in an aqueous solution of PEO with a molecular mass of 1.6×10^5 (the concentration is 1.5×10^{-4} g ml^{-1}), the repulsive forces follow curve *II*. The same law of variation of the steric forces is obeyed during the repeated bringing together of the surfaces, but only when they have been kept apart for 1 h. Curve *III* corresponds to the repeated compression of the adlayers (bringing the surfaces together), 5 min after the preceding drawing them apart, and to the subsequent fast drawing apart. This short (5 min) period the surfaces are kept far from each other is insufficient for the initial structure of the adsorption layers to be restored. Similar slow rearrangement effects are involved in the case of PEO with a lower molecular weight (1.4×10^4), which is shown by the corresponding

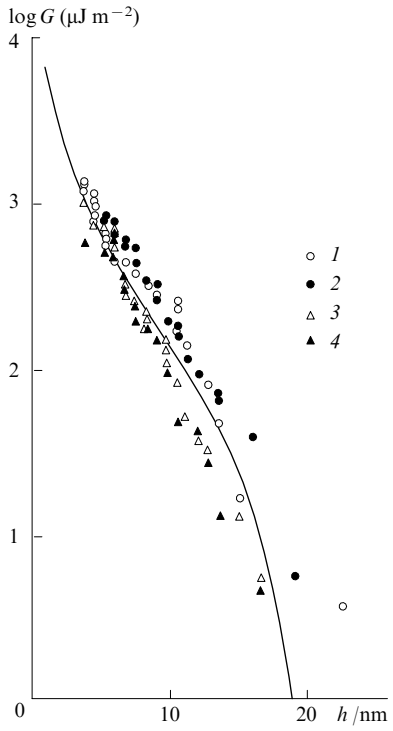

Figure 4. Steric repulsion energy of methyl methacrylate/ethylene oxide copolymer layers grafted to a mica surface in an aqueous 10^{-2} M solution of KNO_3 *vs.* the interlayer thickness.[73]

$$G(h) = \int_h^\infty \Pi_{st}(h)\mathrm{d}h$$

Experimental points: (*1*) the first compression of the grafted copolymer layers, (*2*) the first drawing of the surfaces apart, (*3, 4*) data obtained in the second series of experiments; the curve corresponds to the calculations in terms of the de Gennes theory.[74]

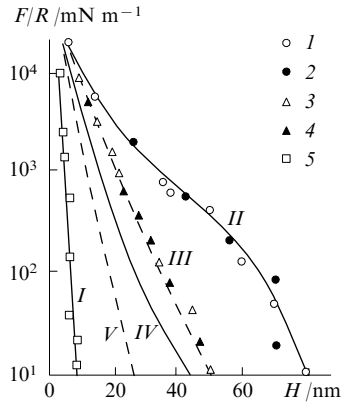

Figure 5. Steric repulsion forces of polyethylene oxide layers adsorbed on mica surfaces *vs.* the distance between the surfaces.[75]
Experimental points: (*1*) the first moving of the surfaces toward each other, (*2*) slow drawing of the surfaces apart after the contact, (*3*) repeated compression of the adlayers 5 min after their preceding separation, (*4*) subsequent fast separation, (*5*) moving of the surfaces toward each other in a 0.1 M solution of KNO_3; (*I – V*) see the text.

curves *IV* and *V*. Thus, the steric forces for grafted and adsorbed polymer molecules are substantially different.

The results of investigations of the interaction forces between various biological objects (cells, lipid bilayers, *etc.*) have been surveyed.[76]

Polyelectrolytes are widely used in modern applied chemistry. This is due to the fact that the charge of the polyelectrolyte chains can be controlled by varying the ion composition and the concentration of the background electrolyte.

The particles of most dispersions used in industry bear a negative charge; therefore, cationic polyelectrolytes (CPE) are used most often for practical purposes. Their influence on the surface interaction was studied by direct measurements of the forces of these interactions in solutions of CPE of various concentrations. It was shown [77] that the electrostatic adsorption of polyethoxylated dodecylamine on a negatively charged mica surface ($\zeta_1 = -105$ mV) takes place at pH < 8 to give a monolayer which shields the surface charge and hydrophobises the surface. This gives rise to molecular attraction forces between the surfaces, which are replaced by steric repulsion forces as the surfaces come closer together. Since the CPE structure contains oxyethyl chains, the hydrophobic attraction forces are not manifested. A decrease in the pH results in reversible structural rearrangement of the adlayer.

Similar results have been obtained for a highly charged cationic polyelectrolyte, poly(2-acryloxyethyl)trimethylammonium chloride with a molecular mass of 1.5×10^6 (see Ref. 78). At a low concentration of the background electrolyte, the molecules of the given CPE were adsorbed on a mica surface as a planar conformation. An increase in the CPE concentration results in gradual shielding of the surface charge of mica and in a decrease in the electrostatic repulsion forces until they completely disappear in the vicinity of the charge reversal point (Fig. 6). The results of measurements (dots) are in good agreement with the results of calculations in terms of the DLVO theory (curves) where the Hamaker constant was taken to be 2.2×10^{-20} J. A further increase in the concentration of poly(2-acryloxyethyl)trimethylammonium chloride induced a slight increase in the adsorption and gave rise to steric forces.

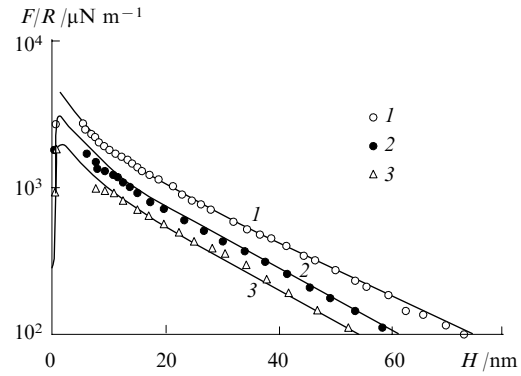

Figure 6. Repulsion force between mica surfaces in aqueous solutions of poly(2-acryloxyethylene)trimethylammonium chloride with a concentration of 1 (*1*), 5 (*2*) and 10 ppm (*3*) containing 0.1 mmol litre^{-1} of KBr *vs.* the distance between them.[78] The curves correspond to the calculation in terms of the DLVO theory.

In dilute solutions of poly(2-vinylpyridine), the interaction forces measured by AFM during moving together of a glass bead and a flat glass substrate also corresponded to analogous forces found in terms of the DLVO theory.[79] However, the adhesion strength at tearing off of the bead was much greater, which is due to the formation of bridging bonds between the surfaces not filled by CPE adlayers with participation of adsorbed CPE molecules. At higher concentrations of CPE and the salt, steric interaction appears and adhesion markedly decreases, which points to a looser state of the adlayer.[79]

It has been reported [80] that at a relatively low concentration of poly(2-vinylpyridine), the AFM-measured interaction remained purely electrostatic. This implies a planar conformation of the

molecules in the adlayer. However, the materials of the bead (quartz) and the substrate (mica) were different; therefore, the surface potentials differed in magnitude, which resulted in switching of the sign of electrostatic forces following a decrease in the solution interlayer thickness. Both the adsorbed CPE molecules and the residual charge of the incompletely shielded substrate contributed to the surface charges formed.

Measurements of the streaming potential of aqueous solutions of the styrene/dimethylaminopropylmaleimide copolymer of various concentrations in thin quartz capillaries with a molecularly smooth surface showed that the isotherm of the electrostatic adsorption of CPE follows the Langmuir equation with an adsorption potential of 25.4 kT (see Ref. 81). This corresponds to the formation of the first layer of planar-oriented molecules. After charge reversal of the solid surface, hydrophobic adsorption of macromolecules takes place to give the second layer. The calculations showed that the hydrophobic adsorption potential is much lower, being equal to 17.7 kT.

Berndt *et al.* [82] have studied the influence on the surface forces of the adsorption of an anionic polyelectrolyte (APE), polystyrenesulfonate with different molecular masses (10^4 to 5×10^5), on positively charged mica surfaces coated by a monolayer of the dioctadecyldimethylammonium cations. For the maximum coverage of the APE monolayer, the interaction forces decrease by an order of magnitude due to the complete neutralisation of the surface charge. The lack of structural forces indicates a planar orientation of the adsorbed APE macromolecules. Thus, these results do not differ qualitatively from those obtained for CPE on negatively charged surfaces.

Using the Mark-4 device, the interaction forces between mica surfaces in sodium polyacrylate solutions, including those containing calcium atoms, have been measured.[83] In the absence of Ca^{2+} ions, no noticeable adsorption of the polymer molecules in mica has been detected. The adsorption started at a $CaCl_2$ concentration higher than 3×10^{-3} mol litre^{-1} due to the formation of bonds between the COO^- groups of the polyelectrolyte and mica with participation of the Ca^{2+} ions. The adhesion strength of the contacting adlayers increased with an increase in the pH.

The same technique was used to measure the interaction forces between mica surfaces in a solution containing 0.2 mg ml^{-1} of proteoglycan (PG) sulfate, which is a part of cellular membranes.[84] The adsorption of PG from a 10^{-4} M solution of NaCl on a hydrophobised mica surface is irreversible. The interaction of the anionic PG adlayers is caused by electrostatic and steric repulsion forces, which show themselves at a distance of less than 10 nm between the surfaces and do not depend on the electrolyte concentration.

The measurement of the interaction forces between the 'brushes' of highly charged diblock copolymer grafted to mica surfaces (hydrophobised by a cationic surfactant) has shown [85] that only electrostatic and short-range steric repulsion can be found between these surfaces. In a salt-free solution, the brushes were straightened under the action of polyelectrolyte counterions. After the addition of a salt, the electrostatic interactions were partially shielded and the polymeric brushes acquired again their flexibility. The region where the interaction is observed depends only slightly on the salt concentration and, when the surfaces move towards each other, it is described adequately by the Pincus scaling theory.[85]

In a number of studies (see, for example, Refs 86–88), osmotic attraction of glass or quartz surfaces in solutions of non-adsorbable polyelectrolytes was detected. The attraction is due to a decrease in the polyelectrolyte concentration in the interlayer between the surfaces whose charge has the same sign as the charge of the polymer.

III. Surface forces in wetting phenomena

1. Wetting films

Wetting films are asymmetrical systems. The surface forces involved in these films can be described using the Derjaguin heterocoagulation theory developed for colloids. Unlike the symmetrical system considered in terms of the DLVO theory, in the wetting films, the field of electrostatic forces is no longer symmetrical as the potentials ψ_1 and ψ_2 of the film surfaces differ in magnitude and, in some cases, also in sign. That is why more diverse combinations of the individual components of the surface forces can be realised in this case. Unlike the symmetrical liquid interlayers between identical surfaces, in the case of wetting films, electrostatic forces often become attractive forces, while dispersion forces are repulsive. The latter is due to the fact that the difference between the dielectric permeabilities $(\varepsilon_2-\varepsilon_3)$ in the equation (5b) for dispersion forces becomes negative in the case of wetting films adjacent to air, because for air, $\varepsilon_2 = 1$.

The thickness h of wetting films formed on planar solid substrates is measured by the method of film-reflected light microinterference or by ellipsometry.[89] The disjoining pressure is specified by the hydrostatic pressure

$$\Pi = \rho g H_h ,$$

where ρ is the density of the liquid, g is the acceleration of gravity and H_h is the difference between the liquid levels in a planar horizontal film and in the vessel it communicates with. By varying the film thickness through specifying different hydrostatic pressures H_h, one can obtain the disjoining pressure isotherms $\Pi(h)$ for wetting films.

It was shown by experiment that the thickness of wetting films of nonpolar liquids is mainly determined by the action of dispersion forces and the isotherm $\Pi(h)$ can be described by Eqn (5a) with the constant A_{130} where subscripts 1, 3 and 0 refer to the substrate, the liquid in the film, and air, respectively.

For volatile liquids, it is possible to obtain the isotherms $\Pi(h)$ by measuring the thickness of polymolecular adsorption films at different relative vapour pressures p/p_s in a preliminary evacuated chamber. In this case, the disjoining pressure in the film is equal to

$$\Pi(h) = -\frac{RT}{\upsilon_m}\ln\frac{p}{p_s}, \qquad (11)$$

where υ_m is the molar volume of the liquid.

Agreement of experimental data with the results of calculation (5a) was obtained for 1–4 nm thick films of alkanes (from pentane to octane) on the surface of quartz.[90] The values of A_{130} thus found were similar for all alkanes — the molecules in the films were mainly oriented parallel to the surface and their different lengths did not affect the result. The possibility of this layered orientation was later confirmed by the Monte Carlo method for n-hexadecane near the gold surface.[91]

Good agreement with the theory of dispersion forces was attained in experiments with cyclohexane, which wets the silicon surface, for thicknesses from 1 to 12 nm.[92] The involvement of other components of surface forces can also be expected in experiments with wetting films of polar liquids.

This is exemplified in Fig. 7, which shows the results of ellipsometric measurements of the thickness of wetting water films on quartz surfaces with different degrees of hydrophilicity. The $h(p/p_s)$ isotherms were obtained for a fully hydroxylated surface of crystalline quartz (curve *1*) and a thermally dehydroxylated surface of the same quartz (curve *4*).[93] The degrees of hydrophilicity of these surfaces are described by water contact angles $\theta = 2-3^\circ$ and 43°, respectively. Isotherms *2* and *3* measured for a polished surface of fused quartz ($\theta = 5-10^\circ$ and 20°, respectively) occupy an intermediate position.[94]

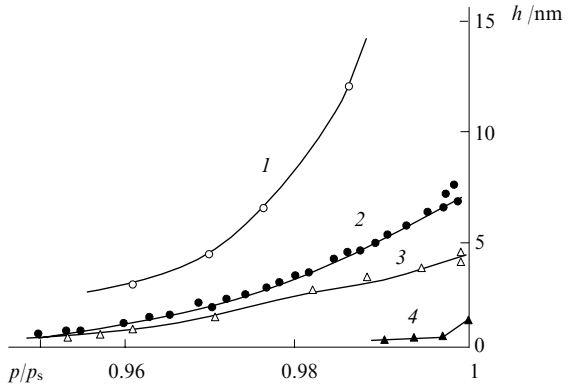

Figure 7. Isotherms of polymolecular adsorption of water vapour on quartz surfaces with different degrees of hydrophilicity. (*1*–*4*) see the text.

The disjoining pressure isotherms obtained for water are consistent with Eqn (8) for structural forces. The influence of electrostatic forces was insignificant, as shown by rough calculations. The involvement of dispersion forces could be expected only for isotherm *4*.

However, it has been shown [95] that isotherms obtained for water films with a thickness of less than 2 nm on mica are not consistent with the isotherms of the theory of dispersion forces. For other polar liquids such as methanol and n-propanol, the isotherms $\Pi(h)$ of thin films (at $p/p_s < 0.8$) are in line with the theory of dispersion forces.[96] However, at a higher vapour pressure, the film thickness exceeds the calculated value due to the additional contribution of electrostatic forces.

Electrolyte solutions form much thicker wetting films, but the region of their existence is limited to a vapour pressure close to saturation. Therefore, the stabilities of these films are studied using the methods described at the beginning of the Section, according to which the disjoining pressure is specified by the hydrostatic pressure (the difference between the liquid levels) or by the capillary pressure of the meniscus.[35, 89] Since electrostatic forces are the longest-range ones, most often, they determine the stability of thick films of aqueous solutions of electrolytes.

The isotherms of the disjoining pressure of the wetting films of aqueous solutions of electrolytes have a characteristic S-shape (Fig. 8). Thick β-films are metastable and at some critical thickness, they break, leaving thinner, thermodynamically stable α-films on the surface. Such films resemble in many aspects the films of pure water on a quartz surface (see Fig. 7).

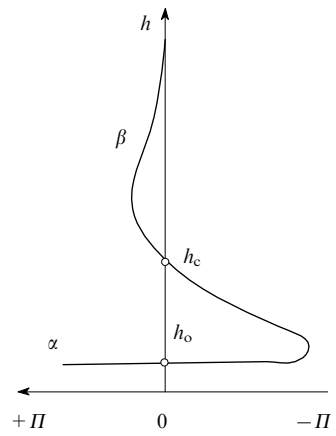

Figure 8. General view of the S-shaped isotherm of disjoining pressure of wetting films including the regions of metastable β-films and thin stable α-films.

The theoretical isotherm for the electrostatic component of the disjoining pressure of water films with the potentials ψ_1 for the boundary with a substrate and ψ_2 for the interface with air has the form

$$\Pi_e(h) = \left(\frac{RTc}{\mathrm{sh}^2(\kappa h)}\right)[2\Phi_1\Phi_2\mathrm{ch}(\kappa h) - (\Phi_1)^2 - (\Phi_2)^2], \qquad (12)$$

where c is the concentration of the solution, mol ml^{-1}, $\Phi = ze\psi/kT$ is the dimensionless potential of the interface.

Using Eqn (12), one can obtain a quantitative interpretation of the upper section of the S-shaped isotherm shown in Fig. 8 and explain the possibility of rupture of β-films upon thinning, namely, switching from the electrostatic repulsion forces, which maintain the stability of thick β-films, to electrostatic attraction forces takes place as the film thickness reaches the critical value

$$h_c = \kappa^{-1}\ln\left(\frac{\psi_1}{\psi_2}\right). \qquad (13)$$

The dependence of the thickness of wetting films on a planar quartz surface on the concentration and pH of an electrolyte (KCl) solution at a constant ionic strength equal to 10^{-3} mol litre^{-1} has been studied by microinterference.[97] The experimental data obtained for thicknesses of about 100 nm were consistent with theoretical results provided that the potentials ψ_1 and ψ_2 of the film surfaces were constant. The potentials ψ_1 and ψ_2 known from electrokinetic measurements and data for foam films were used. According to the theory, the loss of stability occurs at pH < 8 and at an electrolyte concentration of $> 10^{-3}$ mol litre^{-1}. After rupture of the β-films, drops of the bulk solution forming contact angles of 10–25° (which correspond to incomplete wetting) with the remaining thin α-film were left on the surface.

The known analytical solutions for electrostatic forces were obtained for two limiting cases, namely, constant potentials (ψ = const) or constant charges (σ = const) for both film surfaces upon the change in the film thickness. McCormack *et al.*[98] considered cases where different boundary conditions may be fulfilled on the interfaces of the film. In particular, for a constant potential of the surface of the solid substrate (ψ_1 = const) and a constant charge (σ_2 = const) of the film–gas interface, the expression for the electrostatic component of the disjoining pressure assumes the form [94]

$$\Pi(h) = nkT\left[\frac{\Phi_1}{\mathrm{ch}(\kappa h)} + \Phi_2\mathrm{th}(\kappa h)\right]^2 - \Phi_{2\infty}^2, \qquad (14)$$

where n is the concentration of ions; the potential ψ_1 is taken to be independent of the film thickness, and the $\psi_{2\infty}$ potential is taken for $h \to \infty$. As the film thickness decreases, the ψ_2 values start to depend on the thickness, which corresponds to a constant charge σ_2 of the film–gas interface.

The film rupture under the conditions described above takes place at a critical thickness h_c, which can be determined from Eqn (14) using the known criterion for film stability, $d\Pi/dh = 0$

$$\mathrm{sh}(\kappa h_c) = \frac{\Phi_{2\infty}}{\Phi_1}. \qquad (15)$$

This expression has been used [99] to explain the stability of 45-nm films of a 10^{-4} M solution of KCl formed between the surface of a thin quartz capillary (r = 4.5 μm) and a gas bubble.

A clear idea of the properties of wetting films of aqueous solutions of electrolytes at different boundary conditions can be gained from Fig. 9. Here curve *1* is the disjoining pressure isotherm calculated from Eqn (14) with dimensionless surface potentials $\Phi_1 = 8$ and $\Phi_{2\infty} = 2$; for comparison, the Figure shows isotherms *2* and *3* calculated for identical boundary conditions at both interfaces of the film (σ = const or ψ = const, respectively). The Figure demonstrates how different electrostatic boundary conditions influence the thickness and stability of wetting films of aqueous solutions of electrolytes. When the charge is constant on both surfaces of the film (curve *2*), the

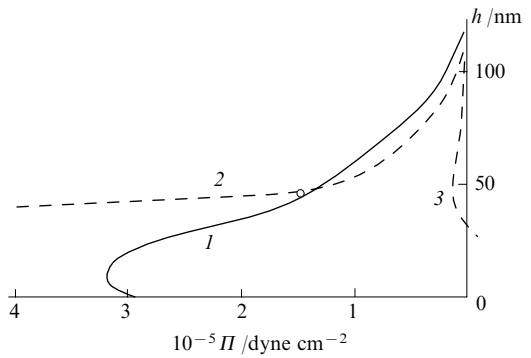

Figure 9. Disjoining pressure isotherms of wetting films calculated for various boundary conditions:
(*1*–*3*) see the text.

films remain stable over a broad range of disjoining pressures, while in the case of constant potentials (curve *3*), the films lose stability even at low pressures when the film thickness approaches the critical value [see Eqn (13)].

The presence of surfactants in aqueous solutions influences considerably the thickness and stability of wetting films. Nonionic surfactants influence the degree of hydrophilicity of the film surfaces; this can change the magnitude and the sign of the short-range structural forces. The influence of the adsorption of ionic surfactants is more pronounced, as it changes the magnitude and the sign of electrostatic long-range forces.

Gee *et al.*[93] have measured the thickness of wetting films on a polished quartz surface as a function of the concentration of aqueous solutions of CTAB by ellipsometry and microinterference. Unlike the preceding studies, the potentials of the film surface ψ_1 and ψ_2 were measured by independent methods.[95] The measurements showed that in the region of $c_{\mathrm{CTAB}} < 10^{-7}$ mol litre^{-1}, the films were metastable, because the surface potentials, though having like signs, still differed in magnitude. On further increase in the surfactant concentration, the films lost stability, and the contact angles they formed with the substrate had a maximum ($\theta \approx 50-60^{\circ}$) at $c_{\mathrm{CTAB}} = 10^{-5}$ mol litre^{-1}. The film stability was restored on approaching the CMC ($c_{\mathrm{CTAB}} \approx 10^{-3}$ mol litre^{-1}) where both film surfaces acquired equal positive charges. The observation of the charge reversal for quartz surfaces in solutions of CTAB has been used, in particular, to evaluate the efficiency of flotation.[100]

The rupture of wetting films of aqueous solutions of another cationic surfactant, dodecylamine, has been observed at concentrations below the CMC.[101] The effect of an anionic surfactant, sodium dodecyl sulfate, on the stability of water wetting films is less pronounced, because its presence increases only slightly the negative charge of the quartz surface.[102] Upon adsorption of sodium dodecyl sulfate, the negative charge of the second surface of the film also increases; therefore, film stability is enhanced.

Comparative analysis of the results obtained for wetting and foam films of surfactant solutions has provided an explanation for the difference in their stability mechanisms.[103, 104]

The same experimental methods were employed to study films of aqueous solutions occurring between a solid surface and a liquid immiscible with water (*e.g.*, oil).[105, 106] Such systems can model emulsion films.

The thickness of a water film formed between quartz and silicone oil (with a molecular mass of 2400) was $\approx 50-60$ nm at a concentration of the background electrolyte (KCl) of 10^{-4} mol litre^{-1} (see Ref. 105); this was much smaller than the thickness of a wetting film adjacent to air. Similar results have been obtained for films of aqueous solutions of CTAB with a concentration from 4×10^{-4} to 10^{-3} mol litre^{-1} in contact with silicon oil or tetradecane. Under these conditions, either an oil-in-water or a water-in-oil emulsion is formed in quartz capillaries, depending on the direction of movement of the oil–water meniscus.[107]

Stable water films were also observed between quartz and xylene,[105] in particular, with solutions containing nonionic surfactants.[106]

Let us consider how the presence of a polymer in the solution influences the wetting film stability. A substantial additional contribution can be expected from steric repulsion forces, caused by the deformation of the polymer adsorption layers when they are brought into contact. The radius of action of these forces depends on the length of the macromolecule and its conformation in the adsorbed state.

Gasanov *et al.*[108] have obtained disjoining pressure isotherms for wetting films of aqueous solutions of polyethylene oxide with a molecular mass of 6×10^5 on a planar quartz surface. However, the thickness of the adsorption layer of the polymer on quartz (20 nm) was much smaller than the thickness of the films studied (50–100 nm). Therefore, the role of the polymer was only to decrease somewhat the film thickness (by 5–10 nm) due to shielding of a part of the surface charge of quartz by the macromolecules adsorbed due to the formation of hydrogen bonds with the surface hydroxy groups.

In wetting films of aqueous solutions of the triblock copolymer F108 with a molecular mass of 1.4×10^4 whose molecules are composed of the central hydrophobic polypropylene oxide block and two terminal hydrophilic PEO blocks, adsorption took place on both interfaces.[109] As the adsorption layers approached each other and finally overlapped, stable (due to steric repulsion forces) 30–40-nm thick films were formed.

The use of cationic polyelectrolytes also allows one to stabilise wetting films. In solutions of the highly charged styrene/dimethylaminopropylmaleimide polymers, the major effect is due to electrostatic forces.[110] In this case, the stability of wetting films can be controlled by varying the composition and chain length of the polymer and the charge and conformation of molecules in solutions with different ion compositions.

2. Wetting control

The use of disjoining pressure isotherms of wetting films makes it possible to estimate the contact angles θ formed by liquids on solid substrates. The corresponding expression is derived from combination of the Frumkin–Derjaguin theory of free surface energy γ_{sv} of a solid substrate coated by an equilibrium wetting film with the thickness h_0,

$$\gamma_{\mathrm{sv}} = \gamma_{\mathrm{sl}} + \gamma_{\mathrm{lv}} + G(h_0), \tag{16}$$

where $G(h_0)$ is the free Gibbs energy of the equilibrium film

$$G(h_0) = \int_{h_0}^{\infty} \Pi(h)\mathrm{d}h,$$

on the one hand, and the known Young equation

$$\gamma_{\mathrm{lv}} \cos\theta = \gamma_{\mathrm{sv}} - \gamma_{\mathrm{sl}}, \tag{17}$$

where γ_{lv} is the surface tension of the liquid, γ_{sl} is the free energy of the solid–liquid interface, on the other hand. By combining the two equations, we get [110–112]

$$\cos\theta = 1 + \frac{G(h_0)}{\gamma_{\mathrm{sl}}}. \tag{18}$$

The equilibrium film thickness h_0 can be found by solving the equation of the overall isotherm, which includes the dispersion, electrostatic, structural and steric forces

$$\Pi(h) = \Pi_{\mathrm{m}}(h) + \Pi_{\mathrm{e}}(h) + \Pi_{\mathrm{s}}(h) + \Pi_{\mathrm{ster}}(h) = 0\,. \tag{19}$$

The equilibrium film thickness h_0 is determined as the smallest root of Eqn (19), which corresponds to intersection of the isotherm with the axis of thicknesses (see Fig. 8). This method of calculation can be used for macroscopic drops and meniscuses

where the equilibrium vapour pressure above the film is close to the saturation pressure.

Examples of calculations of the dependences of contact angles on the magnitude and sign of the surface charge, the Hamaker constants and the structural repulsion and hydrophobic attraction forces have been reported.[111–113] Comparison of the results of calculations with experimental data showed that the effect of hydrophilic repulsion forces can be detected at contact angles of $\theta < 15-20^\circ$, while the effect of hydrophobic attraction forces, at $\theta > 50-60^\circ$. In the intermediate region of θ values, wetting can be described using the DLVO theory.

The proposed calculation methods can be used to predict wetting and to select the optimal composition of solutions that ensure the required process conditions, for example, for flotation, dust extraction and capillary impregnation.

Abstract. Results of studies of physicochemical dynamics of disperse systems, which is a new and rapidly developing field of physical chemistry, are generalised. Most attention is given to frequently occurring disperse systems composed of a solid phase and a liquid dispersion medium. The dynamics of contact interactions between particles of disperse solid phases is a key element of the dynamics of such systems. The physicochemical factors responsible for contact interactions are considered in relation to the bulk structural – rheological properties of disperse systems. The bibliography includes 114 references.

I. Introduction

Among disperse systems, highly dispersed systems characterised by a highly developed interface are of most interest. These are first and foremost structured systems [1, 2] in which dispersed structures form spontaneously through intermolecular interactions due to contacts between particles. Traditionally, the properties of these systems were studied primarily under static conditions.[3] The present review is devoted to problems associated with the behaviour of such systems in dynamic conditions typical of both various chemical engineering processes and many natural phenomena.

Such fields of science as molecular and Brownian dynamics have been extensively developed.[4, 5] The case in point is physicochemical dynamics of microheterogeneous systems [6] containing particles, whose sizes can be substantially (by 2 – 3 orders of magnitude) larger than the sizes of colloidal particles. This area of physical chemistry of disperse systems borders on physicochemical hydrodynamics,[7] which deals with processes occurring in the vicinity of the surface of an individual particle of a solid phase (or a solid – liquid interface), as well as on physicochemical hydrodynamics of capillary systems.[8]

Physicochemical dynamics of disperse systems treats predominantly dynamic processes taking place in ensembles of particles of dispersed phases linked in a spatial structural network through dispersion forces, the mechanism of decomposition of such systems under dynamic exposure conditions to form aggregates, their evolution, interactions with each other and a dispersion medium (up to decomposition into individual particles to release a dispersion medium immobilised in these aggregates). Within the framework of physicochemical dynamics, not only destruction of aggregates but also reverse processes of structure formation under conditions of dynamic action on a dispersion medium are considered.

Physicochemical dynamics includes dynamics of contact interactions between particles as the major component,[9 – 13] which determines the characteristic features of destruction and the mechanism of structure formation in disperse systems in dynamic conditions.

The present review is devoted to the following problems: conditions and the mechanism of structure formation in disperse systems, criteria for their destruction under dynamic conditions, verification of the type and intensity of dynamic actions on structured disperse systems, the dynamics of contact interactions between particles of dispersed phases, including those in the presence of a surfactant adsorption layer on their surface, the flow mechanism for structured disperse systems (fundamentals of the flow theory) in dynamic conditions with substantiation of ways and procedures for achieving the maximum fluidity upon complete deaggregation.

The maximum fluidity is required for creating the optimum dynamic state of disperse systems corresponding to the main condition for optimisation and intensification of various heterogeneous chemical engineering processes in such systems as well as processes for the production of a broad spectrum of dispersed composition materials.

The main concepts in physicochemical dynamics of disperse systems were finally developed in the last 10 – 15 years. However, since some fundamental aspects in this field of physical chemistry of disperse systems have been published before that time, the earlier studies are also briefly considered and analysed in the present review.

II. Main conditions for structure formation in disperse systems

1. Types of contacts between particles in disperse systems

In spite of an enormous variability in the chemical composition and physical properties of disperse systems, most of them are characterised by a combination of two major features: the presence of a highly developed interface and a high concentration of a dispersed phase in a liquid (or gaseous) dispersion medium. As a consequence, these systems have a high interface free energy (F^*). The free energy of systems always tends to decrease. Hence, processes accompanied by a decrease in this energy (ΔF^*) can occur spontaneously in disperse systems.[14]

The free energy can decrease due to formation of contacts between particles on coagulation, which proceeds particularly extensively in lyophobic aggregation-unstable disperse systems. When a certain critical concentration of particles of dispersed phases in liquid or gaseous dispersion media (φ_c) is achieved, this process leads to the spontaneous formation of a spatial structural network. The major components of the latter are the contacts between the particles and the particles as such, which form spatial cells in the bulk of the disperse system. In this case, the disperse system becomes structured, *i.e.*, is transformed from a free dispersed state to a bound dispersed (aggregated) state.

The formation of three-dimensional structures leads to radical changes in the main structural and mechanical properties of such systems. These systems completely lose aggregation stability but become stable with respect to sedimentation, because a structural network prevents particles of immobilised dispersed phases from precipitating. At the same time, such systems lose fluidity and high mobility. Their viscosity continuously increases as the dispersity increases (and, correspondingly, as the size and concentration of particles in dispersion media decrease). Structured disperse systems are characterised by the modulus of elasticity and the ultimate strength τ_p (or P_m). These are only the most typical features of such systems.

Of numerous factors responsible for the properties of structured disperse systems, two main groups are associated with the following fundamental parameters:[9–13,15–17] first, the cohesive force f_c and the cohesive (interaction) energy E_c in contacts between particles of dispersed phases; second, the number of contacts n between particles per unit volume.

The strength and energy of interactions in contacts between particles depend on the type (nature) of contacts (Fig. 1, Table 1). The characteristic feature of relatively unstable structures with contacts of the first and second types is their complete reversibility with respect to strength. A consideration of direct (atomic) and coagulation contacts as two different types is somewhat tentative. For example, in the case of strong lyophobic interactions between particles, a liquid in coagulation structures can be completely displaced from the interspace between the particles, and the difference between these types of contacts disappears. After cessation of external mechanical actions, contacts in the destroyed structure can be spontaneously restored to the initial level. This property (so-called thixotropy) is typical of various powder- and paste-like dispersions. Structures with strong phase contacts do not possess this property at all. Such structures (so-called condensation structures) are formed in disperse systems, in which contacts are reversible with respect to strength as a result of phase and/or chemical transformations, for example, upon crystallisation from supersaturated solutions or melts (on their cooling), polymerisation, sintering, plastic deformation on pressing, removal of a liquid dispersion medium, *etc*. The minimum phase

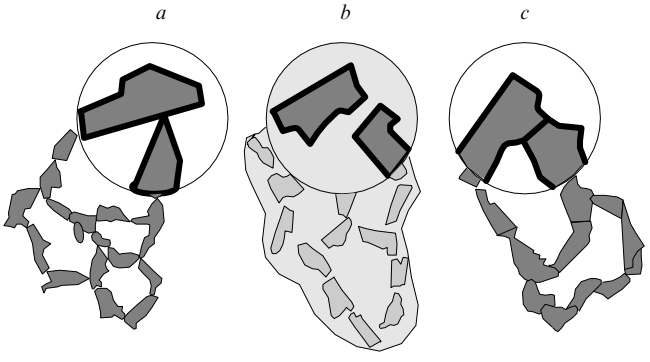

Figure 1. Main types of contacts between particles of dispersed phases according to Rehbinder.[1]
Contacts: (*a*) direct (atomic), (*b*) coagulation, (*c*) phase.

Table 1. Types and characteristics of contacts between particles.

Contacts	f_c/N	E_c/J	Note
Direct (atomic)	10^{-8}–10^{-9}	10^{-17}–10^{-16}	contacts occur in finely dispersed powders
Coagulation	10^{-10}–10^{-8}	10^{-19}–10^{-18}	contacts occur in pastes (suspensions) or emulsions through a thin liquid interlayer
Phase	$\geqslant 10^{-7}$–10^{-6}	$\geqslant 10^{-17}$–10^{-16}	strong contacts typical of condensation structures of dispersed materials

contact corresponds to $\sim 10^2$ interatomic bonds. This contact is essentially no different from an atomic contact typical of finely dispersed powders. Since the contact surface area is only $\sim 10^{-16}$ m^2, the probability of occurrence of a defect is very low, and the strength of the contact approaches that of an ideal solid body. As the area of the phase contact increases, the force f_c generally reaches $\sim 10^{-3}$ N.

The mechanical properties of disperse structures appeared in different steps of structure formation depend on the force f_c for an individual contact determined by its nature as well as on the number of such contacts per unit volume. Coagulation structures play an important role in the properties of disperse systems and (particularly) dispersed materials. It is their formation that is the first step in the synthesis of structured disperse systems and materials.

2. Criteria for the formation of dispersed structures

a. Characteristic critical particle size

Dispersed structures can be generated if two conditions, which determine the critical particle size of a dispersed phase d_c and their critical concentration in liquid or gaseous dispersion media, are fulfilled.

To a first approximation, these conditions can be described as follows.

1. Depending on the type of contacts, systems have a particular characteristic critical particle size; if $d < d_c$ (d is the characteristic particle size), the structure can form and exist; if $d > d_c$, the structure becomes unstable in a gravitational field, *i.e.*, can be self-destructed under gravity forces of the particles involved in this structure.

2. At the critical concentration of particles of dispersed phases in a dispersion medium, a spatial structure with the strength $\tau_p > 0$ can form spontaneously.

Let us consider successively the quantitative values of these criteria.

According to the first conditions, the criterion for aggregability characterising the possibility of formation of dispersed structures is based on a simple principle: a coagulation structure in disperse systems can appear if the cohesive forces between particles are comparable to the particle weight (or larger than this weight in a particular dispersion medium [2])

$$f_c \geqslant G^*, \tag{1}$$

where

$$G^* = \rho_{ef}\, d^3 g, \tag{2}$$

G^* is the particle weight, ρ_{ef} is the effective density of the particle in a dispersion medium ($\rho_{ef} = \rho_0 - \rho_1$, where ρ_0 is the density of the solid phase and ρ_1 is the density of the dispersion medium), g is the gravitational acceleration.

For structures with direct atomic contacts (the coordination number of the particle $z = 1$),[1,2,15]

$$d_c \sim \left(\frac{f_c}{\rho_{ef} g}\right)^{1/3}. \quad (3)$$

For dispersions with a liquid medium (pastes, suspensions), which have lyophobic coagulation contacts [15–18] and contain particles in a short-range potential well ('short-range' coagulation: $h \approx h_2$, h is the distance between the particles),[17]

$$\overline{d}_c \sim \frac{k}{h_2}\left(\frac{A^*}{\rho_{ef} g}\right)^{1/2}, \quad (4)$$

where k is the dimensionless coefficient equal to ≈ 0.2 and A^* is the Hamaker constant.

For coagulation structures containing particles in a long-range potential well ('long-range' coagulation, $h \approx h_1$),[15]

$$\overline{d}_c \sim \frac{1}{h_1}\left(\frac{\pi}{2}\frac{B}{h_1 \rho_{ef} g}\right)^{1/2}, \quad (5)$$

where B is the Lifshits constant.

An important result of calculations of d_c for the typical values $A^* \sim 10^{-19}-10^{-20}$ J, $B \approx 10^{-28}$ J m and $\rho_{ef} \sim 2$ is that $d_c \gg 1$ μm and can amount up to 100 μm. This value is several orders of magnitude larger than the size of colloidal particles. Relations (3)–(5) are given with respect to one contact between two particles. This is a hypothetical limiting case characteristic of the initial step of formation of aggregates from particles.

In actuality, the coordination number of particles in the structure is $z \geqslant 2$. Hence, d_c for each of the above-considered structural types can be larger than those calculated by Eqns (3)–(5).

In the general form, the criterion for aggregation in the case of solid phase — liquid medium dispersions can be determined from the condition that the potential energy of interaction between particles in a contact must be comparable to the energy of external actions on the disperse system.[19]

Let us assume that the potential energy of interaction between two spherical particles of radius $r = d/2$ is expressed by the equation

$$U(r, h) = r\,[C_1(h) + C_2(h)], \quad (6)$$

where C_1 describes the contribution of the molecular attractive forces [18]

$$C_1(h) = -\frac{B}{h^2} \quad \text{at } h \gg h_k, \quad (7)$$

$$C_1(h) = -\frac{A^*}{12h} \quad \text{at } h \ll h_k, \quad (8)$$

$h_k \cong 10^{-8}$ m corresponds to the characteristic wavelength of the line in the absorption spectra of atoms and molecules of the contacting particles; $A^* \cong 10^{-19}$ J, $B \cong 10^{-27}-10^{-28}$ J m; $C_2(h)$ reflects the contribution of the Coulombic repulsion forces.[18, 20, 21]

Let us write $C_2(h)$ as follows

$$C_2(h) = 64\pi \frac{NT}{k^2}\gamma^2 e^{-\kappa_1 h}, \quad (9)$$

where N is the concentration of the electrolyte, T is the temperature expressed in terms of energy,

$$\gamma = \text{th}\frac{U_1}{4},\ U_1 = q\frac{\Psi}{T},$$

Ψ is the electrical potential on the particle surface, q is the charge on ions of the electrolyte,

$$\kappa_1 = \left[8\pi q^2 N(\varepsilon T)\right]^{1/2},$$

ε is the dielectric constant.

A sequence of transformations of Eqn (9) gives the following expressions for low ($U_1 \ll 1$) and high ($U_1 \gg 1$) energy potentials at $\kappa_1 h \ll 1$: [21]

$$C_2(h) = A_0\,|\ln \kappa_1 h|, \quad (10)$$

where

$$A_0 = \frac{\delta \varepsilon T^2}{q^2},$$

$$\delta = \begin{cases} \dfrac{\pi^2}{4} & \text{at } U_1 \gg 1, A_0 \sim 10^{-11} \text{ J m}^{-1} \\ 2U_\infty^2 & \text{at } U_1 \ll 1, A_0 < 10^{-11} \text{ J m}^{-1}. \end{cases}$$

Here, U_∞ is the value of U_1 with $h \to 0$.

From Eqns (6)–(8) and (10), it follows that h_{max} corresponding to the maximum of the barrier separating the short- and long-range potential wells can be calculated as follows:

$$h_{max} = \frac{A^*}{12A_0}. \quad (11)$$

In the case of short- and long-range coagulation, the equations for the binding energy of the particles in the structure are as follows:

for short-range coagulation

$$U_2 = z[U(h_{max}) - U(h_2)] = -zA_0 \ln\frac{h_{max}}{h_2} + \frac{zA^* r}{12}\left(\frac{1}{h_2} - \frac{1}{h_{max}}\right), \quad (12)$$

for long-range coagulation

$$U_1 = -zU(h_1) = z\frac{Br}{h_1^2}\left(1 - \frac{2}{\kappa_1 h_1}\right). \quad (13)$$

If the potential energy of interactions between particles (6) is represented as a model function composed of two potential wells taking the shape of parabolic curves of depth U_2 and U_1, the stability (or aggregation) criterion for static conditions is expressed in the general form as follows:

$$U_i > \frac{4}{3}\pi \rho_{ef} r^3 g h_i, \quad (14)$$

The index $i = 1$ corresponds to long-range coagulation, and $i = 2$ corresponds to short-range coagulation. Equation (14) serves as the energy criterion for stability of the structure with respect to sedimentation, *i.e.*, to destruction followed by sedimentation of the particles under their own weight.

A combination of Eqn (14) and the condition for stability of the structure with respect to Brownian motion [3, 15] gives an equation, which determines the range of the critical sizes of particles capable of forming structures stable in static conditions,[19]

$$\frac{d_i}{2} = r_i = \left[\frac{U_i}{r}\left(\frac{4}{3}\pi \rho_{ef} g h_i\right)^{-1}\right]^{1/2}. \quad (15)$$

Assuming that $A^* = 10^{-19}$ J, $A_0 = 10^{-11}$ J m^{-1}, $B = 10^{-27}$ J m, $h_1 \sim 5 \times 10^{-8}$, $h_2 = 10^{-9}$ m, $\rho_0 \sim (1-2) \times 10^3$ kg m^{-3} and $z = 6$, one obtains $d_c/2 \sim 10^{-7}-10^{-5}$ m for systems with long-range coagulation of particles and $d_c/2 \sim 5 \times 10^{-5}-10^{-4}$ m for systems with short-range coagulation.

The maximum values of $d_c/2$ correspond to the criteria for aggregability (4) and (5).

Therefore, calculations of the criterion for aggregability according to Eqns (4), (5) and (15) give analogous results. The values of d_c demonstrate that coagulation structures can form spontaneously in dispersions with particle sizes of tens or even hundreds of micrometers. This indicates that the surface phenomena, contact interactions and structure formation are to a large extent responsible for the properties and characteristic features of most natural disperse systems, which were traditionally assigned to coarsely dispersed materials (for this reason, these materials were treated within the framework of mechanics of continua and hydrodynamics). The following systems belong to such materials: various powdered materials,[2, 22] for example, mineral binders (cements, lime, gypsum); fillers for varnishes and dyes, resins and

polymers; powdered fuels; mineral fertilisers, powders for fire extinction; nutritive disperse systems (flour, sugar powder), paste systems and suspensions, including slurries of chemical industries, suspensions of cellulose fibres used in the production of paper and cartons, suspensions and pastes for the production of porcelain, faience and ceramics; heterogeneous fuels; powdered and paste-like by-products and wastes from manufacturing, in particularly, from concentration plants; numerous natural disperse systems (grounds and soils); bottom sediments of rivers, lakes, seas and oceans.

At the same time, particles in these systems cannot participate in thermal Brownian motion, because their characteristic size is several orders of magnitude larger than the colloidal particle sizes. Hence, the conditions for the creation of a dynamic state of particles in such systems (*i.e.*, the movement of these particles necessary for various chemical engineering processes, for example, mass transfer processes) cannot be achieved through thermal motion. To produce a dynamic state analogous to Brownian motion in dilute aggregation-stable (lyophilic) colloids, it is necessary to deliver energy from external sources with an acceleration of no smaller than g.

b. Concentration factor and strength of coagulation structures

Let us consider quantitative estimates of the concentration factor, which determines the possibility of formation of dispersed structures. In essence, the minimum strength of a structural network, which can hold its constituent particles in a gravitational field, can serve as this criterion. Eventually, it is the strength of the structure that is responsible for its stability in dynamic conditions.

The theories of strength developed in the studies [23–26] are based on an additive approximation, which can be represented in the general form as follows:[3]

$$P_m \sim \chi f_c,$$

where χ is the number of contacts between particles per unit surface.

The corresponding plot of the structure strength *vs.* the concentration of a dispersed phase in a dispersion medium is shown in Fig. 2 *a*. A series of additional parameters characterising the degree of an increase in the strength depending on the concentration can be proposed: $\tan\alpha = dP_m/d\varphi$ for $\varphi_0 < \varphi < \varphi_c$ and $\tan\beta'$ for $\varphi > \varphi_c$, where φ_0 and φ_c are the minimum concentrations at the beginning of structure formation and at the beginning of a sharp strengthening, respectively.[2,26]

Assuming the irregular random particle distribution in the bulk (unlike the distribution assumed in the studies [23–26] and the regular particle distribution in the bulk [27–29]),[30] a more general dependence of the strength on the porosity of dispersed structures was obtained. This approach is based on the concepts of the percolation theory.[31,32]

An earlier attempt to solve this problem [33] was based on the use of a simplified model of the Bethe lattice,[34] which is far from real coagulation structures formed in disperse systems.

A model of a lattice of randomly packed spheres [27] used in the study [30] made it possible to take into account the possibility of the formation of dispersed structures characterised by various particle distributions in a broad range of the coordination numbers from 3 to 9.

When developing a theory for the description of the dependence of the structure strength on its relative porosity $v = \varphi/\varphi_0$ by analogy with the dependence of the conductivity on the porosity of the structure consisting of current-conducting spheres,[30–35] the authors proposed the parameter C, which reflects a particular topological property of a disperse system and is determined by the equation

$$C = \frac{P_m(v)}{P_m(I')}, \tag{16}$$

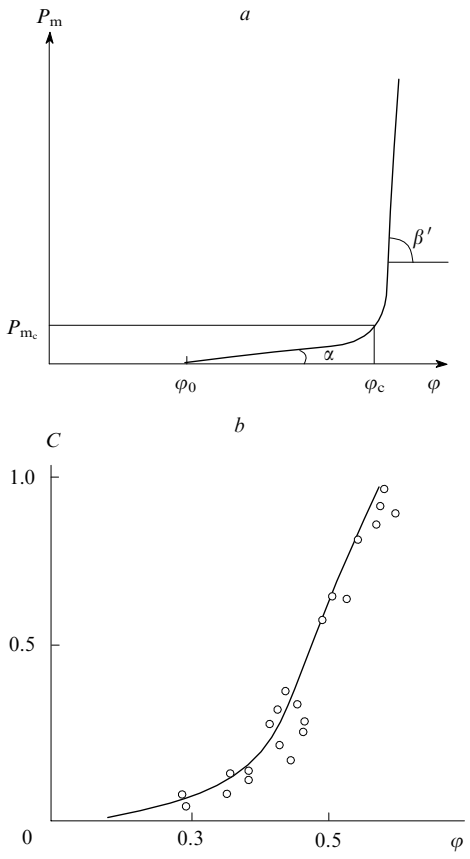

Figure 2. Plots of the strength of dispersed structures *vs.* the concentration (porosity) of a dispersed phase in a dispersion medium.
(*a*) The general character of the dependence,[24] (*b*) the dependence found using the percolation theory; the experimental data are shown by circles.[26]

where $P_m(v)$ is the strength of the porous structure with any effective porosity, $P_m(I')$ is the strength of the system at the maximum volume concentration of the particles (φ_{max}) in the dispersion medium.

The critical relative porosity $v_c = \varphi_0/\varphi_{max}$ corresponds to the maximum porosity at which a structural network is formed in the bulk of a dispersion.

At $v < v_c$,

$C(v) = 0$;

at $v > v_c$ (or $v \to v_c$),

$C(v) = (v - v_c)^{\mu}$,

where μ is determined by the dimensionality of the space (for a three-dimensional space, $\mu \approx 1.8$);[35,36]

at $v \to 1$,

$$C(v) = 1 - K(1 - v), \tag{17}$$

the coefficient K, in turn, depends on the coordination number z

$$K = \frac{2z - 2}{z - 2}. \tag{18}$$

The latter equation allows one to find the dependence of $C(v)$ on the coordination number in the range from 3 to 9, *i.e.*, virtually for all types of quasi-lattices. From Eqns (17) and (18) taking into account the values of K for various z, one has

$$C(\Pi) = 1 - K\left(1 - \frac{1 - \Pi}{1 - \Pi_0}\right) \approx 2.7 - 4.2\,\Pi \tag{19}$$

where $\Pi = 1 - \varphi$, $\Pi_0 = 1 - \varphi_0$.

The experimental data obtained for a model porous structure formed from monodispersed spherical particles of polystyrene and the theoretical dependence (19) are presented in Fig. 2 *b*. It can be seen that there is a good agreement between the theoretical and experimental results.

Based on this theory, the dependences of the strength on the porosity of spatial structures formed in finely dispersed structured systems consisting of clusters and particles and, in a more general case, of aggregates of primary particles (at $d \ll d_c$), were found.

The strength of structures consisting of aggregates can be described by the following equation:[30, 37]

$$C(\varphi) \sim \left(\frac{\varphi}{\varphi_{max}}\right)^{\gamma} \tag{20}$$

where

$$\gamma = 3 + \frac{f/f_a}{3-f},$$

f is the fractal dimensionality of the structure and f_a is the fractal dimensionality of the cluster (aggregate).[38]

This equation is true at $f < 3$. In particular, for percolation clusters, $f_a = 1.8$ at $f = 2.5$, and then $\gamma = 8.8$. For branched clusters, $f_a = 1.5$ at $f = 2$, and then $\gamma = 4.3$.[38–40]

Therefore, Eqns (17), (19) and (20) derived with the use of the percolation theory made it possible to describe the dependence of the strength on the porosity for a random distribution of particles and aggregates in the bulk of the structure. This is the most general case corresponding to real conditions.[41]

III. Destruction of disperse systems in dynamic conditions

1. Dynamic state of disperse systems

Due to the spontaneous formation of a spatial structural network at $d \leqslant d_c$ and $\varphi > \varphi_0$, both a disperse system as a whole and its constituent phases completely lose mobility, *i.e.*, the possibility of relative movement, under static conditions, which is accompanied by the corresponding increase in the viscosity, strength and modulus of elasticity. These structural and rheological characteristics particularly sharply increase at $\varphi > \varphi_c$, whereas φ_c (as well as φ_0) substantially decrease as the dispersity (S) increases at $d \leqslant d_c$. This is also favoured by an increase in the degree of particle anisometry and the occurrence of lyophobic-lyophilic mosaicity on the particle surface, particularly, if the particle surface is predominantly lyophobic. If there are no conditions for easy mobility (fluidity) and, hence, for the possibility of movement of the particles of dispersed phases with respect to each other and relative to a dispersion medium, there is no possibility to carry out various chemical engineering processes and control structural and rheological properties.

For highly concentrated and, particularly, finely disperse systems, this problem is much more difficult to solve because of a spontaneous increase in the number of contacts between particles per unit volume. The line of attack on this problem consists in going from static conditions, in which highly viscous and stable dispersed structures are formed (particularly, at $\varphi \geqslant \varphi_c$ and $d \ll d_c$), to dynamic conditions, in which these structures can be efficiently destroyed due to breaking of coagulation contacts between particles of dispersed phases. These conditions can be achieved by creating an isotropic dynamic state in a disperse system such that an equally probable degree of destruction occurs throughout the bulk of the disperse system. In the limit, coagulation structures are completely destroyed and all coagulation contacts are broken (Fig. 3). It is these conditions that could provide the maximum fluidity and the corresponding lowest viscosity level of the ultimately and isotropically destroyed structure. The dynamic aggregation stability of a disperse system corresponds only to this 'limiting' isotropic dynamic state produced by delivering an energy higher than the cohesive energy to each particle.

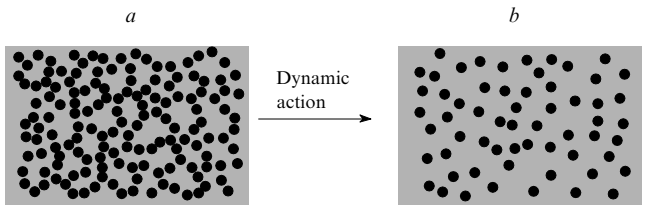

Figure 3. Scheme illustrating conditions for the creation of the optimum dynamic state of disperse systems.
(*a*) A structured dispersion, (*b*) complete ultimate deaggregation.

The type of this energy, its values and conditions of energy delivery to a system depend on the particle size of a dispersed phase, the number of the particles per unit volume, the binding energy between particles (lyophilic or lyophobic interactions) and the viscosity of a dispersion medium.

To determine the main parameters of actions (or their combination) on a disperse system with the aim of creating a controlled dynamic state, it is necessary to determine responses of both individual particles of dispersed phases and the disperse system as a whole to various actions. The responses of particles of dispersed phases to various actions can be described using the characteristic times (τ) of the following microprocesses, which were determined using the dimension theory:[6, 9]

interparticle interactions ($f_{c,\mu}$) through surface forces (molecular attractive forces f_c and Coulombic repulsive forces f_μ)

$$\tau_{f_{c,\mu}} \sim \frac{\eta d^2}{f_{c,\mu}};$$

thermal motion due to the internal energy of molecules of a dispersion medium

$$\tau_B \sim \frac{\eta d^3}{kT};$$

inertial motion of particles under external forces

$$\tau_i \sim \frac{\rho_{ef} d^2}{\eta};$$

sedimentation under gravitational forces

$$\tau_s \sim \frac{\eta}{\rho_{ef} d^2 g},$$

where η is the viscosity of the dispersion medium.

The dependences of the inverse relaxation times of various microprocesses on the particle size are shown in Fig. 4. It can be seen that the contribution of each of the actions on particles to τ (and, correspondingly, to $\dot{\varepsilon} = 1/\tau$) changes substantially (by orders of magnitude) with changes in the particle size; correspondingly, the conditions for producing a dynamic state of disperse systems change.

A combination of the factors responsible for a dynamic state of finely disperse colloidal systems, which are classical objects of physical chemistry of disperse systems and surface phenomena, have been studied in most detail.

For such systems, the main characteristic times of microprocesses of a dynamic state are determined by the ratio between $\tau_{fc,\mu}$ and τ_B. For such systems, the contributions of the inertial effects and sedimentation processes are insignificant due to small masses and sizes of particles.

The possibility of formation of dispersed structures or their self-destruction (deaggregation) in the case of colloidal dispersions is determined by the known criterion [3]

$$U_c \sim \frac{\beta^* kT}{(1/2)z}, \tag{21}$$

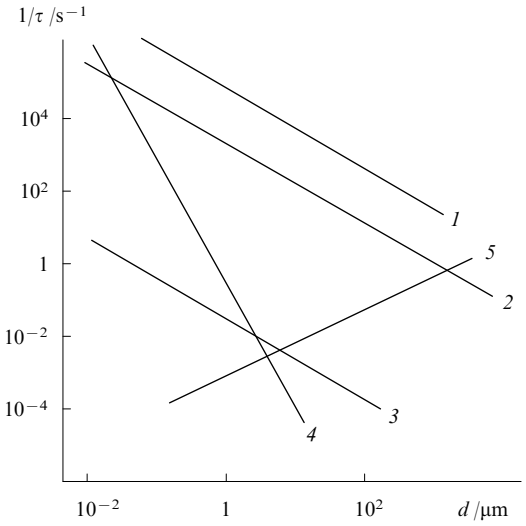

Figure 4. Dependence of the characteristic times of microprocesses on the particle size of a dispersed phase.[9, 30]
(*1*) Inertial effects, (*2*) molecular attraction, (*3*) Coulombic repulsion, (*4*) Brownian motion, (*5*) sedimentation. The results were obtained at $A^* \sim 5 \times 10^{-20}$ J, $\eta \sim 1$ mPa s, $\rho = 2 \times 10^3$ kg m^{-3}.

where U_c is the energy of molecular interactions between the particles in a structural network, β^* is the coefficient

$$\beta^* = \ln \frac{n_a}{n_p},$$

(n_a is the number of particles in the aggregated state, n_p is the number of particles in the deaggregated (peptised) state) and z is the coordination number of particles in a loose aggregate (~ 2).

The coagulation structure in a colloidal disperse system is stable if the energy of molecular interactions between particles is higher than that calculated by Eqn (21). If this energy is lower than the energies of thermal motion and random Brownian oscillations of the particles of dispersed phases, this structure undergoes self-destruction.

In essence, Eqn (21) determines the conditions for the creation of an isotropic dynamic state in colloidal systems. However, if $U_c > (10-15)\,kT$, such systems lose aggregation stability and become also unstable with respect to sedimentation. The dynamic state of such systems loses an isotropic character. When the size of aggregates formed from colloidal particles is larger than 1 μm, the possibility of the creation of a dynamic state under the action of thermal energy of molecular oscillations in a dispersion medium is very low, if at all.

For disperse systems with a particle size larger than 1 μm, the occurrence of an isotropic dynamic state is determined primarily by the relation between $\tau_{fc,\mu}$, τ_i and τ_s.

Based on the above-considered facts, the conditions (criteria) for the attainment of an isotropic dynamic state in disperse systems can be represented in the general form:

for a region of colloidal systems ($d_c < 1$ μm)

$$U_c \geqslant (10-15)\,kT,$$

$$\frac{1}{\tau_B} > \frac{1}{\tau_{f_{c,\mu}}};$$

for a region of microheterogeneous structured disperse systems (1 μm, $< d_c < 100$ μm)

$$E_c = \frac{mV^2}{2} > U_c,$$

$$U_c \sim \frac{k^* d}{h^n},$$

where E_c is the kinetic energy imparted to a particle from an external source of mechanical power, m is the mass of the particle, V is its relative velocity, U_c is the total energy of molecular interactions in contacts between a particle and the adjacent particles, k^* is the constant of molecular interactions between condensed phases, n is the coefficient;

for the region of coarsely disperse systems

$$A > g,$$

where A is an acceleration imparted to a particle from an external source.

Taking into account these criteria, the conditions for the creation of an isotropic dynamic state in structured disperse systems ($\varphi > \varphi_0$ and $d \ll d_c$) are determined by a combination of macroscopic ($\eta_{ef} = \eta_{min}$, where η_{ef} is the effective viscosity) and microscopic parameters.

The conditions for the delivery of energy to a disperse system from an external source depend on the nature of a disperse system. In two-phase systems, such as solid dispersed phase – liquid dispersion medium (pastes, suspensions), liquid – liquid and liquid – gas (foam), the energy is supplied predominantly in the course of their deformation

$$\dot{\varepsilon} = \frac{d\varepsilon}{dt},$$

where $\dot{\varepsilon}$ is the deformation rate, ε is the relative deformation, t is the time. In two-phase systems, such as solid phase – gaseous medium (powders), and three-phase systems, such as solid phase – liquid medium – gaseous medium, the energy is supplied in a combined way by changing both the volume and shape.

However, the choice of the type of action on disperse systems is not limited to only changes in their volume and shape. The determining factor is the possibility of the creation of a controlled isotropic dynamic state in a system under conditions of the chosen type of action.

The main problem in the description of the dynamic state of disperse systems is to reveal the relationship between the contact interactions of the particles of dispersed phases and the bulk properties of the dispersion. For static conditions, this problem was, in essence, solved. The functional relationship between the strength of individual contacts of the particles and the strength of the structure as a whole was found in the context of the theories of strength of dispersed structures. For dynamic conditions, this problem is substantially complicated already because the formation and breaking of individual contacts between the particles occur in non-equilibrium conditions with a simultaneous change in the distance (interspace) between the particles and a manifestation of the hydrodynamic factor associated with leakage of a dispersion medium inside and outside the interspace. Therefore, let us consider the characteristic features of contact interactions between particles of dispersed phases under such conditions prior to analysis of the conditions for the creation of a dynamic state of disperse systems.

2. Dynamics of contact interactions in disperse systems

a. Non-equilibrium as an important feature of the dynamics of contact interactions

To describe the behaviour of most disperse systems in the course of various heterogeneous chemical engineering processes,[41] which proceed under conditions of forced convective diffusion of dispersed phases, as well as of many natural phenomena involving natural disperse systems, it is necessary to go from a consideration of contact interactions in static conditions to non-equilibrium dynamic conditions.

For such processes, a non-equilibrium dynamic state of disperse systems prevails. Interactions between particles to form contacts or, on the contrary, the breaking of contacts can occur at high particle velocities. Therefore, it is incorrect to consider the conditions for their coagulation (breaking of contacts) without regard for the dynamics of their movement toward or away from

each other.† For example, in real heterogeneous processes, $\dot{\varepsilon}$ is as high as 10^2-10^3 s^{-1} under deformation of disperse systems. An analogous situation is observed also when a deformable disperse system is subjected to orthogonally directed oscillation. In the study,[9] it was demonstrated that the relative particle velocities reach 1–1.5 m s^{-1} at the oscillation frequency $f_v = 50$ Hz and the amplitude of $10^{-2}-10^{-3}$ m. The non-equilibrium is even more pronounced in the case of oscillations of polydisperse systems and also in the presence of anisometric particles. As the oscillation frequency increases (particularly, when such dispersions are subjected to low-frequency mechanical oscillation in combination with high-frequency ultrasonic oscillation region), the velocity can substantially exceed 10^3 s^{-1}.

Below are considered the basics of the dynamics of contact interactions predominantly in systems composed of a solid phase and a liquid dispersion medium. The preparation of such dispersions is generally preceded by dynamic processes in solid phase–gas (S–G) systems. In the case of the addition of a liquid medium, the preparation is also preceded by dynamic processes in intermediate solid phase–liquid–gas (S–L–G) systems. Hence, this section of the review deals with certain aspects of the dynamic theory of contact interactions in powders and three-phase systems.

b. Dynamics of contact interactions in two-phase dispersions composed of a solid phase and a liquid dispersion medium

Consideration of the Coulombic component of the disjoining pressure and the slip of a dispersion medium. The solution of problems of dynamic coagulation of particles and, correspondingly, the determination of the conditions for the formation of coagulation contacts are based on calculations of dependences of the force F, which prevents two particles from approaching each other, on the initial velocities, the distance between the particles h and the viscosity of a dispersion medium η.[9–11]

For $h \gg r$ (where r is the particle radius) and the initial velocity V, this force is determined by the equation:

$$F(V,h) = -6\pi\eta r\frac{\mathrm{d}h}{\mathrm{d}t} \equiv \sigma\pi\eta r V. \tag{22}$$

In the case of interaction between two particles in concentrated dispersions, $h \ll r$. Then, taking into account the slip effect of a liquid determined by the coefficient β, the force $F(V,h)$ is given by the expression [9]

$$F(V,h) = \frac{\pi V r^2}{12\beta^2\eta}\left[(h+6\beta\eta)\ln\left(1+6\frac{\beta\eta}{h}\right)-\right.$$
$$\left.-(r+6\beta\eta)\ln\left(1+6\frac{\beta\eta}{r}\right)\right]. \tag{23}$$

In the case of strong slip over the surface of lyophobic particles ($6\beta\eta \gg r$),[47,48] Eqn (23) is simplified

$$F(V,h) = \frac{\pi V r^2}{2\beta}\ln\frac{r}{h}, \tag{24}$$

In the case of weak slip (lyophilic systems, $6\beta\eta \ll r$), $F(V,h)$ is given by the following equation:[9]

$$F(V,h) = \frac{3\pi}{2}\eta\frac{Vr^2}{\beta}. \tag{25}$$

The solution of the problem of inertial coagulation (dynamic conditions) for lyophilic systems in the presence of a high ($U_1 \gg 1$) and low ($U_1 \ll 1$) potential barriers between particles (U_1 is the potential barrier in units of kT) consists in determining the initial critical velocity at which particles approach each other (V_{c_0}), *i.e.*, the maximum velocity above which the particles undergo coagulation,[9]

$$V_{c_0} = V_1\left[\frac{|\ln(A^*kr/12A_0)|}{krA^*/A_0}\right] + V_2\ln\left(12\frac{h_0A_0}{rA^*}\right), \tag{26}$$

where

$$V_1 = \left(\frac{A^*rk'}{6m}\right)^{1/2},$$
$$V_2 = \frac{3}{2}\frac{\pi\eta r^2}{m}, \tag{27}$$

h_0 is the distance between the particle surfaces at the start time ($h_0 \sim r$), m is the effective mass of the particle and k' is the inverse Debye radius.

If the velocity V, at which particles approach each other under an external action, is higher than that calculated by Eqn (26), the particles undergo coagulation.

Analysis of stability in dynamic conditions showed that the Coulombic factor is of importance only in the case of relatively low-intensity external actions. The contribution of this factor decreases, for example, as the deformation rate increases and in the case of deformation of polydisperse systems (particularly, in the presence of strongly anisometric particles). The slip effect of a dispersion medium over the particle surface of a dispersed phase increases substantially as the relative particle velocity increases and the distance between the particles decreases.[9,11–13]

The slip effect is most pronounced when particles with a hydrophobic surface approach each other in a polar liquid.[11] For water, this effect can be attributed, in particular, to the fact that the dipoles of water molecules are parallel to the hydrophobic surface, which substantially facilitates their mobility in the tangential direction and, apparently, decreases the viscosity in a wall boundary layer.[47,48] For example, the slip coefficient β of water relative to hydrophobised quartz can be as high as $\sim 10^{-4}$ m^3 N^{-1} s^{-1} (see Ref. 48). In this case, the contribution of the slip effect is much larger than that for hydrophilic particles. Hence, the corresponding critical velocities will also be substantially different. In the case of weak and strong slip of particles, the critical velocities at which particles approach each other are calculated by the equations [10]

$$V_{c_0} > \frac{9\eta}{4\rho r}\ln\frac{h_2}{h_0}, \tag{28}$$

$$V_{c_0} > \frac{3}{4\beta\rho}\frac{h_0}{r}\gamma, \tag{29}$$

where h_2 is the distance between the particle surfaces at which they are fixed due to dynamic coagulation and γ is the coefficient

$$\gamma = 1 + \ln\frac{r}{h_0}.$$

According to the results of the study,[10] the distance h_2 corresponds to the distance at which the potential energy of interactions between particles has a positive maximum. It should be noted that, due to lyophobic–lyophilic mosaicity of the particle surfaces in real dispersions, the critical coagulation rates are determined by the probability of pair collisions between particles at lyophobic, lyophilic or both lyophobic and lyophilic regions.[49] Taking into account the above three types of collisions, the probability of particle coagulation under dynamic conditions is given by the expression [50]

$$E^* = \alpha(1-\Theta)^2 + \beta^*\Theta + \gamma^*\Theta(1-\Theta), \tag{30}$$

where E^* is the probability of the formation of a bond between two particles, α and β^* are the probabilities of coagulation and

† Strictly speaking, the breaking of a contact even as a result of very slow detachment of particles, *i.e.*, in 'static' conditions, cannot, in essence, be considered as an equilibrium process because the transformation from the 'contact-is-present' state to the 'contact-is-broken' state is accompanied by a series of non-equilibrium phenomena (for example, in a double electrical layer).[42–46]

flocculation, respectively, Θ is the fraction of a modified particle surface, γ^* corresponds to the probability of binding as a result of a contact between a stabiliser immobilised on the surface of one particle and the surface of another particle.

Consideration of the particle shape factor. The consideration of the particle shape is an important problem in the dynamic theory of contact interactions, which was solved in the general case in the studies.[9,10] Below are considered two typical cases. In one of them, the possibility of coagulation of strongly anisometric particles with a very small radius of curvature of the frontal surface (for example, as extended needle-like rods) was taken into account. In another case, the conditions for collision between two disk-like particles in the case of both parallel and 'edge – plane' orientations were considered. The critical rates of dynamic coagulation are expressed by the following equations, respectively:

$$V_{01} = \frac{9\eta}{\rho r_{\max}} \left(\frac{r_1}{r_{\max}}\right)^2, \tag{31}$$

$$V_{02} = 12\frac{\eta}{\rho r_0}\left(\frac{r_2}{r_0}\right)^{1/2} = 12\frac{\eta}{\rho r_{\max}}\left(\frac{3}{2}\right)^{3/4}\left(\frac{r_2}{r_{\max}}\right)^{5/4}, \tag{32}$$

where r_1 is the local radius of curvature of particles of linear size

$$r_{\max} = \left(\frac{3m}{4\pi\rho}\right)^{1/3},$$

m is the mass of particles, ρ is their density, r_0 is the radius of the disk-like particle with thickness $2r_2$, r_2 is the radius of curvature of its frontal surface, $r_2 \ll r_0$. In Eqns (31) and (32), r_1 and $r_2 > 0$.

The plots of the critical coagulation rate *vs*. the particle radius are shown in Fig. 5. It can be seen that the shape factor has a strong effect on the critical coagulation rate. For anisometric particles with a size ratio of 1 : 100, the rate decreases by an order of magnitude. Hydrophobisation of the surface, particularly, of anisometric particles, also leads to a decrease in the critical rate of dynamic coagulation by several orders of magnitude.

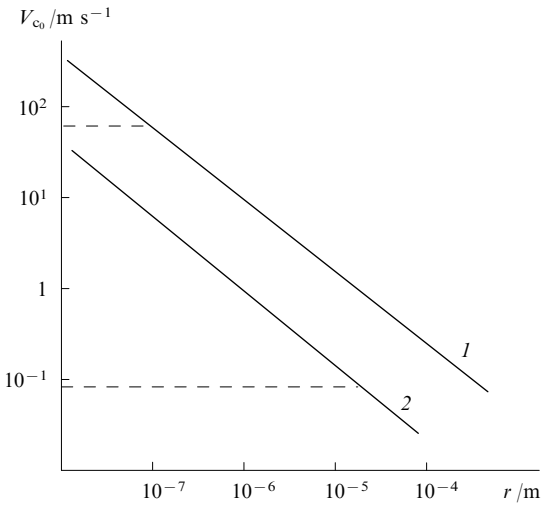

Figure 5. Plots of the coagulation rate *vs*. the particle radius r.[3,10,30] (*1*) For spherical particles ($r = r_0$), (*2*) for anisometric particles ($r_1/r_0 = 0.01$). Dashed lines correspond to particles with a hydrophobic surface.

Role of elastic properties of particles and the structure-mechanical barrier produced by a surfactant adsorption layer. Dynamic particle coagulation is preceded by the approach of the particles to each other accompanied by the displacement of a liquid medium from the interspace between their surfaces. This process is attended by an excess pressure in the interspace and corresponding particle deformation, whose value depends on the outflow rate of the liquid, its viscosity and modulus of elasticity of the particles.[51,52] The contribution of the structural component of the disjoining pressure should be taken into account if the particles are separated by a very small distance ($h_c \sim 2-3$ nm). The range of action of the structural component of the disjoining pressure is $h_c \geqslant 2$ nm.[3,18] For inertial coagulation of particles with a rough surface, the consideration of the roughness leads to an increase in h_c to 100 nm.

As mentioned above, the attainment of the critical coagulation rate V_{c_0} is a prerequisite for the formation of a 'dynamic' contact between particles. If V_{c_0} is higher than a particular value, elastic rebound of particles becomes possible because elastic 'recoil' exceeds the viscous resistance of a liquid to motion. Taking into account this factor, the range of the critical coagulation rates should satisfy the condition determined by the relation

$$\frac{10^2\zeta^2\eta}{\rho r_{\max}} \ll V_{c_0} \ll \frac{10^2\zeta^2\eta}{\rho r_{\max}E}\left(\frac{\eta}{\rho r_{\max}}\right)^2\zeta^4\left[\frac{1}{\zeta}\left(\frac{r_{\max}}{h_c}\right)^5\right]^{4/7}. \tag{33}$$

Here, $\zeta = r_1/r_{\max}$ and E is the modulus of elasticity of the particles. Inertial coagulation of particles under dynamic conditions can take place only in a particular range of the rates V_{c_0}, which depends on the elastic properties, the shape (the degree of anisometry), the density of the particles and the liquid viscosity.

The conditions of aggregation dynamic stability are substantially influenced by the presence of a surfactant adsorption layer on the particle surface and the properties of this layer, *viz*., the binding energy with the particle surface, the elasticity and the degree of lyophilicity of radicals exposed to a dispersion medium. The criterion for loss of aggregation stability under dynamic conditions in the presence of a surfactant adsorption layer on the particle surface can be expressed by the following equation:

$$V_{c_0}^2 - 9\frac{\eta}{\rho r_{\max}}\left(\frac{r}{r_{\max}}\right)^2\lambda^*\ln\left(\frac{h_0}{L}\right)V_{c_0} - \frac{E_L}{2\rho}\left(\frac{L}{r_{\max}}\right)^2\frac{r}{r_{\max}}(\lambda^*)^2\left(\frac{P_L}{E_L}\right)^3 > 0, \tag{34}$$

where r is the local radius of curvature of the particle surface with a surfactant adsorption layer, λ^* is the particle shape coefficient, L is the thickness of the surfactant adsorption layer, P_L and E_L are the strength and the modulus of elasticity of this layer, respectively.

The structure-mechanical barrier is an essential factor of aggregation dynamic stability of a system, if

$$E_L > E_{L_c} \equiv \left(\frac{E_L}{P_L}\right)^3 2\rho\left(\frac{r}{r_{\max}}\right)^3\left(\frac{r_{\max}^2}{L}\right)\left(9\rho\frac{\eta}{r_{\max}}\ln\frac{h_0}{L}\right)^2, \tag{35}$$

where E_{L_c} corresponds to the critical modulus of elasticity, below which a 'breakdown' of the adsorption layer is possible.

c. Aspects of dynamics of contact interactions in finely dispersed powders

A knowledge of the parameters of formation and breaking of direct (according to Rehbinder [1]) contacts between particles under dynamic conditions is necessary for the description of the macrorheological characteristics and properties of powders in processes of flow, compaction or creation of an air-boiling or vibroboiling layer.[53–55]

Contact interactions between particles of solid phases in air and various media under static conditions have been studied extensively (see, for example, Refs 3, 15–17 and 56). The extension of the views of contact interactions, which are based on results of static measurements, to dynamic conditions appeared to be incorrect for dynamic actions on dispersed powders.[9] In particular, this follows from the dependence of the work of detachment on the detachment rate of contacting solid phases.[57–59] The differences in the works of detachment in static and dynamic conditions can be as high as two or even more orders of magnitude. The available methods (even their advanced mod-

ifications) for high-precision measurements of the cohesive forces in contacts allow one to take into account the influence of the detachment rate only at very low values of the latter, which differ from the real values corresponding to conditions of flow, boiling or compaction of powders by several orders of magnitude.

In this connection, approaches were developed,[58–62] which enable one to determine the strength and energy of interactions between particles from the results of dynamic (vibration) measurements with the use of apparatus and methods described in the studies.[58, 59, 61, 62] These approaches involve measurements of the structural and rheological properties of powders (effective shear stresses and viscosities) in the course of compaction or transformation of a powder from the vibrofluidisation state to the vibroboiling state accompanied by breaking of contacts between particles. The developed theory of this process allows one to calculate the energy and strength of interparticle interactions from the results of rheological measurements under vibration.

Equations derived in the studies [58, 61] can be used for determining the characteristics of contact interactions under vibration in powders with the rigorously characterised parameters of the particles (monodispersed spherical particles). As an example, let us give one of these formulas

$$f_{cv}C_v = \frac{\pi a^2 \omega \eta_v^0}{\zeta^*(r^{*2} - r_1^2)\ln(r_2^*/r_1^*)}\,. \tag{36}$$

Here, f_{cv} is the average autohesive force in the contact under dynamic conditions, C_v is the number of autohesive contacts per unit volume in the vibroboiling state, a and ω are the amplitude and circular frequency of vibrations, respectively, r_1^* and r_2^* are the radii of coaxial cylinders of a viscosimeter, ζ^* is the distance of autohesion, whose minimum value is 0.4 nm, η_v^0 is the largest value of the effective vibroviscosity [59] determined by extrapolating the rate of shear deformation to $\dot{\varepsilon} \to 0$.

Calculations using Eqn (36) demonstrated that the cohesive forces under dynamic conditions depend on the rate and acceleration of vibrations. For a number of polymer powders [poly(vinyl chloride), Fluoroplast, polyethylene] in dynamic conditions, f_{cv} is 2–4 orders of magnitude larger than f_c determined in static measurements on an adhesiometer.[15, 16] For glassy particles, these forces differ by no more than a factor of 6–7 (Table 2). The disagreement between the results of static and dynamic measurements increases as the detachment rate of particles increases.

Table 2. Autohesive characteristics of powders in static (f_c) and dynamic (f_{cv}) conditions (at the harmonic vibrational frequency of 200 Hz).

Powder	$\bar{d}$ /μm	$10^8 f_c$ /N	η_k /Pa s	f_{cv} /N
Ion-exchange resin KB-4P2	250	40	–	–
Polystyrene	50	100	40	2×10^{-3}
Poly(vinyl chloride)	20	4	10	3×10^{-3}
Glass	10	30	20	2×10^{-6}
Fluoroplast F30P	5	5	10	9×10^{-5}
Polyethylene	5	2	3	1×10^{-4}

Upon elimination of physicochemical inhomogeneity (lyophilic–lyophobic mosaicity) due to formation of a saturated adsorption monolayer of a surfactant on the particle surface, the cohesive forces in contacts between particles not only sharply decrease (because the particles move away from each other to a distance equal to twice the thickness of the hydrocarbon fragment of the surfactant molecule) but also become virtually independent of the prehistory of the structure formation of a finely dispersed powder (Table 3). Correspondingly, the autohesion level in contacts between particles changes.

To describe the macrorheological and mechanical properties of finely dispersed powders,[62, 63] one should use the characteristics of autohesion determined not in static (as is often the case) but in adequate dynamic conditions.

Table 3. Autohesive forces in contacts between particles of SiO_2 and $CaCO_3$ powders.

φ	$f_{c1}/10^{-5}$ N (without surfactants)	$f_{c2}/10^{-5}$ N (surfactant monolayer)	f_{c1}/f_{c2}
Powder of SiO_2 ($s = 1\times10^3$ m^2 kg^{-1}), surfactant — octadecylamine			
0.45	6.8	2.61	2.6
0.5	22.5	2.25	10.0
0.536	114.0	2.86	40.0
Powder of $CaCO_3$ ($s = 3\times10^3$ m^2 kg^{-1}), surfactant — stearic acid			
0.3	0.645	0.55	1.26
0.35	1.22	0.425	2.88
0.38	1.93	0.48	4.0

Note. Specific surfaces (s) were determined by low-temperature adsorption of nitrogen [Brunauer–Emmett–Teller (BET) method].

d. Dynamics of contact interactions in three-phase systems

The formation of three-phase structures under dynamic conditions in the course of their transformation into two-phase S–L systems (in particular, under conditions of mixing under vibration) proceeds as follows.

Contacts between solid-phase particles in powders are the first to be broken,[62, 63] then a liquid dispersion medium penetrates between the particles [62] to form microgranules, which act as kinetic units. The final step of this process involves association ('coalescence') of granules upon their collisions accompanied by the transformation of the disperse S–L–G system into the S–L system. Let us consider the kinetics of this process.

The structure in a powder is destroyed under vibration if the following condition is fulfilled:

$$a\omega^2 \geqslant \frac{f_c}{\rho d^3}\,, \tag{37}$$

where ρ and d are the density and diameter of the particles, respectively.

If a liquid medium penetrates into a vibroboiling layer consisting of powder particles and wets their surface,[64, 65] a capillary meniscus appears [15] and a granular structure forms. Subsequent interactions between the granules can lead to either their coalescence or recoil.

It can be assumed that the average kinetic energy produced by collisions between granules is determined by the equation

$$\overline{E}_a = D^3\rho_a\left[\overline{(V_a + a\omega\cos\omega t)^2 - V_a^2}\right] \sim D^3\rho_a(a\omega)^2, \tag{38}$$

where D is the diameter of granules, ρ_a is their density, V_a is the granule velocity prior to collisions, the overline denotes the averaging over time.

'Coalescence' of granules occurs if the energy determined by Eqn (38) is smaller than the energy required for the rupture of the meniscus formed between the granules. The energy required for breaking of the contact between two granules linked through a capillary meniscus is equal to $D^2\sigma$, where σ is the surface tension of the liquid phase. From this, the first condition for coalescence of granules can be obtained

$$D \leqslant \frac{\sigma}{\rho_a(a\omega)^2}\,. \tag{39}$$

This inequality determines the condition for cohesion of not-too-large granules (or individual particles), whose collisions can be considered as purely elastic. As the granules grow, their rheological properties become increasingly important. The condition for 'coalescence' of large granules can be obtained by comparing the collision time t of elastic spheres with diameter D (see Ref. 66) and the time of stress relaxation in the granule τ

$$t \sim \frac{D}{C_1^*}\left(\frac{C^*}{V}\right)^{1/5}, \qquad (40)$$

$$\tau \sim \frac{\eta_a}{E_a},$$

where

$$C_1^* \equiv \left(\frac{E_a}{\rho_a}\right)^{1/2},$$

V is the vibrational rate, η_a is the viscosity of the granule, E_a is the modulus of elasticity of the granules.

From this, it follows that the second condition for 'coalescence' of granules is described by the relation

$$D > \eta_a\left(\frac{V}{\rho_a^2 E_a^3}\right)^{1/5}. \qquad (41)$$

By comparing Eqns (39) and (41) on the assumption that $V \sim a\omega$, the following condition, which provides association of the particles to form granules and their subsequent growth, can be written as

$$a\omega < (C_1^*)^{6/11}(C_2^*)^{5/11}, \qquad (42)$$

where

$$C_2^* = \frac{\sigma}{\eta_a}.$$

In simplified form, Eqn (42) can be written as follows:

$$a\omega \leqslant (C_1^* C_2^*)^{1/2} \equiv \left[\frac{\sigma}{\eta_a}\left(\frac{E_a}{\rho_a}\right)^{1/2}\right]^{1/2}. \qquad (43)$$

Conditions (37) and (42) define the range of vibrational rates at which the 'old' S–G structure is destroyed and the 'new' S–L structure is formed in the system:

$$\frac{f_c}{\omega\rho d^3} \leqslant a\omega \leqslant \left[\left(\frac{E_a}{\rho}\right)^{1/2}\left(\frac{\sigma}{\eta_a}\right)\right]^{1/2}. \qquad (44)$$

Hence, in particular, it follows that this range of rates $a\omega$ exists only under high-frequency vibrations.

It should be noted that Eqn (44) was derived on the assumption that the S–G structure is completely destroyed (up to primary particles). However, this process occurs rarely in real highly disperse systems ($d \sim 1$ μm). Therefore, the size of the microaggregates D and their cohesive force F_c should be substituted for d and f_c, respectively, into expressions (37) and (44). In this case, expression (44) takes the form

$$\frac{F_c}{\omega\rho_a D^3} \leqslant a\omega \leqslant \left[\frac{\sigma}{\eta_a}\left(\frac{E_a}{\rho_a}\right)^{1/2}\right]^{1/2}. \qquad (45)$$

In particular, from this it follows that this rate range exists at a relatively high frequency of vibrations, whose value can be calculated by the formula

$$\omega \geqslant \frac{F_c}{\rho_a D^3}\left[\frac{\eta_a}{\sigma}\left(\frac{\rho_a}{E_a}\right)^{1/2}\right]^{1/2}. \qquad (46)$$

As an example, let us consider a model system consisting of a quartz powder ($d \approx 1$ μm) and calcium bentonite serving as a binder. At $A^* \approx 10^{-20}$ J and $h_1 \sim 10^{-8}$ mm, the binding force f_c of particles is $\approx 10^{-11}$ N. Assuming that the modulus of elasticity of granules is of the same order of magnitude as their strength, E_a is taken to be approximately 10^6 N m^{-2}. The viscosity of granules is close to that of the structure formed upon their 'coalescence' $\eta_a \approx 10^2$ Pa s, $\sigma \approx 0.1$ N m^{-1}. Let us assume that the size of inhomogeneities in the structure after granule coalescence is no larger that 30 μm. According to Eqn (46), the minimum vibrational frequency providing the formation of this structure is higher than 100 Hz. From this it follows that the allowable vibrational rate at which an S–L–G system is transformed into an S–L system is ~ 1 m s^{-1}, which is consistent with the experimental data.[2]

All the above have the following important consequences.

The energies and strength of contact interactions between particles in dynamic conditions differ substantially (in some cases, by several orders of magnitude) from the corresponding values measured or calculated in static conditions. This difference depends on the chemical nature and physical properties of dispersed phases and the intensity of external mechanical actions on disperse systems.

The inertial effects and hydrodynamic resistance of a medium[66] as well as the particle shape and lyophobic–lyophilic mosaicity of the particle surface are important factors determining the critical parameters corresponding to conditions of formation or breaking of contacts between particles in liquid media.

Under dynamic conditions, the structure-mechanical barrier (according to Rehbinder) formed by surfactant adsorption layers on the particle surface and the properties of these layers play an essential role in achieving dynamic aggregation stability of dispersions. Micelles in solutions of surfactants can serve an analogous function.[67]

In the case of finely dispersed powders, the energy and strength of interparticle interactions depend substantially on the intensity of external actions.

The dynamics of contact interactions in three-phase disperse systems is determined by a combination of complex processes of formation and breaking of coagulation and direct point contacts between particles, capillary meniscuses between the aggregates and their structural and mechanical properties.

At the same time, the kinetics of structure formation under dynamic conditions and the properties of the resulting structures also depend on the intensity of external actions, in particular, on the frequency and amplitude of oscillations.

3. Dynamic state of two-phase disperse systems of the solid phase – liquid medium type under continuous shear

The method most commonly used for describing the properties of S–L structured disperse systems under continuous shear deformation consists in constructing complete rheological flow curves.[68–73] These curves characterise the dependence of the effective shear viscosity η_{ef} on the shear rate $\dot{\varepsilon}$ or the shear stress P under the necessary condition of isotropic destruction‡ of a dispersion located in the interspace between the surfaces of coaxial cylinders or in a measuring cell of rotational viscosimeters. It is assumed that the shear at a given rate is extended throughout the interspace (or throughout the cell),[69,74] thus providing the isotropic character of destruction.

The complete flow curve of structured dispersions with viscosity drop $\eta_{ef} = f(\dot{\varepsilon},P)$ of up to 8–10 orders of magnitude on the assumption that the above conditions are fulfilled, *i.e.*, under purely homogeneous shear (according to Rehbinder), was first reported in the study.[75] The authors of the cited study introduced the notions of the highest viscosity of a virtually non-destroyed structure (η_0), which corresponds to the upper plateau in the flow curve, and the lowest Newtonian viscosity of an ultimately destroyed structure (η_{min} or η_∞).

‡ For the same degree of destruction in the bulk of the disperse system under consideration.

It was assumed that each level of the measured effective viscosity corresponds to a particular equilibrium level of isotropic destruction characterised by a certain ratio between the broken and acting coagulation contacts between particles of dispersed phases.

Consequently, the minimum level of the lowest Newtonian viscosity and, accordingly, the maximum fluidity should correspond to the limiting isotropic dynamic state. This interpretation of the flow mechanism of structured dispersions under continuous shear was embodied in studies of the rheological properties of various disperse systems.[68, 69, 71, 74] These notions were developed, primarily, by elaborating the idea of the aggregation (cluster) mechanism of destruction with complete deaggregation at $\eta_{ef} = \eta_{min}$ (Refs 76–81) as well as by introducing Krieger's correction (d^3/kT),[82] which takes into account the contribution of Brownian motion. This contribution is essential for dispersions containing particles of characteristic size $\ll 1$ μm (Fig. 6).

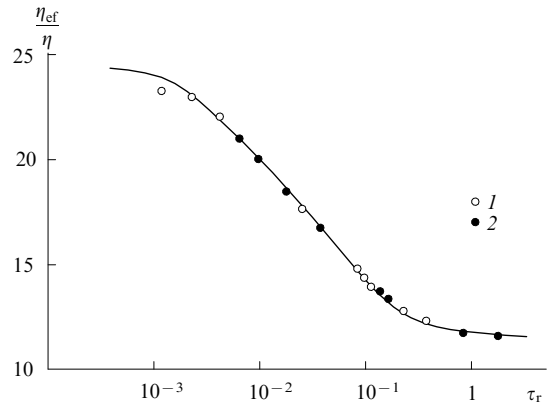

Figure 6. Plot of the relative viscosity *vs*. the effective shear stress τ_r for a suspension of polystyrene particles taking into account Krieger's correction.[82]
(*1*) In benzyl alcohol, (*2*) in cresol.

According to these views, the flow mechanism of structured dispersions as successive destruction under the action of the increasing shear rate $0 < \dot{\varepsilon} < \dot{\varepsilon}_\infty$ (or increasing shear stress P) is as follows: breaking of the bonds followed by their virtually complete recovery in a flow ($\eta_{ef} \approx \eta_0$ with $\dot{\varepsilon} \to 0$), destruction first into superaggregates and then into aggregates with the possible formation of new aggregates through inertial coagulation (at $\eta_\infty < \eta_{ef} < \eta_0$ and $0 < \dot{\varepsilon} < \dot{\varepsilon}_\infty$) and, finally, complete deaggregation at $\eta_{ef} \approx \eta_{min}$ and $\dot{\varepsilon} \geqslant \dot{\varepsilon}_\infty$.

The known flow theories involving this mechanism can be arbitrarily divided into two groups.[30, 76] The theories of one group are based on the concept of the 'average field',[77, 78] which assumes that particles linked in poorly deformable spherical aggregates exist in a homogeneous medium with viscosity η_i. These theories are applicable primarily to dilute and moderately concentrated structured dispersions.

The effective viscosity of thixotropic systems can be estimated according to the equation [9, 30]

$$\frac{\eta_{ef}}{\eta_1} = 1 + \frac{1}{\eta_{ef}/\eta_2 + (\dot{\varepsilon}\tau)^n}, \tag{47}$$

where $\eta_1 \equiv \eta_{ef}(\dot{\varepsilon} \to 0)$, τ is the relaxation time of the major process of interactions between particles through surface forces

$$\tau = \frac{\eta_1 d^2}{f_c},$$

the exponent n depends on the type of the structural model (for weakly aggregated systems, $n \sim 1/2$).

The results of calculations using Eqn (47) and by analogous expressions [71, 83–86] are in good agreement with the experimental data for monodisperse suspensions containing spherical particles, if their concentration (φ) is lower than 60% (this concentration corresponds to a random cubic packing φ_c). For dispersions with $\varphi \sim \varphi_c$ and $\varphi > \varphi_c$, the calculated data differ substantially from the experimental results, and these differences increase with $\dot{\varepsilon} \to 0$, *i.e*., as the highest viscosity of the virtually non-destroyed structure (according to Rehbinder) is approached.

For structured dispersions, this viscosity level $\eta_{ef} \sim \eta_0$ is adequately described in a broad concentration range ($\varphi < \varphi_c$) relying on the concepts of the quasi-crystalline character of the structure on the assumption of its continuity.[87–89] In the general form, this viscosity level is determined by the equation [87]

$$\frac{\eta_{ef}}{\eta_1} \sim C_1 \exp\left[\frac{h}{d}\left(\frac{\tau_B}{\tau_{f_c}} - \frac{\tau_B P}{\eta_1}\right)\right], \tag{48}$$

where

$$C_1 \equiv \lambda\left(\frac{d\tau_1}{h\tau_{f_c}}\right)^{1/2},$$

$$\lambda \equiv \left\{1 + \left[\frac{d}{h}\left(\frac{\eta_0}{\tau_i}\right)^2 \frac{\tau_{f_c}}{\tau_i}\right]^2\right\}^{1/2} - \frac{d}{h}\left(\frac{\eta_0}{\eta_1}\right)^2 \frac{\tau_{f_c}}{\tau_i}. \tag{48a}$$

Here, τ_B, τ_{fc} and τ_i are the characteristic times of the corresponding microprocesses (see above), h is the distance between the particle surfaces in the quasi-lattice, $\eta_1 = \eta$ at $\varphi = 0$.

If $h = d$, this equation is transformed into the expression reported in the studies.[88, 89] It should be noted that at $\eta_{ef} \sim \eta_0$, the general expression (48) and its special analogues (see Refs 87 and 89) provide a satisfactory description of the dependence $\eta_{ef}(\dot{\varepsilon})$ with $\dot{\varepsilon} \to 0$ regardless of the concentration, whereas at $\dot{\varepsilon} > 0$, the deviation of the theoretical curve described by Eqn (47) from the experimental data increases with increasing φ. As $\dot{\varepsilon}$ and φ increase, the $\Delta\eta_{ef}/\Delta\dot{\varepsilon}$ ratio sharply increases. This fact is taken into account in the theory developed in the studies.[30, 62] According to this theory, the effective viscosity depends on the rate as follows:

$$\frac{\eta_{ef}}{\eta_1} \sim \frac{1}{(\tau\dot{\varepsilon})^n}. \tag{49}$$

This formula describes satisfactorily all steps of destruction of an aggregated suspension with increasing $\dot{\varepsilon}$ (or P), which was confirmed by comparing the calculated and experimental data for dispersions formed by monodispersed particles of poly(methyl methacrylate) in decalin stabilised by a monolayer of dihydrostearic acid (Fig. 7, curve *1*). Each step of destruction has a particular prevailing characteristic time of a microprocess τ and the corresponding Debora number [30, 62, 76]

$$D^* = \dot{\varepsilon}\tau.$$

For the region A in Fig. 7 (curve *1*),

$$\eta_{ef} \sim \eta_0,\ \dot{\varepsilon} < \frac{1}{\tau_\mu \exp(-\tau_B/\tau_\mu)},\ D^* \sim \dot{\varepsilon}\tau_B,\ \dot{\varepsilon}\tau_\mu.$$

For the region B corresponding to destruction into superaggregates,

$$\eta_{ef} < \eta_0,\ \frac{\eta_{ef}}{\eta_1} \sim \frac{1}{(\dot{\varepsilon}\tau_B)^{3/5}};\ \frac{1}{\tau_\mu} \ll \dot{\varepsilon} \ll \frac{1}{\tau_B};\ D^* \sim \dot{\varepsilon}\tau_B,\ D^* = \dot{\varepsilon}\tau_{f_c}.$$

For the region C corresponding to destruction of superaggregates into aggregates,

$$\eta_{ef} \ll \eta_0,\ \frac{\eta_{ef}}{\eta_1} \sim \frac{1}{(\dot{\varepsilon}\tau_B)^{1/2}};\ \frac{1}{\tau} \ll \dot{\varepsilon} \ll \frac{1}{\tau_\mu},\ D^* = \dot{\varepsilon}\tau_\mu.$$

For the region D corresponding to complete deaggregation,

$$\eta_{ef} \sim \eta_1\left(\frac{1}{\tau_B}, \frac{1}{\tau_\mu} \ll \dot{\varepsilon} \ll \frac{1}{\tau_1}\right);\ D^* \sim \dot{\varepsilon}\tau_i.$$

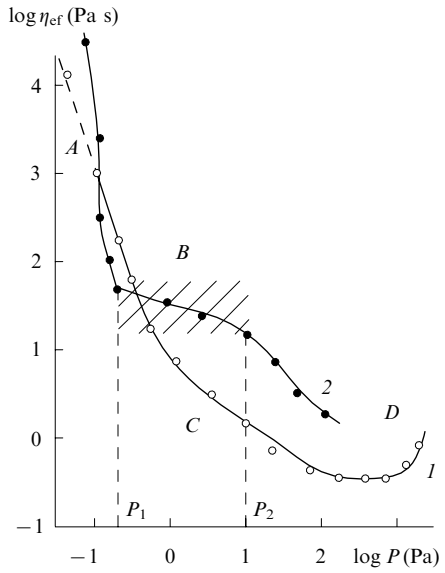

Figure 7. Complete flow curve of a suspension of poly(methyl methacrylate) in decalin.[68]
The solid curve represents the results of calculations by Eqn (49), the points correspond to the experimental values; the concentration of the suspension (%): (*1*) 59.5, (*2*) 60.1; the portion of the flow curve corresponding to a plateau, which is not exactly reproduced, is dashed.

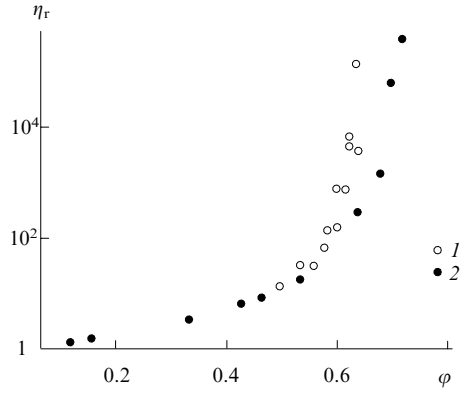

Figure 8. Dependence of the relative viscosity η_r on the concentration of a dispersed phase [monodispersed particles with a diameter of 129 (*1*) and 84 nm (*2*) of poly(methyl methacrylate) in decalin].[69]

Finally, in going to the dilatancy region accompanied by percolation of an adsorption layer,

$$\frac{\eta_{ef}}{\eta_1} \sim \dot{\varepsilon}\tau_i,\ \dot{\varepsilon} \gg \frac{1}{\tau_i},\ P > \frac{r^* h_i}{d^2} P_L\ ,$$

where r^* is the local radius of curvature in the zone of contacts between particles with diameter d, h_i is the thickness of the adsorption layer on their surface, P_L is the strength of the adsorption layer.

Therefore, for lyophilic disperse systems formed by monodispersed spherical particles at a concentration $\varphi < \varphi_c$, destruction of a coagulation structure is isotropic in character; at $\dot{\varepsilon} \sim \dot{\varepsilon}_\infty$, complete deaggregation and the corresponding limiting isotropic dynamic state with maximum fluidity are achieved.

When creating a controlled isotropic dynamic state in dispersions under continuous shear deformation, it should be taken into account that flow curves are completely reversible. The reversibility was confirmed by the fact that the effective viscosity levels and the corresponding degrees of isotropic destruction depending on $\dot{\varepsilon}$ and P throughout the range of their changes in rheological measurements are the same irrespective of whether these levels are attained with increasing or decreasing $\dot{\varepsilon}$ and P (*i.e.*, when moving in upward or downward directions). This indicates that rheological flow curves obtained under purely homogeneous shear are completely reversible.

However, in attempting to construct flow curves for the same systems at concentrations $\varphi > \varphi_c$ (*i.e.*, at $\varphi > 60\%$) in compliance with all the above-mentioned conditions and, correspondingly, to use Eqn (49) for their theoretical description, it was found that the calculated data differ substantially from the experimental results and the flow curves, which were measured in upward and downward directions (see Fig. 7, curve *2*), were poorly reproduced. The degree of these deviations, which is manifested in the presence of a plateau in the flow curve $\eta_{ef} = f(P)$, increases as φ increases in the region $\varphi > \varphi_c$.[89,90]

Such plateaus in the flow curves were found, in particular, in the studies.[71,90] However, the reasons for their appearance were considered to be an artefact[91] or were not discussed at all. The fact that the flow curves are irreproducible in the plateau region is unambiguously indicative of the violation of the isotropic character of a dispersion flow in this region.

At the same time, analysis of theoretical dependences of the strength of a dispersed structure on its porosity (see Fig. 2)[23,24] and experimental data[92,93] on the dependence of the relative viscosity on the effective concentration of a dispersed phase for monodispersed spherical particles of poly(methyl methacrylate) in decalin (Fig. 8) demonstrated that the region $\varphi = \varphi_c \approx 60\%$ corresponds to the onset of a sharp increase in the strength and viscosity with increasing φ. It is this limit, where the inhomogeneity of the structure becomes observable.

An analogous phenomenon, which takes place in going to the region $\varphi \geqslant \varphi_c$, was reported in monograph.[94] Apparently, the authors of the cited monograph were the first to interpret the anomaly of the flow process, which is characterised by a sharp jump (drop) of the shear stress P when its critical value is reached with increasing $\dot{\varepsilon}$, and an ambiguous dependence of the viscosity on the shear stress as a consequence of the appearance of local discontinuity.

This phenomenon, its possible variations and reasons for its occurrence both in well-characterised disperse systems and systems formed by polydispersed (in some cases, anisometric) particles of dispersed phases in liquid media were analysed in-depth.[2,76]

The interpretation assuming discontinuity at $\varphi > \varphi_c$ is supported by the results of studies of dispersions formed by monodispersed spherical particles with lyophilic surfaces (see, for example, Refs 90, 91 and 95).

The theoretical description of this phenomenon[30,62,68] was based on the comparison of the following three relaxation times of the processes, which together determine the discontinuity condition: τ_1, the time of elastic energy release under deformation; τ_2, the time of formation of a new surface due to the development of a macroscopic crack, *i.e.*, a slip zone with an inhomogeneous structure; τ_3, the time of mass transfer to the discontinuity zone as a result of vacancy drift, *i.e.*, the time of the possible 'healing' of the structure under shear deformation.

The structural discontinuity occurs if the following inequality is fulfilled:

$$\frac{1}{\tau_1} \gg \frac{1}{\tau_2} + \frac{1}{\tau_3}\ . \tag{50}$$

The discontinuity can take place in a broad range limited by the initial (P_1) and final (P_2) shear stresses

$$P_1 \sim P_c \left(\frac{d}{\varepsilon_i}\right)^{1/2},$$

$$P_2 \sim P_c - \frac{d\eta}{h\tau_B} \ln \frac{d}{\lambda h}, \quad (51)$$

where P_c is the flow limit of a disperse system, ε_i is the size of the structure inhomogeneity, λ is the parameter determined from Eqn (48a) and h is the average distance between the particles in the structure.

From a comparison of the available experimental[90,91] and calculated[30,90,91] data, it follows that a change from $\varphi = 59\% - 60\%$ to higher concentrations is accompanied by substantial changes in the flow mechanism of dispersions. The threshold concentration corresponds to a random cubic packing,[27,28] in the case of which the flow of a dispersion consisting of monodispersed spherical particles is isotropic in character under conditions of purely homogeneous shear. However, at concentrations higher than this threshold value, islands, *viz*., elements with a denser hexagonal packing, appear inside dispersions with a random cubic packing. As φ increases in the region $\varphi > 60\%$, the concentration of such islands increases, which is equivalent to the appearance and an increase in the number of inhomogeneity elements of the structure. Their coalescence gives rise to macroinhomogeneities, when a particular critical concentration is reached in the course of deformation. Apparently, a concentration jump in the vicinity of macroinhomogeneity boundaries is responsible for the appearance of local slip zones, which are equivalent to discontinuity, under shear in the range $P_1 \leqslant P_i \leqslant P_2$. The higher the concentration of a dispersed phase in a dispersion medium at $\varphi > \varphi_c$, the higher is the probability of this flow mechanism.

This mechanism of formation and development of discontinuities was confirmed in a computer simulation of the behaviour of an ensemble of monodispersed spherical particles in a Newtonian liquid under shear (Fig. 9).

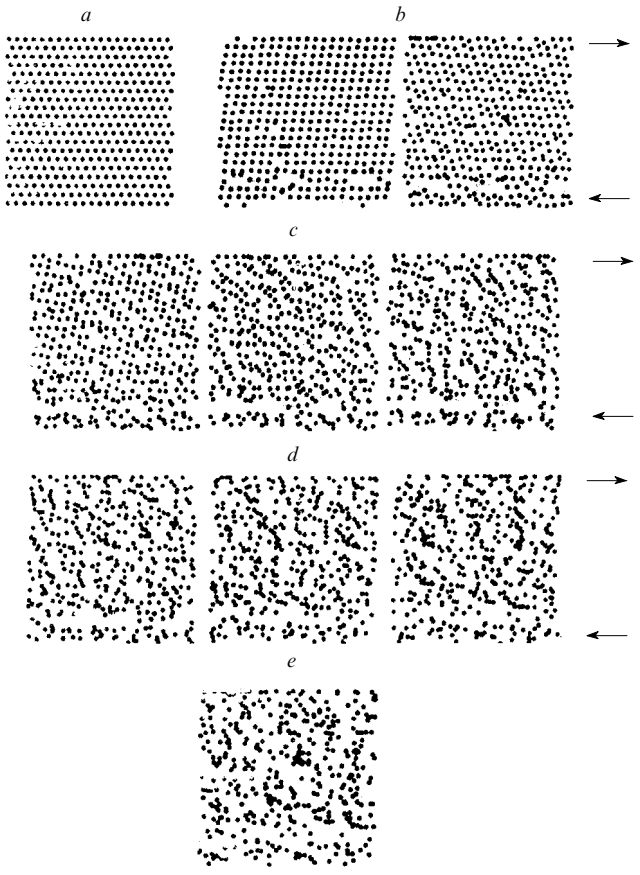

Figure 9. Results of computer simulation of the flow process for suspensions of monodispersed quartz particles with a diameter of 1 μm in water with discontinuity[96] in static conditions (*a*) and under continuous shear at different rates (*b*–*e*).
$\dot{\varepsilon}$ /s^{-1}: (*b*) 10^{-1}, (*c*) 50, (*d*) 100, (*e*) 150.

It can be assumed that this flow mechanism is even more probable for real disperse systems containing polydispersed and anisometric particles, because there are more possibilities for a local increase in the concentration of a dispersed phase in a dispersion medium, particularly, on going to $\varphi > \varphi_c$. This was shown by analysis of the complete rheological flow curve of aqueous dispersions of bentonite at a concentration $\varphi = 20\%$ (for this system, it is higher than φ_c).

The S-shaped flow curve shown in Fig. 10 *a* illustrates an ambiguous dependence of the viscosity η_{ef} on the shear stress P. Such a curve is characteristic of structured dispersions, whose deformation is accompanied by discontinuities.[76]

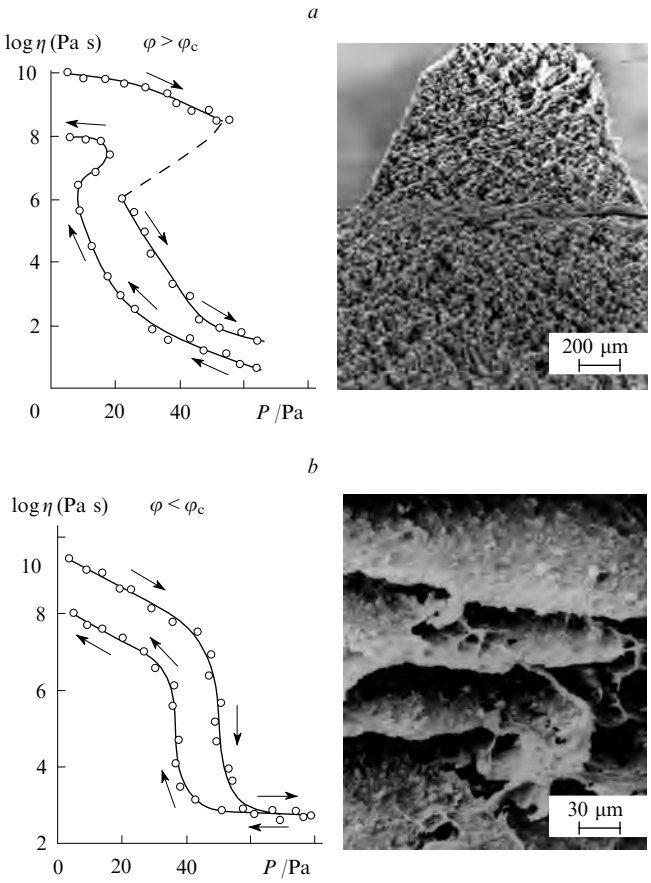

Figure 10. Complete rheological flow curves for aqueous dispersions of calcium bentonite (S_{BET} = 70 m^2 g^{-1}).[68,76]
(*a*) For a system with $\varphi = 20\%$ ($\varphi > \varphi_c$), (*b*) for a system with $\varphi = 11\%$ ($\varphi < \varphi_c$). Solid and dashed lines represent the results of measurements under increasing and decreasing shear stress, respectively; scanning electron micrographs were taken using a specially designed procedure.[62,95]

The hypothesis of discontinuity is supported by photomicrographs taken in the course of deformation of these dispersions (to the right of Fig. 10 *a*,*b*). It can be seen that the discontinuity is developed inside the structure subjected to deformation ($\varphi > \varphi_c$). Its appearance and subsequent development under shear deformation excludes shear propagation in the bulk of the structure outside the discontinuity zone.

All subsequent measurements at an increasing shear rate lead to complete violation of the isotropic character of destruction and a distortion of the results of measurements. Hence, it is impossible to construct flow curves under continuous shear. This is confirmed also by the fact that the flow curves measured in downward and upward directions are irreproducible.

The measured shear stress describes, in essence, only friction between layers bounded by discontinuity zones and the possible partial destruction in the regions adjacent to the discontinuity surfaces.

Taking into account the above notions, it could be assumed that the bulk character of destructions without discontinuities would be observed at lower concentrations of a dispersed phase in the region $\varphi < \varphi_c$. This assumption is supported by the shape of the flow curve of a dispersion at $\varphi = 11\%$, which reflects an unambiguous dependence of η_{ef} on P (Fig. 10*b*). However, the photomicrographs of the structure (to the right of Fig. 10*b*) are indicative of the opposite phenomenon: the appearance of not one (like at $\varphi > \varphi_c$), but even numerous discontinuities with the formation of periodically repeating dense structured layers, which are oriented along the shear direction and are separated by a dispersion medium. It should be noted that the concentration of a dispersed phase in these layers is as high as 60%, *i.e.*, is several times higher than the volume-average concentration before deformation (11%). Correspondingly, the strength and viscosity of the structure should increase many-fold [see Eqns (19) and (20); Figs 2 and 8]. The flow curves for the same compositions as those reported in the studies [1, 75] were reproduced in experiments.

The possible mechanism of such a sharp increase in the density of a structure in solid-like layers is associated with the effect of inertial coagulation of anisometric particles, the probability of which increases as the rate of movement of the layers with respect to each other increases [see Eqns (28) – (32)].

As mentioned above, the critical rate of inertial coagulation for anisometric particles can be many times lower than that for spherical particles. This is also favoured by the slip of a liquid with respect to the particle surface,[48] which was taken into account in the study.[12]

Therefore, inertial coagulation can give rise to structures stable to an extent that they cannot be destroyed even at high shear rates corresponding to $\dot{\varepsilon}_\infty$. This becomes even more favourable if the particle surfaces have lyophobic regions with a small radius of curvature, at which selective inertial coagulation with fixation of particles in the short-range potential well is substantially facilitated.[50]

Consequently, the commonly accepted notions of the attainment of the lowest viscosity level of an 'ultimately destroyed structure' $\eta_{ef} \approx \eta_{min}$ at $\dot{\varepsilon} \to \dot{\varepsilon}_\infty$ (see Refs 1, 75 and 97) can be assigned not to the structure as a whole but only to low-concentration (in essence, structureless) layers oriented along the shear direction. Moreover, it can be assumed that it is this portion of the flow curve corresponding to $\eta_{ef} \approx \eta_{min}$, where high-viscosity and dense (and, hence, particularly stable) structures can form, which is very typical of systems containing anisometric particles.

Periodically repeated structure layering was revealed (from a change in the density) in the course of sedimentation in highly disperse systems formed by particles, whose surface is characterised by lyophobic – lyophilic mosaicity (Fig. 11). This was demonstrated [62, 98] using an annihilation gamma probe. Apparently, layered sediments are formed according to this mechanism. This mechanism is responsible for natural phenomena, such as landslides and landslips of bottom sediments of rivers, lakes, *etc*.

Under dynamic conditions, the formation of layered structures is favoured by possible changes in the sedimentation rate V_1 and the rate of increase in the sediment density (V_s) depending on the shear rate in a flow and, hence, on the effective viscosity.

The drops of the shear rate $\Delta\dot{\varepsilon}$, which are characteristic of both natural phenomena and a series of industrial processes (chemical engineering and pipeline transportation) involving structured dispersions, inevitably lead to changes in V_1 and V_s and variations in the sediment density $\Delta\rho$. In the theoretical study,[9] this dependence was revealed on assumption of the aggregation mechanism of destruction of a coagulation structure under shear and the dependences of the size D and the density of aggregates ρ_a on $\dot{\varepsilon}$. The above dependence is expressed by the equation

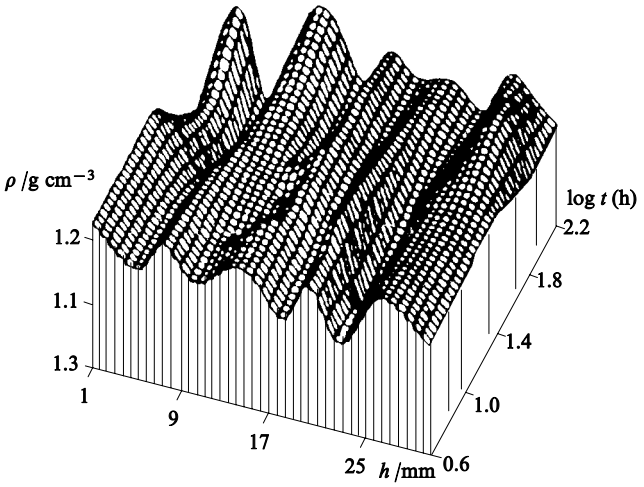

Figure 11. Periodic layers of different densities formed in the course of sedimentation in an aqueous suspension of technical carbon (d = 42 nm, φ = 28%).[98]

$$V_1 = \frac{(1-\varphi_{max})D^2 g \Delta\gamma_1}{12\lambda z \eta_1 \varphi_{ext}} \left(\frac{\eta_1 \varphi_{ext} \dot{\varepsilon}}{2.7 P_m}\right)^{1/2}, \qquad (52)$$

where φ_{max} is the maximum concentration of the dispersion in a sediment, η_1 is the viscosity of the dispersion in an interaggregate space, φ_{ext} is the concentration of the dispersed phase in an interaggregate space, $\Delta\gamma_1$ is the difference between the average densities of the aggregates and the suspension between the aggregates, λ is the dimensionless parameter, P_m is the strength of the aggregate structure

$$P_m = z_1 \frac{4 f_c}{n d^2},$$

z_1 is the number of bonds per particle on the aggregate surface, n is the number of particles in the aggregate.

According to Eqn (52), the rate V_1 is proportional to $(\dot{\varepsilon})^{1/2}$. The rate of sediment growth is related to V_1 by a simple equation

$$V_s = V_1 \varphi_{max}.$$

Hence it follows that any change in $\dot{\varepsilon}$ leads to changes in the rates of these processes. Since $\Delta\gamma_1$ also varies with V_1, the probability of the formation of layered sediments increases as $\Delta\dot{\varepsilon}$ and the frequency of its change increase. This is illustrated in Fig. 12, which displays the dependence of V_1 on $\dot{\varepsilon}$ and the corresponding change in η_{ef} for a concentrated aqueous carbon suspension.

An analogous result for suspensions of monodispersed spheres was obtained in the study.[98] The effect of layering of dispersions was mentioned in the studies.[99, 100]

Therefore, the appearance of structure macroinhomogeneities under dynamic conditions (including discontinuities, along which shears occur in structured disperse systems) results from the fact that the critical concentrations of not only a dispersed phase in a dispersion medium φ_c but also, in a more general case, of microinhomogeneity elements in the bulk of the structure are attained and exceeded. What this means is discontinuities in disperse systems formed by anisometric particles with lyophobic – lyophilic surface mosaicity can appear at concentrations $\varphi < \varphi_c$ (see Fig. 10*b*).

As a consequence, the limiting isotropic dynamic state and the corresponding condition for true ultimate destruction, *i.e.*, η_{ef} (with $\dot{\varepsilon} \to \dot{\varepsilon}_\infty$) = η_{min} in the bulk of the system subjected to deformation, cannot be attained under shear deformation.

Let us consider the mechanism of destruction of disperse systems with $\varphi < \varphi_c$ and analyse the data obtained for a model

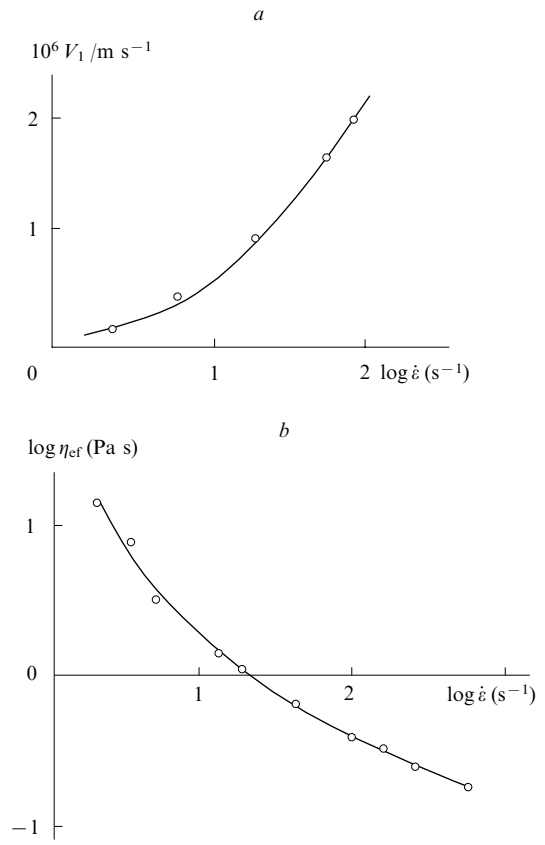

Figure 12. Plots of the sedimentation rate (*a*) and effective viscosity (*b*) *vs.* the shear rate for an aqueous carbon suspension ($\varphi_m \approx 60\%$).[68]

system of a dispersion of spherical polystyrene particles ($d = 70$ nm) in a gelatin gel in the presence of stabilisers [additives of a NaCl electrolyte and an anionic surfactant, *viz.*, aliphatic alcohol (Fig. 13)].

Destruction of a coagulation structure under shear leads to its decomposition into aggregates, which appear when the yield stress

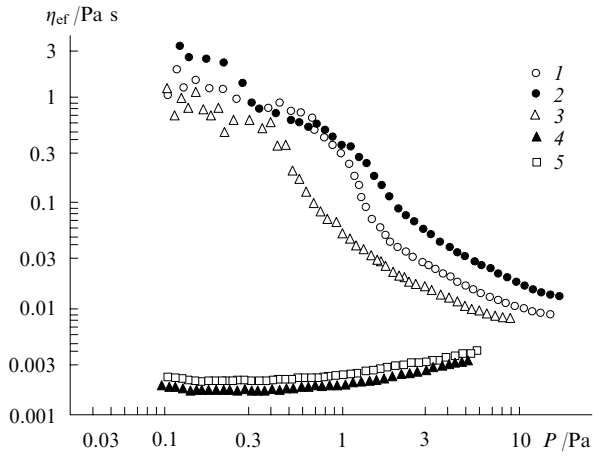

Figure 13. Complete flow curves for a suspension of polystyrene particles in gelatin gel ($\varphi = 4.8\%$).[101]
(*1*) A suspension of particles without additives, (*2*) a suspension of particles with an NaCl additive (0.02%), (*3*) a suspension of particles with an additive of an aliphatic alcohol (0.1%), (*4*) a liquid dispersion medium, (*5*) a theoretical curve under the condition of complete deaggregation.

P_c of the system is reached with increasing shear stress.[2] The characteristic size of aggregates in this region can be calculated by the equation [68]

$$D_a = \left(\frac{\alpha A^* z r^2}{16 P_c h^2 \varphi}\right)^{1/3}, \qquad (53)$$

where $A^* \approx 7 \times 10^{-20}$ J; h was varied from 60 to 100 nm, $r = 35$ nm and $z = 3$. The calculated values D_a varied with the temperature of the system from 300 to 1000 nm. The measurements of the rheological properties of these dispersions showed that even in the region of very high shear rates (as high as $\dot{\varepsilon} \approx 1300$ s^{-1}), the level $\eta_{ef} \approx \eta_{min}$ is more than 30 times higher than that found from the condition of complete destruction for $\varphi = 4.8\%$ according to Batchelor's formula [102]

$$\eta_{ef} \approx \eta_1(1 + 2.54 + 6.25\varphi^2),$$

where η_1 is the viscosity of a dispersion medium. Hence, not individual particles but their aggregates, whose effective concentration is 35% – 60% (*i.e.*, is approximately an order of magnitude higher than the concentration of polystyrene particles), serve as kinetic units at $\eta_{ef} \approx \eta_{min}$.

The above-described mechanism of destruction is even more strongly supported by the results of analysis of the structural and rheological properties of a dilute dispersion formed by monodispersed spherical SiO_2 nanoparticles ($d = 14$ nm) in ester.[103]

Lyophobic interactions in this dispersion give rise to a fractal structure formed by aggregates of particles. The complete flow curve (Fig. 14) shows two pronounced Newtonian viscosity levels, *viz.*, the highest level $\eta_0 \approx 10^8$ Pa s and the lowest level $\eta_{min} \simeq 10^{-1}$ Pa s. Therefore, the effective viscosity drop is nine orders of magnitude. Taking into account that the level attained at $P = 10$ Pa remains virtually the same as P increases to 100 Pa, it can be assumed that this level should actually correspond to the lowest viscosity of the ultimately destroyed structure.[1]

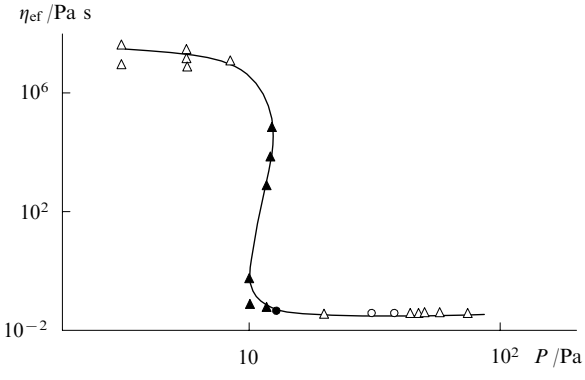

Figure 14. Complete flow curve for a suspension of SiO_2 ($d = 14$ nm) in ester ($\varphi_{ef} = 2.5\%$).[103]
Different triangles and circles correspond to different geometries of a measuring cell.

The validation of this assumption is substantially facilitated by the fact that the dispersed phase consists of monodispersed spherical particles and its volume content in the dispersion medium is < 3%. Therefore, the Einstein equation can be used for the description of the region $\eta \approx \eta_1(1 + 2.5\varphi)$ (see Refs 104 and 105) on condition that complete deaggregation of the dispersion in this region is attained.

However, a comparison of η and η_{ef} demonstrated that the latter values are tens of times larger. Consequently, the experimental values of η_{ef} do not correspond to the condition of true ultimate destruction, but they correspond to bulk thickening of a dispersion medium with kinetic structural elements ($\varphi_{ef} \gg 3\%$) retained at $\eta_{ef} \approx \eta_{min}$. Therefore, the Einstein equation is inappli-

cable for the estimation of the real volume concentrations of these elements, and the equations derived by Patel and Russel[78] or Frankel and Acrivons[86,106] should be used. According to these equations, φ_{ef} for aggregates is $\sim 49\%$. The initial size of these aggregates at the shear stress $P = P_c = 10$ Pa, which corresponds to the onset of a sharp decrease in the effective viscosity, can be determined by Eqn (53). The value calculated by Eqn (53) is 1500 nm, which was confirmed by direct measurements of the average size of aggregates by neutron diffraction ($D_a \approx 1560$ nm).[68]

As a further development of the concepts reported in the study,[107] it was demonstrated that the flow process of such colloidal disperse systems as fractal gels analogous to those described above can be considered as a flow of a system consisting of 'solid-like' and 'liquid-like' components, whose viscosities differ by many orders of magnitude ($\eta_{ef1} \sim 10^8$ Pa s and $\eta_{ef2} \sim 10^{-1}$ Pa s, respectively), and the corresponding relaxation times are $\tau_1 \sim 10^5$ s and $\tau_2 \sim 10^{-4}$ s.

It should be noted that the flow giving rise to alternating 'solid-like' and 'liquid-like' quasi-phases, which form layers oriented along the shear direction, was interpreted[107] as the most probable process in the context of thermodynamics of non-equilibrium processes.

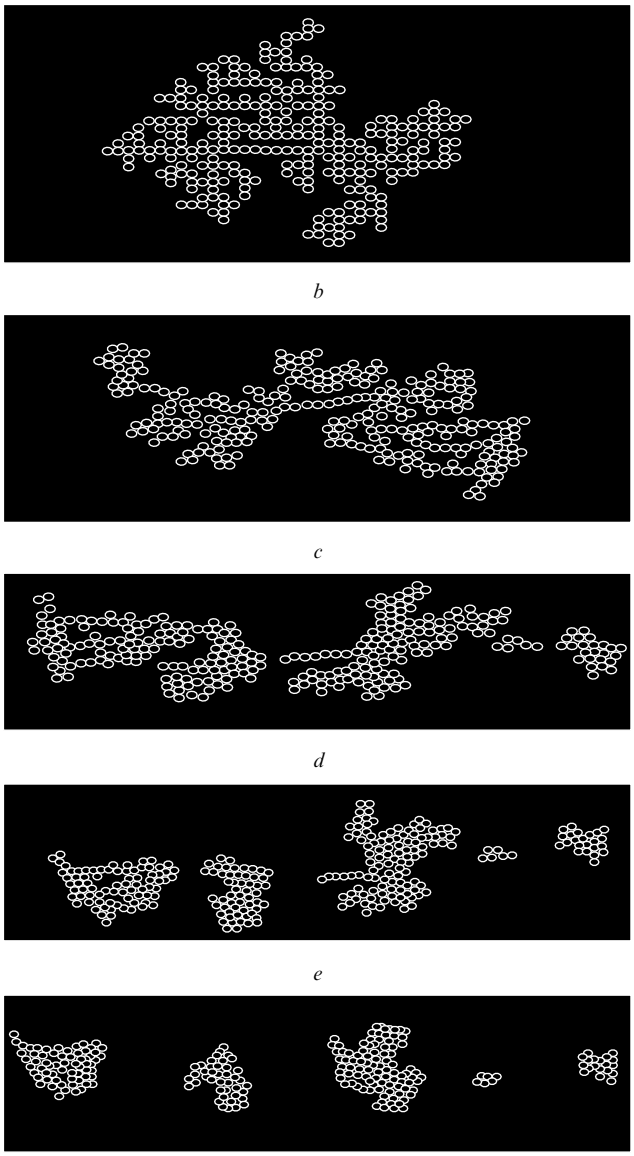

Figure 15. Evolution of a superaggregate in the course of shear deformation (computer experiment).[68]
$\dot{\varepsilon}$ /s^{-1}: (*a*) 0, (*b*) 0.3, (*c*) 1, (*d*) 10, (*e*) 50.

The results of computer simulation of the structure evolution of aggregated disperse systems with increasing shear rate (Fig. 15) are also indicative of the formation of smaller aggregates, which are characterised by an increasing density and, correspondingly, increasing strength and viscosity, against the background of destruction of superaggregates under deformation. This effect follows from the theory of destruction of aggregated dispersions under shear deformation. The aggregate radius R_a is related to the particle radius by the equation[19,30,62]

$$\frac{R_a}{r} \sim n^{1/f}, \tag{54}$$

where n is the number of particles involved in the aggregate and f is its fractal dimensionality. Then, the concentration of particles in the aggregate φ_{int} also increases with increasing shear rate $\dot{\varepsilon}$

$$\frac{\varphi_{int}}{\varphi_{max}} \sim \left(\frac{r}{R_a}\right)^{3-f}, \tag{55}$$

where φ_{max} is the maximum particle concentration in a particular disperse system.

Aggregates form a chain (layer) oriented along the shear direction. It can be stated that this mechanism, which combines destruction and formation of dispersed structures with a higher strength, excludes the possibility of attaining the true and complete destruction, and, hence, the limiting dynamic state even at very high $\dot{\varepsilon} \to \dot{\varepsilon}_\infty$ in the region of $\eta_{ef} \approx \eta_{min}$.

4. Dynamic state of disperse solid phase – liquid medium systems under combined action of shear and orthogonal oscillation

Anisotropic destruction of dispersed structures oriented along the shear direction, which is accompanied by decomposition into aggregates and formation of new more stable aggregates through inertial coagulation, excludes the attainment not only of an isotropic dynamic state but also of equivalent aggregation dynamic stability of disperse systems.

Consequently, to attain the limiting isotropic dynamic state, it is necessary to subject a disperse system to action in such a way as to either exclude the formation of structure inhomogeneity elements as aggregates and structured layers or achieve their ultimate destruction. For this purpose, the energy delivered to a disperse system and imparted to particles fixed in a structural network should be higher than the binding energy with adjacent particles.

As mentioned above, until the binding energy of a particle (whose size is smaller than 1 μm) in contact with adjacent particles is lower than $(10-15)kT$, the structure can be destroyed through thermal motion (random Brownian oscillations) of particles. In all cases of lyophobic interactions between particles, the total energy of their binding with adjacent particles in a structure is, generally, much higher than $(10-15)kT$, and destruction *via* Brownian motion becomes impossible.

Besides, it can be suggested that just as particles of sizes larger than 1 μm in aggregation-stable colloidal disperse systems undergo random oscillations under the action of thermal impacts of molecules of a dispersion medium, so can such particles in structured dispersions if they are subjected to forced oscillations using an external source. The necessary condition for the attainment of aggregation dynamic stability of such systems in the case of their complete deaggregation is that the energy of forced oscillations should be higher than the total energy (U_c) of binding of particles with adjacent particles in a structural network (taking into account z). It can also be assumed that forced oscillations play a decisive role in destruction under combined action of continuous shear and oscillations, whereas the mass transfer of elements of the destroyed structure proceeds under continuous shear.

The destruction under shear involves two main steps, *viz.*, destruction of a continuous structural network to form layers and/or aggregates of particles and destruction of aggregates as such. Correspondingly, the results of an external oscillation action first on a continuous structure and then on the aggregate structure should be considered with the aim of determining the parameters necessary for complete destruction of a coagulation structure. Various aspects of this problem were considered in-depth.[2, 30, 62]

Assuming that particle oscillations are excited with an external source through a medium, the rate of particle motion in the vicinity of the aggregate surface can be taken as

$$V(t) = V_0 a \sin \omega t.$$

Here, V_0 is the maximum rate of particles under oscillation, a is the oscillation amplitude and ω is the oscillation frequency. In the case of such harmonic oscillations, a particle undergoing forced oscillations with a frequency ω comparable to the eigenmode frequency can escape from a structural network. The eigenmode frequencies at which the particle can escape from long-range ($i = 1$) and short-range ($i = 2$) coagulation sites are determined, respectively, by the equations

$$\omega_1 \sim \frac{1}{r}\left(\frac{B}{\rho h_2^4}\right)^{1/2} \sim \frac{10}{r}, \qquad \omega_2 \sim \frac{1}{r}\left(\frac{A^*}{10\rho h_1^3}\right)^{1/2} \sim \frac{10^2}{r}. \tag{56}$$

For a comparative numerical analysis, let us assume that $\eta_1 \sim \eta = 10^{-1}$ Pa s, $A^* \sim 10^{-19}$ J, $B = 10^{-28}$ J m, $h_2 \sim 5 \times 10^{-8}$ m, $h_1 \sim 10^{-9}$ m, $\rho = 1000$ kg m^{-3}.

As expected, the results of numerical estimates differ sharply (by several orders of magnitude) and depend on r and h. Thus, the frequency increases by five orders of magnitude as r decreases from 10^{-4} to 10^{-7} m and, particularly, as h_i decreases from 5×10^{-8} to 10^{-9} m.

From this it follows that it is worthwhile to combine low-frequency mechanical oscillations and ultrasonic oscillations, particularly, in the case of destruction of colloidal disperse systems. It should be emphasised that it is technically quite possible to expose dispersed structures to oscillations with such parameters. This was demonstrated, in particularly, in the studies,[7, 62, 108] where structures were destroyed in the course of compaction of finely dispersed powders as well as of highly filled suspensions containing ultra-dispersed aerosil particles ($s_{BET} \approx 400$ m^2 g^{-1}).[62]

The effect of oscillations on a disperse system at $\eta_{ef} \to \eta_0$ can be expressed by the simple equation

$$\frac{\eta_{ef}}{\eta_0} \sim e^{U_c/\Theta} \tag{57}$$

where

$$\Theta = kT + m(a\omega)^2.$$

The first term of the latter equation takes into account the possible contribution of thermal motion. The second term accounts for the kinetic energy imparted to a system subjected to oscillation with an amplitude a and a circular frequency ω.

This approach to estimations of oscillation action on disperse systems was also used in the study.[109]

The second step of destruction of dispersions is associated with aggregate disintegration under combined action of oscillation and shear. In these conditions, the effective viscosity of a dispersion consisting of aggregates can be expressed as follows:[30, 61]

$$\eta_{ef} \sim \eta_{ef}^0 \frac{L}{d^*} \sim \eta_{ef}^0 \left[1 + \frac{1}{a\omega L/z_a\eta + (\dot{\varepsilon}/\dot{\varepsilon}_a)^{1/2}}\right]. \tag{58}$$

Here, η_{ef}^0 is the highest effective viscosity, d^* is the average distance between the aggregates, L is the distance between the centres of the aggregates ($L = D + d^*$, D is the diameter of the aggregate) and z_a is the coordination number of the aggregate,

$$\dot{\varepsilon} \approx \frac{z_a P_c}{\eta_{ef}^0}.$$

Equation (58) was derived from the condition that the parameter L/d^* is expressed as follows

$$\frac{L}{d^*} \sim \frac{z_a \eta}{\rho a \omega L},$$

where ρ is the density of particles of a solid phase.

It is worthwhile to represent the dependence of the effective viscosity on the oscillation intensity

$$I \approx a^2\omega^3.$$

This parameter determines the oscillation power per unit oscillating mass. In essence, this parameter can be considered as a 'vibrotemperature',[30] an increase of which leads to an increase in the intensity of motion of kinetic units (particles or aggregates), much as an increase in the temperature in colloidal systems leads to intensification of Brownian motion.

The dependence of the effective viscosity on this parameter can be described by the following equation:[30, 62]

$$\eta_{ef} \sim \eta_1 \left(\frac{z_a h}{a\omega\rho D} + 1\right) \sim \eta_1 \left[\frac{z_a \eta}{\rho L}\left(\frac{\omega}{I}\right)^{1/2} + 1\right], \tag{59}$$

where h is the distance between particles in an aggregate.

It was demonstrated[62, 68] that the results of calculations by Eqns (57)–(59) are in good agreement with the results of studies of the rheological properties of concentrated suspensions of aluminosilicates in water subjected to oscillation. The selected parameters of these suspensions are as follows: $\varphi \sim 0.46$–0.6; $A^* \sim 10^{-20}$ J; $h = 1$–10 nm; $(R/r)_{min} \sim 10$. Under conditions of continuous shear, irreversible macroscopic discontinuities appear at $P = P_c$ or $\dot{\varepsilon} \approx \dot{\varepsilon}_c$. The possibility of the occurrence of these discontinuities is completely eliminated under combined action of continuous shear and orthogonally directed oscillation with a frequency $f_v^* = 50$ Hz ($\omega = 2\pi f_v^* = 300$ s^{-1}) and with increasing intensity (Fig. 16). In particular, this is evidenced by a relatively

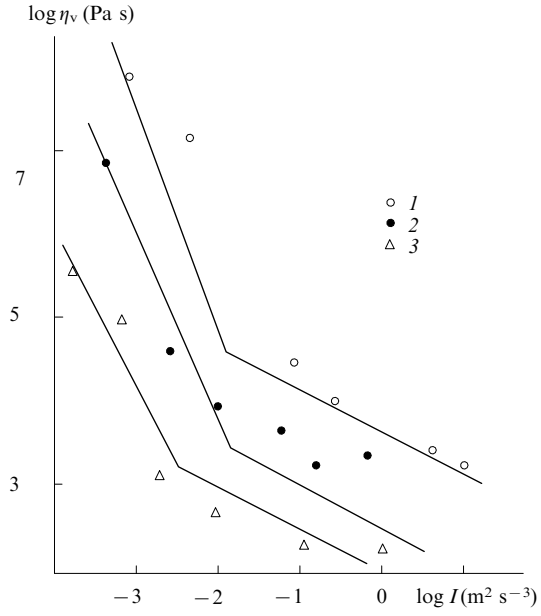

Figure 16. Vibrorheological curves of aqueous suspensions of aluminosilicates.
Circles and triangles represent experimental data;[2] curves show the results of calculations by Eqns (58) and (59); $\varphi = 0.6$ (*1*), 0.53 (*2*), 0.46 (*3*).

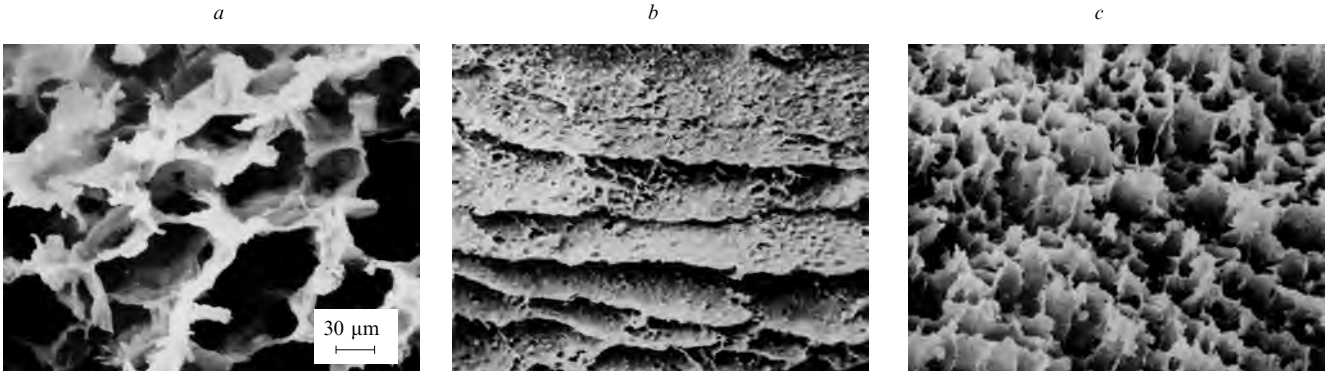

Figure 17. Characteristic features of destruction and formation of coagulation structures for aqueous dispersions of CaB, $\varphi_{max} = 11\%$ ($\times 1000$). (*a*) A structure before deformation (static conditions), (*b*) a structure under conditions of continuous shear ($\dot{\varepsilon} = 0.3\ s^{-1}$), (*c*) a structure under combined action of continuous shear ($\dot{\varepsilon} = 0.3\ s^{-1}$) and orthogonal oscillation ($f_v^* = 50$ Hz, $a = 10^{-3}$ m)

high reproducibility of vibrorheological flow curves (with slight deviations within several percentage) in viscosity measurements in going both from the minimum to the maximum values of I and in the reverse direction.

The flow curves have two main portions characterising various steps of destruction of a coagulation structure (see Fig. 16): the first sharp decrease in the viscosity corresponds to decomposition of a continuous structure into aggregates, whereas the second decrease corresponds to destruction of the latter into aggregates of smaller sizes and individual particles. At the same time, these curves reflect some essential features of destruction under oscillation.

Although eliminating discontinuity and destroying the structure, oscillation does not lead to complete destruction of aggregates, as evidenced by retention of substantial differences in the level of η_v (up to an order of magnitude) at $I \geqslant 1$. Destruction of aggregates of very small sizes is a very energy-consuming process. This is confirmed by the fact that an increase in I by 3–4 orders of magnitude in lower portions of the flow curves leads to a small decrease in the viscosity.

Analogous results were obtained for aqueous suspensions of calcium bentonite (CaB) both for systems with $\varphi > \varphi_c$ and suspensions at concentrations $\varphi \leqslant \varphi_c$. Figure 17 presents scanning electron micrographs of dispersed structures taken with the use of a procedure described in the studies.[62,95] The photomicrographs show successive structural transformations. It can be seen that discontinuities, which appear under continuous shear, are completely eliminated under orthogonally directed oscillation. This important result indicates that a combination of continuous shear and orthogonal oscillation allows one, in principle, to control an isotropic dynamic state. However, the destruction under oscillation and shear is not limiting (although is close to the limiting value) but is characterised by the presence of aggregates throughout the range of changes in $\eta_{ef} = \eta_v$, where η_v is the effective viscosity under oscillation.

Vibrations destroy structures predominantly at weak contacts thus initiating the formation of dense microaggregates, in which particles are fixed in a short-range potential minimum due to inertial coagulation. This fact complicates substantially the attainment of ultimate destruction. In combination with continuous shear, oscillation facilitates mutual dynamic scanning of the surfaces of contacting particles and, in the presence of lyophobic–lyophilic mosaicity of these surfaces in most real disperse systems, leads to a 'manifestation' of mosaicity and selective formation of new strong contacts predominantly in lyophobic regions.[2] This spontaneous formation of microaggregates, in which particles are fixed in sites of short-range coagulation, is manifested as the effect of strengthening of the structure under oscillation.[2] This phenomenon resides in the fact that after cessation of exposure to orthogonal oscillation, the effective viscosity η_{ef} (the effective stress P at $\dot{\varepsilon} = \text{const}$) sharply increases compared to its equilibrium value in a steady shear flow at the same value of $\dot{\varepsilon}$ prior to exposure to oscillation (Fig. 18). Hence it follows that the limiting isotropic dynamic state and, correspondingly, aggregation dynamic stability of disperse systems can be attained only if both inertial (short-range) coagulation and the effect of strengthening due to oscillation (this effect is associated with coagulation and lyophobic–lyophilic mosaicity of the particle surface) are excluded.

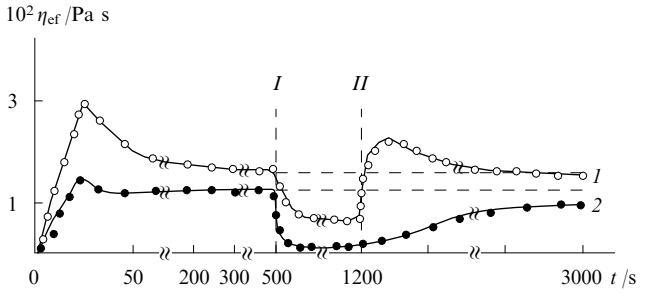

Figure 18. Dependence of the effective viscosity of an aqueous dispersion of CaB ($s_{BET} = 70\ m^2\ g^{-1}$, $\varphi = 0.33$) on the time under continuous shear deformation $\dot{\varepsilon} = 0.3\ s^{-1}$ (see Ref. 2).
(*1*) a dispersion in the absence of surfactant additives, (*2*) a dispersion of particles whose surface was modified with a monolayer of oxyethylated alkylphenol (OP-10); (*I*) the onset of oscillation orthogonal to continuous shear ($f_v^* = 50$ Hz, $a = 5 \times 10^{-4}$ m), (*II*) cessation of oscillation.

It was demonstrated[94] that an efficient way for solving this problem consists in combining the exposure of a disperse system to oscillation and the introduction of surfactant additives, which lyophilise the particle surface and create a structure-mechanical barrier (according to Rehbinder). Therefore, inertial coagulation under dynamic conditions is hindered in the presence of a surfactant adsorption layer, which serves as a structure-mechanical barrier. From Eqn (35) it follows, in particular, that the attainment of aggregation stability of dispersions under dynamic conditions requires an increase in the strength of an adsorption layer, particularly, in the presence of asperities with a small radius of curvature on the particle surface. The modulus of elasticity of the layer can be decreased by increasing the thickness of the layer L, the particle size and the distance between their surfaces.

In the presence of an adsorption layer, the critical coagulation rate can be determined by Eqn (34) or from the following relation:

$$V_c^* > \lambda_i \frac{L}{r_{max}} \left(\frac{P_L}{E_L}\right)^{3/2} \left(\frac{E_L\, r^*}{2\rho r_{max}}\right)^{1/2}, \qquad (60)$$

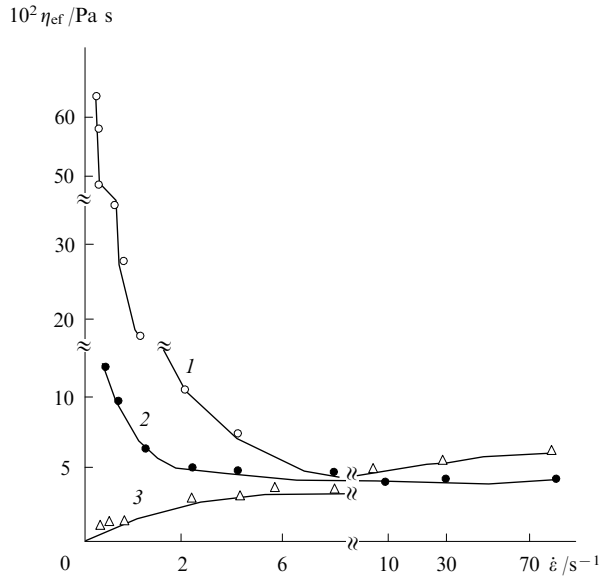

Figure 19. Dependence of the effective viscosity of highly concentrated aqueous carbon suspensions (φ = 72.5%) on the shear rate.[111]
(*1*) In the absence of oscillation action; (*2*) in the absence of oscillation action with an additive of an anion-active surfactant, *viz*., a sulfonation product of oil tars (1% of the mass of the solid phase); (*3*) under conditions analogous to those used in run (*2*) combined with orthogonal oscillation with a frequency of 50 Hz and acceleration $A = 2.5g$.

where the parameter λ_i determines the curvature of the particle surface in the contact zone: for spheres, $\lambda_i = 1$; for particles with a radius of curvature $r^* < r_{max}$, in particular, for two disk-like particles, which collide perpendicular to one another, $\lambda_i = 2(r_{max}/r^*)^{3/4}$. Assuming $L \sim 10^2$ nm for disk-like particles with $r^* \sim 3 \times 10^2$ nm and $r_{max} = 10$ μm, the aggregation stability in dynamic conditions will take place at $E_L \sim P_L > E_{Lc} \sim 10^5$ Pa. For polyvinyl alcohol, this condition is fulfilled [110] at a rather high rate $V_c^* \sim 0.5$ m s^{-1}. The same condition is obviously fulfilled for a polyfunctional anion-active surfactant of a new type, which was prepared starting from dehydrated liquid products of hydrocarbon pyrolysis, which were mixtures of water-soluble salts of sulfonic acids of bicyclic aromatic hydrocarbons (sulfonation product of oil tars).[111] When choosing surfactants, which satisfy the above-mentioned conditions, one should take into account the characteristic features of their micellar structures, because micelles formed in solutions of surfactants can produce a structure-mechanical barrier.[67]

The results of experimental test of the efficiency of a combined action of orthogonally directed oscillation and the presence of surfactants, which create a structure-mechanical barrier on the surface of particles of dispersed phases are presented in Figs 18 and 19.

Upon modification of the CaB particle surface with oxyethylated alkylphenol OP-10, both the depth and the destruction rate under oscillation (a decrease in η_{ef}) increase (see Fig. 18, curve *2*) compared to the analogous values observed under oscillation but in the absence of surfactants (curve *1*). This fact can be attributed to a substantial decrease in the strength and energy of interparticle interactions under oscillation. At the same time, the vibrostrengthening effect completely disappears in the presence of surfactants, and the rate of thixotropic recovery of a structure decreases sharply, which is indicative of the absence of 'breakdown' of the adsorption layer under oscillation and the retention of a structure-mechanical barrier in the course of prolonged (for more than 10 min) high-intensity oscillation.

An analogous effect of a combination of orthogonal oscillation and surfactant additives was revealed in a shear flow of highly concentrated aqueous carbon suspensions (see Fig. 19). A particularly sharp decrease in η_{ef} (by two orders of magnitude) was observed at low shear rates ($\dot{\varepsilon} \leqslant 2$ s^{-1}). The viscosities calculated by the equations reported in the study [30] had close values in this region, which indicates that the ultimate destruction was reached. A slight increase in the viscosity with increasing $\dot{\varepsilon} > 2$ s^{-1} is not associated with the structural effects, but apparently results from turbulisation of a flow under oscillation ('vibrodilatancy'). This is confirmed by full reversibility of the effect. Thus, the viscosity reaches the initial minimum level when $\dot{\varepsilon}$ decreases to 2 s^{-1}. The effect of a decrease in the vibroviscosity and oscillation intensity in concentrated cement aqueous dispersions as a result of the surface modification of cement particles with surfactant additives is illustrated in Fig. 20. This effect is noticeable in the presence of OP-10 (curve *2*) and, particularly, of sodium methylsiliconate (curve *3*). In the latter case, a decrease in η_{ef} amounts to as much as four orders of magnitude and a decrease in the oscillation intensity necessary for the attainment of η_{ef} ranges up to three orders of magnitude.[68] It should be emphasised that both these effects are

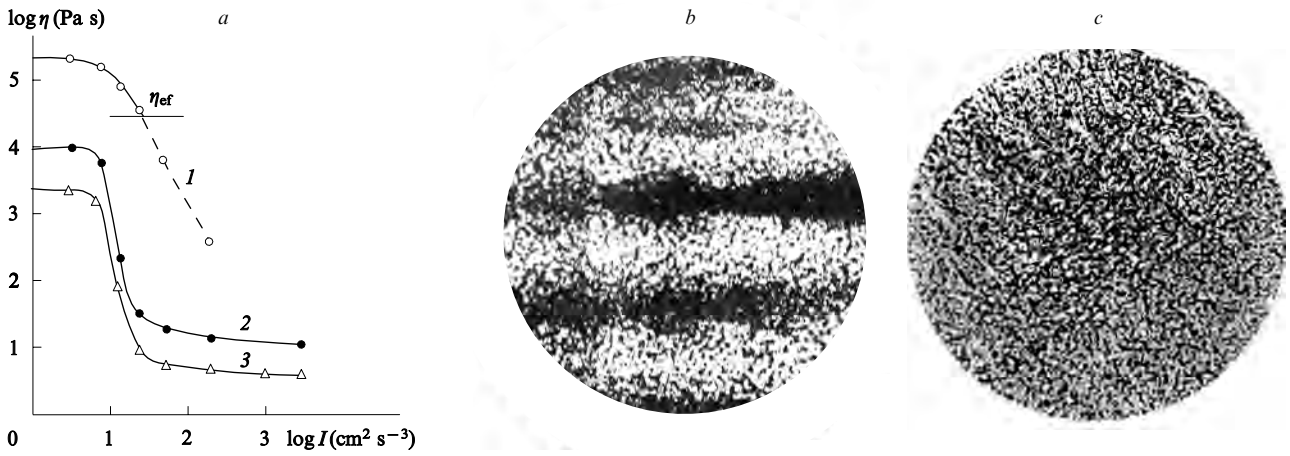

Figure 20. Effect of combined action of shear deformation, orthogonal oscillation and surfactant additives.[68]

(*a*) rheological flow curves: (*1*) under shear without oscillation (η_{ef}), (*2*) a combination of continuous shear ($\dot{\varepsilon}$ = 0.3 s^{-1}) and oscillation with increasing intensity, (*3*) under conditions analogous to those used in run (*2*) in combination an additive of sodium methylsiliconate (0.3%). Photomicrographs of the structure formed under dynamic conditions: (*b*) under continuous shear for 600 s, (*c*) under combined action of continuous shear, orthogonal oscillation and a surfactant additive (15 s).

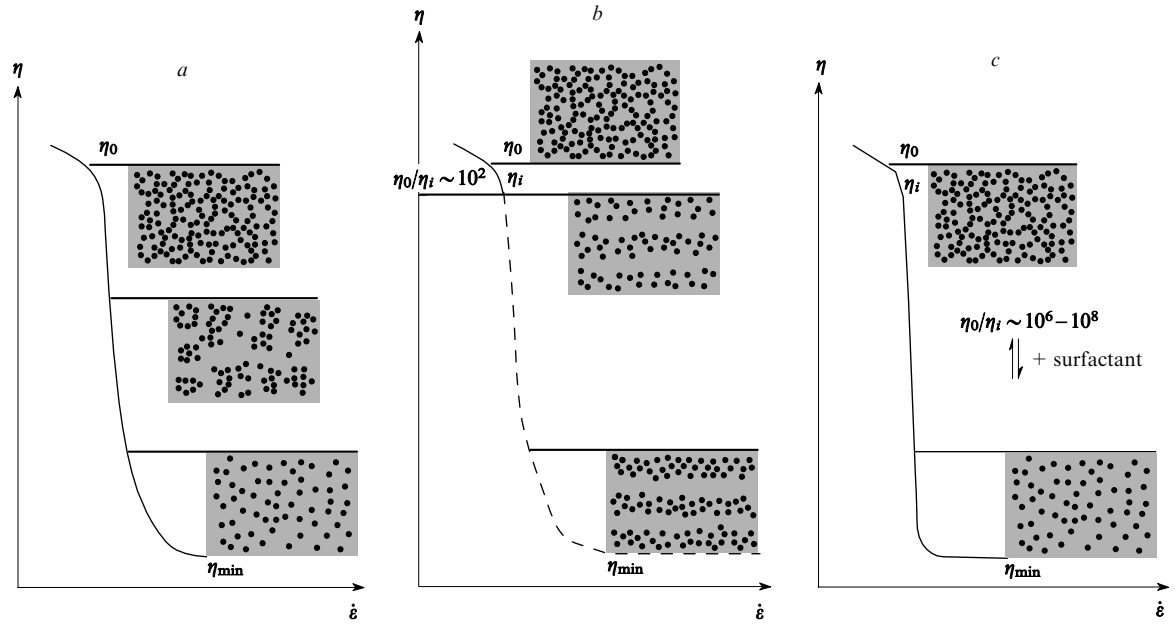

Figure 21. Scheme illustrating the destruction mechanism of coagulation structures in disperse systems under dynamic conditions.[68]
(*a*) Under continuous shear deformation with increasing shear rate (commonly accepted views), (*b*) the real pattern of destruction of dispersions under continuous shear, (*c*) spontaneous ultimate destruction with the attainment of the true maximum fluidity and complete ultimate deaggregation under conditions of an optimum combination of continuous shear and orthogonally directed oscillation in the presence of surfactant additives.

most pronounced in the region of the lowest vibroviscosity levels. This indicates that oscillations suppress the formation of dense and stable microaggregates as a result of inertial coagulation, which is typical of destruction under oscillation in the absence of surfactants. At the same time, this fact is also indicative of isotropic destruction, *i.e.*, of the attainment of the limiting dynamic state in the case of both highly concentrated aqueous carbon suspensions and cement aqueous dispersions.

A combination of orthogonal oscillation and the introduction of surfactant additives can be considered as an efficient way of intensifying processes of wetting and flowing of non-Newtonian structured high-viscosity dispersions as a result of their transformations into low-viscosity Newtonian liquids.[64,65] This phenomenon is of considerable importance in the preparation of composition materials with a binder as a structured dispersion.[62]

The main steps of the generation of a controlled dynamic state of two-phase structured disperse systems of the solid phase – liquid dispersion medium type are illustrated in Fig. 21. The main step involves the construction of complete rheological flow curves describing the overall range of changes in dynamic states, which are determined by the effective viscosity levels corresponding to a given deformation rate. When constructing these curves, it was assumed that a certain equilibrium degree of isotropic destruction (degree of deaggregation) corresponds to each viscosity level, and complete deaggregation corresponds to the lowest Newtonian viscosity level η_{min} (see Fig. 21 *a*). In actuality, the destruction is often anisotropic in character and gives rise to solid-like layers, which are strengthened as the deformation rate increases, are separated by an interlayer of a dispersion medium and are oriented along the shear direction (see Fig. 21 *b*). Consequently, contrary to the commonly accepted views of the flow mechanism of structured dispersions, the true ultimate destruction as well as the maximum fluidity of dispersions are not achieved.

The use of the above-described approaches and methods for creating of the optimum dynamic state in structured dispersions actually allows one to achieve the complete and isotropic destruction with complete spontaneous deaggregation and, correspondingly, to attain true maximum fluidity (Fig. 21 *c*).

IV. Conclusion

The dynamic state of structured disperse systems depends on the degree and conditions of destruction of dispersions. Depending on the type and intensity of external actions, disperse systems in dynamic conditions are characterised by the presence of macroscopic quasi-phases as aggregates consisting of particles and solid-state layers, which are oriented along the direction of the high-intenisty continuous action (for example, shear). The sizes and densities of aggregates and layers depend on the state of the surface, the shape of primary particles and the degree of destruction. The same factors are responsible for the effective viscosity of disperse systems under dynamic conditions. Methods for the creation of a controlled dynamic state of such systems are based on the following two main factors: first, the modification of particle surfaces (their lyophilisation) to form a surfactant adsorption layer serving as a structure-mechanical barrier, which hinders inertial coagulation of particles; second, the complex exposure of a disperse system to continuous shear and orthogonally directed oscillation, whose intensity (in combination with the modification of the particle surface) corresponds to the condition of complete (ultimate) deaggregation.

This level of the limiting isotropic dynamic state corresponds to dynamic aggregation stability and maximum fluidity of structured disperse systems. In essence, the views of the characteristic features and methods for creating a dynamic state and controlling the properties of disperse systems under dynamic conditions provide the basis for physicochemical dynamics of structured disperse systems.

The attainment of the true maximum fluidity of structured disperse systems with complete deaggregation allows one to radically change the conditions for performing various chemical engineering processes, including those for the preparation of dispersed composition materials. It is known that the rate of heterogeneous processes carried out under conditions of forced convective diffusion is inversely proportional to the viscosity. Hence, the attainment of complete destruction, deaggregation of a system and the true lowest Newtonian viscosity by decreasing the effective viscosity of dispersions by 5 – 7 orders of magnitude

provides the possibility of accelerating many heterogeneous chemical engineering processes to the same extent.

Liberation of an immobilised dispersion medium from a structural network and a sharp increase of the 'operating' active interface due to complete deaggregation make it possible to increase the rate and degree of completion of a series of heterogeneous processes by several orders of magnitude.

In the case of complete deaggregation under conditions of attainment of the optimum dynamic state of dispersions, both the dispersity of the solid phase S and its concentration φ increase and, hence, it is possible to pass to the previously 'forbidden' (due to a sharp increase in the viscosity and the limiting shear stress) region of highly concentrated ($\varphi > \varphi_c$) and finely disperse systems, which also allows one to accelerate sharply heterogeneous processes, whose rates are proportional to the areas of operating interfaces.

By attaining the highest degree of homogeneity of phase distribution with a simultaneous increase in their dispersity and concentration in dispersion media, one can prepare both traditional and new types of highly filled dispersed composition materials possessing the desired properties and structures.

Numerous examples of various applications of the principles of the creation of a controlled dynamic state in disperse systems lie at the basis of new methods and high-performance technologies for the production and procession of disperse systems and composition materials.[2, 54, 55, 105, 112–114]

In conclusion, let us formulate briefly the main results of studies carried out in the last 10–15 years, which provide the basis for physicochemical dynamics of disperse systems:

— the dynamic theory of contact interactions was devised;

— the theory of complete rheological flow curves taking into account discontinuities was developed;

— foundations of the theory of the creation of the limiting dynamic state of disperse systems and their maximum fluidity were laid;

— the mechanism of a combined action of oscillation and the introduction of surfactant additives in flow processes of dispersions for the attainment of their maximum fluidity was revealed.

In addition, new characteristic features of sedimentation processes both under static and dynamic conditions were found. The results of these fundamental studies were supported by experimental investigations and have found practical applications in various fields of technology and engineering. Among new promising lines of physicochemical dynamics, let us note the elucidation of the mechanism of flowing of structured dispersions, investigations of the dynamics of three-phase disperse systems and the development of theoretical foundations of new methods for performing various chemical engineering processes in highly concentrated and finely disperse systems.

Abstract. Experimental, methodical and theoretical studies dealing with phase equilibria and phase structures of polymer blends are generalised. The general and specific features of the change in solubility of polymers with changes in the molecular mass and copolymer composition and upon the formation of three-dimensional cross-linked networks are described. The results of the effect of the prehistory on the phase structure and the non-equilibrium state of polymer blends are considered in detail. The bibliography includes 125 references.

I. Introduction

The problem of phase equilibria and phase structures of polymer systems is one of the central problems in physical chemistry of polymers. This problem combines surprisingly interests of fundamental science and requirements of practice, polymer materials science and technology of polymer processing, the thermodynamics of polymer solutions and blends, the kinetics of phase decomposition and structure formation. This field of science has been extensively studied, and each investigation concerned different aspects of this problem to a lesser or greater extent.

Studies of phase equilibria of polymers can be divided into two periods. The first period can be tentatively called the 'period of compatibility'. In studies of this period, phase structures of particular polymer composites prepared under certain blending conditions were examined by various methods (mechanical, relaxation, thermochemical and sorption). Based on these results, conclusions were drawn about the polymer compatibility or incompatibility without regard for the temperature and concentration conditions for the preparation of composites.[1–9]

The second period of studies is being continued. It can be called the period of 'phase diagrams'. In investigations of this period, particular attention is given not to estimation of the polymer compatibility based on indirect data,† but to the directed construction of phase diagrams in broad ranges of temperature, compositions and molecular weights of the components. A comparative analysis of the monographs and reviews of the first and second periods shows that phase diagrams of binary, ternary or multicomponent systems were reported in virtually all modern large studies dealing with the properties of polymer and oligomer blends.[11–15]

However, the available extensive experimental data, which have partially been surveyed in the monographs,[15,16] demonstrate that, in spite of obvious progress, many results concerning phase structures and phase diagrams are contradictory with respect to both compositions of co-existing phases and positions of critical points. Besides, radically different phase diagrams were obtained for a number of systems by different researchers with the use of various methods of investigation and procedures for the preparation of blends. For example, diagrams with an upper critical solution temperature (UCST), a lower critical solution temperature (LCST) or two critical temperatures were reported for the same systems in different studies.

The paradox of the situation in this area of physical chemistry of polymers is that some researchers ignore results inconsistent with their point of view, other researchers believe that discrepancies in the experimental results are associated with the specificity of the methods used, whereas yet other researchers explain the contradictory results in the context of particular theories of polymer solutions.[16–24]

In our opinion, investigations of polymer blends have now come to a new stage. The main aim of such investigations is to obtain balanced non-contradictory information on phase equilibria and thermodynamic parameters of polymer blending. We consider the published data on phase compositions and characteristics of polymer blends from this standpoint. A detailed analysis of all experimental results is beyond the scope of our brief review. We focussed our attention on the most prominent examples, analysed the reasons for the above-mentioned contradictions and made attempts to find ways of resolving these contradictions.

II. Methods of construction of phase diagrams

The classification of methods which are used or will be used for constructing phase diagrams (rather than for estimating compatibility between components of polymer systems or the phase composition of materials) should be based not on methods of measurement, as suggested in the studies,[7,16,23,25] but on phenomena occurring in the system under study in the course of

† It should be noted that such studies are still published.[10]

measurements. Within the framework of this approach, all available and newly developed methods for the construction of phase diagrams can be divided into three groups.

Methods of determining critical points in the temperature–concentration field of polymer systems from the appearance and/or dissolution of particles of a dispersed phase of a particular nature belong to the first group. The second group includes methods associated with the determination of the compositions of co-existing phases. Calculation (semiempirical) methods for the construction of boundary lines in phase diagrams comprise the third group.

Two ways of performing experiments are used in the first group of methods. In one case, the composition of a solution, melt or blend remains constant throughout the experiment, and the figurative point (*A* in Fig. 1) moves along the temperature scale in response to changes in external conditions. In the second approach, phase decomposition or homogenisation of a polymer system initiated by forced changes in the composition of the system is performed under isothermal conditions. In this case, the figurative point of the system (*B* in Fig. 1) moves over the isotherm along the axis of compositions. It should be noted that in the first approach, measurements for a given composition are carried out continuously and the periodicity appears only on going from one composition of the system to another, whereas periodic measurements are almost always carried out in the second approach. This is associated with the procedure for changing the composition: a particular component is either additionally introduced into or removed from the mixture. In polymer–solvent or polymer(1)–polymer(2)–solvent systems, this is achieved by either dilution of the mixture or evaporation of a low-molecular-weight component.[1,8,26–28] In the case of polymer blends, all operations associated with the preparation (blending, pressing, thermal annealing, quenching) are carried out, but each time for blends of different compositions.[3,5,12] Evidently, to obtain reproducible results, particularly in the latter case, conditions under which components are mixed and samples for analysis are prepared should be rigorously constant, which is often impossible to achieve.

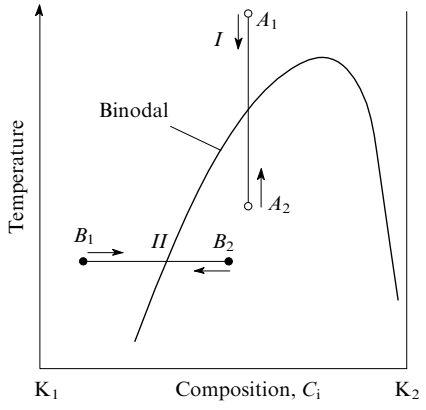

Figure 1. Scheme for performing experiments on the construction of phase diagrams (K_1 and K_2 are components of the system). Method *I*, the figurative point *A* moves along the temperature scale. Method *II*, the figurative point *B* moves along the composition axis.

In both approaches, the temperature $T_{ph.s}$ (at a given composition) or the composition $C_{ph.s}$ (at a given temperature), at which the phase state of the system changes, is determined from one of the chosen parameters (optical or electron density, intensity of light or neutron scattering, refractive index, thermal effect or changes in the local mobility of macromolecules and their fragments, labels, viscosity of the system as a whole, *etc.*). Particles of a dispersed phase either appear, if a true solution or melt is used as the starting system, or dissolve, if the starting state of the system corresponds to a heterogeneous region in the phase diagram.[29–37]

Methods belonging to the second group allow one to determine compositions of co-existing phases at different temperatures. These methods also employ different techniques for performing experiments. One of these techniques is based on interdiffusion. In this case, the phases of the starting components are brought into contact and then the character of the concentration distribution in the region of their spontaneous diffusion mixing is studied *in situ* by a particular local method.[38,39] Numerous experiments demonstrated[15,40–42] that there is a pronounced relationship between the character of the concentration distribution in the region of interdiffusion of semi-infinite phases and the phase diagram, which reflects the essence of processes of their spontaneous mixing. If phase conjugation is carried out at a temperature higher than UCST (or lower than LCST), $T > T_m$ or at a temperature higher than the isotropisation temperature, the formation of a concentration profile accompanied by a continuous change in the composition from one component to another is observed in the region of interdiffusion (Fig. 2 *a*).

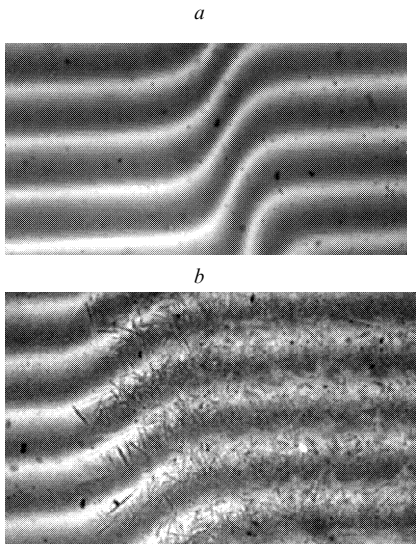

Figure 2. Concentration profiles of the CS ($M_w = 5.1 \times 10^4$)–PDMS ($M_w = 1.8 \times 10^3$) system above (*a*) and below (*b*) the isotropisation temperature of CS. The diffusion time is 4 min.[43]

If phase conjugation is performed at a temperature lower than UCST (or higher than LCST), $T < T_m$ or below the isotropisation temperature, the interface which separates the regions of diffusion mixing of components appears in the region of interdiffusion (Fig. 2 *b*). For systems with amorphous layering, these are regions of true solutions (to the right and left of the binodal curve) but with a variable composition. For crystalline or liquid-crystalline equilibrium systems,‡ these are the region of solutions to the left of the liquidus line in phase diagrams and the region of dissolution of an amorphous component in an amorphous phase of a crystalline or liquid-crystalline component (region below the liquidus line).

In all cases, the concentrations of solutions corresponding to compositions of co-existing phases are established on each side of the interface. Therefore, information required for the construction of phase diagrams can be obtained by performing interdiffusion at different temperatures and determining the compositions of co-existing phases in each experiment.

‡ In our review, we restrict ourselves to the consideration of thermotropic liquid-crystalline systems. Phase equilibria for lyotropic liquid-crystalline systems have been described in sufficient detail in the monograph.[44]

It should be borne in mind that in systems characterised by rather high diffusion mobility of components ($10^{-10} < D < 10^{-5}$ cm^2 s^{-1}), the above-described measurements are carried out *in situ*, which enables one to obtain phase diagrams on modern diffusiometers [45] within very short periods of time.

For systems characterised by low translational mobility of components ($D < 10^{-10}$ cm^2 s^{-1}), steps of formation of the diffusion zone and studies of the concentration distribution in this zone are, as a rule, separated in temperature and time. For example, interdiffusion in such systems [most often, these are polymer(1) – polymer(2) systems] is generally carried out at high temperatures ($T \geqslant T_g + 50°$; T_g is the glass transition temperature) over a long period of time. This process is followed by quenching of the gradient structure, the preparation of a sample and investigation of the concentration profile. If these conditions are met, the measured concentration profiles and the compositions of co-existing phases should be assigned to the annealing temperature of the system under study.

Another method of performing experiments involves an examination of swelling. In the practice of investigation of phase equilibria, this method is named the 'method of limited swelling' [25] and is recommended for determining the right branch of the binodal.[28] However, the traditional version (weight or volumetric determination of the equilibrium degree of swelling [1] followed by the calculation of the composition of the sample) of this method can be used only in the case of strictly limited swelling, *i.e.*, when the left branch of the diagram is actually absent. Apparently, this requires not only special preliminary measurements of the kinetics of polymer swelling but also the simultaneous determination of the composition of the liquid in which swelling occurs. These measurements can be used for the construction of a fragment of the binodal curve only if the composition of the liquid remains unchanged in the course of swelling. One must verify experimentally that the degree of swelling determined for the same sample is reproduced when moving along the temperature axis. In all other cases, this method can be recommended only as a preliminary step.

The third group of methods involves semiempirical calculation methods. These methods are based not on direct experimental data on phase decomposition of systems but on concentration dependences of the thermodynamic characteristics of solutions, whose extrapolation provides estimates of the positions of binodal or spinodal curves. Methods of measuring excess light scattering,[23] calculations of the thermodynamic correction $(\partial \ln a_i / \partial \ln \varphi_i$, where a_i are the activities of components, φ_i are their bulk concentrations) in experiments on self-diffusion and interdiffusion [31, 46, 47] or evaluation of the effective parameter of interaction from the results of inverse gas chromatography [1, 48] are used most extensively.

Most of the above-mentioned methods in combination with differential scanning calorimetry,[24, 49] static sorption,[50] relaxation spectroscopy,[51, 52] X-ray microanalysis,[39] electronic and atomic force microscopy [53] or photoelectron spectroscopy [54] are used for studying phase structures and compositions of polymer blends. The specificity of these studies is associated not with the organisation of experiments or interpretation of the results but with the determination of the position of the figurative point for the sample under investigation in the temperature – concentration field of the phase diagram.

As an example, we refer to the results of structural – morphological studies of blends of poly(vinyl chloride) (PVC) and poly(methyl methacrylate) (PMMA) prepared according to different methods: using a common solvent, polymerisation of methyl methacrylate in PVC, extrusion and pressing.[55, 56] It should be noted that investigations of the phase structures of these materials were carried out either at room temperature (static sorption of tetrahydrofuran and X-ray microanalysis) or using continuous heating to determine the glass transition temperatures and rheological parameters at temperatures higher than their flow temperatures. The results of measurements for this system are summarised in Fig. 3 (ω is the weight concentration) as isoconcentration lines in the temperature – concentration field of the phase diagram, because the assignment to temperatures is ambiguous. All these lines are located in a heterogeneous metastable or labile region of the diagrams,[58] and the compositions of co-existing phases measured for these blends (in the study,[57] these lines are called the compatibility boundaries) differ substantially from equilibrium values. Evidently, these structures are unstable in spite of the fact that the free energies of mixing (to be more precise, the free energies of formation of the phase structure) for some of these structures have negative values, and heating to temperatures higher than the glass transition temperature leads to secondary phase decomposition accompanied by changes in the composition of co-existing phases and their dispersion characteristics.

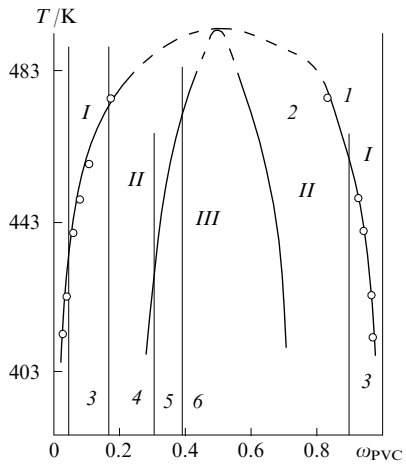

Figure 3. Phase diagram of the PVC – PMMA system.
(*1*) Binodal, (*2*) spinodal; vertical lines correspond to the compatibility limits for blends prepared by different methods: extrusion (*3*), pressing (*4*), using a common solvent (*5*), polymerisation of methyl methacrylate in PVC (*6*);[50, 57 – 59]
(*I*, single-phase solution; *II*, metastable region; *III*, region of labile solutions.)

We are sure that structural methods can also be used for the construction of phase diagrams, if special studies confirming the reversibility and equilibrium of the compositions of co-existing phases determined by a particular method are carried out and the phase transition temperature is identified.

III. State-of-the-art studies of phase equilibria

As mentioned above, the characteristic feature of the state-of-the-art studies of polymer blends is that researchers seek to obtain balanced non-contradictory data on phase equilibria and phase structures. When solving this problem, it is necessary to take into account the following facts:

— different research teams obtain experimentally reliable and adequate information on phase structures and properties of polymer blends using various methods;

— interpretation of the results is the subjective opinion of researchers, and different conclusions can be drawn based on the same experimental data;

— analysis of phase equilibria should be uniform [§] for all regions of phase diagrams and for all possible types of phase equilibria rather than being restricted to particular fragments of boundary curves (sometimes, of an unidentified phase nature);

§ Taking into account the temperature and concentration dependences, for example, for pair interaction parameters, the effect of the molecular mass, the composition of a copolymer, *etc*.

— experimental information on the phase state of particular polymer blends carries, among other things, information on the thermal prehistory of blends, conditions of preparation, thermal stability and reactivities of the components.

Polymer systems with amorphous layering are, as a rule, characterised by the following features.

1. An increase in the molecular mass (MM) of one of the components in systems with UCST generally leads to an increase in the critical temperature, extension of the two-phase region and a shift of the critical point in accordance with the Flory – Huggins theory (Fig. 4 – 6). Recall that the dependence of the solubility of polymers and oligomers on their MM (Fig. 7) served as the starting information for the development of the concept of segmental solubility of polymers in interface layers.[5] In the studies,[14, 42, 60] the dependence of the solubility on the molecular weight at a constant temperature was demonstrated to be described by linear equations on the $\varphi - (1/M)$ coordinates in a broad MM range (Figs 8, 9). These equations, in turn, can be used for the determination of critical molecular masses and compositions.

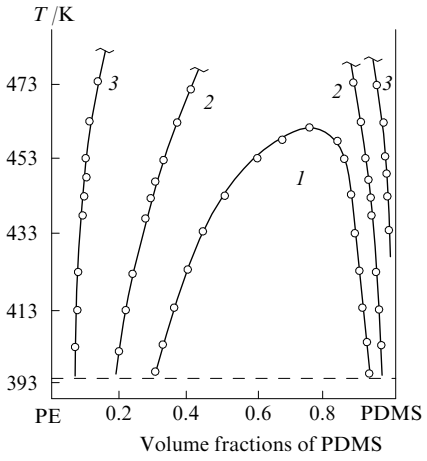

Figure 4. Phase diagrams[60] of the PE (5×10^3) – PDMS system. (Hereinafter, M_n are given in parentheses)
Molecular masses of PDMS: (*1*) 310; (*2*) 400; (*3*) 1200.

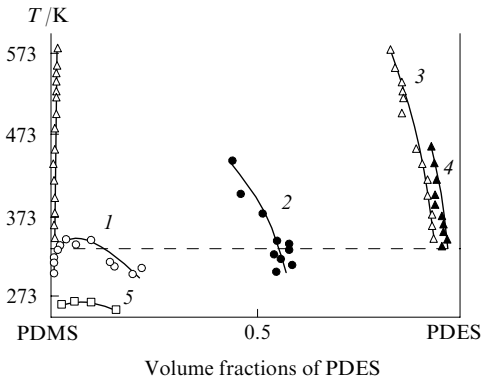

Figure 5. Phase diagrams of the polydiethylsiloxane (PDES) (3×10^5) – PDMS systems.
Molecular masses of PDMS: (*1*) 1×10^3, (*2*) 2.5×10^3, (*3*) 5.5×10^3, (*4*) 8.1×10^3 (see Ref. 42), (*5*) 1×10^3 (see Ref. 61).

Systems with LCST (Fig. 10) are characterised by somewhat different features. For these systems, an increase in the molecular mass leads to a decrease in the critical temperature, extension of the two-phase region and a shift of the critical point toward a higher-molecular-mass component.

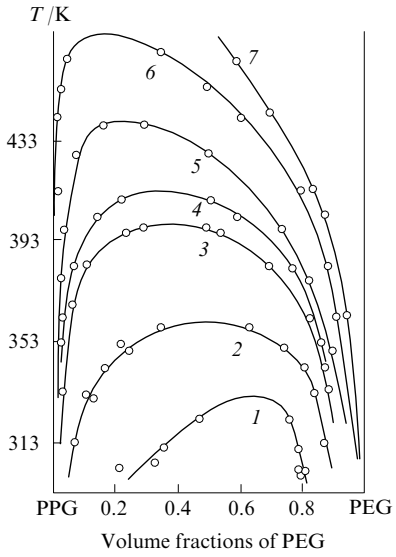

Figure 6. Phase diagram of the PPG (1×10^3) – PEG systems with different molecular masses.[15]
Molecular masses of PEG: (*1*) 600, (*2*) 1000, (*3*) 3000, (*4*) 4000, (*5*) 6000, (*6*) 15000.

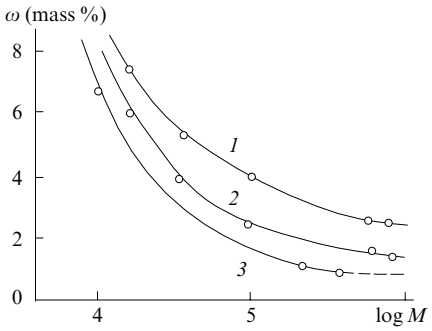

Figure 7. Solubilities of PS in PMMA (*1*, *3*)[5, 62] and PMMA in PS (*2*)[62] as functions of the molecular mass of PMMA.

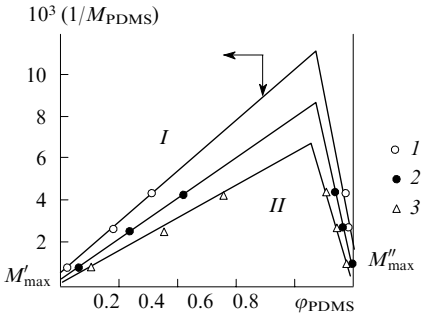

Figure 8. Isothermal sections of binodals on the $\varphi - (1/M)$ coordinates for the PE – PDMS systems at 398 (*1*), 428 (*2*) and 453 K (*3*) (*I*, one-phase region; *II*, two-phase region).[60]

2. For blends of statistical copolymers with homopolymers, the influence of the change in the molecular mass is consistent with the above-described effects. A change in the composition of a copolymer (in the case of constant molecular masses of the components) fulfils the following unified rule: the closer is the composition of the copolymer to that of the homopolymer (which is identical to a decrease in the difference in the solubility parameters of the copolymer and homopolymer), the lower is the

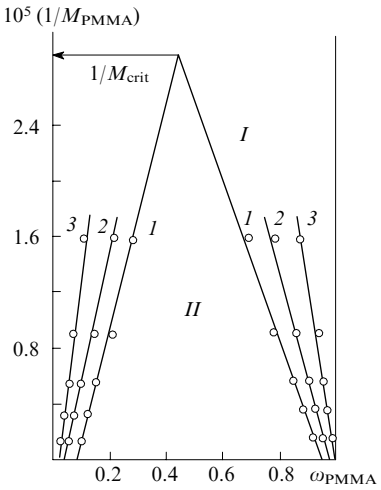

Figure 9. Isothermal sections of binodals on the $\omega-(1/M)$ coordinates for the PVC–PMMA systems at 473 (*1*), 453 (*2*) and 433 K (*3*) (*I*, one-phase region; *II*, two-phase region).[58]

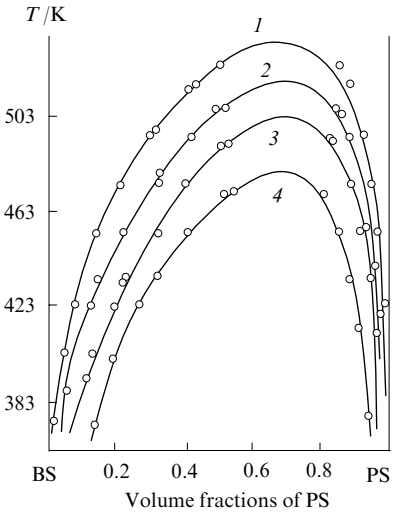

Figure 11. Phase diagrams of the PS (7.7×10^3) – BS (1.8×10^5) systems.[15] The composition of the copolymer [number of styrene units (%)]: (*1*) BS-25, (*2*) BS-65, (*3*) BS-75, (*4*) BS-85.

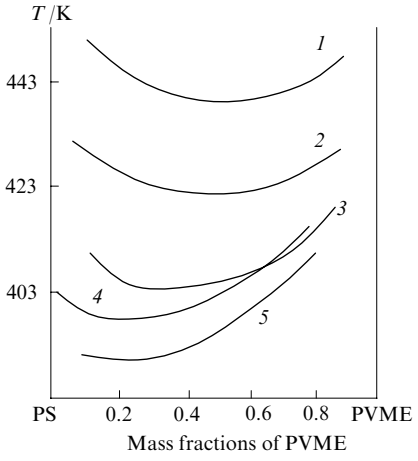

Figure 10. Phase diagrams of the PS – PVME (5.4×10^4) systems.[63] Molecular masses of PS: (*1*) 2×10^4, (*2*) 3.57×10^4, (*3*) 6.7×10^4, (*4*) 10.6×10^4; (*5*) 23.3×10^4.

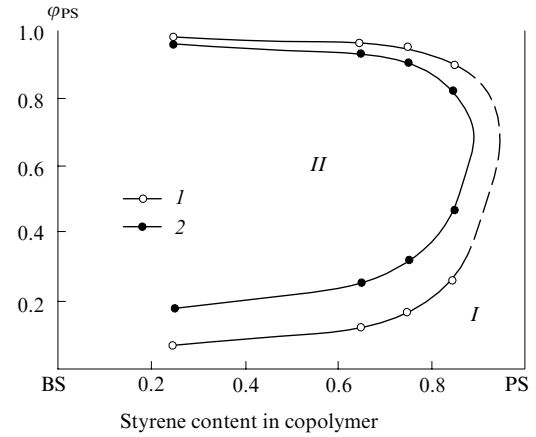

Figure 12. Isothermal sections of binodals of the PS – BS system at 423 (*1*) and 463 K (*2*) depending on the composition of the copolymer (*I*, one-phase region; *II*, two-phase region).

critical temperature of mixing (for systems with UCST) and the smaller is the region of the heterogeneous state, *i.e.*, the binodal curve as a whole is shifted downward along the temperature axis with retention of the position of the critical point. An example is a system of polystyrene (PS) and butadiene–styrene random copolymers (BS) (Fig. 11). It should be noted that the construction of isothermal sections of binodal curves allows one (as can be seen from Fig. 12) to determine the critical compositions of copolymers and the critical concentration of a blend containing components with particular molecular masses at a particular temperature. For example, in the PS–BS system with MM $\approx10^5$, the critical composition of the copolymer above which the system is compatible corresponds to 90 mass % and 95 mass % of polystyrene units in the copolymer chain at 463 and 423 K, respectively.

3. The formation of a three-dimensional cross-linked network in one of the components leads to extension of the two-phase region, a shift of the branch of the binodal curve corresponding to solubility of the sol fraction toward the axis of the linear homopolymer (and its degeneration at high degrees of conversion) and location of UCST in the region of thermal destruction of the material.[64,65]

It should be noted that a series of systems described in the literature are not characterised by the above features. For example, the solubility in the PMMA–poly(ethylene glycol) (PEG) system (Fig. 13), unlike that in poly(propylene glycol) (PPG) (Fig. 14), increases with increasing molecular mass of PEG in spite of the fact that the former system has UCST. At MM (PEG) $>3\times10^3$, UCST is lower than the melting point of PEG, and the dome of the binodal is located under the liquidus line of high-molecular-mass PEG. In this case, the position of the critical point, as expected, is shifted to the middle of the composition region. It should be noted that a phase diagram reported in the studies[22,67] for the same system but with another ratio between the molecular weights of the components has both a binodal and a liquidus line (Fig. 15). This behaviour is not specific to the above systems. Analogous results were obtained in the studies[14,68,69] for the following systems: butadiene–acrylonitrile random copolymers (BAN) and acrylated oligoesters (AOE), PVC–AOE and polyethylene (PE)–saturated alcohols, respectively. For these systems, unusual dependences of isothermal sections of phase diagrams on the molecular masses of the components were obtained. As can be seen from Fig. 16, the polyisoprene (PI)–acrylated oligoester system is completely compatible if the number of methylene groups (*n*) in the hydrocarbon frag-

ment is 10, whereas this system is only partially compatible at $n > 15$. This effect should be related to the influence of the terminal groups on the solubility parameter of oligomers.

Other examples of the anomalous behaviour of polymer – polymer systems are substantial differences in UCST (Fig. 17) with retention of the critical concentration, the presence of two critical temperatures in the same temperature – concentration region [PVC – PMMA, Fig. 18; poly(vinyl methyl ether) (PVME) – PS, Figs 10 and 19; PE – polyisobutylene melt],[60, 73] substantial differences in the shape of the binodal curve in the vicinity of the critical temperature (PS – PI) [74, 75] and independence of the critical concentration of the molecular mass of the components with retention of the usual dependence of the critical temperature in the polycarbonate (PC) – epoxide oligomer (EO) systems (Fig. 20).[76]

The results of studies of polymer systems containing crystallisable components are also often contradictory. Generally, liquidus curves for polymer – solvent systems obtained by different researchers by various experimental methods are identical or close to each other,[77, 78] the melting point depressions being in satisfactory quantitative agreement in a broad composition range for a homologous series of solvents (Fig. 21),[79] whereas there is no

quantitative agreement between the melting point depressions for polymer – polymer systems even if extrapolations to the equilibrium melting temperatures are used.[24, 80–82] Unfortunately, the preliminary experimental data on liquidus curves rather than equilibrium melting temperatures were reported in most studies.[24] Besides, the results of these measurements were often considered as the most suitable data for calculations of pair interaction parameters (χ) of the components.[83, 84]

Fragments of the diagrams for crystalline equilibrium in the PMMA – PEG system are shown in Fig. 22. It can be seen that the melting point decreases in all cases, which is consistent with the general thermodynamic relations.[85, 86] However, different researchers reported substantially different melting point depressions. For example, it was found [67] that a change in the composition by 20% led to depression of 10 – 15 K, whereas this value was estimated at 1 – 5 K in the studies.[22, 87, 88] The estimates of χ obtained from these data in the context of the approach proposed by Nishi and Wang [84] demonstrate a scatter from -5.0 to -0.5, which cannot evidently be ignored.

The same problems arise in the analysis of data on liquid-crystalline equilibrium in blends of thermotropic polymers. Data on blends of polydimethylsiloxane (PDMS) and cyclolinear siloxanes (CS) [40] are exemplified in Fig. 23. Interestingly, the isotropisation temperature depression (ΔT_{iso}) is substantially larger than the melting point depression (ΔT_m). In the system presented in Fig. 23, $\Delta T_m \approx 5^\circ$, whereas $\Delta T_{iso} \approx 30^\circ$ at the same concentration of amorphous PDMS.

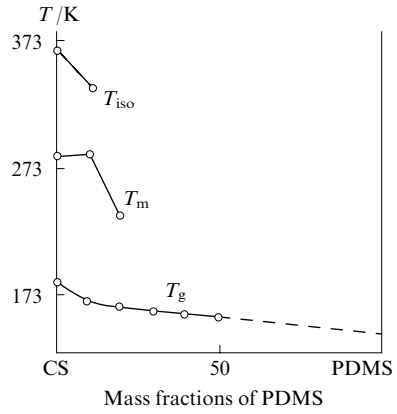

Figure 23. Phase diagram of the CS (4.4×10^4) – PDMS (600) system.[40]

The equilibrium in the poly(butylene terephthalate) (PBTF) – liquid cristalline polyether (PET) system belongs to complex equilibria (Fig. 24)[41] involving liquid-crystalline components, which undergo the mesomorphic transition. The problem of the equilibrium mesomorphic transition was virtually not discussed, *i.e.*, it was implicitly assumed that the mesomorphic component passes completely into a liquid-crystalline phase. However, this assumption requires structural validation.

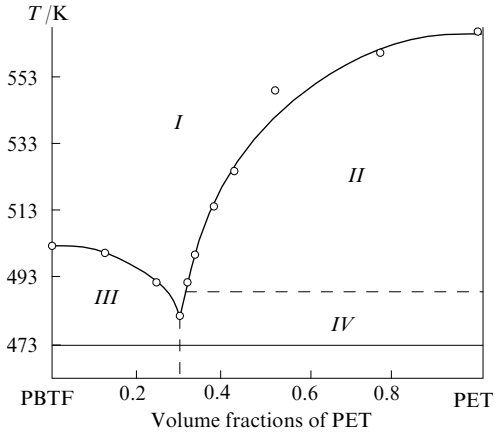

Figure 24. Phase diagram of the PBTF – PET system.[41]
(*I*) Region of isotropic solutions, (*II*) region of the liquid-crystalline state of PET, (*III* and *IV*) regions of the crystalline state of PBTF and PET, respectively.

Since all the above-described diversity in the phase behaviour of polymer blends seems to be a rule rather than the exception, the questions arise of whether it is possible to obtain a balanced general picture of phase equilibria in the context of the physico-chemical concepts and which parameters and/or conditions should be additionally used to obtain information on equilibrium and non-equilibrium states of the compositions of co-existing phases.

IV. Theoretical analysis

Although there are several theories of polymer solutions, we believe that it is possible to use the simplest and most widely accepted one, *viz.*, the classical version of the Flory – Huggins theory,[90] for several reasons. First, it was demonstrated[6,12] that the predictive ability of this theory is no worse than that of the new Flory theory, the Prigogine – Patterson theory, the Sanchez – Lacombe theory and the new Huggins theory. Second, the basic concepts of this theory are simple and evident. Third, we are sure that this theory has a high undisclosed potential.

Recall that the Flory – Huggins theory, as applied to polymer – polymer systems, gives the following expressions[91–93] for the free energy of mixing ¶

$$\Delta G_m = RT\left[\frac{\varphi_1 \ln(\varphi_1)}{r_1} + \frac{\varphi_2 \ln(\varphi_2)}{r_2} + \chi\varphi_1\varphi_2\right],$$

the chemical potentials of components

$$\Delta\mu_1 = RT\left[\frac{\ln(\varphi_1)}{r_1} + \left(\frac{1}{r_1} - \frac{1}{r_2}\right)\varphi_2 + \chi\varphi_2^2\right],$$

$$\Delta\mu_2 = RT\left[\frac{\ln(\varphi_2)}{r_2} + \left(\frac{1}{r_2} - \frac{1}{r_1}\right)\varphi_1 + \chi\varphi_1^2\right],$$

the parameters of critical points

$$\chi_{crit} = \frac{1}{2}\left(\frac{1}{\sqrt{r_1}} + \frac{1}{\sqrt{r_2}}\right)^2,$$

$$\varphi_{2,crit} = \frac{\sqrt{r_1}}{\sqrt{r_1} + \sqrt{r_2}}, \qquad (1)$$

the spinodal concentration

$$\frac{1}{r_1\varphi_{1,s}} + \frac{1}{r_2\varphi_{2,s}} - 2\chi = 0,$$

the melting point depression[77,84]

$$\Delta T_m = \frac{\Delta\mu_{2,cr} T_m^\circ}{\Delta H_m}$$

and the isotropisation temperature depression[94]

$$\Delta T_{iso} = \frac{\Delta\mu_{2,meso} T_{meso}^\circ}{\Delta H_{meso}},$$

where ΔG_m is the molar free energy of mixing, φ_1 and φ_2 are the volume concentrations of the components, r_1 and r_2 are the ratios of the molar volumes to the reference volume, which are approximately equal to the degrees of polymerisation of the components, χ is the pair interaction parameter, $\Delta\mu_1$ and $\Delta\mu_2$ are the chemical potentials of the components in the amorphous state, χ_{crit} and $\varphi_{2,crit}$ are the parameters of the critical point, $\varphi_{1,s}$ and $\varphi_{2,s}$ are the spinodal concentrations, ΔT_m is the melting point depression, T_m° is the melting point of a pure component, ΔH_m is the enthalpy of melting, $\Delta\mu_{2,cr}$ is the chemical potential of the crystallisable component in the crystalline state, ΔT_{iso} is the isotropisation temperature depression, T_{iso}° is the isotropisation temperature of a pure component, ΔH_{meso} is the enthalpy of the mesomorphic transition and $\Delta\mu_{2,meso}$ is the chemical potential of a component in the liquid-crystalline state.

The following conclusions can be drawn from these equations:

— the isotropisation temperature depression is larger than the melting point depression $\Delta T_{iso} = \Delta T_m \Delta H_m / \Delta H_{meso}$ in the case of equal chemical potentials and phase transition temperatures of a pure component;

— the position of the critical point is always determined by the molecular mass ratio; hence, if the molecular mass of one component is known, the mass of another component can be calculated from the experimentally determined positions of critical points;

¶ All thermodynamic potentials are excessive with respect to the standard state (pure components).

— this theory allows one to analyse the region of true solutions from the viewpoint of the existence of concentration fluctuations, which are considered as clusters by Zimm and Lundberg:[95–97]

$$\frac{G_{11}}{v_1} = -(1-\varphi_1)\left[\frac{\partial(a_1/\varphi_1)}{\partial a_1}\right] - 1\,,$$

$$\frac{G_{11}}{v_1} = \frac{1}{\varphi_1}\left[\frac{1}{\varphi_1(1/r_1\varphi_1 + 1/r_2\varphi_2 - 2\chi)} - 1\right],$$

$$N_c = \frac{\varphi_1 G_{11}}{v_1} + 1 = \frac{1}{\varphi_1(1/r_1\varphi_1 + 1/r_2\varphi_2 - 2\chi)},$$

where G_{11}/v_1 is the integral of clusterisation and N_c is the number of molecules in the cluster.

It can be seen that the integral of clusterisation is determined by the distance to the spinodal curve. Hence, traditional phase diagrams can be supplemented with regions in the vicinity of binodal curves, where the appearance of heterophase fluctuations and cluster structures would be expected.[98] The results of NMR spectroscopy using pulsed gradient magnetic field (Fig. 25)[32] provide direct evidence for the existence of such heterophase fluctuations and cluster structures.

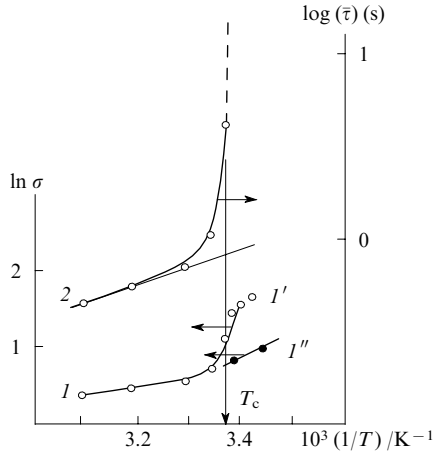

Figure 25. Temperature dependences of the spectral width (σ), the self-diffusion coefficients (*1*, *1′*, *1″*) and the average lifetime ($\bar{\tau}$) of macromolecular associates (*2*) in the PS – cyclohexane system.[32] $\varphi_{PS} = 0.15$; (*1′*) microlayering, (*1″*) macrolayering of the system.

Phase diagrams not only contain information on temperature – concentration regions of co-existence of phases, miscibility of components and the ratio between the dispersed phase and dispersion medium but also enable one to obtain information on the thermodynamic parameters of interaction, in particular, on the pair interaction parameter.

Figure 26 exemplifies the temperature dependence of the parameter χ for the PMMA – PEG system. It can be seen that χ for systems characterised by one critical temperature (UCST or LCST) depends linearly on $1/T$. Consequently, χ can be divided into the enthalpy (χ_H) and entropy (χ_S) components,[99] and the critical temperature can be estimated by extrapolating to χ_{crit}. For systems possessing two critical temperatures, the dependence takes the form shown in Fig. 27. For these systems, both critical temperatures (Fig. 28) can be estimated by extrapolating χ to χ_{crit}.

The thermodynamic parameters of mixing determined from analysis of complex equilibria should be characterised by similar dependences on the concentration, temperature and molecular mass. If the boundary curves of different types intersect at a single point (see, for example, Figs 15 and 22), the thermodynamic parameters should be equal in magnitude. In many cases, this condition is not fulfilled. For example, according to the results of

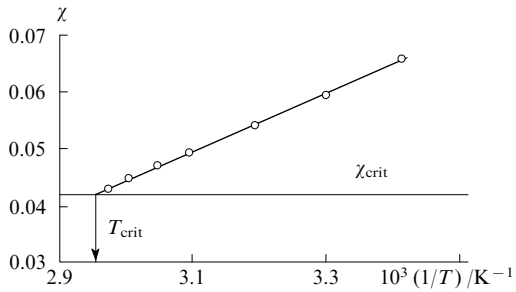

Figure 26. Plot of the pair interaction parameter *vs.* the inverse temperature for the PMMA (2×10^5) – PEG-600 system. (The phase diagram of this system is shown in Fig. 13.)

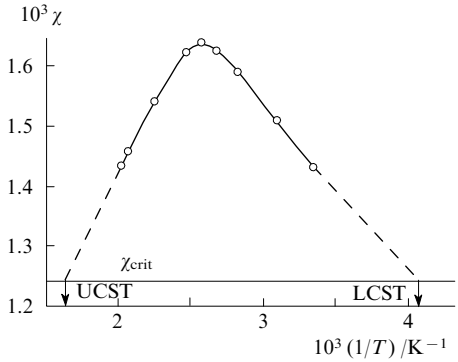

Figure 27. Plot of the pair interaction parameter[100] *vs.* the inverse temperature for the PCP (1.2×10^5) – BAN-26 (2.3×10^5) system.

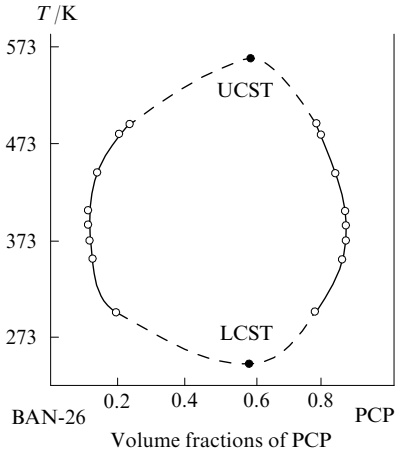

Figure 28. Phase diagram[100] of the BAN-26 (2.3×10^5) – PCP (1.2×10^5) system; UCST and LCST are extrapolated.

the study,[22] the parameter χ for the PMMA – PEG system, which was calculated from the crystalline equilibrium state at the point of tangency of the binodal and liquidus curves, is -0.584, whereas, according to the results of another study,[67] this parameter for the same system at the same tangency point is -4.97. At the same point, the parameters χ calculated from the data on amorphous equilibrium are 2.7×10^{-4} and 2.5×10^{-4}, respectively. Evidently, these facts require a more thorough thermodynamic and structural analysis.

In the study,[60] it was demonstrated that the phase behaviour of a polymer system can be predicted based not only on the pair interaction parameter but also on the solubility parameters of components (δ_1 and δ_2), which are related to χ by the following equation

$$\chi = \frac{z\Delta\omega_{12}}{kT} = \frac{z(\delta_1 - \delta_2)^2}{kT}, \qquad (2)$$

where z is the coordination number of the system and $\Delta\omega_{12}$ is the exchange energy.

The positions of the boundary curves of the miscibility region of a particular polymeric component and any other component can be calculated according to Eqn (2). For PMMA and a PE melt, these regions are presented in Figs 29 and 30, respectively. As can be seen from these figures, the higher is the molecular mass of the component, the smaller is the hypothetical region of mutual compatibility of this component and other components, which agrees with the Flory – Huggins theory.

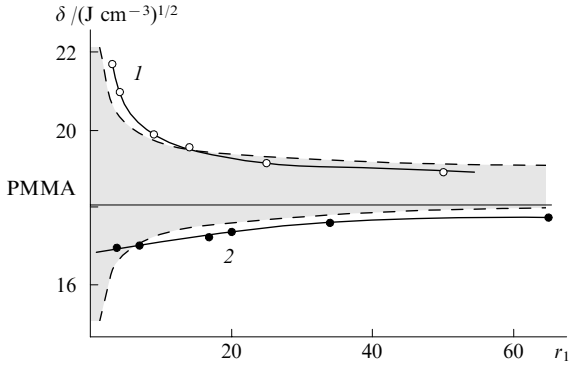

Figure 29. Plots of the solubility parameters of PEG (*1*) and PPG (*2*) *vs.* the degree of polymerisation (r_1) of oligoglycol.[88] The region of compatibility with PMMA is shaded.

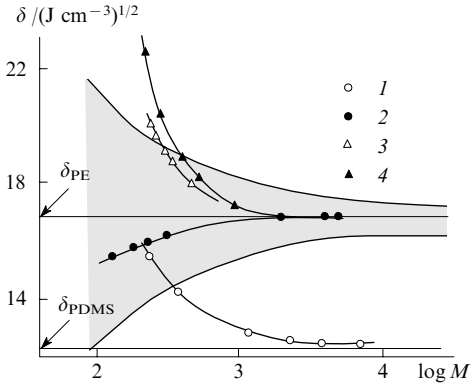

Figure 30. Plots of the solubility parameters of PDMS (*1*), saturated hydrocarbons (*2*), *p*-methylene dimethacrylates (*3*) and phthalic esters (*4*) *vs.* their molecular masses. The region of complete compatibility of oligomers with polyethylene is shaded.[60]

The position of the figurative point of the second component, which is determined by the degree of its polymerisation, the solubility parameter and the nature of the terminal groups and monomer units, shows how the compatibility between components changes with the molecular mass. This representation of the data on miscibility enables one to reveal the influence of the terminal groups, which generally differ in nature from monomer units, and, correspondingly, differ in the local solubility parameter, on the compatibility between components. As the molecular mass increases, this influence decreases and the trajectory of motion of the figurative point of the second component on the $\delta - \log M$ coordinates becomes flatter.

Let us consider the trajectories of motion of the figurative points for PEG and PPG (Fig. 29) in more detail. As the molecular mass of PEG increases, its figurative point goes from the two-phase region into the one-phase region and then again passes into the two-phase region at very high MM ($\sim 100\,000$). For PPG, the situation is simpler and more traditional: the figurative point is initially located in the one-phase region and then leaves this region and moves farther and farther away as the molecular mass of PPG increases. Based on Fig. 29, one can predict how the compatibility between the components will change depending on the nature of the terminal group of polyglycol or on going from a homopolymer to copolymers of ethylene glycol and propylene glycol. Analogous changes in the compatibility are observed in blends of PE with low- and high-molecular mass compounds.[101] Therefore, information on the influence of the terminal groups on the compatibility between components is also indirectly present in the Flory – Huggins theory of polymer solutions.

In conclusion of this section, it should be noted that knowing the temperature dependence of χ (experimentally determined or calculated)[12] and the starting phase state of the components, the possible phase states can be estimated in a broad temperature range and the full concentration range. The generalised phase diagram of the PDMS – CS system[94] is exemplified in Fig. 31.

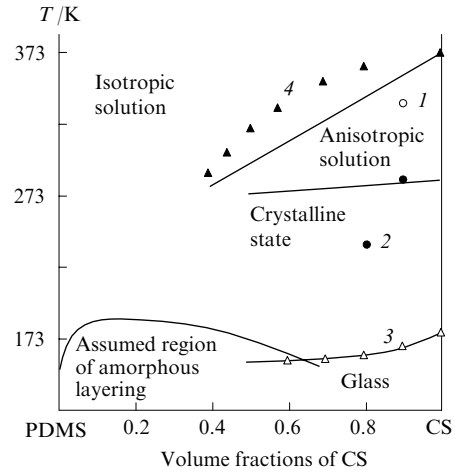

Figure 31. Generalised diagram of phase and physical states[94] of the PDMS (600) – CS (5.1×10^4) system.
Calculated curves are indicated by solid lines. Circles and triangles represent the experimental temperatures of the mesomorphic transition (*1*)[40] and (*4*),[94] crystallisation temperature (*2*)[40] and glass transition temperatures (*3*).[40]

The above-considered facts lead to the following important conclusions.

1. If data obtained for a polymer system by different researchers using various methods are consistent with each other, the results would be expected to be equilibrium or close to equilibrium. The thermodynamic parameters calculated from these data should demonstrate self-consistent behaviour depending on external parameters and do not contradict the major theoretical conclusions.

2. If there is a discrepancy between data obtained by different researchers with the use of various methods, one cannot say with certainty which experimental data are close to equilibrium or how much they differ from equilibrium without resorting to additional structural and, sometimes, kinetic studies. In this case, one can speak only about trends in changes in the boundary curves. The thermodynamic parameters of the compounds with the same phase structure may, for good reason, differ from each other, but their changes depending on external parameters should be of the same character. In our opinion, it is this requirement that is the distinguishing feature of the present stage of investigation of phase equilibria in polymer systems.

The results [71] (see Fig. 18) for the PVC – PMMA system, which has been studied many times and in sufficient detail, provide a prominent example of a fundamental contradiction in the experimental data on phase structures and phase equilibria. It can be seen that the binodals with LCST are located in the region of active thermal destruction of PVC, and the observed turbidity is, most likely, attributable to a change in the chemical structure of the macromolecular chain (formation of polyene sequences [102]) and the appearance of gaseous destruction products. This problem was discussed in detail in the study.[103] A change in the phase state of the system under changes in the chemical nature of the components is of its own interest. At present, theoretical aspects of this problem are in their developmental stage and the required experimental data are being accumulated.[14, 20, 64, 104]

V. Non-equilibrium and metastable states

In a general way, the non-equilibrium state of any system, including polymer systems, can be determined as a deviation from equilibrium. This deviation can be estimated from one of the following parameters: the density, compositions of co-existing phases, the presence of the concentration gradients, dispersion and interface characteristics, *etc*. The metastable state of a system is a special case of a non-equilibrium state in which phase decomposition of the system is hindered or does not occur at all. It should be noted that the location of the figurative point of a system in metastable or labile regions of the phase diagram is necessary but insufficient evidence for the assignment of a material with a particular composition to a metastable state or to materials with a spinodal structure. It is more probable that this is the initial state of a blend, which is responsible for the trajectory of further structural transformations as the system approaches equilibrium.[105 – 107]

Right there the simplicity and obviousness of characterisation of a non-equilibrium state end, because it is necessary to determine experimentally and characterise the equilibrium state and its parameters for each particular system under study; otherwise, one cannot speak about the equilibrium or non-equilibrium state of a particular sample or material prepared under certain conditions.

Non-equilibrium states of polymer blends occur much more frequently than the equilibrium state.[108] However, the thermodynamic description of materials, which is presently used in physical chemistry of polymers and polymer materials science, is based on theories of polymer systems belonging to equilibrium states of blends, solutions and melts.[109] The reasons for this fact are known and have been discussed in many monographs.[14, 15, 110]

In one of his publications, Prigogine [110] determined the place of equilibrium thermodynamics within the framework of non-equilibrium thermodynamics as a limiting case of non-equilibrium thermodynamics with energy fluxes tending to zero. Based on this opinion, we believe that the non-equilibrium state of polymer blends can be described, but only on condition that the time of experiment is much shorter than the time it takes for the structure to be noticeably changed, *i.e*., shorter than the time it takes for the non-equilibrium state of the mixture to be essentially changed.[31]

In studies of particular polymer systems by various methods, the temperature dependences of the compositions of co-existing phases are found, the structure and morphology of blends are determined and the thermodynamic potentials of mixing are calculated. Evidently, to compare experimental data and reveal possible contradictions, it is necessary that the thermodynamic parameters under consideration should have the same physical sense. For this purpose, we interpreted [100] results using the following sequences.

1. Phase diagrams → calculation of the temperature dependence of the pair interaction parameters → construction of the generalised diagram → calculation of the concentration dependence of the free energy of mixing.

2. Sorption isotherms of a common solvent → determination of the chemical potential of the polymeric component → calculations of partial free energies of pure polymers and their mixtures → calculation of the free energy of mixing of a polymer blend with a particular composition possessing a certain processing prehistory.

3. Phase structure → determination of the compositions of co-existing phases (from results of X-ray spectral analysis) → determination of the medium size of the dispersed phase and its size distribution → calculation of the interface surface energy → calculation of the total free energy of a particular sample.

Therefore, all experimental evidence reduces to the only comparable characteristic, *viz*., the free energy of mixing of a particular object possessing a certain processing prehistory.

The phase diagram of the polychloroprene (PCP) – BAN-18 system [100, 111] is shown in Fig. 32. Processing of this diagram gave the temperature dependence of the pair interaction parameter and the concentration dependence of the free energy of mixing for the isotherm corresponding to the temperature at which sorption measurements were carried out (Fig. 33). The dashed line links the free energies of co-existing phases, *i.e*., the free energies of mixing of a completely equilibrated two-phase system. The solid line located between the binodal concentrations corresponds to a non-equilibrium one-phase solution. The difference between these lines

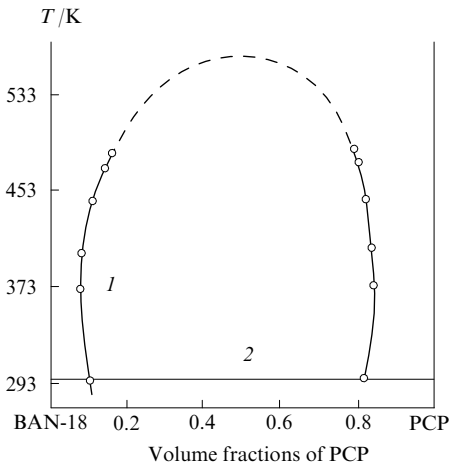

Figure 32. Phase diagrams [15] of the PCP (1.2×10^5) – BAN-18 (2.2×10^5) system.
(*1*) Binodal, (*2*) isotherm corresponding to the temperature at which sorption measurements were carried out.

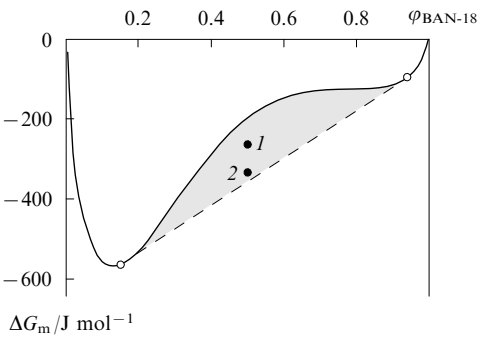

Figure 33. Dependence of the free energy of mixing [112] for the PCP (1.2×10^5) – BAN-18 (2.2×10^5) system.
The common tangent is shown by a dashed line. The compositions of co-existing phases are represented by empty circles. Solid circles indicate $\Delta G_{m,sorp}$ for samples prepared by milling (*1*) and using a common solvent (*2*).

is equal to a gain in energy achieved on going from the one-phase non-equilibrium state to the two-phase equilibrium state.

A traditional thermodynamic analysis of sorption isotherms [113] of tetrahydrofuran on the same polymer blends using the Gibbs–Duhem equation [114] and the Hess cycle [1] allows one to determine free energies of mixing of polymer blends (points *1* and *2* in Fig. 33). As can be seen from Fig. 33, calculated $\Delta G_{m,sorp}$ have negative values in spite of the fact that the systems under study are heterogeneous, and the experimental values for samples of materials prepared under particular conditions of mixing of polymers differ from each other as well as from the theoretical values for equilibrium and non-equilibrium states of the system. The free energies of polymer materials, which were determined from sorption measurements, are located in the shaded region some distance from the equilibrium state.

We believe that with a knowledge of these thermodynamic data, it is possible to characterise quantitatively the non-equilibrium state of a particular material by determining the degree of non-equilibrium (α) as follows

$$\alpha = \frac{\Delta G_{object} - \Delta G_{sep}}{\Delta G - \Delta G_{sep}}. \qquad (3)$$

The notations are explained in Fig. 34.

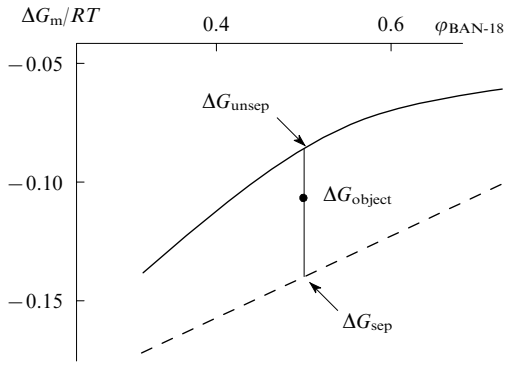

Figure 34. Fragment of the dependence (Fig. 33) of ΔG_m on the composition of the blend; ΔG_{sep} and ΔG_{unsep} correspond to the layered and non-layered systems, respectively.

It should be noted once again that the degree of non-equilibrium calculated according to this equation characterises all non-equilibria (with respect to compositions, particle size, the state of interfaces, *etc*.) resulting in a deviation of the position of the figurative point of the sample from its projection onto the common tangent line.

Analysis of the structural and morphological organisation of blends and estimations of interface surface energies revealed the reasons for the appearance of non-equilibrium in this system in more detail.[115, 116] It was demonstrated [100] that the compositions of co-existing phases in materials subjected to sorption studies (Fig. 35) correspond to binodal concentrations, and the samples differ from each other in the particle size distribution. Therefore, the non-equilibrium state of these materials is associated with an excess interface surface and, correspondingly, with the excess Gibbs free energy

$$\Delta G_m = \varphi \Delta G' + (1 - \varphi)\Delta G'' + \sigma S,$$

where $\Delta G'$, $\Delta G''$ are the free energies of mixing of each phase, φ is the fraction of a dispersed phase and σS is the interface energy.

Taking into account the latter expression for ΔG_m, the numerator of Eqn (3) is σS. The average sizes of phases estimated from structural and morphological data are in satisfactory agreement with the estimates based on thermodynamic data.[100]

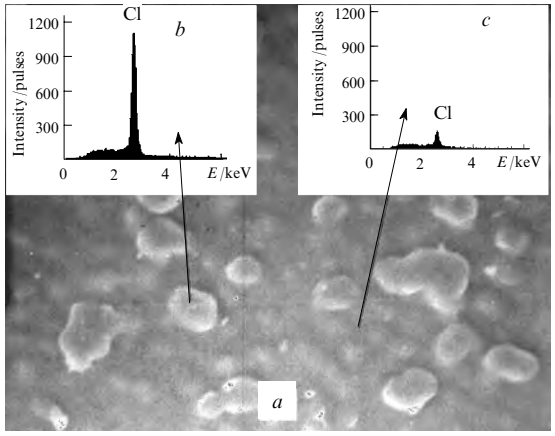

Figure 35. Surface morphology of a low-temperature chip of the PCP (1.2×10^5) – BAN-26 (2.3×10^5) blend obtained by scanning electron microscopy (*a*). The spectra of characteristic X-ray radiation of the dispersed phase (*b*) and the dispersion medium (*c*) are shown in insets.

Other systems also show analogous non-equilibrium behaviour upon the formation of polymer blends in solution in a common solvent.

In the study,[112] the above-described approach and the results of structural–morphological investigation were used for calculating free energies of mixing for equilibrium, non-equilibrium and real systems. As can be seen from Fig. 36, the character of changes in the free energy of mixing upon the formation of a binary polymer blend from a three-component solution is analogous to that described above. Using Eqn (3), it is also possible to estimate quantitatively the degree of non-equilibrium for various composites, which is associated with the excess Gibbs free energy located in interface layers of co-existing phases. It should be noted that the figurative points of particular samples are remote from non-equilibrium curves. It was demonstrated [112] that this effect may be attributed to the energy spent for nucleation of a dispersed phase.[117]

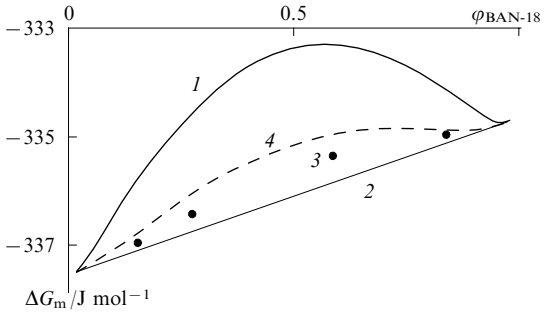

Figure 36. Plot of the free energy of mixing *vs*. the concentration of one of the polymers for the PVC – BAN-18 – dichloroethane system.
(*1*) Non-equilibrium one-phase system, (*2*) equilibrium two-phase system, (*3*) (circles) free energies of materials taking into account the total interface energy, (*4*) free energies of materials taking into account the total interface energy of critical nuclei.

A more complex situation is observed for the PVC – PMMA system. Analysis of the experimental data on the prehistory of the preparation of polymer blends shows that the largest discrepancy in the results is observed when THF or ethyl methyl ketone is used as a common solvent. As can be seen from Fig. 37, a change in the composition of solutions on going from a ternary system to a binary one gives rise to a region of stable phase structures in the

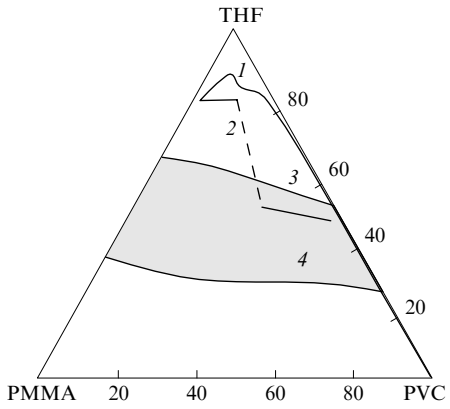

Figure 37. Diagram of phase and physical states[118] for the PVC – PMMA – THF system at 293 K.
(*1*) Binodal, (*2*) line of stabilisation of the phase structure, (*3*) line of critical viscosity, (*4*) glass transition.

middle region of the phase diagram.[118] The structure formed in this region remains unchanged upon removal of the solvent and going to a binary system.

Such materials are characterised by several types of non-equilibrium: first, the deviation of the compositions of co-existing phases of particular composites from equilibrium values (see Fig. 3); second, high dispersity and, as a consequence, a high excess surface energy; third, a large excess free volume because evaporation of the solvent is accompanied by the glass transition of the system and the latter is rather far removed from the glass transition temperature.

All the above-mentioned types of non-equilibrium are most pronounced when a binary polymer blend is prepared with the use of a common solvent and are much less pronounced in the case of mixing in a melt or polymerisation of the MMA monomer in the PVC matrix.

Direct structural – morphological studies[39, 119, 120] demonstrated that annealing of non-equilibrium structures led to secondary phase decomposition resulting in degeneration of the first and third types of non-equilibrium. In the phase diagram, the character of the binodal curve in the vicinity of the critical point is noteworthy. It should be noted that the double-hump shape of the curve is reversible and highly reproducible, depends only slightly on the molecular mass of PMMA and is observed only in experiments with the use of a limited range of common solvents.

Detailed IR spectroscopic studies of the conformational states of macromolecular chains of PVC in solutions, melts and starting powders prepared under various conditions of suspension polymerisation revealed[121, 122] three stable conformational states of PVC characterised by different glass transition temperatures, melting points and supramolecular organisation. The first state has regular helical TGTGTGT conformations of the chain with an isotactic sequence as well as long planar TGTG conformations in a syndiotactic configuration and appears in the synthesis of PVC. This state corresponds to a supramolecular structure of the fringed-micelle type. The second state is formed from solution and is characterised by short TT sequences and the micellar folded morphology. The third (intermediate) type is characterised by a set of conformers of the first and second types.

Following the principle of independence of phase equilibria proposed by Papkov,[28] it can be assumed that the double-hump shape of the binodal curve results from the presence of two conformational states of PVC in the system; the ratio between these states varies depending on the nature of the solvating agent.

Based on the aforementioned facts, a new type of non-equilibrium, which is associated with the possible existence of the temperature – concentration region of stable conformers of macromolecular chains, should be taken into account. In this case, the appearance of LCST (see Fig. 18) is, presumably, caused by a change in the set of conformations.

An analogous effect of the change in the character of the phase equilibrium under the influence of the solvent and the appearance of UCST (see Fig. 19) were observed in the PS – PVME system characterised by LCST.[62]

This complex phase behaviour is typical of many systems containing PVC as a component. Examples are provided by the PVC – dioctyl phthalate[105] and PVC – BAN-40 – solvent systems.[123]

Pseudobinodal curves, which are not reproduced in heating – cooling cycles, were also observed. In a number of studies, two glass transition temperatures and melting points were detected.[124] The influence of the nature of the solvent on the phase state of a system was also reported.[125] Interestingly, all these anomalous phenomena are correlated to the position of the region of conformational rearrangements.

VI. Conclusion

The main characteristic features of the influence of the molecular-mass characteristics on phase equilibria in polymer – polymer systems were revealed and confirmed in studies of many binary and ternary systems. The deviations from these features described in original studies reflect the specificity of the behaviour of particular polymers rather than argue against these general features. The development of polymer materials science is associated with both further accumulation of experimental data, primarily, on phase diagrams, and elucidation and classification of specific features of the behaviour of polymer systems.

We believe that the notions 'system' and 'material' should be distinguished for a more clear understanding of experimental and theoretical data. Systems are characterised by a phase equilibrium and a phase diagram, equilibrium and reproducible thermodynamic parameters, parameters determining the translational characteristics, the identity of the intermediate region of conjugated phases and the interface, the minimum interface surface.

Materials are characterised by a specific phase structure, which depends on the thermal and processing prehistory, and a set of non-equilibria of various types. The interface is only a part of the intermediate region of conjugated phases. Both the translational and thermodynamic characteristics depend on the prehistory of the material and can vary with time.

This classification seems to be necessary and fruitful for the development of the concept of the determination of equilibrium characteristics and the degree of non-equilibrium of particular materials.

In our opinion, the following conditions should be met to solve the problem of non-equilibrium states of binary and ternary polymer systems.

— Researchers must overcome the psychological barrier associated with the identification of the thermodynamic parameters for particular materials (thermal capacity and its temperature dependence, free energy of mixing, interaction parameters) with the thermodynamic parameters of equilibrium systems. For example, the results of determination of ΔG_m for polymer blends from sorption measurements[1] or by inverse gas chromatography[48] characterise not ΔG_m for the equilibrium state but the free energy of mixing of a particular sample with a particular phase structure prepared under particular conditions.

— Further investigation of the mechanism of formation of the non-equilibrium structural – morphological organisation of materials is required. It is customary to assume that materials in which mutual dissolution or structure formation and establishment of the thermodynamic equilibrium are complicated by the glass transition of solutions, melts and blends, should be assigned to non-equilibrium materials. However, in a number of studies,[5, 62, 118] it was demonstrated that the structural – morphological organisation of a sample is stabilised also in highly elastic and plastic states, if partial coefficients of translational diffusion of

components, which are responsible for nucleation of a new phase and nucleus growth, amount to as much as 10^{-12} cm^2 s^{-1}.

Within the framework of the proposed approach, a number of important problems remain to be solved and call for special systematic studies.

1. For amorphous equilibrium systems, the most important aims are to study experimentally and elucidate the behaviour of the composites of co-existing phases in the vicinity of a dome of double-hump binodals, find the number and positions of critical points and determine the spinodal curve.

2. Based on the available experimental data, polymers can be considered as sets of stable conformers. Evidently, in this case, the phase diagram should be constructed in another concentration – temperature field.

3. Partially crystalline polymers are, generally, non-equilibrium primarily with respect to their supramolecular and phase structures. This initial non-equilibrium state of a material has a determining effect on the thermodynamic characteristics of polymer solutions and blends and complicates seriously calculations of the thermodynamic parameters of mixing for crystalline equilibrium systems.

4. The observed changes in the positions of boundary curves in the temperature – concentration field of phase diagrams under mechanical effects of various types call for interpretation from the structural, conformational and thermodynamic standpoints.

In the future, fundamental investigations of phase equilibria and phase structures of polymers can be applied to prediction problems in materials science, *i.e.*, predictions of processing conditions, efficiency and service life of polymer materials. However, theoretical predictions are years in the future. At present, semiempirical methods are used. For these methods, information on phase diagrams is of most importance. One of the major aims is still to improve methods for the empirical and semiempirical prediction of equilibrium states of polymer systems.

Abstract. The state-of-the-art of research dealing with the development and perfection of metal corrosion inhibitors in aqueous solutions is analysed. The main mechanisms involved in formation of protective layers on metals by inhibitors are discussed. Ways of creating mixed corrosion inhibitors with high protective properties are considered. The bibliography includes 150 references.

I. Introduction

The method of prevention of metal corrosion based on the use of corrosion inhibitors (henceforth referred to as inhibitors), *i.e.*, chemical compounds or compositions 'which, when present in a system at sufficient concentrations, decrease the corrosion rate without causing considerable changes in the concentration of any corrosive reagent', has been known for several centuries.[1] However, it was only in the middle of the twentieth century that a scientific concept about the mechanism of the inhibitor action was created and first achievements in the directed synthesis of inhibitors appeared after that. Corrosion inhibitors are used in numerous systems, from water supply systems and virtually any power plants to the protection of microelectronics and contemporary military equipment. Considering that losses from metal corrosion exceed 5% of the gross national product in industrial countries, the development and application of inhibitors, which is one of the main methods of corrosion protection, should be considered as a scientific and engineering task of current interest.

The action of inhibitors is always associated with changes in the state of the surface being protected due to adsorption or formation of poorly soluble compounds with metal cations. Such compounds decrease the area of active metal surface and/or increase the corrosion activation energy; as a rule, corrosion is of electrochemical nature in aqueous media. It is no wonder that the first classification of inhibitors was based on their ability to slow down cathodic or anodic (or both) electrochemical reactions. Later, a group of inhibitors capable of suppressing corrosion by accelerating rather than slowing down cathodic reactions was added to this classification.[2] In the latter case, the action of an inhibitor is based on its electrochemical conversion, *viz.*, reduction. This process provides conditions for the thermodynamic stability of a thin protective oxide film, which, in turn, slows down the anodic reaction. A modern classification includes oxidants as well as adsorption, complexation and polymeric inhibitors.[3] Such a division suggests that inhibition mechanisms are diverse and that achievements in different fields of chemistry can be utilised for corrosion protection.

Only inhibitors used in aqueous solutions are considered in this review. The use of inhibitors in other systems has specific features which, from a chemist's viewpoint, deserve a separate discussion. However, the action of inhibitors is almost always based on their ability to prevent metal corrosion caused by the presence of water in a system, hence the leading role rightfully belongs to water-soluble corrosion inhibitors.

II. Oxidising inhibitors

Salts of chromic acid are the best-known oxidising inhibitors; they show protective properties toward many metals in a broad pH range. An important role in the mechanism of their action belongs to the reduction of chromate ions, *e.g.*, according to the reaction

$$CrO_4^{2-} + 4H_2O + 3e \longrightarrow Cr(OH)_3 + 5OH^-, \; E^0_{cor} = -0.13 \text{ V}.^{\dagger} \qquad (1)$$

Judging by the values of its standard potential and the free corrosion potential of iron in water (E_{cor} is -0.3 to -0.4 V), this reaction can occur even in neutral aqueous solutions. However, chromate undergoes reduction only at the initial instant when a metal contacts with the solution; after a film of hardly soluble chromium and iron hydroxides has been formed on its surface, reaction (1) virtually ceases [2] and a kind of equilibrium between Cr^{3+} compounds and adsorbed chromate ions is established. If a defect appears in the passivating film for some reason, chromate migrates into such a defect, undergoes reduction and 'heals' the film. This is one of the main reasons for the continuing use of chromates in conversion and protective paint coatings in spite of serious environmental restrictions.[4, 5]

Naturally, chromates manifest their oxidising properties more readily in acid solutions, especially on those metals whose E_{cor} is more negative than E_{cor} of iron, *e.g.*, on aluminium. However, acceleration of the cathodic reaction can also stimulate corrosion if an oxidant cannot create conditions for the formation of a passive film on a metal surface. The effect of oxidants is consid-

† Hereinafter, the electrode potentials are presented *versus* the standard hydrogen electrode.

erably affected by the solution pH (especially in the case of aluminium due to its amphoteric properties). At certain stoichiometric ratios of components involved in electrochemical reactions, conditions can be created such that only foreign or mixed oxide layers are formed on the aluminium surface, whereas other oxoanion reduction products capable of loosening the oxide structure are absent.[6] Judging by the changes in the corrosion inhibition coefficient

$$\gamma = \frac{K_0}{K_{in}}$$

(where K_0 and K_{in} are the corrosion rates in a reference solution and in a solution containing the additive under study), chromate acts as a corrosion activator at $2.0 < pH < 6.0$ (Fig. 1), whereas its inhibiting effect is more pronounced in more acidic (or more alkaline) solutions.

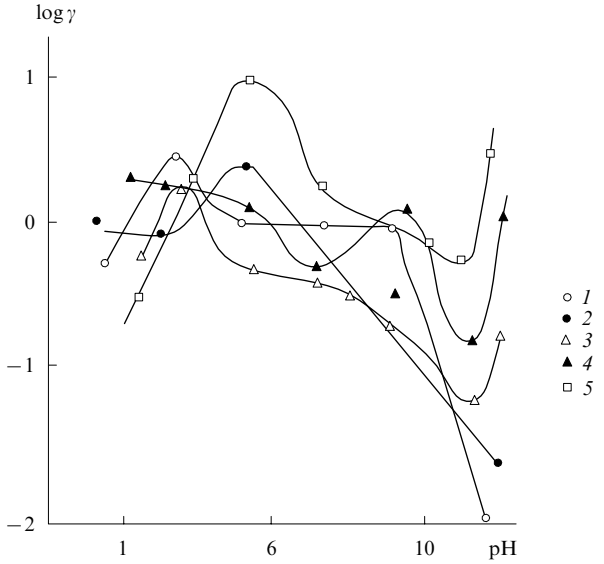

Figure 1. Effect of pH in a solution containing 0.01 N SO_4^{2-}, 0.1 N Cl^-, 0.1 N F^- and oxoanion additives on the inhibition coefficient of aluminium corrosion.[6]
Additive: (*1*) 0.1 N $Cr_2O_7^{2-}$, (*2*) 0.1 N MnO_4^-, (*3*) 0.05 N VO_4^{3-}, (*4*) 0.05 N WO_4^{2-}, (*5*) 0.05 N MoO_4^{2-}.

It has long been an important problem to find inhibitors that are less environmentally hazardous than toxic chromates. Most commonly, molybdates are used as substitutes; their oxidising properties are inferior to those of chromates (see Fig. 1). Thermodynamic calculations showed[7] that molybdate forms a barely soluble salt at potentials of active dissolution of iron in weakly acidic solutions (at $pH < 6.0$),

$$Fe + HMoO_4^- = FeMoO_4 + H^+ + 2e,\ E = E^0 - 0.0295\,pH. \quad (2)$$

The oxidising properties of molybdate with respect to steel do not manifest themselves in neutral media, so efficient protection of the steel surface requires the presence of yet another oxidant.[8] Black MoO_2 films are formed at $pH < 5$, which suggests that reduction of molybdate or, more accurately, isopolymolybdate compounds occurs. However, passivation phenomena manifest themselves only slightly even at pH 3. On metals whose free corrosion potentials are more negative than that of steel, the effect of molybdate is also observed in neutral media, let alone in weakly acidic solutions. In fact, the protective properties of molybdate with respect to zinc attain a maximum in solutions with pH 5.0; however, the following reaction is possible at pH 7:

$$MoO_4^{2-} + 2H_2O + 2e = MoO_2 + 4OH^-. \quad (3)$$

Corrosion inhibition occurs due to the formation of a thin layer of a molybdate reduction product on the zinc surface.

In the past, molybdates have attracted the attention of researchers as compounds that can prevent pitting of various steels, including stainless steels. The effect of MoO_4^{2-} as a corrosion inhibitor is even compared with the effect of molybdenum as an alloying component of ferrite iron–chromium alloys.[9,10] However, MoO_4^{2-} acts as an adsorption inhibitor rather than an oxidant, since the nucleation and development of pits occur in the passive region of potentials where molybdenum can, in fact, be oxidised into MoO_4^{2-}.

In a discussion of molybdates, tungstates and similar salts, one cannot neglect their ability to form heteropoly compounds.[11] Many of them are stronger oxidants than molybdate, hence they can be regarded as suitable compounds for the protection of metals in highly corrosive media. For example, salts of phosphomolybdic acid have long been known as corrosion inhibitors in hot brines, but some specific features of their protection mechanism have been revealed only recently.[12] It was proven that phosphomolybdic acid is an efficient corrosion inhibitor of steel in acid brines (65% LiBr) only at temperatures above 120 °C. Its addition to brine accelerates the cathodic reaction on steel and thus increases E_{cor} by 0.1–0.15 V. In weakly alkaline brines (pH 8.5), this acid can decrease the corrosion rate of steel by an order of magnitude in a broad temperature range (80–220 °C). The effect of phosphomolybdic acid on the effective activation energy of corrosion (ΔG^*_{ef}) depends on the solution pH: the value of ΔG^*_{ef} decreases at pH 5.0 but increases at pH 8.5; this suggests that the mechanism changes due to decomposition of the acid and incorporation of its fragments into the oxide film. Thus, the mechanism of steel protection is not limited to the increase in the oxidative properties of the solution upon addition of phosphomolybdic acid; to a considerable extent, it results from changes in the composition of oxide films resulting in an increase in their corrosion resistance.

Inhibition of metal corrosion in solutions of acids by inhibitor reduction products is typical of weaker oxidants, too. Iron protection by phenylarsonic acid ‡ is believed to occur according to this mechanism.[13]

Oxidants that do not form oxides (hydroxides) upon reduction can also be efficient inhibitors.§ Organic nitro compounds that are reduced at high rates even in neutral media can serve as examples. For example, the current density in the reduction of 3,5-dinitrobenzoate (> 10 mA cm^{-2}) exceeds considerably the passivation current density (i_p) of iron in borate buffer solution.[2] An oxidant of this kind does not affect directly the anodic reaction of iron dissolution, but it can increase the pH of the near-electrode layer due to generation of hydroxyl anions, which favours passivation. The efficiency of this type of inhibitor (*e.g.*, derivatives of benzoic acid, phenol, naphthol, *etc.*) was proven in numerous studies generalised in a monograph by Rozenfeld and Persiantseva.[15]

Trabanelli[16] correctly noted that reduction of organic inhibitors in acids can give chemical compounds some of which can protect metal surfaces whereas others can stimulate metal dissolution. Reduction of sulfoxides to organic sulfides, which are more efficient inhibitors, is a typical example of secondary inhibition.

‡ However, this acid inhibits the corrosion of titanium for a different reason, *viz.*, due to the formation of insoluble complex compounds with its cations.

§ The reference to steel protection by sodium nitrite leaves room for discussion. Some authors ascribed its protective effect in neutral solutions solely to adsorption of the NO_2^- anion on the metal, relating passivation in acid media only to the oxidation properties of nitrite.[2] However, it has already been proven that the oxidation properties of nitrite may not be ignored in the former case, near the free corrosion potential, as well.[14]

III. Adsorption inhibitors

If a protective layer is formed by adsorption-type inhibitors, adsorption is not only the first but also the main step. Obviously, it can play an important role in mechanisms of action of other inhibitors as well, but their interactions with metals are not limited to adsorption.

The kinetics of metal corrosion depends on many factors (local phase and chemical equilibria, surface tensions and activities of components in interphase layers), but the most important role belongs to the electric and energy characteristics of the surface. It is not surprising that one can slow down metal corrosion by affecting the adsorption of a medium component, since adsorption can change the above characteristics considerably. On the other hand, the majority of studies were performed with polycrystalline metal surfaces where it is difficult to detect the reconstructing effect of an inhibitor on the near-surface layer and on the electronic structure of the adsorbent. Therefore, though admitting the importance of studies on such effects,¶ let us limit ourselves to consideration of the 'macro effects' of an inhibitor that is adsorbed, *i.e.*, how it affects the rates of electrode reactions and the metal corrosion itself. If an adsorption-type inhibitor is used, an exceptionally important role belongs to the redox properties of the medium components and their adsorptivity.

The processes of adsorption and formation of protective layers on a metal substantially depend on the charges of the surface and inhibitor species. As a rule, cation-active inhibitors slow down cathodic reactions and active metal dissolution. Local corrosion is more efficiently prevented by anion-active inhibitors. However, the electrostatic interaction of an inhibitor with a metal surface is not the only motive force of adsorption. Some contributions to it can made by 'squeezing-out' of inhibitor species from the interionic space [18] and by hydrophobic interaction of non-polar inhibitor fragments with water.[19] Donor–acceptor interactions between a metal and an inhibitor can result in a stronger chemisorption binding of the latter to the surface.

If a metal is dissolved from the active state, which is usually the case in acids, then, for moderate metal surface coverages (θ), it is possible to single out two main contributions to the corrosion inhibition coefficient, *viz.*, related to changes in the ψ_1-potential and to surface blocking:

$$\log\gamma = \text{const} \times \Delta\psi_1 - \log(1-\theta). \qquad (4)$$

Even this simplified approach proposed by Antropov back in the 1970s [20] proved to be useful for formulating the concept of inhibitor action. However, it does not answer the important question: what structure should a compound have in order to be an efficient inhibitor?

Other approaches are required to establish the inhibitor structure–efficiency relationship. The majority of adsorption inhibitors are organic compounds; that is why many researchers used the linear free energy (LFE) relationship to reveal the role of the inhibitor structure.[14, 21–25]

Grigoriev and Ekilik [21] studied this problem in most detail in relation to acid corrosion, which usually occurs in the active dissolution region of potentials. They showed that if the inhibitor species are small and their adsorption increases the corrosion activation energy ($\Delta G^{\neq}$) due to charge redistribution in the double electric layer, the following equation is valid:

$$\log\gamma_R = \log\gamma_H + \rho\sigma, \qquad (5a)$$

where ρ is the reaction parameter, which is assumed to be equal to unity for a standard reaction series and which depends on the nature of the reaction being studied and on the conditions under which it occurs; σ is a constant of a substituent R, which accounts for its electron-donor ($\sigma < 0$) or electron-acceptor ($\sigma > 0$) effect on the reaction centre in comparison with hydrogen. In the general case of inhibitors capable of partial blocking of the active sites, equation (5a) assumes the form

$$\log\left(\frac{\gamma_R}{\gamma_H}\right) = \rho\sigma - \log\left(\frac{\theta_R}{\theta_H}\right), \qquad (5b)$$

where θ_H and θ_R are the degrees of coverage of the metal surface by the non-substituted and substituted inhibitor of the given reaction series, respectively. Similar regularities were also observed by many authors, not only in acidic but also in other media. For example, the efficiency of *N*-benzylideneaminoethanol derivatives in neutral medium containing hydrogen sulfide increases linearly with an increase in the electron-donor effect of the substituent R taken into account by its Wepster's σ^n-constant (Fig. 2).[24] According to Eqn (5b), substituents affect the protective properties of organic compounds solely by increasing the inhibitor adsorption; as a result, the value $\Delta G^{\neq}$ increases, whereas the surface area of the metal that undergoes corrosion decreases. For example, if the inhibitor being adsorbed is an electron donor, the inhibitor–surface binding strengthens with an increase in the electron density on the reaction site. Other mechanisms of inhibitor adsorption are also possible (see, *e.g.*, the monographs [14, 20]).

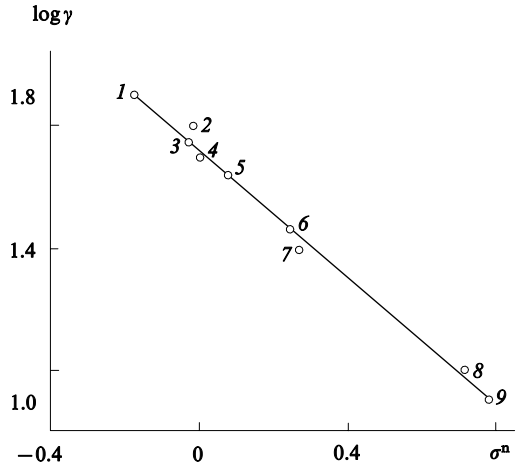

Figure 2. Dependence of the inhibition coefficient of steel corrosion in aqueous solution (0.5% NaCl, 0.25 g litre^{-1} CH_3COOH, 0.4 g litre^{-1} H_2S, pH 6.0) by substituted *N*-benzylidenaminoethanols with general formula $HO(CH_2)_2N=CH-C_6H_4-R$ on Wepster's constants of substituents.[24]
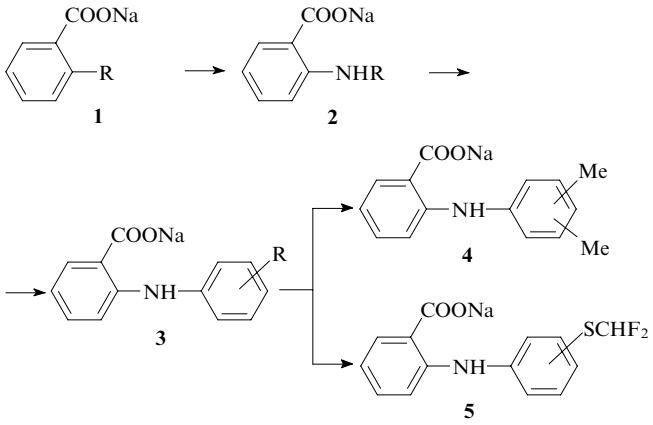
Substituents: (*1*) *p*-$N(CH_3)_2$; (*2*) *m*-OH, *p*-OCH_3; (*3*) *m*-OCH_3, *p*-OCH_3; (*4*) H; (*5*) *m*-OCH_3; (*6*) *p*-Br; (*7*) *p*-Cl; (*8*) *m*-NO_2; (*9*) *p*-NO_2. The inhibitor concentration is 0.004 mol litre^{-1}.

The approach considered above can also be applied for describing the effect of organic compounds on the passivation current density of metals, though the surface blocking in the active–passive transition region can be caused by oxide formation to a greater extent than by the inhibitor adsorption. Both linear and more complex dependences of $\log\gamma_p$ (here, $\gamma_p = i_p^0/i_p$, i_p^0 and i_p are the current densities in the reference and inhibited solutions, respectively) on substituent σ-constants were obtained for acidic [21] and neutral [14] media.

Studies of the effect of the organic anion structure on iron passivation in neutral solutions made it possible to find [14] new efficient adsorption-type inhibitors. Benzoate (**1**) hinders passivation; however, by introducing various substituents in the benzene ring, it was found that anthranilates (**2**) facilitate passivation. In the series of *N*-substituted anthranilates **2**, sodium *N*-phenyl-

¶ An attempt to generalise them was undertaken previously.[17]

anthranilate (SPA) **3** is notable for its passivating capability. It is in an aqueous solution of this corrosion inhibitor that the possibility of iron passivation without the formation of an oxide film was shown for the first time.[26] The discovery of this phenomenon, which was called adsorption passivation,[14,27] inspired a search for novel, even more efficient passivators; of the compounds tested, salts of mefenamic acid **4** (MEF) and isodiftorant **5** are noteworthy.



The linear free energy relationship principle was successfully used to describe the inhibition of local corrosion of metals, which is an even more complex process. In this case, the displacement of the electrode local depassivation potential [or the potential of the formation of the first pit (E_{pit})] to more positive values

$$\Delta E = E_{\text{pit}} - E_{\text{pit}}^{\text{background}}$$

was used as the inhibitor efficiency criterion. This value is determined from potential–time dependences or from anodic polarisation curves. In many cases, V-shaped dependences of ΔE on substituent σ-constants were observed, *i.e.*, the value of ρ changed its sign within a reaction series; this is caused by a change in the rate-determining step of the process. For example, this is typical of passive state stabilisation of the D16T aluminium alloy by *o*-substituted benzoates.[3] In this case, the branches corresponding to electron-donor and electron-acceptor substituents can have different sensitivities to the nature of the corrosive anion,† pH and solution temperature.

If solvation effects for a reaction series in question and a standard reaction series differ considerably, it is worthwhile to take into account, aside from the substituent σ-constant, its hydrophobicity π- or *f*-constants calculated from distribution factors of compounds in an octanol–water system

$$P = \exp\frac{\Delta G_{\text{o-w}}}{RT},$$

where $\Delta G_{\text{o-w}}$ is the distribution free energy for a compound.[28] This approach, which takes into account the electronic and hydrophobic properties of a substituent simultaneously, was originally used in biochemical studies; however, it also proved to be useful for description of efficient inhibitors.

Using quantitative prediction methods, it was shown that the efficiency of metal protection is limited if adsorption inhibitors that are individual chemical compounds are only used. This is connected with the tightening of environmental requirements. In many systems, the best protection is achieved by surfactants with high hydrophobicity ($\log P > 3$), *i.e.*, compounds poorly soluble in water and therefore unsafe ecologically.[29] In view of this, it becomes ever more urgent to develop inhibitor mixtures from components that could improve metal protection more efficiently than any of its components.

† Not only Cl^- but also other anions (I^-, Br^-, NCS^-) can cause depassivation in the system studied.[3]

The majority of such inhibitors for acidic media were created on the basis of the double electric layer recharging effect by some anions discovered back in the 1950s. The essence of this effect is as follows: an anion adsorbed on a surface that was initially charged positively gives some negative charge to that surface. Large organic cations that have considerable shielding effects can be adsorbed on such a surface; this improves the metal protection. There are many examples of successful corrosion inhibition by this method in complex systems. Schmitt *et al.*,[30] who considered the synergism and antagonism of various inhibitors of carbon dioxide-induced corrosion of steels, found that, though the surfaces to be protected contain carbonate deposits, the inhibition efficiency is largely determined by cooperative adsorption of anions and alkylammonium cations. According to results obtained by Shikai and Yufen,[31] the activity of anions in mixed inhibitors containing organic cations depends on the nature of the acid and decreases in the following series:

H_2SO_4	$I^- > SCN^- > HS^- > Br^- > Cl^-$;
HCl	$I^- > HS^- > Cl^- > SCN^- > Br^-$;
HF	$SCN^- > I^- > HS^-$;
CH_3COOH	$HS^- > SCN^- > I^- > Br^- > Cl^-$.

The mutual effects of components in a mixed inhibitor are usually evaluated by comparing the product of their corrosion inhibition coefficients ($\Pi\gamma_i$) with a similar value measured in the presence of the corresponding mixture (γ_{mix}). If the mutual effect coefficient *m* of the components

$$\kappa_m = \frac{\gamma_{\text{mix}}}{\Pi\gamma_i} \tag{6}$$

is larger than 1, one can say that their protective effect is enhanced, whereas if it is lower than 1, the protective effect is weakened.

A similar criterion was suggested [32] for the analysis of the concentration dependences γ of individual and mixed inhibitors. For example, if *n* portions of an individual inhibitor Δc_i are introduced successively (with its zero initial concentration), the overall concentration effect coefficient is expressed by the formula

$$\kappa_c = \frac{\gamma_{\Sigma c}}{(\gamma_{\Delta c_i})^n}, \tag{7a}$$

where the subscripts show whether the measured values reflect the effect of the total inhibitor amount (Σc) or of its certain portion (Δc_i). In the case of the power-law dependence common for adsorption inhibitors

$$\gamma = \gamma_0 c^{\beta},$$

where γ_0 and β are constants, Eqn (7a) assumes the form

$$\kappa_{\Sigma c} = \gamma_0^{1-n} n^{\beta} (\Delta c_i)^{\beta(1-n)}. \tag{7b}$$

For *m* inhibitors in a mixture and a variable concentration (c_i) of one inhibitor, designating the $\gamma_{\Delta ci}$ for the mixed inhibitor as $\gamma_{\Delta ci,\Sigma}$, the following equation is obtained:[32]

$$\kappa_m = \frac{\kappa_{\Sigma c}(\gamma_{\Delta c_i,\Sigma})^n}{\Pi\gamma_i}. \tag{8}$$

Ekilik and Ekilik [32,33] analysed the equation they derived for the inhibition of iron corrosion in 1 M H_2SO_4 by 2-(2-pyridyl)-benzoimidazole, NaCl, NaF, NaSCN and their binary and ternary mixtures. They concluded that the effect of chloride on the protective action of the azole exceeds the mutual effect coefficients for all other combinations studied. It was also shown that evaluation of mutual effects of mixture components in the case of iron acid corrosion inhibition requires that not only the kinetic equations of partial electrode reactions but also the free corrosion potential be taken into account. If changes in E_{cor} are ignored, erroneous conclusions about the mutual enhancement of mixture components can be drawn.

It is in much more rare cases that the presence of certain cations increases the protective effect of organic anions. For example, local depassivation of iron in weakly alkaline solutions is more strongly inhibited by phenylanthranilic acid if this inhibitor is combined with hexamethylenediamine.[34] However, this kind of synergy of protective effects of inhibitors is not versatile. Selective dissolution of binary alloys (45% Ni + 55% Zn, 70% Cu + 30% Zn, 90% Cd + 10% Zn, 97% Sn + 7% In) in weakly acidic solutions of mixtures of cation-active organic compounds (acridine, substituted pyrylium salts, 2-aminobenzoimidazole) and halides [35] was found to involve mainly an antagonism of the mutual effects of inhibiting mixture components caused by their competitive adsorption.

The approach based on the linear free energy relationship is also used to study the mutual effects of inhibitors and to search for more efficient inhibitor mixtures.[36–38] For a mixture of inhibitors corresponding to the same reaction series and at their constant total concentration

$$c_1 + c_2 + \ldots + c_i = \text{const}$$

the following relationship is valid:

$$\log\gamma = a + \rho\sum_{i=1}^{n} N_i\sigma_i\,, \qquad (9)$$

where a is a constant and N_i is the molar fraction of the ith compound in the mixture (*i.e.*, $\Sigma N_i = 1$). If the inhibitors present in the system and corresponding to m different reaction series are designated by the left subscript 1, 2, ..., m, then for an ideal system, *i.e.*, a system where no mutual effects of the inhibitors exist, one can write:

$$\log_m\gamma_c = $$

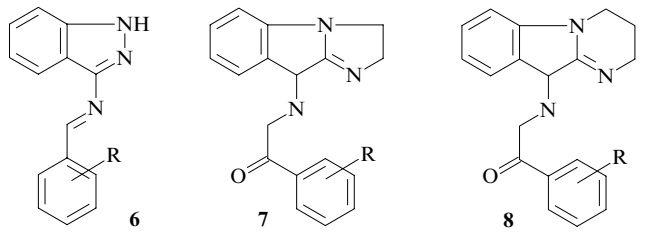
$$= \sum_{1}^{m} a + {}_1\rho\sum_{i=1}^{{}_1n}\left({}_1N_i \times {}_1\sigma_i\right) + \ldots + {}_m\rho\sum_{i=1}^{{}_mn}\left({}_mN_i \times {}_m\sigma_i\right). \qquad (10)$$

In a similar equation for real corrosion systems, the first term and the coefficients do not match those in Eqn (10). Taking this into account, Grigoriev *et al.*[38] assumed that, provided that the concentrations of the components are unchanged, *i.e.*, N = const, the ρ values, which are different for different reaction series, become equal for mixtures of these compounds. In such a case, the following equation is valid:

$$\log_m\gamma_{\text{mix}} = $$

$$= {}_m a_{\text{mix}} + {}_m\rho\left[\sum_{i=1}^{{}_1n}\left({}_1N_i \times {}_1\sigma_i\right) + \ldots + \sum_{i=1}^{{}_mn}\left({}_mN_i \times {}_m\sigma_i\right)\right]. \qquad (11)$$

In fact, Eqn (11) is well obeyed for mixtures of azomethine **6**, imidazobenzoimidazole **7** and pyrimidobenzoimidazole **8** derivatives



in 1 M H_2SO_4 + 0.25 M NaCl solution at different temperatures and with different numbers of components (m). It was found that the concentration of a mixed inhibitor (consisting of representatives of the above reaction series) ensuring the required corrosion inhibition coefficient ($_{\text{mix}}c$) can also be found using substituent σ-constants and taking the molar fractions of each mixture component into account

$$\log {}_{\text{mix}}c = a + \rho\sum N_i\sigma_i. \qquad (12)$$

To optimise the composition of inhibitor mixtures, it is necessary to establish the reasons for deviations of their action from 'additivity'. This requires additional studies, primarily on joint adsorption of mixture components on metal surfaces. In this respect, attention should be paid to effects of mutual enhancement of inhibiting effects and adsorption of organic anions.

For example, experiments on corrosion protection of steel by mixtures of hydroxynaphthoates (HNP) with substituted anthranilates showed [39] the synergistic effect of these inhibitors, which is only observed if the anion of the aromatic amino acid has high hydrophobicity, *e.g.*, in mixtures with MEF anions (Fig. 3). Ellipsometric studies showed that the synergism results from the ability of one of the anions (at its low concentration) to initiate the adsorption of the other anion. In this case, the free adsorption energy ΔG_a° increases, *i.e.*, the bond between the inhibitor and the oxidised iron surface strengthens. This effect is expressed even more clearly for SPA – sodium oleate mixtures; however, in this case an adduct, which interacts with the surface through chemisorption, is formed in the solution bulk; the ΔG_a° value reaches 40 ± 4 kJ mol^{-1} (see Ref. 40), which is more than two times higher than $\Delta G_a^\circ = 16.8 \pm 0.3$ kJ mol^{-1} for SPA.

The hard – soft acid – base (HSAB) principle is widely used to estimate possible interactions involved in joint adsorption of inhibitors.[14, 31, 41–46] This approach mainly relies on the nature of the reaction centres rather than on the nature of the substituent.

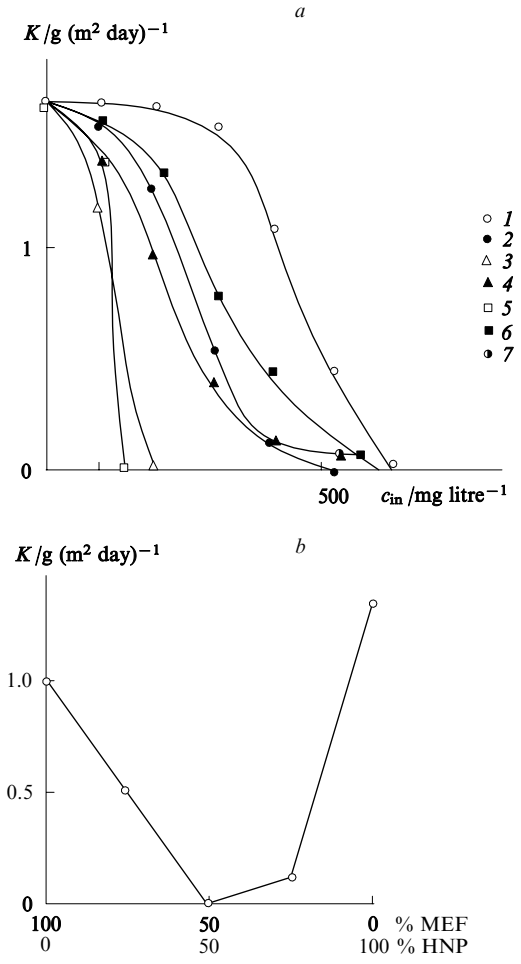


Figure 3. Dependence of the corrosion rate of St.3 steel in water containing 30 mg litre^{-1} NaCl and 70 mg litre^{-1} Na_2SO_4 on the inhibitor concentration (*a*) and on the component ratio in HNP – MEF mixtures at c_{in} = 200 mg litre^{-1} (*b*).[39]
Inhibitor: (*1*) SPA, (*2*) HNP, (*3*) sodium *N*-methylanthranilate (SMA), (*4*) MEF – HNP mixture (1 : 1), (*5*) MEF, (*6*) SMA, (*7*) SPA.

The surfaces of metals, primarily d-metals, are comparatively 'soft' reagents; however, they become 'hard' reagents upon oxidation, at least when Fe_2O_3, Al_2O_3 or MgO is formed. In the former case, strong adsorption can be expected for compounds with readily polarisable (soft) reaction centres; in the latter case, adsorption is mainly determined by electrostatic (*i.e.*, hard) interaction of the adsorbate with the surface.

In corrosion studies, estimation of hard and soft properties of reagents became possible owing to the use of the equation for nucleophile reactivity [14]

$$S = \alpha \log \mathrm{MR} + \beta \mathrm{H} + \gamma\pi, \tag{13a}$$

where S is a kinetic parameter of the process reflecting the relative change in the activation energy due to changes in the nucleophile nature; α, β, and γ are coefficients; MR is the molar refraction of the nucleophile's reaction centre,‡ and H is its relative basicity

$$H = \mathrm{p}K_\mathrm{a} + 1.74.$$

The parameter π characterises the hydrophobicity of an atom or a group of atoms with respect to the hydrogen atom; this is calculated from distribution coefficients,

$$\pi = \log P_{\mathrm{C_6H_5R}} - \log P_{\mathrm{C_6H_6}}.$$

The effect of the nucleophile basicity on the reactivity is weak; therefore, it is possible to use only two parameters, *viz.*, molar refraction and hydrophobicity

$$S = \alpha \lg \mathrm{MR} + \beta + \gamma\pi, \tag{13b}$$

which certainly simplifies the verification of this equation and its use for interpretation of mechanisms of complex heterogeneous reactions, such as corrosion, anodic dissolution of metals, *etc*. For example, the increase in polarisability of halides in the series $F^- < Cl^- < Br^- < I^-$ should increase the degree of charge transfer in the adsorbed complex, which facilitates covalent binding and blocking of the electrode surface. Taking into account that the hydrophobicity of anions increases in the same series, it becomes clear why not only Cl^- and Br^- but also I^- (to an even greater extent) being adsorbed on the iron surface from acidic solutions slow down its dissolution. It is important that the highest protective effect in acids is shown by organic cations combined with soft bases, *viz.*, I^- and CNS^-. The F^- anion, which is a hard base, is weakly adsorbed by the non-oxidised iron surface (which can be considered as a soft acid) and therefore does not enhance the protective effects of organic cations.

However, such a joint corrosion inhibition results not only from surface recharging. It was noted a long time ago that a metal surface can undergo partial hydrophobisation upon chemisorption of anions and can become somewhat 'softer' upon adsorption of soft bases.[3] Both factors can facilitate subsequent adsorption of large organic molecules or ions on a metal; those molecules or ions which are capable of covalent interactions through π-electrons of an aromatic ring or unsaturated bonds are the most efficient inhibitors.

The application of the HSAB principle to metal dissolution and corrosion inhibition processes has been considered in detail in a number of reviews.[43–46] It will only be noted here that the use of this principle is especially efficient if medium components interact with a metal surface more strongly than in the case of physical adsorption. Self-assembling molecules that chemically modify a metal surface can serve as an example. It is no coincidence that the use of alkanethiols for the protection of iron [49–52] or copper [50, 53] requires special surface cleaning to remove oxides and enable soft interaction of the SH group with the metal. Except for specific cases where surface preparation is performed *in vacuo* or using the Langmuir–Blodgett technique, alkanethiols are inefficient as corrosion inhibitors since chemisorption of these molecules only occurs on non-oxidised surfaces.[54] It is possible that the use of alkanethiols combined with other corrosion inhibitors can improve protective properties of self-assembling surface layers, as shown for dodecane-1-thiol and Schiff's bases (*N*-2-hydroxyphenyl- or *N*-2-octadecyl-3-methoxysalicylideneimine);[55] however, practical implementation of this kind of inhibition could be hampered considerably by the toxicity of alkanethiols.

Less toxic alkylphosphonates deserve attention in this connection: they can form oriented layers on oxidised surfaces of aluminium [56] and iron.[57, 58] However, metal surface modification by this method has been studied insufficiently. Further studies in this direction are needed to reveal advantages of adsorption of alkylphosphonates in comparison with that of more common inhibitors, *e.g.*, dialkyl phosphates that are also capable of irreversible adsorption on an oxidised iron surface.[59]

IV. Complexation-type inhibitors

It is not easy to draw a border between adsorption-type and complexation-type inhibitors, since inhibition by a single compound can involve different mechanisms depending on the metal to be protected and the pH of the medium. On the other hand, taking complexation into account, it is often possible to explain corrosion inhibition that is inexplicable within the adsorption theory. The antagonism of action of two depassivators, which was originally discovered on nickel and then on other metals and alloys,[60–62] can serve as an example. For example, the E_pit of nickel in solutions of corrosive sodium caproate ($C_5H_{11}COONa$) does not depend any more on the activator concentration if the concentration of the first anion is $c_{\mathrm{an},1} > c_\mathrm{c}$.[60] Seemingly, the addition of as little as 10^{-8} mol litre^{-1} of NaCl, which is less corrosive under these conditions, to a comparatively concentrated (0.05 M) $C_5H_{11}COONa$ solution should not affect E_pit; however, this value does increase, *i.e.*, nickel depassivation is hindered. Chloride cannot activate nickel at such a low concentration (c_Cl); furthermore, adsorptive displacement of caproate by chloride is impossible at the ratio $c_{\mathrm{an},1}/c_\mathrm{Cl} = 5 \times 10^6$. As c_Cl is increased to 0.1 mol litre^{-1}, the inhibition effect becomes obvious, since the E_pit values in the individual solutions of both activators are lower than those in mixed solutions. The effect of low Cl^- concentrations can be explained as follows: although chloride cannot displace caproate, it can prevent hydration of the complex by replacing a weaker nucleophile, *viz.*, water, in this complex. The changes in the complex composition probably decrease its solubility, which can result in a change in the rate-determining step of depassivation and in the blocking of some of the active sites; as a result, E_pit increases. As the chloride concentration is increased, the inhibiting effect increases until chloride becomes capable of displacing caproate. In such a case, depassivation is inhibited by caproate until c_Cl becomes sufficiently high to displace $C_5H_{11}COO^-$ completely, and E_pit becomes equal to that in pure chloride solutions. This effect was also observed with other carboxylates, $RCOO^-$, where R = H, C_nH_{2n+1} ($n = 1–9$), $HC{\equiv}C$, $CClH_2$ and CF_3. The inhibiting effect of Cl^- increases with an increase in the substituent hydrophobicity expressed through its f-constant,

$$\Delta E = E_{(\mathrm{an}+\mathrm{Cl})\,\mathrm{pit}} - E_{(\mathrm{an})\,\mathrm{pit}} = 0.05 + 0.17f, \tag{14}$$

which does not contradict the explanation proposed for such an unusual inhibiting effect.

Two groups of complexation-type inhibitors can be distinguished. The first group comprises heterocyclic compounds that can form insoluble complexes with copper, zinc and other metals in aqueous solutions. The second group includes complexones (chelating reagents) and their complexes with metal cations.

In the first group, the widely used azoles (imidazoles, triazoles, thiazoles, *etc*.) are notable for their efficiency. Azoles, particularly

‡ Equation (13a) differs from the widely known Edwards equation, which was considered in detail in a number of publications,[14, 47, 48] by the third term. Like in Edwards' calculations, it is legitimate here to use the MR of the entire nucleophile, rather than its reaction centre, for comparatively small nucleophiles.

benzotriazole and its derivatives, have almost no competitors for protection of copper and copper alloys. Their recent uses include the protection of electronic equipment,[63,64] in cooling systems (inhibitors resistant to chlorine have been developed [65]) as well as in brines,[66] for modification of conversion coatings on copper,[67] steel,[68] zinc [69] and silver.[70]

The mechanisms of action of these inhibitors differ considerably from those considered above; they are discussed in several reviews.[71–73] In most cases, azoles form thin insoluble surface films of complex compounds with cations of those metals that are often present on oxidised surfaces.[74–76] The interest in azoles has not weakened during the past decade; their ability to form thin self-assembling layers on copper, observed, *e.g.*, for 2-mercaptobenzoxazole [77] or *N*-vinylcarbazole,[78] opens new prospects for corrosion prevention by these compounds.

Other heterocyclic inhibitors that can form insoluble metal complexes, *e.g.*, certain macrocyclic compounds (porphyrins, phthalocyanines), are also worthy of attention.[79] The number of publications dealing with this group of inhibitors is growing steadily, and they should probably be reviewed in a separate paper. It will only be noted here that the efficiency of copper and zinc protection with azoles is closely related to the ability of these metals to form different bonds in complexes and can be estimated using the linear free energy relationship approach.[71] The increase in the electron density on the reaction centre in 2-substituted benzoimidazoles (BI), which is reflected by substituent induction constants (Fig. 4), strengthens the σ-bond in protective zinc complexes and increases the protection efficiency. In contrast, copper, which can act as an electron donor owing to its low ionisation potential and high electronegativity, forms π-complexes with BI; therefore, electron-acceptor substituents enhance copper protection.

The leading position in the second group of inhibitors belongs to phosphorus-containing complexones, such as 1-hydroxyethanediyldiphosphonic acid (HEDP), nitrilotri(methylphosphonic acid) (NTP), ethylenediamine-*N*,*N*,*N*′,*N*′-tetra(methylphosphonic acid) (EDTP) and 2-phosphonobutane-1,2,4-tricarboxylic acid (PBTC) as well as their metal complexes. The mechanism of their protective action is rather complex. It is possible to distinguish (maybe, somewhat arbitrarily), as has been done elsewhere,[80] three types of systems 'metal–solution of a complex-forming reagent' with the following features:

(1) ligands are hydrophilic, and their complexes are highly soluble in the corrosive medium;

(2) ligands are rather hydrophobic, while their complexes are either poorly soluble or insoluble;

(3) metal corrosion is controlled by interaction with complexes (soluble in the medium) of the same or some other metal.

In the former case, complexones often accelerate corrosion; if it occurs at potentials of the active metal dissolution range, carboxyl-containing complexones are most dangerous, whereas phosphonic acids are most dangerous for oxidised metal as they can cause the formation of small pits.[14,81] If the value of E_{cor} is outside the potential range where metal ionisation with formation of a soluble complex is thermodynamically possible, adsorption of a suitable ligand can block the corroding surface (at least partially), change the ψ_1 potential of the electrode, *etc.* Furthermore, many phosphonic complexones form barely soluble polynuclear complexes at high metal/ligand activity ratios

$$m = [M^{n+}]:L$$

Since *m* should be high in the near-electrode layer at low complexone concentrations and active metal dissolution, it is such complexonates that can be formed on the surface. This results in corrosion inhibition, though the inhibition is unlikely to be highly efficient because mononuclear highly soluble complexes, in particular those with iron, are formed as *m* decreases.[82] In fact, the i_p of iron in a borate buffer (pH 7.36) initially decreases and then increases with an increase in the concentrations of many complexones.[14] It was noted [83] that HEDP, NTP and similar complexones show no passivating properties for steel even in oxygen-saturated neutral solutions.

However, more hydrophobic phosphorus-containing complexones do not cause pitting on iron, *i.e.*, they can be attributed to the second type of the systems in question. For example, pits on iron were not formed up to oxygen evolution potentials in a borate buffer containing 10^{-3}–10^{-6} mol litre^{-1} hexamethylenediamine-*N*,*N*,*N*′,*N*′-tetra(methylphosphonic acid) (HMDTP).[81] In comparison with HNP and EDTP, the HMDTP complexone is less hydrophilic and more surface-active; it can even hinder iron depassivation by chlorides: at equimolar NaCl : HMDTP ratio and their concentrations equal to 0.01 mol litre^{-1}, the E_{pit} increases by 0.08 V. This effect is comparable to the action of the

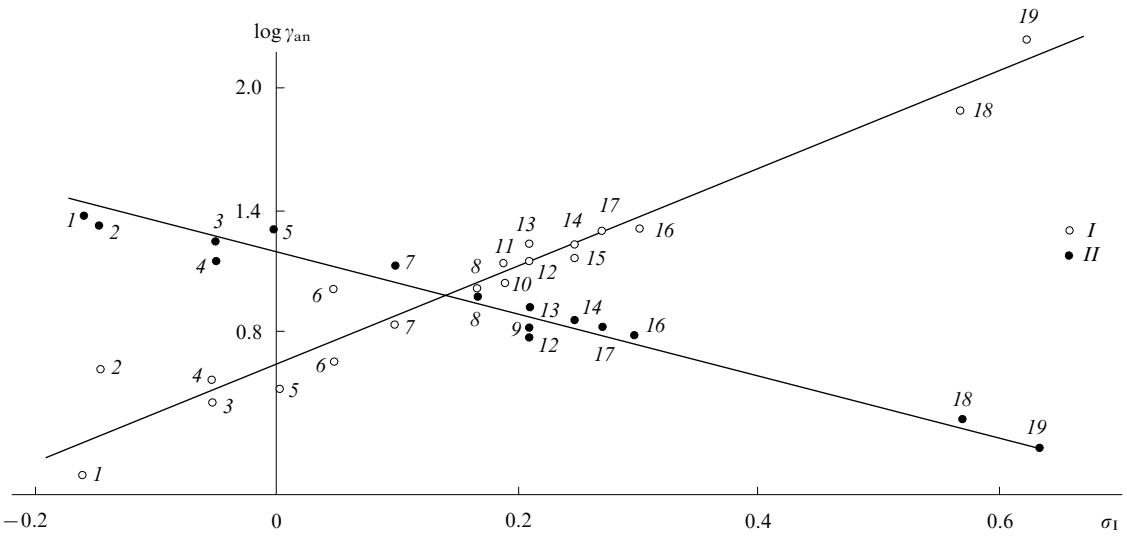

Figure 4. Effect of the inhibition coefficient of anodic dissolution of copper (*I*) and zinc (*II*) in 0.5 M phosphate solution at pH 11.4 on the induction constants of substituents in benzoimidazole.[71]
(*I*) $c_{in} = 5 \times 10^{-4}$ mol litre^{-1}, $E = -0.14$ V; (*II*) $c_{in} = 5 \times 10^{-3}$ mol litre^{-1}, $E = 1.0$ V.
Substituent: (*1*) OH, (*2*) COO^-, (*3*) C_2H_5, (*4*) CH_3, (*5*) H, (*6*) CH_2SCH_3, (*7*) NH_2, (*8*) NHC_2H_5, (*9*) $CH_2SO_2C_4H_9$, (*10*) $NHCH_3$, (*11*) SCH_3, (*12*) $SCH=CH_2$, (*13*) $CH_2SO_2C_6H_5$, (*14*) SH, (*15*) SC_6H_5, (*16*) OCH_3, (*17*) OC_3H_5, (*18*) CN, (*19*) NO_2.

caproate anion, but it is lower than that in the case of higher alkanecarboxylates [14] or dialkyl phosphates.[59]

In acid solutions (0.5 M H_2SO_4), nitrilotri(methylphosphonic acid) does not act as a corrosion inhibitor with respect to iron, (2-hydroxyethyl)iminodi(methylphosphonic acid) shows weak protective properties, whereas the more hydrophobic diethylenetriamine-*N*,*N*,*N*′,*N*″-penta(methylphosphonic acid) (DTPP) and (2-hydroxyethyl)iminodi(methylphosphonic acid) are rather good inhibitors.[84] It is of note that the addition of small amounts of iodide anions, as well as of ethylenediamine or diethylenetriamine, enhances the protective properties of aminophosphonic acids. These complexones probably behave as cation-active adsorption-type inhibitors in acidic media.

It was shown [85] that DTP and EDTP taken at optimum concentrations passivate steel in weakly alkaline carbonate solutions (pH 9.8) but do not hinder its pitting in the presence of chloride ions.

Complexones become rather good corrosion inhibitors of steel in hard water due to the presence of Ca^{2+} and Mg^{2+} ions. Probably, these cations partially neutralise the negative charge of complexones and thus decrease the adsorbate hydrophilicity and increase adsorption.[14,41] It is likely that these systems correspond to the third type of system, metal–solution of a complex-forming reagent, though calcium complexonates are usually characterised by the lowest stability constants among similar complexes of divalent metals. It was found [86,87] that even small Ca^{2+} concentrations strongly affect the efficiency of steel protection with HEDP or hydroxyphosphonoacetic acid (HPA), but not with PBTC. In fact, the efficiency increases from 64% to 88% as the Ca^{2+} : HPA concentration ratio increases from 0 to 1.0 due to stronger inhibition, first of the cathodic reaction and then of the anodic reaction as well. It was shown [88] that in stirred aqueous solution with low concentrations of corrosive anions (8.2 and 14 mg litre^{-1} Cl^- and SO_4^{2-}, respectively) but with a comparatively high content (130.2 mg litre^{-1}) of calcium ions, HEDP displays protective properties for low-carbon steel at as low a concentration as 1 mg litre^{-1}. The protection efficiency increases up to the concentration of 50 mg litre^{-1}; however, HEDP accelerates corrosion at concentrations $\geqslant$ 100 mg litre^{-1}. This fact was explained by decomposition of the protective oxide film. The best protection of steel in 0.5 M $NaClO_4$ solution (pH 7) is achieved with the molar ratio Ca : HEDP = 0.5. Using an atomic force microscope, the formation of a relatively uniform protective film was observed on the surface under these conditions.[89]

Neagle [86] analysed steel surfaces after exposure to hard water in the presence of HPA as the inhibitor. It was concluded that Ca^{2+} facilitates HPA transport and adsorption and is incorporated in the thin (20–40 nm) protective film that almost does not weaken heat transfer. In an alkaline solution [$Ca(OH)_2$, pH 12.5] simulating the concrete pore-filling liquid, the presence of calcium facilitates steel protection by NTP.[90] Studies of a steel surface by FT-IR spectroscopy and XPS revealed the formation of an NTP film with polymeric structure, in which Ca^{2+} is bound with three phosphonic groups.

Important information about the mechanism of steel protection by complexonates can be obtained by studying the dependence of the inhibitor concentration, which provides the maximum degree of protection, on the stability constant (K_s). It was shown [14,91] that in water containing no hardness salts (*i.e.*, in soft water), Ca^{2+} and especially Mg^{2+} phosphonate complexes are often more efficient corrosion inhibitors than the corresponding acids themselves. For example, complexes of NTP with magnesium or calcium can prevent completely the corrosion of steel in soft water. Complexes of HEDP, 1-carboxy-1-hydroxypropane-3-aminodi(methylphosphonic acid) (CHADP) or EDTP with these metals are more efficient than the acids themselves.[92,93] However, HMDTP and PBTC are more efficient than their complexes with Ca^{2+}, and complexes of HMDTP with Ca^{2+} and Mg^{2+} maintain the ability to suppress the corrosion of steel in water completely. In contrast, although imino-*N*-acetic-*N*,*N*-di(methylphosphonic acid) is more efficient than its magnesium complex, its protective efficiency is lower than that of its calcium complex.[81]

In order to explain the entire data on the efficiency of complexonates, one should take into account that the stability constants of magnesium and calcium phosphonates are usually lower than those of the corresponding iron complexonates, hence electrophilic substitution of the complex-forming agent is thermodynamically favourable.[91] It results in the precipitation of barely soluble hydroxides

$$MH_kL^{2-a} + Fe^{2+} = FeH_kL^{2-a} + M^{2+} \xrightarrow{2OH^-} M(OH)_2, \qquad (15)$$

which, along with the inhibitor adsorption, facilitates steel protection. However, if the stability constant is low, the complexonate is dissociated to a considerable extent and its actual concentration in solution is lower. It is no wonder that the left branch of the $\log c - \log K_s$ dependence (Fig. 5) is ascending, which indicates that the inhibitor efficiency increases with an increase in the complexonate stability to a certain threshold. If it is exceeded, the inhibitor efficiency decreases, probably due to the kinetic hindrance of electrophilic substitution of complex-forming cations by iron.

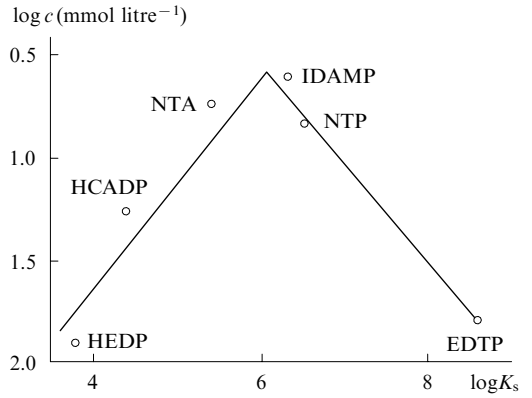

Figure 5. Dependence of the concentration of calcium complexonates providing the maximum protection of steel in water containing 30 mg litre^{-1} NaCl + 70 mg litre^{-1} Na_2SO_4 on their stability constants.[81]
IDAMP is imino-*N*,*N*-diacetic-*N*-methylphosphonic acid.

The presence of hardness salts in water can decrease the inhibiting effect of complexones, therefore zinc phosphonates are often used as inhibitors. The effect of mutual enhancement of the protective action of zinc salts and phosphonic acids has been known for a long time,[14,41] but studies of this effect are still under way for different complexones and metals to be protected.

The zinc–HEDP complex can passivate steel not only in pure water but also in a borate buffer (pH 7.4) containing 0.03 mol litre^{-1} Na_2SO_4.[14] According to XPS data, washing of a steel surface with water after its exposure for 16 h to a solution of this complex (200 mg litre^{-1}, pH 7.6) did not completely remove the inhibitor from the film. The film was rather thin, as the X-ray photoelectron spectrum recorded before ion etching of the sample clearly displayed a signal of metallic iron. The film contained phosphorus in the outer layer only, whereas zinc, which has been in excess with respect to its content in the inhibitor, was still detected during layer-by-layer argon etching of the sample. Probably, the complex is decomposed, at least partially, during the initial stages of film formation, *e.g.*, due to displacement of Zn^{2+} by iron ions. The zinc ions that are released react with hydroxyl ions generated in the cathodic reaction to give barely soluble $Zn(OH)_2$, which shields the surface and slows down corrosion. As the corrosion rate decreases, the deposition of $Zn(OH)_2$ slows down, and

predominant adsorption of the inhibiting complex on the surface starts.

It was found [89] that zinc salts synergistically enhance steel protection by an inhibitor such as HEDP in 0.5 M $NaClO_4$ solution; the strongest effect was observed with the molar ratio Zn : HEDP = 3. It was shown that $Zn(OH)_2$ deposition is responsible to a considerable extent for the higher effect of zinc on the protective properties of HEDP in comparison with calcium. This fact agrees with results of earlier studies.[14,91] The ability of HEDP – Zn^{2+} mixtures to hinder the anodic dissolution of steel was also confirmed for aqueous solutions containing up to 0.01% Cl^- (see Ref. 94). For static conditions, it is recommended to use a binuclear complex with Zn : HEDP = 2, since HEDP anions themselves are corrosive with respect to steel. On the other hand, an excess of zinc ions favours hindering of the cathodic reaction of oxygen reduction.

In sea water, HEDP itself has poor protective properties, whereas its complex with zinc protects steel more efficiently, especially at high flow rates ($V = 3$ m s^{-1}).[95] In this case, high degrees of protection ($\geqslant 95\%$) are reached at a complex concentration equal to 0.1 mmol litre^{-1} (this value is by an order lower than that at $V = 1$ m s^{-1}).

The synergistic effect of components in mixtures of zinc salts with NTP used for steel protection was observed by different researchers.[91,96] The inhibitor forms a thin compact film on the metal surface, which comprises both $Zn(OH)_2$ and NTP – zinc complexes. It was shown [97] that the NTP – zinc complex prevents pit corrosion of Kh18N9T steel in chloride-containing water, though it does not suppress it completely.

Enhancement of the protection of low-carbon steel due to synergism was also found for mixtures or complexes of zinc with EDTP,[92] CHADP,[93] PBTC,[98] *N*,*N*-di(phosphonomethyl)glycine,[99] ethyl- and chloroethylphosphonic,[100] phenylphosphonic,[101] 2-dimethylamino-2-hydroxypropylenediphosphonic and benzyliminodi(methylphosphonic) acids.[14] A similar effect was observed [101] for protection of brass [14,102] and aluminium alloys.[103]

Thus, the mechanism of metal protection by complexonates involves not only adsorption but also surface reactions of electrophilic substitution of complex-forming cations, deposition of barely soluble hydroxides and formation of hetero- and polynuclear complexes. No wonder that the dependences of their efficiency on chemical composition are rather complex in many cases. For example, the concentration of a complexonate-type inhibitor required to manifest protective properties depends on its stability constant: if the nature of the complex-forming cation is the same, *e.g.*, for zinc complexes (Fig. 6 *a*), this value increases with an increase in the stability constant, since the possibility of the formation of zinc hydroxide decreases. If the complex-forming cation is varied while the complexone remains the same, the dependence of the inhibitor efficiency on the solubility product of the hydroxide formed upon electrophilic substitution passes through a maximum (Fig. 6 *b*).[3] The protective properties of phosphonates of divalent metals are enhanced with a decrease in the solubility of their hydroxides and an increase in the stability of their complexonates, until their stability constants exceed those of iron(II) phosphonates. The mechanism of protection by more stable complexonates also involves the electrophilic substitution of a divalent metal ion, but probably due to the formation of more stable iron(III) complexonates.

The protection mechanism considered above, which we proposed and described in detail previously,[14,91] is also valid for complexonates of metals other than divalent ones. Cations of rare-earth metals (REM), which are recommended as metal corrosion inhibitors more and more often due to environmental problems,[104–107] are worthy of attention. The mechanism of steel protection by REM phosphonates was first studied for NTP derivatives.[108] Electrophilic substitution of REM by Fe^{2+} cations is thermodynamically unfavorable due to the high stability of the phosphonates [their stability constants are 4 – 8 orders larger than

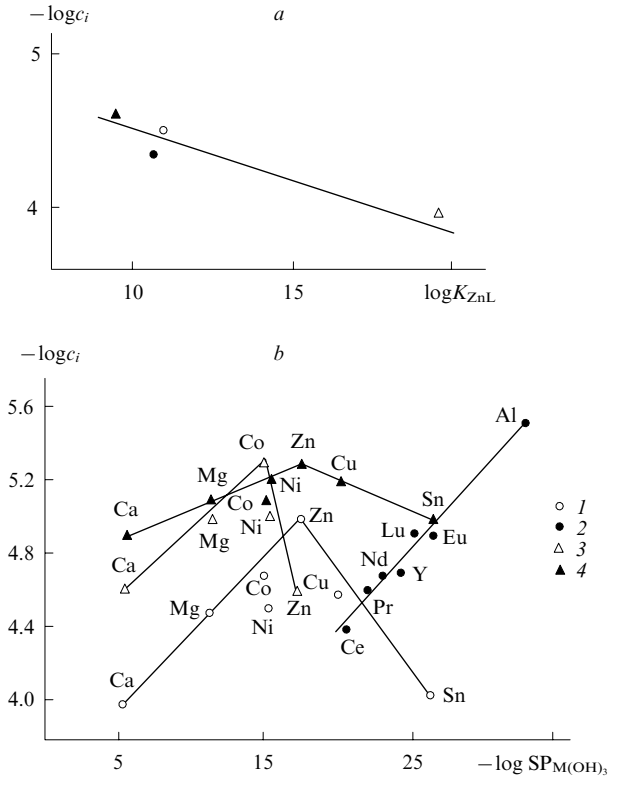

Figure 6. Effect of the stability constants of zinc complexes with phosphonic acids (*a*) and of the solubility products of hydroxides of complex-forming metals in phosphonate corrosion inhibitors (*b*) on their protective concentrations for St.3 in water containing 30 mg litre^{-1} NaCl and 70 mg litre^{-1} Na_2SO_4. The speed of solution movement relative to steel cylinders is 0.8 m s^{-1}.
Phosphonic acids: (*1*) HEDP, (*2*) NTP, (*3*) EDTP, (*4*) CHADP.

that of the similar iron(II) complex]. However, in neutral solutions, the Fe^{2+} ion is readily oxidised to Fe^{3+}; the latter forms a complexonate whose stability is comparable to that of the yttrium – NTP complex, which is the most stable of all REM – NTP complexes. Hence, in this case, electrophilic substitution can occur according to the following scheme:

$$MH_kL^{3-a} + Fe^{3+} = FeH_kL^{3-a} + M^{3+} \xrightarrow{2OH^-} M(OH)_3. \qquad (16)$$

Simultaneously, competing formation of $Fe(OH)_3$ occurs; the latter is characterised by weak protective properties. Thus, reaction (15), which, at least partially, prevents Fe^{2+} oxidation, does not occur, and the protective effects of REM complexonates are appreciably inferior to those of NTP complexes with divalent metals. Auger electron spectroscopic studies of the surface film on iron formed in water containing a cerium – NTP complex showed that the film was enriched with cerium. The Ce : Fe ratio was close to 1.0 throughout the film thickness and even somewhat higher in the inner layer. On the other hand, P : Ce $\leqslant$ 0.6 (this ratio equals 3.0 in the inhibitor); it is smaller in deeper layers, which are less accessible to washing water, than in the outer layers. This suggests that hydroxides play an important role; it is therefore not surprising that the efficiency of NTP complexes with trivalent metals increases with a decrease in the solubility product of $M(OH)_3$ (see Fig. 6 *b*).

It is of note that the protective film formed by the less stable aluminium(III) complexonate, which can undergo reaction (15), is more perfect and probably free of the adverse effect of $Fe(OH)_3$. Therefore, the NTP – aluminium complex is one of the most efficient inhibitors in soft water with low chloride content.

Metal complexonates are used in the reagent-based treatment of aqueous systems,[14, 109] in acid washing solutions, in cutting fluids, *etc*. Small additions of such complexonates facilitate the cathodic protection of steel in sea water [110] and improve the protective properties of magnetite coatings when added to oxidising nitrate solutions.[111] The nature of complex-forming cations is also important in magnetite coatings modified by complexonates. Complexonates which form barely soluble hydroxides are preferable; yet another condition should be met, *viz*., complexonates should not be too large, otherwise the structure of a magnetite coating can be violated and its defectiveness can increase.

The comparatively high cost of reagents and the tightening of environmental requirements for the content of phosphorus in water restrict the usage of phosphonate inhibitors in water consumption systems. To decrease the concentration of phosphonates, it was recommended to use them as mixtures with inexpensive additives, *e.g*., adsorption-type inhibitors (aliphatic amines,[112] phthalic anhydride,[113] and other compounds [14]), complex-forming reagents (tartrates,[114] gluconates [115]) or extracts from certain plants.[116]

The combined use of phosphonates and oxidants is justified by their mechanism of action. Since reduction of some oxidants can increase pH of the near-surface solution layer, metal phosphonates are destabilised: in effect, nucleophilic substitution of the ligand by hydroxyl groups occurs, which results in the deposition of $M(OH)_x$ hydroxides poorly soluble in water. Furthermore, it is known that the addition of nitrite enhances steel protection by complexones (HEDP [117] or PBTC [118]); at elevated temperatures, small amounts of sodium *m*-nitrobenzoate (SNB) act similarly. It was shown [119] that both oxidants can also enhance the inhibiting effect of the HEDP–zinc complex in hot water (80 °C). This is only possible at a certain ratio of the complexonate and oxidant concentrations, which depends on the nature of the oxidant. Although SNB is a stronger oxidant than $NaNO_2$, its inhibiting effect is weaker. Both oxidants play an auxiliary role, that is, they only provide better conditions for the protective layer formation by the phosphonate.

However, though numerous patents on mixed inhibitors based on complexonates have been issued, the scientific grounds for formulating such mixtures are still poorly explored. Aside from the methods for improving the efficiency of complexonate inhibitors considered above, yet another promising method should be noted, *viz*., their joint use with water-soluble polymers.

V. Polymeric inhibitors

It was known back in the 1930s that the addition of polyphosphates to water (a few milligrams per liter) inhibits not only scaling but also steel corrosion. However, while the anti-scaling effect of polyphosphates results from their adsorption and dispersing ability, their inhibiting properties are associated with the ability to form poorly soluble compounds with metal cations. Polyphosphates are most efficient in mixtures with Zn^{2+}, Ca^{2+} or Ni^{2+}; steel corrosion is mainly hindered due to inhibition of the cathodic reaction. The use of water-soluble polymers, along with polyphosphates, for the anti-scaling protection of aqueous systems started in the 1970s; these polymers containing COOH and OH groups (and mostly based on derivatives of acrylic and maleic acids) had high hydrolytic stability. Water treatment with mixtures of zinc phosphates or phosphonates with such polymers became popular 10–15 years later; a short time after that, the ability of polymers to inhibit metal corrosion was also discovered. In the early 1980s, the first 'phosphorus-free' (zinc-polymeric) water treatment programmes were developed in Japan due to restrictions on the content of phosphates (even non-toxic ones) in waste water. Suzuki and Kawamura [120] presented a brief review of these programmes and concluded that, despite certain achievements, 'phosphate-free' water treatment still cannot be widely used.

Studies on the mechanism of action of an acrylic acid–2-hydroxyethyl methacrylate–methyl methacrylate copolymer (MM = 3000) showed that adsorption of the polymer on a calcium phosphate film slows down the film growth, makes it less porous and thinner, and improves its protective properties. Presumably, in order to improve the efficiency of polymeric reagents that can eventually become leaders in scaling and corrosion prevention in cooling systems, it is necessary to study the dependence of their efficiency on the most important characteristics of polymers (molecular mass, number of functional groups, *etc*.). Analysis of the results of such studies has led to the conclusion [121] that polymers with molecular masses not exceeding 10 000–12 000 are most efficient for scaling inhibition. Unfortunately, these polymers have been little studied in application to metal corrosion inhibition, though numerous publications are available on the properties of new polymeric inhibitors.

Zinc salts are added in almost all cases to carboxylic [29] or sulfonate [122] polymers in order to confer on them corrosion-inhibiting properties with respect to steel in water, while phosphonate polymers do not require such addition. On the contrary, the efficiency of steel corrosion inhibition in water without stirring with polyvinylpyrrolidone (MM = 40 000) decreases in the presence of Zn^{2+} (see Ref. 123), suggesting that the activities of the polymers' functional groups differ considerably. Certain bipolar polypeptides, primarily polyasparaginates with MM = 1000–2000, are efficient inhibitors of carbon dioxide corrosion of steel [124] and scaling.[125] Reaction products of polysuccinic acid with aliphatic amines, particularly poly(succinimides) and poly(dodecyl-succinamides), proved to be rather efficient inhibitors of hydrogen sulfide-induced corrosion of steel. Owing to low toxicity, such polymers are likely to have considerable promise for application in oil-extracting and petrochemical industries.[126]

Apart from the nature of a polymer's functional groups and molecular mass, its protective properties can be affected by the presence of hydrophobic radicals. For example, in weakly alkaline solutions (pH 8–10), the efficiency of aluminium protection with a maleic acid–styrene–acrylic ester copolymer increases with an increase in the number of carbon atoms in the ester alkyl chain.[127]

Polymers containing acid groups are more commonly used as scaling inhibitors, whereas cation-active polymers are used to prevent the metal corrosion. It was shown, for example,[128] that the ultra-thin film (70 nm) obtained by layer-by-layer deposition of poly(diallyldimethylammonium chloride) or poly(*N*-octyl-4-vinylpyridinium iodide) and poly(styrenesulfonate) inhibits considerably the dissolution of 316L steel in 0.6–0.7 M NaCl solution and suppresses pitting on its surface, despite the high water content in the film and its high ionic permeability.

Even thinner conductive polyaniline films (which can be obtained not only by chemical techniques but also by anodic polarisation of a metal) show passivating properties toward stainless steels in acids. This was originally shown by De Berry [129] and then confirmed by many researchers. Protective polyaniline films were also obtained on aluminium,[130, 131] copper [132, 133] and titanium.[134] However, for a long time, similar protective films could not be obtained on low-carbon steel in aqueous solutions, partially due to the corrosion of the anode. To avoid corrosion, Yagova *et al*.[135, 136] applied films from a 0.4 M aniline solution containing arenecarboxylate inhibitors, *e.g*., 0.08 M solution of salicylic acid. As a result, they obtained a film that protected steel in 0.05 M H_2SO_4 and in humid atmosphere. Polyaniline films on iron were also obtained in the presence of phosphates and 3-aminobenzenesulfonic acid (ABSA).[137, 138] The protective properties of the film increased in both cases; however, whereas ABSA formed a copolymer with polyaniline, phosphates were just incorporated in the passivating layer of iron oxides but did not react with the polymer. However, some researchers do not acknowledge the protective properties of films based on polyaniline, polypyrrole, *etc*. on iron or steel, and discussions on this subject continue.[139, 140]

Polyhexamethyleneguanidinium (PHMG) $-[(CH_2)_6-NH-C(=NH^+)-NH]_n-$ is also a polymeric cation worthy of note, as well as its salts synthesised by Antonik *et al.*[141] and Tomin *et al.*[142] At $n = 10-100$, PHMG is a strong base and a biocide; its anticorrosion properties depend strongly on the counter-ion. PHMG phosphate mixed with small amounts of sodium nitrite and tetraborate provides good protection of steel in non-stirred aqueous solutions but is inefficient against scaling. The PHMG–HEDP salt shows both protective and technological properties required for its usage in cooling systems of oil refineries. Tomin *et al.*[142] also reported good protective properties of a polymer synthesised by the reaction of hexamethylenediamine with phosphoric acid and urea in the presence of glycerol.

Yet another group of this class of inhibitors includes hydrophilic monomers that can polymerise upon adsorption on a metal surface rather than polymers. This kind of polymerisation can decrease the solubility of the adsorption layer, increase the protective effect and make adsorption irreversible. Acetylene derivatives known since the 1940s as corrosion inhibitors of steel in acids are examples of such compounds. Brief reviews on the mechanism of action of these inhibitors, starting from the first experiments with iron powder, which showed that corrosion inhibition in HCl with acetylene results from the formation of a hydrophobic film of a hydrogenation and polymerisation product, are known.[2, 3, 143]

Aliphatic acetylenic alcohols in protonated form are relatively stable in acids and undergo various reactions only in the presence of an electrochemically active metal surface. There is no doubt at present that alkynols first undergo reduction and then dehydration and polymerisation, and that protective films formed by them consist of products of not only polymerisation but also other chemical transformations. It was shown [144, 145] that the susceptibility of alkynols to electrochemical reduction correlates with their ability to undergo polymerisation on iron in acids. According to Frignani *et al.*,[146] the inhibiting effects of alkynols can be enhanced by replacing the acetylenic hydrogen by a halogen. Small anodic polarisation of iron in a 1 M HCl solution facilitates the formation of a chemisorption layer, whereas cathodic polarisation accelerates the growth of a polymeric film.[147]

Aromatic acetylenic alcohols are reactive in acids.[148] They form products that are also efficient inhibitors and that undergo further reactions; as a result, steel is coated with a poly(phenyl ketone) protective film.

It was shown in a number of studies that preliminary application of certain monomers on a metal surface from aqueous solution can protect it in a corrosive medium owing to the formation of a polymeric structure. For example, immersion of aluminium samples for 15 min in 0.5% solution of methacryloyloxypropylmethoxysilane (at 80 °C) results in an alumosiloxane film stable even in 3.5% NaCl solution.[149]

The results of these studies give a reason to assume that the achievements of polymer chemistry, especially if they are used to search for ways of controlling the polymerisation of inhibitors in thin adsorption layers, will make it possible to create a new approach for efficient protection of metals by inhibitors. However, the currently known inhibitors of this type, *viz.*, acetylenic alcohols or alkenals, have a noticeable toxicity (the maximum permissible concentrations of propynol and acrolein are 1.0 and 0.7 mg m^{-3}, respectively); besides, they present fire and explosion hazards. In view of this, attention should be paid to the less toxic cinnamaldehyde, which is adsorbed on steel and protects it from acid corrosion by forming a polymeric film.[29] Probably, the efficiency of protection of monomers can be increased by using them together with polymerisation initiators, as was observed for methacrylonitrile and potassium persulfate used to protect steel in 1 M HCl solution.[150]

* * *

Intense studies on the mechanism of metal corrosion inhibition and its dependence on the composition and properties of inhibitors have continued in the past decade. Unfortunately, it is impossible to discuss all physicochemical aspects of corrosion inhibition within a single paper. Achievements of the quantum-chemical approach to the description of this complex process undoubtedly deserve a special discussion. The development of the theory of action of quite specific volatile inhibitors and the mechanisms of metal protection in organic solvents, paint and conversion coatings were also left outside the scope of this review. However, the author hopes that the presented material on the current state of corrosion inhibitor science, whose development has been one of the most important fields of research at the Institute of Physical Chemistry, will attract the attention of not only physicochemists already working in this field but also researchers in other fields of chemistry.

II. Crystal structures of Np(V) compounds with cation – cation bonds 90
III. Influence of the cation – cation interactions on the properties of Np(V) compounds 94
IV. Cation – cation interactions in compounds of other actinide ions 97
V. Comparison of cation – cation interactions in solutions and crystals of actinide compounds 98

Abstract. The published data on the structures and properties of crystalline actinide compounds having mutually coordinated AnO_2^+ or AnO_2^{2+} cations as structural elements are surveyed. This cation – cation interaction is an important structure-forming factor for many crystalline compounds of Np(V) and U(VI). It strongly affects their UV-Vis and IR spectra as well as other properties. Differences and similarities between the cation – cation interactions of actinide ions in solutions and crystals are discussed. The bibliography includes 114 references.

I. Introduction

The specific complexation of AnO_2^+ and AnO_2^{2+} ions with certain cations commonly referred to as cation – cation (CC) interaction has been observed for the first time [1] in a study of behaviour of Np(V) in solutions of uranyl perchlorate. Later, the CC interactions were also revealed in NpO_2^+ solutions containing such cations as Th(IV), Cr(III), Fe(III), Al(III), Ga(III), Sc(III), In(III), Bi(III), Pb(II), Hg(II), Hg(I) (see Ref. 2) and Rh(III).[3] As for sodium, magnesium and some lanthanide [*e.g.*, La(III), Ce(III) and Y(III)] cations, they are inactive with respect to NpO_2^+.[1,2] Apart from Np(V), CC interactions are characteristic of U(V),[4,5] Pu(V) [6] and Am(V) [7] ions.

Different aspects of the CC interaction in solutions of pentavalent actinides have been considered in numerous publications.[1–41] For its characterisation, traditional spectrophotometry in visible and nearest IR regions as well as other techniques, such as potentiometry,[1] IR,[28] Raman,[31,34,36] Mössbauer,[24] ESR,[26] NMR [33] spectroscopies, large-angle X-ray scattering (LAXS) [32,35] and laser-induced photoacoustic spectroscopy [41] have been used. Special attention has been paid to the elucidation of the nature of the CC interactions in solutions. The principal results of these studies are considered below (Section V).

The kinetics of formation [2,3,9,12,17] and stability [1,3,9,29,34,36,40,41] of CC complexes have been studied in numerous publications. In particular, it has been shown that the complexation rate is defined primarily by the nature of highly charged cations interacting with the AnO_2^+ ions. This process proceeds very fast (*viz.*, during mixing of the components) with cations that have labile coordination spheres. In contrast, such cations as Cr_{aq}^{3+} (see Refs 2, 9, 12 and 17) and Rh_{aq}^{3+} (see Ref. 3) behave differently. In those cases, the formation and dissociation of CC complexes proceed quite slowly which is typical of substitution of water molecules by other ligands in the inner coordination spheres of aforementioned hydrated ions. The kinetic stability of AnO_2^+ CC complexes with Cr(III) and Rh(III) ions makes possible the utilisation of strongly basic cation-exchange resins for their isolation and purification by means of consecutive sorption, washing and desorption avoiding a significant decomposition.[2,3,6,24]

The stability of actinide CC complexes is relatively low but it increases substantially with an increase in the ionic strength (μ) of solutions or with a change from aqueous to organic solutions.[14,39] Neptunoyl cation [NpO_2^+, also referred to as neptunyl (V)] forms most stable complexes with such 'active' cations as UO_2^{2+} (see Refs 40 and 41), Cr(III) [9] and Rh(III).[3] The respective stability constants at 25 °C and $\mu = 6-10$ lie in the range of 2 – 4 litre mol^{-1}. The stability of An(V) CC complexes with a specific 'active' cation decreases in the series $UO_2^+ > NpO_2^+ > PuO_2^+ > AmO_2^+$.[29,41] The activity of AnO_2^{2+} ions as coordinating centres in the CC interactions decreases in the same series:[29] $UO_2^{2+} > NpO_2^{2+} > PuO_2^{2+} > AmO_2^{2+}$. These regularities correlate well with decreases in the effective positive and negative charges localised on the actinide atom and oxygen atoms of the corresponding dioxocations, respectively.[37,42] Therefore, it may be soundly assumed [3] that the electrostatic forces play a crucial role in the CC interactions though an involvement of other factors, such as the energy difference between donor and acceptor orbitals of the dioxocations, cannot also be ruled out.[37]

As has been established by numerous studies, the CC interactions strongly affect the rates of various redox reactions [6,8,11,16–19,23,26] and the isotope exchange [12] involving the AnO_2^+ ions. Typically, the reactivity of AnO_2^+ ions is reduced in the presence of 'active' cations. For instance, a complex of PuO_2^+ with a hydrated Cr(III) cation reacts with Cr(VI), Np(VI) and Ce(IV) more slowly by several orders of magnitude than hydrated PuO_2^+ under identical conditions.[6]

The CC interaction or CC bond in solid compounds was revealed for the first time in the $Rh(H_2O)_5NpO_2F_4$ complex.[3] However, this compound has not been isolated in the individual form and its structure has remained obscure. The existence of CC bonds in the crystal structures of several Np(V) compounds was first established by X-ray diffraction in the mid 1980s.[43–46]

Subsequently CC bonds have been revealed in many (more than 20) actinide compounds, whose crystal structures have been determined. This made it possible to analyse some general features of the CC interactions in crystalline compounds of actinides and compare them with the known data for the corresponding solutions. This is the aim of the present review, which surveys the results of studies published prior to 2001 inclusive and, partly, in 2002. Some aspects of the CC interactions in An(V) compounds are discussed elsewhere.[47–49]

II. Crystal structures of Np(V) compounds with cation–cation bonds

To date, there are 23 compounds whose crystal structures involve CC bonds as confirmed by single-crystal X-ray diffraction studies (Table 1). It would be helpful to precede the discussion of the above compounds with a brief description of their structural features. More detailed information may be found elsewhere.[43–46,49–68]

The most striking structural peculiarity of double Np(V)-sodium mellitate $Na_4[(NpO_2)_2C_6(COO)_6]\cdot 8H_2O$ (**1**) is the presence of dimeric groups composed of two mutually coordinated NpO_2^+ ions (see Refs 43 and 44). Therein, both neptunoyl ions act as coordinating centres and ligands simultaneously (Fig. 1). Such a coordination type is not found in structures of other Np(V) compounds listed in Table 1. It is characterised by a relatively short distance between neighbouring Np atoms (*ca.* 3.48 Å). The neptunoyl ions within the dimers are additionally linked by two bridging bidentate carboxyls of different mellitate ions. Two other mellitate anions are bound to NpO_2^+ through adjacent monodentate carboxy groups.

The crystal structure of double Np(V)-ammonium pyromellitate $(NH_4)_3[(NpO_2)_5\{C_6H_2(COO)_4\}_2]\cdot 7H_2O$ (**2**) is quite complicated.[45] It includes five crystallographically nonequivalent NpO_2^+ ions forming the CC bonds (Fig. 2*a*). Two of them may be considered as bidentate ligands, which both act as coordination centres for an oxygen atom of an adjacent neptunoyl group. Therefore, they both form three CC bonds though they differ from each other in the origin of oxygen atoms in the equatorial planes and the Np–O bond lengths. Two other NpO_2^+ ions also form three CC bonds but they act as monodentate ligands and coordinate two adjacent neptunoyl groups. The fifth NpO_2^+ ion forms only two CC bonds. It acts as a monodentate ligand and a coordinating centre for one neighbouring neptunoyl ion.

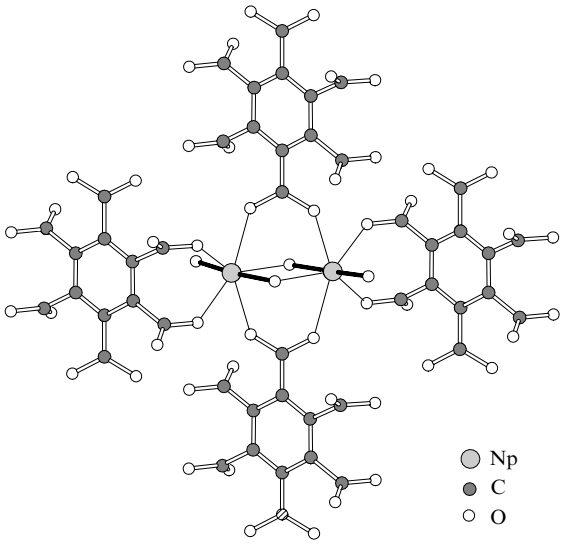

Figure 1. The CC interaction in the crystal structure of **1**.[44]

The crystal structure of $Cs_4[(NpO_2)_2Cl_4NpO_2Cl_2(NO_3)H_2O]$ (**3**) also contains nonequivalent NpO_2^+ ions, which however differ

Table 1. Np(V) compounds with known crystal structures containing CC bonds.

[a] Notations: PBP, SBP, HBP and TBP stand for pentagonal, special (see text, Fig. 3*b*), hexagonal and tetragonal bipyramids, respectively; [b] $O\overset{l_2}{=}Np\overset{l_1}{=}O\overset{l_3}{\cdots}Np$; [c] estimated standard deviations of Np–O bond lengths lie in the range of 0.003–0.01 Å except for **3**, for which it amounts to 0.03 Å.

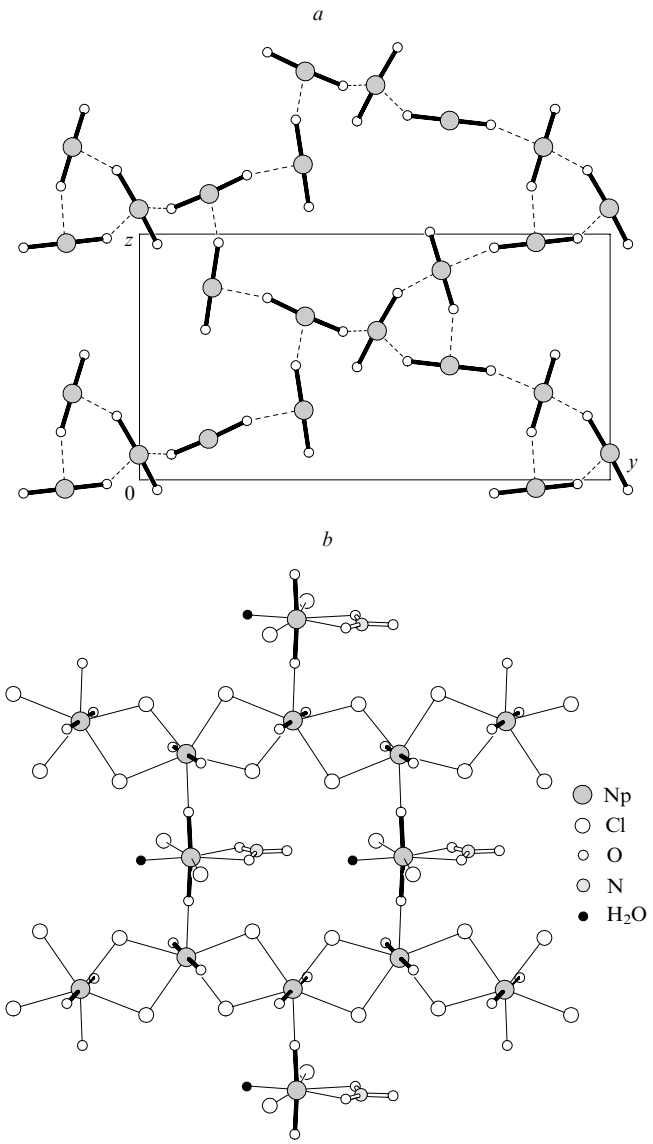

Figure 2. The CC interaction in the crystal structures of **2** (*a*)[45] and **3** (*b*).[46]

in the CC interactions from **2**.[46] One third of the NpO_2^+ ions is coordinated to adjacent Np atoms through both oxygen atoms and does not form other CC bonds (Fig. 2 *b*). In the equatorial plane, each ion of that type is coordinated by two Cl^- ions, two oxygen atoms of the NO_3^- ligand and a water molecule. The remaining neptunoyl groups form only single CC bonds acting as coordinating centres. Their equatorial coordination numbers are also equal to 5: an oxygen atom of an adjacent NpO_2^+ ion and four bridging Cl^- ions are located in their equatorial planes. The Np···Np interatomic distance corresponding to the CC interaction is 4.222 Å.

The pattern of CC bonds in $[(NpO_2)_2SO_4(H_2O)_2]$ (**4**)[50] is of particular interest since it is often found in the crystal structures of other Np(V) compounds. It may be represented as a distorted square net built up of two crystallographically nonequivalent NpO_2^+ ions (Fig. 3 *a*). All neptunoyl ions act as bidentate ligands and at the same time coordinate two adjacent neptunoyls. As a result, each Np atom is involved in four CC bonds. The square nets are linked through tetradentate bridging SO_4^{2-} anions, which are bound to four Np atoms. For both types of NpO_2 ion, the coordination polyhedra (CP) of the central atoms are pentagonal bipyramids though the Np – O bond lengths are slightly different. The equatorial planes of both coordination polyhedra include,

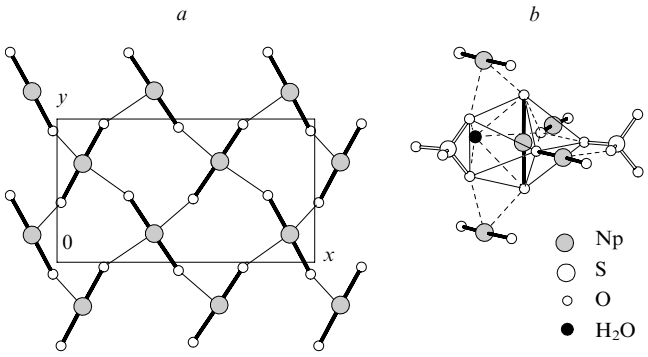

Figure 3. The CC interaction in the crystal structures of **4** (*a*)[50] and **5** (*b*).[51]

apart from oxygen atoms of the SO_4^{2-} anions and adjacent NpO_2^+ ions, one water molecule.

A similar type of CC interaction is also revealed in the crystal structures of $[NpO_2Cl(H_2O)]$ (**6**),[52] $[NpO_2HCOO(H_2O)]$ (**12**),[58] $[NpO_2C_6H_5COO(H_2O)]\cdot 0.75\,H_2O$ (**15**),[60] $[(NpO_2)_2CH_2.(COO)_2(H_2O)_2]\cdot H_2O$ (**20**)[65] and $[(NpO_2)_2\{o\text{-}C_6H_4(COO)_2\}.(H_2O)_3]\cdot H_2O$ (**22**).[67] Nevertheless, nets of cations in these compounds have some distinctions. For example, the crystal structure of **6** includes NpO_2^+ cations of two types differing from each other in numbers of bridging Cl^- ions (1 *vs.* 3) and H_2O molecules (2 *vs.* 0) in their coordination spheres. In contrast, all neptunoyl groups in the crystal structure of **12** are equivalent: in the equatorial plane, they contain two oxygen atoms of adjacent NpO_2^+ groups, two oxygen atoms of bridging carboxy groups and a water molecule. The net of cations in the crystal structure of **15** is formed by neptunoyl ions of four nonequivalent types though in all cases, the central atom CP is a pentagonal bipyramid. The equatorial planes of the coordination polyhedra revealed in **15** are similar to those in **12**. They differ only in the interatomic distances and the dispositions of oxygen atoms from various ligands. The crystal structures of **20** and **22** reveal two nonequivalent NpO_2^+ ions, which are characterised by the coordination number 5 and contain oxygen atoms of various origins in their equatorial planes. In compound **20**, the first type of neptunoyl ions bind two oxygen atoms of adjacent neptunoyls, one oxygen atom of a carboxy group and two water molecules. In the case of the second type of neptunoyl ions, the equatorial plane is built up of two oxygen atoms of adjacent NpO_2^+ ions and three oxygen atoms of two carboxy groups. In compound **22**, the CP of neptunoyl ions of the first type is analogous to that in **20**. Another type of NpO_2^+ ions in **22** coordinates one water molecule, two oxygen atoms of adjacent NpO_2^+ cations and two oxygen atoms of carboxy groups. The shortest Np···Np distances within the cation nets of **4**, **6**, **12**, **15**, **20** and **22** lie in the range of 3.776 – 4.238 Å.

The pattern of the CC bonds in the crystal structure of $[(NpO_2)_2SO_4(H_2O)]$ (**5**) is substantially more complex than in **4** though NpO_2^+ ions in both cases act as bidentate ligands and coordinate two adjacent neptunoyl ions.[51] In the crystal structure of **5**, the CC interactions give rise to a spatial net involving two types of CP. The first one is a pentagonal bipyramid and the second one is a special polyhedron type, which has not hitherto been observed (Fig. 3 *b*). It can be represented as a pentagonal bipyramid with one of the equatorial vertices occupied by two oxygen atoms, which are situated above and below the equatorial plane. The two oxygen atoms belong to one SO_4^{2-} anion. Other oxygen atoms in the equatorial plane come from two NpO_2^+ ions, H_2O and SO_4^{2-}. The equatorial plane of the normal pentagonal bipyramid is composed of three oxygen atoms of different bridging sulfates and two O atoms of the NpO_2^+ ions. The distances between neighbouring Np atoms involved in the CC interaction lie in the range of 3.923 – 4.253 Å. The layered structure of **16** reveals CC interactions and coordination polyhedra of a similar charac-

ter.[61] Nevertheless, the pattern of CC bonds therein differs from that in **5**. The pattern may be described as a distorted square net resembling the structure of **4**.

In the crystal structure of $K_4(H_5O_2)[(NpO_2)_3(MoO_4)_4]\cdot H_2O$ (**7**), neptunium atoms have two types of coordination polyhedra, *viz*., pentagonal and tetragonal bipyramids, in the ratio 2 : 1, respectively.[53] The former polyhedra are linked by molybdate ions to form layers. In those layers, NpO_2^+ ions act as monodentate ligands for neptunoyl ions of the latter type, which have four oxygen atoms in their equatorial planes and are located between the layers (Fig. 4 *a*). Therefore, NpO_2^+ ions of the latter type (with equatorial coordination number 4) form two CC bonds without involvement of their own oxygen atoms. The Np···Np distance responsible for the CC interaction is 4.130 Å.

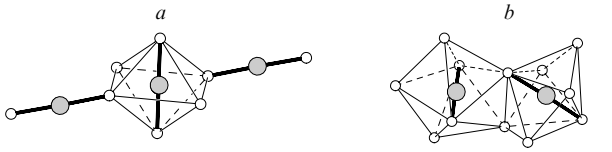

Figure 4. The CC interaction in the crystal structures of **7** (*a*)[53] and **8** (*b*).[54] Notations are the same as in Fig. 3.

The crystal structure of $Na_2[(NpO_2)_2(MoO_4)_2(H_2O)]\cdot H_2O$ (**8**)[54] includes two types of NpO_2^+ ions with coordination numbers 5. Ions of the two types are bound in pairs by virtue of the CC interaction and bridging ligands (Fig. 4 *b*). In the pairs, one of the NpO_2^+ ions acts as a monodentate ligand, while the second one acts only as a coordinating centre. The Np···Np distance within the dimers is 3.727 Å. Equatorial planes of both types of NpO_2^+ ions are occupied by oxygen atoms of bridging MoO_4^{2-} ions, which thus link the neptunoyl dimers into a three-dimensional framework. A similar type of CC interaction giving rise to formation of neptunoyl dimers was revealed in the crystal structure of $[(NpO_2)_2(DMSO)_7(H_2O)_2](ClO_4)_2\cdot H_2O$ (**21**) (see Ref. 66). In this compound, the dimers may be considered as complex cations occupying sites of an ionic crystal lattice. They are composed of two CP (pentagonal bipyramids) linked by an oxygen atom of one of the NpO_2^+ ions. For the latter NpO_2^+ ion, which acts as a ligand, the equatorial plane includes one water molecule and four DMSO molecules. The second neptunoyl ion of the dimer binds one water molecule, three DMSO molecules and one oxygen atom of the adjacent NpO_2^+ ion. The Np···Np distance within the dimer (4.252 Å) is noticeably longer than that in the structure of **8**. The reason for this difference relates to the different ways of assembling the Np coordination polyhedra in the CC interaction. In the crystal structure of **21**, the polyhedra have a shared vertex, which is apical for one of the CP and equatorial for another. In contrast, in the crystal structure of **8**, the Np atoms involved in the CC interaction are linked through one of the oxygen atoms of a molybdate ion so the polyhedra have a shared edge. In one of the polyhedra, this edge connects an apical and an equatorial vertex, while in the other one, it connects two equatorial vertices.

The crystal structure of $[NpO_2ClO_4(H_2O)_4]$ (**9**) (see Ref. 55) reveals particular zigzag chains formed by NpO_2^+ ions owing to the CC interaction (Fig. 5 *a*). Each neptunoyl group in the chains is involved in two CC bonds acting as a monodentate ligand and a coordinating centre simultaneously. The equatorial planes of the CP of Np atoms consist of an oxygen atom of an adjacent NpO_2^+ ion and four water molecules. Similar zigzag chains are also present in the crystal structures of $[NpO_2CH_2(OH)COO(H_2O)]$ (**14**) (see Ref. 59), $[(NpO_2)_2C_2O_4(H_2O)_4]\cdot 2H_2O$ (**18**) (see Ref. 63), and $[NpO_2NO_3(CH_3CONH_2)_2]$ (**23**) (see Ref. 68). In the crystal structure of **14**, the equatorial plane of NpO_2^+ ions consists of a water molecule, an oxygen atom of an adjacent NpO_2^+ ion, two oxygen atoms of a carboxy group and a hydroxy group. Meanwhile, in the crystal structure of **18**, the equatorial plane includes two H_2O molecules, two O atoms of a tetradentate bridging oxalate group and an oxygen atom of an adjacent neptunoyl. In the crystal structure of **23**, the equatorial plane is formed by an oxygen atom of an adjacent neptunoyl, two oxygen atoms of an NO_3^- ion and two oxygen atoms of two acetamide molecules. The shortest Np···Np interatomic distances within the neptunoyl chains revealed in the crystal structures of **9**, **14**, **18** and **23** lie in the range of 4.075 – 4.207 Å.

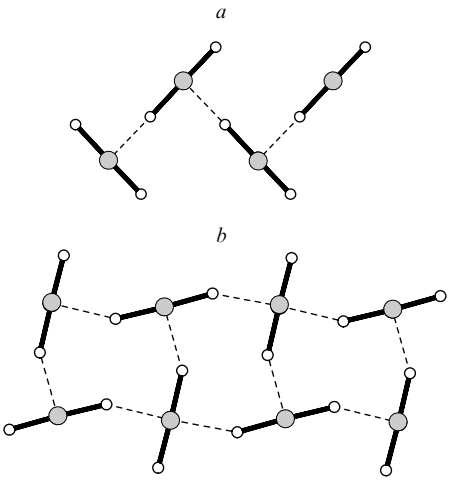

Figure 5. The CC interaction in the crystal structures of **9** (*a*)[55] and **10** (*b*).[56] Notations are the same as in Fig. 3.

In the crystal structure of $[(NpO_2)_2(NO_3)_2(H_2O)_4]\cdot H_2O$ (**10**) (see Ref. 56), the system of CC bonds may be described as ribbons formed by NpO_2^+ cations with two types of coordination polyhedra, *viz*., pentagonal and hexagonal bipyramids (Fig. 5 *b*). Neptunoyl cations of the former type act as bidentate ligands and coordinate four water molecules and one NpO_2^+ cation of the latter type. Neptunoyl cations of the latter type are involved in three CC bonds acting as monodentate ligands. Their equatorial planes contain two oxygen atoms of adjacent NpO_2^+ cations and four oxygen atoms of two NO_3^- ions. The Np···Np interatomic distances lie in the range of 4.130 – 4.200 Å.

The crystal structure of $[La(H_2O)_6][(NpO_2)_3(NO_3)_6]\cdot 4H_2O$ (**11**) (see Ref. 57) is characterised by the presence of a highly symmetrical net of mutually coordinated NpO_2^+ cations acting as bidentate ligands (Fig. 6 *a*). Equatorial planes of the neptunoyl ions contain four O atoms of two bidentate NO_3^- ligands and two oxygen atoms of adjacent NpO_2^+ cations, which occupy *trans*-positions with respect to each other. The shortest Np···Np distances are 4.058 Å and 4.159 Å.

In the crystal structure of $[NpO_2HCOO]$ (**13**) (see Ref. 58), each NpO_2^+ is involved in four CC bonds, similarly to many other Np(V) compounds. Nevertheless, the pattern of CC bonds in **13** is peculiar. Indeed, it combines neptunoyl ions to form a diamond-like framework (Fig. 6 *b*). The coordination polyhedra of the Np atoms are pentagonal bipyramids containing two O atoms of adjacent NpO_2^+ ions and three carboxylic oxygen atoms of two bidentate chelate bridging $HCOO^-$ anions. The distances between neighbouring Np atoms within the framework of cations are 3.783 Å and 4.003 Å.

The crystal structure of $NH_4[NpO_2C_2O_4]\cdot 2.67H_2O$ (**17**) (see Ref. 62) reveals trimers of neptunoyl ions that are coordinated to each other as monodentate ligands (Fig. 7 *a*). As a consequence, each NpO_2^+ ion is involved in two CC bonds. The coordination polyhedra of the Np atoms are pentagonal bipyramids, whose equatorial planes contain one O atom of an adjacent NpO_2^+ ion and four carboxylic oxygen atoms of two tetradentate bridging oxalate ions. The Np···Np distance within such a cyclic trimer is 4.093 Å.

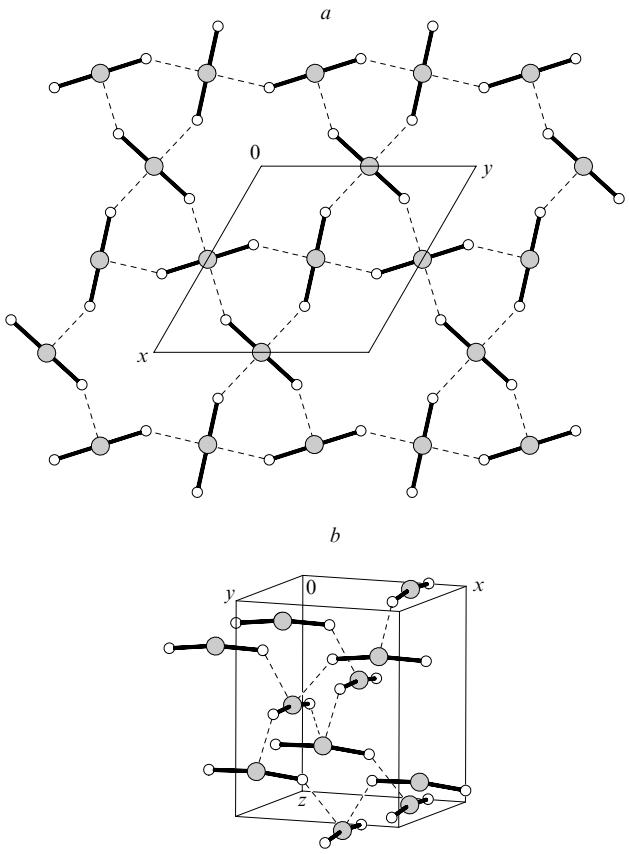

Figure 6. The CC interaction in the crystal structures of **11** (*a*)[57] and **13** (*b*).[58] Notations are the same as in Fig. 3.

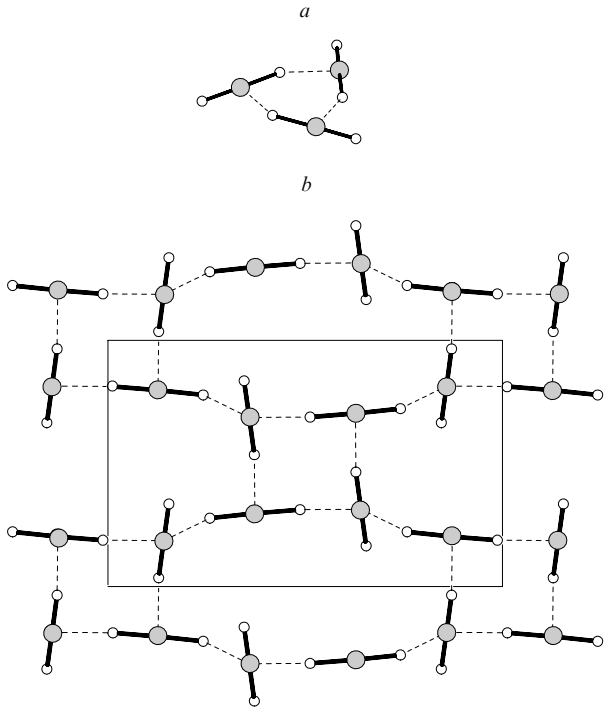

Figure 7. The CC interaction in the crystal structures of **17** (*a*)[62] and **19** (*b*).[64] Notations are the same as in Fig. 3.

Finally, in the crystal structure of $[(NpO_2)_2CH_2(COO)_2.(H_2O)_3]\cdot H_2O$ (**19**) (see Ref. 64), there is a planar net of cations composed of four- and eight-membered rings due to the CC interaction (Fig. 7 *b*). One half of the NpO_2^+ ions within the net acts as monodentate ligands coordinating at the same time two adjacent neptunoyl ions, a water molecule, and two oxygen atoms of two malonate ions. The remaining NpO_2^+ ions act as bidentate ligands and contain one O atom of NpO_2^+, two carboxylic O atoms of one $CH_2(COO)_2^{2-}$ anion and two water molecules in the equatorial planes of their CP. The shortest Np···Np distances within the net of cations lie in the range of 4.182 – 4.234 Å.

The data outlined above clearly demonstrate that the CC interaction is a widespread phenomenon in crystalline compounds of Np(V), which often governs their crystal structures. Below, we summarise some general regularities which characterise the CC interaction.

1. In the crystal structures of all Np(V) compounds studied, the CC bonds are always formed through the bridging oxygen atom, which belongs to one of the interacting neptunoyl groups. However, the identity of NpO_2^+ ions forming a CC bond is not lost since the corresponding Np – O bond lengths are significantly different ($l_1 \ll l_3$, for notations, see Note [b] to Table 1). This conclusion is supported by the fact that the geometry of the coordination environment of NpO_2^+ ions as regards their equatorial planes is only slightly modified by the formation of the CC bond.

2. The formation of the CC bond is accompanied by a significant change in the Np – O bond lengths within the NpO_2^+ ions. It is due to the electrostatic forces: the effective negative charge localised on the oxygen atom causes its attraction to the coordinating centre, which possesses a high positive charge. This positive charge, in turn, determines the repulsion of the Np atoms involved in the CC bond. As a result, the l_1 distance within the NpO_2^+ ion becomes noticeably longer than l_2. According to Table 1, the mean $l_1 - l_2$ difference is 0.04 Å. The fluctuation of this difference may be explained by effects of composition and structures of specific compounds on the distribution of the effective charges within NpO_2^+.

3. The bond length between the oxygen atom of the NpO_2^+ cation and the coordinating centre (denoted l_3 in Table 1) lies in the range of 2.33 – 2.54 Å. The respective mean value of 2.45 Å is close to typical bond lengths between an Np atom and O atoms of various ligands coordinated in the equatorial plane.

4. Neptunium atoms involved in a CC bond may have different coordination polyhedra though pentagonal bipyramids occur most frequently (see Table 1).

5. Neptunoyl ions may be involved in one or more (up to four) CC bonds. According to this criterion, they can be classified into eight types shown schematically in Fig. 8. Those types occur in Np(V) compounds in various combinations. For instance, the types *a* and *b* NpO_2^+ ions are present as dimers in the crystal structures of **8** and **21**. The type *c* mutual coordination of ions ensures the formation of dimers in **1**, cyclic trimers in **17** and

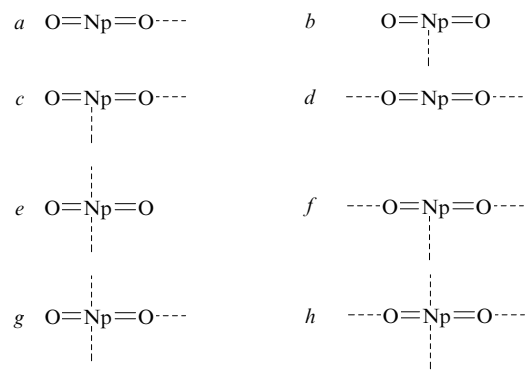

Figure 8. Types of NpO_2^+ ions depending on the number and character of the CC bonds formed.

zigzag chains in **9**, **14**, **18** and **23**. A mutual combination of the type *h* NpO_2^+ ions produces planar (**4**, **11**, **12**, **15**, **16**, **20** and **22**) or three-dimensional (**5** and **13**) cationic nets. The types *d* and *e* neptunoyl ions were found only in the crystal structures of **3** and **7**, respectively. Combinations of the types *f* and *g* NpO_2^+ ions were revealed in the crystal structures of **2** and **10**.

The formation of a specific pattern of CC bonds in the crystal structures of Np(V) compounds depends upon a number of factors, among which the following are of major importance:

— the nature of anionic or molecular ligands in the equatorial planes of NpO_2^+ ligands involved in the formation of the CC bonds;

— the number and the nature of outer-sphere cations in the case of double salts of Np(V);

— the number of water molecules in the crystal structure;

— preparation conditions.

The influence of the nature of ligands in the equatorial plane of NpO_2^+ ions on the CC pattern can be clearly illustrated with the crystal structures of Np(V)-sodium double mellitate [43, 44] and pyromellitate.[69] Despite the similar character of the ligand coordination in the two structures, CC bonds are present in the former compound and are absent in the latter. This can be due to different charges localised on the respective ions. A typical effect of the ligand nature on the CC interaction between neptunoyl ions is also observed in the crystal structures of **16** and **14**. Both compounds, *viz*., Np(V) acetate and glycolate, are characterised by similar compositions whereas planar nets composed of the *h* type of the NpO_2^+ ions as opposed to zigzag chains of the *c* type of the neptunoyl ions are revealed in the crystal structures of the former and the latter, respectively.

In double salts of Np(V), the CC interaction between NpO_2^+ cations is generally weaker than in monocationic derivatives. Probably, this is caused by the electrostatic interactions of NpO_2^+ ions with outer-sphere cations, which impedes a mutual coordination of neptunoyls. The effect of monovalent cations (M^+) on the CC interaction of the NpO_2^+ ions decreases in the series $Na^+ > NH_4^+ \approx K^+ > Cs^+$, in agreement with expectations. For instance, CC bonds are absent in the crystal structure of the $Na[NpO_2C_2O_4(H_2O)]\cdot 2H_2O$ double salt [70] although cyclic trimers of NpO_2^+ ions are revealed in the structure of a closely related compound $NH_4[NpO_2C_2O_4(H_2O)]\cdot 2.67H_2O$ (**17**).

The CC interaction in double salts of Np(V) strongly depends not only on the nature of the cations M^+ but on their number, *i.e*., on the $M^+ : NpO_2$ ratio as well. An increase in this ratio increases saturation of the coordination sphere of NpO_2^+ ions with anionic ligands, which evidently hampers the formation of the CC bonds. This effect can be illustrated with the crystal structure of $Cs_3[NpO_2(SO_4)_2]\cdot 2H_2O$ (see Ref. 71), which contains no CC bonds.

An increase in the number of water molecules in an Np(V) compound generally results in a substantial weakening of the CC interaction. For example, in the crystal structure of **20**, every NpO_2^+ ion is involved in four CC bonds whereas only two CC bonds are formed by neptunoyl ions in the crystal structure of **18**. This effect may be explained by the formation of H-bonds between oxygen atoms of NpO_2^+ ions and water molecules, which interfere with the CC interaction.

Synthetic conditions often have a definitive influence on the composition of Np(V) compounds and thus on the occurrence and the character of the CC bonds in their crystal structures. For instance, compounds **12** and **13** are crystallised from formate solutions under hydrothermal conditions at 120 °C and 160 °C, respectively. As has been mentioned above, these compounds have totally different patterns of the CC bonds.

Unfortunately, the regularities formulated above are only qualitative and do not allow an unambiguous prediction of patterns of the CC interaction in the crystal structures of novel Np(V) compounds. Meanwhile, they provide valuable assistance in suggesting occurrence and the type of the CC bonds in compounds of a known composition but unknown crystal structure.

III. Influence of the cation – cation interactions on the properties of Np(V) compounds

1. Crystallisation and dissolution

The cation – cation interactions in crystalline compounds of Np(V) have a strong influence on their properties. In particular, many compounds possessing CC bonds behave abnormally on dissolution and crystallisation. Probably, it is due to the involvement of the CC bonds in the formation of infinite fragments of the crystal structure. This conclusion can be illustrated with several examples. The solubility of Np(V) double oxalates with the common stoichiometry $MNpO_2C_2O_4\cdot nH_2O$, where M^+ is ammonium or alkali metal ion, decreases noticeably upon their storage for several days.[72] As has been shown,[73] this decrease is explained by slow conversion of the above compounds into simple oxalate $(NpO_2)_2C_2O_4\cdot 6H_2O$. The low solubility and slow formation of the latter compound relate evidently to the infinite chain-like system of the CC bonds revealed therein.[63]

A typical trend in the solubility change due to formation of an infinite system of the CC bonds is also observed in the precipitation of simple Np(V) formates.[58, 74] Solutions of NpO_2OH with the concentration $[NpO_2^+] = 0.1 - 0.3$ mol litre^{-1} in an excess of HCOOH remain transparent for several hours. Then, slow crystallisation of $NpO_2HCOO\cdot 2H_2O$ begins. The latter is characterised by a solubility of 5.32×10^{-2} mol litre^{-1} at 23 °C and [HCOOH] = 0.2 mol litre^{-1}. With an increase in temperature up to 65 °C, the solubility does not change significantly. Nevertheless, upon heating of the saturated solution in a boiling water bath, crystals of **12** precipitate. This compound is characterised by a solubility of 2.42×10^{-2} mol litre^{-1} at 100 °C and [HCOOH] = 0.3 mol litre^{-1}. At temperatures above 140 °C, the monohydrate **12** converts into anhydrous salt **13**, which leads to a further decrease in the concentration of Np(V) in the liquid phase.

Similar trends in the crystallisation of various hydrates are observed in the preparation of Np(V) simple salts with sulfate,[50, 51, 75] acetate,[76] benzoate [60, 77] and other carboxylate [59, 78, 79] anions. In general, slow formation and dissolution of precipitates as well as relatively low solubility in water and organic solvents are characteristic of Np(V) compounds with infinite nets of CC bonds. Such compounds are typically nonhygroscopic.

2. UV-Vis absorption spectra

The cation – cation interaction specifically affects optical properties of Np(V) compounds. This is confirmed by an analysis of the UV-Vis absorption spectra of more than 30 simple and complex neptunoyl salts with known crystal structures.[55, 56, 77 – 87] A comparison of UV-Vis spectra of crystalline compounds with CC bonds and those without CC bonds, on the one hand, and of the respective solutions, on the other hand, revealed several important regularities.[81, 88, 89] One of them concerns correlations between the symmetry of the CP of Np atoms in a compound and the general shape of its UV-Vis spectrum. As has been noted above, pentagonal bipyramid and, less frequently, hexagonal bipyramid are the major types of coordination polyhedra occurring in neptunoyl compounds. According to extensive experimental studies, UV-Vis spectra of all crystalline salts of Np(V) characterised by the pentagonal-bipyramidal coordination of the central atom (D_{5h} symmetry) manifest narrow and intense absorption bands in the region of 970 – 1050 nm similar to the dominant band in the spectra of hydrated NpO_2^+ ions (Fig. 9 *a*). In contrast, such narrow absorption bands are absent in the case of compounds with hexagonal bipyramids (D_{6h} symmetry) as the coordination polyhedra of the Np atoms (Fig. 9 *b*). This can easily be rationalised.[90] According to the Laporte selection rules, *f*–*f* transitions are forbidden in a centrosymmetric ligand field (including the case of D_{6h} symmetry). For CP without an inversion centre (such as the pentagonal bipyramid), the probability of such transitions

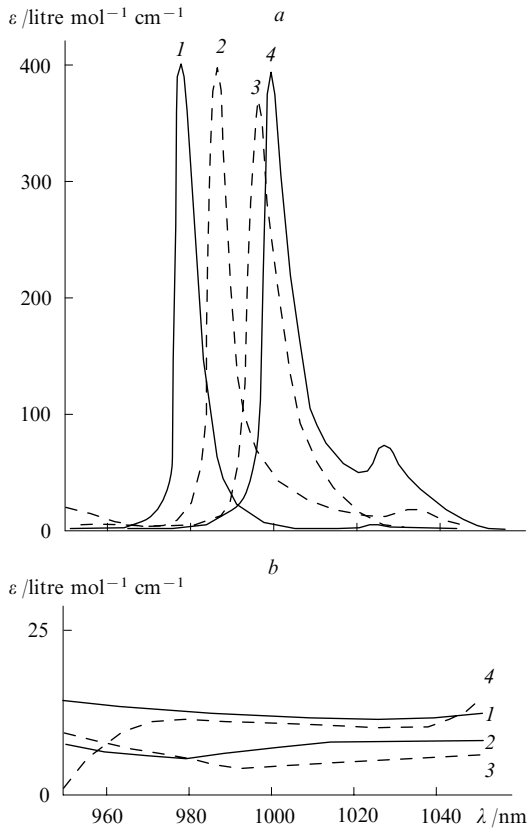

Figure 9. The UV-Vis absorption spectra of hydrated Np(V) ions and different neptunoyl compounds: (*a*) NpO_2^+ (aq) (*1*), **24** (*2*), **28** (*3*),[84] **12** (*4*);[82] (*b*) $NH_4[NpO_2(HCOO)_2]$ (*1*),[74] $K[NpO_2CO_3]$ (*2*),[81] $Cs_2[NpO_2.(CH_3COO)_3]$ (*3*),[82] **11** (*4*).[57]

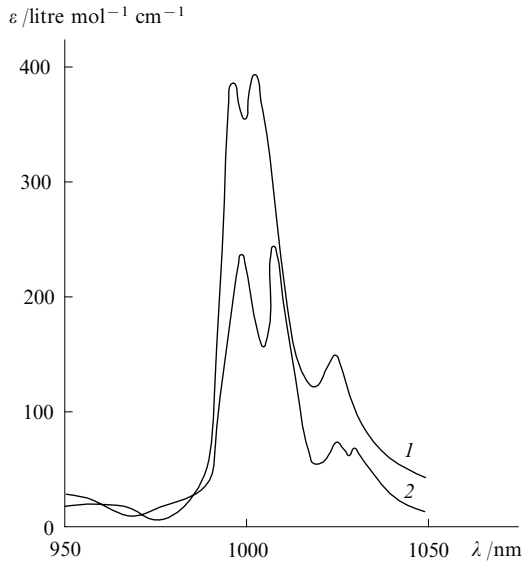

Figure 10. The UV-Vis absorption spectra of **4** (*1*) and **6** (*2*).[62]

becomes appreciable giving rise to narrow and fairly intense absorption bands in the UV-Vis spectra.

UV-Vis spectra of crystalline compounds and respective solutions are normally characterised by similar values of the molar extinction (ε_m) at the absorption maxima. Somewhat reduced ε_m values are observed only for amorphous, such as Np(V) hydroxide, or poorly crystalline substances.[89]

Based on the resemblance of the UV-Vis spectra of neptunoyl derivatives in aqueous solutions to those of crystalline compounds characterised by the D_{5h} symmetry of the coordination polyhedron of the neptunium atoms, one may assume that the hydration number (h) of NpO_2^+ ions in dilute aqueous solutions is 5. Suggestions that $h = 6$ or 4 adopted by several authors[33,77,91] are most probably erroneous.[92] A similar conclusion is also valid for AmO_2^+ ions, since the UV-Vis spectra of the respective aqueous solutions manifest narrow and fairly intense bands assigned to f–f transitions. Furthermore, the effects of the CP symmetry on the UV-Vis spectra established for neptunoyl ions are also applicable to PuO_2^{2+} ions as confirmed by the UV-Vis spectra of a series of Pu(VI) double oxalates (see Ref. 93). Thus, plutonoyl like other actinoyl ions are characterised by the hydration number 5 in aqueous solutions.

In the UV-Vis spectra of some crystalline compounds with D_{5h} symmetry of the Np coordination polyhedra, the main absorption band is split (Fig. 10).[66,78,80,85] This suggests the presence of several nonequivalent neptunoyl groups in the crystal structure. However, an unsplit UV-Vis band does not necessarily imply the crystallographic equivalency of all NpO_2^+ ions. For example, in the crystal structure of **15**, there are four types of neptunoyl ions despite the major absorption band in the UV-Vis spectrum of this compound being only slightly broadened rather than split.[77]

The position of the major absorption maximum in the UV-Vis spectrum of a crystal is normally red-shifted with respect to the corresponding solution provided that the CP of the Np(V) atoms in the crystal structure of this compound have no inversion centres. The magnitude of this shift ($\Delta\lambda_m$) depends on the nature of ligands in the equatorial plane of the NpO_2^+ ions and the occurrence of the CC bonds. For compounds without CC bonds, the positions of absorption maxima in the UV-Vis spectra of crystalline samples are quite close to those of the respective solutions with the shift not exceeding $\pm$ 5 nm (Table 2).

Table 2. UV-Vis spectral parameters of crystalline Np(V) compounds with known crystal structures without CC bonds.

The situation changes dramatically if the crystal structure of an Np(V) compound involves CC bonds. In those cases, the absorption band in the UV-Vis spectrum of the crystal is quite strongly shifted towards longer wavelengths with respect to the spectra of the corresponding complex in a solution. The magnitude of this shift depends on the character of the CC bonds. For compounds that contain neptunoyl ions acting as monodentate ligands, $\Delta\lambda_m$ lies in the range of 8 – 17 nm (Table 3). In the case of a bidentate coordination of NpO_2^+ ions, the shift amounts to 15 – 39 nm (Table 4). Crystal structures of some compounds contain both mono- and bidentate neptunoyl ions simultaneously. The major absorption bands in the UV-Vis spectra of such compounds are split into two components with distinctly different red shifts. The UV-Vis spectrum of **19** may be taken as a striking example of such a situation.

In the course of systematic UV-Vis studies of NpO_2^+ crystalline compounds, several unusual facts have been revealed. In particular, the spectra of Np(V) chromates[83,96–98] manifest intense broad bands strongly (> 40 nm) shifted towards longer wavelengths. According to X-ray crystallographic data,[96–98] this

shift is not induced by the CC interaction. Probably, a partial charge transfer from the Np atoms to the CrO_4^{2-} due to a strong oxidising ability of the latter is responsible for the phenomenon.

Yet another anomaly, *viz*., a broad irregularly shaped band characterised by a strong red shift, was observed in the spectrum of crystalline Np_2O_5[99] (Fig. 11). Apparently, the neptunoyl moiety is substantially weakened or totally absent in the crystal structure of Np_2O_5.

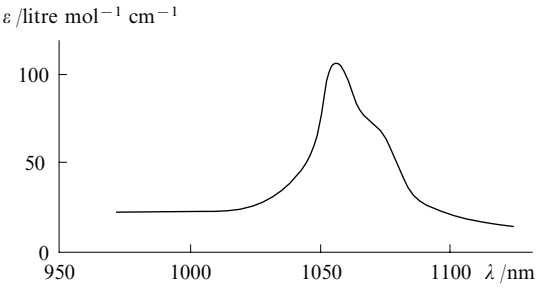

Figure 11. The UV-Vis absorption spectra of crystalline Np_2O_5.[99]

Finally, we note that the aforementioned regularities often allow reliable predictions of the occurrence and the character of the CC bonds in the crystal structures of novel Np(V) compounds on the basis of their UV-Vis spectra. Such predictions were made for a number of compounds including neptunoyl chloride,[87] oxalates,[84] malonates,[78] benzoates[77] and phthalates.[87] Afterwards, all of these predictions proved correct through direct determinations of the crystal structures of the respective compounds by means of single-crystal X-ray diffraction.[52, 60, 62–65, 67] Definitely, these predictions are only of qualitative character. The UV-Vis absorption spectroscopy of crystalline Np(V) compounds and conclusions based on the spectral results should not be taken as a substitute for other techniques. It should rather be considered as the first step in the structural study of newly prepared Np(V) compounds.

3. Infrared and other spectra

It has been demonstrated[100,101] that IR spectra of a number of simple Np(V) salts are characterised by intense broad bands of antisymmetric (ν_{as}) vibrations of the neptunoyl moiety. This observation was first explained by formation of H-bonds between water molecules and oxygen atoms of the neptunoyl ions. However, systematic structural studies have recently established that simple Np(V) salts usually contain CC bonds. Therefore, one may suggest that it is the CC interaction that is responsible for the intense broad vibrational bands of NpO_2^+ observed in these compounds. This suggestion is supported by IR spectroscopic studies of many Np(V) compounds with known crystal structures.[58, 66, 68, 75–79, 87] The distinct difference in the ν_{as} band between IR spectra of neptunoyl salts with (*a*) and without (*b*) the CC bonds is illustrated in Fig. 12 for a few typical cases.

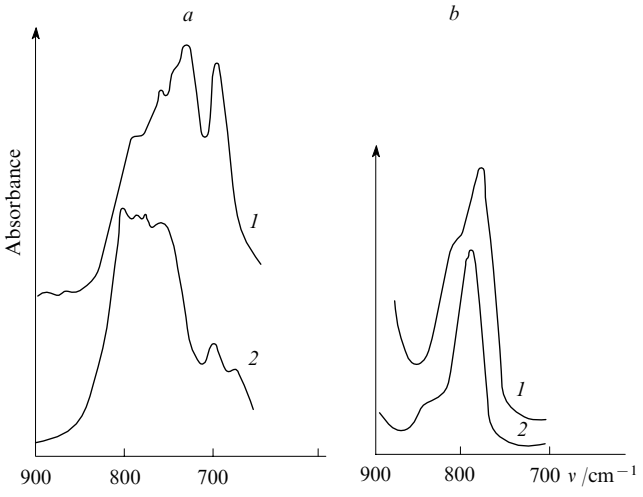

Figure 12. The IR spectra of some Np(V) compounds (see Ref. 78): (*a*) **20** (*1*) and **19** (*2*), which involve CC bonds; (*b*) $NH_4[NpO_2CH_2(COO)_2]$ (*1*) and $Cs[NpO_2CH_2(COO)_2]$ (*2*) without CC bonds.

Yet another distinctive feature of the IR spectra of Np(V) compounds possessing CC bonds in their crystal structures is a pronounced shift of the ν_{as} bands towards lower frequencies. The magnitude of this shift depends upon the number and the character of the CC bonds. In particular, it correlates to a certain extent with the changes in the Np–O bond lengths resulting from the CC interaction as well as with the red shift of bands in the UV-Vis spectra (Table 5). Unfortunately, this correlation bears only a qualitative character, partially due to ambiguities in the determination of precise positions of maxima for broad irregularly shaped ν_{as} vibrational bands in the IR spectra of compounds with the CC bonds. On the other hand, Np–O bond lengths change within a relatively narrow range and the precision of their determination is not sufficiently high.

Several publications[24, 43, 49, 58, 87, 93, 102] have reported on the Mössbauer spectra of Np(V) compounds, crystal structures of which reveal the CC interaction. However, no suggestions of spectral effects attributable exclusively to the CC interaction have been made.

An interesting result has been obtained in a study of magnetic properties of compound **14**.[103] According to the low-temperature magnetic susceptibility measurements, this salt (note that its crystal structure reveals a distorted planar square net of CC bonds[58]) undergoes a ferromagnetic transition at 12 K. It is the first observation of ferromagnetism for Np(V) compounds. We

believe that further investigations into the magnetic properties of Np(V) compounds will lead to new important findings.

IV. Cation – cation interactions in compounds of other actinide ions

The mutual coordination of UO_2^{2+} ions has been observed for the first time in a crystallographic study of UO_2Cl_2 (**30**) by means of neutron diffraction.[104] In the orthorhombic crystal lattice of this compound, the uranyl ions form infinite zigzag chains through the CC bonds, which is similar to the pattern of NpO_2^+ ions in the crystal structures of compounds **9**, **14**, **18** and **23**. Each UO_2^{2+} ion is involved in two CC bonds acting as a monodentate ligand with respect to the adjacent ion.

Similar infinite zigzag chains were revealed in the crystal structure of UO_2MoO_4 (**31**).[105] Furthermore, it has to be taken into account that all anhydrous salts with the common stoichiometry UO_2EO_4, where E = S, Se, Cr, Mo or W, are isostructural according to powder X-ray diffraction data.[106–108] Thus, their crystal structures contain identical chain-like patterns of the CC bonds.

Quite another pattern of the CC bonds was revealed in uranyl hexafluoroacetylacetonate $UO_2(C_5HF_6O_2)_2$ (**32**).[109] Its crystal structure, like that of compound **17**, contains trimers of uranyl ions. Nevertheless, in this compound all UO_2^{2+} ions in the trimers are crystallographically nonequivalent. According to some indirect evidence,[110, 111] CC bonds may also be formed in other uranyl β-diketonates though the corresponding crystal structures have not been determined so far.

The formation of CC bonds has been confirmed for a rather complicated and structurally uncommon oxothiolate uranyl complex $(HNEt_3)_2[(UO_2)_4(\mu_3\text{-}O)_2(SC_5NH_4)_6]\cdot Me_2CO$ (**33**). The crystal structure of this compound reveals tetranuclear anions composed of two identical fragments $(UO_2)_2(SC_5NH_4)_3^-$, in which uranyl ions form CC bonds of the O=U=O···U type. These fragments are bound to each other through two bridging O atoms. Therefore, as regards the pattern of the CC bonds within the complex anion, the two UO_2^{2+} ions act as monodentate ligands whilst two other ions act exclusively as coordinating centres.

No other uranyl derivatives possessing CC bonds have been reported so far. Nevertheless, we assume that CC bonds may well be revealed in further structural studies of a number of anhydrous uranyl salts containing anions of low coordination capacity as ligands.

The character of the CC bonds and their influence on the properties of uranyl compounds are similar to those discussed above for neptunoyl compounds. In both cases, the CC bonds are formed through bridging oxygen atoms, which are characterised by different An – O bond lengths ($l_1 \ll l_3$, Table 6). The formation of the CC bonds is also accompanied by a significant increase in the U – O bond length within the uranyl ions. The mean value of the $l_1 - l_2$ difference is 0.06 Å. The U – O distance to the oxygen atom of an adjacent uranyl ion coordinated in the equatorial plane is 2.51 Å on average, which is slightly longer than values typical of uranyl complexes with various oxygen ligands. Thus, UO_2^{2+} ions behave as relatively weak ligands in the formation of the CC bonds.

Table 6. U – O bond lengths (Å) in the crystal structures of uranyl compounds with CC bonds.[a]

Compound	l_1	l_2	l_3	Ref.

[a] $O\overset{l_2}{=}U\overset{l_1}{=}O\overset{l_3}{\cdots}U$.

Apart from the aforementioned Np(V) and U(VI) derivatives, no other An(V) or An(VI) compounds exhibiting CC bonds have been reported. Attempts to synthesise NpO_2MoO_4 and NpO_2EO_4, where E = S, Cr or W, which are presumably isostructural to UO_2MoO_4, failed due to reduction of Np(VI) to the pentavalent state. Nevertheless, the possibility of an occurrence of CC bonds in some anhydrous neptunyl compounds cannot be totally ruled out.

Several attempts to prepare Am(V) compounds analogous to Np(V) salts with known crystal structures have been undertaken. It was established that the isolation conditions and the crystal structures of $[Co(NH_3)_6][AmO_2(SO_4)_2]\cdot 2H_2O$ and $[Co(NH_3)_6]\cdot[NpO_2(SO_4)_2]\cdot 2H_2O$ devoid of CC bonds are virtually identical.[113] Meanwhile, it turned out that $(AmO_2)_2SO_4\cdot nH_2O$ is not isostructural to any of the known simple Np(V) sulfates with CC bonds. Moreover, Am(V), in contrast to Np(V), is not precipitated from concentrated formate solutions as $AmO_2HCOO\cdot nH_2O$ but rather is slowly converted into poorly soluble $Am(HCOO)_3$.[114] With a high level of confidence, we may assume that these results suggest a significant weakening of the CC bonds upon transition from NpO_2^+ to AmO_2^+. However, preparation of Am(V) com-

pounds with CC bonds should not be judged as completely impossible. Indeed, AmO_2^+ ions in solutions can serve as weak ligands in the CC interactions with highly charged cations, although uranyl ions do not manifest this ability. At the same time, as has been noted above, some crystalline compounds of U(VI) reveal CC bonds.

Since Pu(V) and, in particular, U(V) are prone to the CC interaction in solutions, one should expect the occurrence of CC bonds in crystal structures of some of their compounds. Most probable candidates in the search for such compounds are salts of suitable anions with kinetically stable cationic complexes of PuO_2^+ or UO_2^+ with Cr^{3+} or Rh^{3+} like $Rh(H_2O)_5NpO_2F_4$ (see Ref. 5). Preparation of compounds with a mutual coordination of PuO_2^+ or UO_2^+ ions is hardly possible taking into account their easy disproportionation.

V. Comparison of cation – cation interactions in solutions and crystals of actinide compounds

As has been noted in the Introduction, different aspects of the CC interaction have been considered in numerous publications. Special attention has been paid to the elucidation of the nature of this phenomenon. Several authors suggested that the CC interaction can be reduced to a special type of incomplete redox reaction between the AnO_2^+ cation and an 'active' cation.[7, 13, 14, 19, 20, 22, 23, 25] A series of arguments have been adduced in support. In particular, according to several reports, kinetics of formation of complexes owing to the CC interaction of NpO_2^+ with U(VI), Fe(III), Th(IV) or In(III) and of AmO_2^+ with U(VI) does not obey the law of mass action. Moreover, the UV-Vis spectra of NpO_2^+ (see Refs 14 and 20) and AmO_2^+ (see Ref. 7) in the presence of some 'active' cations manifest broad bands in the region of 600 – 900 nm attributed to the exciton absorption. The experimentally established weakening of the CC interaction in the series $UO_2^+ > NpO_2^+ > AmO_2^+$ was explained [7, 25] by an increase in the redox potentials of the corresponding An(VI)/An(V) pairs. These and some other arguments [14, 15] have been consistently rebutted in a series of studies,[26, 29 – 35] which at the same time substantiated an alternative suggestion stating that the CC interaction in a solution originates from complexation between the AnO_2^+ ions and the 'active' cations. However, the character of this complexation remains disputable. Two alternative concepts of the nature of the CC interaction in solutions have been formulated based on numerous experimental results.[2, 29, 32 – 35] The first concept states that the CC interaction may be considered as a process of substitution of water molecules within the coordination sphere of the 'active' cation by oxygen atoms of the actinoyl ion. The second concept suggests an outer-sphere interaction mediated by such ligands as H_2O or ClO_4^-. The following arguments may be adduced in favour of the first concept:

1. The formation of CC complexes of AnO_2^+ with Cr_{aq}^{3+} (see Refs 2 and 9) and Rh_{aq}^{3+} proceeds slowly, which is typical of inner-sphere substitution of water molecules by various ligands in 'active' cations mentioned.

2. The NMR data [33] on the CC interaction between NpO_2^+ and UO_2^{2+} support the hypothesis of the formation of a T-shaped inner-sphere complex (two linear AnO_2^{n+} groups arranged perpendicularly to each other).

3. The major band in the UV-Vis absorption spectra of hydrated NpO_2^+ ions at 980 nm is shifted in the presence of 'active' cations by 9 – 17 nm towards longer wavelengths.[1 – 3, 8] Such a large shift may be induced by either direct involvement of oxygen atoms of the neptunoyl groups into chemical bonds or incorporation of sufficiently strong ligands into the equatorial plane of the NpO_2^+ ions. Note that H_2O molecules and ClO_4^- anions are generally considered as weak ligands.

4. According to IR [28, 100, 101] and Raman [31, 34] spectra, vibrational frequencies of NpO_2^+ change substantially due to the CC interaction. The character of these changes is similar to that in the UV-Vis spectra.

5. The An···An interatomic distance in CC complexes of NpO_2^+ with UO_2^{2+} is 4.2 Å,[32, 35] which is surprisingly close to the sum of the Np – O bond length within neptunoyl (*ca.* 1.8 Å) and a typical distance between the U atom of uranyl and oxygen atoms of ligands coordinated in the equatorial plane (*ca.* 2.4 Å).

The above arguments strongly assume that the outer-sphere model of the CC interaction is hardly probable although these are not sufficient to rule it out decisively. In this respect, we note rather unexpected negative values of enthalpy and entropy of the CC interaction determined for NpO_2^+ complexes with Rh(III) (see Ref. 3), Cr(III) (see Ref. 9) and U(VI) (see Ref. 40). Though the negative values are normally typical of the outer-sphere complexation of actinides, these results can be rationalised taking into account higher hydration energy of the CC complex with respect to the starting species due to formation of a binuclear complex, which is characterised by a high specifically distributed charge.

Convincing evidence in favour of the inner-sphere nature of the CC interaction involving AnO_2^+ ions comes from results of the characterisation of the CC complexes in crystalline compounds of Np(V) summarised above. Indeed, in all crystalline structures discussed, the CC bonds are formed by direct incorporation of an oxygen atom of a neptunoyl ion into the coordination sphere of the adjacent NpO_2^+ ion. On the other hand, there is a close analogy between the CC interaction formed by AnO_2^+ ions in solutions and in crystals. This analogy becomes apparent if the UV-Vis spectra of NpO_2^+ CC complexes in solutions are compared with the spectra of the respective compounds in the crystalline state. As has already been mentioned, upon formation of CC complexes in solutions, the UV-Vis absorption band of Np(V) ions shifts by 9 – 17 nm. Crystalline compounds with a monodentate mutual coordination of NpO_2^+ ions (see Table 3) are characterised by virtually the same shift. Besides, the Np···Np interatomic distances between CC-interacting neptunoyl ions in perchloric acid solutions [32, 35] and in crystalline $[NpO_2ClO_4(H_2O)_4]$ (see Ref. 55) are close to each other being both equal to ~ 4.2 Å. Therefore, there is sufficient evidence that the CC interactions of actinoyl ions in solutions and in crystals are realised in similar ways. Notwithstanding, the two cases have distinctive features due to the following factors:

1. In solutions, the CC interaction is usually limited to formation of binuclear complexes. Trimeric and larger (*i.e.*, higher-nuclearity) species have been detected only in very concentrated ($c > 0.5$ mol litre^{-1}) solutions of Np(V) perchlorate.[31, 34] In contrast, formation of infinite systems of CC bonds (*viz.*, chains, ribbons, planar nets or three-dimensional frameworks) is typical of crystalline neptunoyl compounds. Dimeric ions have been revealed in the crystal structures of only two out of twenty-three compounds listed in Table 1, namely, in **1** and **21**.

2. Neither mutual coordination of AnO_2^+ ions nor their CC interaction with other 'active' ions (apart from AnO_2^+) in solutions has been observed. Meanwhile, the crystal structures of a number of uranyl compounds (see Table 6) contain CC bonds. This may be explained by a rather small effective charge localised on oxygen atoms within the AnO_2^+ ions. As a result, they cannot substitute water molecules in the coordination spheres of 'active' cations in aqueous media. Nevertheless, some U(VI) compounds with CC bonds can be crystallised from organic solutions or prepared by solid state methods.

3. Systematic structural studies of crystalline compounds of Np(V) have shown that the incorporation of a large number of water molecules in the crystal structure results in a weakening of the CC bonds and a prevalence of the monodentate coordination of NpO_2^+ ions. Upon transition from crystals to aqueous solution, this tendency becomes more pronounced. This may be explained by the formation of hydrogen bonds between oxygen atoms of the neptunoyl ions and H_2O molecules. This suggestion is supported by the fact that the CC interaction is intensified provided that a weaker proton donor is taken as a solvent instead of water.[14, 39]

The absence of infinite systems of CC bonds and their weakening in aqueous solutions result in a relatively low influence

of the CC interaction on the UV-Vis spectra of Np(V) compounds in concentrated aqueous solutions.[32, 35] Probably, the same factors along with the larger $l_3 - l_1$ difference are responsible for some peculiarities of the Raman spectra of Np(V) compounds in solutions.[31, 34, 36]

Therefore, one may conclude that the CC interaction of actinoyl ions both in solutions and in crystals is realised through the inner-sphere coordination of AnO_2^+ by the 'active' ions. The only difference for the two cases consists of the intensity of the processes.

* * *

According to the experimental data summarised above, the CC interaction of NpO_2^+ ions is a common phenomenon occurring in many Np(V) compounds with known crystal structures. It strongly affects physicochemical properties of compounds under consideration, such as precipitation and dissolution kinetics, UV-Vis and IR spectra, *etc*. The number of Np(V) compounds in which the presence of the CC bond has been confirmed constantly increases. Meanwhile, structural data for other pentavalent actinides, in particular, PuO_2^+ are lacking. Therefore, the development of preparative chemistry of Pu(V), which is immature as yet, is an urgent task. Undoubtedly, the accomplishment of this task will make a significant contribution to coordination chemistry of actinides.

Abstract. The results of pulse radiolysis studies of the kinetics and mechanism of fast one-electron redox reactions of halide ions, metal ions, actinides and other compounds with hydrated electrons, hydroxyl and other radicals and hydrogen atoms and the properties of intermediates formed in these reactions are analysed. The oxidation of a mixture of chloride and bromide ions yields mixed radical anions $ClBr^{-\bullet}$. Data on the formation of metal atoms and ions in unusual and unstable oxidation states by the reduction of metal ions in aqueous solutions and on the reactions involving such ions are presented. It is shown that the reduction of compounds in aqueous solutions with organic radicals takes place through outer- or inner-sphere electron transfer. The bibliography includes 116 references.

I. Introduction

The use of pulse radiolysis has made a considerable contribution to the studies of the kinetics and mechanism of redox reactions and the nature and properties of the short-lived intermediates thus arising. This technique was implemented into the research practice at the Institute of Physical Chemistry of the USSR Academy of Sciences in the early 1970s by initiative and with all-round support from Academician V I Spitsyn and Corresponding member of the Academy A K Pikaev. The description of the method and the results obtained using this method by Russian and foreign researchers before 1980 are considered in detail in a monograph.[1] Data on the properties of metal atoms and metal ions in unusual oxidation states formed upon one-electron reduction or oxidation of metal ions in stable oxidation states in aqueous solutions and on the small clusters formed upon their aggregation are presented in recent reviews.[2–4] The results of pulse radiolysis study of the redox reactions of actinides have been summarised.[5]

This review is a discussion of the results of pulse radiolysis studies of one-electron redox reactions involving diverse inorganic and organic compounds in aqueous solutions obtained mainly during the last 15 years. To cover the problem comprehensively and to provide substantiated interpretation of the data, earlier publications are also considered. Particular attention is paid to the oxidation of halide ions in aqueous solutions. The redox reactions involving chlorine, bromine and iodine are frequently encountered in nature and are used in practice. Thus water disinfection by chlorination still remains the main method for potable water treatment. The production processes involving halogens are widely used in industry. Therefore, considerable attention in the review is paid to the latest advances in the kinetic and mechanistic studies of halogen reactions. Owing to the use of modern investigation techniques for fast redox processes, the formation of mixed short-lived radical anions of the $ClBr^{-\bullet}$ type was detected.[6,7] In addition, characteristic features of a number of one-electron redox reactions of hydrated electrons, hydroxyl radicals, and other inorganic and organic radicals with various compounds in aqueous solutions are analysed.

II. Radiation chemical formation of oxidising and reducing reagents

When investigating by pulse radiolysis the kinetics and mechanism of one-electron reduction or oxidation of compounds in aqueous solutions and the nature and the properties of the arising intermediates, radical ion species formed upon radiolysis of the solution are taken as the reagents. These species are formed upon ionisation of water molecules on exposure to radiation and in secondary reactions with dissolved compounds. The chemical stage of water radiolysis yields hydrated electrons (e_{aq}^-), hydrogen atoms, protons, and hydroxyl radicals ($OH^\bullet$) as well as hydrogen and hydrogen peroxide molecules. In the general form, the process of water radiolysis can be represented as follows:

$$H_2O \rightsquigarrow e_{aq}^- (2.7) + H^\bullet (0.6) + OH^\bullet (2.9) + \\ + H_2 (0.5) + H_2O_2 (0.7) + H^+ (2.7). \quad (1)$$

The values in parentheses are the initial radiation chemical yields of the products formed in the radiolysis of water and dilute aqueous solutions per 100 eV of absorbed energy for light types of radiation (γ-rays or accelerated electrons for which the linear transfer of energy is insignificant), recorded 10^{-7} s after the action of ionising radiation when the reactions at the sites of local formation of these species ('tracks' and 'spurs') have been completed. The hydrated electrons and hydrogen atoms behave as effective reducing agents. The standard reducing potentials of the

H_2O/e_{aq}^- and $H^+/H^\bullet$ pairs are -2.87 and -2.3 V, respectively.[8] The hydroxyl radical, conversely, is a strong oxidant; its redox potentials in water depend on the pH and amount to 1.9 and 2.73 V for the $OH^\bullet/OH^-$ and $OH^\bullet, H^+/H_2O$ pairs, respectively. These species are used to study one-electron reduction and/or oxidation. However, their simultaneous presence in an aqueous solution initiates the occurrence of both processes and markedly hampers study of the kinetics and the mechanism of redox reactions. Therefore, researchers use such compositions of aqueous solutions which ensure the predominant formation of either oxidising or reducing species. The oxidising radicals $OH^\bullet$ are produced most easily by saturating the solution with nitrous oxide. In a neutral solution, the limiting concentration of the gas under normal conditions equals approximately 0.05 mol litre^{-1}. The exposure to ionising radiation initiates the reaction

$$N_2O + e_{aq}^- + H_2O \longrightarrow N_2 + OH^\bullet + OH^-, \quad (2)$$

whose rate constant equals 9×10^9 litre mol^{-1} s^{-1} (see Ref. 9). As a consequence, hydroxyl radicals are formed in the solution almost alone. It is noteworthy that in the reaction with N_2O, the hydrogen atoms can also be converted into $OH^\bullet$ radicals; however, the rate constant for this reaction is only 1.3×10^4 litre mol^{-1} s^{-1} (see Ref. 9).

Conversely, to create a reducing medium in an aqueous solution, it is necessary to remove the hydroxyl radicals. This is done using solutions containing organic compounds acting as traps for $OH^\bullet$ radicals, *e.g.*, alcohols or salts of organic acids. These compounds also allow binding of hydrogen atoms. For example, upon the addition of isopropyl alcohol or formate ions, the reactions

$$(CH_3)_2CHOH + OH^\bullet\,(H^\bullet) \longrightarrow (CH_3)_2C^\bullet OH + H_2O\,(H_2), \quad (3)$$

$$HCO_2^- + OH^\bullet\,(H^\bullet) \longrightarrow CO_2^{-\bullet} + H_2O\,(H_2), \quad (4)$$

initiated by ionising radiation give rise only to reducing species, namely, hydrated electrons and organic radicals, $(CH_3)_2C^\bullet OH$ or $CO_2^{-\bullet}$. The standard reducing potentials (E°) of some organic radicals used most often are given below.[8]

Species	$CO_2^{-\bullet}$	$(CH_3)_2C^\bullet OH$	$CH_3CH^\bullet OH$	$^\bullet CH_2OH$
E°/V	-1.9	-1.39	-1.25	-1.18

The hydrated electron, the hydroxyl radical, the hydrogen atom, and organic radicals are highly reactive species, and, as a rule, the rates of their interaction with dissolved compounds are controlled by diffusion, the rate constants of the corresponding reactions being about $10^9 - 10^{10}$ litre mol^{-1} s^{-1}. The products of one-electron reduction or oxidation (most often, of a radical nature) are also highly reactive species. Therefore, they are generated and studied in aqueous solutions using a technique of fast processes, first of all, pulse radiolysis with optical or conductometric recording of short-lived products.[1]

III. Oxidation of halide ions

We have already noted that redox reactions involving chlorine, bromine, and iodine are widely used in practice. Therefore, the kinetics and the mechanisms of these reactions are under comprehensive research. Upon photolysis, radiolysis, or other types of physicochemical treatment of aqueous solutions containing halide ions, these ions are oxidised to give first halogen atoms. Subsequently, the process goes through a number of intermediate stages and affords halogen molecules and halogen compounds and the subsequent hydrolysis affords oxygen-containing compounds. The use of pulse radiolysis allows one to study the kinetics and the mechanism of oxidation of halide ions, to establish the nature of the intermediates, in particular, the possibility of formation of mixed radical anions containing atoms of different halogens.

1. Oxidation of Cl^- ions by $OH^\bullet$ radicals

The $OH^\bullet$ radicals are used as the reagent in the kinetic and mechanistic studies of the one-electron oxidation of Cl^- ions in aqueous solutions. In a neutral aqueous solution, Cl^- ions are not oxidised as the reaction is endothermic. Oxidation takes place only in acidic solutions to give $Cl_2^{-\bullet}$ radical anions. The UV spectra of the latter species exhibit an absorption band with a maximum at $\lambda = 340$ nm, the extinction coefficient (ε) at this wavelength being $(8.8 \pm 0.5) \times 10^3$ litre mol^{-1} cm^{-1}. The most detailed pulse radiolysis study of the reaction mechanism has been reported by Jayson *et al.*[10] The process includes the following reversible reactions:

$$Cl^- + OH^\bullet \rightleftharpoons ClOH^{-\bullet}, \quad (5)$$

$$ClOH^{-\bullet} + H^+ \rightleftharpoons Cl^\bullet + H_2O, \quad (6)$$

$$Cl^- + Cl^\bullet \rightleftharpoons Cl_2^{-\bullet}. \quad (7)$$

The $Cl_2^{-\bullet}$ radical anions disappear according to second-order reactions

$$Cl_2^{-\bullet} + Cl_2^{-\bullet} \longrightarrow Cl_2 + 2\,Cl^-, \quad (8)$$

$$OH^\bullet + Cl_2^{-\bullet} \longrightarrow OH^- + Cl_2. \quad (9)$$

It is worth noting that reactions (6) and (8), important in the redox transformations of chlorides, involve charged species, and, hence, they should depend on the ionic strength of the solution. The rate constants for reactions (6), (8) have been measured by pulse radiolysis and their dependences on the ionic strength have been elucidated.[11] In addition, some other reactions involving $Cl_2^{-\bullet}$ radical anions have been studied. This was done using N_2O-saturated weakly acidic (5×10^{-4} M HCl) aqueous solutions of NaCl after a 20-ns pulse of accelerated electrons [the absorbed dose per pulse was $(1.5 \pm 0.3) \times 10^{17}$ eV ml^{-1}]. It was found that after the pulse, optical absorption at $\lambda = 340$ nm passes through a maximum and then diminishes with time. This is due to the formation and subsequent decay of the $Cl_2^{-\bullet}$ radical anions. With an increase in the salt concentration, the rate of disappearance of $Cl_2^{-\bullet}$ increases, which is due to the increase in the ionic strength.

The rate constants for reactions (6), (8), and (9) at different ionic strengths of the solution have been determined by comparing the experimental data with the results of computations performed with the assumption of simultaneous reactions between the products of radiolysis of pure water.[11] The rate constant for reaction (6) increases with an increase in the salt concentration, whereas the rate constant for reaction (8) decreases. This result is consistent with the expected influence of the ionic strength on the rate of reactions between likely and oppositely charged species. Note that high concentrations of dissolved substances in water and the ionic strength of the solution have a pronounced influence on the yields of radiolysis products formed by reaction (1).[12] This must be taken into account when performing calculations. Figure 1 shows the dependences of the rate constants for reactions (6) and (8) on the solution ionic strength both experimental and calculated taking into account the dependence of the reaction rate constant on the activity of the charged species involved in the reaction. The last-mentioned type of dependence can be written as follows (the activity coefficient of the intermediate complex is taken to be unity according to the Brønsted – Bjerrum theory):

$$k = k_0\,\gamma_1^{\nu_1}\gamma_2^{\nu_2} = k_0\gamma_\pm^{\nu}, \quad (10)$$

where k and k_0 are the reaction rate constants for nonzero and zero ionic strengths of the solution, respectively; γ_1 and γ_2 are the activity coefficients of species 1 and 2; $\gamma_\pm$ is the average molal coefficient of activity of the electrolyte; ν_1 and ν_2 are the numbers of particles 1 and 2 involved in the reaction ($\nu = \nu_1 + \nu_2$).

The change in the $\gamma_\pm$ coefficient in the concentration range from 0 to 1 mol litre^{-1} is described adequately by the Debye – Hückel equation:[13]

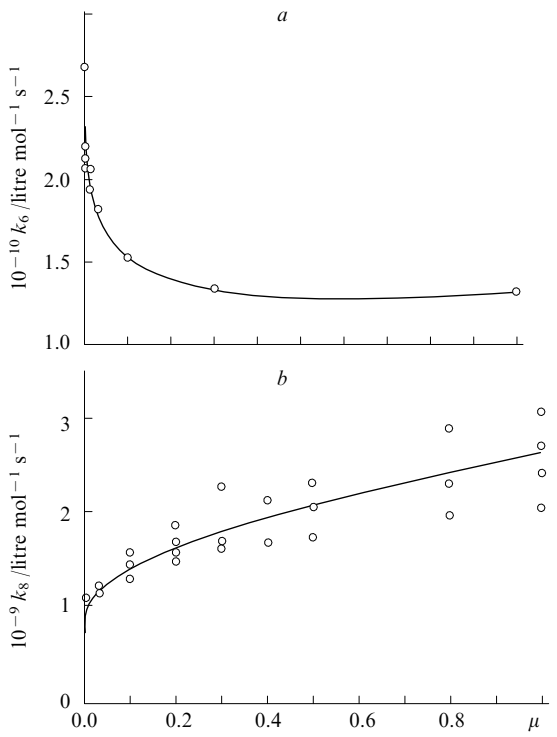

Figure 1. Rate constants for reactions (6) and (8) (k_6 and k_8 , respectively) *vs.* ionic strength of the solution (μ).
The dots correspond to experimental results and the curves, to the calculation from Eqns (10), (11): (*a*) reaction (6); (*b*) reaction (8). The calculation parameters are given in the text.

$$\log \gamma_{\pm} = \frac{A_1 z_1 z_2 \mu^{1/2}}{1 + Ba\mu^{1/2}} + b\mu, \qquad (11)$$

where A and B are coefficients that are constant for the given temperature and solvent; z_1 and z_2 are the charges of the reactants; μ is the ionic strength of the solution for concentrations expressed in mol litre^{-1}; and a and b are experimental parameters.

As can be seen from Fig. 1, the rate constants for reactions (6) and (8) as functions of the solution ionic strength found by optimisation are well described by the Debye–Hückel theory. This fact made it possible to determine their magnitudes for zero ionic strength.[11] For reaction (6), the value $k_6 = 8.3 \times 10^8$ litre mol^{-1} s^{-1} was obtained and the parameters a and b in relation (11) are equal to 0.46 nm and 4.8×10^{-2} litre mol^{-1}, respectively. The value $k_6 = 1.6 \times 10^9$ litre mol^{-1} s^{-1} calculated for an ionic strength of 0.2 is in satisfactory agreement with the rate constant measured in another study,[14] which is equal to 2.0×10^9 litre mol^{-1} s^{-1}. McElroy[15] has studied recombination of the $Cl_2^{-\bullet}$ radical anions produced in the photochemical reaction of $SO_4^{-\bullet}$ with the Cl^- ions. On extrapolation to zero ionic strength, the estimated rate constant for this reaction is 7×10^8 litre mol^{-1} s^{-1}, which is in rather good agreement with the value found in another publication.[11]

For reaction (8) and $\mu = 0$, the value $k_8 = 2.5 \times 10^{10}$ litre mol^{-1} s^{-1} was found; the calculated parameters a and b are 0.42 nm and 0.77 litre mol^{-1}, respectively. The constant $k_8 = 1.4 \times 10^{10}$ litre mol^{-1} s^{-1} calculated for $\mu = 1$ proved to be somewhat lower than the value 2.1×10^{10} litre mol^{-1} s^{-1} reported in another publication.[10]

The rate constant for reaction (9) (k_9) does not depend on the ionic strength of the solution, being equal to 9.2×10^9 litre mol^{-1} s^{-1}. A study of flash photolysis of chloride ions in water[15] gave a value of 1×10^9 litre mol^{-1} s^{-1} for the same rate constant. However, McElroy[15] used conductometry as a technique for recording the variation of the electrical conductivity of the solution, which is not selective in the presence of other reactions involving charged species.

Studies of the kinetics and the mechanism of the oxidation of Cl^- ions with the $OH^\bullet$ radicals made it possible to measure once again the rate constant for a very important reaction between hydrogen atoms and hydrogen peroxide:

$$H^\bullet + H_2O_2 \longrightarrow OH^\bullet + H_2O. \qquad (12)$$

The reported[16] value of 9.0×10^7 litre mol^{-1} s^{-1} did not correspond to the results of computer simulation of the radiation-induced chemical transformations of pure water and water containing added hydrogen and/or hydrogen peroxide and appeared clearly overestimated.[17] Therefore, systematic research into the radiation-induced transformations of argon-saturated chloride solutions (0.1 M HCl) containing hydrogen peroxide has been carried out.[18] Analysis of the kinetics of the additional formation of $Cl_2^{-\bullet}$ radical anions for short radiolysis times (5 μs), caused by the additional generation of the $OH^\bullet$ radicals by reaction (12) allowed Ershov *et al.*[18] to determine the rate constant for this reaction $k_{12} = 3.5 \times 10^7$ litre mol^{-1} s^{-1}. This value is consistent with the constant found for the decay of hydrogen atoms by EPR.[19] For long radiolysis times (250 μs), recombination of the $Cl_2^{-\bullet}$ radical anions and their reaction with H_2O_2 are the predominant processes

$$H_2O_2 + Cl_2^{-\bullet} \longrightarrow 2\,HCl + O_2^{-\bullet}. \qquad (13)$$

The role of reaction (13) increases with an increase in the concentration of hydrogen peroxide. When the H_2O_2 content is $\geqslant 5 \times 10^{-2}$ mol litre^{-1}, the kinetics of the decay of $Cl_2^{-\bullet}$ absorption is better described by a pseudo-first-order equation, which indicates that these radical anions mainly disappear by reaction (13). Modelling of the kinetic curves for the decay of the $Cl_2^{-\bullet}$ species allowed Ershov *et al.*[11] to determine the rate constant for reaction (13): $k_{13} = 9.5 \times 10^5$ litre mol^{-1} s^{-1}. For solutions containing hydrogen peroxide, it was necessary to include additional steps taking into account the reactions of $H^\bullet$ and $OH^\bullet$ with H_2O_2 and with the $HO_2^\bullet$ radical.

The results of a kinetic study of the redox reactions of Cl^- ions in aqueous solutions induced by ionising radiolysis are summarised in Table 1.

Table 1. Rate constants (k) for the oxidation of the Cl^- and Br^- ions.

Reaction	k /litre mol^{-1} s^{-1}	Ref.
$OH^\bullet + Cl^- \longrightarrow ClOH^{-\bullet}$	4.3×10^9	10
$ClOH^{-\bullet} \longrightarrow OH^\bullet + Cl^-$	6.1×10^9 (see [a])	10
$H^+ + ClOH^{-\bullet} \longrightarrow Cl^\bullet + H_2O$	2.5×10^{10}	10
$Cl^- + Cl^\bullet \longrightarrow Cl_2^{-\bullet}$	8.0×10^9	20
$Cl_2^{-\bullet} \longrightarrow Cl^\bullet + Cl^-$	1.1×10^5 (see [a])	10
$Cl_2^{-\bullet} + Cl_2^{-\bullet} \longrightarrow Cl_3^- + Cl^-$	8.3×10^8	11
$H^\bullet + Cl_2^{-\bullet} \longrightarrow Cl^- + HCl$	7.0×10^9	14
$OH^\bullet + Cl_2^{-\bullet} \longrightarrow OH^- + Cl_2$	9.2×10^9	11
$H_2O_2 + Cl_2^{-\bullet} \longrightarrow 2\,HCl + O_2^{-\bullet}$	9.5×10^5	11
$Cl_2^{-\bullet} + Br^- \longrightarrow ClBr^{-\bullet} + Cl^-$	4.0×10^9	7
$ClBr^{-\bullet} + Cl^- \longrightarrow Cl_2^{-\bullet} + Br^-$	1.1×10^2	7
$ClBr^{-\bullet} \longrightarrow Cl^- + Br^\bullet$	8.5×10^7 (see [a])	7
$Cl^- + Br^\bullet \longrightarrow ClBr^{-\bullet}$	1.0×10^{10}	7
$ClBr^{-\bullet} + Br^- \longrightarrow Br_2^{-\bullet} + Cl^-$	8.0×10^9	7
$Br_2^{-\bullet} + Cl^- \longrightarrow ClBr^{-\bullet} + Br^-$	4.3×10^6	7
$Br_2^{-\bullet} \longrightarrow Br^\bullet + Br^-$	4.6×10^4 (see [a])	21, 22
$Br^\bullet + Br^- \longrightarrow Br_2^{-\bullet}$	1.0×10^{10}	21, 22
$Br_2^{-\bullet} + Br_2^{-\bullet} \longrightarrow Br_3^- + Br^-$	3.4×10^9	7

[a] The rate constant is expressed in s^{-1}.

2. Oxidation of Br^- ions by $Cl_2^{-\bullet}$ radical anions and the formation of $ClBr^{-\bullet}$ radical anions

Most often, chlorine is accompanied by bromine and/or iodine impurities. Therefore, the redox reactions with chlorine are accompanied by chemical transformations of these halogens. Indeed, chlorination of water yields bromate ion BrO_3^- (see Ref. 21), which is carcinogenic. Lots of other examples can also be cited. This underlines the topicality of comprehensive investigation of the influence of bromine and iodine impurities on the oxidation of chlorine.

Radiation-induced or photochemical oxidation of Br^- ions in aqueous solutions is known [22] to give $Br_2^{-\bullet}$ radical anions [$\lambda_{max} = 360$ nm, $\varepsilon = (9.9\pm0.6)\times10^3$ litre mol^{-1} cm^{-1}]. However, their spectra, unlike the spectra of the $Cl_2^{-\bullet}$ radical anions, exhibit also a weak optical absorption in the region of 650–700 nm. The standard reduction potentials of the $Cl_2^{-\bullet}$ and $Br_2^{-\bullet}$ radical anions are as follows: $E^\circ(Cl_2^{-\bullet}/2\,Cl^-) = 2.30$ V; $E^\circ(Br_2^{-\bullet}/2\,Br^-) = 1.66$ V;[8] hence, these species behave as rather strong oxidants. The rate constants for many reactions of one-electron oxidation of organic and inorganic compounds involving these radical anions have been measured by pulse radiolysis and photolysis.[23] Comparison of the $E^\circ(Cl_2^{-\bullet}/2\,Cl^-)$ value with $E^\circ(Br_2^{-\bullet}/2\,Br^-)$ and also with $E^\circ(Br^\bullet/Br^-) = 2.0$ V may indicate that the $Cl_2^{-\bullet}$ radical anions are able to oxidise Br^- ions in an aqueous solution to give $Br_2^{-\bullet}$ radical anions.

Recently, oxidation of the Br^- ions by $Cl_2^{-\bullet}$ radical anions [6, 7, 24] has been studied by pulse radiolysis. The interest in this important reaction was stimulated not only by fundamental but also by practical problems. First of all, this was due to the need to study the oxidation of bromine during water chlorination and the radiation-induced chemical reactions in natural water near sites of nuclear waste disposal, first of all, in salt mines (see for example, Refs 25–27). Apart from substantial amounts of chlorides, this water contains bromides. Chemical transformations of the latter initiated by ionising radiation can substantially influence the ultimate composition of the obtained products and, hence, the safety of waste storage. The studies showed that in N_2O-saturated concentrated solutions of chlorides (1 M NaCl, pH 3.3) containing 1.0×10^{-3} mol litre^{-1} of bromine, oxidation of Br^- ions by $Cl_2^{-\bullet}$ radical anions proceeds at a high rate and ends in the formation of the $Br_2^{-\bullet}$ radical anions.[6, 7] At $[Br^-] \leqslant 1.0\times10^{-4}$ mol litre^{-1}, mixed radical anions $ClBr^{-\bullet}$ are produced. Similar mixed intermediates ($ClSCN^{-\bullet}$ and $BrSCN^{-\bullet}$ radical anions) have been detected previously by pulse radiolysis upon oxidation of chloride [28] and bromide ions,[29] respectively, in the presence of small amounts of the SCN^- ions added. The $ClBr^{-\bullet}$ radical anions arise and coexist in an equilibrium with the $Cl_2^{-\bullet}$ and $Br_2^{-\bullet}$ species, in accordance with the reactions

$$Cl_2^{-\bullet} + Br^- \rightleftharpoons ClBr^{-\bullet} + Cl^-, \quad (14)$$

$$ClBr^{-\bullet} + Br^- \rightleftharpoons Br_2^{-\bullet} + Cl^-. \quad (15)$$

Redox reactions (14) and (15) can be written in the following way:
reaction (14),

$$Cl_2^{-\bullet} + e^- \longrightarrow Cl^- + Cl^-,$$

$$Cl^- + Br^- \longrightarrow ClBr^{-\bullet} + e^-;$$

reaction (15),

$$ClBr^{-\bullet} + e^- \longrightarrow Br^- + Cl^-,$$

$$Br^- + Br^- \longrightarrow Br_2^{-\bullet} + e^-.$$

The corresponding redox potentials are $\Delta E_{14}^\circ = E^\circ(Cl_2^{-\bullet}/2\,Cl^-) - E^\circ(ClBr^{-\bullet}/Cl^-,Br^-)$ and $\Delta E_{15}^\circ = E^\circ(ClBr^{-\bullet}/Cl^-,Br^-) - E^\circ(Br_2^{-\bullet}/2\,Br^-)$. The ΔE° value can be expressed *via* the equilibrium constant (K) as $\Delta E^\circ = 0.059 \log K$. By using the known values, $E^\circ(Br_2^{-\bullet}/2\,Br^-) = 1.66$ V and $E^\circ(Cl_2^{-\bullet}/2\,Cl^-) = 2.3$ V, one can find [2, 4] $K_{14}\times K_{15} = 7.0\times10^{10}$.

Optimisation of the time dependence observed in the optical spectra for the intensity of the signal at 700 nm, which is composed of the absorption of the $ClBr^{-\bullet}$ and $Br_2^{-\bullet}$ radical anions, has given [7] the following values: $K_{14} = 3.78\times10^7$, $K_{15} = 1.85\times10^3$, $\varepsilon_{ClBr^{-\bullet}} = 110$ litre mol^{-1} cm^{-1} (for $\lambda =$ 700 nm). The K_{14} and K_{15} values were used to calculate the oxidation potential for the $ClBr^{-\bullet}/Cl^-,Br^-$ pair, which proved to be 1.85 V. As was to be expected, this value is intermediate between the potentials of $Br_2^{-\bullet}$ (1.66 V) and $Cl_2^{-\bullet}$ (2.30 V).

For the equilibria,

$$ClBr^{-\bullet} \rightleftharpoons Br^\bullet + Cl^- \quad (16)$$

and

$$Br_2^{-\bullet} \rightleftharpoons Br^\bullet + Br^-, \quad (17)$$

the relation $K_{15} = K_{16}/K_{17}$ is valid. Using the known [30, 31] $K_{17} = 4.6\times10^{-6}$ mol litre^{-1} and the equilibrium constant $K_{15} = 1.85\times10^3$ determined by Ershov *et al.*,[7] we get $K_{16} = 8.5\times10^{-3}$ mol litre^{-1}. Similarly, for the equilibria,

$$ClBr^{-\bullet} \rightleftharpoons Cl^\bullet + Br^- \quad (18)$$

and

$$Cl_2^{-\bullet} \rightleftharpoons Cl^\bullet + Cl^-, \quad (19)$$

it can be written that $K_{14} = K_{19}/K_{18}$. Using the above-indicated value $K_{14} = 3.78\times10^7$ and the reported [20] constant $K_{19} = 5.3\times10^{-6}$ mol litre^{-1}, one can calculate the value $K_{18} = 1.4\times10^{-13}$ mol litre^{-1}. Comparison of the values of K_{16} and K_{18} shows that the probability of the decay of the $ClBr^{-\bullet}$ species according to reaction (18) is low compared to that by reaction (16).

Computer simulation of the experimental data on the oxidation kinetics of the Br^- ions by the $Cl_2^{-\bullet}$ radical anions has been reported.[7] The calculated rate constants for the formation of the $Cl_2^{-\bullet}$ radical anions and for their reaction with Br^- ions and the known rate constants of other reactions are presented in Table 1. It was found [7] that the set of reactions proposed describes

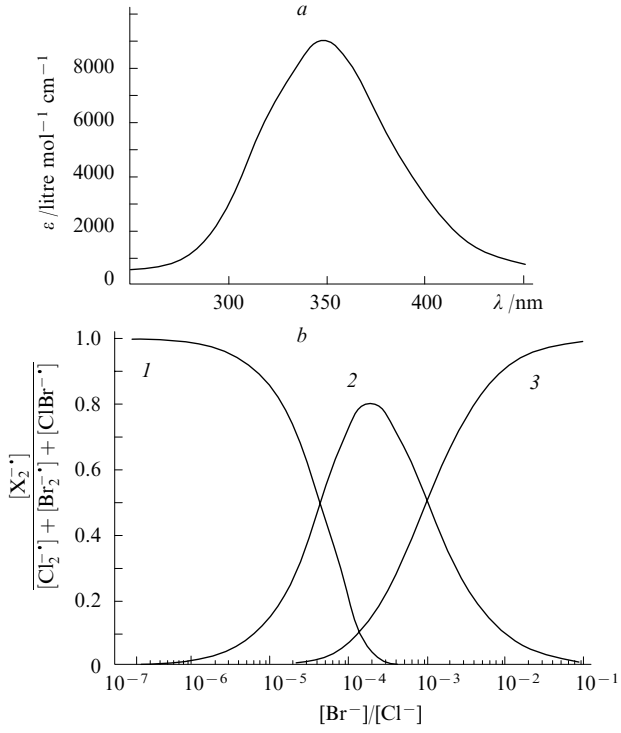

Figure 2. (*a*) Absorption spectrum of the $ClBr^{-\bullet}$ radical anion. (*b*) Equilibrium concentrations of the $X_2^{-\bullet} = Cl_2^{-\bullet}$ (*1*), $ClBr^{-\bullet}$ (*2*) and $Br_2^{-\bullet}$ (*3*) radical anions in solution *vs.* $[Br^-]/[Cl^-]$ [7, 24] ratio.

adequately the kinetics of variation of the optical absorption generated by an electron pulse at all wavelengths. For each wavelength, known [9,22] extinction coefficients were used for the $Cl_2^{-\bullet}$, $ClOH^{-\bullet}$ and $Br_2^{-\bullet}$ radical anions, while the $\varepsilon_{ClBr^{-\bullet}}$ values were calculated.

Figure 2*a* shows the absorption spectrum of the $ClBr^{-\bullet}$ radical anions obtained by matching the experimental data to the calculations in terms of the set of chemical reactions indicated in Table 1.[7] The spectrum is a broad absorption band with a maximum at $\lambda = 350\pm3$ nm and with the coefficient ε at this wavelength equal to 9300 ± 200 litre mol^{-1} cm^{-1}. Thus, the optical characteristics of $ClBr^{-\bullet}$ prove to be intermediate between the corresponding characteristics of the $Cl_2^{-\bullet}$ ($\lambda_{max} = 340$ nm and $\varepsilon = 8800$ litre mol^{-1} cm^{-1}) [10] and $Br_2^{-\bullet}$ radical anions ($\lambda_{max} = 360$ nm and $\varepsilon = 9900$ litre mol^{-1} cm^{-1}).[32]

Figure 2*b* presents an illustration of the dependence of the ratio of the equilibrium concentrations of the $Cl_2^{-\bullet}$, $ClBr^{-\bullet}$, and $Br_2^{-\bullet}$ radical anions on the concentration ratio of the Cl^- and Br^- ions.[7,24] The $Cl_2^{-\bullet}$ radical anions oxidise the Br^- ions to give $ClBr^{-\bullet}$ and $Br_2^{-\bullet}$ radical anions. As the concentration of Br^- increases, the equilibrium shifts towards $Br_2^{-\bullet}$.

3. Decay of the $Cl_2^{-\bullet}$ radical anions and the formation of molecular chlorine and the Cl_3^- anions

The oxidation of chloride ions in water gives rise to molecular chlorine as a result of recombination of the $Cl_2^{-\bullet}$ radical anions arising at an intermediate stage

$$Cl_2^{-\bullet} + Cl_2^{-\bullet} \longrightarrow Cl_3^- + Cl^- \qquad (20a)$$

or

$$Cl_2^{-\bullet} + Cl_2^{-\bullet} \longrightarrow Cl_2 + 2\,Cl^-. \qquad (20b)$$

The Cl_3^- ion exists in equilibrium with molecular chlorine

$$Cl_3^- \rightleftharpoons Cl_2 + Cl^-. \qquad (21)$$

Zimmerman and Strong [33] have measured the absorption spectra of Cl_3^- and Cl_2 in neutral and acidic aqueous solutions containing dissolved chlorine. The spectrum of Cl_3^- ions is a broad optical band with a maximum at $\lambda \approx 220$ nm and $\varepsilon = 1\times10^4$ litre mol^{-1} cm^{-1}. These data were confirmed by more advanced investigation techniques.[34] It was found that for Cl_3^-, the extinction coefficient at $\lambda = 220$ nm equals 1.04×10^4 litre mol^{-1} cm^{-1}; the spectrum also exhibits a weak peak at 320 nm ($\varepsilon = 180$ litre mol^{-1} cm^{-1}). The value of ε at 330 nm for chlorine does not exceed 70 litre mol^{-1} cm^{-1}. The stability constant of the Cl_3^- ions (K_{21}) was found to be 0.18 ± 0.02 mol litre^{-1} (see Ref. 34). Hence, the equilibrium of reaction (21) shifts towards the trichloride ions Cl_3^- only when the content of the Cl^- ions in solution is very high.

Until recently, trichloride ions have not been detected as products of photochemical or radiation chemical oxidation of Cl^- ions or transformations of $Cl_2^{-\bullet}$ radical anions in aqueous solutions. It was not clear which species, Cl_3^- or Cl_2, arises as the primary product of the transformations of the $Cl_2^{-\bullet}$ radical anions by reactions (20a) and (20b), respectively. This and some other questions were answered by Ershov *et al.*,[24] who suggested, proceeding from the value $K_{21} = 0.18\pm0.02$ mol litre^{-1}, that Cl_3^- can be found in relatively concentrated ($\geqslant 1$ M) solutions of Cl^-. This conclusion was confirmed experimentally.[24] A weak absorption with a maximum at 220 nm was found to appear in the spectrum of a 1 M solution of NaCl during the decay of the $Cl_2^{-\bullet}$ radical anions, the signal intensity being higher for higher concentrations of the salt. A rather clear-cut optical absorption was detected in the spectra of a 5 M solution of NaCl. It seemed reasonable to relate the appearance of the signal at 220 nm to the formation of Cl_3^- ions upon the decay of $Cl_2^{-\bullet}$. The rate of disappearance of the signal increased with an increase in the absorbed dose per pulse. The kinetics of the decay of the $Cl_2^{-\bullet}$ radical anions was well described by a second-order equation and the $\tau_{1/2}$ value decreased in proportion with the dose per pulse. Unlike the decay of the $Cl_2^{-\bullet}$ species, the appearance of Cl_3^- ions depended only little on the dose per pulse and could not be described by simple first- or second-order kinetics. The $\tau_{1/2}$ values did not change much upon variation of the absorbed dose per pulse. All this indicated that the formation of the signal from Cl_3^- ions is not limited by the decay of the $Cl_2^{-\bullet}$ radical anions but is limited by another process, which is slower. It was found [24] that the slow process of establishing the equilibrium in reaction (21) is the rate-limiting step in the formation of Cl_3^- ions. Analysis of the kinetics of appearance of the Cl_3^- ions allowed the researchers to determine the rate constants for the forward (the subscript f) and back (the subscript b) reactions (21) to be $k_{21f} = 1.1\times10^5$ s^{-1}, $k_{21b} = 2.0\times10^4$ litre mol^{-1} s^{-1}. The equilibrium constant of reaction (21) obtained by this optimisation, $K_{21} = k_{21b}/k_{21f}$, amounts to 0.18 litre mol^{-1}, which is in full agreement with the value measured previously.[33,34] Thus, the reaction between two $Cl_2^{-\bullet}$ species is most likely to afford the Cl_2 molecule. Apparently, the like charges of the radical anions prevent these species from approaching each other and the reaction occurs at a certain distance between them upon an electron transfer by reaction (20b). The subsequent appearance of the Cl_3^- ion is due to establishment of equilibrium (21).

4. Oxidation of the Br^- ions and formation of the Br_3^- anions

The radiation-induced oxidation of Br^- ions by $OH^\bullet$ radicals in acidic aqueous solutions gives rise to $Br_2^{-\bullet}$ radical anions.[22,32] The oxidation mechanism is similar to the mechanism considered above for chlorides. The pattern of transformations of bromide ions includes the following reactions:

$$Br^- + OH^\bullet \rightleftharpoons BrOH^{-\bullet}, \qquad (22)$$

$$BrOH^{-\bullet} + H^+ \rightleftharpoons Br^\bullet + H_2O, \qquad (23)$$

$$Br^- + Br^\bullet \rightleftharpoons Br_2^{-\bullet}, \qquad (24)$$

$$Br^\bullet + OH^- \rightleftharpoons BrOH^{-\bullet}, \qquad (25)$$

$$BrOH^{-\bullet} + Br^- \longrightarrow Br_2^{-\bullet} + OH^-. \qquad (26)$$

The mechanism of recombination of $Br_2^{-\bullet}$ radical anions has been studied.[31] It was found that disappearance of $Br_2^{-\bullet}$ absorption, which was observed 1 μs after the action of an electron pulse on a 0.1 M solution of NaBr (N_2O, pH 3.3), is accompanied by the formation of a new band with a maximum at 265 nm. This is due to the formation of Br_3^- ions in accordance with the reactions:

$$Br_2^{-\bullet} + Br_2^{-\bullet} \longrightarrow Br_2 + 2\,Br^-, \qquad (27)$$

$$Br_2 + Br^- \rightleftharpoons Br_3^-. \qquad (28)$$

For bringing the experimental data in correspondence with the results of computation, the following rate constants for reactions (22)–(26) were used:[22,35] (the subscripts f and b refer to the forward and back reaction, respectively): $k_{22f} = 1.06\times10^{10}$ litre mol^{-1} s^{-1}; $k_{22b} = 3.3\times10^7$ s^{-1}; $k_{23f} = 4.4\times10^{10}$ litre mol^{-1} s^{-1}; $k_{23b} = 1.4$ s^{-1}; $k_{24f} = 1.0\times10^{10}$ litre mol^{-1} s^{-1}; $k_{24b} = 4.6\times10^4$ s^{-1}; $k_{25f} = 1.3\times10^{10}$ litre mol^{-1} s^{-1}; $k_{25b} = 4.2\times10^6$ s^{-1}; $k_{26} = 1.9\times10^8$ litre mol^{-1} s^{-1}. The values of k_{27}, k_{28f} and k_{28b} were varied during optimisation. It was found [32] that the formation and disappearance of the $Br_2^{-\bullet}$ radical anions is described adequately using the values $\varepsilon_{Br_2^{-\bullet}} = 9900$ litre mol^{-1} cm^{-1} (see Ref. 22) and $k_{27} = 3.0\times10^9$ litre mol^{-1} s^{-1}. The resulting k_{27} value is in good agreement with the experimental rate constant measured for dilute solutions of Br^- ions, which is equal to 2.2×10^9 litre mol^{-1} s^{-1} (see Ref. 23). The agreement for the kinetics of appearance of the Br_3^- anions is attained for $k_{28f} = 9.6\times10^8$ litre mol^{-1} s^{-1}, $k_{28b} = 5.5\times10^7$ s^{-1} and $\varepsilon_{Br_3^-} = 4.4\times10^4$ litre mol^{-1} cm^{-1}. The equilibrium constant for reaction (28) calculated using the k_{28f} and k_{28b} as $K_{28} = k_{28f}/k_{28b}$ amounts to 17.4 litre mol^{-1}. Thus, the obtained values of $\varepsilon_{Br_3^-}$ and K_{28} are in good agreement with the extinction coefficient and the equilibrium constant determined [34] in a study of reaction (28)

in slightly acidic solutions of molecular bromine and Br^- ions, which are equal to 4.1×10^4 litre mol^{-1} cm^{-1} and 16.1 litre mol^{-1}, respectively.

5. Chlorine and bromine mixed trihalide ions

It was established [24, 36] that the presence of even very small amounts ($\geqslant 10^{-6}$ mol litre^{-1}) of Br^- ions in concentrated (1–5 M) solutions of NaCl results in substantial changes in the oxidation mechanism of chloride ions. During the decay of $Cl_2^{-\bullet}$ radical anions, Cl_3^- ions are no longer formed but, instead, the reaction gives a new intermediate characterised by an intense absorption band. As the bromine concentration increases (up to 10^{-3} mol litre^{-1} NaBr), new products responsible for intense optical bands with maxima at 230 and 245 nm are formed successively. On a further increase in the bromine content in the solution, an absorption band with a maximum at 265 nm corresponding to the Br_3^- ion appears in parallel with the disappearance of the $Cl_2^{-\bullet}$, $ClBr^{-\bullet}$ and $Br_2^{-\bullet}$ radical anions.

Analysis of the variation of the spectral pattern in the UV region demonstrates the complexity of the chemical transformations involved, in particular, transition from Cl_3^- ($\lambda_{max} = 220$ nm) to Br_3^- ($\lambda_{max} = 265$ nm) through consecutive formation of mixed chlorine/bromine oxidation products. It was shown [24, 36] that the absorption bands with maxima at 230 and 245 nm refer to mixed trihalide ions, Cl_2Br^- and $ClBr_2^-$, respectively. It has been noted previously [34] that these species are also formed in the reactions of Cl_2 and ClBr molecules with Cl^- and Br^- ions in acidified aqueous solutions.

A reaction scheme for the formation of Cl_2Br^- ions upon radiation-induced chemical oxidation of chloride ions in slightly acidic aqueous solutions has been proposed.[24] First, it includes reactions (20a) and (21) we considered above (with the rate constants found for them), which give rise to molecular chlorine and Cl_3^-. Second, it is supplemented [34] by steps yielding mixed compounds of chlorine and bromine upon reactions of Cl_2 molecules with Br^- ions:

$$Cl_2 + Br^- \longrightarrow Cl_2Br^-,\ k_{29f} = 6.0 \times 10^9 \text{ litre mol}^{-1}\text{ s}^{-1}; \quad (29f)$$

$$Cl_2Br^- \longrightarrow Cl_2 + Br^-,\ k_{29b} = 9.0 \times 10^3\ \text{s}^{-1}; \quad (29b)$$

$$ClBr + Cl^- \longrightarrow Cl_2Br^-,\ k_{30f} = 1.0 \times 10^6 \text{ litre mol}^{-1}\text{ s}^{-1}; \quad (30f)$$

$$Cl_2Br^- \longrightarrow ClBr + Cl^-,\ k_{30b} = 1.7 \times 10^5\ \text{s}^{-1}; \quad (30b)$$

$$Cl_2Br^- + Br^- \longrightarrow ClBr_2^- + Cl^-,\ k_{31} = 3.0 \times 10^8 \text{ litre mol}^{-1}\text{ s}^{-1}. \quad (31)$$

Previously, the rate constant for the reaction of Cl_2 with Br^- ions in 1 M HCl (k_{29f}) was measured to be $(7.7 \pm 1.3) \times 10^9$ litre mol^{-1} s^{-1}. The order of magnitude of the constant shows that this reaction is controlled by diffusion. By modelling in terms of this set of reactions, the constants $k_{29b} = (6.0 \pm 1.0) \times 10^9$ litre mol^{-1} s^{-1} and $K_{29} = k_{29f}/k_{29b} = (6.7 \pm 1.3) \times 10^5$ litre mol^{-1} were determined.[24] The ratio of the constants for the forward and back reactions (30) was selected proceeding from the known $K_{30} = k_{30f}/k_{30b}$ value, equal to (6.0±0.3) litre mol^{-1} (see Ref. 34). The partial transformation of Cl_2Br^- into $ClBr_2^-$ upon the reaction with Br^- ions has also been taken into account (the extinction coefficient of the last-mentioned trihalide at $\lambda = 230$ nm is 1.8×10^4 litre mol^{-1} cm^{-1}). The proposed set of reactions [24] describes adequately the radiation-induced oxidation of chloride ions in aqueous solutions containing some bromide ions. The extinction coefficients of the Cl_2Br^- (230 nm) and Br_2Cl^- (245 nm) trihalide ions were calculated to be $\varepsilon = (3.6 \pm 0.4) \times 10^4$ and $(2.2 \pm 0.3) \times 10^4$ litre mol^{-1} cm^{-1}, respectively. These values are in good agreement with the values 3.27×10^4 and 2.49×10^4 litre mol^{-1} cm^{-1} measured in another study,[34] where the trihalides Cl_2Br^- and Br_2Cl^- were prepared by reactions of Cl_2 and ClBr with Br^- ions.

Table 2. Rate constants (k) and equilibrium constants (K) for the formation of trihalide ions X_3^- (X = Cl, Br) and optical characteristics of the X_3^- ions [24, 36]

Reaction	k (see [a])	K (see [b])	X_3^-	λ_{max} /nm	ε (see [c])
$Cl_2 + Cl^- \longrightarrow Cl_3^-$	2.0×10^4	0.18	Cl_3^-	220	1.3×10^4
$Cl_3^- \longrightarrow Cl_2 + Cl^-$	1.1×10^5 (see [d])				
$Cl_2 + Br^- \longrightarrow Cl_2Br^-$	6.0×10^9	6.7×10^5	Cl_2Br^-	230	3.6×10^4
$Cl_2Br^- \longrightarrow Cl_2 + Br^-$	9.0×10^3 (see [d])				
$ClBr + Cl^- \longrightarrow Cl_2Br^-$	1.0×10^6	6.0			
$Cl_2Br^- \longrightarrow ClBr + Cl^-$	1.7×10^5 (see [d])				
$Cl_2Br^- + Br^- \longrightarrow ClBr_2^- + Cl^-$	3.0×10^8		$ClBr_2^-$	245	2.2×10^4
$Br_2 + Br^- \longrightarrow Br_3^-$	9.6×10^8	17.5	Br_3^-	265	4.4×10^4
$Br_3^- \longrightarrow Br_2 + Br^-$	5.5×10^7 (see [d])				

[a] The rate constant is expressed in litre mol^{-1} s^{-1}; [b] the equilibrium constant is expressed in litre mol^{-1}; [c] the extinction coefficient is expressed in litre mol^{-1} cm^{-1}; [d] the constant is in s^{-1}.

Table 2 presents the reactions responsible for the formation of anionic and molecular products in aqueous solutions containing Cl^- and Br^- ions and the corresponding equilibrium constants.

Thus, the results of pulse radiolysis studies attest to an important role of admixtures of Br^- ions in the oxidation mechanism of the Cl^- ions. At an early radical ion step, in the presence of Br^- ions, the $Cl_2^{-\bullet}$ radical anions tend to be converted into $ClBr^{-\bullet}$ and $Br_2^{-\bullet}$. The subsequent decay of these species gives rise to a large number of molecular (Cl_2, ClBr, Br_2) and ionic (Cl_3^-, Cl_2Br^-, $ClBr_2^-$, Br_3^-) products which occur in equilibrium. It is noteworthy that this behaviour is caused by the fact that bromine is a weaker oxidant than chlorine. Therefore, it is reasonable to expect that iodine, whose oxidative properties are even less pronounced, would also tend to produce mixed radical anions and molecular products in the redox processes in aqueous solutions in the presence of Cl^- and Br^- ions.

6. The reactivity of $X_2^{-\bullet}$ radical anions

The $Cl_2^{-\bullet}$, $Br_2^{-\bullet}$ and $I_2^{-\bullet}$ radical anions behave as fairly strong oxidants. Table 3 lists the reduction potentials for these species and for halogen atoms (the values were taken from a paper by Stanbury,[37] who summarised the data on theoretical and experimental determination of the potentials of inorganic radicals). It can be seen that the oxidising properties of the radical anions and atoms diminish in the sequence Cl, Br, I. On passing from a halogen atom to the radical anion, the potential also decreases, which is due to complexing of the halogen atom by the halogen ion.

Table 3. Reduction potentials (E°) of some inorganic radicals.[37]

Pair	E° /V	Pair	E° /V
$Cl^\bullet/Cl^-$	2.41	$SO_4^{-\bullet}/SO_4^{2-}$	2.43
$Br^\bullet/Br^-$	1.92	$SO_3^{-\bullet}/SO_3^{2-}$	0.63
$I^\bullet/I^-$	1.33	$NO_3^\bullet/NO_3^-$	~2.5
$Cl_2^{-\bullet}/2\,Cl^-$	2.09	$CO_3^{-\bullet}/CO_3^{2-}$	~1.5
$Br_2^{-\bullet}/2\,Br^-$	1.62	$(CSN)_2^{-\bullet}/2\,CSN^-$	1.32
$I_2^{-\bullet}/2\,I^-$	1.03	$SeO_3^{-\bullet}/SeO_3^{2-}$	1.68

Note. The error of determination of the potential does not exceed ±(0.05–0.10) V.

A multitude of publications have been devoted to the reactivity of the $Cl_2^{-\bullet}$, $Br_2^{-\bullet}$, and $I_2^{-\bullet}$ radical anions. This interest points to an important role of these species in the oxidation processes involving halogens. Selected values of the rate constants for the reactions of radical anions with some organic and inorganic ions and compounds in an aqueous solution are presented in Table 4. For most of reactions, the constants decrease in the sequence $Cl_2^{-\bullet}$, $Br_2^{-\bullet}$, $I_2^{-\bullet}$ in parallel with weakening of the oxidising properties of radical anions. The rate constants for one-electron oxidation are, most often, rather high; however, they are substantially lower than those for the $OH^{\bullet}$ radicals,[9] which can be attributed to lower potentials of the $Cl_2^{-\bullet}$, $Br_2^{-\bullet}$ and $I_2^{-\bullet}$ radical anions compared to the potentials of $OH^{\bullet}$. Most of the constants given in Table 4 are lower than the values typical of diffusion-limited reactions. The rate of these reactions may be expected to depend substantially on the free energy [or the difference between the reduction potentials (ΔE°)] of the reacting species]. Indeed, for reactions of the same type between Np^{III} or Pu^{III} and $Cl_2^{-\bullet}$, $Br_2^{-\bullet}$ or $I_2^{-\bullet}$, one can follow the expected linear dependences of the logarithm of the rate constant on the ΔE°.[5] The review [5] describes in detail features of the kinetics and the mechanism of the reactions of halogen radical anions (and other inorganic radical anions) with actinides.

Table 4. Rate constants (k) for one-electron oxidation of a number of compounds by the $X_2^{-\bullet}$ radical anions [23, 38–50]

Compound	k /litre mol^{-1} s^{-1}

IV. Reactions of metal atoms and metal ions in unusual oxidation states

The hydrated electron and the hydrogen atom have high reduction potentials, whereas the $OH^{\bullet}$ radical, conversely, is an effective oxidant. Therefore, when these species react with metal ions, one-electron reduction or oxidation occurs provided that the ratio of the potentials meets the requirement of decreasing the free energy of the system. In the case of Pb^{2+} ions, both processes can take place

$$Pb^{2+} + e_{aq}^- \longrightarrow Pb^+,$$

$$Pb^{2+} + OH^{\bullet} \longrightarrow Pb^{3+} + OH^-.$$

This gives rise to Pb^{3+} and Pb^+ ions in unusual and unstable oxidation states; their electronic configurations are $d^{10}s^1$ and $d^{10}s^2p^1$, respectively. Due to the presence of one electron in the outer s or p orbital, this metal ion or atom is extremely reactive. These species can be compared to radicals having an unpaired electron. The lifetimes of these species in aqueous solutions are determined by kinetic factors and, as a rule, they are measured in micro- or milliseconds.

Many metals thermodynamically able to exist in water in unusual oxidation states have now been studied by pulse radiolysis. Data on the rate constants for the formation of metal ions in unusual oxidation states upon the reduction of stable metal ions with hydrated electrons and hydrogen atoms or their oxidation by means of $OH^{\bullet}$ radicals have been reported in the book.[9] The rate constants for some reactions involving metal atoms and ions in unusual and unstable oxidation states are documented.[51] The properties of these short-lived species are considered in most detail in reviews.[2, 3]

Table 5 presents characteristics of optical absorption and electrochemical potentials of metal atoms and ions in unusual oxidation states with the structure of aqua complexes. It can be seen that species with the electron configuration $d^{10}s^1$ exhibit one intense absorption band in the UV region. It was found [2, 3] that the energies of optical transitions in the absorption maxima ($E_{\lambda max}$) increase linearly with an increase in the ion charge (z). Within a Subgroup, the energy increases with an increase in the Period number. The pattern of optical absorption of the metal aqua complexes with other electronic configurations proves to be more complex. However, for metal ions with the electron configuration $d^{10}s^2p^1$, the longer-wavelength absorption band shifts to the UV region in the sequence Tl^0, Pb^+, Bi^{2+}, and the $E_{\lambda_{max}}$ value increases linearly with an increase in z, as for ions with the electron configuration $d^{10}s^1$.

Comparison of the potentials presented in Table 5 shows that copper, silver and gold atoms are effective reductants. This is due to the presence of one electron in their outer s orbitals. In isoelectronic series of metals, the potential tends to decrease with an increase in the charge of the metal ion. Within a single Subgroup (*i.e.*, for ions with the same charge), the potential increases with an increase in the Period number.

Metal atoms and metal ions in unusual oxidation states are highly reactive and, depending on the potential, they can either reduce or oxidise organic and inorganic compounds. The rate

Table 5. Optical characteristics and reduction potentials of metal atoms and aqua complexes of metal ions in unusual oxidation states (see the studies [1–3, 52–54] and references cited therein).

constants for some reactions involving metal atoms and ions in unusual oxidation states are summarised in Table 6. (This Table was compiled using data from the book.[51]) The reaction rate constants are usually fairly high; in some cases (for example, for reactions of Ag^0, Cd^+ and Co^+ with O_2, H_2O_2 and inorganic anions), they correspond to the diffusion limits. Apparently, the electron transfer occurs by an outer-sphere mechanism. Among the reactions not controlled by diffusion of the reactants, no reactions can be found for which the rate constant would follow a clear-cut dependence on the reduction potential of the metal ion.

Some metal atoms and metal ions in unusual oxidation states tend to add more metal ions to yield small clusters.[3,55–57] This ability is especially characteristic of atoms that can attach an additional metal cation with a σ_s-bond (Ag, Cu) or a σ_{sp}-bond (In, Tl), thus forming small homoelement clusters consisting of two to about ten atoms.[3,54–56] It was also found[58,59] that silver atoms, Ag_2^+ cations and, perhaps, Ag_3^{2+} cations form complexes with cyanide anions, ethylenediaminetetraacetic acid or ammonia. The optical properties, the redox potentials and the kinetic characteristics of such clusters differ appreciably from analogous properties of the clusters having a hydration shell. The nucleation processes of silver in polymeric membranes,[59–62] in gelatin[63] and on the surface of colloidal silica[64] follow similar mechanisms, *i.e.*, they include the intermediate formation of the same clusters as those formed in homogeneous aqueous solutions of silver ions, which have been described in detail in our review.[3]

The possibility of formation of short-lived mixed (heteroelement) clusters has also been established.[65–69] These arise upon the reactions of metal ions in unstable oxidation states, in particular Co^+ ion, with other metal ions in stable oxidation states, for example, with the Ag^+ ion. Under these conditions, a short-lived $(CdAg)^{2+}$ cluster is formed.[65,68] A similar approach has been used[66] to obtain mixed clusters, $(CdTl)^{2+}$, $(TlAg)^+$ and $(TlCd)^{2+}$.

A metal ion in an unusual oxidation state can not only react with a different metal ion to give a mixed cluster; it can also reduce or oxidise a different ion. For instance, Zn^+ ions obtained upon the reduction of Zn^{2+} with hydrated electrons, unlike Cd^+ ions, enter into electron transfer reactions with silver, thallium and cadmium ions, no mixed clusters being formed.[65,66,68] In addition, the Tl_2^+ ions reduce Pb^{2+} ions. By using metal ions with various reduction potentials and various electron structures, the conditions that favour one or another reaction were identified.[3] It was found that mixed clusters are formed in those cases where the potentials of reacting metal ions either coincide or do not differ much. This also requires the possibility of formation of a bonding molecular orbital between the atomic orbitals of the reacting metal ions. Fast electron transfer between metal ions takes place when the standard potentials of the ions are appreciably different.

V. Reactions of actinides

During recent years, a substantial contribution has been made to the study of the kinetics and mechanisms of one-electron redox reactions involving actinides. A specific feature of these elements is the diversity of stable oxidation states depending on the pH value and the presence of diverse ligands. The reduction of tetra-, penta-, hexa- and heptavalent actinides with hydrated electrons has very high rate constants ($\sim2\times10^9$ to 1×10^{11} litre mol^{-1} s^{-1}, see Refs. 70–78). As in the case of other diffusion-controlled one-electron redox reactions, no clear-cut correlation can be followed between the rate constants and the reduction potentials (E°) of the corresponding pairs of actinide ions. The rate constants for the reactions of actinides with hydrogen atoms which occur predominantly in acidic media are much lower (10^7–10^9 litre mol^{-1} s^{-1}).[79–81] This difference can hardly be explained by the fact that the reduction potential of a hydrogen atom (−2.3 V) is less negative than the potential of the electron (−2.87 V). The researchers cited attributed this to different reduction mechanisms. In the case of the hydrated electron, the reaction occurs as an outer-sphere electron transfer. The reaction of actinides with hydrogen is apparently an inner-sphere reaction, which includes the insertion of an H$^\bullet$ atom into the hydration shell to give the $H_3O^\bullet$ complex with subsequent transfer of an electron from this complex to the central ion. The logarithms of the rate constants for the reactions between a hydrogen atom and AnO_2^{2+} ions (An = U, Pu, Am, Np) were found to follow a nearly linear dependence on the reduction potential.[5] Thus, the mechanisms of reactions for them are identical and are not controlled by diffusion. Hydrogen atoms act as one-electron oxidants with respect to the U^V, Np^{III} and Pu^{III} ions. Apparently, this is due to the formation of hydride complexes of these actinides at an intermediate stage of the reaction.[80,82]

The rate constants for the actinide reactions with the OH$^\bullet$ radicals are 10^8–10^9 litre mol^{-1} s^{-1}, their values being markedly dependent on the acidity of the aqueous solution.[83–87] The reactions follow an inner-sphere mechanism involving either detachment of a hydrogen atom from a water molecule by the OH$^\bullet$ radical or the replacement of the OH^- ion in the hydration shell of the actinide ion by this radical.[5]

The oxidation of halide ions in aqueous solutions by hydroxyl radicals giving rise to the $X_2^{-\bullet}$ radical anions has been described above in detail. In aqueous solutions containing SO_4^{2-}, NO_3^- or CO_3^{2-} ions, similar processes give $SO_4^{-\bullet}$, $NO_3^\bullet$ or $CO_3^{-\bullet}$ radical anions, respectively. In recent years, systematic research of the kinetics and mechanism of one-electron redox reactions of actinides involving these species has been carried out. It was found that their reduction potentials are commensurate with the potential of the OH$^\bullet$ radical in the pH region of 1–13 and they tend to oxidise actinides. Moreover, the rate constants for the $SO_4^{-\bullet}$ radical anion,[81,84] $NO_3^\bullet$ radical[84,88,89] and $CO_3^{-\bullet}$ radical anion[77,87] usually do not differ much from those for the OH$^\bullet$ radical. In the case of noncharged $NO_3^\bullet$ radical, the reaction rates are most likely controlled by diffusion, as for the $HSeO_3^\bullet$ radical.[90]. The rate constants for the reactions of Np^V and Np^{VI} with the ozonide $O_3^{-\bullet}$ radical anions are as low as 2×10^6 and 2×10^5 litre mol^{-1} s^{-1}, respectively.[91]

The reactions with halogen radical anions usually have lower rate constants than the reactions with sulfate and nitrate radicals.[84,88,89,92–94] As has already been noted, for the reactions of Np^{III} or Pu^{III} with $Cl_2^{-\bullet}$, $Br_2^{-\bullet}$ or $I_2^{-\bullet}$, the logarithm of the rate constant obeys a linear dependence on the difference between the reduction potentials (ΔE°) of the reacting species. Similar correlations can be followed for reactions of $CO_3^{-\bullet}$ with the carbonate complexes of Am^{III}, Np^{III} and Pu^{III} (see Ref. 77) or U^V, Np^V and Pu^V (see Ref. 95). Thus, if the reaction rate is not controlled by diffusion, it often depends on the reduction potentials of actinide ions and the inorganic radicals they react with. For example, the

reactivity in redox processes decreases in the following sequence: $SO_4^{-\bullet} > NO_3^{\bullet} > OH^{\bullet} > Br_2^{-\bullet} > Cl_2^{-\bullet} > I_2^{-\bullet} > O_3^{-\bullet}$ (see Ref. 5). The reactivity of actinides towards the $OH^{\bullet}$ radical and the inorganic radical anions listed above is appreciably affected by their charge and complexation state. This is due to the inner-sphere mechanism of the reactions involved.

Reactions of actinides with organic radicals are discussed in the following Section.

VI. Reactions of organic radicals

A large body of experimental data (mainly obtained by pulse radiolysis) concerned with the reactivity of organic radicals towards the one-electron reduction of organic and inorganic compounds in aqueous solutions has been accumulated to date. The measured rate constants have been summarised in a book.[96] Table 7 presents the rate constants for the reduction of a number of organic and inorganic compounds with various organic radicals and with hydrogen atoms. These particular constants were chosen [97–103] among the multitude of known rate constants because they allow one to follow the requlrities of their variation in a series of related organic radicals. These are 1-hydroxyalkyl radicals formed upon pulse radiolysis of aqueous solutions of alcohols in reactions of type (3). It is reasonable to expect that the reactivity of organic radicals in the one-electron reduction of organic and inorganic compounds should depend, most of all, on the reaction mechanism and limiting step. The reduction potential of the hydrogen atom is −2.3 V; the rate constants for the reductions involving the hydrogen atom are usually very high and are restricted by the rate of diffusion. In the case of organic radicals, the constants are also fairly high,[96] but they are still markedly lower than those for hydrogen. The rate constants for a large number of redox reactions involving organic radicals, including alkyl radicals ($^{\bullet}CH_3$, $CH_3C^{\bullet}H_2$, *etc.*) formed upon abstraction of a hydrogen atom from the α- or β-position of mono- or polyhydric alcohols, amines, nitro derivatives and other organic compounds, have now been measured. Most of these species react at high rates (10^6–10^9 litre mol^{-1} s^{-1}) with organic and inorganic compounds, mainly as reducing agents. The reduction of nitro, sulfo and halogen compounds and other organic compounds containing electronegative substituents and the reduction of various quinones, dyes, and their derivatives proceed at high rates, their rate constants reaching the values normally observed for diffusion-controlled reactions. Unfortunately, the reduction potentials of organic radicals are not always known, which restricts the possibility of comparison of rate constants and hampers elucidation of the reaction kinetics. However, the potentials of 1-hydroxyalkyl radicals $^{\bullet}CH_2OH$, $CH_3C^{\bullet}HOH$ and $(CH_3)_2C^{\bullet}OH$ have been determined; they decrease along the given series as follows: −1.18, −1.25 and −1.39 V.[8] Thus, the reducing ability of the radicals is enhanced in this sequence. It appeared of interest to find the relationship between the reactivity and the reducing capacity and the size of the radicals. Analysis of the reactivity (see Table 7) showed that the rate constants for the reactions of 1-hydroxyalkyl radicals with metal ions (Cu^{2+} and Cr^{2+}) decrease, while those for reactions with organic compounds (nitrobenzene, RNO, PNAF and NF), conversely, increase in the sequence $^{\bullet}CH_2OH$, $CH_3C^{\bullet}HOH$, $(CH_3)_2C^{\bullet}OH$. It is worth mentioning that for some other compounds,[96] it is not always possible to distinguish a clear-cut regularity in the variation of the constant as a function of the potential or the size of the radical. It should be borne in mind that determination of the rate constants of reactions involving organic radicals by pulse radiolysis with optical recording is faced with some experimental difficulties, which are caused by the following reasons. Organic radicals absorb in the far UV region and the extinction coefficients are relatively low. This hampers the measurement of the rate constants of reactions involving such radicals directly by following their absorption. The rate of appearance of the absorption of the reaction product is not always measurable. Therefore, many constants have not been determined by the direct method but were found by comparing the reactivity of the compound under study with a known reactivity of a different compound, the product of whose reduction has optical characteristics suitable for the measurements. These difficulties have been taken into account by Ershov *et al.*[104–106] They performed a systematic pulse radiolysis study of the reactivity of hydrogen atoms and a series of 1-hydroxyalkyl radicals $^{\bullet}CH_2OH$, $CH_3C^{\bullet}HOH$ and $(CH_3)_2C^{\bullet}OH$ towards the reduction of Hg^{2+} ions and I_2 molecules. These radicals differ in size and in the values of known redox potentials. The reagents (Hg^{2+} and I_2) differ appreciably in the outer-sphere and electronic structures. Therefore, different reduction mechanisms could be expected. The products of reduction of the radical acceptors (Hg^{+} and $I_2^{-\bullet}$) have appropriate optical characteristics which allow the rate constants of these reactions to be measured with high accuracy.

The reactions were carried out in acidic (pH 1.0–2.0, $HClO_4$) aqueous solutions of $Hg(ClO_4)_2$ and I_2 containing small amounts of an alcohol (methanol, ethanol or 2-propanol). Under these conditions, hydrated electrons reacted with H^+ to give hydrogen atoms

$$e_{aq}^- + H^+ \longrightarrow H^{\bullet}. \quad (32)$$

The hydrogen atoms, like $OH^{\bullet}$ radicals, entered into a reaction of type (3) with alcohols, which were thus converted almost entirely into alcohol radicals ($R^{\bullet}$).

Then the alcohol radicals reacted with the Hg^{2+} ions or I_2 molecules:

$$R^{\bullet} + Hg^{2+} \longrightarrow Hg^{+} + X + H^{+}, \quad (33)$$

$$R^{\bullet} + I_2 \longrightarrow I_2^{-\bullet} + X + H^{+}, \quad (34)$$

where X is CH_2O, CH_3CHO and $(CH_3)_2CO$ in the case of CH_3OH, CH_3CH_2OH and $(CH_3)_2CHOH$, respectively.

The rate of the reaction of the alcohol radicals with the Hg^{2+} ions was measured based on the appearance of absorption bands with maxima at $\lambda = 225$ and 255 nm corresponding to the Hg^{+} ion formed in reaction (33).[107, 108] The reaction with I_2 was monitored by following the absorption at $\lambda = 725$ nm due to the the $I_2^{-\bullet}$ radical anion produced in reaction (34).[109, 110]

Table 7. Rate constants (k) for some reactions involving hydrogen atoms and organic radicals.

Atom, radical	E°/V	k /litre mol^{-1} s^{-1}							
		Hg^{2+} (see [103]) (pH 2)	Cu^{2+} (see [95, 96]) (pH 5–6)	Cr^{2+} (see [97]) (pH 1)	I_2 (see [104–106])	RNO (see [98])	NF (see [99])	PNAF (see [100])	$C_6H_5NO_2$ (see [101])
$H^{\bullet}$	−2.30	2.0×10^9	–	–	3.5×10^{10}	–	–	–	–
$^{\bullet}CH_2OH$	−1.18	7.0×10^8	1.6×10^8	1.6×10^8	5.0×10^9	7.9×10^8	8.0×10^8	1.0×10^8	3.2×10^9
$CH_3C^{\bullet}HOH$	−1.25	3.8×10^8	9.0×10^7	7.9×10^7	6.5×10^9	2.4×10^9	1.5×10^9	8.0×10^8	3.9×10^9
$(CH_3)_2C^{\bullet}OH$	−1.39	3.1×10^8	5.0×10^7	5.1×10^7	8.0×10^9	3.2×10^9	3.3×10^9	3.8×10^9	5.0×10^9

Note. RNO is *N*,*N*-dimethyl-4-nitrosoaniline; NF is *anti*-5-nitro-2-furaldoxime; PNAF is *p*-nitroacetophenone.

The data on the formation of the Hg^+ cation were analysed in terms of the reaction scheme composed of the following reactions with known rate constants:[9,96]

$$R^\bullet + R^\bullet \longrightarrow \text{product},$$

$$H^\bullet + H^\bullet \longrightarrow H_2,$$

$$Hg^+ + Hg^+ \longrightarrow Hg^0 + Hg^{2+},$$

$$H^\bullet + Hg^{2+} \longrightarrow Hg^+ + H^+.$$

The rate constants for the recombination of alcohol radicals are 2.4×10^9, 1.5×10^9 and 1.1×10^9 litre mol^{-1} s^{-1} for $^\bullet CH_2OH$, $CH_3C^\bullet HOH$ and $(CH_3)_2C^\bullet OH$, respectively.[111] Computer simulation gave the following rate constants for reaction (33) with the $^\bullet CH_2OH$, $CH_3C^\bullet HOH$ and $(CH_3)_2C^\bullet OH$ radicals: 7.0×10^8, 3.8×10^8 and 3.1×10^8 litre mol^{-1} s^{-1}, respectively. Thus, the rate constants for the reactions of the alcohol radicals with the Hg^{2+} ions decrease in the above sequence.

A similar approach has been used to calculate the rate constants for reactions (34) between the alcohol radicals and I_2 on the basis of the kinetics of the appearance of $I_2^{-\bullet}$ absorption. The following reactions were taken into account:

$$H^\bullet + I_2 \longrightarrow I_2^{-\bullet} + H^+,$$

$$I_2^{-\bullet} + I_2^{-\bullet} \longrightarrow I_3^- + I^-,$$

$$I^\bullet + I^- \rightleftharpoons I_2^{-\bullet},$$

$$I_2 + I^- \rightleftharpoons I_3^-,$$

$$I^\bullet + I^\bullet \longrightarrow I_2.$$

In this case, the rate constants for the forward and back reactions and the extinction coefficients of the reactants and the products are known.[109,110] The rate constants for the reduction of iodine in reaction (34) by the $^\bullet CH_2OH$, $CH_3C^\bullet HOH$ and $(CH_3)_2C^\bullet OH$ radicals are 5.0×10^9, 6.5×10^9 and 8.0×10^9 litre mol^{-1} s^{-1}, respectively. Thus, the rate constants for the reactions of alcohol radicals with I_2, unlike reactions with Hg^{2+}, increase in this sequence. It is also noteworthy that an increase in the values of constants with an increase in the size of the radical definitely indicates that the reactions involving these radicals are not controlled by diffusion.

The rate constants for the alcohol radicals and hydrogen atoms with I_2 increase with an increase in the reduction potentials (see Table 7). Moreover, a good linear dependence of $\log k$ on the reduction potential of the reagent can be followed (Fig. 3 *a*). Therefore, it can be concluded that the efficiency of the outer-sphere transfer of an electron from the alcohol radicals to the I_2 molecule is determined by their reducing capacity. It is of interest that the hydrogen atom fits well in this series of radicals as regards the reduction mechanism and the variation in the potential.

The rate constants for reactions of the Hg^{2+} ions with the hydrogen atoms and alcohol radicals increase with a decrease in the size of the reducing agent (see Table 7). Therefore, it can be suggested that the reaction of the radicals $R^\bullet$ with Hg^{2+} gives initially the short-lived $[Hg^{2+} \cdots R^\bullet]$ complex; this is followed by an inner-sphere electron transfer and separation of the reaction products. Note that the formation of relatively stable complexes in similar reactions is typical of many metals, most often, transition metals.[2,3] Due to steric hindrance, which becomes more pronounced with an increase in the size of the radical, the rate of formation of the intermediate complex should limit the rate of reduction; this is actually observed in experiments. The tendency of transition metals to form unstable hydride complexes upon reactions with hydrogen atoms has been confirmed experimentally in some cases.[1,2,53] It is also assumed that the reactions of hydrogen atoms proceed with participation of water present in the hydration shell of the ion; this may give intermediately the $H_3O^\bullet$ species, an electron from which passes to the central metal ion.

The conclusions drawn from the study of the reactivity of alcohol radicals with respect to the Hg^{2+} ion and with I_2 can be extended to the reactions of these radicals with other metals and compounds (see Table 7). Indeed, for the Cu^{2+} and Cr^{2+} ions, as for Hg^{2+}, the rate constants for reactions with alcohol radicals regularly decrease in the sequence $^\bullet CH_2OH$, $CH_3C^\bullet HOH$ and $(CH_3)_2C^\bullet OH$, which can also be attributed to the steric hindrance involved in the reactant interaction. Conversely, in the reactions with organic compounds (nitro- and nitrosobenzene, RNO and NF), the rate constants increase in the given sequence (see Table 7). This is due to the fact that the efficiency of the electron transfer to a molecule of the organic compound is determined by the reduction potential of the radical. In this case, as in the case of iodine, the logarithm of the rate constant follows a linear dependence on the potential (see Fig. 3 *b*).

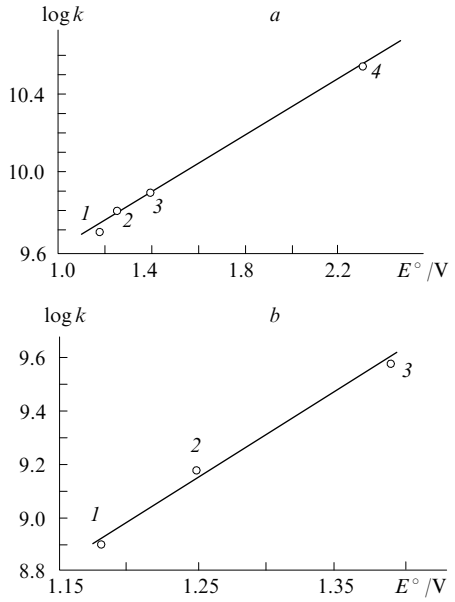

Figure 3. Dependence of $\log k$ on the potential (E°) in the reactions of $^\bullet CH_2OH$ (*1*), $CH_3C^\bullet HOH$ (*2*) and $(CH_3)_2C^\bullet OH$ (*3*) radicals and hydrogen atom (*4*) with I_2 (*a*) and with *N*,*N*-dimethyl-4-nitrosoaniline (*b*).

However, the conclusion concerning the inner-sphere mechanism of the reduction of transition metal ions, Hg^{2+}, Cu^{2+} and Cr^{2+}, with organic radicals is not universal and it cannot be extended to all other ions. For example, the alcohol radicals reduce the Fe^{3+} cations, their reactivity increasing in the sequence $^\bullet CH_2OH$, $CH_3C^\bullet HOH$ and $(CH_3)_2C^\bullet OH$ ($k = 8 \times 10^7$, 3.8×10^8 and 5.8×10^8 litre mol^{-1} s^{-1}, respectively).[96] This fact rather attests in favour of a mechanism with outer-sphere electron transfer in which the reducing properties of the radical are of crucial importance. Note that reactions of the alcohol and many other organic radicals with transition metal complexes [$Fe(CN)_6^{3-}$, $IrCl_6^{2-}$, *etc.*] are diffusion-controlled, the rate constants reaching $\sim 5 \times 10^9$ litre mol^{-1} s^{-1} and depending only slightly on the type of the reducing radical used.[96]

The rates of reactions of organic radicals with oxygen are also controlled by diffusion; they are characterised by constants of $\sim 10^9 - 10^{10}$ litre mol^{-1} s^{-1}. These reactions yield the $RO_2^\bullet$ radicals or the $O_2^{-\bullet}$ peroxide radicals. Conversely, the reactions with H_2O_2 are very slow ($\sim 1 \times 10^5$ litre mol^{-1} s^{-1}) and seem to be accompanied by the formation of the $OH^\bullet$ radicals.

The reactions of the $CO_2^{-\bullet}$ radical anion with various inorganic and organic compounds have been studied in detail. The reduction potential of this radical anion is -1.9 V; as a reducing agent, it markedly surpasses other radicals, being inferior only to the hydrated electron and the hydrogen atom. Therefore, this species tends to enter into electron transfer reactions with various compounds and the rate constants of such reactions approach the diffusion limit.[96]

Comparison of the reduction potentials of metal ions in unusual oxidation states and organic radicals (see Tables 5 and 7) shows that some metal ions, for example, Zn^+, Cd^+, *etc*., surpass organic radicals in reducing ability. Therefore, in those radiation-induced chemical reactions where they arise simultaneously [for example, in the reduction of metal ions, Zn^{2+}, Cd^{2+}, *etc*., by hydrated electrons or in dehydrogenation of organic compounds by reaction (3)], organic radicals are reduced by metal ions. Conversely, for higher potentials of metal ions (for ions like Pb^+, Hg^+ and, probably, Pd^+ and Pt^+), the radicals reduce the ions to give metal atoms.

In the studied reactions of actinides with organic radicals, the latter behave as reducing agents.[5,112–115] It is noteworthy that data on the reactivity of organic radicals towards actinides and on the nature of the products are important for evaluation of the radiation stability of organic extractants used in the radiochemical industry and for predicting the efficiency of actinide separation. According to publications,[112–115] the rates of the reactions of the $^{\bullet}COOH$ and $(CH_3)_2C^{\bullet}OH$ radicals and *o*-phenanthrolinium, 2,2′-bipyridinium and some other electron adducts with actinide ions can be fairly high and, most likely, they are controlled by diffusion. This is supported by calculation of the diffusion-limited rate constant for the reaction of Np^{VI} with $(CH_3)_2C^{\bullet}OH$ using the Smolukhovsky equation.[115] The value calculated theoretically proved to be rather close to the experimental value. In addition, it was found that the activation energies for the reaction of U^{VI} with the *o*-phenanthrolinium and 2,2′-bipyridinium electron adducts are equal to 10 and 16.7 kJ mol^{-1}, respectively. These values do not differ much from the activation energy of water diffusion and are usual for reactions whose rates are controlled by diffusion or approach the diffusion limit.

It is worth mentioning that the electronic structure of organic radicals has a considerable influence on the rates of their reactions with actinides. It was found [116] that reactions of uranium, neptunium, plutonium and americium ions with the *o*-phenanthrolinium and 2,2′-bipyridinium H-adducts proceed much more slowly than reactions with the electron adducts of the same compounds. This is attributable to the fact that the electron adduct arises upon protonation of the nitrogen atoms in the molecules, whereas the H-adduct is produced upon incorporation of the hydrogen atom into the aromatic rings. Therefore, in the electron adducts, the unpaired electron is delocalised over the aromatic π-system, whereas in the H-adducts, the system of conjugation is violated due to the formation of a cyclodienyl type radical. The electron transfer proceeds more easily from the electron adduct than from the H-adduct due to the difference between their electronic structures.

Thus, it can be concluded that, at least for some reduction reactions involving organic radicals, the redox process follows a classical pattern, according to which the reaction proceeds either in the outer or in the inner sphere. For the former type, the interaction between the oxidant and the reductant is not significant during the electron transfer and, most likely, it does not affect the coordination spheres of the reactants. As has been shown, for these reactions, a clear-cut dependence of the reactivity of organic radicals on their reducing potential can be observed. A necessary condition for reactions of the latter type is the presence of a strong bond between the reductant and the oxidant during the electron transfer, which is implemented by the formation of a short-lived intermediate complex. In this case, the rate of electron transfer is limited by this step and depends more appreciably on steric factors.

VII. Conclusion

The results of investigation of a number of redox reactions in aqueous solutions initiated by exposure to ionising radiation indicate that development of this line of research is quite promising. The pulse radiolysis method provides broad opportunities for the study of the kinetics, the mechanism and the nature of the short-lived intermediates of fast one-electron redox reactions. By the early 1990s, a great amount of information had been accumulated on the reactivity of hydrated electrons, hydrogen atoms, hydroxyl radicals and $HO_2^{\bullet}$ radicals,[8] diverse inorganic [23] and organic [96] radicals, metal ions in unusual oxidation states [51] and actinides.[5] During the last 15 years, new data have been obtained, which are largely summarised in this review. Of these, mention should be made first of all of the studies of the redox processes involving halide ions. The rate and equilibrium constants for many reactions have been measured for the first time and the tendency of halogens for the formation of mixed products of not only molecular but also radical nature has been established. The $ClBr^{-\bullet}$ radical anion is probably only the first representative of this series. The research along these lines, important from not only a theoretical but also a practical standpoint, will undoubtedly be continued.

In our opinion, the theoretical analysis of the data on the reactivity of diverse one-electron oxidants and reductants of radical nature towards various compounds still receives inadequate attention. Systematic analysis of these data would be useful for the development of chemical kinetics and for extension of the knowledge on the mechanisms of chemical reactions.

Abstract. Various approaches to the formation of ordered structures of colloid particles are described. The emphasis is placed on the formation of such structures by nanoparticles at interfaces. A number of processes involving the so-called self-assembly of particles are considered. Examples of the formation of ordered structures (two- and three-dimensional colloid crystals) are given. The driving forces of the self-assembly of nanoparticles and the salient features of the physicochemical properties of ordered ensembles of such nanoparticles are analysed. The bibliography includes 502 references.

I. Introduction

Studies on the properties of nanoparticles and nanoscale structures have attracted increasing interest of researchers in the last fifteen years. Extensive literature on various methods of producing nanoparticles and fabricating nanostructured materials has been published. This was accompanied by the development of experimental techniques for studying the processes occurring in nanoscale systems.

The results obtained were reviewed and summed up (see, *e.g.*, Refs 1 – 11) and the main fields of research on nanoscale systems were pointed out. The new research avenues, which are rapidly developing at present, were in the early stage of development five or six years ago. They include investigations into the self-assembly of nanoparticles at interfaces.

Interest in the self-assembly of particles is due to some reasons. First, research on such processes gives an insight into the laws governing the behaviour of nanoscale objects under different conditions. Second, self-organised ensembles of nanoparticles exhibit new (and often quite unexpected) properties. Third, if nanoparticles themselves are mainly of interest for basic research, the ensembles of nanoparticles are considered to be a kind of working element in certain devices. Fabrication of such devices implies targeted arrangement of particles on solid substrates. Because of this, investigations on the behaviour of nanoparticles at interfaces are to a great extent governed by practical demands. This opens up the possibility of creating a new generation of nanoscale devices with a multilevel architecture based on an intrinsic property of nanoparticles, namely, on their ability to spontaneously form ordered ensembles. Attempts at simulating self-organisation processes observed in real biological systems also give an impetus to research in this field.

In this review we will describe various approaches to the formation of ordered structures at interfaces. The emphasis is placed on self-assembly of colloid systems and on the methods facilitating this process. The major part of our review will be dedicated to the so-called colloid crystals that are the most interesting and promising objects. The most important properties of self-assembled structures and the conditions for their formation will also be considered.

We will not dwell on the problems concerning self-assembly of nanoscale systems in the broad sense, because this is beyond the scope of the review. We can only point to recent attempts at fabricating nanomechanical devices that are based on nanotubes and fullerenes and operate following a certain algorithm (see Ref. 12). Investigations in this field are in the early stage of development and the models and schemes proposed are to a great extent hypothetical ones despite good reproducibility in computer experiments.

We will also consider some problems concerning the formation of ordered ensembles of particles in the bulk of colloid dispersions. At the same time, the formation of disordered composite materials based on nanoparticles (in particular, using silica matrices [13 – 18]) will be left out of consideration despite the fact that in some cases this process results in the formation of quite interesting structures [14, 19] possessing unique optical and catalytic properties. This research avenue has been intensively developing and deserves detailed consideration elsewhere.

We will leave essentially untouched the problems concerning changes in the properties of the particles deposited on solid substrates. The interaction between the particles and the substrate can result in significant changes in the characteristics of the former.[20] This is due to distortion of the crystal lattice of nanoparticles,[21] which is probably responsible for, *e.g.*, the enhanced catalytic activity and the changes in the optical characteristics of nanoparticles on solid substrates.

Uspekhi Khimii **73** (2) 123 – 156 (2004); translated by A M Raevsky

† This is the last publication in the series of reviews concerning the main avenues of research carried out at the Institute of Physical Chemistry, Russian Academy of Sciences [see *Russ. Chem. Rev.* **73** (1) 2004].

Ordered ensembles of molecular clusters[22,23] will also be excluded from consideration. The advantage of such systems is that the corresponding 'building blocks' are of the same size. However, these systems belong to molecular crystals rather than colloid systems. Because of this, both the mechanisms of formation and the physical properties of such ordered structures are strongly different from those typical of colloids.

Yet another problem left out of consideration is self-assembly of macroscopic particles, which is similar to that of microparticles. It should only be noted that revealing self-assembly processes at microscopic level gave an impetus to studies on self-assembly of millimetre-scale particles.[24,25] To this end, such particles of various shape were specially treated (*e.g.*, different faces of cubic polyurethane particles were coated with different materials). Using particles of different geometry and different conditions for modification of their surfaces, it is possible to cause aggregation of particles to give a variety of ordered structures.

II. Periodic colloid structures

The title of this section is exactly the same as that of a book by Efremov, which was published more than three decades ago.[26] Numerous examples in this book showed that it is possible to form ensembles of particles with ordered structures (the so-called colloid crystals) in the colloid systems. These examples can be divided into two groups. The first group comprised highly ordered structures (at that time, they were observed only in natural objects, in particular, opals). The second group comprised the systems that exhibited a trend to formation of ordered structures (it included colloid dispersion prepared under laboratory conditions).

Considerable progress towards fabrication of ordered structures has been achieved since the publication of the above-mentioned book.[26] This was provided by the high level of the development of methods for the synthesis of monodisperse colloid particles, which became the subject of routine studies. Currently, search for the procedures suitable for forming colloid crystals with desired properties is carried out.[27–30] Considerable advances towards the formation of colloid crystals with perfect structure (Fig. 1) have also been achieved.

1. The interparticle interaction

Ordered ensembles of colloid particles (colloid crystals) can serve as model systems in the studies of the gas–liquid and liquid–crystal phase transitions, because they allow the processes to be visualised. The properties of the colloid structures formed in such experiments and the laws of the phase transitions in these systems are governed by the forces of the interparticle interaction. These forces are of various nature and are determined by the properties of the dispersion medium, by the state of the particle surface and by the presence of additives in the colloid system. Consider now several expressions for the potentials of the interparticle interaction, which are most often used in theoretical description of colloids. The potential of the dispersion or van der Waals interaction, which occurs in virtually all systems,[31] is given by

$$U_{\mathrm{d}}(r) = -\frac{\mathrm{A}}{12}\left\{\frac{4r^2}{(2R)^2 - 4r^2} + \frac{4r^2}{(2R)^2} + 2\ln\left[\frac{(2R)^2 - 4r^2}{(2R)^2}\right]\right\}, \qquad (1)$$

where r is the distance between the centres of the particles, A is the Hamaker constant and R is the radius of the particles.

Yet another widely used potential describes an electrostatic interparticle interaction, which is due to the overlap of ionic atmospheres that form in electrolyte solutions near the surfaces of the charged particles. Theoretical analysis usually employs a simplified model of this interaction,[31] which is described by the modified Yukava potential

$$U(r_{ij}) = \frac{Z_i Z_j e^2}{4\pi\varepsilon_0\varepsilon r_{ij}}\left(\frac{\mathrm{e}^{\kappa R_i}}{1+\kappa R_i}\right)\left(\frac{\mathrm{e}^{\kappa R_j}}{1+\kappa R_j}\right)\mathrm{e}^{-\kappa r_{ij}}, \qquad (2)$$

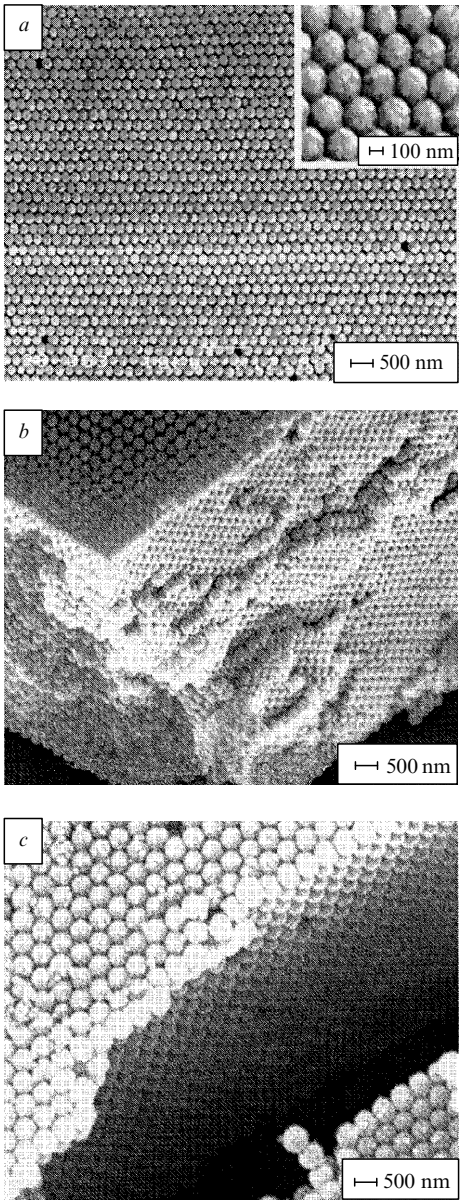

Figure 1. SEM images of three-dimensional crystalline ensembles of polystyrene beads in 12 μm-thick packs.[27]
Particle size: 220 nm for the surface of the crystal (*a*) and for the cleaved facet (*b*) and 480 nm (*c*).

where r_{ij} is the distance between the particles of the sorts i and j; Z_i and Z_j are the corresponding particle charges; e is the charge of electron; ε_0 is the electric constant; ε is the dielectric permittivity of the medium; e is the base of natural logarithm; R_i and R_j are the radii of the particles of the sorts i and j, respectively; and κ is the reciprocal Debye radius defined as follows:

$$\kappa^2 = \frac{e^2}{\varepsilon_0\varepsilon kT}\sum_i n_i z_i^2, \qquad (3)$$

where n_i is the concentration of ions of the sort i in the solution and z_i is the charge of these ions.

If particles are stabilised sterically rather than electrostatically (steric forces are due to the presence of adsorption layers of polymers or surfactants), the interparticle interaction can be quite correctly described by the repulsive potential of dense monolayers in a good solvent [32]

$$E_{st} = \frac{100R\delta_s^2}{(r-2R)\pi\sigma_{th}^3} kT \exp\left[\frac{-\pi(r-2R)}{\delta_s}\right], \quad (4)$$

where δ_s is the monolayer thickness and σ_{th} is the surface area per molecule in the monolayer.

When considering the interparticle interaction, one should take into account two potentials, *viz*., the attractive potential and the repulsive potential, which are in essence some combinations of the potentials mentioned above. Often, numerical calculations are simplified using certain model potentials, *e.g*. a rectangular potential well

$$\frac{U(r)}{kT} = \begin{cases} \infty & \text{at} \quad r < 2R \\ -\dfrac{E_0}{kT} & \text{at} \quad 2R < r < (1+\delta_w)2R \\ 0 & \text{at} \quad r > (1+\delta_w)2R, \end{cases} \quad (5)$$

where E_0 and δ_w are the depth and width of the potential well, respectively. The stick sphere potential is given by

$$\frac{U(r)}{kT} = \lim_{\Delta \to 0} \begin{cases} \infty & \text{at} \quad r < 2R \\ \ln\left(\dfrac{12\psi\Delta}{2R+\Delta}\right) & \text{at} \quad 2R < r < (1+\Delta)2R, \\ 0 & \text{at} \quad r > (1+\Delta)2R, \end{cases} \quad (6)$$

where ψ is the parameter determining the adhesive binding energy and Δ is the variable parameter. The Lennard-Jones potential (its exponents are sometimes chosen arbitrarily) has the form

$$U(r) = 4E_{LD}\left[\left(\frac{\delta_{LD}}{r}\right)^{12} - \left(\frac{\delta_{LD}}{r}\right)^{6}\right], \quad (7)$$

where E_{LD} and δ_{LD} are the energy and spatial parameters, respectively.

The potentials listed above can be used to calculate various characteristics of colloid dispersions, *viz*., the osmotic pressure, second virial coefficient, particle solubility, phase diagram, *etc*. By comparing the calculated and experimental data it is possible [33] not only evaluate the parameters of a particular potential but also determine which of them is more convenient for the description of a given colloid dispersion. If not only the thermodynamic characteristics but also the structure factor is known, one can reconstruct the pair potential of the interparticle interaction even for polydisperse colloid systems.[34]

2. Simple systems

The development of methods for the synthesis of nearly monodisperse colloid particles permitted the growth of rather large colloid crystals with a high degree of crystallinity under laboratory conditions.[35] Initially, high-quality colloid crystals were formed from electrically stabilised latex particles. The stabilisation of the particles was enhanced due to deionisation of the aqueous dispersion medium. In this medium, the interparticle interaction involves the screened Coulombic potential (2), which causes a strong repulsion between particles at long distances due to a large Debye radius. Because of this, the transition to the crystalline state occurs at a volume fraction of the particles of less than 0.01, resulting in the formation of both face-centred cubic (f.c.c.) and body-centred cubic (b.c.c.) crystals.[36, 37] Ordered structures comprised of sterically stabilised colloid particles were obtained much later.[38, 39] The steric stabilisation provided a strong repulsion between particles at short distances so the transition of the colloid dispersion from the liquid to the crystalline state occurred at a volume fraction of particles of nearly 0.5 (as a rule, the f.c.c. structure was formed). Then, more complex systems and phase transitions in them have become the focus of research activity in the field of colloid crystals.

As mentioned above, colloid systems can serve as models for studying the behaviour of atomic and molecular systems. Colloids offer some obvious advantages. In particular, their parameters, *viz*., the size, shape and potential of the interparticle interaction can be measured and varied with ease. The properties of the medium in which colloid particles are dispersed can also be controlled and measured. Because of this, a wide variety of phase states of colloid systems, namely, the gaseous, liquid-like (including glassy state) and crystalline states is observed. Even the existence of a quasi-crystal structure in the single-component colloid system was predicted.[40] Such a structure (icosahedral quasi-crystal) is typical of some binary and ternary metal alloys. It is formed at a rather high osmotic pressure in a specific concentration range.

Various models [41, 42] including those predicting the existence of the glassy state of a colloid fluid [43] were proposed to describe the phase behaviour of colloid systems. Such models are employed in the analysis of the phase transitions in colloid dispersions.[44, 45]

Under particular conditions, sterically stabilised colloid particles behave as a system of hard spheres.[39] To enhance this similarity, particles are coated with a thin adsorption layer of a polymer and then dispersed in a medium characterised by the same refractive index to weaken the van der Waals interaction. Not only the solidification transitions but also the glass transitions were observed in such systems at a volume fraction of particles of about 0.58.[39] At higher particle concentrations, no homogeneous nucleation of crystals was observed and long-range diffusion displacements of particles were suppressed (this was indicated by the shape of the fluctuation correlation function of the particle concentration).[46] Heterogeneous nucleation under the same conditions resulted in large plate-like colloid crystals. This points out that the glassy state is thermodynamically unstable and exists due to the inability of a concentrated homogeneous colloid liquid to go to the crystalline state (for this transition to occur, long-range particle diffusion must be possible). The existence of glassy colloid systems was confirmed by Speedy [47] who also showed that the equation of state of the hard-sphere fluid has singularities indicating some implicit phase transitions. These results were tested [48] and it was shown that larger (compared to those observed in Ref. 47) hard-sphere particles always crystallised at a volume fraction of 0.63 to 0.64. These values are close to the volume fraction of hard-sphere particles in a random close packing (0.644). A series of experiments with 1.03 μm poly(methyl methacrylate) particles stabilised by poly(12-hydroxystearic) acid was carried out to determine the limiting volume fraction of particles at which crystallisation of a dispersion of hard-sphere particles is possible.[49] The results obtained show that at a volume fraction of particles of 0.63 crystallisation still takes a reasonably short time; if the volume fraction of particles exceeded a value of 0.64, no crystals were formed.

Experiments with nanoparticles have opened yet another possibility of controlling the parameters of a colloid system. The nanoparticle size is comparable with the thickness of the protective shell. Experiments show that the structure of colloid crystals depends on the ratio of the chain length, L, of the ligand shell molecules to the particle radius. For saturated linear hydrocarbons, the chain length (in nanometres) is related to the number of monomeric units, n, as follows

$$L = 0.154 + 0.1265\,n. \quad (8)$$

Because of this, it is possible to obtain particles with a prescribed L/R ratio. Depending on the value of this parameter, the structures with the f.c.c. lattice (at small L/R ratios) or the b.c.c. packing of particles (at large L/R ratios) are formed. This is probably due to the fact that it is the f.c.c. lattice that is the most preferable in the case of hard spheres,[50] while the b.c.c. lattice is formed [51] if the potential of the interparticle interaction has a repulsive term (*e.g*., the Yukava potential) or some contribution that decreases in proportion to r^{-n} ($n < 6$). The mechanism of formation of ordered structures with the b.c.c. lattice from sterically stabilised nanoparticles is still to be clarified, because in this case the range of action of the repulsive potential is too short.

Korgel and Fitzmaurice [34] varied the size of gold nanoparticles stabilised by dodecanethiol or octanethiol and observed the f.c.c. – b.c.c. transition at $L/R = 0.59$ and 0.60, respectively. These values differ from that obtained for polymer micelles [52] but are close to the value determined for electrostatically stabilised colloids. [51] Calculations [34] of changes in the free energy upon the f.c.c. – b.c.c. transition were carried out assuming the Lennard-Jones potential of the interaction between nanoparticles and showed that this transition corresponds to $L/R = 0.65$ for the dodecanethiol-stabilised nanoparticles.

3. Coulombic systems

Dispersions of charged colloid particles behave as liquid metals. Such particles can be treated as ions, while the co-ions and counter-ions in solution can be considered as electrons. This is not a complete analogy because the size of colloid particles can be three orders of magnitude larger than the size of ions in liquid metals. Mixing of colloid particles of two different sizes significantly complicates the situation as compared to that in the single-component systems, because two new parameters appear, which determine the structure of the colloid dispersion, *viz*., the ratio of the particle diameters and the fraction of particles of a given sort in the mixture.

Experiments showed that if the particle diameters are close, a homogeneous crystalline solid solution is formed at any component ratio in the mixture. The solid solution is characterised by a finite shear modulus and the Bragg diffraction pattern, which is similar to that observed in the case of disordered substitutional alloys. At large differences between the particle sizes in the binary mixture, the system is either in the glassy state or in the crystalline state depending on the time interval available to reach the equilibrium state. For instance, it was found [53] that the dispersion of a mixture of polystyrene latex particles of sizes 110 and 54.5 nm is a disordered solid characterised by a finite shear modulus and non-Bragg diffraction pattern at the volume fraction of the particles of the minor fraction of greater than 5%. At the same time, the crystal structure is formed almost without no exception if the volume fraction of the minor fraction is less than 5%.

Disordered phases are also formed in dispersions of the mixtures of larger particles. For instance, the formation of a disordered phase in the system of particles of sizes 5 and 7 μm at the volume fractions of the larger particles between 10% and 90% was reported.[54] In these experiments, the disordered structure existed over a period of short observation time. If the colloid solution is allowed to stay for a rather long time, a crystal structure typical of intermetallic compounds is formed. However, the transition to crystalline state can take more than a year.[53] Four different intermetallic structures (of the $NaZn_{13}$, AlB_2, $CaCu_5$ $MgCu_2$ types) of binary mixture of spherical particles whose sizes varied from 200 to 800 nm were observed.[55, 56] The type of the crystal structure depends on the ratio of the particle diameters, on the volume fractions of different particles and on the total particle concentration. The attainment of equilibrium in such systems is a slow process and can take several years.

Thus, it does not always happen that the equilibrium in colloid systems can be achieved after passage of a reasonably short time. For this reason, conventional model experiments usually deal with metastable structures. Therefore, the glassy state of colloid dispersions rather than the formation of ordered structures similar to intermetallic compounds has been the subject of a rather large number of publications. Formally, the glassy state region of a colloid can be determined theoretically as the region corresponding to the existence of an intermetallic alloy in the equilibrium phase diagram.[57]

The thermodynamic parameters of colloid crystals can be calculated in a rather simple way. For instance, if the interparticle interaction is given by the pair potential (2), the free energy, F, of a binary system has the form

$$F = \frac{1}{2N}\sum_{i,j}\left\langle \frac{Z_i Z_j e^2}{4\pi\varepsilon_0\varepsilon r_{ij}}\left(\frac{e^{\kappa R_i}}{1+\kappa R_i}\right)\left(\frac{e^{\kappa R_j}}{1+\kappa R_j}\right)e^{-\kappa r_{ij}}\right\rangle + E_k - TS, \quad (9)$$

where $N = N_1 + N_2$ is the total number of particles in the system; the angular brackets denote the averaging over the canonical ensemble and summation is carried out over the lattice sites of the colloid crystal; E_k is the kinetic energy of the particles and the entropy, S, can be calculated using the known relationship [58]

$$S = 3k\sum_{i=1}^{2} x_i\left(1 - \ln\frac{\theta_i}{T}\right), \quad (10)$$

where $x_i = N_i/N$, $\theta_i = 2\pi\hbar\omega_i/k$ is the Einstein temperature [58] determined assuming that the particles of the first and second sorts execute oscillations at their eigenfrequencies ω_i.

The so-called dusty plasmas provide yet another group of examples of electrostatically stabilised colloid systems capable of forming ordered structures. These objects became the subject of research interest in the last decade. Dusty plasma is a sort of low-temperature plasma containing mesoscopic particles whose sizes range from a hundredth of micrometre to several tens of micrometres. Such plasmas are formed in the course of plasma etching and sputtering and in the combustion products, as well as existing near the space objects. Large plasma particles acquire a rather large charge (up to 10^5 e per particle), which is responsible for their strong, long-range repulsion. As a result, such particles form structures that are similar to those observed in liquids and solids.[59–63] In contrast to colloid systems, the mechanism of formation of ordered structures in dusty plasmas is still to be clarified. A feature of dusty plasmas is simultaneous action of the forces typical of the equilibrium systems and the forces due to the nonequilibrium state of the system. For instance, nonuniform temperature fields produce thermophoretic forces [64, 65] that are comparable in magnitude [66] with the electrical forces exerted on particles. Thermophoretic forces to a great extent govern the conditions for the formation, shape and geometry (arrangement) of the dusty plasma structures. Various models of such structures have been proposed.[67, 68] They are mainly based on the non-equilibrium state of dusty plasmas and predict realistic values of the parameters of crystals (they are close to those observed in the experiments) but sometimes include unsubstantiated admissions, which prevents the dusty plasma problem from being considered as solved. At the same time, numerical simulation of dusty plasmas is usually carried out assuming only the screened Coulombic potential of the type (2) for the interparticle interaction. Even with this limited set of the interaction parameters it is possible to predict [69] the existence of various structures in plasma.

4. Mixtures of sterically stabilised particles

Mixtures of sterically interacting colloid particles of different shape are characterised by a wide variety of the phase states and serve as well-defined models in studies of a broad spectrum of phenomena. The mixtures can be prepared in such a way that the major contribution will come from the interaction of particles considered as hard bodies (the thermodynamics of the system is governed by the entropy effects). Considerable attention is given to the systems prepared by adding various admixtures to monodisperse hard spheres. Smaller spherical particles,[70] globular non-adsorbable polymers [71] or rod-like colloid particles [72] are used as the second component. In most cases, the admixture is considered as an agent affecting the interparticle interaction. Such admixtures usually initiate attraction between particles, which is due to the presence of 'depleted layers.' The interaction following this mechanism can be explained with ease. We will consider it taking non-adsorbable polymers as an example (these are most often used for controlling the interaction between colloid particles).

Polymer molecules are separated from the surface of colloid particles by a distance of the order of the radius of gyration. The near-surface region free from the polymer molecules (more exactly, from the centres of mass of the macromolecules) is called

the depleted layer. As the colloid particles bring closer together, their depleted layers are overlapped and the volume accessible to the polymer molecules decreases. As a result, an excess external pressure is produced and applied to the particles; this is equivalent to the action of attractive forces.

The behaviour of mixtures of colloid particles and polymers (see, *e.g.*, Ref. 73) has been the subject of extensive literature concerning the corresponding theoretical models.[74] The phase diagrams constructed using the experimental data show the presence of the gas–liquid, gas–solid and liquid–solid transitions. The transition of the system to the nonequilibrium glassy state was also pointed out.[75]

The interaction due to the presence of depleted layers is typical of not only the mixtures of colloid particles and polymers but also the mixtures of colloid spherical particles of different sizes as well as the mixtures of spherical and rod-like particles. The potential of the interaction between large spherical particles dipped in a medium containing small spherical particles is given by the following approximate expression [76]

$$U(h) = -3kT\varphi\frac{R}{\sigma}\left(1-\frac{h}{\sigma}\right)^2, \tag{11}$$

where h is the distance between the surfaces of large spherical particles, φ is the volume fraction of small spherical particles, R is the radius of large spherical particles and σ is the diameter of small spherical particles. In the case of spherical particles of radius R (and rods of length L and diameter D) the depletion force potential has the form

$$U_{\mathrm{r}}(h) = -\frac{3}{2}kT\varphi\frac{L}{D}\frac{R}{D}\left(1-\frac{h}{L}\right)^3. \tag{12}$$

As can be seen, rod-like particles more efficiently 'tighten' large spheres. This was also confirmed in the experiments. The phase diagram of a mixture of spherical and rod-like colloid particles was constructed based on simple statistical considerations.[77] The results of experiments with the mixtures of 370 nm spherical silica particles and boehmite particles of length 230 nm and diameter 9 nm showed good agreement with the calculated phase diagram which included the gas–liquid, gas–solid and liquid–solid transitions. What is more, a two-step phase transition was observed. Namely, particle aggregation to give hard-sphere clusters was followed by a slower process of the formation of ordered arrangement of the clusters. In this case it is possible to draw an analogy to the phase transitions in the mixtures of hard-sphere particles of different diameters.[78] It was pointed out [77] that it was impossible to consider all the phase states of the system studied, because yet another, orientational, phase transition must be observed for the colloid dispersion of rod-like particles.[79] Calculations of thermodynamic parameters of the mixtures of spherical and rod-like particles should be carried out on the microscopic level [80] because of the key role of many body interactions. Relevant information can be found in the literature.[81,82]

Summing up, mention may be made that not only highly ordered structures but also liquid-crystalline phases can also be observed in colloid systems. The liquid-crystalline phases are formed in the dispersions of rod-like or plate-like particles as the dispersion concentrations increase. Onsager explained the transition between the isotropic and nematic phases occurring with an increase in the particle concentrations based on the entropy considerations [83] taking the phase transition in dispersions of plate-like clay particles, which was observed by Langmuir.[84] Then, analogous phase transitions were observed for many colloid systems; however, almost all experiments were carried out with rod-like particles (see, *e.g.*, Refs 85–88). New plate-like particles [gibbsite, $Al(OH)_3$, particle of thickness 20 nm and diameter 170 nm], in which the transition between the isotropic and nematic phases was observed, were obtained only recently [89] (the transition occurred even in the systems characterised by high polydisperse indices [90]). In polydisperse systems, the dispersions separated into two zones. In one zone, the isotropic phase was formed, while the nematic phase was formed in the other zone. The relative arrangement of the phases along the vertical axis (in the gravitational field) was determined by the dispersion composition. The experimental data are in qualitative agreement with the results of numerical simulation,[91] which gives the following conditions for the coexistence of the isotropic and nematic phases:

$$n_{\mathrm{i}}D^3 \cong 3.8,$$

$$n_{\mathrm{n}}D^3 \cong 3.9,$$

$$\frac{\Pi D^3}{kT} \cong 32,$$

where n_{i} and n_{n} are the particle concentrations in the isotropic and nematic phases, respectively, D is the particle diameter and Π is the osmotic pressure.

It should be noted that the matrix (dispersion medium) can also favour the formation of ordered structures (colloid and liquid crystals); here the matrix can be either a thermotropic [92] or lyotropic [93–96] liquid crystal.

5. Nonequilibrium processes

Recently, the focus of research activity in the field of colloid crystals has moved towards the investigations on the kinetics of phase transitions. In particular, the effect of the thickness of the stabilising shell on the growth rate of a colloid crystal was analysed.[97] Experiments were carried out with nearly 170 nm silica particles using various surfactants as stabilisers. This allowed the thickness of the adsorption layer to be varied from 2 to 50 nm. Colloid crystals were formed by centrifugation of dispersions. An increase in the thickness of the stabilising layer was accompanied by a dramatic increase in the rate of crystallisation. This can be explained by a decrease in the work done to form a seed crystal. The introduction of a non-adsorbable polymer into the system also led to a significant change in the rate of crystallisation. The depleted layers caused the interparticle attraction to strengthen, which favoured faster formation of colloid crystals.

Quantitative studies on the kinetics of the growth of colloid crystals were carried out taking electrostatically stabilised particles as examples.[98,99] It was found that the growth rate obeys the classical Wilson–Frenkel law

$$\upsilon^* = 1 - \exp\left(-\frac{\Delta\mu}{kT}\right), \tag{13}$$

where $\upsilon^* = \upsilon/\upsilon_\infty$ is the relative growth rate, υ_∞ is the growth rate at infinite supersaturation ($\Delta\mu = \infty$) and $\Delta\mu$ can be expressed through the chemical potential difference between the liquid and solid phases of the colloid dispersion at a given pressure p and temperature T

$$\Delta\mu = \mu_{\mathrm{f}}(p,T) - \mu_{\mathrm{s}}(p,T).$$

Theoretical estimates of the kinetic parameters of the crystal growth have been reported.[100] Calculations were carried out assuming the Yukava potential of the interparticle interaction [see Eqn (2)]. The phase coexistence curves obtained are in good agreement with the experimental data and the results of numerical simulation (see Ref. 101).

Taking into account an ordered arrangement of particles, the nonequilibrium macrocharacteristics of colloid crystals can also be calculated with ease. This was demonstrated taking calculations of the viscosity of colloid crystals as an example.[102] The viscosity was determined by numerically solving the system of hydrodynamic equations using the mapping method assuming a Newtonian fluid. Calculations were carried out for three cubic (simple, b.c.c. and f.c.c.) lattices. In this case, the viscosity is a

function of two parameters and the viscosity tensor takes the form (no summation over the repeating subscripts is performed):

$$(\eta_c)_{ijkl} = \frac{1}{2}\eta(1+\beta)\left(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk} - \frac{2}{3}\delta_{ij}\delta_{kl}\right) + \eta(\alpha-\beta)\left(\delta_{ij}\delta_{jl}\delta_{lk} - \frac{1}{3}\delta_{ij}\delta_{kl}\right).$$

At low volume fractions, φ, of particles, the coefficients α and β can be expressed by the following series expansions

$$\alpha = \frac{5}{2}\varphi\left[1 + A_\alpha\varphi + B_\alpha\varphi^{5/3} + O(\varphi^{10/3})\right]^{-1},$$

$$\beta = \frac{5}{2}\varphi\left[1 + A_\beta\varphi + B_\beta\varphi^{5/3} + O(\varphi^{10/3})\right]^{-1}.$$

The parameters A_α , B_α and A_β, B_β are listed in Table 1.

Table 1. Parameters determining the viscosity of a colloid crystal at low particle concentrations.

$-A_\alpha$	B_α	A_β	B_β
Simple cubic lattice			
3.78699	3.42673	0.85800	−2.286
b.c.c. lattice			
0.14079	−1.07874	−1.57281	0.71916
f.c.c. lattice			
−0.23611	−0.82315	−1.50926	0.54877

At large φ values, the viscosity depends on the volume fraction of particles in another manner. The coefficients α and β can be approximated as follows:

for the simple cubic lattice

$$\alpha = \frac{3}{16}\pi\chi^{-1} + \frac{27}{80}\ln\chi^{-1} + C_\alpha + D_\alpha\chi\ln\chi^{-1} + O(\chi),$$

$$\beta = \frac{1}{4}\pi\ln\chi^{-1} + C_\beta + D_\beta\chi\ln\chi^{-1} + O(\chi);$$

for the b.c.c. lattice

$$\alpha = \frac{1}{4}\sqrt{3}\pi\ln\chi^{-1} + C_\alpha + D_\alpha\chi\ln\chi^{-1} + O(\chi),$$

$$\beta = \frac{1}{8}\sqrt{3}\pi\ln\chi^{-1} + \frac{37}{120}\sqrt{3}\pi\ln\chi^{-1} + C_\beta + D_\beta\chi\ln\chi^{-1} + O(\chi);$$

and for the f.c.c. lattice

$$\alpha = \frac{3}{32}\sqrt{2}\pi\ln\chi^{-1} + \frac{87}{160}\sqrt{2}\pi\ln\chi^{-1} + C_\alpha + D_\alpha\chi\ln\chi^{-1} + O(\chi),$$

$$\beta = \frac{3}{16}\sqrt{2}\pi\ln\chi^{-1} + \frac{47}{80}\sqrt{2}\pi\ln\chi^{-1} + C_\beta + D_\beta\chi\ln\chi^{-1} + O(\chi),$$

here

$$\chi = 1 - \left(\frac{\varphi}{\varphi_c}\right)^{1/3},$$

and φ_c is the volume fraction of particles, corresponding to the dense packing of spheres. The values of the corresponding constants are given in Table 2.

The results obtained (dependences of the viscosity on the packing density of spherical particles) are in reasonable agreement with the experimental data.

Table 2. Parameters determining the viscosity of a colloid crystal at high particle concentrations.

$-C_\alpha$	D_α	$-C_\beta$	D_β
Simple cubic lattice			
2.85	−1.3	0.604	−0.30

1.83	−12.0	7.5	6.0
f.c.c. lattice			
9.54	14.0	7.4	−9.0

III. Self-assembly of nanoparticles at interfaces

1. Solid substrates

Nanoparticles possess the ability to form ordered self-assemblies both in the bulk of the dispersion [4, 103] and at interfaces.[4] Ordered layers of nanoparticles exhibit unique optical, electric, magnetic and catalytic properties.[104, 105] Recently, highly ordered colloid structures have been considered as candidates for optoelectronic devices,[106] photonic materials,[107] biosensors [108] and a new generation of memory devices. With nanoparticles it is possible to significantly shorten the time necessary for fabrication of nanoscale devices compared to, *e.g.*, electron-beam lithography (the ion-beam and X-ray lithography usually require massive equipment). Nanostructured surfaces are also required in studies of the interaction between cells and surfaces.

Depending on the character of the interparticle interaction (electrostatic, capillary, or van der Waals forces, biospecific recognition) and on the goal of a particular study, various methods of fabrication of ordered ensembles of nanoparticles are employed. It is possible to form two-dimensional and three-dimensional (3D) [24, 109, 110] ordered arrays of particles, as well as mesoporous structures and particle aggregates of specific shape. The properties of the systems obtained depend on both the characteristics of the particles (size, shape, composition) and the architecture of the ensembles (interparticle distance, structural hierarchy, *etc*.).

The simplest method of formation of ordered structures comprised of nanoparticles (see, *e.g.*, Ref. 111) is to evaporate a droplet of the nanoparticle dispersion deposited on the substrate, which causes the formation of a spatially ordered arrangement due to the capillary effects. The pioneering experiments involved fabrication of two-dimensional colloid nanocrystals by evaporating a droplet of a dispersion containing lyophobic particles, which was deposited on the substrate. This procedure was used to form the f.c.c. crystals from CdSe nanoparticles (see Ref. 111) and microscopic polystyrene particles (see Ref. 112).

The formation of a colloid crystal involves two stages.[113] First, seed crystals are formed from spheres under the action of capillary forces. Then, the solvent and spheres are supplied to the nuclei of the new phase in the course of evaporation of the liquid from the film at the peripheral area of the droplet. The formation of the colloid crystal is affected by the tilt angle of the substrate and the rate of solvent evaporation. The substrate must be tilted for nucleation to begin at the top of the droplet and for the crystal to grow on the substrate downward. Deformation of the droplet determines the limiting tilt angle for the substrate; it is related to the wetting angle hysteresis, while the capillary forces compensate the gravitational force. By changing the tilt angle it is possible to vary the parameters of the crystals grown.

Yet another important parameter is the rate of evaporation of the dispersion medium. Generally, the lower the rate of evaporation, the larger the colloid crystals that can be formed. The effect of the rate of evaporation was studied in detail.[114] Using video microscopy technique, it was shown that the particle attached to the edge of the crystal can be treated as mobile for some time, so

the freshly formed 'microcrystals' undergo rearrangements and experience reorientations on incorporating into the larger crystal. Rapid evaporation reduces the rearrangement time, thus resulting in the formation of polycrystals. The nature of the substrate also plays a significant role. For instance, the presence of hydroxyl groups on the surface of a glass substrate favours growth of larger crystals comprised of negatively charged colloid particles, because repulsion from the surface enhances their mobilities. In this case, growth of the crystals comprised of positively charged particles is strongly suppressed. Finally, an important role is played by the concentration of the dispersion medium. Knowing the droplet size, it is possible to estimate the concentration corresponding to the formation of a monolayer of particles on the substrate surface. However, in all model experiments we deal with the formation of multilayered crystals along the perimeter of the droplet. This is due to the fact that it is the peripheral area of the droplet where evaporation occurs more intensely; convective flows of the dispersion medium favour transfer of particles to that area. Therefore, fabrication of a monolayer requires that the actual particle concentration be higher than the corresponding calculated value.

Because of its simplicity, the droplet evaporation method remains quite attractive as yet.[115, 116] The technique was employed to grow colloid crystals comprised of the oxide,[117] sulfide,[118] noble metal [115, 116, 119, 120] and polymer [121] nanoparticles. Two-dimensional colloid crystals of nearly micrometre size were grown.[116] The methods developed to form ordered arrangements of the metal and semiconductor particles are also applicable to magnetic nanoparticles.[111, 122–125] In contrast to micrometre-size spheres, self-assembly of nanoparticles is governed by not only the entropy factor.[119, 126] Here, an important role is played by the particle–particle and particle–substrate interactions and by the nature of the stabiliser and binding agent molecules.[127]

The droplet evaporation method also involves self-assembly of particles on the mesoscopic level, namely, evaporation of large droplets leads to the formation of ring structures,[128, 129] which can be explained with ease [129] by analysing the hydrodynamics of the process. It should be noted that the use of more complex methods for the formation of ordered layers of nanoparticles sometimes causes [130, 131] complication of structural organisation on the mesoscopic level.

On the nanometre level, the degree of local order of the deposited nanoparticles is strongly dependent on the average particle size, because the larger particles are usually characterised by lower polydispersity [132] and are therefore more suitable for the formation of ordered structures. Such structures comprised of particles of size less than 2 nm are rare. Two-dimensional arrays of 'large' particles are characterised by orientation of the atomic lattices of nanoparticles relative to one another;[133] however, 3D-systems are usually disordered. At the same time, high-quality colloid crystals can be formed under particular conditions from particles of different size even using the classical scheme of fabrication of ordered ensembles *via* evaporation of a dispersion droplet. This was demonstrated taking alkylamine-stabilised gold nanoparticles as an example (see Ref. 134; the particle size varied from 1.8 to 8 nm). Using electron microscopy, a high degree of order of the nanoparticles in the colloid crystals was revealed, the atomic lattices of nanoparticles also being oriented in some way. Ordered structures were observed for both large and small particles organised into two- and three-dimensional arrays.

These results point out that the laws of self-assembly of particles to give ordered structures are still to be clarified. Therefore, the influence of various factors on the properties of the crystals formed from nanoparticles is studied. In particular, the effects of the temperature and initial particle concentration on the nucleation and growth of 3D-structures comprised of dodecanethiol-stabilised 5 nm silver nanoparticles were investigated.[135] Different methods of deposition of particle dispersions on the substrate were employed. In all experiments, 3D crystal structures were formed with good reproducibility. The average distance between the monolayers of spherical particles corresponded to the f.c.c. lattice or to hexagonal dense packing. Similarly to the case of monolayers, the size of the domains with ordered structure reduced as the temperature increased. This can be explained by the fact that faster evaporation of the solvent at elevated temperatures leads to shortening of the crystal growth time and the particles have no time to form ordered arrangements on large surface areas. As a consequence, fine-grained polycrystals are formed, which, by and large, corresponds to the situation with conventional crystalline substances.

However, the droplet evaporation technique has some drawbacks. There are (sometimes) irreproducible results and impossibility of fabrication of large ordered structures that are necessary in designing biosensors, biomaterials and catalysts. Large-area nanostructures are also necessary in creating functional bioactive surfaces. The nanoscale morphology of the surface strongly affects the interaction between the surface and cells and should be taken into account in the design of implants.[136]

Various methods are employed to control the nanoparticle–substrate interaction.[137–142] First of all, these are the ability of surfactant molecules to self-assemble on the substrate [143] and modification of substrates [140] by surfactant monolayers of different density to affect the structural organisation of the deposited nanoparticle layers. In some cases, substrates are covered [141, 142] with monolayers of the molecules (including dendrimer ones) containing the NH_2, CN and SH terminal groups, which are characterised by high affinity to metal particles.[141]

Particles are coated with bifunctional molecules [137–139] to bind them to the surface, which permits self-organisation of particles on the substrate surface [138] similarly to surfactant molecules. Using this method, it is possible to form rather stable structures comprised of nanoparticles. However, the procedure is of limiting use because the molecules used must form strong bonds with both the particle and the substrate.

In the early stage of studies on the self-organisation the formation of 3D colloid crystals faced some problems,[110, 144] though sometimes such objects were also formed by simply evaporating the dispersion droplets.[135] To enhance self-assembly of nanoparticles into three-dimensional crystals, electrochemical deposition of particles [145] and modification of their surfaces are employed.[144, 146, 147] Recently, it has been understood that this requires the use of special procedures that are determined by the nature of nanoparticles. For instance, two main methods employed to form ordered ensembles of gold nanoparticles are as follows. The first method involves the binding of gold nanoparticles *via* dithiol molecules, which form chemical bonds with two different particles through the terminal SH groups. By changing the alkyl chain length of dithiols, one can vary the constant of the nanoparticles' lattice.[148–153] According to the second method, ordered ensembles of nanoparticles are obtained from identically functionalised gold nanoparticles using a binding agent. Here, self-assembly of particles proceeds by the antigen–antibody reaction mechanism [154] or by the DNA binding,[155] hydrogen bonding [156] and complexation [157] mechanisms. The last-named technique is very often used to form hybrid inorgano-organic composites.[158] A comparative study of these two methods was reported.[159] Self-assembly of gold nanoparticles was performed using alkanedithiols and mercaptoaniline. In the latter case, succinyl chloride was added to the solution to control the bonds between NH_2 groups. Experiments with dithiols showed that nanoparticles on the substrate form a hexagonal lattice with a lesser degree of perfection than in the case of mercaptoaniline. This can be explained by faster aggregation of nanoparticles in the case of dithiols.

At present, a number of methods of fabrication of three-dimensional lattices have been developed. The next step is to perform targeted control of the structures of three-dimensional crystals to impart particular electrophysical and other characteristics to these objects.[160, 161] Recently, studies on the laws of formation of ordered structures in three-dimensional arrangements of polydisperse particles have begun.

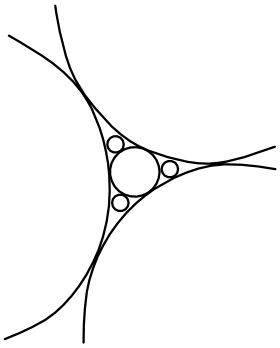

Figure 2. Ordered ensemble of polydisperse particles that form an Apollo figure.

The formation of cubic lattices in monodisperse systems of nanoparticles has been repeatedly pointed out. A bimodal ensemble of particles on the substrate can either undergo a separation into the components or form an ordered binary 'alloy'.[162, 163] Ordered structures in binary mixtures were also observed for two-dimensional systems.[164] Usually, the formation of ordered ensembles in polydisperse systems is thought to be impossible. However, numerical experiments[165] showed that the so-called Apollo figures (small particles fill the voids that form upon contact of large particles, see Fig. 2) can be formed in the systems characterised by 'hierarchical' polydispersity. Even more complex structures comprising polydisperse nanoparticles were observed in the experiments,[166] namely, the particles self-assembled into ordered structures in compliance with their sizes and the transition regions between the areas covered with particles of different sizes were smooth and defect-free. The formation of structures in ensembles of colloid spheres with controllable polydispersity was studied. The particle sizes varied between 5 and 50 nm. The ensemble of nanoparticles was prepared to provide a Gaussian particle size distribution with a polydispersity index of 30%. Particles were dispersed in an organic solvent and then a droplet of the dispersion was transferred on a solid substrate. Visual observations showed that after evaporation of the solvent the substrate surface is covered with large aggregates containing large particles in the central region and small particles in the peripheral regions. Within the aggregates, particles also form ordered arrangements (Fig. 3). The formation of such structures, which were called the 'Zenon clusters', was explained by the strength of the van der Waals interparticle interaction and by peculiarities of the fluid flow in the evaporating droplet.

A few theoretical studies on self-organisation of nanoparticles on substrates are available. Simulation[167] of particle deposition on solid substrates was carried out to study salient features of the structural organisation of nanoparticles that form upon electrochemical deposition on substrates.[29] Numerical experiments reproduced the situation corresponding to the binding of particles to the surface through bifunctional molecules and allowed the effect of polydispersity on the ordering of the particle monolayer to be studied.[168, 169] It was shown that the length of the binding agent molecule governs the particle layer morphology, which can correspond to the liquid, the hexatic phase or to two-dimensional crystal. Theoretically, the liquid–solid phase transition in two-dimensional system of hard disks has long been reported.[170] Recently, considerable attention has been given to the existence of the hexatic phase as intermediate between the liquid and crystalline phases[171] (for more detailed discussion, see below). Investigations on the effect of polydispersity on the two-dimensional phase transitions showed[169, 172, 173] that in polydisperse systems the liquid–crystal phase transition is shifted towards larger coverages and there is a limiting polydispersity value, starting from which no phase transition occurs. No hexatic phase is formed if the polydispersity index is rather high.[169]

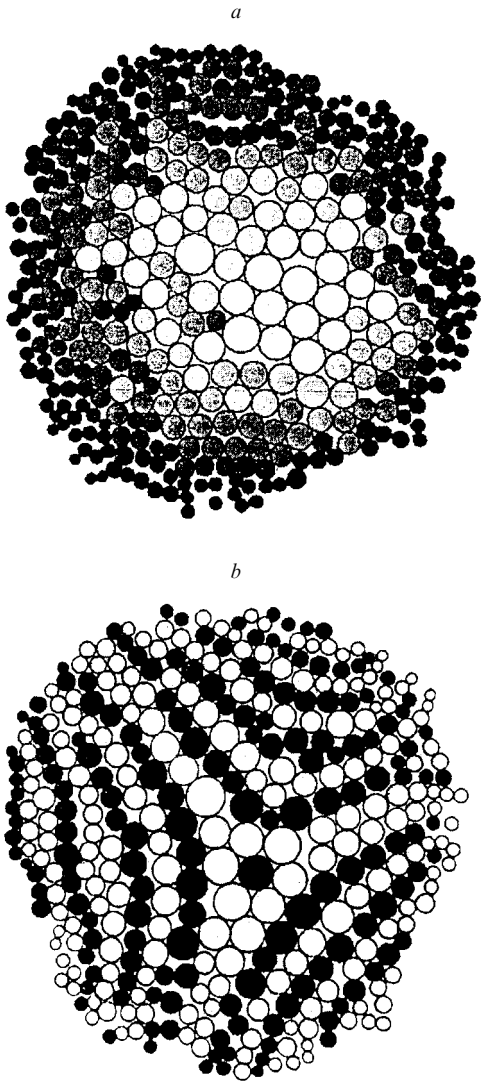

Figure 3. Ordered arrangement of polydisperse particles.[166] Experiment (*a*) and model (*b*).

Numerical experiments were also carried out to study peculiarities of the deposition of polydisperse nanoparticles on substrates in the case of random successive adsorption[174] and various packing types of particles in the monolayer at a given volume fraction of the particles.[175]

2. Non-spherical particles

The structural organisation of non-spherical particles on substrates corresponds to the cases reported in the literature[88, 176] and observed in bulk systems.[177–179] In the case of two dimensions, the phase behaviour is also governed by the maximum entropy condition. Various methods of formation of two-dimensional ordered structures comprised of non-spherical nanoparticles are developed. For instance, melt growth of silicon nanocrystals in the gap between two SiO_2 plates permits fabrication of ordered ensembles of such crystals with mutually oriented atomic lattices.[180]

It is possible to deposit rod-like cadmium selenide nanoparticles in such a way that their principal axis will be directed along the normal to the surface while the particles will be hexagonally packed in the plane of the substrate.[181] This way of packing nanoparticles imparts unusual optical properties to the crystal. Ordered ensembles of rod-like particles can also be fabricated by the droplet evaporation technique, which was demonstrated taking gold particles of length 55 nm and diameter

12 nm as an example.[182] The particle layers exhibited not only translational but also orientational symmetry. According to X-ray diffraction data, nanorods have a nearly identical crystallographic orientation at a length scale of the order of 500 nm. Namely, a total of 200 rod-like particles have the same crystallographic orientation (either [110] or [100]). This can be explained by the fact that nanorods on the {110} and {100} faces can be involved in the intercrystalline contacts.

The formation of ordered structures was attributed to the effect of capillary forces. If rod-like particles are oriented normal to the surface, the forces acting along the principal axis of the particles are greater than those acting in the transverse direction (for spherical particles, lateral capillary forces are proportional to the square of the particle radius).[183] This reason and the pressure applied to the particle monolayer [184] determined the packing of nanorods.

3. Effects of external fields

Self-assembly of particles (first of all, magnetic particles) can be favoured by the external fields. Most studies carried out in this field are concerned with the single-domain particles and their ensembles; however, data on the magnetic properties of ensembles of nanoparticles are strongly different. A possible reason for such discrepancies is the inhomogeneity of the ensembles studied. Because of this, increasing interest in the synthesis of ordered ensembles of magnetic particles has been expressed recently.[122, 123] Note that fabrication of ordered ensembles comprised of the nanoparticles that can be involved in strong interaction with external fields involves the formation of structures whose properties change under the action of external factors (the structures are usually similar to those formed by the 'inert' particles).

In contrast to the gold, silver and sulfide particles, no self-assembled three-dimensional ordered crystals comprised of magnetic cobalt particles are available as yet.[185] Usually, experiments resulted in structureless multilayered ensembles, which can be explained by magnetic interaction between nanoparticles. However, application of a magnetic field along the normal to the substrate led to the formation of two-dimensional structures [186] with hexagonally packed magnetic cobalt nanoparticles, which exhibited co-operative magnetic properties. Search for optimum methods of formation of ordered ensembles of magnetic particles is currently in progress.[187–189] The magnetic field can be used for both preliminary fractionation of nanoparticles and control of their self-assembly. For instance, evaporation of a droplet of a dispersion containing nanocrystallites of ferromagnetic or superparamagnetic cobalt on various substrates in a field of strength less than 1 T gave two-dimensional colloid crystals. An increase in the field strength up to 6 T led to the formation of three-dimensional crystals. The character of the structures obtained was independent of the size of the cobalt nanoparticles but changed with the change in the direction of the magnetic field. In some cases application of the magnetic field caused partial ordering of nanoparticles, which formed ensembles of isolated aggregates (points) or labyrinth structures.[185] The magnetic properties of the nanoparticle films differ from those of dispersions or bulk materials. This opens prospects for practical applications of the structures fabricated.

Deposition of 8 nm cobalt nanoparticles from a droplet of dispersion on the substrate (highly oriented pyrolytic graphite) at different orientations of the external magnetic field was studied.[190] If the field was directed normal to the substrate, evaporation of the dispersion medium led to the formation of a hexagonal arrangement of nanoparticles. If the field was directed along the substrate surface, aligned nanoparticle 'filaments' with nearly equidistant separation were formed. The lattice constant and the filament width depended on the magnetic field strength and decreased as the field strength increased. The 'filaments' were nearly 2 μm thick. This is close to the size of the 'points' at the sites of the hexagonal lattice formed upon deposition of nanoparticles in the field directed normal to the substrate.

A way to fabricate ordered colloid structures is to expose a colloid system to the standing electromagnetic waves created by interfering laser beams.[191] Colloid particles placed in the field of the standing electromagnetic wave can be considered as being in the potential

$$V_e(r) = -\frac{1}{2}\chi_p E^2(r),$$

where χ_p is the particle polarisability and $E(r)$ is the electromagnetic field strength at a given point. By varying the fringe pattern it is possible to change the structure formed from colloid particles. A number of nonlinear effects were observed at rather strong external electromagnetic fields. For instance, a colloid liquid compressed by an electromagnetic wave experienced a phase transition (crystallisation).[192] Often, the structures created using laser radiation are used to study the dynamics of colloid particles, *viz*., the diffraction characteristics of the probe beam are used to determine the spreading velocity of the structures, which allows the dynamic characteristics of the colloid dispersions to be determined.

Two- and three-dimensional colloid structures were also formed using the field of external mechanical forces.[193] On the glassy substrate covered with a thin layer of poly(methyl methacrylate), a system of grooves was created, which had the shape of stripes or rectangles. The plate was dipped in the colloid solution of poly(methyl methacrylate) spheres stabilised by 12-hydroxystearic acid. Then, a non-adsorbable polymer was introduced into the system. The polymer produced a pressure (by the depleted layer mechanism) to press the particles against the surface of the 'puckered' substrate. This resulted in the formation of ordered structures on the substrate. The particle size was either smaller or larger than the intergroove separation. Depending on the particle size, the structures had different symmetry (from linear to hexagonal). In the latter case, successive multilayered deposition of particles gave a f.c.c. crystal.

4. Gas–liquid interface

In the text above, we considered the main methods of fabrication of ordered arrangements of nanoparticles, namely, the droplet evaporation method and self-assembly due to modification of nanoparticles by bifunctional molecules. Both of them have some drawbacks. The first method gives poorly reproducible results, while practical implementation of the second procedure requires that particles be rather strongly bound to the substrate. In both cases, ordered structures are obtained only from the particles with specific ligand shells. The reactivity of particles, electron transfer between them, the ability of particles to participate in various physicochemical processes depend on the nature of the ligand shell. For instance the electrical conductivity of thiolate-stabilised gold nanoparticles can be substantially enhanced upon replacement of the alkanethiol ligands by bifunctional molecules (*e.g*., molecular wires). Electron transfer also depends on the character of the chemical bonds between the ligand shell and the metal core (the Au–S bond in thiolate molecules). It was established [194] that some thiolate ligands used to obtain metal nanoparticles can be replaced by other ligands, which opens up great prospects for variation of the functional properties of nanoparticles and their ensembles (surprisingly, ligands exhibit some mobility on the particle surfaces). In this connection we can say that a new research avenue, *viz*., the 'tuning' chemistry, is now in the early stage of its development. Research in this field requires the elaboration of such methods for fabrication of ordered nanoparticle layers that are almost independent of the nature of the ligand shell. The Langmuir–Blodgett method meets this condition.

Probably, it was Nagayama *et al*.[195, 196] who first employed the Langmuir–Blodgett method to this end. To form self-organised layers of polymer nanoparticles, they proposed to use the capillary forces, which are due to the meniscus between particles,

belong to attractive forces and can therefore favour self-assembly of crystals from nanoparticles.

Owing to the capillary forces, the Langmuir – Blodgett method also permits the formation of ordered particle monolayers on vertical surfaces; removal of the plate from the colloid solution and subsequent evaporation of the solvent causes the formation of ordered arrangements of particles. This method works well for the particles of size less than 400 nm, because larger particles precipitate under the action of the gravitational force faster than the solvent evaporates. However, sedimentation can be suppressed by, *e.g.*, applying a temperature gradient to the meniscus (such a gradient causes a convective motion of the fluid, which hampers sedimentation of particles).[197]

Hydrophobised nanoparticles can also be organised at the air – water interface and assembled in multilayered structures using the conventional Langmuir – Blodgett technique. Self-assembly of such particles at the interface is also possible in the absence of the ordering effect of the Langmuir surfactant monolayers, while hydrophobisation as such can be achieved in the course of particle formation in the organic medium.[198] This technique was employed in the fabrication of ordered arrangements of various metal and oxide nanoparticles [199–208] and bimetallic particles.[209] Bimetallic nanoparticles were obtained [209] immediately in the subphase and then, after special treatment, came to the surface. The Langmuir – Blodgett method can also be used for the formation of heterocolloid layers.[210, 211]

The Langmuir – Blodgett technique allows the particle size to be varied from several to several tens and even hundreds of nanometres. Nanoparticles can be stabilised using various compounds [212] and form a variety of structures on the surface of the liquid phase.[213] The hexagonal structure, which is usually formed at high monolayer pressures, remains after transfer of the monolayers to solid substrates. The degree of local order in the particles strongly depends on the stabiliser type. In the case of charged particles, the character of their packing is affected by the pH value of the solution. Under particular conditions, wire structures are formed.[214, 215] Usually, the compression isotherms of nanoparticle monolayers do not reflect structural peculiarities (see, *e.g.*, Refs 216 and 217, where both the particle size and the parameters of the stabiliser molecules were varied). At the same time, they exhibit hysteresis, the width of the hysteresis loop being dependent on the compression – expansion rate.

Practical implementation of the Langmuir – Blodgett method is complicated by the problem of fabrication of extended ordered structures. Similarly to compression of surfactant monolayers, compression of a monolayer of nanoparticles causes the formation of a domain structure, the particles being ordered only within domains. To some extent this problem can be considered solved.[218] Rather large ordered structures were fabricated due to particle aggregation caused by an increase in the system's temperature. On raising the temperature, convective flows are induced on the surface of the liquid phase and displace particles towards the growing two-dimensional crystal. Intense convection and capillary waves favour a rapid escape of defects from the growing crystal, which results in extension of the ordered structure.

Ordered structures can be transferred from the surface of the liquid phase to the solid substrate without significant distortion of two-dimensional crystal order (see above). However, the growing ensembles of nanoparticles are unstable, especially if monolayers are transferred at rather low surface pressures. This is due to weak particle – particle and particle – substrate interactions. Therefore, methods for improving the stability of nanoparticle monolayers are required. One of them is to modify the existing layers.[219] However, more efficient is the procedure for fabrication of stable monolayers from nanoparticles bound through bifunctional molecules,[220, 221] *e.g.*, dithiols (remember that these compounds are used [147] to form three-dimensional ordered structures) using the Langmuir – Blodgett method. By chemically binding nanoparticles it is possible to obtain rather stable ensembles. For instance, nanoparticles stabilised by alkanethiols (C_6 – C_{12}) can be strongly bound by arenedithiols at rather high monolayer pressures.[220, 221] To form two-dimensional structures, nanoparticles and the solid dithiol were simply placed in contact on the surface of the aqueous phase. Nanoparticle binding occurred due to the exchange reaction between dithiol and thiol that forms a protective layer on the particle surface. Transmission electron microscopy (TEM) studies showed that particles form two-dimensional layers with hexagonal packing. The interparticle distance was determined by the length of the binding agent molecule (dithiol), being virtually independent of the length of the stabiliser molecules.

If ordered arrangement of particles in the monolayer is not required, the Langmuir – Blodgett procedure is significantly simplified. At the same time, it permits fabrication of layered structures from nanoparticles [222] with the interlayer spacing, which is determined by the thickness of the ligand shell. According to data of X-ray diffraction studies, such layered structures exhibit a rather high degree of perfection.

Practical implementation of the Langmuir – Blodgett method in the case of magnetic particles faces some problems. Attempts at using this technique in experiments with iron oxide particles protected by fatty acid layers led to the formation of inhomogeneous films [223, 224] (multilayered ferroparticle films were also formed).‡ A procedure for fabrication of two-dimensional ensembles of magnetite (Fe_3O_4) and cobalt ferrite ($CoFe_2O_4$) particles stabilised by oleic acid was reported.[225] The particles were characterised by a broad size distribution. They were fractionated and fractions with narrow size distributions (particle size range 2 to 10 nm with a scatter of 10% to 20%) were isolated. Dispersions of the particles in octane or heptane were placed on the surface of water and the solvent was evaporated at 80 °C. The degree of order of the structures formed was particle size dependent, namely, larger particles (6 nm) formed ordered 'crystals' while small particles (2 nm) formed disordered structures. The size of the ordered areas reached several micrometres.

The Langmuir – Blodgett method can also be applied to non-spherical particles, which form a greater variety of ordered arrangements. The self-assembly technique was employed to obtain three-dimensional structures comprised of anisotropic $BaCrO_4$,[226] FeOOH [227] and CdSe [181] particles stabilised by oleic acid, as well as gold [182] and silver [228] nanorods. The formation of structures from rod-like $BaCrO_4$ particles of length 20 nm and diameter 5 nm was TEM monitored to follow the effect of the monolayer pressure on the organisation of particles.[229] At low pressures, 'raft'-shaped isotropic particle aggregates were observed. As the pressure increased, the 'rafts' formed the two-dimensional nematic phase, then the smectic phase and, finally, the three-dimensional nematic phase (Fig. 4). These changes in the structural organisation correspond to the Onsager scheme, according to which the ordering processes are responsible for an increase in entropy due to a decrease in the volume per particle.

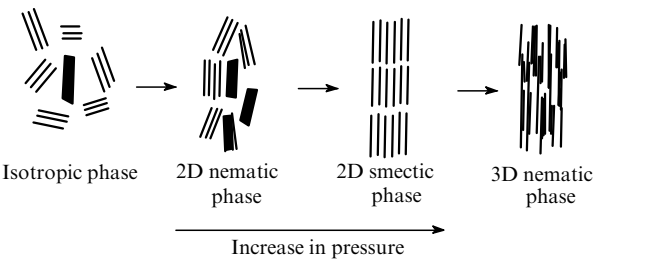

Figure 4. Structural rearrangement of the monolayer of rod-like particles upon an increase in the surface pressure.[229]

‡ Taking into account successful experiments with gold particles, these results seem to be quite unexpected.

5. Liquid – liquid interface

Self-assembly of particles can also occur at the liquid – liquid interface. It was shown that liquid-like colloid silver films can be obtained at the interface between the organic (dichloromethane) and aqueous phases.[230] However, these films are insulators.[231] More recently,[232] similar films were formed from both electrostatically and surfactant-stabilised gold nanoparticles. The formation of ordered structures nanoparticles at the liquid – liquid interface was also reported.[233]

Gold nanoparticles at the interface between the organic and aqueous phases can be immobilised by introducing aromatic molecules (*e.g.*, benzene or anthracene, which are strongly bound to the particle surfaces) into the organic phase.[232] In the case of anthracene the nanoparticle film formed at the liquid – liquid interface is a highly elastic membrane. Films can be transferred to the solid substrate by simply evaporating the contacting solvents. A detailed study on the mechanism of formation of such films showed [234] that the benzene and anthracene molecules are strongly bound to the gold particles due to the π-interaction with the gold cations present on the surface of nanoparticles and that ordered structures cover rather large surface areas.

Ordered layers of nanoparticles at an interface between two immiscible liquids can also be formed by chemical reduction immediately at the interface. For instance, interfacial reaction between an aqueous solution of cadmium carbonate and a solution of carbon disulfide in carbon tetrafluoride resulted in the formation of multilayered films comprised of cadmium sulfide nanoparticles of size from 1.8 to 3.9 nm.[235]

The thermodynamic properties of the particle monolayers were studied taking the monolayers of 2.6 μm polystyrene latex particles at the octane – aqueous surfactant solution interface.[236] In this system under particular conditions it is possible to form ordered interfacial structures, which represent hexagonally packed monolayers of particles with a polycrystalline structure. The monolayer compression isotherm exhibited no features. It was found that the pressure necessary to destroy the monolayer coincided with the interfacial tension at the interface between the above-mentioned liquids in the absence of particles. Destruction of the monolayer occurred by bending rather than transfer of particles to a certain phase. A similar phenomenon was observed [237] for the Langmuir monolayers of negatively charged latex particles of size 0.2 to 2.6 μm at the air – water and octane – water interfaces. The structure of the monolayer at the surface of water is sensitive to the electrolyte concentration. At low electrolyte concentrations, an ordered ensemble of hexagonally packed nanoparticles was formed; an increase in the concentration led to particle aggregation and the formation of disordered structures. At the octane – water interface, a hexagonal packing was formed at low surface pressures and a rhombohedral arrangement was formed at elevated pressures; the electrolyte concentration had little effect on the degree of local order of the monolayer.

6. Layer-by-layer deposition of nanoparticles

The method of layer-by-layer deposition developed [238] as an alternative to the Langmuir – Blodgett method involves successive immersion of a substrate into a dispersion of particles and into a solution of oppositely charged polymer or surfactant. To form polylayers of nanoparticles, this technique was first employed [239] in order to obtain stable ultrathin films comprised of alternating layers of the polyelectrolyte and semiconductor particles. The films appeared to be more stable than those formed using the Langmuir – Blodgett method. Yet another important advantage of the layer-by-layer deposition technique is that films can be deposited on substrates of any size and shape. However, similarly to the Langmuir – Blodgett method, the interparticle interaction is hard to control.

The layer-by-layer deposition method can be applied to obtain various structures.[240, 241] The absorption of the perfect films formed by this method increases linearly with their thickness in the visible and UV spectral regions, which means that all particle layers are characterised by the same packing density. High quality (constant period) of the films prepared by the layer-by-layer deposition is illustrated in Fig. 5, where the SAXS intensity is plotted *vs.* the angle of incidence. If nanoparticles are involved in strong electrostatic and dispersion interactions, the deposition of the polymer layer only slightly disturbs the structure of the ensemble. Immobilisation of particles makes it possible to create strongly inhomogeneous films by deposition of different polymer – particle bilayers in a specified order. By changing the order in which layers are deposited it is possible to impart particular functional properties to the films. Yet another advantage of the layer-by-layer deposition method is the possibility of formation of structures that are inhomogeneous in different directions. For instance, the preparation of gradient composite films of CdTe nanoparticles was reported.[242] The size of the films increased with their thickness. Such films are thought to be promising as elements of photodetectors, bipolar transistors and other high-speed electronic devices. They behave in an unusual manner upon injection and charge transport and can be used as light traps. Fabrication of these films using conventional methods based on molecular beam epitaxy or plasma-enhanced chemical vapour deposition requires various tricks (see, *e.g.*, Refs 243 and 244). The gradient films mentioned above [242] were prepared using four types of particles of size from 2 to 6 nm, which exhibit the luminescence bands in the 495 – 505, 530 – 545, 570 – 585 and 605 – 620 nm regions (from the red to green spectral region), thus providing a broadband luminescence spectrum. Note that the layer-by-layer deposition technique also permits fabrication of ordered layers of nanoparticles with a prescribed particle concentration gradient in the plane of the monolayer.[245]

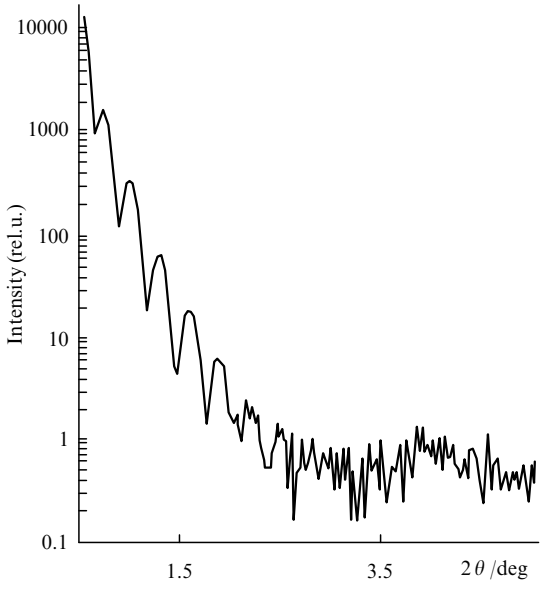

Figure 5. SAXS intensity by the polylayers of particles fabricated by layer-by-layer deposition plotted *vs.* angle of incidence.[241]

7. Biosystems and polymers

One way of development of methods for fabrication of colloid nanocrystals involves stabilisation of nanoparticles using some molecules that have binding sites. Such sites serve as specific 'pointers' of the positions to which other nanoparticles must be attached. On mixing, nanoparticles of one dispersion are linked to particles of the other dispersion through these sites. This permits the formation of a desired architecture of the colloid crystal. In this connection considerable attention is paid to aggregation of nanoparticles that are involved in biospecific interaction.[153, 154, 246 – 251] Interest in the studies of such objects is also

due to great prospects for their application in both microelectronics and biology.

The strategy of using biomolecules is based on their ability to interact with nanocrystals that have various active sites. As biomolecules are introduced into the system, the sites are recognised and a particular arrangement of nanocrystals is formed. Even replication of ensembles of nanoparticles is possible. To this end, it was proposed to use gold nanoparticles covered with adlayer of biotin (more exactly, a sulfur-containing analogue of biotin).[252] As streptavidine (this compound binds biotin) is introduced into the solution, aggregation of gold nanoparticles occurs (Fig. 6). The particles within aggregates are separated from one another by the distance equal to the bond length of the biotin and streptavidine molecules. The diffraction pattern exhibits several maxima, thus revealing some ordered arrangement of particles within aggregates.

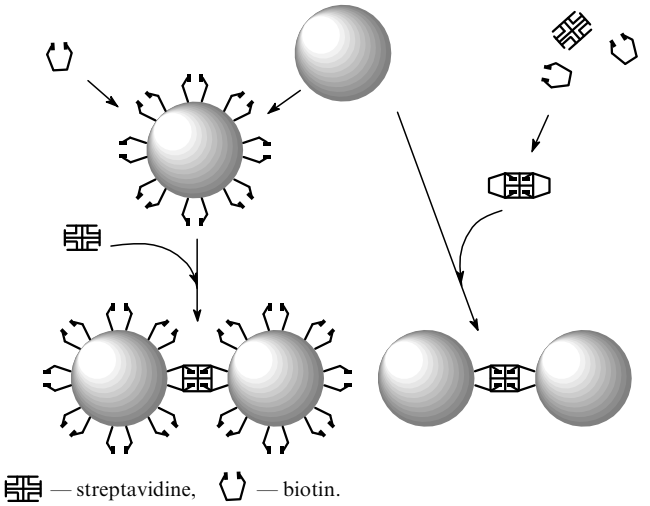

Figure 6. A scheme of aggregation of nanoparticles involving streptavidine molecules.[252]

A procedure for fabrication of gold nanoparticles stabilised by a chemisorbed monolayer of a dodecanethiol derivative and dibenzo-24-crown-8 was reported.[253] Such nanoparticles can recognise dibenzylammonium cations in solution and add them to form a pseudorotaxane shell. Therefore, introduction of bis(dibenzylammonium) into the dispersion of stabilised gold particles causes aggregation due to the assembly of the pseudorotaxane molecules. This approach was employed to study the laws of aggregation of gold and silver nanoparticles.[254]

An analogous procedure was used to obtain ordered (i) monolayers and multilayered structures on substrates and (ii) aggregates in the bulk of solution using proteins,[255] organic molecules [256–259] and polyelectrolytes.[260] Of particular interest is to use DNA molecules for binding particles, because this permits the interparticle distance, period of the particle arrangement and the aggregate compositions to be programmed by choosing a particular amino acid sequence in the DNA molecule.[246, 261–263] In this case, it is also possible to affect the optical characteristics and the melting temperatures of the particle aggregates. Studies on these effects will allow nanoparticle aggregates to be widely used as elements of biosensors. This can be exemplified by the development of a new method of DNA detection using oligonucleotide-functionalised nanoparticle probes.[246, 261, 264, 265] The method is based on the use of two different DNA-complementary oligonucleotides. As the probe meets the DNA molecule and aggregation occurs, the red dispersion turns purple. The change in the colour is due to the interaction between plasmons in the aggregated particles.[262, 266, 267]

This approach differs from other DNA hybridisation methods by enhanced selectivity, which is due to the well-defined melting point of the material fabricated from the oligonucleotide-functionalised gold nanoparticles linked through DNA molecules. The melting transitions in colloid crystals of different sizes formed on silica substrates were studied.[268] Crystals were obtained from 13 nm gold nanoparticles functionalised by various nucleotides. Structures containing different number of layers were formed. Raising the temperature caused breakdown of the adlayer structures due to the melting of nucleotides; the melting temperature depended on the number of the deposited particle layers. The temperature-dependent structure breakdown was found to be reversible; the sharpness of the transition was governed by the number of the layers deposited, while the transition region was nearly three times narrower than in the case of melting of nucleotides in the absence of particles. This narrowing is probably due to the co-operative effect.

It was proposed [269, 270] to use biosystems as substrates for fabrication of ordered colloid ensembles. For instance, latex particles were physically or chemically deposited on a giant lipid vesicle.[269] A single deposited particle deformed the surface of the vesicle and occupied the position corresponding to the highest curvature of the surface. This behaviour can be predicted with ease taking into account the energy expenditure for the deformation of the vesicle. If many particles are deposited, the interparticle interaction is determined by the attractive forces that are also related to the deformation of the vesicle. They cause particle aggregation and the formation of a quasi-two-dimensional hexagonal structure.

A procedure for fabrication of ordered structures, which involves the use of natural two-dimensional crystal order of bacteriorhodopsin molecules, was proposed.[270] This protein forms both *in vivo* and *in vitro* self-organised ordered structures that are called 'purple membranes'. Crystals of bacteriorhodopsin are used as specific templates for fabrication of ordered structures from nanoparticles.

IV. Template methods

1. Template techniques

Recently, methods of increasing the length scale of structural organisation of inorganic materials have been intensively developed. There are several ways of increasing the length scale to which the structural organisation of the assemblies fabricated is extended. One of them involves preliminary formation of 'building blocks'. This approach to fabrication of organised materials was called 'nanotectonics'.[271] Various schemes of practical implementation of the nanotectonics strategy involving biomaterials have been considered.[217] Design of such structures is to a great extent based on the principles of biomimetism (Biomimetic Materials Chemistry). Fabrication of hierarchically ordered structures is of interest for catalysis, materials science and development of resolution methods. Based on the biomimetic principles, some advances were made in creating inorganic materials with prescribed shape, molecular orientation and polymorphous crystal structure.[272] A number of methods for the synthesis of structures of a rather complex shape [273] and highly ordered hybrid ensembles [274, 275] that resemble natural hierarchical structures [276] were also developed. However, these structures are mainly of theoretical interest. More convenient for practical purposes are the 'classical' templates and first of all those based on micro- and nanospheres.

Nanosphere-based templates are used in lithography (see below) and for preparation of composite materials with ordered structure or porous metals with an ordered pore system. Porous metals are necessary for many practical purposes, *e.g.*, production of filters, catalysts, various carriers, heat transfer agents, fuel cells, electrochemical cells, thermal screens and vibration dampers. Often, porous metals with very large specific surface areas are required. Such metals can hardly be obtained by conventional

methods (sintering of powders, production of wires, foaming, *etc*.). This problem can be solved using the method of colloid templates,[277–286] which involves the formation of an ordered structure from spherical particles followed by filling of the interparticle space with the desired material (in particular, metal). The fact that usually the spherical particles contact one another allows them to be completely etched; as a result, a system of ordered spherical voids (the so-called inverted opals) is formed. This permits fabrication of materials with large specific surface areas, three-dimensional ordered pore systems and the pore sizes of several hundreds of nanometres. The pore system is an open system and possesses unique transport properties; these materials are also of considerable interest for photonics [287] (see below).

The technological procedures for fabrication of such materials are based on various methods. For instance, porous structures from Ni, Cu, Ag, Au and Pt were obtained [280] using chemical reduction, colloid crystals (silica) as templates and metal nanocrystals as catalysts. To form 'inverted' colloid crystals from gold the space between large particles was filled with gold nanoparticles.[277] Electrochemical reduction of metals was also employed. Three-dimensional porous crystals were fabricated *via* thermal decomposition of metal (Ni, Co, Fe) salts.[279] Templates are removed using various methods; the properties of the material obtained are strongly dependent on the procedure for template synthesis.

This approach was also used to form ordered structures of metal particles.[288] To this end, a non-metal (*e.g*., oxide) porous matrix was fabricated, which was filled with metal and then etched. This scheme can be used for preparation of ordered structures from not only metals and alloys but also semiconductor materials (see, *e.g*., Refs 289 and 290).

Porous membranes and ensembles of carbon nanotubes are also widely used as templates. In this case, either particles of irregular shape distributed within narrow channels or nanorods are formed.[291–293] It is also possible to obtain ensembles of rather complex composition and morphology. This approach was employed for the synthesis of polymer–cadmium sulfide composite nanowires [294] and various nanotubes [295–297] including those filled with metals [297, 298] (recently, considerable attention has been given to such objects, see review [299]).

Nanorods are most often formed using anodised porous alumina layers as templates. The pore diameter in these templates varies over a wide range (from 5 to 300 nm), the pore length exceeds 100 μm and the pores themselves are characterised by good linearity. Methods of fabrication of alumina templates have been well developed.[300, 301] Using these templates, it is possible to obtain composite materials with various nanowires [302–308] and fill almost all pores up to a depth of 100 μm (usually, only 10% to 20% of the pore space volume is filled) by employing specific procedures.[308] X-Ray studies showed that nanowires formed within the matrices have a crystal structure while their diameter is governed by the pore size. Ensembles of metal nanowires were also obtained using mesoporous silica SBA-15.[309]

Ordered ensembles of metal nanoparticles can be fabricated [310] with mesoporous silicas with an ordered pore structure, *viz*., MCM-41 (hexagonal structure) and MCM-48 (cubic structure). Silica is washed with the solution of a salt of the corresponding metal and then heat treated to form metal nanoparticles within the pore space. At elevated temperatures, the metal nanoparticles go to the outer surface of silica, thus forming an ordered lattice whose structure reproduces the two-dimensional pore structure of the silica template.

Ordered ensembles of nanoparticles can also be obtained by metal reduction in the 'micelles' of block copolymers, which can have a well-organised spatial structure. A procedure for fabrication of gold nanoparticles in laser irradiated copolymer of styrene and 4-vinylpyridine was considered.[311] The results of an experimental and theoretical study of the chemical method of preparation of lead sulfide nanoparticles in films of the same microseparated block copolymer were also reported.[312] The studies on the synthesis and properties of nanoparticles of different nature in polymer matrices were reviewed.[313]

Gel matrices of mixtures of a polyelectrolyte, surfactant [314] and organosilicon polymer [315, 316] are similar to the block copolymer matrices. They were used to obtain ordered ensembles of gold and platinum nanoparticles *via* chemical reduction. By varying the parameters of the microscopic gel network the particle size and the spatial distribution of the particles can be changed with ease.

2. Nanolithography methods

Not only the formation of colloid crystals but also fabrication of large ordered patterns from colloid ensembles is of considerable interest. Such patterns are prepared using a variety of methods, *viz*., lithography,[317] microcontact printing,[318] self-assembly involving polymers,[319] bidentate molecules,[320, 321] evaporation [322–324] or selective wetting.[325, 326] Various lithographic techniques allow one to obtain structures with prescribed geometric distribution, size and shape of the primary elements. The methods employed in the field include electron beam lithography,[327] X-ray lithography,[328] ion-beam lithography [329] and photolithography. The last-named technique is most widely used but, unfortunately, is unsuitable for the formation of structures whose elements are smaller than half the wavelength in the visible region. The region with $\lambda < 300$ nm is accessible to UV lasers [330] and holographic interferometry [331] only. The electron, ion-beam and X-ray lithographies cover the nanometre region; however, wide use of these methods is impossible as yet. The formation of ordered structures using heteroepitaxy of metals [332] and semiconductors [333] also faces some difficulties.

It was proposed [334] to use ordered arrangements of colloid particles as lithographic mask. This method was employed by many researchers. The possibilities of the technique were significantly extended.[335–338] It was shown that the use of two layers of spherical colloid nanoparticles allows the method of fabrication of nanostructures to be significantly simplified and the patterns formed to be diversified. The modified method permits fabrication of nanostructures comprised of different materials on various substrates. According to the data of atomic force microscopy studies, the type of the structure formed can be predicted with ease based on geometric considerations. This method allows the particle size to be varied with ease, thus changing the optical properties of the particles.[339]

A combined technique was also proposed.[340, 341] Patterns comprised of ordered gold nanocrystals were created with an electron beam. First, an ordered arrangement of gold particles was formed on the silicon nitride substrate by the droplet evaporation method. Then, the monolayer was exposed to an electron beam to destroy the protective ligand shell. This led to stronger binding between the particles and the substrate on the electron-beam patterned area of the substrate. The unbound particles were removed from the substrate with a solvent; as a result, the substrate was patterned in the desired manner.

Recently, the method of microcontact printing has been intensively developed. The technique involves fabrication of a pre-patterned stamp followed by transfer of the pattern (nanoparticles) to the substrate [325, 342] and permits the use of substrates of any nature.

Scanning tunnelling and atomic force microscopies are also used to obtain ordered structures. For instance, patterning was done by etching an organosilane monolayer from the substrate using a scanning tunnelling microscope (STM).[343] This was followed by nanoparticle deposition on the etched areas. A similar procedure was employed [320] to obtain ordered arrangements of gold nanoparticles with an atomic force microscope (AFM), which was used for detection of the STM-etched area and subsequent particle transfer to this area. An AFM was used to fabricate two-dimensional and three-dimensional ordered structures.[344] The technique was improved,[345] namely, deposition of 3 nm gold particles on a pre-treated surface area was followed by the formation of ordered structures using an AFM and then by

post-growth of the particles *via* immersion of the substrate in a $HAuCl_4$ solution.

Particular emphasis should be placed on the so-called dip-pen nanolitography technique,[346–349] which allows one to deposit films comprised of both organic molecules containing thiolate groups and nanoparticles on the surface of gold substrates. The method involves the spontaneous condensation of molecules or particles in the gap between the AFM tip and the substrate (Fig. 7); by scanning the surface it is possible to create the desired pattern. In the dip-pen nanolithography scheme, the microscope tip, organic molecules and substrate play the roles of 'pen,' 'ink' and 'paper,' respectively.

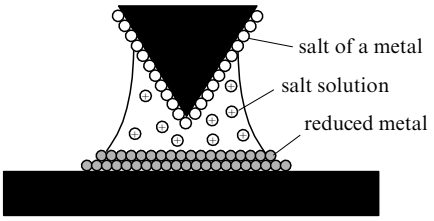

Figure 7. A scheme of dip-pen nanolithography.[349]

A method of preparation of gold 'ink' was proposed.[348, 349] This can be done using both electrochemical reduction of gold and a procedure which does not require a voltage to be applied to the microscope tip. According to the method, the microscope tip is preliminarily covered with a salt of gold and then a nanodroplet of water is placed within the gap between the salt and the silicon substrate. Dissolution of the salt as well as the metal reduction and deposition on the substrate proceed in the absence of special treatment of the system. The gold layer formed in the course of reduction was 0.4 – 1 nm thick. Details of the mechanism of gold reduction are still to be clarified; however, it was pointed out that no reduction of gold proceeds on the silica substrates. By appropriately choosing the salt – substrate pair it is possible to obtain structures from various materials.

3. Nanosphere lithography

Ordered arrangements of metal and semiconductor nanoparticles are usually fabricated by lithography techniques using planar substrates. Recently, a new trend has been towards deposition of ordered arrangements of nanoparticles on the surfaces of organised larger spherical particles. Such systems are of interest in studies on the Raman scattering and photoelectrochemical catalysis and as working elements of optical sensors. A uniform packing of nanoparticles on spherical particles can also be used for further fabrication of hollow spheres (the case where the core is somehow etched) [350] that have found application in pharmacology, catalysis, photonics and materials science.[351]

Metal particles are deposited on the surface of larger dielectric particles using various methods, *e.g.*, chemical reduction on the surface (to cover polystyrene latex particles with platinum [352] and silica particles with silver [353]), reactions with free radicals (to form silver nanoparticles on the surface of microspheres [354]) and sonochemical deposition of platinum,[355] zinc sulfide,[356] nickel [357] and cobalt.[358] An alternative approach involves activation of the surface of large particles with metal 'seeds' obtained by, *e.g.*, reduction of the corresponding precursor.[359, 360] It was employed to fabricate gold shells on silica spheres [359] and silver shells on polystyrene spheres.[360] Both these methods permit a uniform distribution of metals over the surface of spheres, though sometimes it is impossible to provide a dense packing of nanoparticles on large spheres.

The layer-by-layer deposition of nanoparticles and polymers (see, *e.g.*, Refs 361 – 363) is also employed in nanosphere lithography. Using this method, one can obtain composite films of different compositions, containing both the polymer and nanoparticles. The formation of dense layers of gold nanoparticles covered with thin silica layers on the surface of polystyrene spheres was reported.[364] To this end, layers of gold particles and poly(dialkyldimethylammonium chloride) were successively deposited on the surface of polystyrene spheres.

Ordered arrangements of 1 μm silica spheres 'capped' with gold or titanium were fabricated.[365] To this end, an ordered layer of silica particles was formed on the substrate and then covered with a photoresist layer. Then, photoresist was etched from the upper segments of the spheres, metal was deposited on the system and the remaining photoresist layer was completely etched. This led to the formation of ordered layers of metal 'capped' silica particles. The 'cap' size was varied by etching the deposited metal.

4. Functionalisation of substrates

Yet another efficient method of fabrication of ordered layers of nanoparticles involves pre-structurisation of the substrate.[366–368] Particles can be deposited using various procedures including a combination of the self-assembly on functionalised substrates with the droplet evaporation method. Other procedures include flow-induced packing of particles in the cavities with prescribed size and shape (Fig. 8); adsorption of particles on self-assembled monolayers characterised by different surface charge of different surface regions [370] and assembling of particles on the surface regions created by microcontact printing [371] or lithography.[372] A promising approach was also proposed,[373] which involves self-assembly of the charged particles on structured polyelectrolyte polylayers. In contrast to conventional self-assembly methods, this technique permits fabrication of ordered layers not only on the metal and oxide but also on the polymer surfaces. Layer-by-layer deposition of polyelectrolytes and particles allows films with unique properties to be designed.[374] In such films, the polyelec-

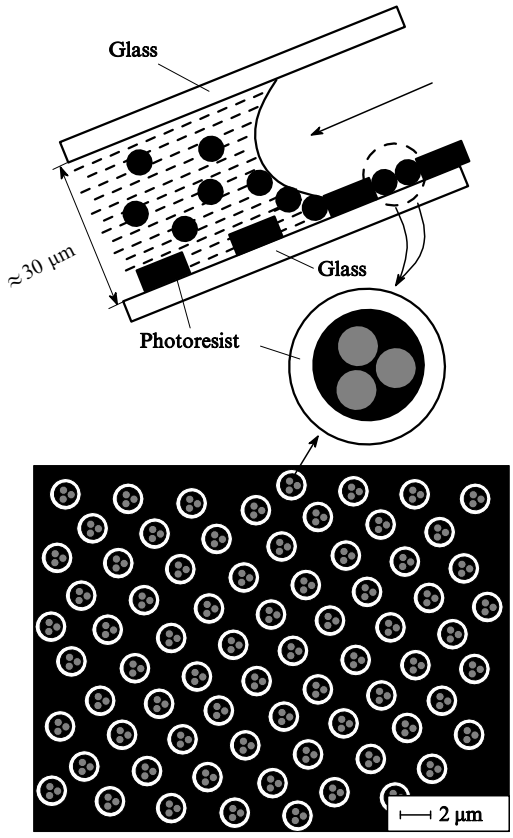

Figure 8. Deposition of nanoparticles on an ordered system of voids on substrate.[369]

trolyte polylayers can contain various functional groups [375] that provide the necessary electro-optic [376] and electroluminescent [377] properties, as well as the conducting [378] or dielectric layers and functional organic [379] and inorganic [380] particles. Polyelectrolytes permit enhancement of the adhesive binding between particles and the substrate. Patterns for polyelectrolyte deposition can be created using the microcontact printing technique;[381] therefore, the structures deposited can have arbitrary geometries.

Yet another widely used method is based on the creation of alternating hydrophilic and hydrophobic zones on the solid surface. It was employed to form ensembles of CdS nanoparticles on gold and silver substrates covered with self-assembled monolayers.[382] The methods necessary to prepare surface regions with different properties are based on the scanning probe nanolithography [383] or electron-beam patterning.[384] They are rather complicated; therefore, search for simpler procedures is currently in progress. Recently,[385] it was proposed to obtain ordered ensembles of nanoparticles as follows. First, a regular structure is formed on a silicon plate covered with the natural oxide layer from a self-assembled monolayer of siloxane containing a terminal CH_3 group by microcontact printing (see, *e.g.*, the procedure for fabrication of polydimethylsiloxane punches [386]). Then, the plate is dipped in a solution of the corresponding metal nitrate. After the plate is taken out from the solution, the droplets cover only the hydrophilic areas. The plate is then tilted so that the droplets are accumulated at the boundaries of the hydrophilic zones. After evaporation of the droplets the samples were heat treated, which resulted in the formation of nanoparticles. This method was used to fabricate ordered arrangements of cobalt, nickel and ferrite (MFe_2O_3; M = Mg, Ni) nanoparticles. The particle size and the interparticle distance were controlled by varying the solution concentration and by changing the structure of the monolayer (template), respectively.

An interesting effect, which can found practical applications, was reported.[387] The Si (100) surface covered with a natural 2 nm thick silica layer was coated with a patterned photoresist layer and the unpatterned photoresist was etched. Then, the a droplet of organic dispersion of thiol-stabilised gold particles was transferred to the substrate. It was found that narrow 'stripes' of the dispersion leak beyond the droplet at the resist – substrate interface. The 'stripe' length is at most 600 μm. Evaporation of the solvent (toluene) resulted in the formation of cluster chains of width $\approx$120 nm. The chain width remains nearly constant along the whole chain length. An analogous effect of 'escape' of nanoparticles along the boundaries of different-nature regions involving the formation of nanowires was also observed.[388]

V. Physicochemical properties of ensembles of nanoparticles

1. Electronic properties

Ordered arrangements of nanoparticles are considered as candidates for elements of electronic devices; because of this, considerable attention has been given to their electronic and optical properties.

The authors of numerous studies (see, *e.g.*, references cited in Ref. 4) observed a nonlinear current – voltage curve (the so-called Coulomb stairs) on passing electric current through individual particles. The current – voltage curves obtained in analogous experiments with self-assembled arrays of nanoparticles also have the shape of the Coulomb stairs.[138, 389, 390] For nanoparticles in organic media it is possible to draw a nearly complete analogy between the Coulomb stairs exhibited by single particles and their monolayers. For aqueous media, the current – voltage curves measured [390] on applying positive and negative potentials to the monolayer (experiments were carried out with 2 nm gold particles stabilised with alkanethiols and self-assembled into a monolayer using dithiols) are significantly different. Namely, the Coulomb stairs were observed after application of the positive potential and were not observed after the negative potential was applied. No unambiguous explanation for this effect has been given as yet.

Currently, considerable attention has been given to the studies on the laws of electron transfer within the monolayer plane. Electron transfer in the monolayered nanoparticle films involves the motion of electrons between the metal nanoparticles and overcoming of the potential barrier in the region of the stabiliser molecules (surfactant). The electron energy diagram for a composite film comprised of nanoparticles and a dielectric matrix is schematically shown in Fig. 9. Electron transfer between particles separated by an insulator proceeds by two main mechanisms, namely, by tunnelling and *via* thermally induced overcoming of the energy barrier. In weak electric fields ($eU_p < kT$, where U_p is the potential difference between the neighbouring particles), the insulator conductivity for electron transfer by the thermoionic emission mechanism is given by:

$$\sigma_e = \alpha T^2 \frac{e}{kT} \exp\left(-\frac{\phi_e}{kT}\right),$$

where α is a constant and ϕ_e is the height of the energy barrier. The barrier height is close to the work done by an electron to go from the metal particles to the matrix and includes the contribution of the image forces, which become significant in the case of small particles.

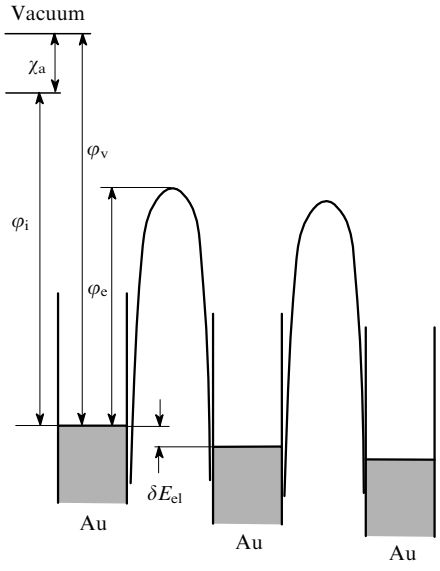

Figure 9. Electron energy diagram for a composite material of the 'nanoparticles – dielectric matrix' type;[390]
χ_a is the electron affinity towards the dielectric matrix, φ_v is the ionisation potential of the metal and φ_i is the ionisation potential of the metal in the dielectric medium.

The image forces reduce the work function by a value of the order of

$$\delta\phi = \frac{2e^2}{\varepsilon_\infty \varepsilon_0 h},$$

where ε_∞ is the high-frequency dielectric permeability of the medium and h is the interparticle distance. For gold particles, the work done to go vacuum is $\approx$5 eV and the decrease in the barrier due to the image forces at an interparticle distance of $\approx$1 nm is $\approx$2 eV. For dielectric media, the work done to go from gold decreases by up to 1 eV. Usually, the height of the energy barrier in the nanoparticle films is $\approx$2.5 eV.

The tunnelling current flowing between two metal particles is given by

$$J \propto \left(\frac{8me}{\pi^2\hbar^3 B}\right)\mathrm{sh}\left(\frac{eU_\mathrm{p}}{kT}\right)\exp(-A\phi_\mathrm{av}^{0.5})\exp\left\{-\left(\frac{\delta E_\mathrm{el}}{kT}\right)\right.$$
$$\left.\times\,[1-\exp(-B\delta E_\mathrm{el})]\right\},$$

$$B=\frac{A}{2\phi_\mathrm{av}^{0.5}},$$

$$A=\frac{4h(2m)^{0.5}}{\hbar},$$

$$\phi_\mathrm{av}=h^{-1}\int_0^h \phi_\mathrm{e}(x)x\mathrm{d}x.$$

Here, m is the mass of an electron and δE_el is the energy required to transfer an electron from one neutral particle to another,

$$\delta E_\mathrm{el}=\frac{0.5\,e^2h}{(4\pi\varepsilon\varepsilon_0 R)(R+h)}, \qquad (14)$$

where R is the particle radius.

Temperature dependences of the conductivity of two-dimensional ordered films fabricated using the Langmuir–Blodgett method from silver nanoparticles were reported.[391] Let us take them as examples. The 8 nm silver particles were stabilised by thiols with different chain length. The films were formed at different monolayer pressures. The temperature dependences of the film resistances are shown in Fig. 10. As can be seen, initially the resistance exponentially decreases with temperature. These dependences are well described by the relationship

$$R \propto \exp\frac{E_0}{kT},$$

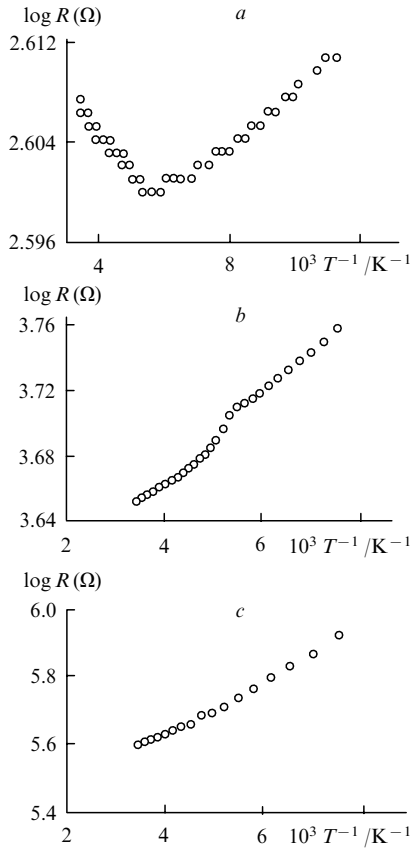

Figure 10. Temperature dependences of the resistance of the films formed by silver nanoparticles stabilised by ethanethiol (*a*), pentanethiol (*b*) and octanethiol (*c*).[391]

where E_0 is the activation energy for all the films under study. At $T \approx 200$ K, the resistance reaches its minimum value, which corresponds to the transition from the activation mechanism to the metal mechanism of conductivity. These dependences are indicative of the metal–dielectric transition in the two-dimensional monolayer. An analogous transition was detected using the tunnelling [392] and impedance spectroscopies.[393] The experimental E_0 values correspond to those calculated assuming that the energy barrier is due to Coulombic interaction between electrons and nanoparticles.

Somewhat different results were obtained in a study [394] on the electrical conductivity, photoconductivity and photoelectrochemical properties of the films comprised of dithiol-stabilised gold nanoparticles. Ordered layers were fabricated by particle deposition on substrates dipped in a colloid dispersion. At nearly the same size (6–8 nm) of particles covered with thiols of different chain lengths, the activation energy was found to lie between 5 and 25 meV, which is two or three orders of magnitude lower than the estimate (see above). Similar activation energies were obtained earlier.[147, 395] This probably indicates that the conductivity in these systems occurs by direct particle–particle contacts. Indeed, Fig. 10 shows that in the case of, *e.g.*, ethanethiol the temperature dependence of the conductivity has a complex shape and the resistance increases with raising the temperature in a certain interval. This is most probably due to the breakdown of interparticle contacts in the conductivity channels. Prolonged heating (100 °C) of the layer of particles was accompanied by a dramatic decrease in the resistance, which can be explained by thermally induced removal of the 'binding agent' from the interparticle space. The dependences of the photocurrent yield on the photon energy (Fig. 11) show that the work done to transfer electrons to the matrix is ~1 eV. Analysis of the dependences presented [the (yield)$^{0.5}$–energy dependence obeys the Fowler law for photoemission] suggested that the conductivity is of mixed character and is due to both the particle–particle contacts and the hopping mechanism. It should be noted that the mixed mechanism of

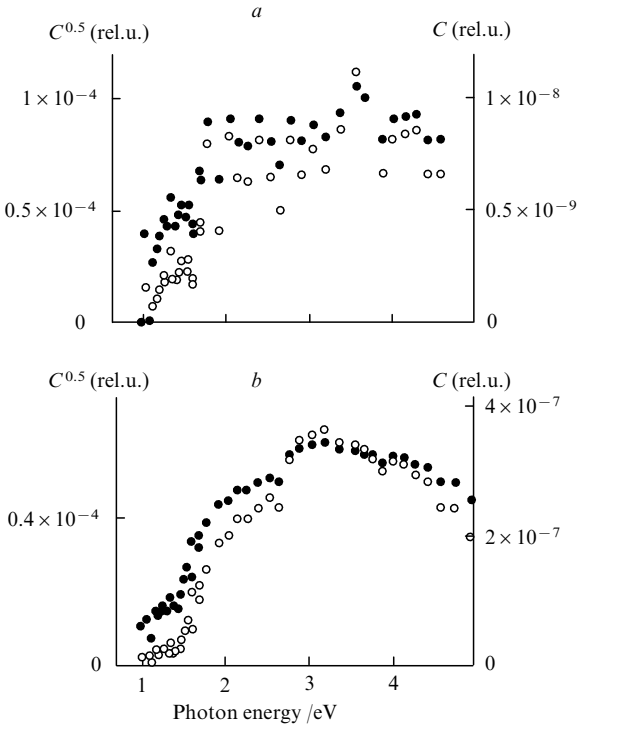

Figure 11. Photocurrent yield (C) for films comprised of silver nanoparticles stabilised by pentanethiol (*a*) and octanethiol (*b*).[391]
The right and left ordinate axes are for the open and full circles, respectively.

conductivity is typical of conventional composite materials.[396–398] The reversible metal–dielectric transition also occurs as the thickness of the ligand shell [213, 399] of nanoparticles changes.

A large number of experimental studies on various characteristics of ensembles of nanoparticles are available. At the same time, theoretical studies in this field are scarce. This is a consequence of the complexity of the systems under study (relevant solvable models can hardly be chosen). Yet another problem is that, strictly speaking, ordered ensembles are inhomogeneous structures. Structural inhomogeneity is due to the following reasons. First, nanoparticles are characterised by some size distribution. Second, it is virtually impossible to obtain a perfect structure comprised of nanoparticles. Third, different nanoparticles have different compositions because their ligand shells are also characterised by some degree of inhomogeneity. Fourth, nanoparticles execute thermal motion, thus introducing distortions in the lattice structure of the colloid crystal. Finally, electron transfer between particles can be accompanied by the electron scattering by structural inhomogeneities of the organic layer (this process can occur in different manner). In spite of this, serious efforts were made to take into account many salient features of the ensembles of nanoparticles. For instance, the following Hamiltonian was proposed to describe the electronic properties of ordered ensembles [400]

$$H_0 = \sum_{i,j}^{n} h_{ij} \sum_{\mu}^{2} \alpha_{i\mu}^{+} \alpha_{j\mu} + \frac{1}{2} I \sum (n_i - 1)^2 + \frac{1}{2} \gamma \sum_{i,j} n_i n_j, \qquad (15)$$

$$h_{ij} = \begin{cases} \alpha_i & i = j \\ \beta_{ij} & i \neq j, \end{cases}$$

where α_i is the energy level of an electron of particle i; β_{ij} is the 'transfer integral,' which is determined by the overlap of the electron orbitals of the neighbouring nanoparticles; $\alpha_{i\mu}^{+}$, $\alpha_{j\mu}$ are respectively the production and annihilation operators of electrons with the spin μ at the particle i; and n_i is the operator of the number of electrons at the particle of the type i,

$$n_i = \sum_{\mu}^{2} \alpha_{i\mu}^{+} \alpha_{i\mu} .$$

In expression (15), the second term describes the effect of Coulombic blockage and is determined by the energy required to charge a single particle

$$I = \frac{e^2}{4\pi\varepsilon_0 \varepsilon R},$$

while the last term describes the mutual polarisation of the neighbouring particles

$$\gamma = e^2 \left[2R \left(\frac{H}{2R} + \frac{e^2}{2IR} + a \right) \right]^{-1},$$

where H is the distance between the centres of the particles and a is a constant.

Calculations were carried out assuming that the constants α_i and β_{ij} fluctuate near their average values with the fluctuation amplitudes $\Delta\alpha$ and $\Delta\beta$, respectively. It was pointed out [400] that all the parameters introduced can be determined experimentally. Calculations of the electronic states of the system revealed the possibility for two types of the metal–dielectric transition (according to Anderson [401] and to Mott [402]) to occur in the system due to the fluctuations of different parameters. The Anderson transition occurs if the interaction between the neighbouring particles is rather weak and does not compensate the energy difference between the levels, which is due to fluctuations of the particles' characteristics. The Mott transition is observed when compression of the lattice of a colloid crystal causes suppression of the mutual repulsion between the electrons bearing oppositely directed spins and belonging to the same particle owing to the cooperative effects (screening), merging of the lowest occupied and upper unoccupied bands and the insulator–conductor transition. Disorder in the system also affects the Mott transition; however, this transition can be masked if the energy fluctuations due to structural inhomogeneities exceed the Coulombic interelectron repulsion energy. At small amplitudes of the energy level fluctuations, the Anderson transition occurs at much shorter interparticle distances compared to the Mott transition. These results were confirmed by the experimental data,[403] according to which at a rather long interparticle distance the ensembles behave as dielectrics due to the Anderson-type electron localisation even in the absence of the Coulombic gap.

The conducting properties of ensembles of nanoparticles can be changed by varying the layer compositions and using those particles whose state can be changed with ease under the action of external factors. In this connection mention may be made that it is possible to control the photoinduced electron transfer between the monolayers of the donor [a polypyridyl complex of Ru(II)] and acceptor [an acetylacetonate complex of Ru(III)] complexes by separating them by insulator layers [404] and that the probability of electron tunnelling in the superlattice of magnetic cobalt particles depends on the external field applied to the system, *i.e.*, on the orientation of the electron spins.[405]

2. Optical properties

Recently, increasing interest in the optical properties of nanoscale systems has been expressed.[406] This is mainly due to some prospects for the use of the near-field effects in creating devices for ultrahigh information recording density and ultrafast reading devices. In the case of three-dimensional ordered structures, of particular interest are the so-called photonic crystals (see below).

We will first consider the optical properties of two-dimensional aggregates and single-layered films comprised of metal nanoparticles. Single spherical particles are characterised by the resonance absorption band at the frequency ω_0 corresponding to the excitation of surface plasmons.[4, 406] Ellipsoidal particles are characterised by two maxima corresponding to the polarisation along and perpendicular to the principal axis. The absorption spectrum is usually calculated based on the Maxwell equations at a given dielectric constant of the external medium. The dependences of the optical and relaxation characteristics of nanoparticles on their size and shape were recently reviewed,[407] so we leave them out of our consideration.

The absorption spectra of aggregates should be calculated with inclusion of the interparticle interaction (*i.e.*, the size and shape of the aggregate formed). Pileni [408] reported the results of a detailed study of the optical and electronic properties of ordered films comprised of silver nanoparticles. Figure 12 presents the absorption spectrum of an aggregate comprising a total of nineteen hexagonally arranged nanoparticles. The characteristic feature of the spectrum is the appearance of maxima at certain ω^- and ω^+ values that meet the condition $\omega^- < \omega_0 < \omega^+$. For the s-polarised wave, there is only one maximum at $\omega = \omega^-$, while for the p-polarised wave there are two such maxima and the amplitude of the high-energy maximum increases as the angle of incidence increases. This is a consequence of the optical anisotropy of the system, namely, its polarisability is different along the normal and parallel to the surface of the substrate. This anisotropy manifests itself for the p-polarised wave, because it has components both in the surface plane and along the normal to this plane (the s-wave has only the component parallel to the surface). Experimental data obtained for silver nanoparticles [408] are in good agreement with the results of calculations.

The optical properties and electronic characteristics of the ordered films comprised of nanoparticles are determined by the classical (dipolar) and quantum (exchange) interactions between nanoparticles. The quantum interaction occurs only at distances shorter than 1 nm.[213] Because of this, the optical properties of composite materials are most often described using the Maxwell–Garnett theory as a first approximation, according to which

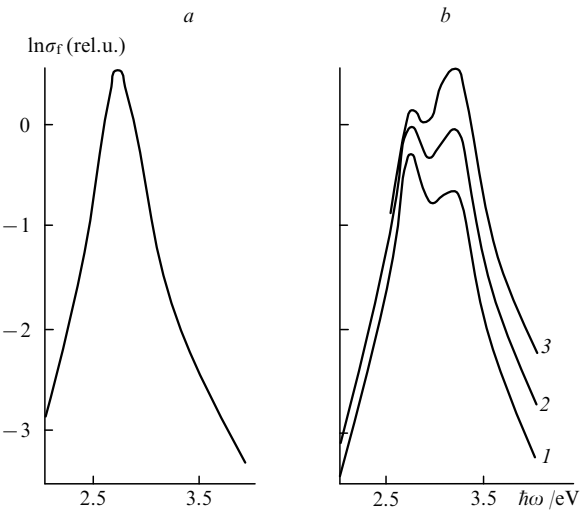

Figure 12. Absorption section by an aggregate comprised of nineteen silver nanoparticles for the s- (*a*) and p-polarised (*b*) waves.[408]
Angle of incidence /deg: 45 (*1*), 51 (*2*) and 60 (*3*).

the dielectric susceptibility of the medium is determined *via* the dielectric susceptibility of individual particles. This theory works well for dilute colloid systems. Various methods have been developed to calculate the dielectric susceptibility at a large volume fraction of particles. Here, we will present the main results of the most consistent approach.[409, 410] The frequency dependence of the nanoparticle polarisability can be obtained using the data on the dielectric response of bulk silver, on the electron relaxation time in nanoparticles and the Clausius–Mossotti formula. The dielectric susceptibility of bulk silver is given by the Drude relationship

$$\varepsilon_{\rm p} = 1 - \frac{\omega_0^2}{\omega^2 + v^2} + \frac{i\omega_0^2 v}{\omega(\omega^2 + v^2)},$$

where ω_0 is the plasmon frequency for the bulk metal and v is the collision frequency of electrons with impurities in the bulk of the metal and with the surface of nanoparticles (the width of the plasmon band),

$$v = \left(\frac{1}{l} + \frac{1}{R}\right) v_{\rm F},$$

where l is the free path length of electrons in the bulk metal, R is the particle radius and $v_{\rm F}$ is the Fermi velocity of electrons.

The Clausius–Mossotti formula for the polarisability of a metal sphere dipped in a dielectric medium with permeability $\varepsilon_{\rm m}$ has the form

$$\chi_{\rm p} = \frac{\varepsilon_{\rm p} - \varepsilon_{\rm m}}{\varepsilon_{\rm p} + 2\varepsilon_{\rm m}}.$$

The effective dielectric permeability of a two-dimensional composite medium comprised of spherical particles that are uniformly distributed over the volume of the matrix is given by

$$\varepsilon_{\rm ef} = \frac{1 + \chi_{\rm p}\varphi - (1-\varphi)^2\chi_{\rm p}^2\zeta}{1 - \chi_{\rm p}\varphi - (1-\varphi)^2\chi_{\rm p}^2\zeta}\varepsilon_{\rm m},$$

where φ is the packing density of the particles and ζ is the structure parameter, which includes three-particle correlations in the arrangement of spheres (calculated in Ref. 409). The parameter ζ depends on φ and changes from 0 (for dilute systems) to 1 (for close-packed systems). It also depends on the character of the packing of spherical particles, being much larger for random packing compared to regular one. In the former case, the parameter ζ has virtually the same value for both two-dimensional and three-dimensional systems.

Having found the dielectric permeability, it is an easy matter to calculate various optical characteristics of films, *e.g.*, the reflection coefficient $|R_{\rm s}|^2$, where

$$R_{\rm s} = \frac{r_1 + r_2 e^{-2i\delta}}{1 + r_1 r_2 e^{-2i\delta}}.$$

Here r_1 and r_2 are the Fresnel coefficients for the air–film and film–substrate interfaces,

$$\delta = \frac{2\pi}{\lambda} d n \cos\theta,$$

λ is the radiation wavelength, d is the film thickness, n is the refractive index of the films, θ is the angle of incidence of radiation.

The dependence of the reflection coefficient on the interparticle distance is shown in Fig. 13. As can be seen, the calculated and experimental data are in good agreement at rather long interparticle distances, being substantially different at short distances. Good correspondence between the theory and experiment holds up to $H/2R \approx 1.25$. This is due to the fact that the dielectric–metal transition occurs in the monolayer at $H/2R \approx 1.15$, which is not included in the model considered above. As the system approaches the transition point, rather large clusters are formed, which are characterised by the metal conductivity. For this reason, the differences between the theory and experiment increase. The metal–dielectric transition is also

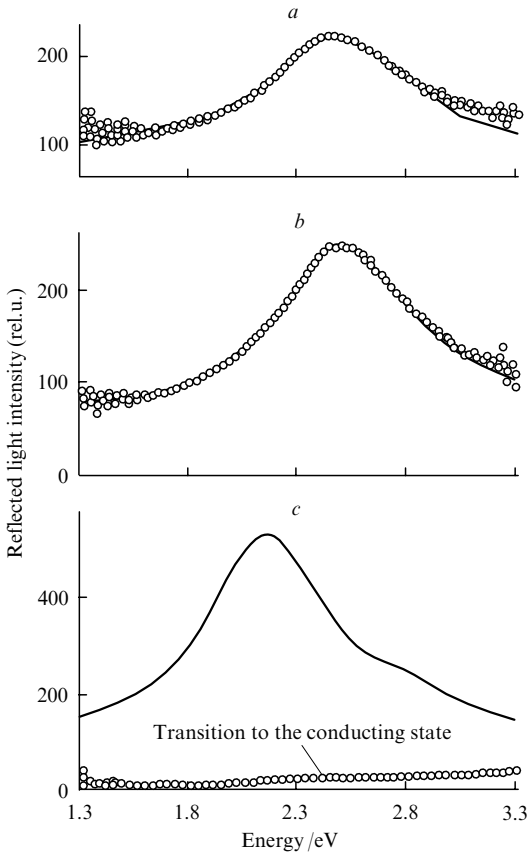

Figure 13. Reflected light intensity plotted *vs.* photon energy for different interparticle distances.[399]
Experimental data (open circles) and results of calculations (solid lines). The 'interparticle distance-to-particle-size' ratio ($H/2R$) is 1.60 (*a*), 1.38 (*b*) and 1.17 (*c*).

Experiment (*1*) and results of calculations using the classical model (*2*) and exponential approximation (*3*).

clearly detected in measuring the intensity of the second optical harmonic (Fig. 14), namely, marked deviations of the calculated values from the experimental data are observed on approaching the point of the metal–dielectric transition.

A study on photon emission from a monolayer of particles under the action of a voltage applied to the tip of an STM also led to quite unexpected results.[408] Experiments were carried out with ordered layers of 4 nm silver nanoparticles separated by a distance of 2 nm on the Au(111) surface. First, the motion of particles across the surface was observed. Second, surprisingly, photon emission from the monolayer was inhomogeneous, that is, dark zones were observed near certain particles (the darkest zones corresponded to the vertices of the particles). The intensity of emission from the particle vertices was ten times lower than from the other sites. Experiments showed that highly mobile particles are bad photons emitters (*i.e.*, quenching of the emission is due to the motion of particles). The measurements were carried out in the d.c. regime, which is manily due to the resonant tunnelling of electrons. Non-resonant electron transfer and, correspondingly, photon emission are of the fluctuation nature. The photon emission is related to the relaxation of plasmons that are excited in the case of non-resonant electron transfer (non-resonant tunnelling).[411] Therefore, photon emission is affected by many factors. Electron relaxation can occur *via* the excitation of a plasmon, production of a photon or interaction with the surface phonons. For small particles, electron transfer to the particle occurs in the ballistic regime.[412] Because of this, electron relaxation is possible only *via* the electron–plasmon or electron–phonon interaction. The latter interaction is known to play an important role in the relaxation processes in the particles whose size is less than the free path length of an electron. It is assumed that the phonon excitation of highly mobile particles is facilitated as compared to the immobilised particles. Probably, the excitation of collective phonons also occurs. This effect, along with the well-known effect[4,413] of change in the transmission and reflection of light upon electrochemical injection of charges into the film, opens up new possibilities in controlling the electronic properties of nanofilms. In the latter case, changes in the electronic properties of the films can be explained by the change in the electron density in certain particles for which the relative changes in the electron density much exceed the corresponding value for the bulk material.

It should be noted that the interaction of electromagnetic waves with two-dimensional arrangements of particles are still poorly studied. At the same time, their understanding is necessary for not only the description of the optical properties of films but also creation of a new generation of memory devices. At the nanometre scale and femtosecond times, the electromagnetic energy is transferred by plasmons. For this reason, revealing the localisation effects of electromagnetic waves is of great practical interest. Delocalised modes govern energy transfer in the whole system, while the localised modes allow the energy to be concentrated within small regions of the system. A study[414] was reported on the properties of the eigenmodes in a two-dimensional composite containing randomly distributed metal inclusions that covered half the surface area. According to calculations, localisation of the surface plasmons in the whole spectral region is impossible. The localisation radius is distributed over the whole admissible range of sizes, from the smallest size to the size of the entire system. A typical eigenmode is simultaneously localised and delocalised, that is, there are small areas with intense field, which are distributed over a large surface area and are coherent. This propertiy of the surface plasmons makes them a promising object for data storage and transmission applications for ultrafast computations. The localisation areas can serve as energy reservoirs, while their long-range coherence allows information to be rapidly transmitted over long distances.

Currently, a new research avenue in the optics of nanofilms deposited on substrates is in prospect. It was shown[415] that the $Au@SiO_2$ particles (gold particles covered with silica layer) are suitable for fabrication of plasmon waveguides whose size is of the order of the particle size. Numerical experiments[416] showed that nanoparticles organised in linear chains are capable of transferring the energy localised in the regions with the characteristic size much smaller than the optical diffraction limit. The most important requirement is that the particles be separated by a layer, which must be sufficiently thin for the interaction between the plasmon modes in nanoparticles to occur in the near field.[417] According to numerical simulation, the signal propagation velocity in this plasmon waveguide is one tenth of the speed of light. The waveguide geometry admits the presence of acute angles.

From the aforesaid it follows that the optical properties of nanoparticle films are still far from being completely studied; therefore, they have been the subject of intensive research. The dependences of the optical characteristics of films on the properties of the substrate[418] and the dispersion medium were studied in detail.[419] Ellipsometry can also be used to study the properties of films.[420] Enhancement of the plasmon resonance upon reflection of light from bilayered films (from the substrate side)[421] and the luminescent characteristics of quantum dots upon their self-assembly into ordered structures were reported;[422–424] self-organised structures do possess not only the electroluminescence properties[425] but also enhance the laser effect.[426,427]

The surface plasmon resonance is used to study the interaction between various materials and thin metal films.[428] This method has found its main application in biochemical systems, especially in studies of proteins and DNA molecules. It involves studies on the shift of the plasmon resonance caused by the change in the refractive index of the medium contacting the metal. Such a change is observed upon variation of the interaction between macromolecules and solvents; it also manifests itself as a change in the angular dependence of the coefficient of reflection of electromagnetic radiation from metal films. The well-known effect of change in the scattering coefficient in the case of interaction between biomolecules and nanoparticles[265,266] can be considerably enhanced[429] by depositing nanoparticles on the surface of metal films. Experiments showed that the coefficient of reflection of laser radiation from a gold film significantly changes after deposition of gold nanoparticles of size 30–60 nm on the surface of the film (Fig. 15). The magnitude of the change depends on the particle size and is nearly proportional to the particle concentration on the surface. This effect permits significant improvement

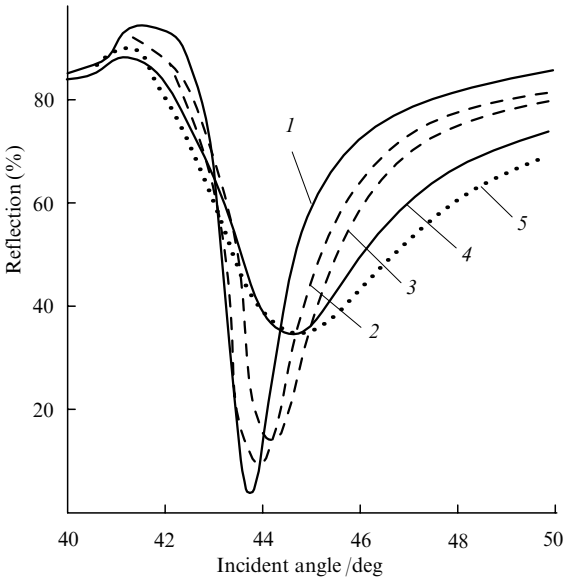

Figure 15. Reflected intensity *vs.* incident angle in the presence of gold particles of different size on the substrate.[429]

of the sensitivity of detection of biomolecules using gold nanoparticles. The nature of the effect of the particles deposited on the surface is obvious: these particles make the surface rough, which causes broadening of the resonance peak.

Yet another biochemical application of single-layered films comprised of metal nanoparticles involves the use of the effect of surface enhanced Raman scattering (SERS), which is intrinsic in some metal nanoparticles. In the case of SERS, the section of scattering by the molecules adsorbed on rough metal surfaces increases by several orders of magnitude.[430] It is assumed that the nature of the SERS effect is related to both localisation of the surface plasmons and to the charge-transfer induced increase in the molecular polarisability near the metal surface.[431] In most cases, the former effect predominates; therefore, considerable attention has been given to the formation of various rough surfaces (in most cases, using colloid particles). The shape of the particle strongly influences the magnitude of the effect,[432] while the particles on the substrate should not be necessarily ordered.[433]

Numerous studies on the molecule – photon – surface interaction have been carried out since the discovery of the SERS effect; however, the mechanism of this effect is still to be clarified. It was established [434–436] that only a small fraction of particles is SERS active and that the active particles enhance the Raman scattering by 14 – 15 orders of magnitude. It was also found that the nanoparticle size is related to the exciting radiation wavelength corresponding to the SERS maximum.[434] For instance, 90 nm (140 nm) silver particles are most efficiently excited at 514 nm (570 nm). For 63 nm gold particles, the maximum enhancement is observed at an exciting radiation wavelength of 647 nm. This indicates that by sizing nanoparticles it is possible to obtain nanostructured materials with enhanced optical characteristics. Indeed, pre-fractionation of particles permits significant enhancement of the SERS effect.[437] To this end, films comprised of fractionated nanoparticles (particle size ranged from 30 to 100 nm) were obtained. Experiments confirmed that the use of certain fractions causes enhancement of the SERS effect by several orders of magnitude. The magnitude of the effect is also strongly influenced by the interaction between nanoparticles within the film.

Figure 16 presents the dependence of the SERS intensity on the degree of coverage of the substrate surface by nanoparticles for rhodamine 6G. As can be seen, the SERS intensity remains

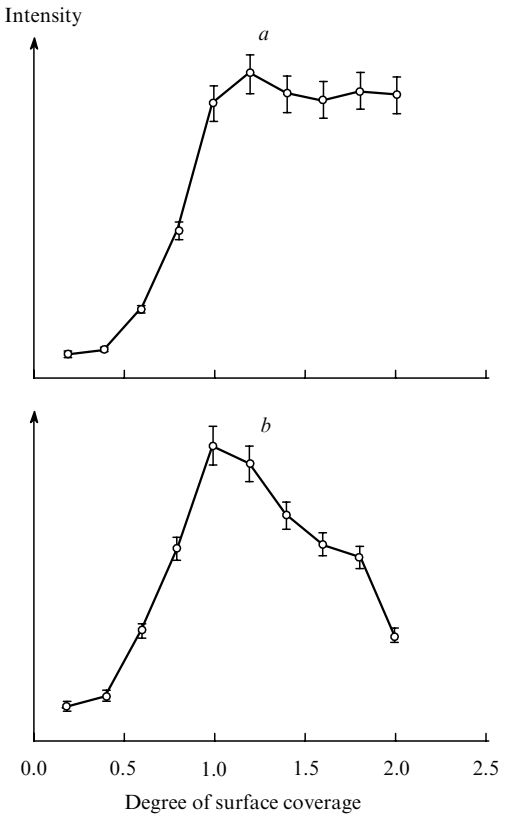

Figure 16. Absolute (*a*) and normalised (*b*) SARS intensities plotted *vs.* the degree of coverage of the substrate surface by nanoparticles.[437]

virtually unchanged as the coverage increases from 0 to 0.5, then markedly increases as the coverage approaches a unity and then remains constant. The presence of a plateau indicates that the three-dimensional ensemble of particles behaves as a two-dimensional film. Introduction of salt into the system causes a twofold increase in the intensity of the SERS signal.[437] The laws established permit the use of nanogranulated metal films as sensors in detecting biomolecules.

Consider now the optical characteristics of three-dimensional ordered colloid structures. Such structures are characterised by unusual colour gamma, being in many cases responsible for the unique protective colour of animals due to the formation of microstructures comprised of colloid particles on the surface of their bodies. Diffraction of light by such structures provides the appearance of a colour gamma which is different from that formed in the case of light absorption by dyes. Recently, studies on the optical properties of three-dimensional colloid structures have become of great importance, because colloid crystals are used as sensors,[438] tunable diffraction gratings,[439] narrow-band filters [440] and photonic crystals.[441–445] Photonic crystals serve as the basis for design of pigments and creation of a new generation of optical devices.[446–449]

The use of three-dimensional colloid crystals opens up new prospects for nanophotonics (because of this, such crystals are called photonic crystals). Nanophotonics is a new branch of optics, which describes the propagation, scattering and interaction of electromagnetic waves on the nanometre length scale. Research in this field is concerned with the interaction between the electromagnetic waves and matter at the length scales shorter than the wavelength of electromagnetic radiation, and, in particular, localised photochemical reactions. At present, nanophotonics has stimulated the elaboration of a number of novel technologies. Namely, a new type of laser and a number of optical systems and physicochemical methods were developed.[450] Colloid crystals allowed localisation of light to be performed experimentally and

have found application in laser physics and laser chemistry.[446, 447, 451–454] Recently, it has been shown that photonic crystals with band-shaped optical structure and thoroughly chosen parameters permit localisation of light, which is multiply scattered by nanoparticles.

Photonic crystals are three-dimensional structures with a periodic arrangement of particles (different phases). The refractive index of such a system is a periodic function with a period of the order of the optical wavelength. The propagation of light in photonic crystals is similar to the motion of electrons in a conventional crystal lattice. The refractive index difference between the particles and the matrix and the ordered arrangement of particles cause a strong scattering of electromagnetic waves with particular wavelengths. The Bragg diffraction occurs, which is characterised by forbiddenness for waves with particular wavelengths to propagate through the photonic crystal. Figure 17 presents the dependence of the transmission of a 12 μm-thick colloid crystal formed by polystyrene latex particles of diameter 0.23 μm on the wavelength for different angles of incidence. As can be seen, the transmission maximum (λ_{max}) is shifted from 574 to 538 nm as the angle changes from 0 to 40°. In Fig. 17 *d* we present the dependence of transmission on the wavelength for 0.36-μm latex particles at the same crystal thickness. The relation between λ_{max}, the angle of incidence and distance d_{111} between the (111) planes of a colloid crystal is given by the Bragg equation

$$\lambda_{max} = 2d_{111}(n_a - \sin^2\theta)^{1/2},$$

where n_a is the refractive index (1.489 for the ensemble of polystyrene spheres characterised by a packing density of 0.74%). Figure 18 presents the experimental and calculated λ_{max} values for colloid crystal comprised of polystyrene spheres.

Experimental data (open circles) and results of calculations (solid lines).

It is possible to draw an analogy between the electron energy bands in semiconductors and in photonic crystals; however, in the latter case some features are observed. It should be noted that in photonic crystals it is possible to implement the lasing mechanism and superradiation associated with the boson nature of light, according to which a large number of photons can be in the same state. Recently, photonic crystals were fabricated,[456–458] which are characterised by localisation of electromagnetic waves in the spectral region extending from near IR to UV. Laser physics applications require that photonic crystals be tunable in the whole visible region.

A feature of photonic crystals is the change in the type of the interaction between the atoms and electromagnetic radiation. In particular, only radiation with particular wavelengths can propagate without losses through the band-type photonic crystals; therefore, atoms or molecules for which transitions between the energy levels correspond to the forbidden wavelengths, are not affected by the fluctuating vacuum field responsible for spontaneous quenching of excited states. As a result, a bound state atom–photon is created. A photon can travel a distance of several lattice constants from the atom by tunnelling before being trapped by another atom. As a consequence, relaxation of the excited

states of atoms in a photonic crystal obeys somewhat different laws compared to the case of free atoms and molecules.

Most often, photonic crystals are fabricated from silica spheres that are usually packed into the f.c.c. lattice.[459–461] By varying the size of the spheres it is possible to tune the band gap to the desired spectral region. Thermally induced tuning of the band gap is also possible.[462, 463] Fabrication of photonic crystals whose optical properties can be changed by applying the magnetic field was reported.[464, 465] By applying an external magnetic and electric field one can change the structure of the colloid crystals formed from particles of complex structure.[465] For instance, a martensite transition of the tetragonal b.c.c. lattice to the b.c.c. lattice followed by changes in the dielectric characteristics of the crystal was observed in crossed electric and magnetic fields. Recently, fabrication of inverted photonic crystals formed by the voids in the dielectric medium (usually, titania) was reported.[460, 461] Experiments showed that this structure is optimum for photonic crystals. To date, methods of fabrication of photonic crystals from various materials have been developed [466–472] and preparation of photonic crystals with the record characteristics seems not to be impossible. In this case, the interparticle distance is of great importance. Recently, methods of formation of nanoparticles coated with a thin silica shell were developed.[461, 473–476] This opens new possibilities of control of the optical properties of nanoparticles because permits variation of the core size and the thickness and composition of the shell. Spherical particles obtained following the above-mentioned routes are characterised by a narrow size distribution, being convenient building blocks for fabrication of photonic crystals. Ordered crystals obtained from such nanoparticles can be formed using various methods; however, the main procedure is based on the use of capillary forces. In particular, ordered structures from 50 nm gold nanoparticles covered with silica layers of different thickness were obtained.[415] Some examples illustrating the changes in the optical properties of photonic crystals fabricated from these particles covered with the SiO_2 shell of different thickness are shown in Fig. 19.

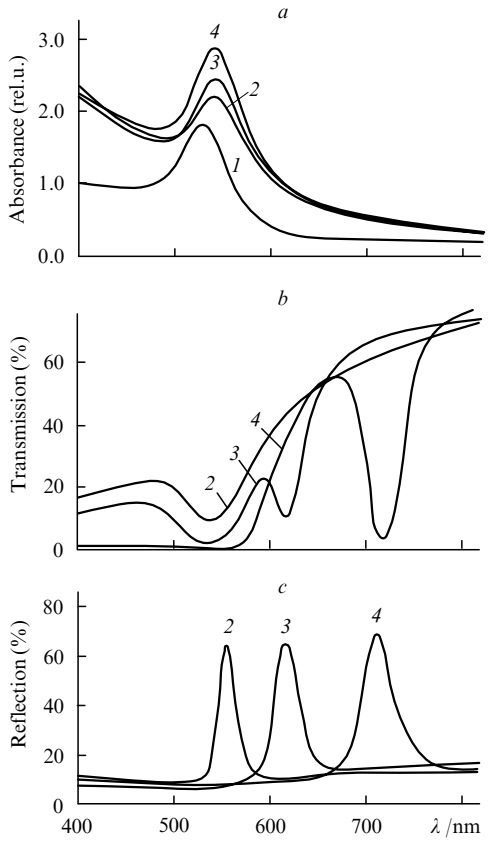

Figure 19. Optical characteristics of photonic crystals as functions of the thickness of the silica layer covering 50-nm gold nanoparticles.[415] Coverage thickness /nm: 0 (*1*), 70 (*2*), 80 (*3*) and 100 (*4*).

3. Magnetic properties

The monodomain structure of magnetic nanoparticles makes them of considerable interest, especially for fabrication of magnetic memory devices. The magnetic properties of nanoparticles differ from those of bulk magnets,[1, 6] because a decrease in the particle size is accompanied by an increase in the fraction of surface atoms. The electronic and magnetic structures of such atoms are affected by the smaller number of atoms in the particle compared to the bulk material; however, they are influenced by a large number of atoms of the dispersion medium (matrix). The surface effects can reduce the magnetic moment of particles;[477] however, for 'free' iron, cobalt and nickel particles the magnetic moment per atom increases [478] with the decrease in the particle size and tends to the limiting value characteristic of the single atom. Besides, the magnetic anisotropy of particles exceeds the corresponding bulk value.[479] The difference between these values is related to the increase in the magnetic orbital momentum of peripheral atoms.[480]

Magnetic nanoparticles are convenient objects for studying the quantum effects that manifest themselves on the mesoscopic length scale (between the quantum microscopic and classical macroscopic length scales).[481] However, real systems represent ensembles of particles, which are characterised by different size and shape. This hampers measurements of the quantum effects. The magnetic properties of such systems are determined by the properties of both the particles and the entire ensemble and these contributions are hard to be discriminated. Because of this, search for the systems suitable for wide-range variation of the average particle size, the particle size distribution and the spatial arrangement of the particles is topical. The properties of monolayers comprised of magnetic particles also depend on the procedure employed to form these objects.

A detailed study [482] on the magnetic properties of ensembles of nanoparticles involved the preparation of composites with different structural organisation of nanoparticles by layer-by-layer deposition [483] of magnetic cobalt particles on the Al_2O_3 matrix. Both ordered layers with controllable interparticle distance and random distributions of particles in the matrix (the particle size was 1 to 7 nm) were formed. Particles were formed by layer-by-layer deposition of cobalt and alumina. The results of electron microscopy study showed that the system contains isolated spherical nanoparticles whose size depends on the cobalt deposition time. This technique was used to form the films containing up to three hundred Co/Al_2O_3 bilayers. Measurements of the static and dynamic magnetic susceptibilities of these systems revealed the magnetic moment blockage effect, which is due to the magnetic anisotropy of particles. The reorientation time of the magnetic moment varies as follows

$$\tau = \tau_0 \exp\left(\frac{U_b}{kT}\right),$$

where $\tau_0 \approx 10^{-10}-10^{-13}$ s and U_b is the height of the energy barrier and is governed by the interaction between the magnetic moment of the particle and the phonon and magnon thermostats. The U_b value depends on the magnetic anisotropy constant K_{ef} and the particle volume V

$$U_b = K_{ef} V.$$

The magnetic anisotropy constant varies with the average particle size as

$$K_{ef} = K_\infty + \frac{6K_s}{\langle d \rangle},$$

where K_∞ is the magnetic anisotropy constant for the bulk material (5×10^4 J m^{-3}) and $K_s = 3.3 \times 10^{-1}$ mJ m^{-2}. An analogous increase in the magnetic anisotropy of nanoparticles was reported by many authors.[6, 479, 484]

The effect of the dipole–dipole interaction on the relaxation time of the magnetic moments of particles has been the subject of extensive literature. It was shown that the magnetic anisotropy constant increases as the number of the nearest neighbours increases.[485, 486] However, a model was proposed,[487] according to which the interaction between the magnetic moments causes a decrease in the parameter U_b. Experimental evaluation of these models faces some problems because the packing density of the particles can hardly be varied without changing the particle size. This can be done[482] by fabricating structures with different number of layers at the same cobalt sputtering tine. Experiments were carried out with the samples containing 1 and 30 monolayers of cobalt particles. The fact that both samples exhibited identical magnetisation curves confirmed coincidence of the particle sizes. The Curie–Weiss temperatures of the single-layered and thirty-layered films differed by nearly a factor of 2, which indicated a marked change in the average interparticle interaction. Measurements showed that the interaction between particles of the neighbouring layers (4.5 nm interlayer spacing) causes a substantial increase in the activation energy ($\sim$200 K for the systems under study). This value is nearly equal to the energy of the interaction between six nearest neighbours in the monolayer.

The magneto-optical properties of nanoparticles were studied.[225] Ordered ensembles of magnetite (Fe_3O_4) and cobalt ferrite ($CoFe_2O_4$) nanoparticles were first formed on the surface of the aqueous phase from the corresponding dispersions in organic solvents and then transferred on solid substrates. Particles stabilised by oleic acid were characterised by a broad size distribution; they were fractionated to obtain fractions with narrow size distributions in the range 2–10 nm and a scatter of 10% to 20%). It was established that the degree of local order of the structures under study depends on the particle size, namely, larger particles (6 nm) form ordered 'crystals', while small particles (2 nm) do not form ordered arrangements. The size of the ordered area can reach several micrometres. Figure 20 illustrates the effect of the strength of external magnetic field on the magnetic circular dichroism in the case of reflection of laser radiation by single-layered films. Measurements were carried out at different temperatures. The magnetisation curve of the two-dimensional ensemble of particles can be plotted using the results of measurements of the absorption difference between the waves with different circular polarisation as a function of the field strength. As can be seen, at room temperature the films behave as superparamagnetics. They exhibit no pronounced magnetisation hysteresis. As should be expected, the cobalt ferrite particles are first to possess hysteresis on lowering the temperature. The blocking temperature of cobalt ferrite is 200 K, while that of magnetite is 100 K. It should also be noted that cobalt ferrite is characterised by greater coercive force compared to magnetite. No significant changes in the magnetisation behaviour were observed after deposition of several layers. This indicates that in the systems under study the energy barrier associated with the crystal anisotropy is higher than the energy of the dipole–dipole interaction.

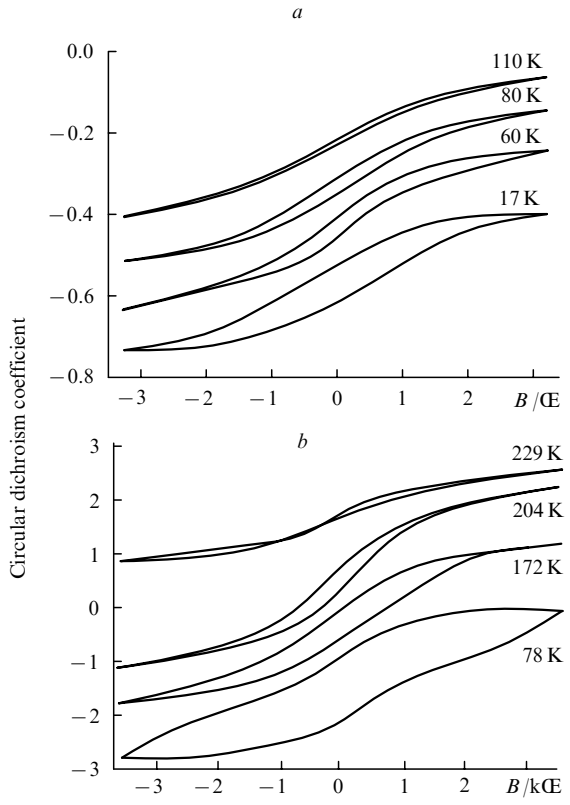

Figure 20. 'Circular dichroism–magnetic field strength (B)' dependences measured at different temperatures for a monolayer of magnetic particles;[225]
6 nm Fe_3O_4 particles (*a*) and 6 nm $CoFe_2O_4$ particles (*b*).

4. Thermal and mechanical properties

Colloid crystals are convenient for studying the phase transitions. Of particular interest are two-dimensional colloid crystals. It was established[488] that the melting transition in two-dimensional systems differs from the melting transition in three-dimensional crystals and occurs continuously involving dissociation of pair dislocations. More recently,[489, 490] it was shown that the newly formed phase is not an isotropic liquid and a second phase transition, which is due to the formation of disclinations, is necessary for the system to go from the so-called hexatic phase to the isotropic liquid. Such a two-step melting model is called the Kosterlitz–Thouless–Galperin–Nelson–Yang (KTGNY) theory. This theory predicts the temperatures at which the system becomes unstable and the topological defects (dislocations and disclinations) are formed. To test the theory, which was not necessarily confirmed in numerical experiments, the phase transition in a two-dimensional colloid crystal with well-defined magnetic interparticle interaction was studied.[491] Experiments with 4.7 μm iron oxide particles dispersed on the surface of water showed that melting of the crystal follows the KTGNY scenario. The shape of the pair distribution function was determined at different temperatures using a video camera. On melting of the two-dimensional crystal, the density correlation function first decreased following a power law with the exponent determined from the KTGNY theory and then decreased exponentially. Direct visual observations revealed the presence of a phase that was intermediate between the crystalline and liquid phases.

Two-step melting of two-dimensional ordered dusty plasma clusters was reported.[130] Numerical simulation showed that different cluster areas are disordered at different temperatures. However, this two-step mechanism can also be due to the finite size of the two-dimensional clusters under study.

The following should be pointed out. In spite of a large number of studies concerned with the formation of ordered monolayers comprised of nanoparticles, methods of structural characterisation of monolayers are still poorly developed. For instance, films formed at the gas–liquid interface are often characterised visually or by the packing density of the particles, which is determined from the compression isotherms. The only structural parameter used for the characterisation of monolayers is the regular lattice constant. Therefore, the general scheme[492] of analysis of the structure of nanoparticle monolayers is of great value. Two complementary methods were employed to derive this scheme. The properties of a monolayer were characterised using the pair distribution function while the presence of defects in the

monolayer was described by the Delaunay triangulation. A combination of the latter procedure and analysis of the Voronoi polyhedra can be applied to both two-dimensional and three-dimensional colloid structures.[493] The method was evaluated taking films comprised of silica particles formed on the surface of the liquid phase as an example. The particles were stabilised by alkylsilanes with different length of the hydrocarbon radical, which permitted variation of the force of the interparticle interaction. The properties of the films were also changed by varying the subphase composition and the degree of coverage of the particles with the alkylsilane adlayer. The energy of the particle–particle interaction on the surface of the subphase was calculated with inclusion of the van der Waals interaction and capillary forces. Figure 21 presents the dependence of the packing density of the particles in the monolayer on the surface of the liquid on the energy of the particle–particle interaction (at the minimum of the potential curve). In performing triangulation the triangles with vertices at the centres of spheres were plotted in such a way that no particles could pass through them. Figure 22 demonstrates some examples of the description of pores (defects) by different numbers of triangles (n_t). The pore size distribution was found to be lognormal. The pore size distribution for the monolayers of silica particles on the surfaces of various liquids is shown in Fig. 23.

These results were complemented with the data of a study on the structure and energy of defects in two-dimensional colloid crystal comprised of 0.36 μm polystyrene spheres.[494] Defects were formed using optical 'tweezers'. A colloid crystal with a lattice constant of 1.1 μm was formed by compression of the concentrated dispersion between two molten-quartz plates separated by a 2 μm gap. The motion of defects was studied using a video camera. General trends of the behaviour of dislocations were revealed. In particular, no single dislocations with the coordination number other than 6 (distorted coordination) were detected.

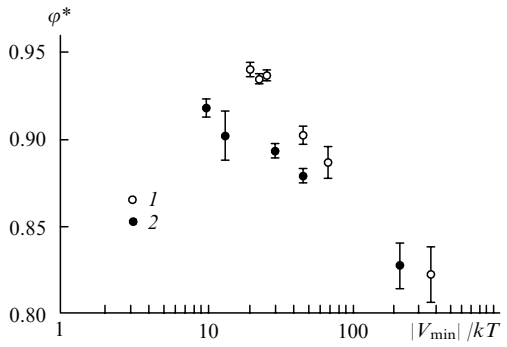

Figure 21. Packing degree of the monolayer of nanoparticles covered with octyltrichlorosilane (*1*) and octadecyltrichlorosilane (*2*) as function of the energy of the interparticle interaction at the potential well minimum.[492]

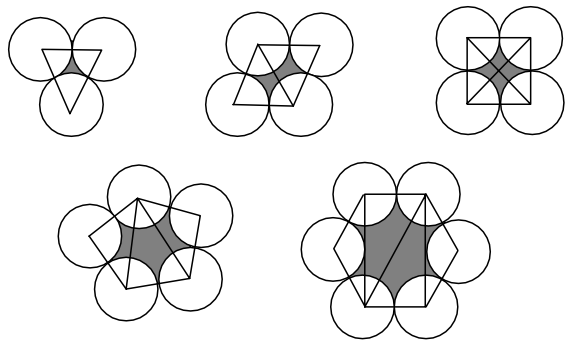

Figure 22. Triangulation schemes for various defects.[492]
For details, see text.

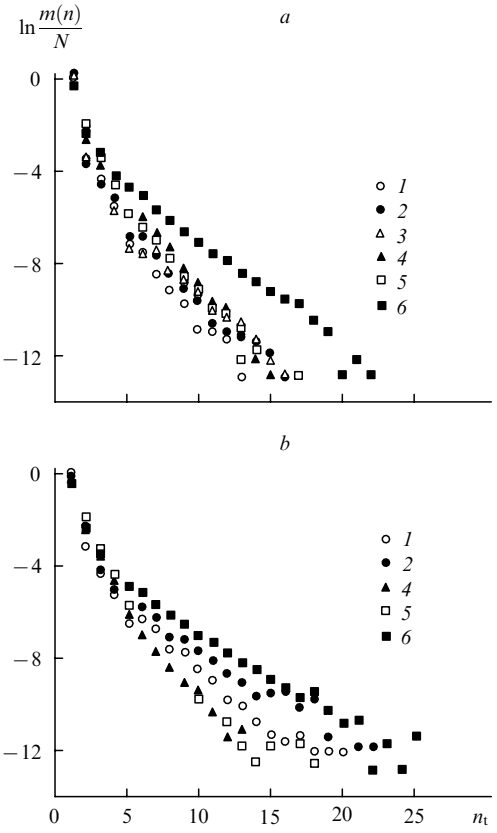

Figure 23. Pore size distribution in the monolayer of silica nanoparticles stabilised by octyltrichlorosilane (*a*) and octadecyltrichlorosilane (*b*) on the benzene (*1*), toluene (*2*), dichlorobenzene (*3*), dioxane (*4*), methoxyethanol (*5*) and water (*6*) surfaces.[492]

Only the pair, triplet, *etc*. dislocations with an average coordination number of 6 were observed. The sum of all vectors that emanate from the particles with a coordination number smaller than 6 and end at the neighbouring particles with a coordination number exceeding 6 equals nearly zero. This allows dislocations to be considered as multipoles with a zero summary Burgers vector.

The thermal and mechanical stability of the self-assembled ensembles of particles and their components play a significant role, because they can be at high temperature and pressure in the case of, *e.g*., catalytic applications. A particular role is played by the composition of the gaseous atmosphere. For instance, recrystallisation or even decomposition of platinum nanoparticles was observed at elevated temperature in an oxygen atmosphere in contrast to the hydrogen or noble-gas atmospheres,[495] whereas melting of the platinum particles of size from 5 to 20 nm on carbon substrate proceeds at 900 K.[496] The behaviour of single 20 nm platinum nanoparticles and their ensembles in oxygen atmosphere was studied.[497] An increase in the degree of crystallinity of the particles was observed at 700 K. The mechanism responsible for this process is still to be clarified, whereas the increase in the degree of crystallinity in the hydrogen atmosphere and *in vacuo* is due to diffusion of atoms in nanoparticles. According to atomic force microscopy data, the adhesive binding energy of the starting particles to the substrate was ≈ 0.8 mJ m^{-2} (the force measured was ≈ 10 nN). After treatment in hydrogen atmosphere at 700 K the adhesive binding energy became so high that it was impossible to measure its value. The observed changes in the degree of crystallinity and in the shape of the particles cannot be explained by their melting, because the particles of diameter 20 nm must melt at 2020 K even with inclusion of the dependence of the melting temperature on the particle size.

Recently, the properties of not only the metal 'core' of nanoparticles but also the single-layered organic shells have been the subject of investigations. The diversity of self-assembled ensembles of particles that can form on two-dimensional substrates [498] is also an intrinsic property of the molecular monolayers covering nanoparticles. These monolayers have a strong effect on the properties of the self-assembled ensembles of nanoparticles. A study on the ensembles of 4 nm silver and 3 nm gold nanoparticles stabilised by octadecanethiol, octanethiol, pentanethiol and butanethiol was reported.[499] The dried dispersions were mixtures of individual particles and colloid crystals. Analysis of the results of a differential scanning calorimetry study revealed two phase transitions corresponding to the melting of alkanethiol crystals (monolayers) and to the melting of the colloid crystal. The endothermic peak corresponding to the melting of the superlattice of gold particles is less pronounced than in the case of silver nanoparticles, thus indicating a lesser degree of crystallinity of the gold colloid crystal. The melting temperatures of the alkanethiol monolayers on the surface of silver nanoparticles also were found to be higher than on the surface of gold nanoparticles. This was explained by higher fraction of the organic phase in the case of gold particles.

The effect of thermal fluctuations in the ligand shell on the temperature dependence and on the topology of the order–disorder phase transition in the superlattice of nanoparticles was also studied [500] taking silver nanocrystals stabilised by alkanethiols (C_8, C_{12} and C_{16}) as examples. Measurements of the angular dependence of the X-ray scattering intensity at different temperatures showed that for all the samples under study the first diffraction peak disappeared in a rather narrow temperature range, thus indicating the topological disorder in the system. Near this temperature the peak markedly broadened due to enhancement of vibrations in the superlattice. This was similar to the situation observed for bulk crystals. However, above the melting temperature the superlattice behaved in another manner compared to conventional, 'atomic', crystals. All the samples under study were characterised by the appearance of a new peak at smaller values of the scattering vector q compared to those for the (111) diffraction peak. The new peak corresponds to the scattering region of size

$$\xi = \frac{2\pi}{q}.$$

As the temperature increases, the peak intensity increases and the peak is shifted towards small q values. This indicates the formation of a bicontinuous phase with spatially correlated regions whose sizes exceed both the thickness of the ligand shell and the size of nanocrystals. At a certain critical temperature T_c, the correlation region becomes infinitely large and the parameter ξ increases by a power law (Fig. 24):

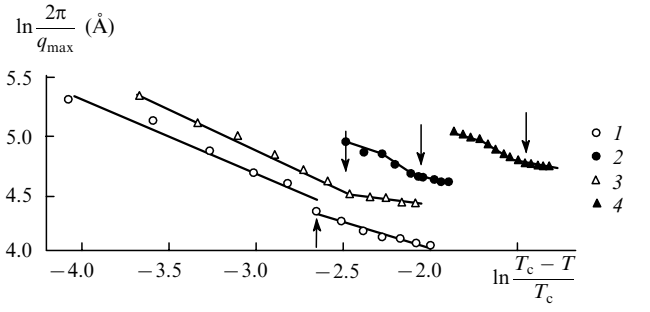

Figure 24. 'Characteristic size–temperature' plot for ensemble of sterically stabilised nanoparticles.[499]
The transition temperatures are shown by arrows. Particles were stabilised by alkanethiols containing a total of 8 (*1*), 12 (*2*, *3*) and 16 (*4*) carbon atoms in the alkyl chain. Chain length is 41 Å for (*2*) and 35 Å for (*3*).

$$\xi \propto \xi_0 \left(1 - \frac{T}{T_c}\right)^{-v}.$$

At a certain temperature T_x, the exponent v increases, becomes independent of the type of the ligand shell and corresponds to the critical index in the Ising model.

The supercrystal behaves similarly to the sponge phase of the surfactant, namely, its stabilisation is due to the long-range entropy forces related to fluctuations of the ligand 'membrane.' At high temperature (above the melting temperature of the superlattice), silver nanoparticles contacting one another bring closer together and form aggregates surrounded by the hydrocarbon chains attached to the surface of particles. The behaviour of such systems is governed by a complex combination of the van der Waals forces that act between the particles and hydrocarbon chains.

In conclusion, we will consider unusual self-assembled structures obtained upon binding of alkanethiol molecules functionalised by the COOH groups (*e.g.*, 11-mercaptoundecanoic or 1-mercaptohexadecanoic acids) and adsorbed on the surface of gold particles. Such structures are formed due to hydrogen bonds of the terminal carboxyl groups. They exhibit the ability to selectively transmit particular ions. The selectivity can be tuned by varying the pH value of the solution.[501] Changes in the morphology of ensembles of hydrogen bond stabilised nanoparticles upon variation of the pH value of the solution were studied.[502] To this end, gold nanoparticles stabilised by functionalised alkanethiols were obtained and alternating regions (of size nearly 2×2 μm) of monolayers of octadecanethiols containing the COOH and CH_3 terminal groups were formed by microcontact printing on a gold plate. The plate was dipped in a colloid solution containing gold nanoparticles. As a result, several layers of functionalised particles were deposited on the monolayer regions bearing the COOH groups, whereas no particle deposition occurred on the other regions. Atomic force microscopy studies revealed that variation of the pH value of the medium from 2 to 11 caused a twofold change in the height of the particle clusters (Fig. 25) due to the fact that the Debye length for the systems under study was several times longer than the interparticle distance and, hence, the charges of the particles were only partially screened. Such systems serve as the basis for fabrication of (i) membranes with tunable permeability towards different ions and (ii) recognition systems.

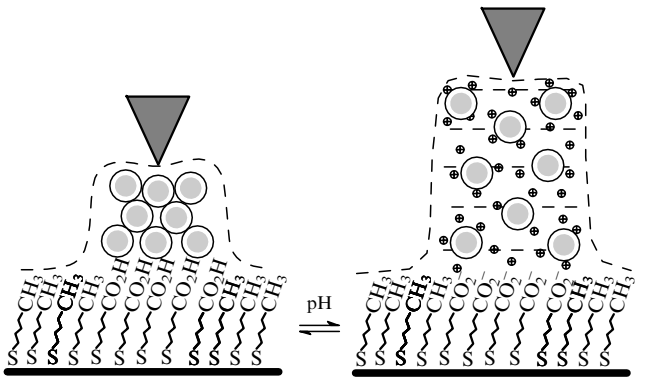

Figure 25. Changes in the size of a gold nanocluster depending on the pH of the solution.
For details, see text.

VI. Conclusion

Analysis of the available data (see above) shows that recently considerable advances in design of ordered ensembles of nano-

particles and in the studies of their properties have been achieved. The results obtained point to great prospects for the use of nanomaterials in the design of new-generation devices which can find various applications from medicine to microelectronics.

At the same time, many problems that arose in studies of ensembles of nanoparticles are still far from being solved. No efficient methods of fabrication of ensembles of monodisperse particles have been developed. Control of the interfacial behaviour of nanoparticles faces some problems (only preliminary results were obtained in this field). Realistic and reliable description of the physicochemical properties of ordered ensembles of nanoparticles with inclusion of co-operative effects is impossible, because most theories are still based on the single-particle approximation. Nevertheless, we hope that intensive research in the field will lead to new advances towards understanding of the physicochemical properties of ensembles of nanoparticles in the nearest future.

The author expresses his gratitude to V M Rudoy for help in the preparation of the review.

The review has been written with financial support from the Russian Foundation for Basic Research (Project No. 03-03-32513) and the Presidium of the Russian Academy of Sciences (Programme 'Fundamental Problems of Physics and Chemistry of Nanosystems and Nanomaterials').

Abstract. The results of recent studies in the field of self-propagating high-temperature synthesis of nanosized materials are surveyed. The possibilities of the synthesis of nanomaterials in the combustion mode are demonstrated. Examples of applications of the self-propagating high-temperature synthesis for the preparation of nanopowders, films and compact materials are given. The bibliography includes 116 references.

I. Introduction

The self-propagating high-temperature synthesis (SHS) is an autowave process analogous to the propagation of a combustion wave.[1] In this process, a chemical reaction is localised in the combustion zone that spontaneously propagates over a chemically active medium. This process is actively exploited in the technology of inorganic materials: this makes it possible to produce powders, compact materials and workpieces as well as make coatings and weld component parts.[2]

The self-propagating high-temperature synthesis is effectively applied not only in technology but in a solution of various problems of modern materials science as well. Among such problems, the following may be mentioned: design of functionally graded materials,[3] single crystal growth,[4] development of gravity-sensitive processes,[5] realisation of chemical reactions under conditions of micro-gravity and zero gravity,[6, 7] mechanochemical treatment of reactants and reaction products,[8] thermochemical generation of electric and magnetic fields,[9] *etc*. As in the powder metallurgy, the particle size of reactants and reaction products plays a crucial role in the self-propagating high-temperature synthesis. In this respect, the SHS is closely interrelated with nanotechnology. Further reduction in the particle size is an urgent task since the size effects have a decisive influence on both the SHS process itself and properties of the resultant materials.

In the present review, the results of recent investigations in the field of SHS of nanosized materials are surveyed. Possibilities of its applications aimed at the preparation of nanopowders and films, compact materials with nanosized grains and pores are considered. Distinctive features of the SHS involving nanosized components (reactants, functional additives) are discussed.

II. Formation of nanostructures in the processes of self-propagating high-temperature synthesis

The possibility of direct preparation of nanosized structures by SHS is not self-evident. Some specialists in materials science believe that SHS products are always large-grain structures due to high temperatures developed during combustion. In fact, conversion of initial reactants into final products as a result of SHS is a complicated multi-parameter process. Therefore, there are several ways to control it. Provided that the ways to adjust the required conditions are established, one may hope to succeed in the synthesis of nanostructured materials.

About one hundred papers devoted to the self-propagating high-temperature synthesis have been published over last few years. Most interesting of them are discussed below.

I P Borovinskaya suggested a concept[10] of further developments of investigations in the field of the SHS of nanomaterials, in which the formation of nanostructures is related to the combustion mechanism. The major types of such processes were considered including: solid flame combustion 'solid + solid' systems (including one of its modifications, *viz*., combustion with an interstitial molten layer); gas-phase SHS (*e.g*., chain flames, combustion of condensed systems with a gaseous interstitial zone); combustion of 'solid + gas' systems (*e.g*., filtration combustion, combustion of gaseous suspensions).

Let us analyse the potentials of these methods.[10]

In the case of a solid flame SHS process, the combustion reaction proceeds in the diffusion mode. As a result of a chemical reaction between two solid reactants, a continuous layer of solid products starts to grow on grains of one of the reactants, which separates the reactants. Thus, the total rate of the process is limited by the diffusion of the second component through the product layer. Since the change in the specific volume of grains of the starting reactants due to the formation of the product layer atop them is rather small, the size of the particles formed is similar to that of particles of the starting reactants. Owing to the high diffusion resistance of contacting areas of the particles, recrystallisation processes are virtually completely suppressed in such systems.

Thus, nanosized reactants have to be used in order to produce nanosized products by solid flame combustion processes.

In solid-state systems with an interstitial molten layer, the possibility of formation of nanocrystallites depends on the crystallisation and recrystallisation processes and thermal regimes of combustion and cooling of the product after the completion of the reaction.

Among synthetic methods allowing production of nanoparticles, the gas-phase SHS, *i.e.*, combustion of gases giving rise to a condensed product, is of particular importance. The reaction proceeds on nuclei that are formed by an agglomeration of primary particles of the product. The particles grow until the reactants are consumed. If the reaction mixture is allowed to rapidly expand, the process stops due to the fast artificial cooling (quenching) of the mixture. Using this technique, one may stop the particle growth at any required stage. A continuous combustion process with a continuous quenching of the mixture at a certain conversion level, which allows a control over the size of the particles formed, is readily realisable for gaseous mixtures.

Sedimentation of particles from a gaseous suspension gives rise to nanopowders that can be further used in various technological steps involving powder mixtures. The flame-cladding of powders (*i.e.*, their coating with a metal layer) is of particular interest. In particular, nanosized powders of titanium carbide coated with a nickel–molybdenum film, which can be used for production of hard alloys, have been prepared in this way.

Synthesis in the chain flames is one of the modifications of the gas flame SHS.[11] It involves the same processes as described above for the generic gas flame SHS but at a lower temperature. This allows preparation of thermally unstable products. Synthesis in the chain flames is most frequently applied to the preparation of nanosized oxides.[12, 13]

It has to be noted that heterogeneous condensation can also be carried out in flames. In order to make a coating (or deposit a film) on a workpiece, it is introduced into the suitable flame.

The chemical condensation combustion of condensed mixtures is of great interest. In this case, the reactants are brought to the gaseous state prior to the initiation of the reaction. If condensed products are formed exclusively or predominantly in the reaction, the gas-phase stage can even elude detection by researchers. This process is insufficiently explored to date. In the SHS processes that include a gas-phase stage of the chemical conversion, the formation of nanosized products is largely determined by conditions of the chemical condensation, which can be deliberately adjusted.

Unusual mechanisms of formation of nanoparticles are often observed for 'solid + gas' systems. In particular, the filtration combustion of porous solids (*e.g.*, powder bitstones or compacted blanks) or gaseous suspensions is worth mentioning.

The above qualitative analysis taken from the conceptual work [10] demonstrates that diverse physicochemical transformations are realised within the SHS processes, such as: chemical reactions, reaction diffusion, melting, dissolution, crystallisation, recrystallisation, evaporation, sublimation, dissociation, chemical condensation, *etc*. All these processes affect the crystal structure of the product formed. Generation and growth of nuclei are most important for the formation of nanoparticles. Therefore, if the problem of preparation of nanosized products by means of SHS is posed, special attention has to be paid to crystallisation, recrystallisation and chemical condensation.

III. Traditional processes of the self-propagating high-temperature synthesis

Let us first consider traditional SHS processes, which allow preparation of nanomaterials. They include the combustion processes in mixtures of powders and in solid + gas systems. Formally, the combustion involving nanosized powder reactants may also be classified as a traditional SHS process but studies in this field have begun only recently. Unfortunately, most authors report only the synthesis of nanomaterials by means of the SHS and do not analyse the mechanisms and kinetic features of their formation.

1. Preparation of nanomaterials based on powder mixtures

SHS processes involving powder mixtures are predominantly applied to the preparation of nanosized metal oxides and silicon carbide. For instance, nanocrystalline α-Al_2O_3 has been synthesised [14] from a mixture of powdered aluminium nitrate and urea. Heating followed by self-ignition of the mixture resulted in a melt from which a foamed α-Al_2O_3 structure was formed. After grinding the product, α-Al_2O_3 powder with the particle size of $\sim$ 100 nm was obtained.

An Al_2O_3–ZrO_2 solid solution has been synthesised [15] from a mixture of aluminium and zirconium nitrates (oxidants) with urea (combustible material). The process was conducted in the thermal explosion mode in the following sequence: heating of the mixture to 450–600 °C, melting, ignition and combustion. The resultant product composed of agglomerates with a size not exceeding 100 nm was ground, coated with BN, compacted and sintered at 1200 °C. The final product manifested high quality as regards its physicomechanical characteristics: relative density, 99%, the Vickers hardness, 4.45 GPa, crack resistance coefficient K_{1c}, 8.38 MPa $m^{1/2}$, the size of Al_2O_3 and ZrO_2 grains, less than 50 nm.

A technology of self-propagating high-temperature synthesis of β-SiC based on the direct heating of the green mixture has been developed.[16] The authors used an original means of heating, *viz*., the burner (flare) was moved along the sample with a velocity equal to that of the combustion front propagation. The size of the β-SiC grains produced was close to the nanorange (< 200 nm) and virtually independent of the particle size of the parent silicon.

Preparation of nanosized silicon carbide attracts a lot of attention. A direct synthesis of SiC has been accomplished [17] in the thermal explosion mode with microwave heating. The initial Si and C particles were of equal size ($\sim$ 43 μm). The silicon carbide powder produced was composed of needle-shaped particles with a diameter of 36–76 nm and length of 360–1500 nm.

In those cases where smaller Si and C particles were used, small fibres were produced. Note that in this process the combustion is initiated in the bulk of the sample and then propagates towards its surface in the SHS mode. This model is supported by conclusions of a theoretical investigation [18] into post-induction phenomena occurring in the course of a thermal explosion in 'porous reagent–reactive gas–solid product' systems.

A procedure for the preparation of an engineering ceramic according to the reaction:

$$TiO_2 + Al + C + ZrO_2 \xrightarrow[Ar]{SHS} Al_2O_3 + TiC + ZrO_2$$

has been described.[19] The reaction product was a mixture of crystalline TiC and ZrO_2 with amorphous Al_2O_3. The size of the TiC and ZrO_2 crystallites was *ca*. 20 nm. Crystallisation of Al_2O_3 from the amorphous phase occurs after completion of the chemical reaction. Note that although ZrO_2 is not involved in the reaction it undergoes structural transitions resulting in a decrease in its particle size from 10 μm to 20 nm.

The problem of what the chemical reactions or phase or structural transitions are that occur in the combustion wave during the SHS processes is of primary importance. Many phase and structural transformations of substances occur far beyond the combustion front when the chemical processes are already completed. This can lead to substantial changes in the microstructures of the combustion products. Figure 1 shows some typical examples of the dependence of the product grain size on the distance from the combustion front. The data presented suggest [20] that the recrystallisation processes leading to an increase in the grain size (by a factor of 10) [20] proceed actively in the system after completion of the chemical reactions in the combustion wave. Definitely, monitoring of the evolution of the microstructure is a

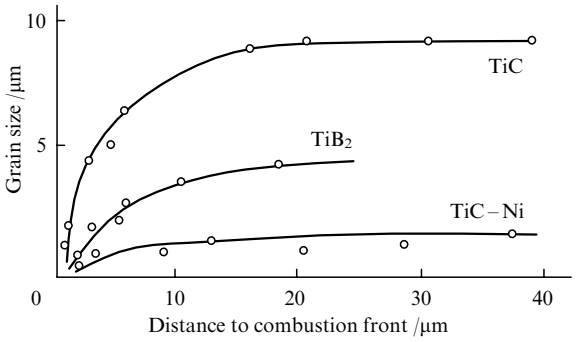

Figure 1. The dependence of sizes of TiC, TiB_2 and TiC – Ti grains on the distance from the combustion front.[20]

complicated task. Its solution requires dedicated techniques and high-resolution instruments.

2. Preparation of nanomaterials based on 'powder + gas' systems

An interesting two-stage synthesis of nanosized silicon carbide has been reported.[21] Its first stage involved combustion of a mixture of powdered Si and C (with an excess of Si) in a nitrogen atmosphere, which gives rise to Si_3N_4 and SiC. The second stage included a reburdening of the mixture produced with carbon (soot) followed by the carbothermal reduction of Si_3N_4 to Si and subsequent interaction of the latter with carbon. As a result of this two-stage process, the initial Si + C mixture is converted into nanosized SiC. Direct interaction of Si with C results in the formation of coarser particles. The chemical reaction may be represented as follows:

$$\mathrm{Si} + m\,\mathrm{C} \xrightarrow{\mathrm{N_2}} \frac{1-m}{3}\,\mathrm{Si_3N_4} + m\,\mathrm{SiC} + Q_1,$$

$$\frac{1-m}{3}\,\mathrm{Si_3N_4} + m\,\mathrm{SiC} + (1-m)\mathrm{C} + Q_2 \longrightarrow \mathrm{SiC} + \mathrm{N_2}\uparrow.$$

The scheme of structural changes occurring with the starting materials and intermediate products during the SHS is shown in Fig. 2.

A method of preparation of SiC – AlN powders (solid solutions) by means of combustion of mixtures of micrometer-sized powders of Al, C and AlN and a submicrometer powder of Si in a nitrogen atmosphere at a pressure of 4 atm has been suggested.[22] The authors used two routes, *viz*., synthesis in the thermal explosion mode and the propagating combustion wave mode. The SiC – AlN solid solutions prepared using both the filtration combustion and thermal explosion represented powders with the particle size smaller than 200 nm. The crystal structure of the SiC – AlN powder synthesised using the SHS showed disorder at the atomic level. In order to produce ceramics, the powdered SiC – AlN solid solutions were sintered. Such a thermal treatment led to the ordering of their crystal structures. The obtained engineering material possessed high mechanical properties, thermal and chemical stability.

Synthesis of filamentous silicon nitride with a particle diameter of 60 – 400 nm has been reported.[23] A silicon powder with the particle size of 0.5 – 2.0 μm doped with NH_4F and Al powder mixed with a β-Si_3N_4 powder (acting as a thinner) was used as the starting material. The reactants were mixed in the following proportions: $Si : Si_3N_4 : NH_4F : Al = 87 : 10 : 2 : 1$ (mass %). The combustion was conducted in a nitrogen atmosphere at a pressure of 100 atm. The authors emphasise the key role of NH_4F (it favours a decrease in the adiabatic combustion temperature and in the heat conductivity and accelerates the crystal growth) in the formation of β-Si_3N_4 nanofibres. The morphology of the silicon nitride microstructure is shown in Fig. 3. It is clearly seen that the crystals are either straight, stranded or wavy in shape.

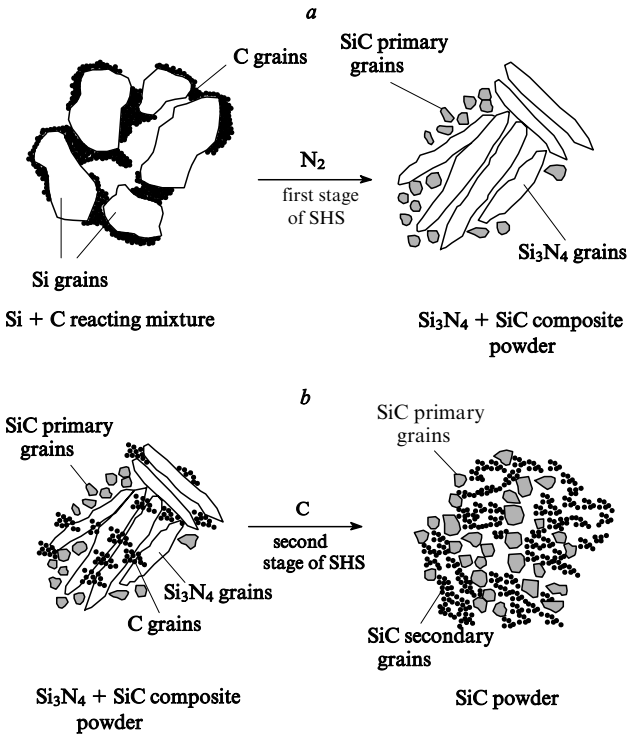

Figure 2. Morphological changes occurring in the course of the SHS of silicon carbide from powdered Si and C in a nitrogen atmosphere; (*a*) the stage of formation of the SHS products, Si_3N_4 + SiC; (*b*) the stage of SiC formation.

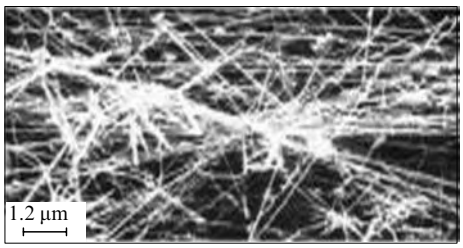

Figure 3. The morphology of silicon nitride microstructure.[23]

Two schemes for the preparation of nanosized β-Si_3N_4 – β-SiC materials by means of the solid-state chemical synthesis (*a*) and in the SHS mode (*b*) [24] are shown in Fig. 4.

Self-propagating high-temperature synthesis of various hydrogen-containing substances [25, 26] including nanosized hydride powders has been accomplished as a part of a systematic investigation into the combustion processes of metals and alloys in a hydrogen atmosphere. Unfortunately, the mechanism of formation of the nanopowders was not discussed.

The preparation of nanosized boron nitride powders in the SHS mode can be carried out in three ways according to the following reactions:[27]

(1) synthesis from elements

$$\mathrm{B} \xrightarrow{\mathrm{N_2}} \mathrm{BN},$$

(2) synthesis involving boron oxide

$$\mathrm{B} + \alpha\text{-}\mathrm{B_2O_3} \xrightarrow{\mathrm{N_2}} m\,\mathrm{BN} + n\,\mathrm{B_2O_3} + \mathrm{O_2}\uparrow,$$

(3) synthesis from B_2O_3 including a stage of magnesiothermic reduction

$$\mathrm{B_2O_3} + 3\,\mathrm{Mg} \xrightarrow{\mathrm{N_2}} 2\,\mathrm{BN} + 3\,\mathrm{MgO}$$

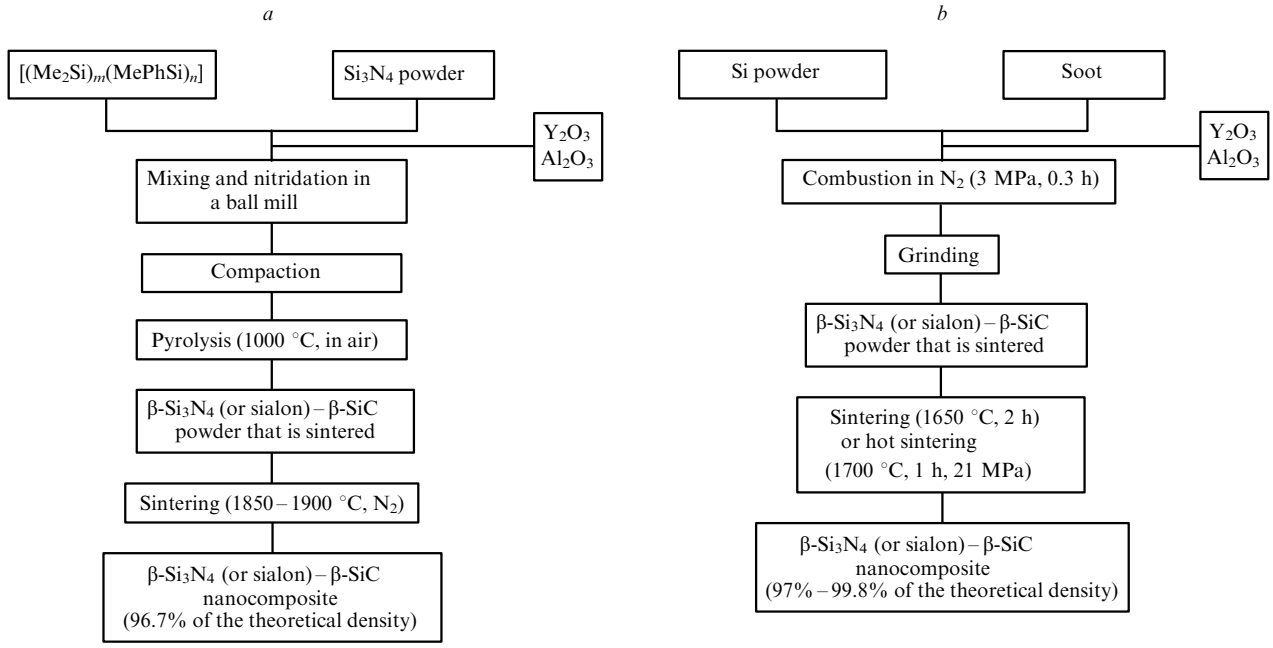

Figure 4. Two schemes of the preparation of Si_3N_4 – SiC nanocomposites from powders;[24] (*a*) chemical pathway, (*b*) in the SHS mode.

In all the cases, the products represented BN crystallites with a size of 100 – 200 nm combined in larger agglomerates.

In order to produce nanosized particles, it was necessary that the combustion product (semi-finished material) underwent further mechanical and thermochemical processing using acids and alkalies under drastic (for the dissolution of MgO) or mild (for the preparation of nanocrystalline samples through the chemical dispersion) conditions. The shape and size of BN particles were determined and the specific surface areas of both semi-finished material and the final product were calculated. Table 1 summarises the major characteristics of BN prepared by different methods.

The mechanical processing of the semi-finished material did not result in complete disintegration of the crystallites and thus the final product represented a powder containing agglomerated particles with different specific surface areas. Subsequent thermochemical treatment (chemical dispersion †) resulted in further disintegration of crystallites and in an increase in the specific surface area of the product. Fully disintegrated powders were obtained only from semi-products prepared by magnesiothermic reduction of B_2O_3. Such powders were composed of pure crystallites with a size of 100 – 200 nm. The specific surface area of the final product amounted to ~ 60 m^2 g^{-1}. The effectiveness of the above approach to the preparation of nanosized particles depends on whether crystallite formation process during the SHS can be controlled.

The microstructures of a boron nitride powder produced in the SHS mode before and after the chemical dispersion are shown in Fig. 5.[27]

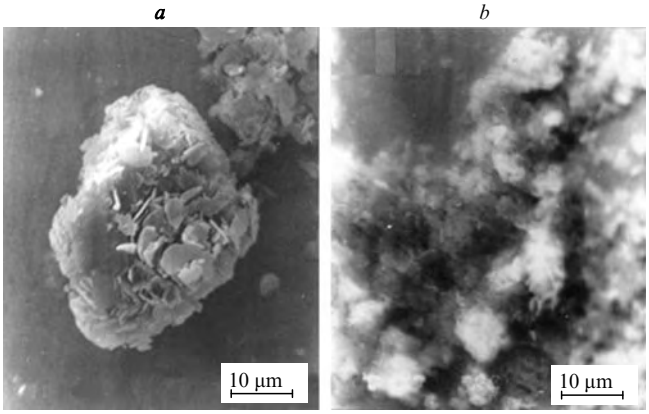

Figure 5. The microstructure of a BN powder;[27] (*a*) agglomerated hollow particles of powdered boron nitride taken from the SHS product, (*b*) single-crystalline BN formed as a result of the chemical dispersion.

† The chemical dispersion is one of the modifications of the thermochemical treatment of a product,[28] which leads to dissolution of boundary (typically, defective) layers of crystallites and to removal of contaminations, whereupon the crystallites themselves are not dissolved. As a result of such a treatment, a polycrystalline product is disintegrated into single-crystalline particles.

Table 1. Self-propagating high-temperature synthesis of fine BN powders.[24]

Powdered reactants	Intermediate product	Method for the isolation of the final product	Specific surface area /m^2 g^{-1}	
			of intermediate product	of target product
B	Polycrystalline BN cake	chemical dispersion	~6	10 – 12
$B + B_2O_3$	BN + B_2O_3 cake	treatment with water, chemical dispersion	4.5 – 5.5	8.5 – 12.0
$B_2O_3 + 3$ Mg	BN + MgO cake	chemical enrichment, chemical dispersion	3.0 – 10.5	9.5 – 60.0

IV. Gas-phase self-propagating high-temperature synthesis

Despite the fact that the combustion of gases is fairly well investigated (in contrast to the combustion of condensed systems), the gas-phase SHS has not been sufficiently explored to date. This is because there are only a few known gaseous systems that can undergo combustion to form condensed products. In particular, three processes have been studied:

(1) sodiothermic reduction of chlorides in the gas phase giving rise to chemical elements or compounds;

(2) gas-phase oxidation of combustible gases (hydrocarbons, silanes, boranes, *etc.*) with the formation of respective oxides;

(3) chemical reactions in independently generated flames that played a role of gas-phase 'chemical furnaces'.

1. Self-propagating high-temperature synthesis including a stage of sodiothermic reduction of chlorides

A remarkable feature of the sodiothermic reduction of chlorides is the formation of water-soluble NaCl as a by-product of the SHS. Therefore, the isolation of the target product from the reaction mixture faces no problems in contrast to that in the cases of magneso- or aluminothermy.

For the first time, the process of the sodiothermic reduction of chlorides by means of the gas flame combustion has been applied to the preparation of powders of reduced silicon and silicon and titanium nitrides [29, 30] using gaseous silicon and titanium chlorides as reactants and sodium or sodium–potassium vapour as the reducing agent. Other examples of syntheses of nanosized products through the SHS including a stage of sodiothermic reduction may be found elsewhere.[31–33] In particular, a gas-phase combustion of $TiCl_4$ and BCl_3 in sodium vapour yielded a titanium diboride powder, which represented agglomerates with a size of 20–100 nm composed of spherical TiB_2 particles with the diameter of less than 15 nm (after vacuum sublimation and annealing at 1000 °C) (Fig. 6).[31]

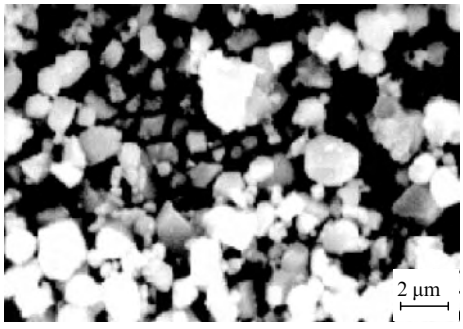

Figure 6. Nanoparticles of titanium diboride.[31]

An interesting example of preparation of a nanosized TiAl powder (~ 6 nm) under conditions of zero gravity, which favoured the formation of a stable air suspension has been reported.[34] Different condensation modes and their influence on the morphology of the particles formed were considered.

2. Gas-phase oxidation of combustible gases

Self-propagating high-temperature synthesis of particles and films of Si, Ge, SiO_2, GeO_2, Si_3N_4 by means of oxidation and pyrolysis of silane or germane [11, 35, 36] as well as gas-phase synthesis of ultradispersed amorphous powders of SiC, Si_3N_4, SiN_xC_y and of crystalline BN in the combustion mode [37] have been reported. The main advantage of this method for the production of insulating, protective and semiconductive films or nanosized powders is the possibility of performing the synthesis at relatively low temperatures and pressures, which allows one to avoid high charge densities on surfaces of the films, which greatly enhances the quality of the semiconducting products.

The chain character of the SHS processes makes it possible to apply a variety of well-established techniques developed for chain processes for their control without recourse to plasmochemistry or photochemistry. In particular, small amounts of suitable additives can be used to promote (*e.g.*, hydrazine) or, *vice versa,* inhibit (*e.g.*, olefins) the SHS. In most cases, the application of plasmochemistry is undesirable since the charged species formed in the plasma increase the surface charge density and thus deteriorate the product quality. Additionally, surface defects are developed under the action of flame or light.

Unfortunately, it is information on the products obtained that is normally given in publications devoted to the gas-phase SHS, whereas a discussion of relations of the combustion mechanism with the condensation processes and the effects of hydrodynamic factors on the combustion and the structure formation is lacking. A dependence of the morphology of the particles formed on the gas flow regime (laminar *vs.* turbulent) and its change upon a flow crisis have also eluded exploration.

To date, the gas-phase SHS has been studied only on a few case systems since gas mixtures forming solid products and having a relatively large thermal effect upon combustion are scarce. Further progress of this method can be connected with the utilisation of additional heating sources (*e.g.*, recuperative heating of reactants, plasma-induced heating, electrogas heating, *etc.*).

Realisation of the SHS using gaseous suspensions as reactants is highly problematic due to low heat evolution and poor heat exchange between particles. In this case, preliminary partial or complete gasification of reacting particles followed by a condensation of the combustion product is typically applied. The particles formed in such processes are usually substantially smaller than those of the starting reactants.

An original version of gaseous suspension SHS has been suggested.[38] In order to initiate the SHS, it is necessary to generate a cloud of metal particles in an atmosphere of a gas (oxygen, nitrogen, ammonia or another gas), which is subsequently ignited by a spark discharge. After completion of the reaction, the products are collected on a filter. Powders of Al_2O_3, MgO, SiO_2, TiO_2, ZrO_2, FeO, TiN and ZrN with the particle size of 10–100 μm were synthesised by this method.

Similar results concerning the preparation of nearly monodisperse spherical particles of γ-Al_2O_3, Fe_2O_3, Fe_3O_4, ZrO_2 with the size of ~40 nm have been reported.[39, 40] Fine metal particles with the size not exceeding 10 μm dispersed in a gas phase were taken as the starting reactants. The combustion process was induced by a diffusion or homogeneous flare.

3. Syntheses in flames

Pyrolysis of substances in flames may also be regarded as a modification of the gas-phase SHS. In this case, both the substances that are introduced into the flame and the chemical components of the flame itself can be involved in the synthesis, the reactions involving the flame components may differ from those involving the external components introduced to the flame (the formation of the target product). In those cases where the flame is chemically inert, it may be considered as a gas-phase 'chemical furnace' that only provides high temperature. Using this approach, it was possible to synthesise the following nanosized substances: TiAl,[41] Ti-W,[42] SiO_2,[42, 43] Si_3N_4,[44] TiB_2,[31] GaN,[45] Y_2O_3–Eu [46] and AlN.[47] For instance, SiO_2 nanopowders were prepared from an SiH_4–H_2–O_2–Ar gas mixture using a hybrid gas burner.[42] Adjustments of combustion conditions (*e.g.*, the stoichiometric composition of the fuel gas for the burner) made it possible to produce particles with the sizes ranging from 6–8 nm (at high oxygen concentration) to 18–20 nm (at low oxygen concentration).

V. Stimulated self-propagating high-temperature synthesis

It is well known that the SHS process can easily be subjected to external stimulation. The simplest and most common means is thermal action. Owing to a thermal energy transfer to the original mixture or the combustion zone, the temperature and combustion rate can be deliberately increased and thus the composition and characteristics of the combustion products can be affected.

Joule heating by passing electric current through the burden is one the simplest ways of such an energy input. Typically, two types of Joule heating are used in experiments, *viz*., the contact heating, which results in bulk self-heating of the whole sample turning into the thermal explosion (the so-called electrothermal explosion, ETE), and local heating leading to a local ignition and formation of a combustion wave.

The former method was first suggested by Knyazik *et al*.[48] in the mid 1980's. It was further developed and applied to the study of heat liberation kinetics of high-temperature (> 3000 °C) and fast reactions in heterogeneous condensed systems (*e.g*., Ti – C, Ti – B, Ta – C, Ni – Al, *etc*.).[49 – 51]

The latter method referred to as field-activated SHS was elaborated by Munir in the late 1990's.[52] It is used to enhance the completeness of the combustion in the solid flame SHS processes.

Several attempts to produce nanostructured materials making use of the thermal action on the combustion products have been undertaken.[20, 53, 54] In particular, quenching of a burning Ti + 2B mixture allowed production of TiB_2 grains with different sizes depending on the combustion front position.[53] The grain growth proceeded very fast resulting in a size change by one order of magnitude (see Fig. 1).

1. Mechanochemical self-propagating high-temperature synthesis

The SHS of nanosized materials can most efficiently be influenced by mechanical actions. These include mechanical treatment of a burden, mechanical action on a burning sample and mechanical treatment of products. All three methods give interesting results.

Mechanical activation of reactants before the initiation of the SHS process is a very important stage. This increases the reactivities of the particles that are treated due to an increase in the defect concentration and/or the reaction area (due to a decrease in the particle size). Therefore, the mechanical activation prepares the particles for the active involvement in the reaction. Its maximum effect is observed in the case of 'ideal' [55] solid flame SHS processes. For the liquid-phase SHS, such an effect can be either weak or even totally absent.

The mechanical activation can influence the velocity and conditions of the combustion front propagation (macrokinetic effect) as well as the shape and size of the crystallites and porosity of the structure (structural effect).

A control over processes of the wave propagation and of the structure formation in the product is a challenging task. To date, only the problems of the initiation of the SHS in weakly exothermic systems and of a decrease in the size of crystallites of the combustion products have been resolved.

Several examples of the influence of the mechanical activation on the course of the SHS are given below.

Preparation of titanium carbide with the composition $Ti_{44}C_{56}$ from a mixture of powdered Ti and C has been described.[56] Prior to the initiation of the SHS process, Ti and C powders were mechanically activated in a ball mill. The titanium carbide particles produced represented polycrystals with the size of ~ 0.5 μm composed of crystallites with the size of ~ 3 nm. It is very likely that subsequent mechanical or thermochemical processing of the product can result in a powder containing true nanosized particles. Note that the product can be formulated as $TiC_{1.27}$ or $Ti_{0.79}C$, which corresponds to carbon overstoichiometry. Therefore, the Ti sublattice of the product should have numerous defects (vacancies). This result is new in principle, which requires, in our opinion, a careful verification.

A mechanochemical synthesis of β-SiC starting from powdered Si and C has been accomplished.[57] It was shown that mixing of the starting reactants in a ball mill resulted in the full conversion of Si and C to β-SiC (100% degree of conversion). The product formed had a homogeneous structure with the grain size of ~ 7 nm.

A titanium carbide powder with the particle size of 30 nm has been produced by pressure-assisted sintering.[58] The deformation temperature of the resulted nanosized powder is 500 °C lower than the conventional temperature. The same authors reported a synthesis of nanostructured TiB_2.[59] The microstructure of the product and the particle size distribution therein are shown in Figs 7 and 8, respectively.

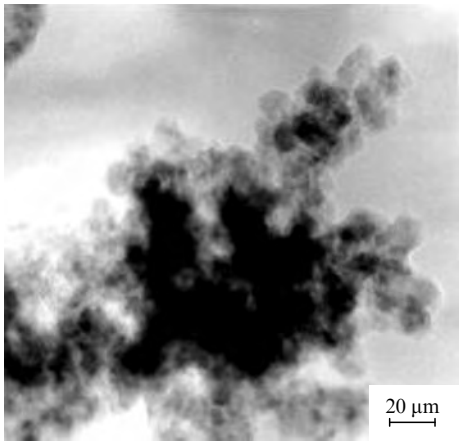

Figure 7. The microstructure of TiB_2.[59]

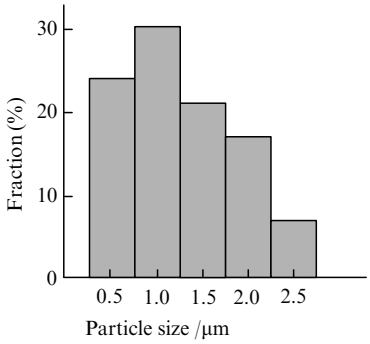

Figure 8. Size distribution of TiB_2 particles.[59]

Grinding of combustion products is an efficient way to produce nanosized particles. For instance, mixing and ball milling of powdered silicon and titanium with the particle sizes of 25 – 30 μm and 44 μm, respectively, yielded a series of silicides $TiSi_x$ (where x is defined by the ratio of the reactants) with a particle size less than 100 nm.[60] In cases of high Si content in the reaction mixture (34 at.% – 60 at.%), the reaction proceeds in the thermal explosion mode. During the mechanical activation, disintegration of the reactants occurs, which is accompanied by formation of grains of products with the following compositions: $Ti_{33.4}Si_{66.6}$, $Ti_{62.5}Si_{37.5}$,$Ti_{50}Si_{50}$ and $Ti_{55.6}Si_{44.4}$. For lower silicon contents, the components interact slowly giving an amorphous product. This process is especially interesting since it provides an example of a control over the final structure of the target powders.

Syntheses of various compounds (*e.g*., TiN) and alloys (*e.g*., Fe – Al – Cr) using mechanical activation have been described.[61 – 63] Unfortunately, the thermal patterns of the proc-

esses (*i.e.*, emergence of heating centres, thermal explosion, flame propagation, *etc.*) were not analysed.

The mechanical activation was shown[64] to have a great potential for the self-propagating high-temperature synthesis of metal alloys (*e.g.*, Ni–Al, Ni–Si, Ni–Ge, Ti–Ni) and oxides [*e.g.*, Ba–Zr(Ti, Hf, Mo, W, Al)–O, Ca–Mo–O, Sr–Mo–O, Pb–Mo–O, *etc.*]. The influence of the mechanical activation of both the reactants and the products was carefully studied and the industrial applicability of the technique was convincingly demonstrated. It was noted that even brief mechanical activation allows production of homogeneous monophasic nanosized powders of complex oxides, nitrides, borides, carbides, and so on with a particle size of ~ 10 nm. It was concluded that metastable phases normally formed as a result of the mechanical activation can be produced from equilibrium intermetallide products of the SHS as well.

A dedicated study aimed at the preparation of nanosized composite powders in the system TiB_2-TiAl_3 starting from powdered Ti, Al and TiB_2 has been conducted.[65] Prior to the SHS, the powder mixtures containing Al–50 at.% Ti and Al–25 at.% Ti–10 vol.% TiB_2 were first activated mechanically in a ball mill and then heated at the rate of 0.33 K s^{-1} and maintained *in vacuo* at various temperatures. After that, flashing and compaction of the mechanical mixtures *in vacuo* were followed by their heating to the sintering temperature. The microstructures of the final products TiB_2-TiAl_3 are shown in Fig. 9. Nanosized grains of TiB_2 (25 nm) are well-resolved in the microphotography (see Fig. 9 *b*).

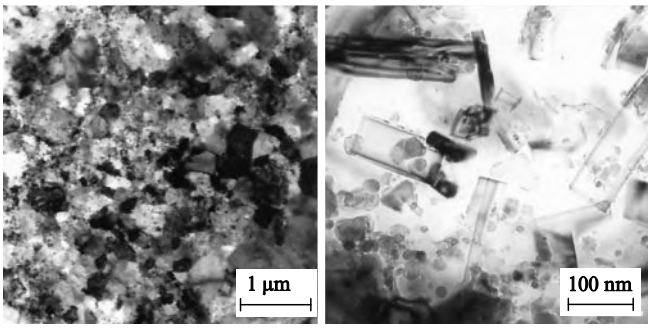

Figure 9. The microstructure of TiB_2-TiAl_3 nanocomposites;[65] (*a*) $TiAl_3$ grain, (*b*) TiB_2 grain.

The dependence of the size of the product grains on the duration of the mechanical treatment is plotted in Fig. 10 for the two systems, *viz.*, Al–50 at.% Ti (*a*) and Al–25 at.% Ti–10 vol.% TiB_2 (*b*). It is clearly seen that in the case of the Ti–Al system (see Fig. 10 *a*), prolonged mechanical treatment leads only to an insignificant increase in the grain size apparently approaching saturation, whereas in the Ti–Al–TiB_2 system (see Fig. 10 *b*), the grains become noticeably smaller after longer treatments under conditions of the isothermal storage at 973 K. Therefore, the effect of the addition of TiB_2 on the growth of $TiAl_3-TiB_2$ grains is revealed.

2. Gravity and shock-wave actions on the SHS products

In order to control the grain structure of materials, one can take advantage of gravity, which can lead to both the increase and decrease in the grain size of the combustion products.

The influence of the load factors on the microstructure has recently been demonstrated[66] for a $TiC-Cr_3C_2-Ni-Mo$ composite material (*i.e.*, a complex titanium–chromium oxide with a nickel–molybdenum binder) prepared by SHS from a powdered mixture of titanium, chromium, nickel and molybdenum oxides with aluminium and carbon (as soot or graphite). The grain size of

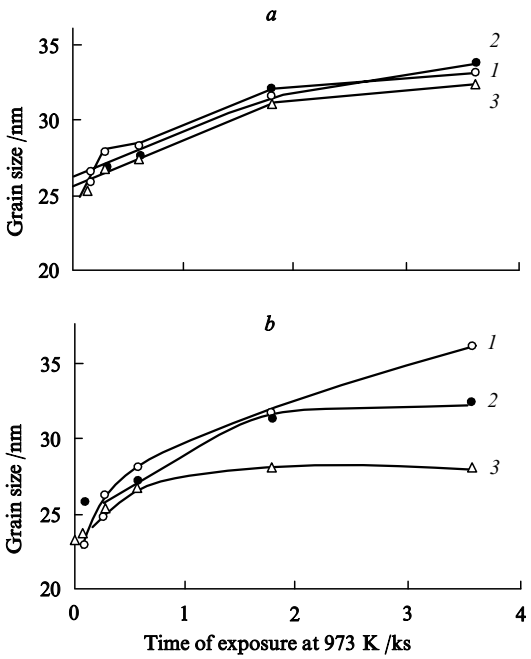

Figure 10. Grain size *vs.* duration of the mechanochemical treatment dependences for two systems: Al–50 at.% (Ti) (*a*) and Al–50 at.% Ti–TiB_2 (*b*).[65]
Duration of mechanical activation /ks: (*1*) 180, (*2*) 360, (*3*) 2880.

the solid product formed is plotted in Fig. 11 as a function of the load factor applied. It was established that this affects not only the microstructure but also the combustion rate and temperature along with the phase and chemical composition of the product. For instance, on going from the load factor of 10 g to 500 g, the content of bound carbon in the material was either increased 1.5-fold (if soot was taken as a reactant) or, *vice versa*, decreased more than two-fold (if coarse-grain graphite was used). This is explained by the gravity-assisted segregation of the reactants in the combustion wave under the action of the load factor.

The formation of unusual structures upon combustion of a NiO–Ni–Al system has been reported.[67] This experiment was conducted aboard the space station 'Mir' under microgravity conditions. As a result of the zero gravity, the molten intermetallide combustion product NiAl was deposited as large drops onto the surface of the oxide phase Al_2O_3 giving rise to mushroom-shaped crystallites (Fig. 12).

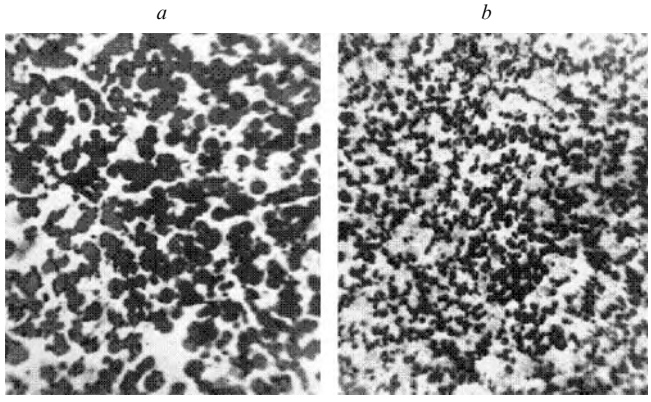

Figure 11. Effects of the load factor on the microstructure of the $TiC-Cr_3C_2$ + Ni–Mo system.[66]
(*a*) load factor of 100 g, (*b*) load factor of 1000 g.

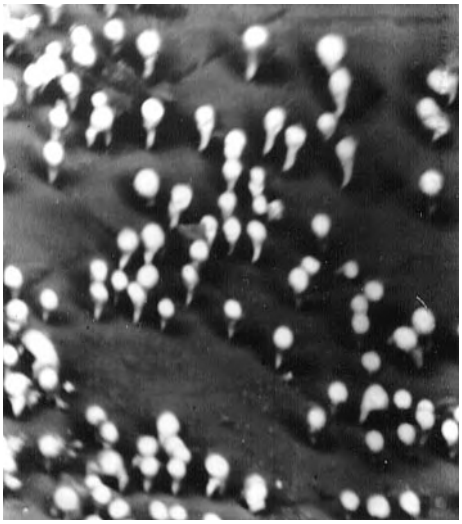

Figure 12. The formation of the NiAl intermetallide phase on the surface of the Al_2O_3 oxide phase under conditions of the zero gravity.[67]

A shock wave can be applied to reactants in the course of the SHS or to reaction products after its completion as an alternative means of the mechanical activation. The effects of shock waves on reactants at a certain stage of the process are different depending on the shock wave amplitude, loading diagram and characteristics of heat dissipation. All other parameters being the same, an increase in the pressure first leads to compaction and deformation of reactants (no chemical reactions are yet initiated). Upon further increase in the pressure, the concentration of structural defects is increased and an intense intermixing and heating of the reactants occurs, which leads to the initiation of the chemical reaction. Shear strains present in the shock wave front disintegrate the product so that only very fine particles are formed. A control over the heavily strained state of the matter that develops upon the shock-wave action would make it possible to deliberately change the chemical composition thus producing materials with preset characteristics at lower energy consumption.

Shock-wave compaction of titanium carbide prepared by the SHS has been reported.[68]

An attempt has been undertaken [69] to combine the SHS with the shock-wave load in the synthesis of titanium carbide. The size of the product grains produced in this experiment did not exceed 1 μm. The authors asserted that titanium carbide prepared in this way manifested improved mechanical properties. Such an approach has also been applied to syntheses of other carbides,[68–71] intermetallides [72, 73] and silicides.[74–79] However, according to the data reported, no nanostructures could be obtained upon the direct shock wave action on a sample during the SHS. Therefore, grinding of the final product remains the most suitable solution of the problem.

3. Self-propagating high-temperature synthesis in electric and magnetic fields

The effects of the electric and magnetic fields on the course of the SHS have been studied. In particular, in the SHS of tantalum carbide, the starting powders of Ta and C were mechanically activated and simultaneously subjected to the electric field.[80]

$$\text{Ta (45 μm)} + \text{C (13 nm)} \longrightarrow \text{TaC (30–50 nm)}.$$

This solid-phase system (neither solid reactants nor the products melt during the SHS) is characterised by a linear increase in the combustion rate and temperature with an increase in the electric field strength. The degree of conversion can be increased (*i.e.*, the underburning degree can be reduced) using Joule heating. It was found that two types of particles (*viz.*, rounded and

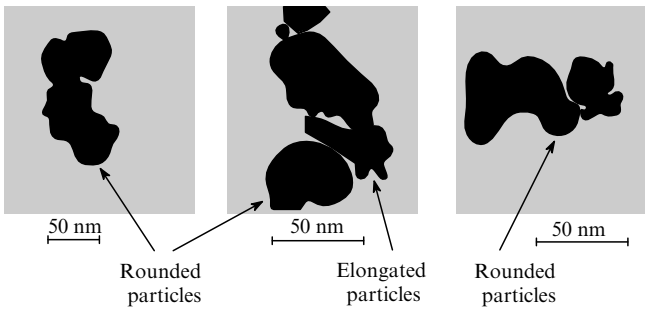

Figure 13. The microstructure of nanosized TaC particles as a function of the electric field strength.[80]
E /V cm^{-1}: 6.92 (*a*), 14.61 (*b*), 30.33 (*c*).

elongated, Fig. 13 *a*, *b*) are formed as a result of the SHS. Presumably, the particles tend to acquire a rounded shape at stronger electric fields. The composition of the product is also affected by the electric field strength. Indeed, the final product is composed of Ta_2C and TaC particles when the synthesis is performed at weak electric fields whereas only TaC particles are found at strong fields.

A procedure for the preparation of nanosized $MoSi_2$ by SHS combined with the mechanical activation and the electric field action has been described.[81] For the synthesis of molybdenum disilicide, a mixture of Mo and Si powders was used:

$$\text{Mo (150 μm)} + \text{Si (45 μm)} \longrightarrow \text{MoSi}_2\text{ (68–75 nm)}.$$

First, the Mo and Si powders were mechanically activated, then compacted, subjected to the electric field and ignited. The mechanical mixtures (Mo + Si) represented agglomerates with the sizes ranging from 0.2 to 200 μm composed of nanosized crystallites of molybdenum and silicon. According to powder X-ray diffraction data, the molybdenum and silicon particles had the sizes of 54 nm and 34 nm, respectively (note that the size of Mo crystallites varies in the range from 5 to 100 nm). The authors compared structures of the $MoSi_2$ products prepared by two routes, *viz.*, by combining the SHS with the mechanical activation (MASHS) and a complex approach involving mechanical activation, SHS and action of the electric current of up to 1500 A (MAFAPAS, Fig. 14). In the former case, the size of $MoSi_2$ grains reached 45 nm whilst in the latter case, 73 nm.

Yet another $MoSi_2$ synthesis has been reported.[82] In this work, the influence of the mechanical and electric activation on the formation of a dense $MoSi_2$ ceramics was elucidated. Finer Mo powders (3–7 μm) were taken for the synthesis. Prior to the SHS initiation, the reactants were mechanically activated in a

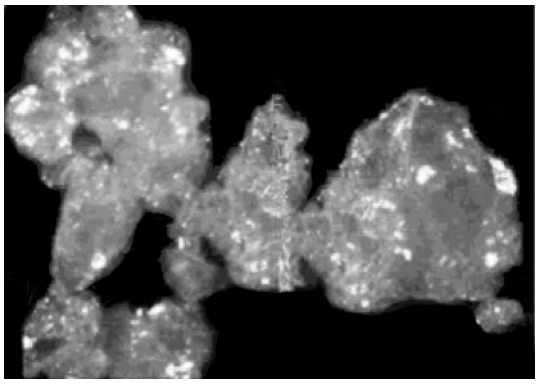

Figure 14. Nanocrystalline $MoSi_2$ produced from Mo and Si powders using the mechanical activation and electric field action.

planetary ball mill, compacted and then subjected to the electric field. The size of crystallites in the dense ceramics produced was ~ 20 nm.

The method applied to the preparation of the starting powders for this SHS process is worth a special note. The Mo and Si powders were ground in separate planetary ball mills. The size of the molybdenum particles decreased from 3–7 μm down to 20–110 nm depending on the milling conditions. With an increase in the duration of the mechanical treatment and in the electric field strength, the grain size decreased. This technique is of potential use in the technology of nanopowders.

The SHS method combined with mechanical activation of reactants has been utilised for the preparation of a composite based on $TiAl_3$ with Al_2O_3 inclusions.[83] Sintering of Ti and Al powders was conducted on a support, through which electric current passed. The growth of grains during sintering was decelerated by the presence of Al_2O_3 particles. The composite material produced had the grain size of ~ 10 nm. The authors noted that a decrease in the particle size resulted in the enhancement of the composite mechanical properties.

Synthesis of an AlN–SiC composite from powdered α-Si_3N_4, Al and C has been described.[84]

$$\alpha\text{-}Si_3N_4\,(0.5\ \mu m) + Al\,(7\ \mu m) + C\,(10\ \mu m) \longrightarrow$$

$$\longrightarrow AlN - SiC\ (< 100\ nm).$$

The synthesis included the following steps (Fig. 15): compaction of the starting Si_3N_4, Al and C powders, formation of blanks for the SHS process, induction heating followed by the thermal explosion turning into the SHS. As a result, a solid solution of AlN–SiC in Si_3N_4–Al–C was produced.

The authors analysed the mechanism of the formation of the AlN–SiC solid solution as a function of the electric field strength. They found that dissolution of silicon nitride in molten aluminium occurs in the first stage and only after that nitridation of aluminium starts. The reaction proceeds in the temperature range from 600 °C (melting point of aluminium) to 1400 °C.

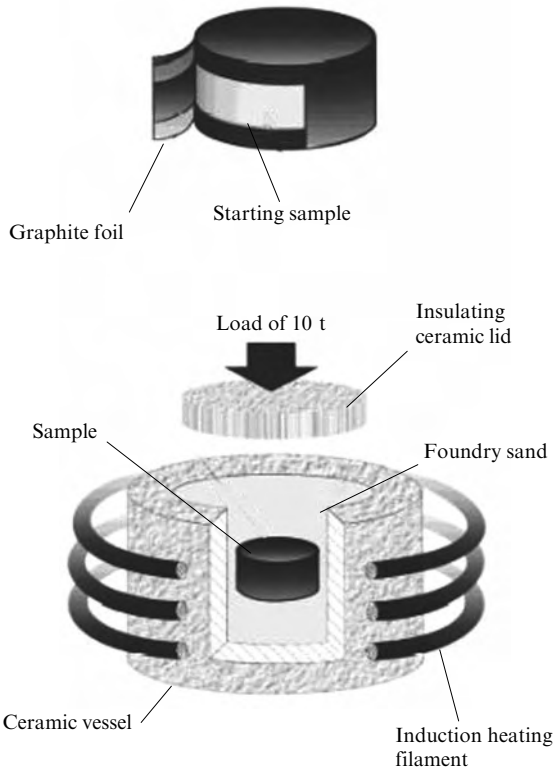

Figure 15. Experimental setup for the SHS of a solid solution of AlN – SiC in Si_3N_4–Al–C.[84]

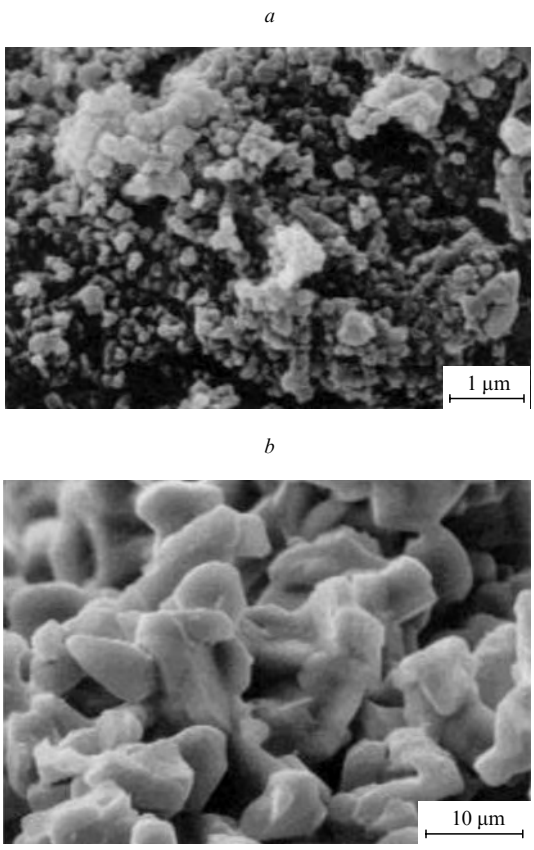

Figure 16. The microstructures of two solid solutions of AlN–SiC in Si_3N_4–Al–C produced at 1750 °C (*a*) and heated to 1850 °C (*b*).[84]

It is noteworthy that the microstructure of the product varies substantially depending on the annealing temperature of the product. The microstructures of solid solutions produced at temperatures of 1750 °C and 1850 °C are shown in Figs 16 *a* and 16 *b*, respectively. The authors did not perform a precise determination of the particle size, but, in their opinion, particles smaller than 100 nm were present in the solid solution.

The efficiency of the mechanical activation in the synthesis of nanosized powders by the SHS has recently been demonstrated [85] in the preparation of nanocrystalline $NbAl_3$ powders. The process was implemented in two steps: the mechanical activation of the starting Nb and Al powders was followed by the SHS. The powders were ground in a mill, compacted and then the SHS was initiated *in vacuo*. It is of note that agglomerates as large as 100 μm were present in the burden after the mechanical activation, which however disappeared after the completion of the SHS. The combustion product contained $NbAl_3$ particles with a size of ~ 60 nm.

Studies devoted to the preparation and compaction of iron powders have recently been reviewed.[86] The authors discuss features of the microwave-induced ‡ syntheses of iron powders and classify diverse methods of the preparation of nanocrystalline iron powders and of ceramic nanopowders (Table 2). They note that all the preparative techniques (except for that based on the microwave technique) are characterised by low performance. Additionally, not all of the techniques allow preparation of powders with the uniform size distribution. The authors conclude

‡ The microwave-induced synthesis can be considered as a modification of the SHS since it involves a stage of a self-propagating reaction that is initiated after ignition of the burden.

Table 2. The methods for the synthesis of ceramic nanopowders.[86]

Method of synthesis	Products
Mechanical activation in ball mills	Fe, Co, Ni, NiAl, TiAl, FeSn
Synthesis under laser irradiation	AlN, MnO_2, TiO_2, Ti
Condensation from a gas-phase	Fe, MgO, Cu, TiO_2
Sputtering deposition	Al, Cu, Mn
Chemical deposition	SiC, $BaTiO_3$, W–Cu, Mo–Cu
Plasma induction	Fe, AlN, Cu, metal borides, nitrides and carbides
Microwave plasma	Fe, Co, Mo, Ni, TiO_2, ZrO_2,Al_2O_3

that the microwave-induced synthesis of powders is the most cost-efficient method for the preparation of powders with the particle size of 10–15 nm.

Methods for the preparation of nanosized niobium aluminide using SHS preceded by the mechanical activation of the burden have been surveyed recently.[87] Different modes of the mechanical activation as applied to the synthesis of iron aluminides by the SHS have been considered.[88] The following scheme of the technological process was suggested: preparation of a mixture in a ball mill, formation of cylindrical blanks for the SHS, combustion of the blanks with the online monitoring by means of synchrotron radiation. The results of this monitoring are summarised in Table 3. It was found that the mechanical treatment of the initial mixture reduces the ignition temperature by more than 100 °C.

Table 3. Powder X-ray diffraction data on the phase composition of different cross-sections of an iron aluminide sample prepared by the SHS.[88]

Probing depth /mm	Phases revealed	Crystallite size /nm
0 (surface of the sample)	FeAl, Fe_2O_3, Fe_2Al_5	–
0.5	FeAl, Fe_2O_3	25
1.5	FeAl	40
2.5	FeAl	35
3.5	FeAl	25
4.5	FeAl	35
5.0 (back side of the sample)	FeAl, Fe_2O_3, Fe_2Al_5	–

The SHS of titanium nitride upon grinding of titanium in a ball mill in a nitrogen atmosphere has been investigated.[63] During the process, the system ignited, *i.e.*, a local thermal explosion occurred, which gave rise to a propagating combustion wave. The authors assume that there is a critical size of titanium particles (80 Å), just below which the system is ignited. Selected results of this study are given in Fig. 17 and Table 4.

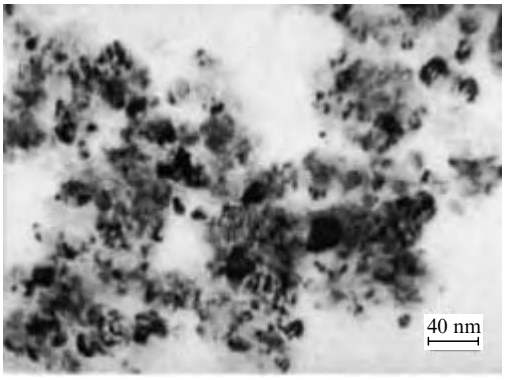

Figure 17. The microstructure of a titanium powder mechanically activated for 492 min.[63]

Table 4. The influence of the duration of mechanical activation on the nitrogen content and on the titanium and titanium nitride crystallite sizes in the sample.[63]

Duration of the mechanical activation /min	c_N (at.%)	d_{101} Ti /Å	d_{200} TiN /Å
Pressure of 11 Bar			
0	–	810	–
31	5.9	166	–
60	9.4	113	76
77	13.5	87	76
85	16.1	84	76
94	43.5	–	155
129	43.7	–	96
240	48.5	–	88
Pressure of 1.5 Bar			
0	–	810	–
60	5.8	134	–
91	9.9	89	76
131	24.0	80	75
152	40.3	–	78
185	42.2	–	84
256	43.9	–	77
492	50	–	76

Therefore, the mechanical activation is one of the most important processes in the technology of nanoparticles. The majority of numerous studies performed in this field confirm the great potential of various methods of activating the SHS aimed at the preparation of nanomaterials (as regards both powdered and compact products).[88–92]

4. Self-propagating high-temperature synthesis in thin films and in systems with nanosized reactants

The self-propagating high-temperature synthesis in thin films and in systems with nanosized reactants is a very new direction within the SHS.[93–97] Multilayer nanofilms built up of hundreds or thousands of alternating layers (each having a thickness of 1–100 nm) are very promising for the design of novel materials and coatings. They often exhibit unique properties. In particular, the hardness of a multilayer film can substantially exceed that of a single layer approaching the hardness of diamond. As has been established quite recently, autowave processes analogous to the gas-free combustion can be initiated in some multilayer films.[98] The velocity of the wave propagation can in such cases reach a few meters per second. To date, self-sustained reaction waves have been observed for several films composed of hundreds of alternating nanolayers, such as Al/Monel 400 (see Ref. 98) and Nb/Si.[99]

Previously, the gas-free combustion has been detected in layered systems built up of alternating Ni and Al foils with the thicknesses of 50 μm.[94] Combustion waves have also been observed in two-layer films prepared by electrochemical deposition [100] or vacuum deposition of a metal vapour.[97] In those films, the layer thickness was in the range from 0.1 to 200 μm.

The gas-free combustion in multilayer Ti/Al films has been studied [95] with the emphasis put on the elucidation of the structure formation in the reaction products (Fig. 18). A previously unknown effect of an inheritance of the preferable crystallographic orientation of the reactants by the gas-free combustion products was revealed.

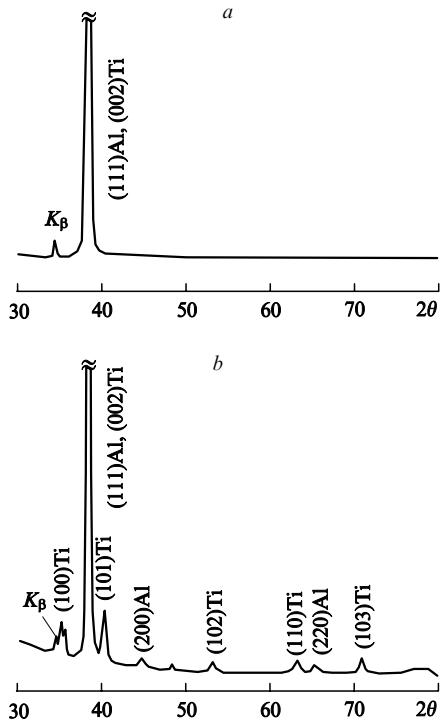

Figure 18. Powder diffraction patterns of the initial multilayer foil (*a*) and of the synthesis product (*b*).
Planes of the close packings of atoms in the initial foil and in the product are parallel to the sample surface.[95]

Combustion of films composed of 150 layers of titanium and aluminium (with the thickness of a single layer of 100 nm and the total thickness of 15 μm) in the SHS mode results in the formation of nanosized two-phase product containing TiAl and Ti_3Al.

First attempts to apply the SHS in thin films with a gradient composition have been undertaken [101] to solve the problem of hardening of composite armors (which is of military significance) (Fig. 19).

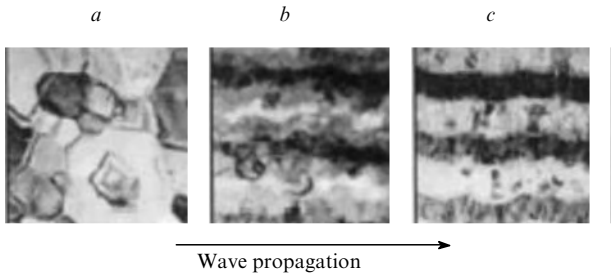

Figure 19. Microphotographs of the evolution of multilayer nanofoils during the SHS
Foils after the reaction (*a*), at the moment of the reaction (*b*), before the reaction (*c*).

The current status of investigations in the field of preparation of multi-component nanostructured thin (~1 nm) films has recently been reviewed.[102]

Nevertheless, it is the SHS using nanosized reactants that found most widespread applications in the synthesis of nanosized products. Primarily, this is due to the simplicity of the approach. Essentially, this implies that the reactants, on the one hand, serve as crystallisation centres and, on the other hand, suppress growth of the product grains.

The influence of the electric field on the morphology of products has been discussed [80] for a case reaction of Ta with C giving rise to TaC particles.[80] The use of a nanosized carbon powder (13 nm) allowed the authors to obtain tantalum carbide with the particle size of 30–50 nm.

Similar results have been reported for syntheses of Al_2O_3–TiAl–Ti_3Al composites [103] as well as of other inorganic powders doped with nanosized particles (ZrO_2, Al_2O_3, W, WC, NbC, *etc.*).[104,105]

The formation of nanosized particles as combustion products have also been confirmed in a series of SHS processes [19, 26, 80, 103, 105, 106] utilising nanosized reactants (*e.g.*, Y_2O_3, ZrO_2, TiO_2, C, *etc.*) (Table 5).

Table 5. Examples of nanosized materials produced by the SHS using nanosized reagents.

Product	Particle size /nm	Ref.
ZrO_2	8–12	106
Ti–H, Zr–H, Ti–N–H, Zr–N–H, Ti–Zr–N–H	<50	26
Al_2O_3–TiC–ZrO_2	10–20	19
(Ti, Cr)C–Ni	500–1500	105
Al_2O_3–TiAl–Ti_3Al	<100	103
TaC	30–50	80

Sol–gel processes and precipitation from solutions are further examples of the use of nanosized reactants for the synthesis of nanomaterials. Essentially, these processes imply conversion of a liquid into a gel (as a result of hydrolysis coupled with polycondensation) and further to a glass, monolithic composite, powder or thin coating (as a result of heating or combustion at relatively low temperatures). The sol–gel technology has several drawbacks related to the high costs of starting materials and to the large shrinkage of gels upon drying and sintering.

Synthesis of a widespread dielectric, $BaTiO_3$, from different precursors, such as BaO_2, $Ba(NO_3)_2$ and $Ba(OAc)_2$, using carbohydrazide, glycine or citric acid as a combustible material has been described in a recent review.[107] The combustion reaction was conducted in the presence of titanyl nitrate. Yet another review [108] lists nanocrystalline oxides (with the particle size of 10–35 nm) prepared by combustion of aqueous solutions containing metal and ammonium nitrates and redox mixtures.

Among chemical processes exploited for the preparation of nanomaterials, the self-propagating low-temperature synthesis is worth a special note. It is realised most easily in gas-releasing systems. For instance, titanyl hydrazinecarboxylate $TiO(N_2H_3COO)_2 \cdot 2H_2O$ undergoes an autocatalytic exothermic decomposition upon heating in air up to 300 °C, which proceeds in the combustion mode and is accompanied by liberation of large amounts of gases, *i.e.*, N_2, CO_2, H_2O. As a result of the reaction, a nanosized TiO_2 powder (8 nm) is formed, which is characterised by high free surface area (110 $m^2\ g^{-1}$). The formation of TiO_2 is described by the following equation:

$$TiO(N_2H_3COO)_2 \cdot 2H_2O \longrightarrow TiO_2 + 2N_2 + 2CO_2 + 5H_2O.$$

The SHS can also be realised in stages of condensation, coagulation and drying of the final product. Different modifications of these techniques are considered elsewhere.[109, 110]

VI. Conclusion

The self-propagating high-temperature synthesis of nanosized materials is a relatively new research field. Its active development was stimulated by a common enthusiasm regarding nanomaterials. Summarising the results discussed in this review, we conclude that the SHS is indeed an efficient route giving rise to nanosized

materials despite high temperatures of the process that typically favour growth of crystallites. Among factors beneficial for the formation of nanosized particles in combustion products, the following are of primary importance: utilisation of nanosized reactants; multitude of nuclei actuating the crystallisation (or condensation) of reaction products; control over the rate of cooling of combustion products; the action of crystallisation, recrystallisation and chemical condensation processes on the SHS; self-limitation of the crystallite growth in multiphase combustion products.

Potential applications of various types of the SHS aimed at the preparation of nanomaterials have not been equally explored. The area most studied is the mechanochemical SHS whereas the gas-phase SHS is the least investigated.

It is the experimental conditions leading to the formation of nanomaterials that attracted major attention of researchers. At the same time, specific properties of SHS-materials and advantages of their practical use are insufficiently represented in the scientific literature (though it is also true for nanomaterials produced by other methods).[111,112] Enhancements of properties of nanomaterials synthesised by the SHS (first of all, as regards their high inclination to sintering and compaction) has been documented by only a few researchers.[113–116] The mechanism and kinetic characteristics of the formation of nanomaterials by the SHS remain virtually unexplored. A quest for the most efficient ways to control the structure formation in combustion products along with investigations into the structure–property relations for the substances produced are promising directions of prospective studies.

Abstract. Methods for the preparation and various transformations of acetylenic derivatives of quinones, which are key intermediates in the synthesis of fused heterocyclic quinoid structures and some highly unsaturated compounds, are surveyed in detail. The bibliography includes 114 references.

I. Introduction

Quinones belong to a unique class of organic compounds, which have a broad spectrum of practical applications.[1–3] Quinone derivatives are traditionally used as dyes, pigments, photomaterials and pharmaceuticals. In recent years, these compounds have found application also as luminophores, laser media, catalysts for chemical processes, *etc*. The latter half of the 20th century has witnessed a rapidly growing interest in biologically active quinones and quinoid compounds. This interest is associated with the fact that both natural quinones (anthracycline, mitomycin and anthrapyran antibiotics) and a series of structurally simple synthetic derivatives were found to exhibit antitumour activity. Some of these compounds were integrated into medical practice. Later on, it was revealed that quinoid compounds possess other physiological activities, including antibacterial, antiviral and fungicidal activities, and exhibit radiosensitising properties. New classes of antibiotics and biologically active pigments were found. An extensive search for new pharmacophore structures, elucidation of the structure – biological activity relationship for quinoid compounds and the synthesis of complex natural products and their analogues called for an extension and upgrade of the traditional synthetic base for investigation of this class of compounds. The problems to be solved included not only the development and application of new synthetic approaches but also the possible uses of new starting compounds, key intermediates and new reagents.

Systematic studies of acetylenic derivatives of the simplest quinones (benzo-, naphtho- and anthraquinones) were started in the late 1970s and the early 1980s.[4–10] Due to the simultaneous presence of two highly reactive fragments, *viz*., the quinoid moiety and the acetylenic group, influencing each other, these compounds were considered as intermediates in the synthesis of more complex quinoid structures. It was also expected that some acetylenic derivatives could be used as precursors of highly reactive unsaturated compounds of other classes. Besides, the possibility that these compounds, particularly, functionally substituted derivatives, could exhibit targeted biological action was not ruled out.

Extensive experimental data on the chemistry of alkynylquinones are presently available. Procedures were developed for the synthesis of these compounds, their chemical characteristic features were revealed and new chemical reactions were discovered and studied. However, the available data on the chemistry of alkynylquinones were not generalised. The aim of the present review is to close this gap, survey, as exhaustively as possible, the results of these investigations published in the literature and to call the attention of chemists to this promising group of polyfunctional compounds for the purpose of extending the scope of application of these derivatives in fine organic synthesis.

II. Synthesis methods

1. Cross-coupling of haloquinones with terminal acetylenes

Presently, cross-coupling of haloquinones with terminal acetylenes is recognised as the most versatile method for the synthesis of acetylenic derivatives of quinones. This method is based on the replacement of halogen atoms in carbo- and heteroaromatic rings as well as in vinyl halides by acetylenic groups.[11,12] Two main versions of this reaction, the catalytic and so-called acetylide, are generally used. In the catalytic version, aryl halides are condensed with terminal acetylenes in the presence of Pd(II) or Pd(0) triphenylphosphine complexes, cuprous iodide and a base (generally, amine). In the acetylide version, either condensation is performed directly with Cu(I) acetylide or the latter is prepared *in situ* from terminal acetylene in the presence of CuI and potassium carbonate. In both versions, the reactions are carried out under an inert atmosphere to prevent oxidative dimerisation of terminal acetylenes. In all cases, the reactivity of aryl halides decreases in the series ArI > ArBr > ArCl.

a. Catalytic method

Efficient cross-coupling in the presence of a combined Pd – Cu catalyst is used to introduce acetylenic substituents into the benzene rings of halogen derivatives of 9,10-anthra- and 1,4-naphthoquinones. The reactions are usually performed in an excess of amine (Et_3N or Et_2NH), which serves as a solvent and base, in the presence of $Pd(PPh_3)_2Cl_2$ and CuI at high temperature.[13–15] In some cases, amine is used in combination with an inert solvent[16] or, alternatively, an inorganic base (for example,

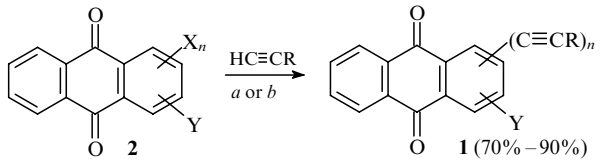
K_2CO_3) in pyridine, DMF or dioxane is employed.[10, 17, 18] Iodine-containing quinones are reagents of choice. However, cheaper bromides were also successfully used in the synthesis of long-chain acetylenic derivatives of functionalised anthraquinones (components of coloured liquid-crystalline composites).[16] The chlorine atoms in the benzene rings of quinones are inactive.[10, 15]

In such catalytic systems, a series of acetylenic derivatives **1** were synthesised from mono- and polyiodo(bromo)anthraquinones **2**. The products were usually prepared in 70% – 90% yields, and the reaction time was 0.5 – 3 h.



X = I, Br; n = 1, 2; Y = H, NH_2, NHMe, Cl, OCOPh;

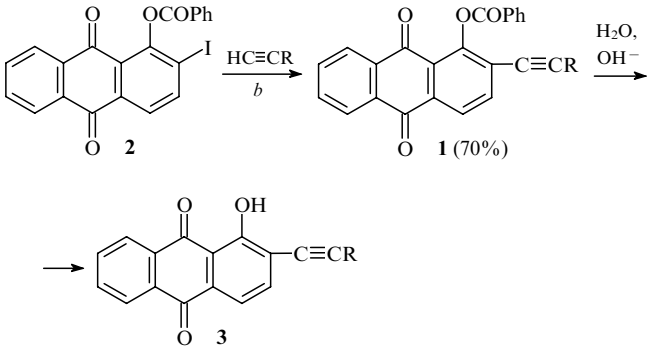
R = C_5H_{11}, C_7H_{15}, CMe_2OH, CH_2N O, Ph;

(*a*) $Pd(PPh_3)_2Cl_2$ – CuI, Et_3N or Bu_3N; 50 – 90 °C;

(*b*) $Pd(PPh_3)_2Cl_2$ – CuI, K_2CO_3; Py, DMF or dioxane; 50 – 90 °C.

In both systems (*a* and *b*), the reactivity of 2-iodo-substituted isomers is comparable with that of 1-iodoanthraquinones.[10, 14] However, the presence of a bulky substituent at position 2 of the latter slows down the reaction due, apparently, to steric factors,[19] which hinder the formation of organopalladium complexes. For example, the reactions of methyl 1-iodoanthraquinone-2-carboxylate with terminal acetylenes, unlike those of 1-iodoanthraquinone, proceed slowly and ambiguously and are accompanied by substantial resinification.

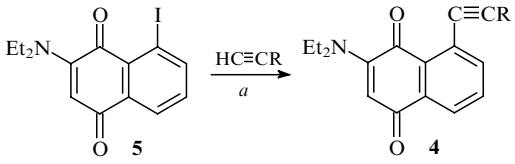
These cross-coupling reactions of haloanthraquinones with acetylenes have virtually no limitations on the nature and arrangement of functional substituents in the starting compound. However, if the quinone moiety of the starting compound contains the hydroxy group adjacent to the halogen atom, the reaction results in intramolecular cyclisation of the primary condensation product, *viz*., hydroxyacetylene (see Section III.3.a). A standard procedure for the protection of the hydroxy group was used in the study.[17] Benzoyloxy derivative **2** (X = 2-I, Y = 1-OCOPh) in the presence of a weak nucleophilic base (K_2CO_3) in pyridine produced alkynyl(benzoyloxy)quinones,[17] whose subsequent alkaline hydrolysis afforded compounds **3**.



R = CMe_2OH, Ph;

(*b*) $Pd(PPh_3)_2Cl_2$ – CuI, K_2CO_3, Py; 50 – 90 °C.

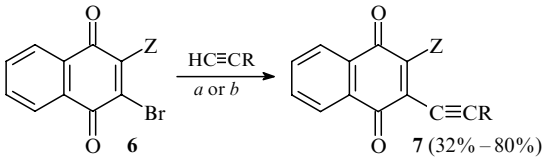
Cross-coupling of halogen derivatives of 1,4-naphthoquinone with acetylenes is complicated by high electrophilicity of the quinoid ring. This ring can be blocked by introducing a strong electron-donating substituent. The efficiency of this protection was exemplified by the synthesis of compounds **4** from 3-diethylamino-5-iodo-1,4-naphthoquinone **5**.[13]



R = CMe_2OH, Ph;

(*a*) $Pd(PPh_3)_2Cl_2$ – CuI, Et_3N or Et_2NH; 50 – 90 °C.

Catalytic cross-coupling is used also for the introduction of acetylenic substituents into the quinoid ring of 1,4-naphthoquinone derivatives **6** to prepare compounds **7**.[20] In these reactions, the molecule is stabilised by the functional group, which is present in the quinoid ring and possesses a strong positive mesomeric effect.



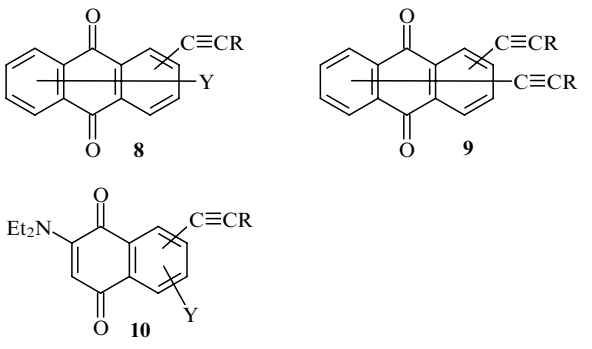
Z = NMe_2, N , N , OEt;

R = C_8H_{17}, CH_2OH, CH_2OMe, CH_2OAc, CH_2OPh, CMe_2OH, CMe_2OMe, CH_2N O, Ph;

(*a*) $Pd(PPh_3)_2Cl_2$ – CuI, Et_3N or Et_2NH; 50 – 90 °C;

(*b*) $Pd(PPh_3)_2Cl_2$ – CuI, K_2CO_3; Py or DMF; 50 – 90 °C.

Cross-coupling of acetylenes with quinones containing halogen atoms in the benzene rings is substantially intensified in an aqueous – organic medium (water – dioxane or water – pyridine mixtures) in the presence of the same Pd and Cu catalysts and an inorganic base (Na_2CO_3, K_2CO_3, $NaHCO_3$ or AcONa).[14 – 18, 21 – 31] The reaction time is an order of magnitude shorter than that in anhydrous media and is, as a rule, 5 – 30 min at 70 – 90 °C. This procedure was used in the synthesis of numerous acetylenic derivatives of quinones **8** – **10** (yields were 48% – 98%). It allows one to perform cross-coupling of haloquinones with labile acetylenes, for example, with ethyl propiolate.[25, 26] It should be noted that attempts to carry out condensation of the latter with aryl iodides in anhydrous media under standard conditions failed.[32]



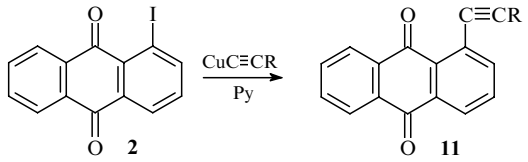
R = , CH_2OH, CH(OH)Pr, CMe_2OH, , , CH(OH)Ph, CH_2OPh, CO_2Et, CH_2N , Ph;

Y = NH_2, NHMe, NO_2, Cl.

Due to a high rate of the reaction in an aqueous – organic system, labile alkynylquinones can be prepared in rather high yields.

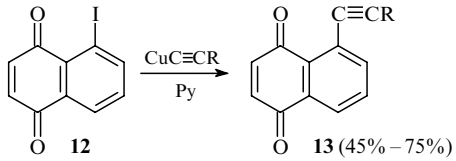
b. Acetylide method

Cross-coupling of quinones with cuprous acetylides in the absence of palladium complexes is used for the introduction of acetylenic substituents exclusively into the benzene rings of quinones. Due to the influence of electron-withdrawing groups conjugated with the benzene ring, the halogen atoms in the latter possess rather high nucleofugicity and can be replaced by acetylenic groups under relatively mild conditions (moderate temperature, moderate nucleophilicity of the medium and the absence of a strong base). For comparison, 1-iodonaphthalene reacts with Cu(I) phenylacetylide in pyridine at 115 °C for 10 h.[33] By contrast, the reaction of 1-iodoanthraquinone **2** (X = 1-I, Y = H) with phenylacetylide is completed in 1.5 h at 90 °C [10] and the reaction with butylacetylide is completed in 40 min at 60 °C to give the corresponding alkynylanthraquinones **11**.[23]



R = Bu, Ph.

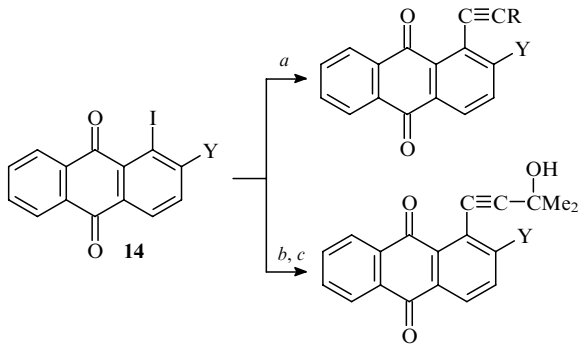
Under these conditions, halonaphthoquinones with unsubstituted quinoid rings can also be introduced into reactions with cuprous acetylides. For example, 5-iodo-1,4-naphthoquinone **12** reacts with Cu(I) aryl- and hetarylacetylides in pyridine at 50 – 80 °C for 5 – 25 min to form the corresponding products **13**.[34]



R = Ph, *p*-$MeOC_6H_4$, *p*-$Me_2NC_6H_4$, *p*-$O_2NC_6H_4$,

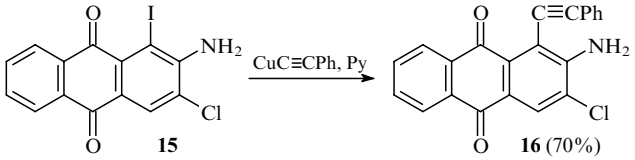
2-naphthyl, 
The iodine atom at the β position of the benzene ring of quinone is less easily replaced under the action of Cu(I) acetylides compared to that at the α position.[10] The reaction of 2-iodoanthraquinone with Cu(I) phenylacetylide proceeds ~20 times more slowly than that of 1-iodoanthraquinone.

Functionalised iodoquinones are, as a rule, readily condensed with acetylides, electron-withdrawing substituents noticeably accelerating the reaction.[10, 17 – 19, 23, 24, 35 – 37] 1-Iodoanthraquinones **14** bearing bulky substituents at position 2, which hinder Pd-catalysed condensation, react without complications with both Cu(I) acetylides and terminal acetylenes in the presence of Cu(I) salts and K_2CO_3.[19, 23, 30, 35, 37] The catalytic method can be applied to terminal acetylenes, which do not form acetylides stable in the solid state.



Y = CO_2Me, $CH(OEt)_2$, CHO; R = Bu, CH_2OPh, Ph;
(*a*) CuC≡CR, Py; (*b*) HC≡$CCMe_2OCH(OEt)Me$, K_2CO_3, CuI, Py;
(*c*) H_3O^+.

Under various conditions, copper-mediated condensation of vicinal hydroxy(halo)quinones results in intramolecular cyclisation to form the furan ring (see Section III.3.a).[38, 39] Unlike this reaction, condensation of *vic*-amino(iodo)anthraquinones with Cu(I) acetylide can be terminated in the step of formation of an acetylenic derivative of aminoanthraquinone. Under more drastic conditions, the latter undergoes cyclisation in the presence of an excess of acetylide to give the corresponding naphthoindoledione (see Section III.2.a).[18] For example, the reaction of 2-amino-3-chloro-1-iodoanthraquinone (**15**) with Cu(I) phenylacetylide in pyridine at 20 °C for 30 min affords 2-amino-3-chloro-1-phenylethynylanthraquinone (**16**).



The *vic*-amino group facilitates the replacement of the halogen atom under the action of Cu(I) acetylides. For instance, the reaction of 1-amino-2-iodoanthraquinone with Cu(I) phenylacetylide in pyridine at 80 °C is completed in 2.5 h [18] (for 2-iodoanthraquinone, the reaction time is 26 h at 90 °C).[10]

The reactions of quinones containing halogen atoms in the quinoid ring with Cu(I) acetylides under rather mild conditions proceed only in the presence of the Pd catalyst.[40] The reactions are carried out in a mixture of DMSO and $CHCl_3$ at 20 – 50 °C. Condensation can be performed with both Cu(I) acetylides as such and acetylides prepared *in situ* from terminal acetylene, CuI and Et_3N. The second approach is used only if it is impossible to isolate stable acetylides in the solid state. The yields of alkynylquinones **17** and **18** vary from 35% to 84%.

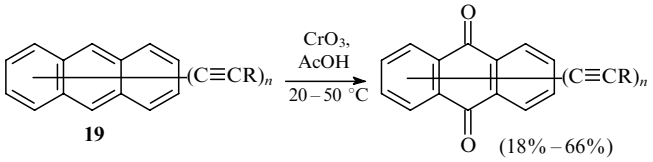
2. Oxidation of alkynylarenes

Oxidation of aromatic compounds is one of the most general methods for the synthesis of quinones.[1 – 3, 41] Owing to the stability of the triple bond with respect to certain reagents, which can oxidise arenes to quinones, alkynylarenes can be used for the preparation of alkynylquinones.

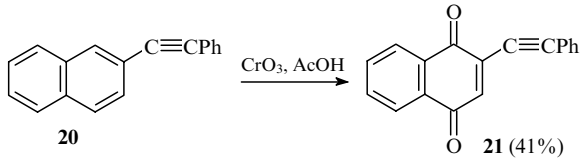
Anthracenes **19** containing acetylenic substituents in the flank rings are readily oxidised with CrO_3 in 80% AcOH with retention of the triple bonds.[5, 7, 29] This procedure allows one to prepare 9,10-anthraquinones with various sets of acetylenic substituents.



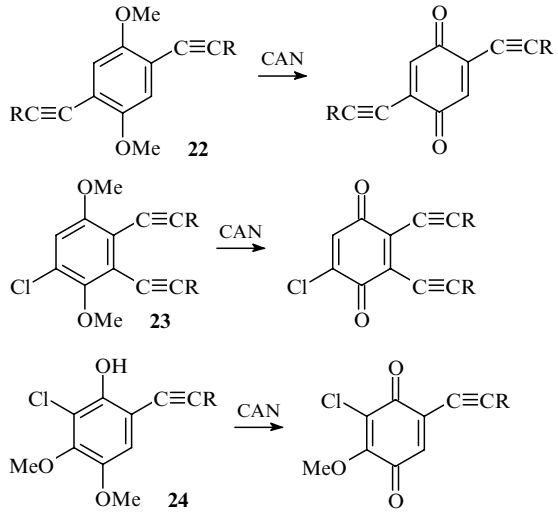
R = H, CH_2N O, COPh, *p*-$MeOC_6H_4$, *p*-$O_2NC_6H_4$, Ph; $n = 1, 2$.

The time of oxidation depends on the concentration of the substrate and the reaction temperature and varies over a wide range (5 – 240 min). Under these conditions, oxidation of 1,8-dialkynylanthracenes is sensitive to the nature of a substituent at the triple bond. For example, an attempt to oxidise 1,8-diethynylanthracene failed, whereas 1,8-bis(phenylethynyl)anthracene was oxidised at 60 °C for 6 min to form the corresponding anthraquinone in 31.5% yield.[7]

2-Phenylethynylnaphthalene (**20**), which contains no other substituents in the aromatic nucleus, is oxidised also with CrO_3 in 80% AcOH, the substituted ring being subjected to oxidation to give 2-phenylethynyl-1,4-naphthoquinone (**21**).[5]

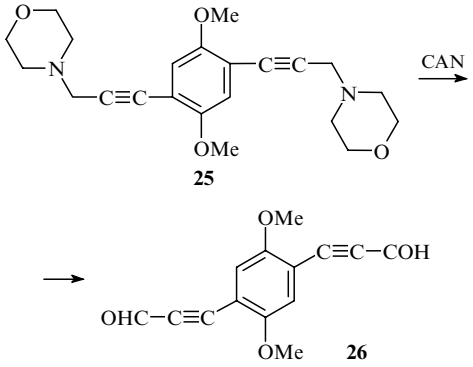


Aromatic compounds bearing two OR groups (R = H and/or Me) at the *para* positions are readily oxidised with Ce(IV) salts to give quinones.[1] These oxidising agents leave the triple bond intact and are used in the synthesis of various (mono- and polycyclic) quinones with acetylenic substituents in the benzene or quinoid ring.[5,8] For example, acetylenic derivatives of 1,4-dimethoxy- and 1-hydroxy-4-methoxybenzenes **22** – **24** were oxidised to the corresponding 1,4-benzoquinones with ammonium cerium nitrate (CAN) in aqueous MeCN or THF at room temperature.[5,8,42]



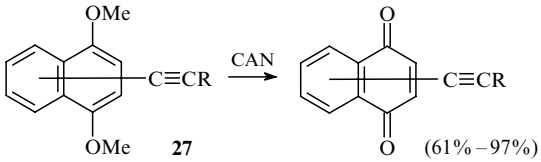
R = Bu, CMe_2OH, CH_2OCH_2Ph, Ph, *p*-$MeOC_6H_4$.

This reaction has a number of limitations. Oxidation proceeds satisfactorily in the presence of electron-donating or weak electron-withdrawing groups at the triple bond (yields are 40% – 89%). Strong electron-withdrawing groups, such as *p*-$O_2NC_6H_4$ or PhCO, hinder the reaction.[8] The substrate also remains non-oxidised if it forms an insoluble complex salt with the oxidising reagent [an example is 2,5-bis(2-pyridylethynyl)-1,4-dimethoxybenzene]. If the side chain of the substrate contains functional groups readily oxidised with cerium(IV), the reaction can afford other oxidation products. For instance, oxidation of 2,5-bis(3-morpholinoprop-1-ynyl)-1,4-dimethoxybenzene (**25**) with CAN gave rise to unsaturated dialdehyde **26** (in 46.5% yield) rather than quinone.



Unsuccessful attempts to prepare some alkynylquinones may also be associated with their lability. For example, an attempt to synthesise 2,5-diethynyl-1,4-benzoquinone from 2,5-diethynyl-1,4-dimethoxybenzene ended in failure.[8]

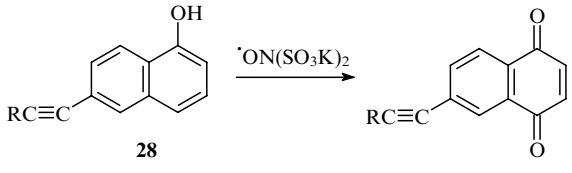
Depending on the structure of the starting compound, oxidation of acetylenic derivatives of 1,4-dimethoxynaphthalene **27** with ammonium cerium nitrate affords 1,4-naphthoquinones containing the substituent with the triple bond in either the quinoid or benzene ring. This procedure was used for the synthesis of 2-, 5- and 6-alkynyl-1,4-naphthoquinones.[5,8,13,43]



R = H, Ph.

In some cases, hydroquinones and their ethers are oxidised to quinones with Ag salts. For example, 2-hydroxymethyl-3-(3-methylbut-3-en-1-ynyl)hydroquinone, which is a metabolite of the natural antibiotic frustulosin, was oxidised with silver carbonate on celite in benzene.[44]

Potassium nitrosodisulfonate (fremy's salt) is a specific oxidising reagent, which allows one to transform aromatic amines and phenols into quinones under mild conditions.[45] This salt was used for oxidation of 1-naphthols **28** containing acetylenic substituents at position 6.[43] The reaction was carried out at 20 °C in an aqueous – methanolic solution of KH_2PO_4.



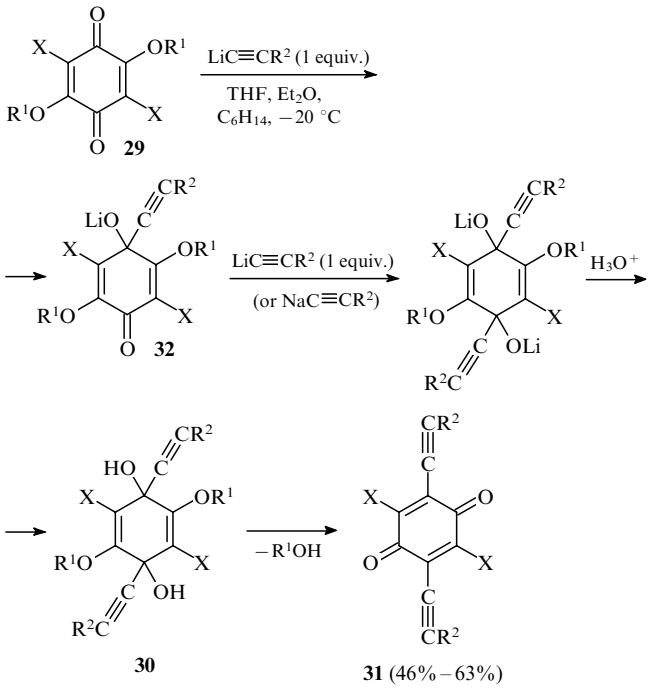
R = H, CMe_2OH, Ph.

On the whole, oxidation of aromatic acetylenic derivatives as a method for the synthesis of alkynylquinones has not been adequately investigated. However, there is no doubt that the scope of this method can be substantially extended.

3. Synthesis of acetylenic derivatives of *para*- and *ortho*-benzoquinones from dialkoxybenzoquinones

Moore and co-workers[4,6,9,42] developed an original procedure for the preparation of alkynylbenzoquinones from dialkoxy derivatives **29**. The synthesis involves the addition of lithium acetylides at the carbonyl groups of the starting quinone followed by acid hydrolysis of vinyl ether fragments of the resulting glycol **30** accompanied by dehydration. In some cases, the second step is

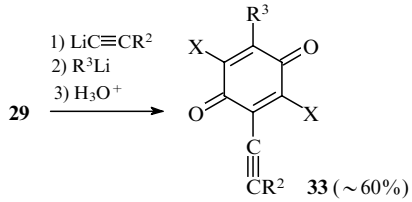
carried out with the use of $(CF_3CO)_2O$ in the presence of concentrated H_2SO_4. As a result of these transformations, the quinoid structure of the ring, which is initially destroyed due to the introduction of acetylenic substituents, is restored. This approach can be exemplified by the synthesis of 2,5-dialkynyl-1,4-benzoquinones **31** from 2,5-dialkoxy-1,4-benzoquinones **29**.[4,6]



X = H, Cl; R^1 = Me, Et; R^2 = CH_2OMe, CH_2OBn, CH_2OTHP (THP is tetrahydropyranyl), CH_2Bn, Ph, *o*-MeC_6H_4, $MeC{=}CH_2$, $SiMe_3$.

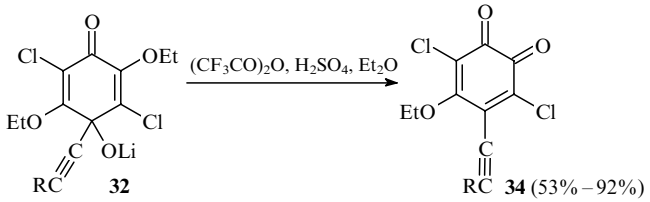
Alkynylation of compounds **29** with some lithium acetylides bearing rather bulky substituents stops at monoadduct **32** or proceeds further very slowly.[42,46] In the latter case, the second step of alkynylation is carried out with the use of sodium acetylides instead of lithium acetylides because the former are less self-associated and, hence, more reactive.[42]

The reaction can be terminated in the step of formation of monoadduct **32** and the latter can be transformed into an unsymmetrical diadduct upon the addition of one equivalent of alkyl- or aryllithium. Hydrolysis and dehydration of the latter afford monoacetylenic *p*-benzoquinones **33**.



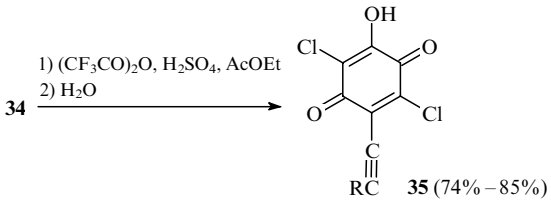
R^2 = CH_2OBn, CH_2OTHP, $(CH_2)_3OTHP$, Ph; R^3 = Me, Ph.

Monoadducts **32** can also serve as precursors of acetylenic derivatives of *ortho*-benzoquinone **34**.[42] In these reactions, a $(CF_3CO)_2O - H_2SO_4$ mixture is used in the second step.



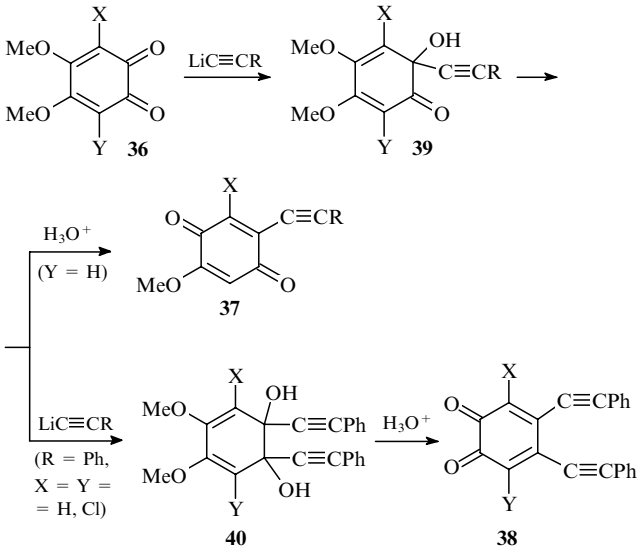
R = H, Bu, CH_2OTHP, $(CH_2)_4C{\equiv}CH$, $(CH_2)_2Ph$, $MeC{=}CH_2$, $CH{=}CHPh$, CO_2Et, Ph, *o*-$MeOC_6H_4$, α-$C_{10}H_7$, $SiMe_3$.

Under more drastic conditions, some 4-alkoxy-5-alkynyl-1,2-benzoquinones **34** can be hydrolysed to 5-alkynyl-2-hydroxy-1,4-benzoquinones **35**.[42]



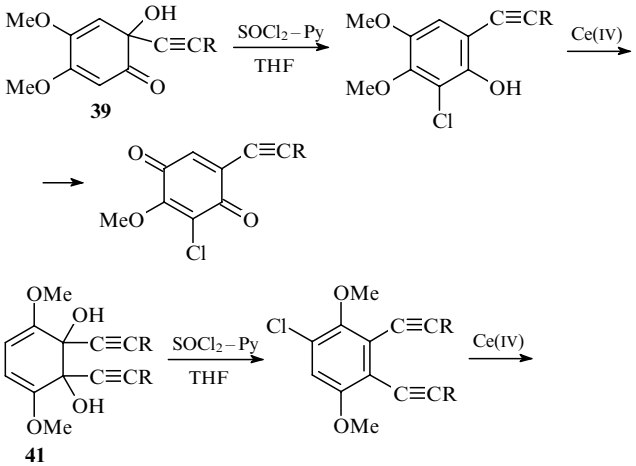
R = H, Bu, $(CH_2)_4C{\equiv}CH$, $MeC{=}CH_2$, CO_2Et.

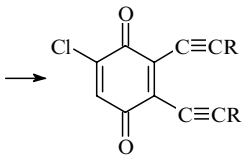
The method developed by Moore and co-workers allows one to prepare 2-alkoxy-5-alkynyl-1,4-benzoquinones **37** and 4,5-dialkynyl-1,2-benzoquinones **38** (in 41% – 90% yields) from 4,5-dialkoxy-1,2-benzoquinones **36** through mono- (**39**) and diadducts **40**, respectively.[9,42]



X = H, Cl, Br; Y = H, Cl; R = H, Pr, Bu, CH_2NEt_2, CH_2OCH_2Ph, $MeC{=}CH_2$, $(CH_2)_4C{\equiv}CH$, CO_2Et, Ph, OEt.

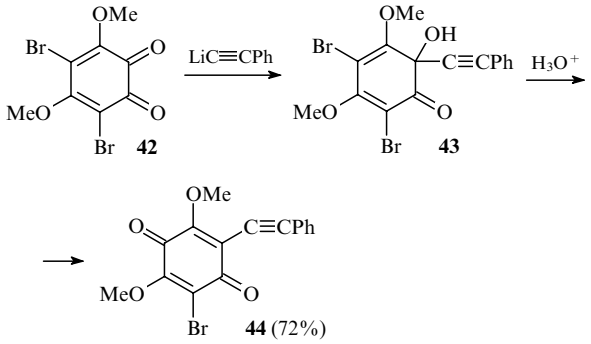
Interestingly, monoadducts **39** (X = Y = H) and diadduct **41** are readily transformed into the corresponding acetylenic derivatives of alkoxy-substituted chlorobenzenes under the action of $SOCl_2$ in THF in the presence of pyridine.[42] These reaction products, in turn, can serve as precursors of mono- or dialkynyl-1,4-benzoquinones (see Section II.2).





R = Bu, CH_2OBn, Ph.

In the reaction of 4,6-dibromo-3,5-dimethoxy-1,2-benzoquinone **42** with lithium phenylacetylide, the latter attacks the carbonyl group at position 2[42] to give monoadduct **43**, which is unstable and readily hydrolysed on treatment. This reaction leaves the methoxy groups intact and gives rise to 2-bromo-3,5-dimethoxy-6-phenylethynyl-1,4-benzoquinone **44**.



Apparently, it is impossible to extend the above-considered procedure for the synthesis of acetylenic derivatives of *p*- and *o*-benzoquinones to naphthoquinone derivatives. Hanhela and Paul[47] attempted to synthesise 1,4-dihydro-2,3-dimethoxy-1,4-di(phenylethynyl)naphthalene-1,4-diol by adding two moles of lithium phenylacetylide to 2,3-dimethoxy-1,4-naphthoquinone followed by reductive aromatisation of the diadduct; however, the reaction afforded a mixture of other products.

4. Other methods

Before the above-described general methods for the synthesis of acetylenic derivatives of quinones were developed, compounds of this class had been prepared according to procedures applicable only to particular cases. For example, bis(anthraquinon-2-yl)acetylene was prepared by reductive cross-coupling of 2-tribromomethylanthraquinone either under the action of copper metal in refluxing nitrobenzene[48] or by thermal condensation of 2-dibromomethylanthraquinone followed by dehalogenation of the resulting substituted dibromoethylene in refluxing diethylaniline or phenol in the presence of K_2CO_3.[49] The addition of chlorine to 1-(anthraquinon-2-yl)-2-(2,4-dinitrophenyl)ethylene followed by dehydrohalogenation of the adduct was used for the synthesis of 2-(2,4-dinitrophenylethynyl)anthraquinone.[50] Dehydrochlorination of a series of functionalised (2-chloro-2-propen-1-yl)anthraquinones was studied.[51,52] Depending on the structure of the starting compound, the chloropropenyl substituent can be transformed into the prop-1-ynyl, propanedienyl or 2-oxopropyl group. If there are two chloropropenyl substituents in the substrate, at least one of them is transformed into the propynyl group. A series of 2-(arylethynyl)anthraquinones were synthesised by the Wittig reaction.[53] Acid-catalysed dehydration of 3-alkynyl-1,2,3,4-tetrahydro-1,3,5,8-tetrahydroxyanthraquinones, in which the acetylenic group is not directly bound to either the quinoid or aromatic ring, afforded 6-alkynyl-1,4-dihydroxyanthraquinones.[54,55]

III. Chemical properties

1. Reactions with amines

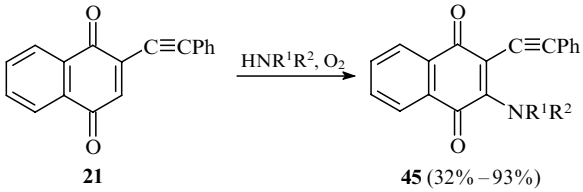
In acetylenic derivatives of quinones, the triple bond is highly electrophilic due to conjugation with carbonyl groups located in the plane of the cyclic moiety of the molecule. These compounds, like other compounds bearing the activated triple bond, can add *N*-nucleophiles, for example, amines.

a. Quinones containing acetylenic substituents in the quinoid ring

Quinones containing acetylenic substituents in the quinoid ring are vinylogs of acetylenic ketones.

The reactions of 2-alkynyl-1,4-naphthoquinones with amines can follow two competitive pathways: addition at the triple bond and oxidative replacement of the hydrogen atom at position 3. The latter reaction involves the Michael-type 1,4-addition of amine to the ketovinyl group of quinone to form 1,4-dihydroxynaphthalene followed by oxidation of the latter.[1]

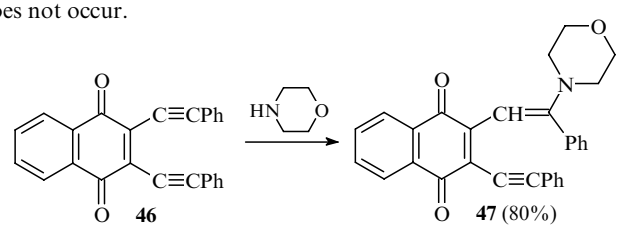
However, of the above two possible pathways, only oxidative amination takes place.[56] For example, 2-phenylethynyl-1,4-naphthoquinone **21** reacts with primary and secondary amines as well as with NH_3 at room temperature to give 2-amino-3-phenylethynyl-1,4-naphthoquinones **45**. Generally, dioxane, aqueous dioxane, diethyl ether or an excess of amine is used as the solvent. An additive of $Cu(OAc)_2$ catalyses oxidation of the hydroquinone intermediate.



$R^1 = R^2 =$ H, Me, Et; $R^1 =$ H: $R^2 =$ Me, Et, cyclo-C_6H_{11}, $(CH_2)_2OH$, CH_2Ph, CH_2CO_2Me, $CH_2CO_2^-$, Ph; $R^1-R^2 = -(CH_2)_5-$, $-(CH_2)_2O(CH_2)_2-$.

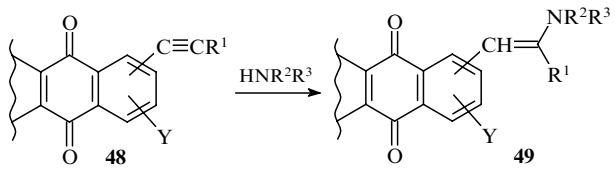
In the reaction with 2-alkynyl-1,4-naphthoquinone containing an electron-withdrawing substituent at position 3 of the quinoid ring, amine adds at the triple bond. The introduction of an electron-donating group (for example, of the amino group) leads to deactivation of the adjacent triple bond. However, acylation of the latter restores the ability of the acetylenic substituent to add amines.[56]

Unlike monosubstituted 2-phenylethynyl-1,4-naphthoquinone, 2,3-bis(phenylethynyl)-1,4-naphthoquinone (**46**) readily adds one equivalent of morpholine (20 °C, 15 min)[56] to give monoadduct **47**. Due to low electrophilicity of the triple bond in the latter compound, the addition of the second amine molecule does not occur.



b. Quinones with an acetylenic substituent in the benzene ring

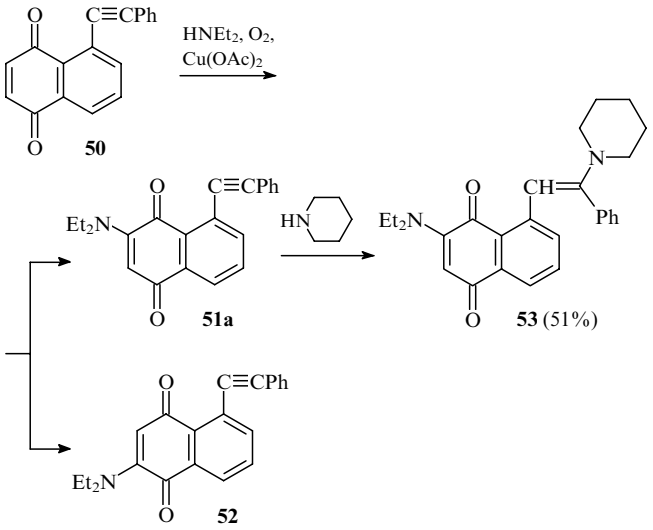
Anthraquinones and naphthoquinones **48** containing an acetylenic substituent in the benzene ring add secondary amines at the triple bond at 20–105 °C in dioxane or in an excess of amine to form adducts **49** in 50%–95% yields.[13,15,19,22,29,57]



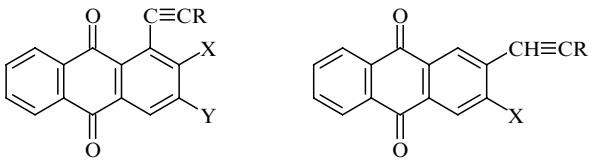
Y = H, Cl, NH_2, NO_2, CO_2Me; R^1 = H, CMe_2OH, CH_2N⟨O⟩, Ph, CH_2OPh; $R^2 = R^3$ = Et, Bu; R^2-R^3 = $-(CH_2)_4-$, $-(CH_2)_5-$, $-(CH_2)_2O(CH_2)_2-$.

Studies by ^1H NMR spectroscopy demonstrated that these reactions always afford only one geometric isomer. For ethynylquinones (R^1 = H), this isomer has a *trans* configuration.

Naphthoquinones devoid of substituents in the quinoid ring are subjected to oxidative amination at one of its positions. For example, the reaction of 5-phenylethynyl-1,4-naphthoquinone **50** with an excess of amine in the presence of $Cu(OAc)_2$ as the catalyst by bubbling air at 20 °C afforded a mixture of 3- (**51a**) and 2-amino derivatives (**52**) in a ratio of ~2 : 1 in 54.5% yield.[13] In isomer **51a**, the triple bond retains the ability to add amines. However, isomer **51a** forms adduct **53** with piperidine under more drastic conditions (at 80 °C for 10 h).



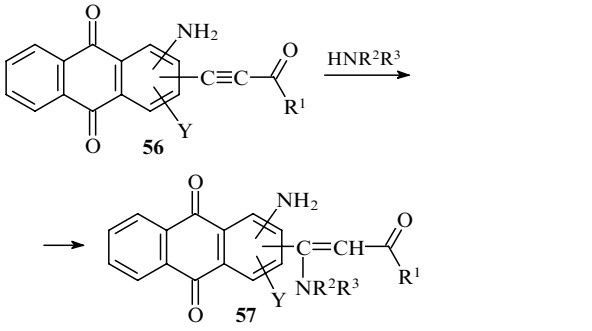
The reactivity of quinones containing an acetylenic substituent in the benzene ring depends on the nature of this substituent, its position and the presence of other functional groups. The acetylenic substituent at the α position of the benzene ring is more active than the substituent at the β position. In both cases, ethynyl derivatives are most reactive. For instance, the reactions of 1-ethynyl- (**54a**) and 2-ethynylanthraquinones (**55a**) with pyrrolidine at 20 °C were completed in 15 min and 12 h, respectively.[15] The reactions of 3-diethylamino-5-ethynyl- (**51b**) and 3-diethylamino-5-phenylethynyl-1,4-naphthoquinone **51a** with piperidine were completed in 1 h at 20 °C and in 10 h at 80 °C, respectively,[13] whereas the reaction time of the addition of piperidine to 2-phenylethynylanthraquinone **55b** at 80 °C was as long as 48 h.[15] The acetylenic substituent and the halogen atom present in the same ring activate each other. In going from 1-phenylethynylanthraquinone (**54b**) to its 2- and 3-chloro-substituted derivatives (compounds **54c**,**d**), the time of the reaction with piperidine decreases from 4 h to 8 and 20 min, respectively (80 °C).[15] The time of the competitive reaction, *viz*., the replacement of the halogen atom in 1-chloroanthraquinone **2** (X = 1-Cl, Y = H) by the piperidine group, decreases in the presence of the phenylethynyl substituent at positions 2 and 4 from 1.5 h to 12 and 20 min, respectively (80 °C). In 3-chloro-2-phenylethynylanthraquinone (**55c**), the addition of piperidine and the replacement of the chlorine atom with piperidine proceed at similar rates. The replacement and addition products (4 : 3 ratio; 79% total yield) do not react with the amine.



54	R	X	Y
a	H	H	H
b	Ph	H	H
c	Ph	Cl	H
d	Ph	H	Cl

55	R	X
a	H	H
b	Ph	H
c	Ph	Cl

In acylethynylanthraquinones, the triple bond is activated both by the carbonyl group of the substituent and the quinone ring. In *vic*-amino(acylethynyl)anthraquinones **56**, the influence of the carbonyl group prevails and the addition of amine occurs at the β position with respect to the carbonyl group[36, 39, 58] to give adducts **57** in 69% – 75% yields.



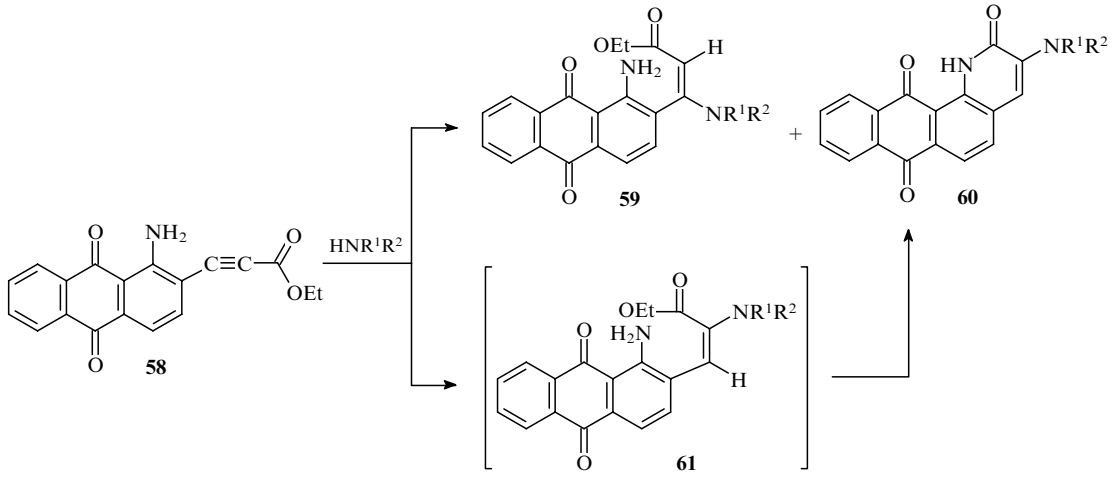
Y = H, Cl, NO_2; R^1 = Ph, Bu^t; R^2 = H: R^3 = Bu, C_8H_{17}; $R^2 = R^3$ = Et; R^2-R^3 = $-(CH_2)_4-$, $-(CH_2)_5-$, $-(CH_2)_2O(CH_2)_2-$.

Unlike ketones **56**, ethyl (1-aminoanthraquinon-2-yl)propiolate (**58**) adds amines to form two products, *viz*., the corresponding β-amino acrylate **59** (in 60% – 66% yields) and 1*H*-3-aminonaphtho[2,3-*h*]quinoline-2,7,12-trione **60** (in 12% – 18% yields).[25, 26] Evidently, the latter products are generated through rapid cyclisation under the conditions of the reaction of regioisomeric α-amino acrylates **61** (Scheme 1).

Apparently, the ease of intramolecular cyclisation of α-amino acrylates of type **61** as well as of the resulting β-amino acrylates (see Section III.4) indicates that the adducts of both types have an *E* configuration. Taking into account the regioselectivity of the addition of amines to acylethynylanthraquinones and the ratio between the yields of linear and cyclic products of addition to aminoanthraquinonyl propiolate **58**, the groups activating the triple bond can be arranged in the following series: CO > CO_2Et > 1-aminoanthraquinon-2-yl.

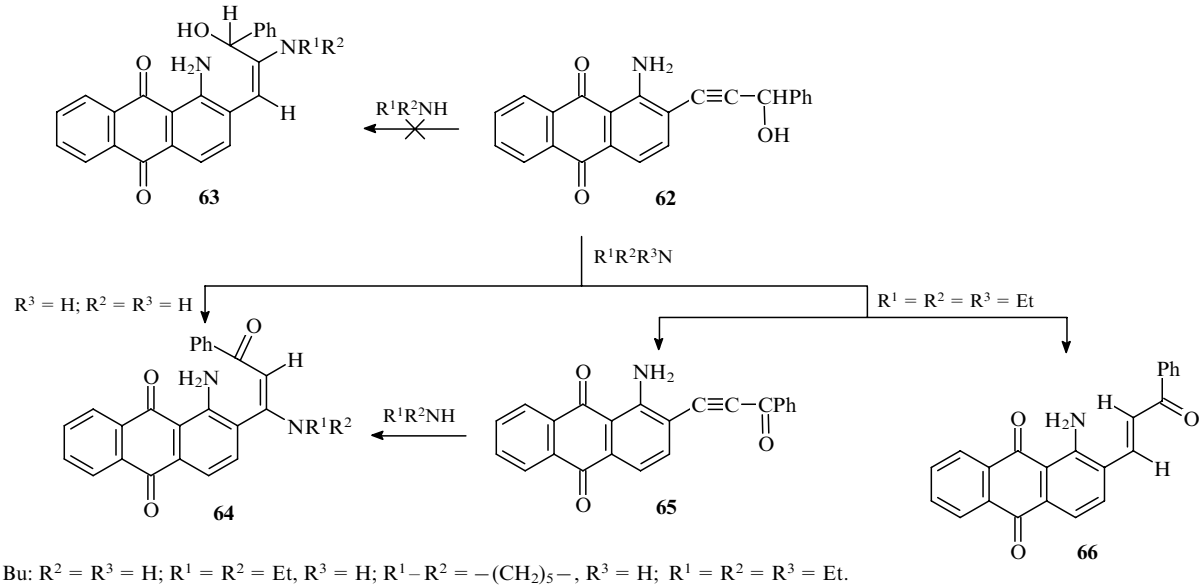
Secondary acetylenic alcohol, *viz*., 1-amino-2-(3-hydroxy-3-phenylpropynyl)anthraquinone (**62**), exhibits an unusual behaviour in reactions with amines.[27] The reactions of alcohol **62** with primary amines lead predominantly to its dehydrogenation. The reactions of alcohol **62** with secondary amines also afford dehydro adducts **64**, which are identical to products of addition of amines to 2-benzoylethynyl derivative **65** (in yields of up to 76%), rather than the expected enamino alcohols **63**. On heating with tertiary amine (Et_3N), alcohol **62** undergoes competitive dehydration to form acetylenic ketone **65** and isomerisation to vinyl ketone **66**. The mechanism of formal oxidation of the alcoholic group in compound **62** remains unclear (see Ref. 27) (Scheme 2).

Scheme 1



R^1 = H, R^2 = Bu; R^1 = R^2 = Et; R^1–R^2 = –$(CH_2)_5$–.

Scheme 2



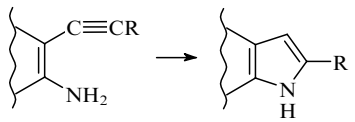
R^1 = Bu: R^2 = R^3 = H; R^1 = R^2 = Et, R^3 = H; R^1–R^2 = –$(CH_2)_5$–, R^3 = H; R^1 = R^2 = R^3 = Et.

The reactivity of amines in nucleophilic addition to alkynylanthraquinones is to a large extent determined by their spatial structure. For sterically similar amines, the reactivity increases as their basicity increases.[15]

Adducts of alkynylquinones with amines are intermediates for the synthesis of various fused heterocyclic quinoid structures.

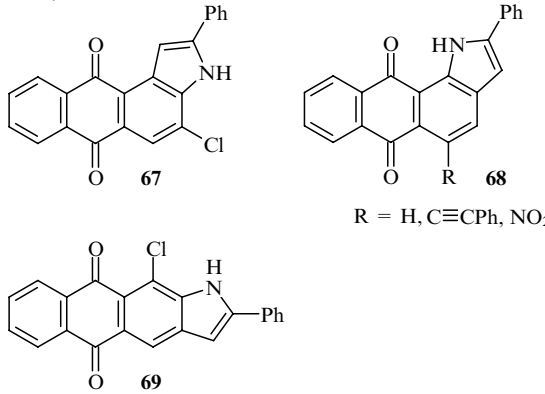
2. Pyrrole-ring closure reactions of *vic*-amino(alkynyl)quinones

It is known that in the presence of Cu(I) compounds, Pd(II) and other transition metal salts, bases or, in some cases, mineral acids, aryl- and hetarylacetylenes containing a primary or secondary amino group in the *ortho* position with respect to the acetylenic substituent undergo cyclisation to form the pyrrole ring.[59–65] This reaction was extended to vicinal acetylenic derivatives of aminoquinones.[18,21,22,29,57,66,67]



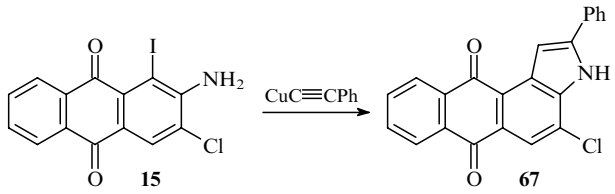
a. Catalytic cyclisation

Originally, intramolecular cyclisation of *vic*-amino(alkynyl)quinones seemed hardly possible due to low nucleophilicity of the amino group. However, it appeared that these compounds undergo intramolecular cyclisation in the presence of cuprous acetylide or powdered copper [but not Cu(I) halides] in pyridine or DMF at 80–153 °C to form the corresponding naphthoindoledione **67**–**69** with the differently fused pyrrole and anthraquinone rings (in 21%–85% yields; the reaction time is 0.5–7 h).[18,21,67]

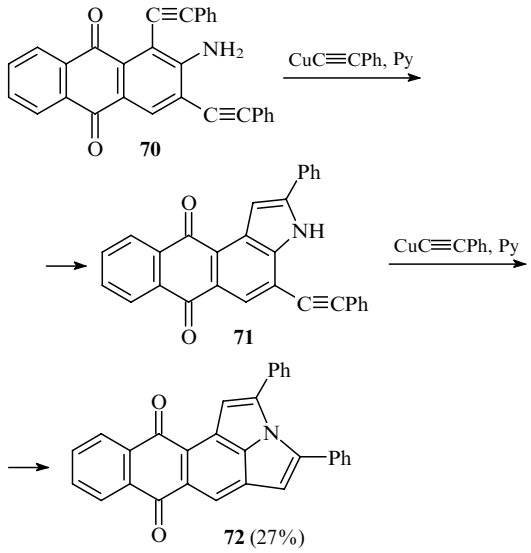


R = H, C≡CPh, NO_2

Naphthoindole **67** was prepared also in one step from *vic*-amino(iodo)anthraquinone **15** by cyclocondensation with CuC≡CPh under analogous conditions.

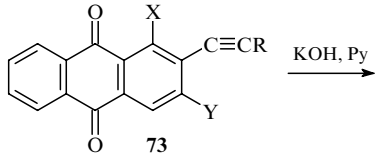


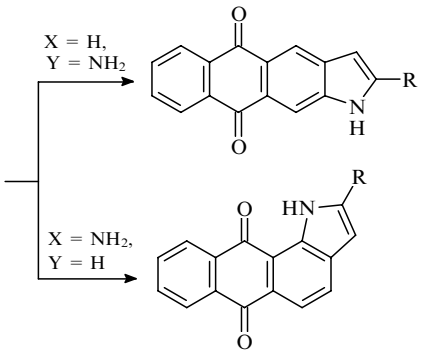
In this catalytic intramolecular reaction, like in the intermolecular addition of amines to alkynylanthraquinones, 1-alkynyl derivatives are more active. For example, 2-amino-3-chloro-1-phenylethynylanthraquinone **16** undergoes cyclisation to 2-phenylnaphtho[2,3-*e*]indole-4,9-dione (**67**) in 82% yield in pyridine in the presence of CuC≡CPh at 80 °C during 1 h, whereas isomeric 2-amino-1-chloro-3-phenylethynylanthraquinone gives 2-phenylnaphtho[2,3-*f*]indole-5,10-dione (**69**) in a yield of only 25% at 115 °C after 2 h. Under analogous conditions (80 °C, 20 min), cyclisation of 2-amino-1,3-di(phenylethynyl)anthraquinone (**70**) proceeds only involving the acetylenic substituent at position 1. In spite of the lower activity of the acetylenic group at position 3 and low nucleophilicity of the NH unit of the pyrrole ring, product **71** can undergo further cyclisation to produce 2,3-diphenylnaphtho[2,3-*e*]pyrrolo[3,2,1-*hi*]indole-6,11-dione (**72**) under more drastic conditions (115 °C, 45 h).



It is also of interest to compare the rates of cyclisation of 1-amino-2-phenylethynylanthraquinone derivatives giving rise to products **68**. Cyclisation of unsubstituted anthraquinone (R = H) was completed in 4.5 h at 115 °C (CuC≡CPh, pyridine), whereas the reaction of its nitro derivative (R = NO_2) was completed in less than 1 h at 80 °C (in spite of the fact that the nitro group should decrease the nucleophilicity of the amine thus slowing down the reaction).

It was proposed that *vic*-amino(alkynyl)anthraquinones, unlike *ortho*-alkynylanilines, can undergo cyclisation with preliminary deprotonation of the amino group under the action of bases. Solid KOH is a catalyst of choice for cyclisation of amino(alkynyl)anthraquinones **73**.[18,29]

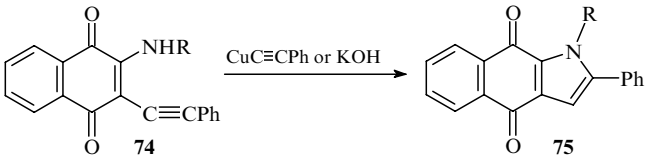




R = H, Ph; X = H, Y = NH_2; X = NH_2, Y = H.

Under these conditions, cyclisation of 1-amino-2-phenylethynylanthraquinone (**73**; R = Ph, X = NH_2, Y = H) in refluxing pyridine was completed in 15 min to give the product in 88% yield (for comparison, cyclisation of the same compound in the presence of CuC≡CPh was completed in 4.5 h, and the yield of the product was 57%). Other naphthoindolediones were prepared in 40% – 88% yields, and the reaction time was 8 – 90 min. To preclude alkaline hydrolysis, *vic*-amino(acylethynyl)anthraquinones are subjected to cyclisation with the use of K_2CO_3 in DMSO (65 – 70 °C, 10 – 20 min).[39]

Cyclisation of amino(alkynyl)-1,4-naphthoquinones **74** containing an acetylenic substituent and a secondary amino group in the quinoid ring proceeded analogously.[66] The reaction was carried out at 100 – 140 °C in pyridine, its mixture with dioxane, DMSO or mesitylene to prepare benzo[*f*]indole-4,9-diones (**75**) in 20% – 82% yields.



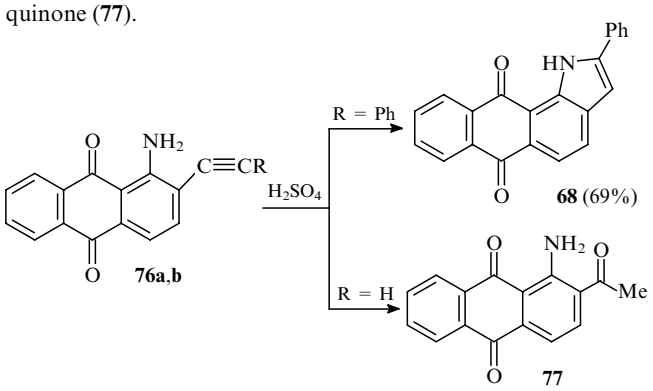
R = Me, $CH_2CH=CH_2$, $(CH_2)_2OH$, $(CH_2)_2OAc$, CH_2Ph, Ac, Ph.

Evidently, the characteristic features of cyclisation of amino(alkynyl)quinones cannot be explained only on the hypothesis that the process involves preliminary deprotonation of the amino group. It is hardly probable that the appearance of a charge on the nucleophilic centre could provide its interaction with the spatially remote β-carbon atom of the triple bond.

In the general case, the mechanism of intramolecular addition of the amino group at the triple bond catalysed by metal compounds involves the formation of a metal acetylenic π-complex and its cyclisation to a mixed organometallic compound (3-indolyl derivative), which is readily hydrolysed to the corresponding indole. Covalently bound copper from acetylide (or oxides on a copper powder surface) can be involved in stronger (compared to copper salts) dative interactions in π-complexes with a triple bond, and these interactions are additionally strengthened due to high electrophilicity of the triple bond in quinones, due to which the π-complex becomes rather stable. As a result of a change in the geometry of the triple bond in the complex, the reaction centres (the amino group and the β-carbon atom of the acetylenic substituent) are brought into proximity and the interaction between them becomes possible. Upon deprotonation of the amino group, the electrophilicity of the triple bond conjugated with this amino group decreases and the formation of a π-complex even with a proton becomes possible (for example, when KOH is used as a catalyst). This π-complex formation accompanied by a change in the geometry of the acetylenic substituent is, apparently, the necessary condition for the closure of the heterocycle.

Some acetylenic derivatives of aminoanthraquinones can undergo cyclisation to naphthoindolediones under acid cataly-

sis.[18,29] The possibility of this reaction is determined by regioselectivity of hydration of the triple bond. Actually, 1-amino-2-phenylethynylanthraquinone (**76a**) undergoes cyclisation in concentrated H_2SO_4 to form substituted naphthoindoledione **68** at 40 °C for 3 min, whereas 1-amino-2-ethynylanthraquinone **76b** gives only the hydration product, *viz*., 2-acetyl-1-aminoanthraquinone (**77**).

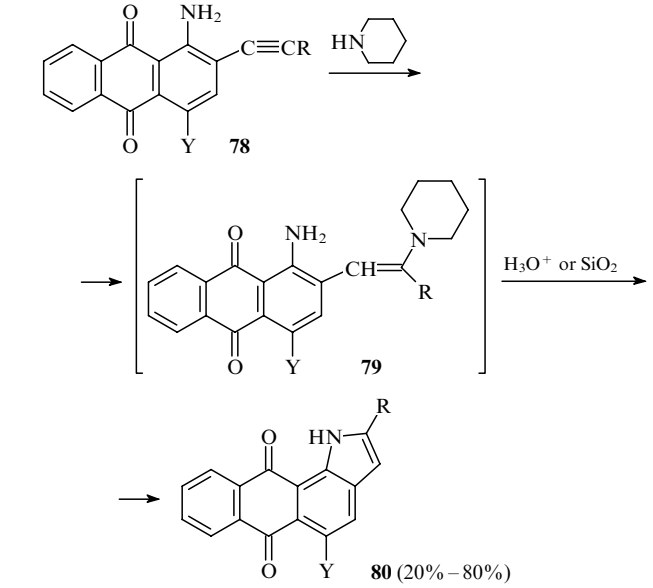


R = Ph (**a**), H (**b**).

b. Cyclisation through adducts with amines

Quinones **78** containing a vicinal primary amino group and an acetylenic substituent in the benzene ring can add secondary amines at the triple bond to form β-dialkylaminovinyl adducts **79**. Due to a change in the geometry of the unsaturated substituent (it is brought into proximity with the adjacent amino group), these adducts are easily subjected to intramolecular cyclisation in the presence of mineral acids or on SiO_2.

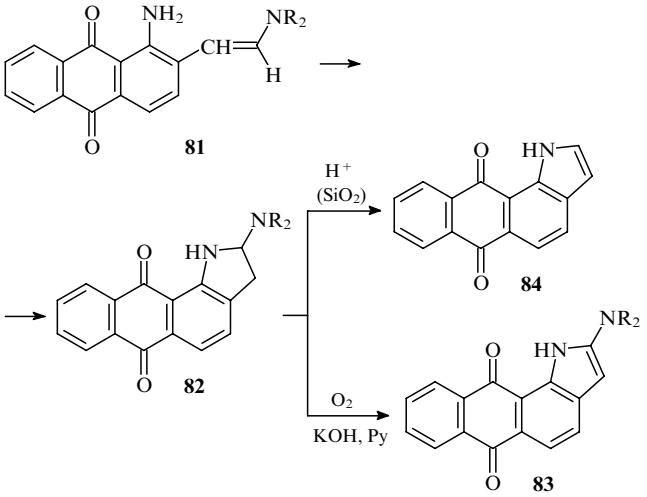
Some *vic*-amino(alkynyl)anthraquinones [for example, 1-amino-2-(3-hydroxyalk-1-ynyl)anthraquinones] are transformed into naphthoindolediones already on heating (80–105 °C) in an excess of secondary amine for several hours. The addition of amine to such acetylenes is hindered, and the resulting adducts are unstable and undergo rapid cyclisation with elimination of amine. This sequence of reactions provides the basis for a simple preparative procedure for annelation of quinones with the pyrrole ring.[18,22,27,29] This procedure was used for the synthesis of a series of naphtho[2,3-*g*]indole-6,11-diones **80**.



R = H, CH_2OH, CH(OH)Pr, CMe_2OH, CH_2OPh, CH_2N⟨O⟩;
Y = H, NO_2.

One of the possible pathways of transformations of dialkylaminovinyl derivatives of 1-aminoanthraquinone **81** into tetracyclic products involves their cyclisation to 2-dialkylamino-2,3-dihydronaphtho[2,3-*g*]indole-6,11-diones **82**, which are labile and readily undergo aromatisation with elimination of amine on silica gel or under the action of an acid.[57] The diethylaminopyrroline intermediate (R = Et) is particularly unstable: it eliminates diethylamine already under the synthesis conditions and is transformed into unsubstituted naphthoindoledione.

However, pyrroline intermediates **82** can undergo aromatisation not only through elimination of amine but also upon dehydrogenation. It appeared that these compounds underwent aromatisation with retention of the amino group at 20 °C in pyridine in the presence of KOH and atmospheric oxygen (yields were ~60%). 2-Diethylaminonaphtho[2,3-*g*]indole-6,11-dione **83** was also prepared in low yield (22%) by cyclisation of 1-amino-2-diethylaminovinylanthraquinone **81** under the same conditions. This reaction afforded unsubstituted naphthoindoledione **84** as the major product.

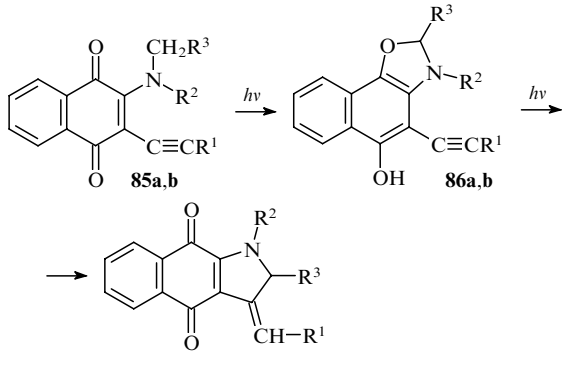


R–R = $-(CH_2)_5-$, $-(CH_2)_2O(CH_2)_2-$; R = Et.

Another pathway of cyclisation of adducts which involves hydrolysis of the dialkylaminovinyl substituent followed by the pyrrole-ring closure, is also not ruled out.

c. Photoinduced heterocyclisation

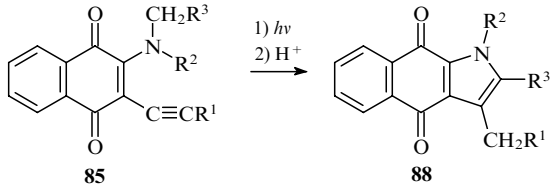
Another method for the construction of a system of fused pyrrole and quinoid rings is based on photochemical cyclisation of 3-alkynyl-2-dialkylamino-1,4-naphtho- or -1,4-benzoquinone.[68,69] This reaction involves two steps, as was exemplified by the reactions of 2-diethylamino-3-phenylethynyl- (**85a**) and 2-dimethylamino-3-(3-phenoxyprop-1-ynyl)-1,4-naphthoquinones (**85b**).[68] The first step is initiated with visible light (λ = 546 nm) and leads to the closure of the dihydrooxazole ring with the participation of the dialkylamino and vicinal carbonyl groups giving rise to intermediates **86**. On irradiation with light



R^1 = Ph, R^2 = Et, R^3 = Me (**a**); R^1 = CH_2OPh, R^2 = Me, R^3 = H (**b**).

(λ = 436 nm), the latter undergo recyclisation to the corresponding 3-alkylidene-2,3-dihydronaphtho[2,3-*b*]pyrrole-4,9-diones **87**.

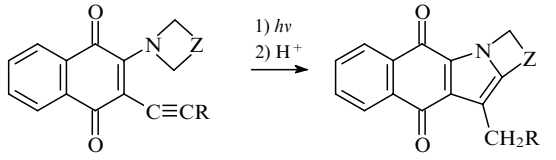
In the presence of catalytic amounts of mineral acids, photocyclisation products (compounds **87**) are isomerised into substituted naphtho[2,3-*b*]pyrrole-4,9-diones **88**.[69] The latter can be synthesised from alkynylquinones without isolation of intermediate dihydroindolequinones.



85 **88**

R^1 = H, CH_2OPh, Ph; R^2 = Me, Et; R^3 = H, Me.

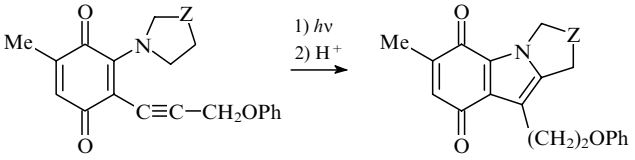
If the dialkylamino group in the starting alkynylquinone **89** is a residue of cyclic amine, photocyclisation affords tetracyclic heterocyclic quinones **90**.[69]



89 **90** (16% – 60%)

Z = $-(CH_2)_2-$, $-(CH_2)_3-$, $-CH_2OCH_2-$; R = Ph, CH_2OPh.

Analogously, tricyclic compounds **92** are derived from 3-alkynyl-2-amino-1,4-benzoquinones **91**.



91 **92**

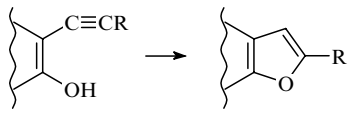
Z = $-CH_2-$, $-(CH_2)_2-$.

Quinones bearing a nitrogen atom at the fusion of two rings are structurally similar to natural antitumour antibiotics of the mitomycin family.

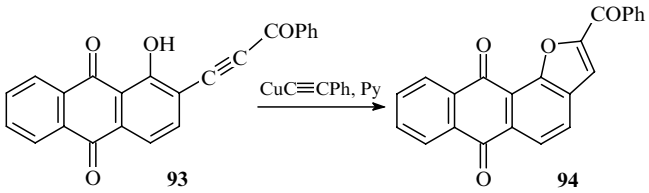
3. Furan-ring closure reaction

a. Reactions of *vic*-hydroxy(alkynyl)quinones

vic-Acetylenic derivatives of hydroxyanthraquinones (like *ortho*-hydroxyarylacetylenes[60,70–72]) undergo cyclisation in the presence of copper or palladium catalysts or bases to form the furan ring. Generally, the reactions proceed under mild conditions and give products in good yields.

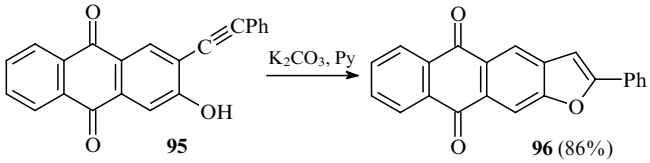


For example, 1-hydroxy-2-benzoylethynylanthraquinone (**93**) undergoes cyclisation under the action of CuC≡CPh in pyridine already at 20 °C during 30 min. Although the presence of the carbonyl group in the acetylenic substituent of quinone should hinder the attack of the nucleophile at the adjacent carbon atom, the yield of 2-benzoylanthra[1,2-*b*]furan-6,11-dione (**94**) amounts to 68%.[39]



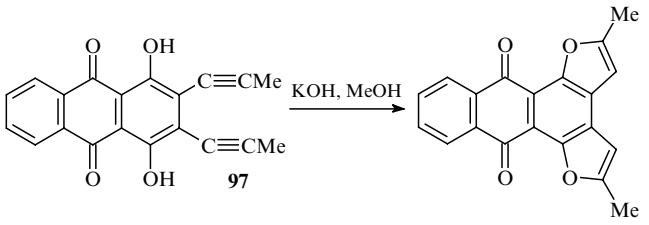
93 **94**

In the presence of solid K_2CO_3, 2-hydroxy-3-phenylethynylanthraquinone **95** undergoes cyclisation in refluxing pyridine to give 2-phenylanthra[2,3-*b*]furan-5,10-dione **96** during 3 min.[69]



95 **96** (86%)

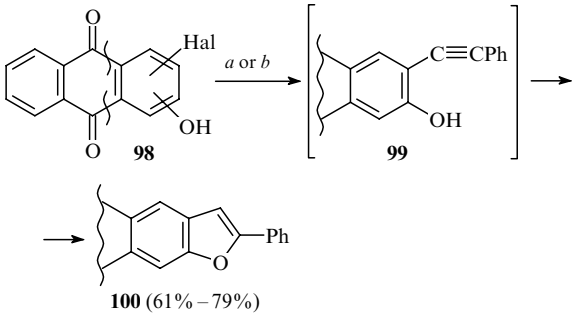
Cyclisation of 1,4-dihydroxy-2,3-di(prop-1-ynyl)anthraquinone (**97**) in a refluxing 1.5% KOH solution in MeOH proceed much more slowly; the conversion is approximately 90% after 24 h.[52]



97

The mechanism of this heterocyclisation under various conditions was not studied in detail. However, this mechanism is, apparently, similar to that of the pyrrole-ring closure (see Section III.2.a).

Cross-coupling of *vic*-hydroxy(iodo)anthraquinones (**98**, Hal = I) both with cuprous acetylides[38,69] and terminal acetylenes catalysed by palladium complexes[17,69] affords directly anthrafurandiones. Unlike condensation of *vic*-amino iodides, the replacement of the halogen atom in this reaction is the rate-determining step and the expected acetylenic intermediates of the reaction (compounds of type **99**) are not detected. Stable cuprous acetylides (for example, CuC≡CPh) have proved themselves in the synthesis of anthrafurandiones. For instance, the reaction time of cyclocondensation at 20–115 °C is only 5–10 min.[38,69] This method was used for the synthesis of all three isomeric anthrafurandiones (**100**).



98 **99**

100 (61% – 79%)

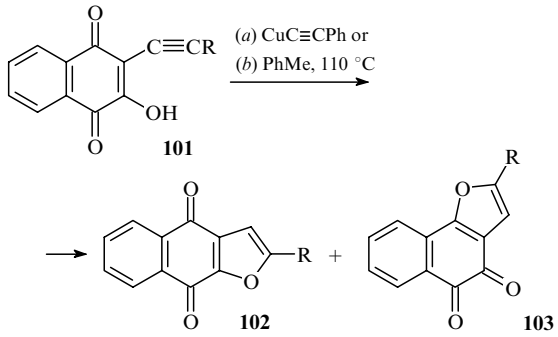
Hal = I, Br;
(*a*) CuC≡CPh; (*b*) HC≡CPh, $Pd(PPh_3)_2Cl_2$, CuI, K_2CO_3, Py.

2-Hydroxy-1-iodoanthraquinone is most reactive in this reaction. In this case, cross-coupling is completed in the above-mentioned time at room temperature. The reactivity of the corresponding bromide is also high. For example, its condensation with CuC≡CPh is completed in 5 min at 115 °C. The reaction of 1-chloro-2-hydroxyanthraquinone virtually does not proceed.

Catalytic cross-coupling of *vic*-hydroxy(iodo)anthraquinones with terminal acetylenes has some advantages over acetylide condensation, because it allows one to use alkynes, which do not form stable acetylides (aminopropynes, acetylenic alcohols, *etc*.). Catalytic cyclocondensation was carried out for different isomers of *vic*-hydroxy(iodo)anthraquinones (the yields were 34% – 80%).[17, 69]

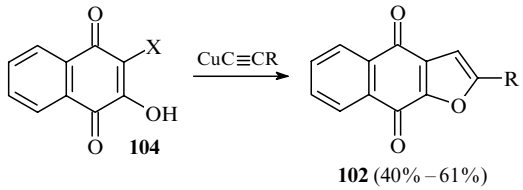
1,4-Naphthoquinones **101** containing the hydroxy and acetylenic groups in the quinoid ring undergo intramolecular cyclisation in the presence of CuC≡CPh under very mild conditions (pyridine – dioxane, 20 °C, 3 – 5 min) [69] to give the expected linear heterocyclic *para*-quinones **102** along with their isomers, *viz*., angularly fused *ortho*-quinones **103**.

2-Alkynyl-3-hydroxy-1,4-naphthoquinones can undergo cyclisation with the closure of the furan ring in the absence of catalysts as well.[69] At 110 °C, compounds **101** in toluene also give mixtures of heterocyclic *para*- and *ortho*-quinones, but in another ratio.



R	Reaction conditions	Yield (%)	
		102	**103**
Ph	*a*	59	16
	b	10	84
C_8H_{17}	*a*	23	6
	b	24	74

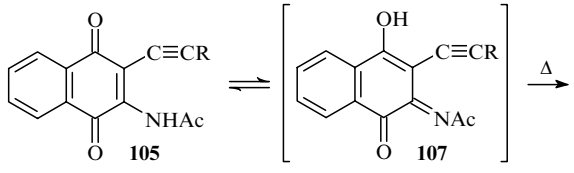
However, cyclocondensation of 2-halogeno-3-hydroxy-1,4-naphthoquinones **104** with Cu(I) acetylides at 100 °C proceeds regioselectively to form linear naphtho[2,3-*b*]furan-4,9-diones **102**.

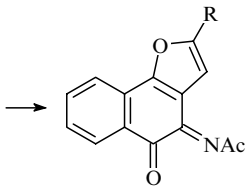


X = I, Br; R = Bu, C_8H_{17}, CH_2OMe, Ph.

b. Other reactions of the furan-ring closure

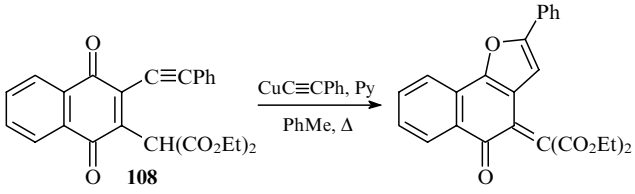
Angular annelation of the quinoid moiety with the furan ring occurred upon thermal cyclisation of 3-acetylamino-2-alkynyl-1,4-naphthoquinones **105**.[66]





R = CMe_2OH, Ph.

The formation of products **106** can be attributed to the transformation of tautomer **107**. Actually, this cyclisation becomes impossible upon the replacement of the *N*-acetyl group by the *N*-alkyl group. Angular heterocyclisation is, apparently, associated with the acidic properties of the acetylamino group and, hence, structurally similar CH acids are also able to undergo this cyclisation. For example, malonic acid derivative **108** was transformed into naphthofuran **109** by heating in toluene in the presence of small amounts of CuC≡CPh and pyridine.[69]

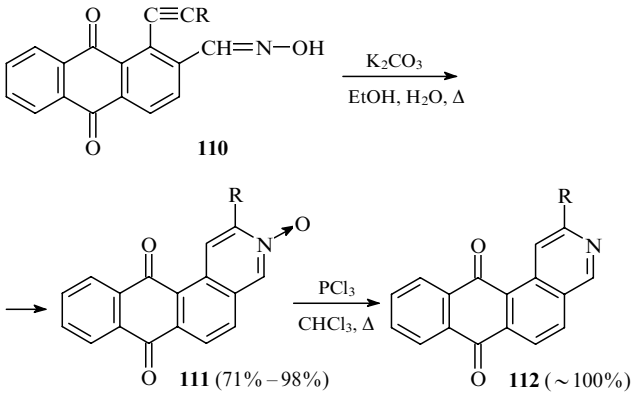


4. Pyridine-ring closure reactions

Intramolecular cyclisation of quinones bearing an acetylenic substituent and a nitrogen-containing group in the adjacent positions of the aromatic ring can be used for their annelation with the pyridine ring. Depending on the structures of the substituents involved in the formation of the heterocycle, the products contain either the quinoline or isoquinoline fragment.

a. Cyclisation of *vic*-alkynylanthraquinone aldoximes

1-Alkynylanthraquinone-2-aldoximes **110** are transformed into 2-substituted naphtho[2,3-*f*]isoquinoline-7,12-dione *N*-oxides **111** by refluxing in 90% aqueous EtOH in the presence of K_2CO_3 for 15 min. Compounds **111** can be reduced to the corresponding naphthoisoquinolinediones **112**.[35]



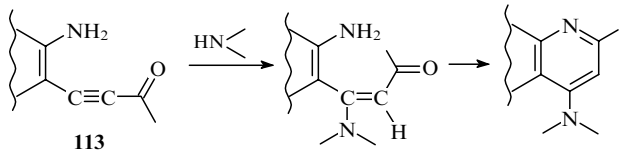
R = Bu, CH_2OPh, Ph.

This cyclisation was carried out also for analogous derivatives of indole,[73] benzene [64, 74] and pyridine.[64, 75]

b. Cyclisation of *vic*-amino(acylethynyl)- and *vic*-amino(ethoxycarbonylethynyl)anthraquinones

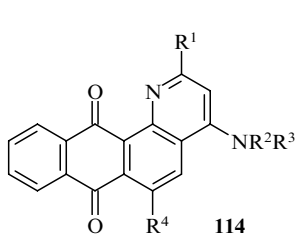
Another method for the construction of the anthrapyridine structure is based on the use of *vic*-acylethynyl derivatives of aminoanthraquinones **113**. This method involves the nucleophilic addition of amines (secondary or primary) at the activated triple

bond of the starting compound followed by intramolecular cyclisation of the adduct with the participation of the carbonyl group of the side chain and the aromatic amino group.[36, 58] The role of the amine addend consists, primarily, of changing the geometry of the unsaturated substituent resulting in a close arrangement of the reacting fragments, which is necessary for the closure of the heterocycle. In this case, the *Z* configuration of the adduct is reactive. The amino group introduced is retained in the newly formed pyridine ring.

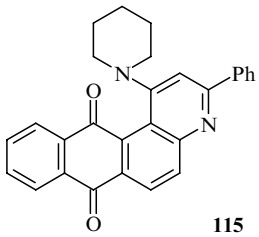


113

Substituted naphtho[2,3-*h*]quinoline-7,12-diones (**114**), naphtho[2,3-*f*]quinoline-7,12-dione (**115**) and naphtho[2,3-*g*]quinoline-6,11-dione (**116**) were synthesised by cyclisation of 2-acylethynyl-1-amino-, 1-acylethynyl-2-amino- and 3-acylethynyl-2-aminoanthraquinones, respectively.

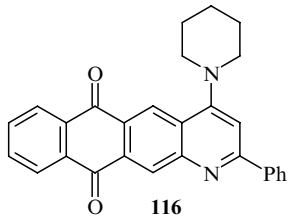


114



115

R^1 = Bu^t, Ph; R^2 = H, Et, R^3 = Et, Bu, C_8H_{17}; R^2-R^3 = $-(CH_2)_4-$, $-(CH_2)_5-$, $-(CH_2)_2O(CH_2)_2-$; R^4 = H, Cl, NO_2.



116

Cyclisation of adducts is carried out at room temperature (by shaking benzene solutions with dilute HCl over a short period of time or stirring with KOH in pyridine) or at 80 °C in the presence of $POCl_3$. In some cases, cyclisation proceeds already under the conditions of the preparation of the adduct (heating of acetylenic ketone **113** in an excess of amine). The rate of cyclisation depends on the structure of the adducts. Under alkaline conditions, the time of cyclisation of amino adducts of 1-amino-2-benzoylethynylanthraquinone is 5–15 min, whereas the time of cyclisation of the adduct of 2-amino-1-benzoylethynyl-3-chloroanthraquinone with piperidine is as large as 2 h due, apparently, to steric hindrance. Cyclisation of (monoalkylamino)vinyl ketones under the action of acids is more difficult to perform compared to that of analogous (dialkylamino)vinyl ketones. The yields of mono- and dialkylaminonaphthoquinolinediones in both acidic and basic media are in the range of 54%–100%.

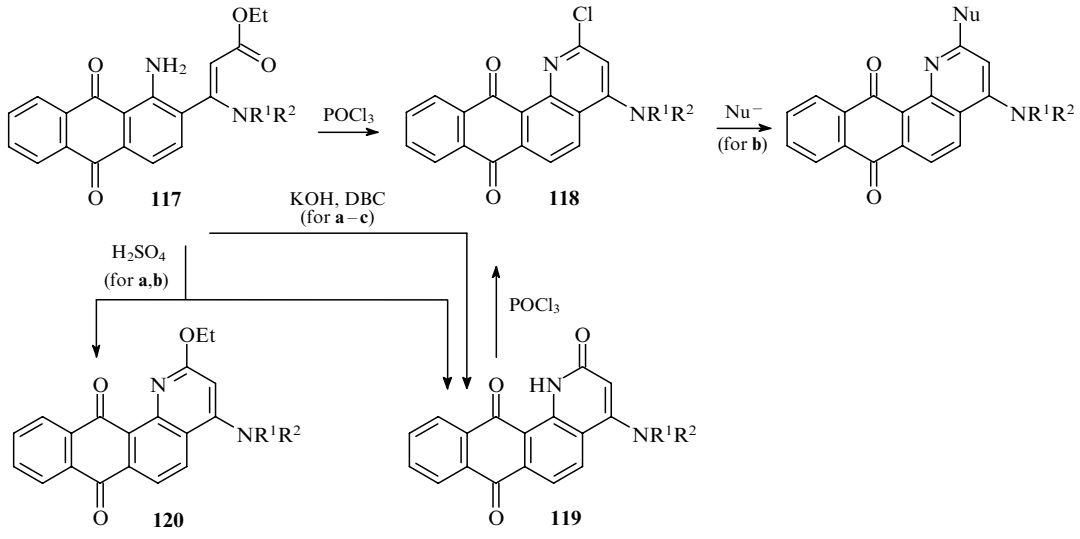
Modified version of this method was used for the preparation of 4-aminonaphtho[2,3-*h*]quinoline-7,12-diones containing functional substituents at position 2.[25, 26] In this case, esters **117** rather than aminovinyl ketones are subjected to cyclisation (Scheme 3).

These compounds are transformed into 2-chloro-substituted 4-aminonaphthoquinolinediones **118** (in 41%–67% yields) under the action of $POCl_3$ in dioxane at 80 °C. The nucleophilic substitution of the labile halogen atom in the pyridine ring allows one to perform further modifications of the molecule.

The same 4-amino-2-chloronaphtho[2,3-*h*]quinoline-7,12-diones **118** can be prepared from esters **117** in two steps through δ-lactams (naphthoquinolinetriones **119**). The closure of the lactam ring in adducts **117** proceeds readily in the presence of solid KOH and dibenzo-18-crown-6 in benzene at 20 °C (the yields are 92%–97%). Under conditions of acid catalysis (H_2SO_4, benzene, 20 °C), adducts **117** give mixtures of lactams **119** and 4-amino-2-ethoxynaphthoquinolinediones **120** in a ratio of ~2 : 1. Naphthoquinolinetriones **119** are transformed into compounds **118** (in 67%–98% yields) by heating with $POCl_3$ in dioxane.

It should be noted that catalytic hydrogenation of secondary (1-aminoanthraquinon-2-yl)alk-1-yn-3-ols giving rise to *cis*-ethylenic alcohols and subsequent oxidation of the latter with MnO_2 or $CrO_3 \cdot 2\,Py$ can be used for the synthesis of naphtho[2,3-*h*]quinoline-7,12-diones, which are structurally analogous to compounds **114** but are devoid of the alkynylated amino group in the pyridine ring.[27] Naphthoquinolinediones **114** form chelate complexes with metal halides (Cr, Mn, Co, Cu, Ga, Zn, Pd, In or Ni) in which the nitrogen atoms of the heterocycle and the oxygen atom of the carbonyl group at position 12 are involved in coordination.[76] 4-Monoalkylamino derivatives **114** (R^3 = H) are involved in complexes as amino tautomers. Some aminonaphthoquinolinediones exhibit high cytotoxic activity with respect to malignant cells.[39, 77]

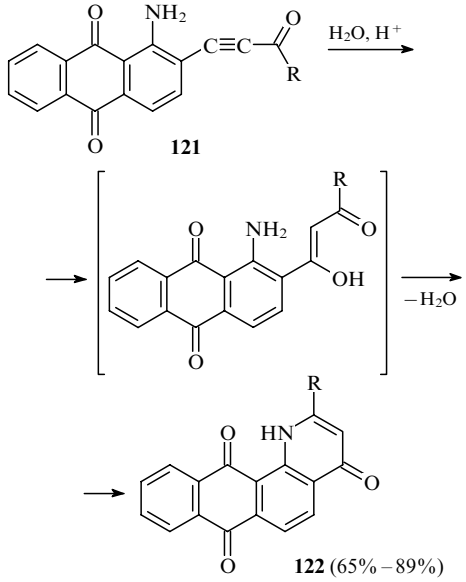
Scheme 3



R^1 = R^2 = Et (**a**), R^1-R^2 = $-(CH_2)_5-$ (**b**); R^1 = H, R^2 = Bu (**c**); Nu = pip, SBu, $CH(CO_2Et)_2$; DBC is dibenzo-18-crown-6.

The above-considered method for heterocyclisation of acetylenic ketones through amino adducts is not specific only for anthraquinone derivatives.[36]

Under conditions of hydration of the triple bond, *vic*-amino(acylethynyl)anthraquinones **121** are subjected to cycloisomerisation to naphthoquinolinetriones **122**.[39,78,79] The reaction proceeds according to a scheme analogous to that of the formation of the aminonaphthoquinoline system under acidic conditions. Initially, water adds at the triple bond and then it is eliminated upon the closure of the heterocycle. Heterocyclisation is carried out either in concentrated H_2SO_4 at 75–85 °C or in the presence of $HgSO_4$ and a small amount of 50% H_2SO_4 by refluxing in dioxane.



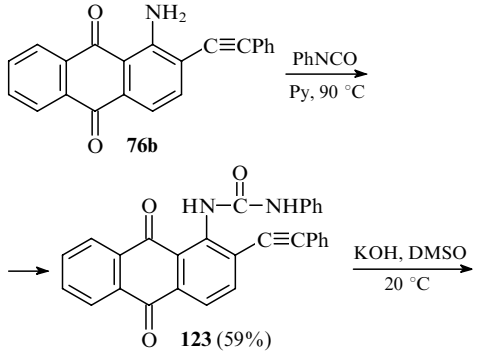
R = Bu^t, Ph.

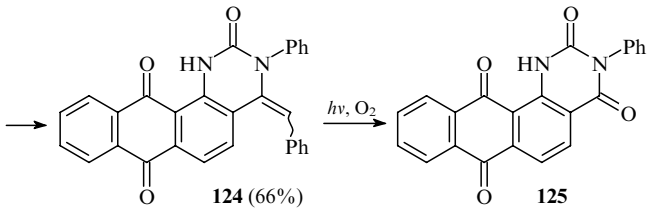
Spectroscopic and quantum-chemical study of the structure of 1*H*-2-phenylnaphtho[2,3-*h*]quinoline-4,7,12-trione (**122**, R = Ph) demonstrated that this compound exists in the polarised quinolone form stabilised by an intramolecular hydrogen bond in both the crystalline state and solutions.[79]

Naphthoquinolinetriones **122** form labile complexes with Lewis acids ($GaCl_3$, $CoCl_2$, $MnCl_2$ or $CuCl_2$) in which the ligand is coordinated to the metal atom through the oxygen atom of pyridone.[80] Protonation of triones **122** also proceeds at this atom.[79]

5. Cyclisation with the pyrimidine-ring closure

N-(2-Phenylethynylanthraquinon-1-yl)-*N*′-phenylurea (**123**), which was prepared by the reaction of the corresponding amino(alkynyl)anthraquinone **76b** with PhNCO, underwent cyclisation to 1*H*-4-benzylidene-3-phenylnaphtho[2,3-*h*]quinazoline-2,7,12-trione (**124**) in the presence of KOH in aqueous DMSO.[81]





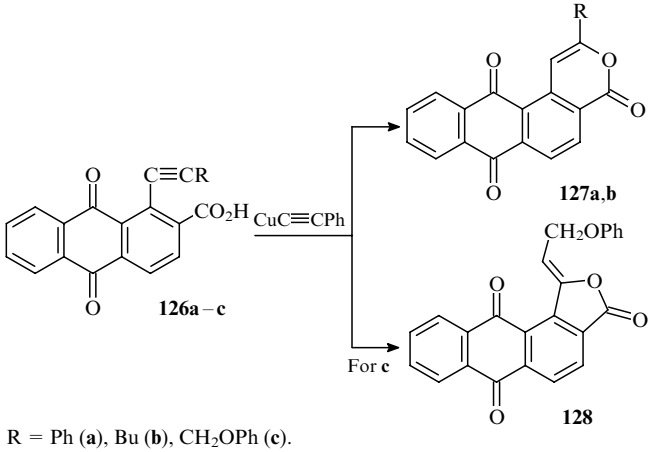
Product **124** was prepared as a mixture of *E* and *Z* isomers (in a ratio of 7 : 2). Upon photolysis (on SiO_2 or in solutions), the isomers are oxidised with atmospheric oxygen to 1*H*-3-phenylnaphtho[2,3-*h*]quinazoline-2,4,7,12-tetrone (**125**).

6. Pyrone-ring closure reactions

a. Reactions of *vic*-alkynylanthraquinonecarboxylic acids

In the presence of Cu(I) compounds, *vic*-acetylenic derivatives of anthraquinonecarboxylic acids (like those of other aromatic carboxylic acids) undergo cyclisation to give lactones. In these reactions, the closure of the γ- or δ-lactone rings (5-*exo*-dig or 6-*endo*-dig addition, respectively) can take place. 1-Alkynylanthraquinone-2-carboxylic acids form lactones in the presence of CuC≡CPh (pyridine, 20 °C, 77%–91% yields).[19] However, Cu-catalysed cyclisations of anthraquinonecarboxylic and parent benzoic acids follow different pathways. Thus anthraquinonecarboxylic acids have a tendency for 6-*endo*-dig addition (to form δ-lactones), whereas 5-*exo*-dig addition (giving rise to γ-lactones) is more typical of benzoic acids.[60,82]

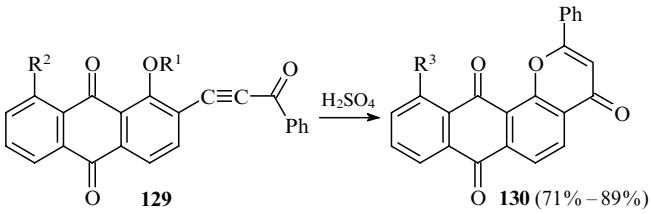
1-Phenylethynyl- (**126a**) and hex-1-ynylanthraquinone-2-carboxylic acids (**126b**) give exclusively δ-lactones **127**, and only 1-(3-phenoxyprop-1-ynyl)-substituted acid (**126c**) forms a mixture of γ- and δ-lactones (**127** and **128**) in a ratio of 4 : 3.



R = Ph (**a**), Bu (**b**), CH_2OPh (**c**).

b. Reactions of *vic*-acylethynyl(hydroxy)anthraquinones

The synthesis of anthra[1,2-*b*]pyran-4,7,12-triones attracts interest because this fused system represents a cyclic moiety of natural antitumour antibiotics of the kidamycin group[83–85] and their biologically active analogues prepared by biochemical methods.[86–88] 2-Acylethynyl-1-hydroxyanthraquinones (**129**, R^1 = H) serve as convenient precursors for the synthesis of these compounds. The simplest pathway of transformations of these compounds into target products **130** involves cyclisation under conditions of hydration of the triple bond.[39] The reaction proceeds readily in concentrated H_2SO_4 at 70–80 °C and is completed in 0.5–1.5 h. *O*-Acyl-substituted derivatives **129** (R^1 = COPh) can also be used in the synthesis.

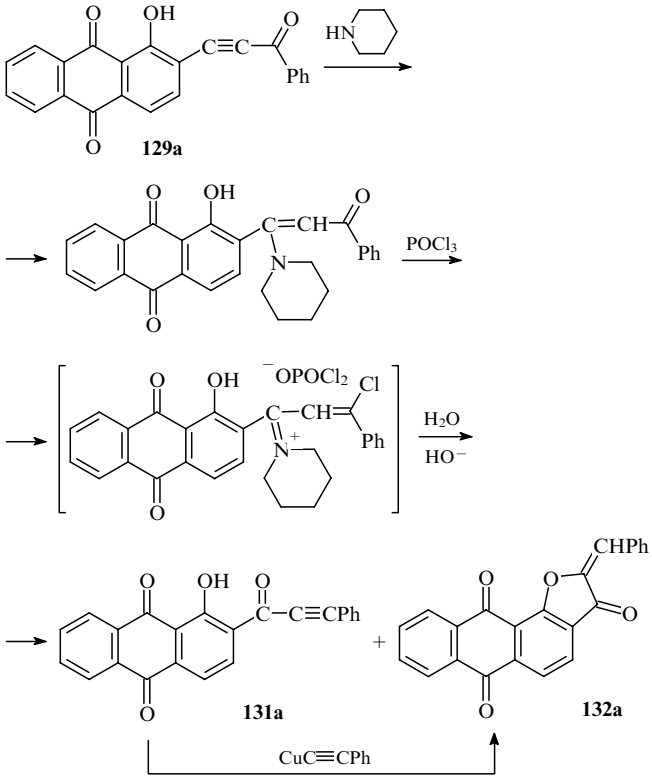


129 **130** (71% – 89%)

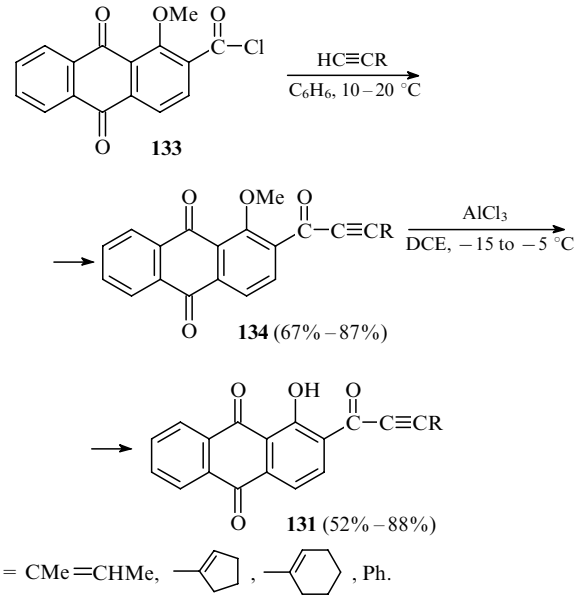
R^1 = H, PhCO; R^2 = H, OH, OAc; R^3 = H, OH.

Unfortunately, this procedure for the closure of the γ-pyrone ring is unsuitable for compounds containing acid-sensitive groups. Besides, kidamycin antibiotics contain unsaturated or epoxide fragments at position 2 of the anthrapyran moiety, which precludes the use of strongly acidic media in the synthesis of the starting compounds. However, under other conditions, the starting acetylenic ketones are more prone to cyclisation giving rise to a five-membered rather than a six-membered heterocycle.

It was expected that the use of alkynyl anthraquinonyl ketones **131a** as the starting compounds would facilitate the formation of the γ-pyrone ring and make it possible to perform cyclisation under rather mild conditions. In this connection, let us mention an attempt to prepare ketone **131a** by isomerisation of ketone **129a**.[39, 89, 90] Unfortunately, this isomerisation is accompanied by partial cyclisation of compound **131a** to isomeric furanone **132a**, which is also generated from **131a** by heating with CuC≡CPh in toluene at 90 °C.[39]



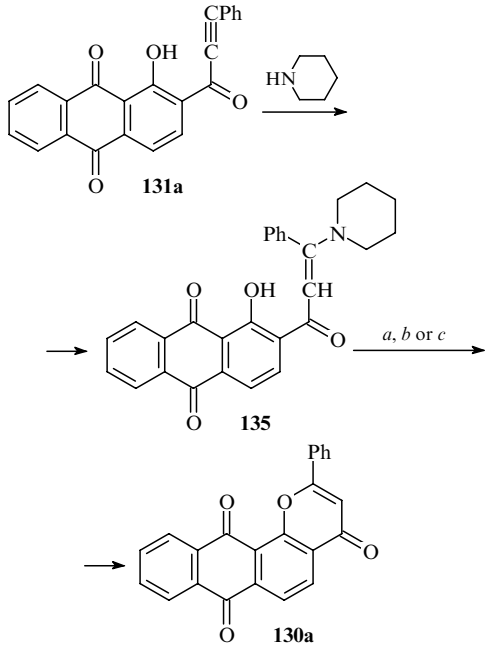
An alternative method for the synthesis of alkynyl hydroxyanthraquinonyl ketones **131** involves catalytic acylation of terminal acetylenes with 1-methoxyanthraquinone-2-carboxylic acid chloride (**133**) in the presence of $Pd(PPh_3)_2Cl_2$, CuI and Et_3N followed by removal of the methyl protective group.[91] Due to the presence of the carbonyl group in the *ortho* position, methoxy ketones **134**[92] are demethylated with Lewis acids under exceptionally mild conditions (dichloroethane, from −15 to −5 °C).



R = CMe=CHMe, , , Ph.

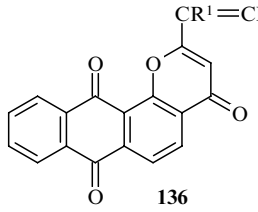
To develop a general procedure for cyclisation applicable to labile highly unsaturated hydroxy ketones, the transformation of 1-hydroxy-2-(1-oxo-3-phenylpropynyl)anthraquinone **131a** into phenylanthrapyrantrione **130a** was studied under various conditions.[39]

Evidently, in order for the desired six-membered ring to be formed, the oxygen atom of the hydroxy group and the γ-carbon atom of the acetylenic substituent must be brought into proximity, which is achieved by the attachment of secondary amine (for example, of piperidine) at the triple bond of the starting ketone. The resulting adduct **135** undergoes cyclisation with the closure of the γ-pyrone ring both under conditions of acid hydrolysis and base-catalysed intramolecular nucleophilic substitution of a secondary amino group. However, cyclisation of adduct **135** on SiO_2 as an adsorbent (82% yield) provides the formation of 2-phenylanthra[1,2-*b*]pyran-4,7,12-trione (**130a**) under the most mild conditions.



(*a*) H_2SO_4, $CHCl_3$ – dioxane – H_2O, 80 °C; (*b*) pip, C_6H_6, 80 °C; (*c*) SiO_2, $CHCl_3$.

This procedure was successfully extended to hydroxyanthraquinonyl vinylethynyl ketones[91] and opened the way to the synthesis of anthra[1,2-*b*]pyran-4,7,12-trione derivatives **136** containing unsaturated substituents at position 2.



136

$R^1 = R^2 = Me$; $R^1 - R^2 = -(CH_2)_3-$, $-(CH_2)_4$.

7. Reactions with hydrazine

a. Cyclocondensation of *peri*-acetylenic derivatives of anthraquinone and naphthoquinone

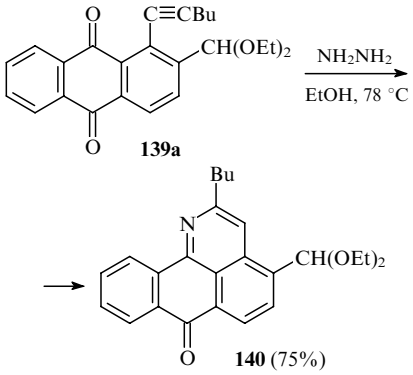
1-Alkynylanthraquinones **11** react with hydrazine or hydrazine hydrate to form mixtures of substituted 4*H*-anthra[9,1-*cd*]-1,2-diazepin-8-one (diazepineanthrone **137**) and 7*H*-dibenzo[*de*,*h*]-quinolin-7-one (pyridineanthrone **138**), which are easily separated by chromatography (Scheme 4).[23, 93, 94]

Prolonged heating of diazepineanthrones **137** in pyridine in the presence of NH_2NH_2 leads to reductive elimination of one nitrogen atom from the seven-membered heterocycle giving rise to pyridineanthrones **138**. For example, the reaction of the compound with R = Ph is completed in 9 h at 115 °C (78% yield). This transformation occurs already under the conditions of cyclocondensation, and, hence, an increase in the reaction time leads to an increase in the percentage of pyridineanthrones **138** in a mixture of reaction products.

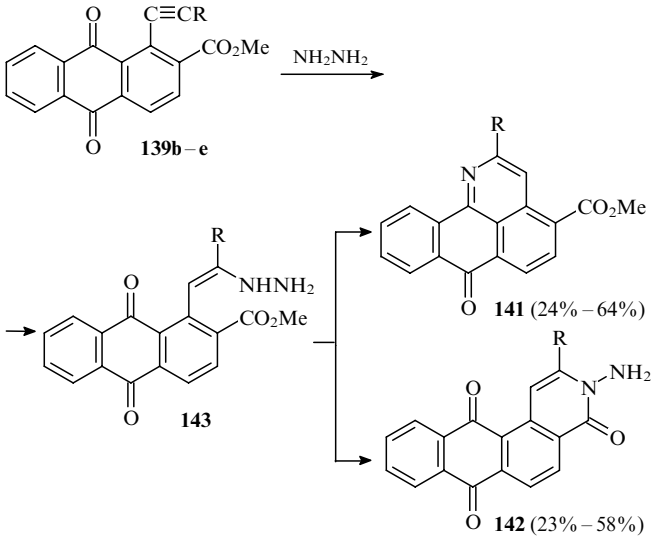
It is assumed that the mechanism of the seven-membered ring contraction involves hydration, ring opening and recyclisation to a six-membered ring followed by reduction with an excess of NH_2NH_2. The reduction step, unlike other steps, is irreversible.

Bulky substituents at position 2 of the starting alkynylanthraquinones hinder the formation of a seven-membered heterocycle. For example, fused pyridine derivative **140** is the only product generated from 1-(hex-1-ynyl)-2-diethoxymethylanthraquinone (**139a**).

In the presence of an alkoxycarbonyl substituent at position 2 (compounds **139b**–**e**), the reaction with hydrazine affords a mixture of substituted pyridineanthrone **141** and *N*-aminolactam **142**.[37, 93, 94] Apparently, the electron-withdrawing alkoxycarbonyl group enhances the reactivity of the acetylenic fragment and the reaction in refluxing EtOH is completed in 2–90 min (total yields are 72%–87%).



139a → **140** (75%)

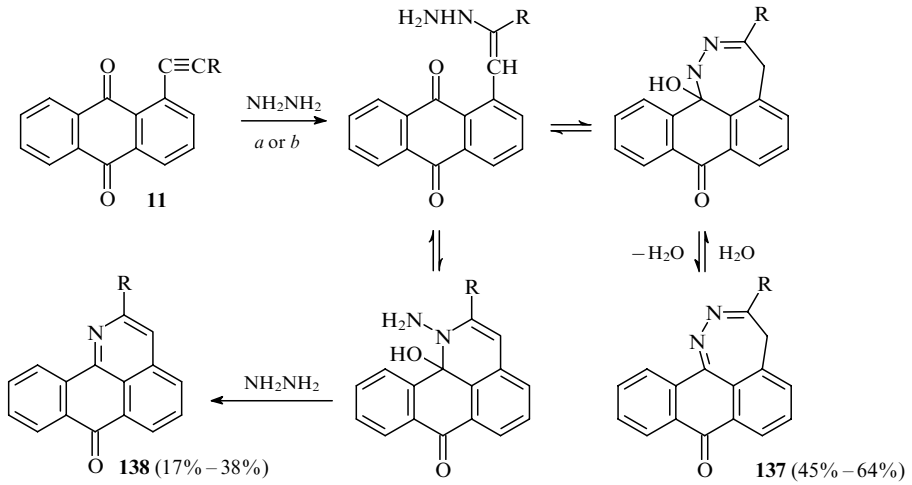


139b–**e** → **141** (24%–64%) + **142** (23%–58%) via **143**

R = H (**b**), Bu (**c**), CH_2OPh (**d**), Ph (**e**).

Investigation of the mechanism of formation of *N*-aminolactams **142** demonstrated that the reaction proceeds through adduct **143** as the intermediate. A comparison of the times of condensation of various acetylenic esters as well as the ratios between the reaction products showed that the formation of lactams through this adduct is the major pathway. It should be noted that cyclisation of *ortho*-alkynylbenzoic acid hydrazides proceeds with the closure of the γ-lactam ring.[95] Apparently, this difference is additional evidence for the fact that adducts **143**

Scheme 4

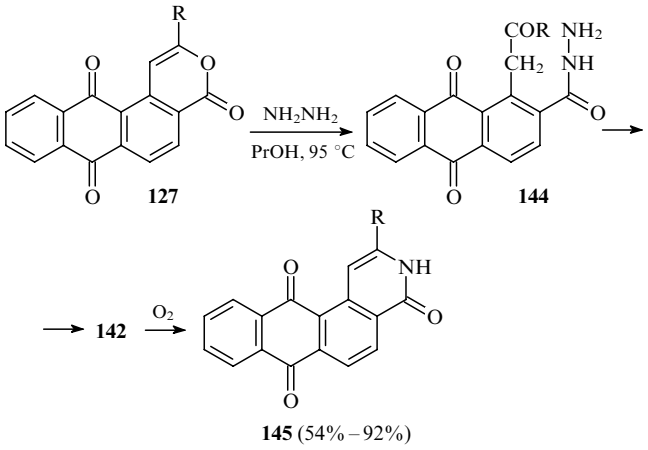


11 → **138** (17%–38%) + **137** (45%–64%)

R = Bu, Ph, CMe_2OH, CH_2OPh. (*a*) Py, 90–115 °C, 20–90 min; (*b*) EtOH, 78 °C, 10 h.

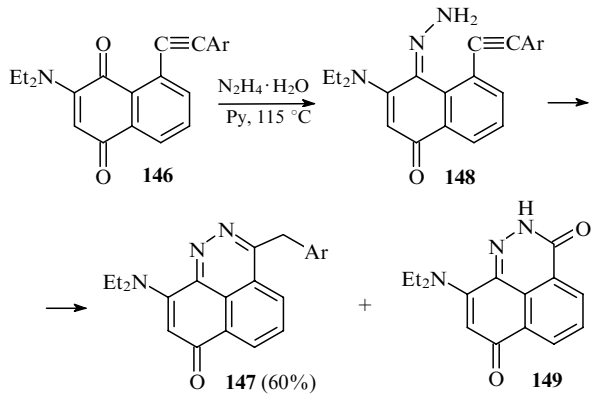
rather than acid hydrazides are initially generated in the course of cyclocondensation of compounds **139**.

N-Aminolactams **142** can also be prepared by hydrazinolysis of the corresponding lactones **127**.[37] The reaction involves the opening of the lactone ring to form labile 1-(2-oxoalkyl)anthraquinone-2-carboxylic acid hydrazides **144**, which undergo subsequent cyclisation. Deamination of aminolactams **142** under the action of oxygen in the presence of CuCl affords δ-lactams **145**.



R = Bu, Ph.

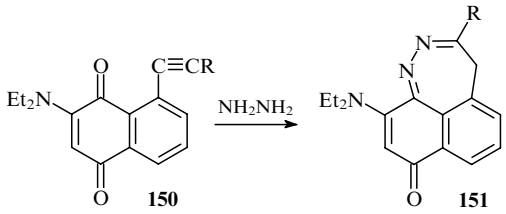
Condensation of *peri*-acetylenic derivatives of 1,4-naphthoquinone with NH_2NH_2 follows a pathway which differs from that of *peri*-alkynylanthraquinones. For example, the reaction of 3-diethylamino-5-phenylethynyl-1,4-naphthoquinone (**146**, Ar = Ph) with an excess of $NH_2NH_2 \cdot H_2O$ in pyridine is accompanied by the closure of the pyridazine rather than the diazepine ring to form 3-benzyl-9-diethylaminobenzo[*de*]cinnolin-7-one (**147**) in 67% yield.[28,96]



Ar = Ph, 4-$MeOC_6H_4$, 4-$NO_2C_6H_4$.

This pathway of cyclocondensation of *peri*-arylethynyl-1,4-naphthoquinones is attributable to the initial formation of hydrazone **148**, which undergoes subsequent cyclisation. This reaction is sensitive to the structure of the starting compound. For example, the introduction of the electron-donating methoxy group at the *para* position of the benzene ring of the acetylenic substituent (Ar = 4-$MeOC_6H_4$) leads to a substantial increase in the reaction time (from 8 to 35 h). In this case, the reaction mixture undergoes substantial resinification and the yield of the product sharply decreases. By contrast, the reaction with a compound containing the electron-withdrawing nitro group (Ar = 4-$O_2NC_6H_4$) proceeds vigorously and is completed in 1 – 3 min. In addition, the nitro group in the starting acetylene serves as an internal oxidiser, as a result of which compound **149**, which was generated due to oxidative elimination of the benzyl fragment, rather than the expected benzocinnolinone **147** (Ar = 4-$NO_2C_6H_4$) was obtained as the major product (the yields were 34% and 19%, respectively).

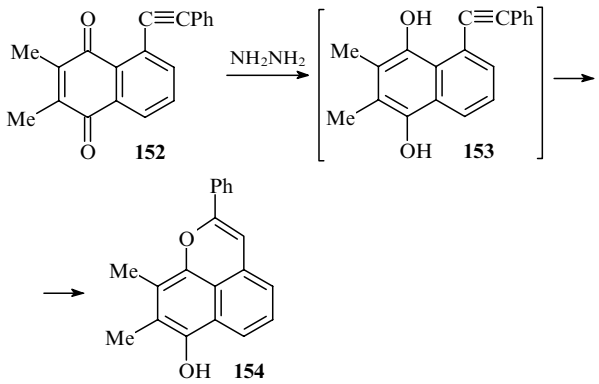
The replacement of the arylethynyl substituent in *peri*-alkynyl-1,4-naphthoquinones by a γ-hydroxyalkynyl group changes the regioselectivity of condensation.[28,97] Under the same conditions, the reactions of 3-diethylamino-5-(3-hydroxyalkyn-1-yl)-1,4-naphthoquinones **150** with $NH_2NH_2 \cdot H_2O$, unlike those of 5-arylethynyl derivatives **146**, lead to the closure of the seven-membered diazepine ring (analogously to the reactions of *peri*-alkynylanthraquinones).



R = CMe_2OH,  , 
The reactions are completed in 5 – 6 h and are accompanied by noticeable resinification. Nevertheless, the preparative yields of substituted 4*H*-naphtho[1,8-*cd*]-1,2-diazepin-8-ones **151** are as high as 53% – 56%.

It is assumed that the direction of cyclisation changes due to association of the hydroxy group of the substrate with hydrazine *via* hydrogen bonds. As a result, the first step of condensation involves the addition of NH_2NH_2 at the triple bond rather than at the carbonyl group.

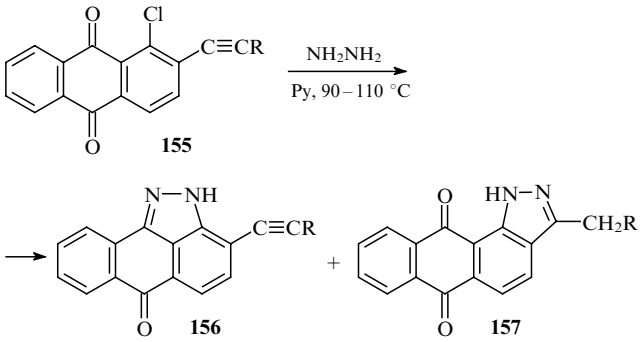
It should be noted that the nature of substituents in the quinoid ring of *peri*-alkynyl-1,4-naphthoquinones can also substantially influence the direction of their reactions with NH_2NH_2. For instance, the reaction of 2,3-dimethyl-5-phenylethynyl-1,4-naphthoquinone (**152**) involves reduction to the corresponding hydroquinone **153**, which undergoes subsequent cyclisation to give naphthopyran derivative **154**.[96]



b. Cyclocondensation of 2-alkynyl-1-chloroanthraquinones

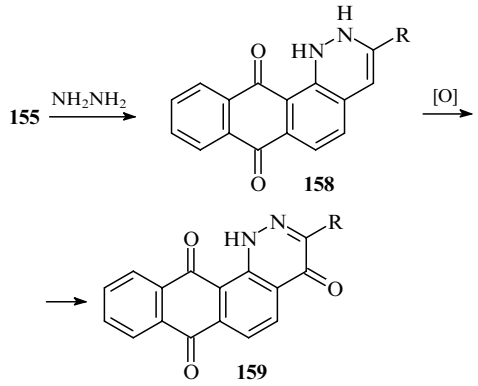
Several studies were devoted to cyclocondensation of aryl- and hetarylacetylenes containing the labile chlorine atom in the *ortho* position with hydrazine and its derivatives.[98 – 101] The reaction starts, apparently, with the replacement of the halogen atom[99] and always gives rise to a five-membered heterocyclic compound, *viz*., a derivative of pyrazole or *N*-substituted pyrrole.

2-Alkynyl-1-chloroanthraquinones **155**, in which the halogen atom has high nucleofugic lability, are readily condensed with NH_2NH_2 on heating in pyridine.[94,97] Under these conditions, the reactions of quinones bearing hydrocarbon (Alk or Ar) acetylenic substituents can follow two pathways with the pyrazole-ring closure involving either the carbonyl group of the quinoid ring (compound **156**) or the triple bond (compound **157**). The regioselectivity of the reaction depends on the nature of the substituent in the starting alkynylquinone.



R	Yield (%)	
	156	**157**
Ph	44	22
C_5H_{11}	45	–

The introduction of the hydroxy or methoxy group at the γ position of the acetylenic substituent changes the regioselectivity of cyclocondensation. In this case, the reaction affords a compound containing the six-membered dihydropyridazine ring, *viz*., substituted 1,2-dihydronaphtho[2,3-*h*]cinnoline-7,12-dione (**158**), as the only product, which is readily oxidised with oxygen to give 1*H*-naphtho[2,3-*h*]cinnoline-4,7,12-trione (**159**).

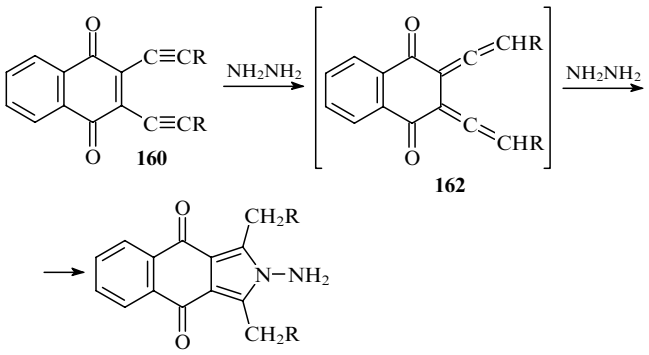


R = CH_2OH, $CH(OH)Pr^i$, CMe_2OH, $C(OMe)Me_2$.

A preparative one-pot procedure was developed for the synthesis of naphthocinnolinetriones **159** from alkynylquinones **155** with the use of 25% – 30% H_2O_2 as an oxidising agent, which is added to the reaction mixture after completion of cyclocondensation (20 – 40 °C, yields are 40% – 85%). This change in the direction of cyclocondensation is, apparently, attributable to association of hydrazine or the hydrazino group with the heterofunctional group *via* hydrogen bonds (see also Section III.7.a).

c. Reductive heterocyclisation of 2,3-dialkynyl-1,4-naphthoquinones

The enediyne system, which is partially involved in the quinoid ring, imparts particular chemical specificity to 2,3-dialkynyl-1,4-naphthoquinones **160**. Upon treatment with hydrazine in dioxane at 50 – 60 °C, these compounds undergo unusual heterocyclisation to give 1,3-disubstituted 2*H*-*N*-aminobenzo[*f*]isoindole-4,9-diones **161**.[94, 102] Apparently, the initial step of this reaction consists in reduction of the enediyne system to the tetraene one. The resulting bis-allenylidene intermediate **162** adds NH_2NH_2 at the double bonds activated by the carbonyl groups and undergoes isomerisation. Therefore, hydrazine serves as both a reducing and heterocyclising agent.

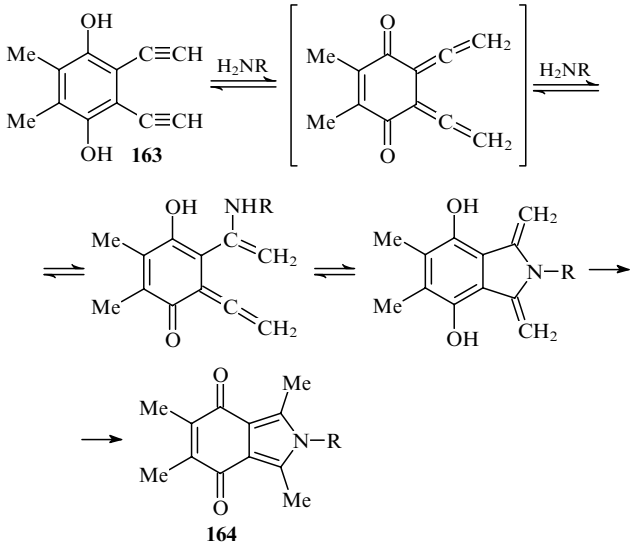


161 (53% – 80%)

R = $C(OH)Me_2$,  , $C(OMe)Me_2$, Ph.

According to the results of X-ray diffraction analysis, 2*H*-benzo[*f*]isoindole-4,9-dione is a planar polycyclic system. The distinguishing feature of this compound is that the quinoid and pyrrole rings share the aromatic C – C bond, which has a lower bond order. This bond length in the 2-amino-1,3-dibenzyl derivative is 1.434 Å (the other C – C bond lengths in the pyrrole ring are 1.370 Å).

Interestingly, a short time before the discovery of this heterocyclisation, the reaction of 2,3-diethynyl-5,6-dimethylhydroquinone (**163**) with primary amines was described.[103] The latter reaction gives rise to 2-substituted 1,3,5,6,-tetramethylisoindole-4,7-diones **164** and proceeds, in essence, by an analogous mechanism.



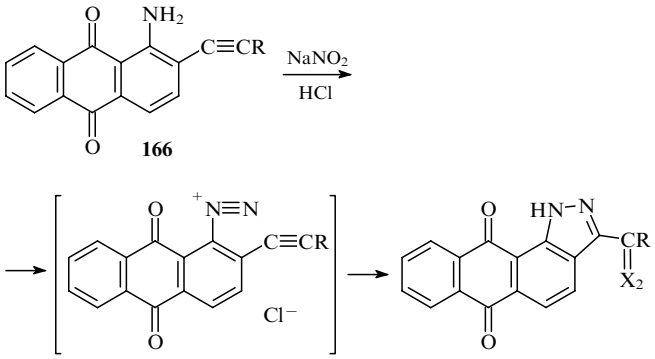
R = H, Me, Et, Pr, Bu, Ph.

A compound which bears the phenylethynyl substituents and is related to hydroquinone **163**, is not involved in analogous condensation with amines. Apparently, this may imply that cyclisation of bis-alkynyl-1,4-naphthoquinones does not afford bis-alkynylhydroquinones and the enediyne system of the substrate is reduced with hydrazine to the 1,2,4,5-tetraene system through another mechanism.

Taken together, these data provide a better insight into the essence of the chemical process responsible for both condensation reactions and give promise that a general procedure for the synthesis of this class of heterocyclic quinones will be developed.

8. Heterocyclisation of *vic*-acetylenic derivatives of anthraquinonediazonium salts

Intramolecular cyclisation of *ortho*-alkynylarenediazonium salts (Richter reaction) provides the basis for a general method for the synthesis of 4-hydroxy- and 4-halocinnolines.[104, 105] In attempting to extend this reaction to quinone derivatives, it was found that 2-alkynylanthraquinone-1-diazonium chlorides **165a**, which were prepared by diazotisation of the corresponding amines **166** ($NaNO_2$ in a mixture of dioxane and dilute HCl at 20 °C), underwent cyclisation to form the pyrazole rather than the pyridazine ring giving rise to 1*H*-3-(1,1-dichloroalkyl)- or 1*H*-3-acylnaphtho[2,3-*g*]indazole-6,11-diones of the general formula **167**.[24, 106, 107]



166 → **165a** → **167a**,**b** (62% – 83%)

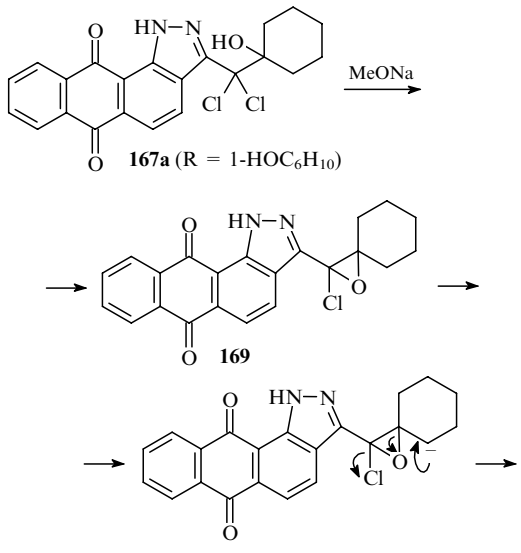
R = H, Bu, CH_2OPh, , COPr, $COBu^t$, COPh, Ph;

X_2 = O (**167a**), Cl_2 (**167b**).

If the triple bond in the acetylenic substituent of the starting compound is conjugated with the carbonyl or aryl group, the reaction affords acyl derivatives of naphthoindazoledione **167a**,[107] otherwise it gives α,α-dichloroalkyl derivatives **167b**.[24] Cyclisation of the former proceeds more slowly.

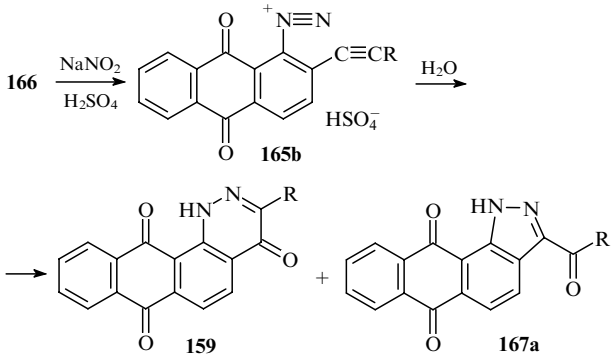
Dichlorides **167b** can be transformed into the corresponding ketones by treatment with MeONa in MeOH followed by acid hydrolysis of the resulting acetals.[24]

In reactions with MeONa, 1*H*-3-[(1-hydroxycyclohexyl)dichloromethyl]naphtho[2,3-*g*]indazole-6,11-dione (**167b**, R = 1-HOC_6H_{10}), unlike other dichlorides, is subjected to dehydrochlorination accompanied by migration of the oxygen atom to give cyclohexenyl ketone **168**.[107] Apparently, the reaction proceeds through the intermediate formation of epoxide **169**.



167a (R = 1-HOC_6H_{10}) → **169** → **168** (73%)

Cyclisation of diazo compounds **165b** was carried out under conditions which differ from those used for cyclisation of diazonium chlorides **165a**.[108] The steps of diazotisation of amines **166** and cyclisation of diazo compounds **165b** were separated. For this purpose, diazotisation of amines **166** was carried out in a mixture of acetone and dilute H_2SO_4 at 20 °C with the use of a 3 – 4 fold excess of $NaNO_2$, which made it possible to decrease the reaction time to 1 – 2 min. After completion of diazotisation, the solution of the diazonium salt was diluted with water or dilute H_2SO_4, thus providing the desired acidity of the medium in the step of cyclisation. The reaction was carried out at 65 °C. The exclusion of chloride anions from the reaction sphere changes its direction and the reaction affords naphthoindazolediones **167a** along with 1*H*-naphtho[2,3-*h*]cinnoline-4,7,12-triones **159**. The percentage of compounds **159** increases with increasing concentration of H_2SO_4 and they become virtually the only reaction products (yields are 71% – 91%) as the concentration of H_2SO_4 reaches 38%.



166 → **165b** → **159** + **167a**

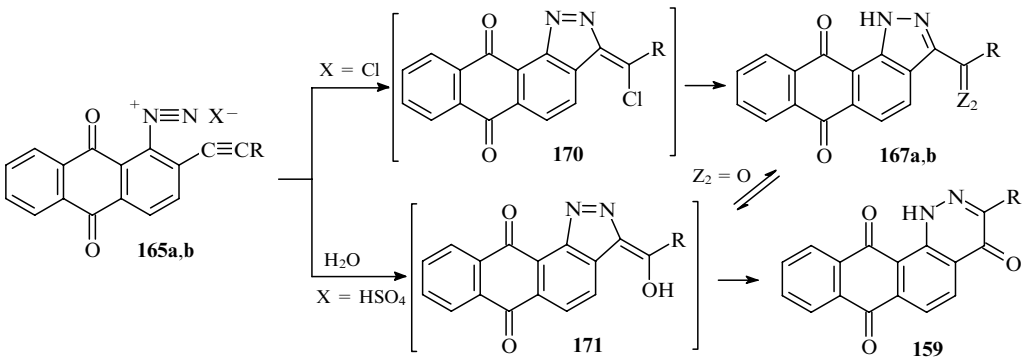
R = H, Bu, $CH(OH)Pr^n$, $CH(OH)Pr^i$, CMe_2OH.

The reason for the influence of the counterions (Cl^- or HSO_4^-) on the course of cyclisation of salts **165** can be understood taking into account the data obtained in the in-depth study of the cyclisation mechanism of acetylenic derivatives of 1,4-naphthoquinone diazonium salts (see below).[109] In the case of highly nucleophilic chloride ions, 1-chloroalkylidene derivative **170** is generated as the key intermediate, which gives product **167a** or **167b** containing the five-membered ring. In the case of non-nucleophilic bisulfate ions, the nucleophilic addition of water giving rise to intermediate enol **171** takes place. The latter can undergo tautomerisation to ketone **167a** or rearrangement to pyridazine derivative **159**. This rearrangement becomes the major process as the concentration of the acid increases (Scheme 5). Therefore, cyclisation of diazonium salts prepared from 2-alkynyl-1-aminoanthraquinones enables one to synthesise derivatives of either 1*H*-naphtho[2,3-*g*]indazole-6,11-dione **167** or 1*H*-naphtho[2,3-*h*]cinnoline-4,7,12-trione **159** depending on the reaction conditions.

Cyclisation of naphthoquinonediazonium chloride **172** was carried out analogously to cyclisation of compounds **165b**.[109] The starting amine was diazotised with an excess of $NaNO_2$ in a mixture of dilute HCl and acetone and diluted with water, 18% HCl or a NaCl solution. It was found that the reaction proceeds through the formation of pyrazole intermediate **173**, which is subsequently transformed with either ring expansion or retention of the size of the heterocycle to give the final reaction products **174** – **176**. The compositions of the products depend on the cyclisation conditions.

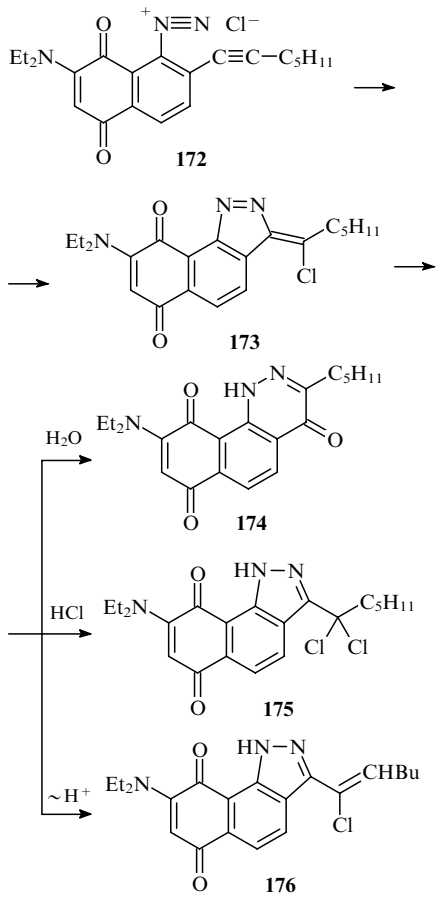
In hydrochloric acid medium, intermediate **173** is generated at a high rate and a large portion of the diazo salt is transformed into

Scheme 5



X = Cl (**a**), HSO_4 (**b**); Z_2 = O (**167a**), Cl_2 (**167b**).

this intermediate already within a few minutes. At that instant, the intermediate can be extracted from the reaction mixture with an organic solvent. Actually, it was isolated in this way in 79% yield. Intermediate **173** is chemically labile and can be transformed either with retention of the size of the heterocycle or its expansion not only in aqueous reaction systems but also on an adsorbent in an organic solvent. The mechanism of its transformation into the final products remains to be elucidated.

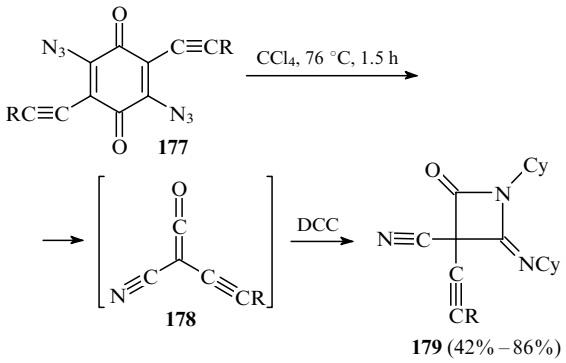


Reaction conditions	Yield (%)		
	174	**175**	**176**
H_2O, 20 °C, 5–6 h	80	–	–
HCl–$CHCl_3$, 7 h	25	60	16

Studies of cyclisation of alkynylquinonediazonium salts demonstrated that this process involves several steps. The reaction is, apparently, initiated by the attack of a nucleophile on the positively charged β-carbon atom of the acetylenic substituent resulting in the appearance of a negative charge on the α-carbon atom and a change in the geometry of this substituent. This leads to the closure of the heterocycle involving the α-C atom to give an intermediate of type **173**. It should be noted that the multistep mechanism of cyclisation of alkynylquinonediazonium salts is in contradiction with the mechanism of the Richter reaction represented as a concerted process of the direct formation of a six-membered heterocycle.[110]

9. Thermolysis of acetylenic derivatives of azidobenzoquinones

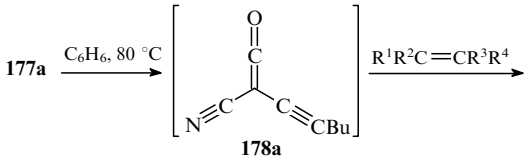
At temperatures above 75 °C, 3,6-dialkynyl-2,5-diazido-1,4-benzoquinones (**177**) are subjected to thermolysis to form alkynylcyanoketenes **178**.[111, 112] These compounds possessing the triple bond conjugated with the ketene group are unstable but can be fixed as rather stable adducts, for example, as azetidinones **179**, by performing the process in the presence of dicyclohexylcarbodiimide (DCC).[112]

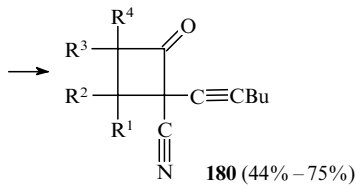


R = Bu (**a**), CMe=CH_2, CH_2OTHP, $(CH_2)_2Ph$, Ph, *o*-MeC_6H_4, *o*-$MeOC_6H_4$; Cy is cyclohexyl.

Schiff bases can also be used as trapping agents. For example, *N*-benzylideneaniline and *N*-(δ-phenylcinnamylidene)aniline react with ketene **178** to form β-lactams, whereas *N*-cinnamylideneaniline gives δ-lactams according to the [2+2]- and [2+4]-cycloaddition reactions, respectively.[111]

Alkynylcyanoketenes **178** are very reactive and, like most ketenes, are readily involved in cycloaddition to alkenes.[112] Hexynylcyanoketene **178a** reacts with substituted alkenes to form the corresponding substituted 2-(hex-1-ynyl)-2-cyanobutanones **180**. Cycloaddition of the ketene proceeds with retention of the configuration of alkenes.

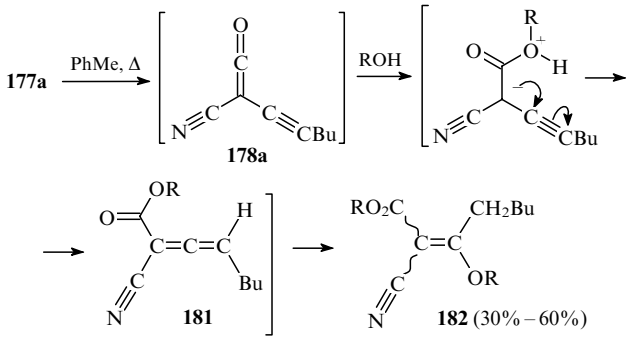




180 (44% – 75%)

$R^1 = R^3 = H$: $R^2 = R^4 = Et$, $R^2 – R^4 = –(CH_2)_4–$;
$R^1 = R^2 = R^3 = Me$: $R^4 = H$, Me.

The reactions of alkynylcyanoketenes **178** with alcohols are more complicated than those of simple ketenes.[111, 112] The initial nucleophilic attack of alcohol on the carbonyl group of ketene **178a** results in 1,4-addition to the enyne fragment to form 2-cyanoalka-2,3-dienoic acid ester (**181**). Then this allenic intermediate adds the second alcohol molecule to give 3-alkoxy-2-cyanoalk-2-enoic acid ester (**182**) as a mixture of *Z* and *E* isomers.

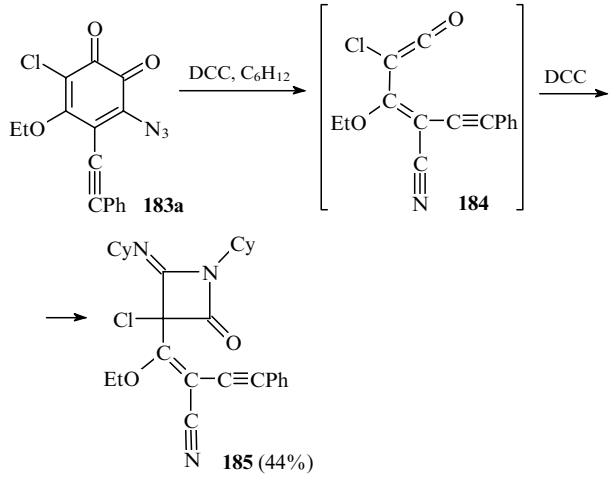


177a; **178a**; **181**; **182** (30% – 60%)

R = Pr^n, Pr^i, Bu^t, CH_2Ph.

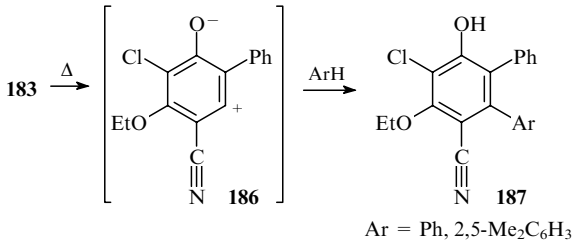
The reaction is carried out by gradually adding a solution of 3,6-dialkynyl-2,5-diazido-1,4-benzoquinone **177** in toluene to refluxing alcohol.

4-Acetylenic derivatives of 3-azido-6-chloro-5-ethoxy-*o*-benzoquinone are also subjected to thermolysis giving rise to ketenes. For instance, refluxing of compound **183a** in cyclohexane affords (2-cyano-1-ethoxy-4-phenylbut-1-en-3-ynyl)chloroketene (**184**), which is easily trapped with dicyclohexylcarbodiimide as the corresponding azetidinone **185**.[113, 114]



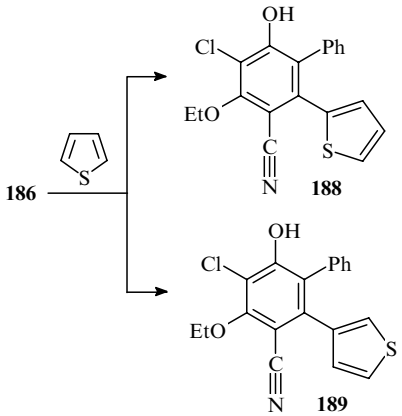
183a; **184**; **185** (44%)

Investigation of the reactions of ketenes generated from *o*-quinones **183** provided evidence that in the absence of trapping agents, these compounds undergo cyclisation to zwitterionic (or, probably, biradical) intermediate **186**, which is transformed into substituted phenol in reactions with external nucleophilic reagents or nucleophilic centres present in the molecule.[113] A solvent can also serve as a nucleophile when decomposition of the starting quinone is carried out by refluxing in benzene, *para*-xylene or thiophene.[113, 114] For example, products **187** – **191** are generated from azidoquinone **183a**.

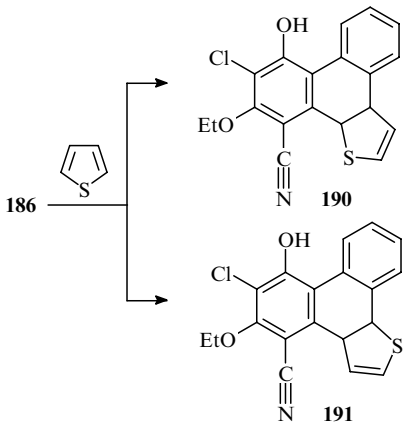


183; **186**; **187**

Ar = Ph, 2,5-$Me_2C_6H_3$

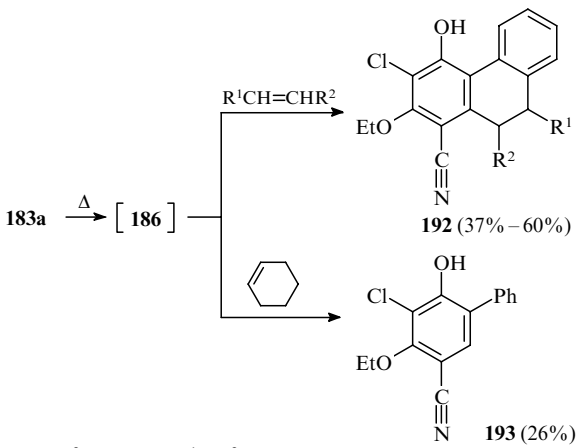


186; **188**; **189**



186; **190**; **191**

Thermolysis of compound **183a** in the presence of alkenes, in which the double bond is conjugated with the π electrons of the aromatic ring or the lone electron pair of the heteroatom, affords substituted dihydrophenanthrenes **192** (analogously to the reaction with thiophene, which gives rise to product **191**).

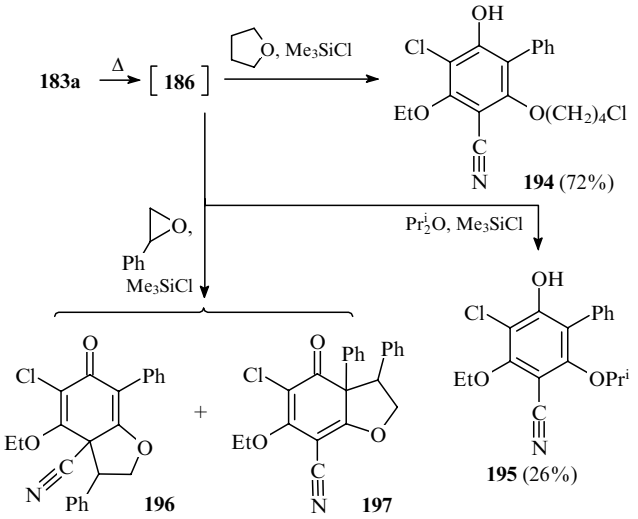


183a; **186**; **192** (37% – 60%); **193** (26%)

R^1 = Ph: R^2 = H, Ph; $R^1 – R^2 = –(CH_2)_3O–$.

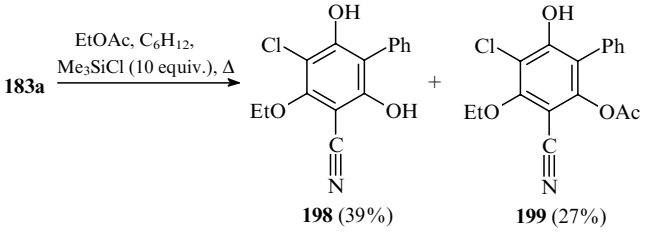
Under these conditions, such alkenes as cyclohexene or tetramethylethylene do not form adducts of type **192** with quinone, but they can serve as hydrogen donors. For instance, thermolysis of phenylethynylquinone **183a** in the presence of cyclohexene afforded a complex mixture of compounds, from which only 2-chloro-4-cyano-3-ethoxy-6-phenylphenol (**193**) was isolated.[114]

Cyclic and acyclic ethers react with zwitterionic intermediate **186** in the presence of Me_3SiCl.[114]

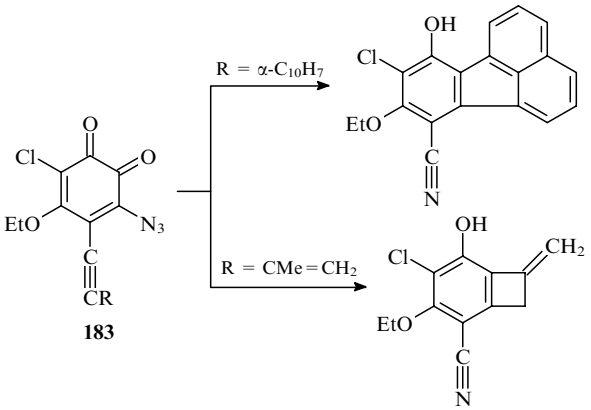


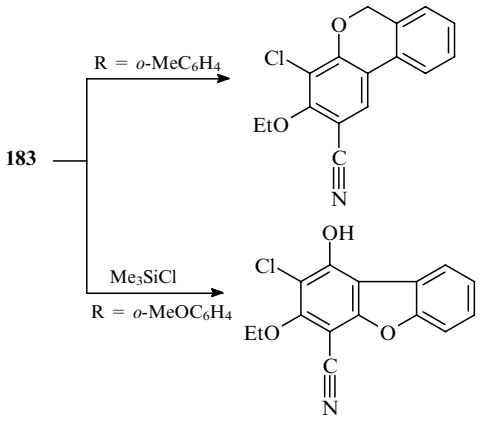
The reactions with tetrahydrofuran and diisopropyl ether give rise to alkoxy-substituted cyanophenols **194** and **195**. Under these conditions, styrene oxide produces two isomeric cyclohexadienones **196** and **197** in a ratio of ~1 : 1 in a total yield of 22%.

Thermal decomposition of compound **183a** in a mixture of ethyl acetate and cyclohexane in the presence of Me_3SiCl involves hydroxylation and partial acetoxylation of the zwitterionic intermediate to give resorcinol derivatives **198** and **199**.

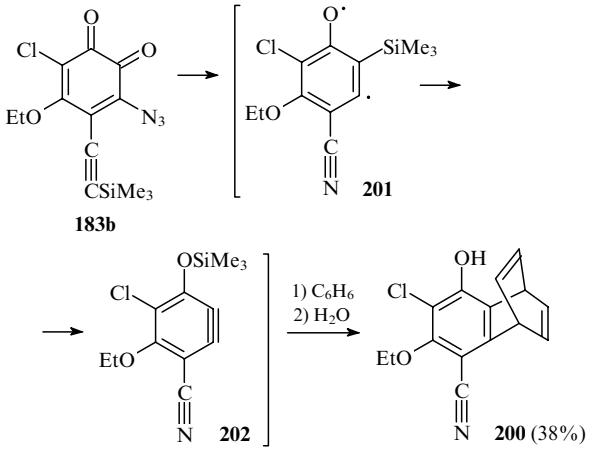


Intermediates generated upon thermolysis of other *ortho*-benzoquinones **183** can be stabilised intramolecularly with the involvement of a group of the acetylenic substituent to form polycyclic compounds (in 16% – 76% yields), which are difficult to prepare by other methods. In some cases, it is necessary to perform decomposition of the quinone in the presence of Me_3SiCl.





Thermal decomposition of the trimethylsilyl derivative of azido(ethynyl)-*o*-benzoquinone **183b** in benzene affords 2-chloro-4-cyano-5,8-etheno-3-ethoxy-5,8-dihydro-1-hydroxynaphthalene (**200**).[46] The authors believed that the reaction proceeds through biradical intermediate **201**, which is rearranged to substituted dehydrobenzene **202** through migration of $SiMe_3$ to the oxygen atom, and then compound **202** adds to benzene at positions 1,4.



10. Other reactions

Alkynylquinones are involved in the addition reactions at the triple bond (for example, such as hydration or hydrogenation) which are typical of acetylenes of various classes. It was found that 1- and 2-acetylenic derivatives of anthraquinone add water in concentrated H_2SO_4 on heating to 40 – 80 °C for 1 – 5 min or in dioxane in the presence of catalytic amounts of $HgSO_4$ and dilute H_2SO_4 (80 °C). Ethynyl and phenylethynyl derivatives give the corresponding acetylquinones and phenacylquinones, respectively.[18, 19, 29, 30] Hydrogenation of the triple bond to the double bond in alkynylquinones on a deactivated palladium catalyst is generally accompanied by reduction of the carbonyl groups to give hydroquinones, which are readily oxidised with aqueous $FeCl_3$ or atmospheric oxygen in the course of isolation.[6, 31]

Ethynyl derivatives of quinones are also involved in usual reactions proceeding with the replacement of terminal hydrogen. Thus, *vic*-amino(ethynyl)anthraquinones are easily acylated by carboxylic acid chlorides in the presence of Et_3N and $Pd(PPh_3)_2Cl_2$ or the same palladium complex in combination with CuI in benzene. This method procedure was used for the synthesis of benzoylethynyl- and pivaloylethynylanthraquinones in 67% – 95% yields from 1-amino-2-ethynyl-, 1-amino-3-chloro-2-ethynyl- and 2-amino-3-ethynylanthraquinones.[36, 58, 78, 79] Cadiot – Chodkiewicz coupling of 3-diethylamino-5-ethynyl-1,4-naphthoquinone with 1-bromo-3-methylbut-1-yn-3-ol and Mannich aminomethylation of the former provide examples of the Cu-

catalysed replacement of the hydrogen atom of the ethynyl group in the quinone series.[69]

The alkaline cleavage of tertiary acetylenic alcohols (retro-Favorskii reaction), which is used for the synthesis of ethynyl-, diethynyl- and butadiynylquinones, belongs to a class of cleavage reactions in which the triple bond remains intact.[13, 14, 37, 69] Decomposition of alcohols is generally carried out in the presence of KOH (sometimes with an addition of dibenzo-18-crown-6 or a mixture of CaO and Na_2SO_4) in benzene or toluene at 60 – 110 °C (yields are 20% – 89%).

$$\mathrm{Quin[(C{\equiv}C)_{\mathit{n}}CMe_2OH]_{\mathit{m}}} \xrightarrow{\mathrm{KOH}} \mathrm{Quin[(C{\equiv}C)_{\mathit{n}}H]_{\mathit{m}}}$$

For the preparation of compounds containing the ethynyl group in the quinoid ring, this method is, apparently, applicable only in exceptional cases.[69]

IV. Conclusion

Acetylenic derivatives of quinones belong to a new group of polyfunctional compounds containing the activated triple bond. Their chemical properties are determined also by the presence of a mono- or polycyclic quinoid moiety containing a specific labile π-electron system and several reaction centres. Each reaction centre possesses particular inherent physicochemical properties, which influence each other and change the properties of the molecule as a whole. For instance, the triple bond in alkynylquinones possesses high electrophilicity due to the influence of the electron-withdrawing quinoid moiety regardless of the position of the acetylenic substituent, and this fact has a substantial effect on the reactivity of these compounds. For example, the nucleophilic addition of hydrazine at the triple bond of 1-alkynylanthraquinones, which proceeds readily and regiospecifically, leads to the closure of the sterically hindered diazepine ring involving the carbonyl group in the *peri* position. Under the reaction conditions, this ring can unexpectedly be transformed into the pyridine ring with a 'loss' of the nitrogen atom (see Section III.7.a). The ability to add N-nucleophiles in the absence of a catalyst also provides the basis for an original procedure for the closure of the pyrrole ring in *vic*-amino(alkynyl)anthraquinones (see Section III.2.b). Reductive cyclocondensation of 2,3-bis-alkynyl-1,4-naphthoquinones with NH_2NH_2 is used for the synthesis of isoindolequinones (see Section III.7.c), which are difficult to prepare by other methods. This reaction is *a priori* unpredictable and is, apparently, typical only of compounds containing two vicinal acetylenic substituents in the quinoid ring. Of other specific reactions of alkynylquinones, let us mention the non-trivial thermal cleavage of azidobenzoquinone derivatives, which serve as precursors of very reactive highly unsaturated ketenes (see Section III.9).

These and the above-considered data on the chemistry of acetylenic derivatives of quinones show that these compounds possess a high synthetic potential. It is evident that these compounds hold promise as key intermediates in the synthesis of fused heterocyclic quinoid structures with the aim of searching for new pharmaceuticals and industrial materials. These compounds are, apparently, applicable also for preparing immobilised biologically active quinones, film sensitisers, immobilised redox systems, components of liquid-crystalline composites, *etc*. However, some aspects of the chemistry of alkynylquinones remain unknown. Data on transformations of alkynyl-*ortho*-quinones and quinones containing acetylenic substituents in the quinoid ring are scarce. Efficient general methods for the synthesis of such compounds remain to be developed. The biological activities of alkynylquinones have been poorly studied.

This review will hopefully be found interesting and useful by chemists and contribute to the progress in the chemistry of acetylenic derivatives of quinones, their use in the practice of fine organic chemistry and pharmacological investigations.

Abstract. Chemical transformations of chlorophyll and physicochemical properties of its derivatives are considered. These compounds can be used in the design of a new generation of chlorophyll- and porphyrin-based dyes environmentally more safe than currently used arene dyes and possessing renewable sources of raw materials. The first results on the use of chlorophyll derivatives for dyeing wool, acetate fibres and cotton are reported. The bibliography includes 91 references.

I. Introduction

Chlorophyll as one of the main representatives of the plant world has been a subject of keen interest for investigators for many years.[1–8] An important characteristic feature of chlorophyll is its ability to absorb solar energy and to transform it into chemical energy in a photochemical reaction of water with carbon dioxide occurring in plant cells:

$$6\,H_2O + 6\,CO_2 \xrightarrow{h\nu} C_6H_{12}O_6 + 6\,O_2. \qquad (1)$$

This process represents a key reaction of photosynthesis of carbohydrates and ATP in the green leaf. The energy liberated in the decomposition of ATP is utilised for the synthesis of all the other classes of biomolecules.[9–16]

The specific chemical, photochemical and photophysical properties of chlorophyll attract attention with regard to the practical application of its derivatives in phototransformation of solar energy,[17] semiconductor engineering,[18] photochemical and electrochemical catalysis,[19] generation of singlet molecular oxygen,[20] thermo- and photostabilisation of fats and polymers,[21] *etc.*

Numerous vitally important applied problems (*e.g.*, purification of waste and heat-carrier gases, design of gas- and ion-sensitive electrodes, production of pure oxygen from atmospheric air, photodynamic therapy of cancerous diseases, *etc.*) that can be solved using chlorophyll derivatives and its structural analogues have been repeatedly discussed in the literature.[4, 22, 23]

One of the main challenges for investigators is the design of up-to-date high-quality dyes manifesting high chemical, thermal and photo stability, spectral colour purity and environmental safety as regards their manufacture and application in the textile, paint-and-varnish, printing, food and light industries. Complexes of Cu, Zn, Fe, Co, Ni and other metals with porphyrins and chlorins derived from chlorophyll meet all these requirements.

II. Structure and chemical transformations of chlorophyll

Specific chemical, spectral, chromophore and photochemical properties of chlorophyll **1** and pheophytin **2**, which determine their biological functions and natural coloristic characteristics, are due to the presence of a macrocyclic aromatic nucleus and functional groups in their molecules. These include a vinyl group, a cyclopentenone ring and two ester groups, *viz.*, a propionyl residue esterified by phytol in position 7 and a methoxycarbonyl group in position 10. Besides, the active reaction centre of chlorophyll **1** is represented by a Mg^{2+} ion coordinated to four pyrrole nitrogen atoms, while the active centre of pheophytin **2** contains two proton-donor (−NH−) and two basic (=N−) groups. The C(10)−H bond is strongly polarised due to the presence of three electronegative fragments (C=O, CO_2Me and the π-system of the macroring) and is therefore chemically active.

It is impossible to consider the whole range of essential characteristics of chlorophyll and pheophytin in one review; therefore, we thought it expedient to highlight only chemical transformations of chlorophyll into its derivatives possessing all the properties of industrial dyes.

One of the main chemical features of chlorophyll is its ability to eliminate Mg^{2+} in acidic media to be converted into pheophytin:

$$MgChl + 2H_3O^+ \rightleftharpoons Mg^{2+}\cdot(H_2O)_2 + H_2Chl, \qquad (2)$$

where MgChl is chlorophyll and H_2Chl is pheophytin.

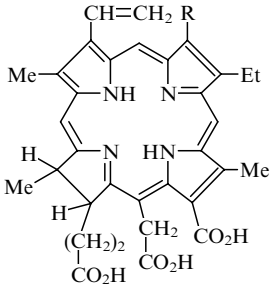
The dissociation of chlorophyll in various organic solvents has been studied in detail. The activation parameters and the mechanism of reaction (2) depending on the specific characteristics of the medium were established.[4] Pheophytin formed upon dissociation of chlorophyll reacts with metal salts in organic solvents (at high rates in carboxylic acids and alcohols and at low rates in pyridine and DMSO)[4] to give metallopheophytinates MChl.

$$MX_2(Solv)_{n-2} + H_2Chl \rightleftharpoons MChl + 2HX + (n-2)Solv, \qquad (3)$$

where MX_2 is the metal salt and Solv are the coordinated solvent molecules.

Pheophytin complexes with d-metals are much more stable than chlorophyll with the exception of Cd^{2+} and Hg^{2+} pheophytinates which, in contrast to MgChl, dissociate in carboxylic acids virtually instantaneously. Stable pheophytin metal complexes, like those of chlorophyll, can find application as dyes.

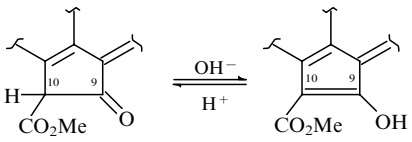
Yet another important feature of chlorophyll and pheophytin is their ability to undergo opening of the cyclopentenone ring. In contrast to four pyrrole rings (*I*–*IV*), the cyclopentenone ring (*V*) polarised by a keto group is insufficiently stable and contains a mobile hydrogen atom in position 10. The ring *V* causes significant distortions in the geometrical parameters of the planar chlorin macrocycle. The opening of the cyclopentenone ring occurs under the action of various reagents (*e.g.*, OH^-, O_2, amines, *etc.*). The oxidative destruction and opening of the cyclopentenone ring result in the formation of chlorin e_6 (**3**) from chlorophyll *a* (**1a**), and of rhodin g_7 (**4**) from chlorophyll *b* (**1b**).



3, 4

R = Me (**3**), CHO (**4**).

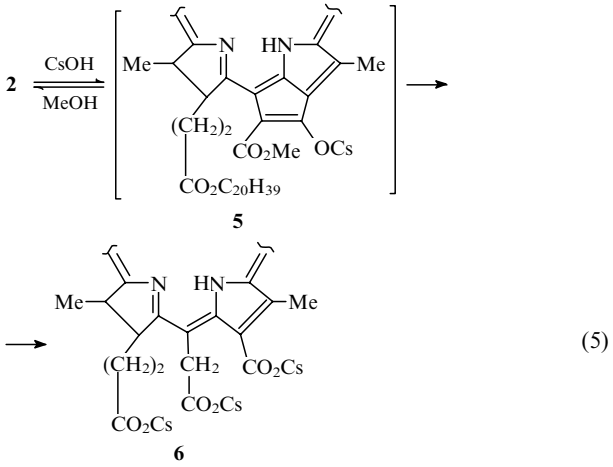
This reaction is most often preceded by keto–enol tautomerism:



(4)

The reaction of a ketone with the OH^- ion may follow two different routes: one of them leads to ionisation of the C(10)–H bond, while the other one entails nucleophilic addition of OH^- to the C(9) atom with subsequent elimination of the H_2O molecule. The enol thus formed is unstable and is rapidly and irreversibly decomposed in alkaline solutions with the opening of the cyclopentenone ring.

The kinetics of cleavage of the cyclopentenone ring was studied under various conditions.[24,25] The addition of 0.1 M CsOH causes changes in the electronic absorption spectrum of pheophytin *a* manifested in the appearance of strong absorption in the region of 460–520 nm and a decrease in the intensity of the first absorption band [λ_I = 667 nm in an ethyl acetate–methanol mixture (12 : 1)]. In this reaction, known in chlorophyll biochemistry as the Molisch 'phase test', an unstable yellow-coloured enol form of chlorophyll or pheophytin (**5**) is initially formed. The electronic spectrum recorded 135 min after the onset of the reaction resembles that of the original pheophytin owing to the formation of a tricaesium salt of chlorin e_6 (**6**):



(5)

The keto–enol equilibrium constants (K_{KE}) have been determined:[24,25]

$$\underset{\text{Ketone form}}{H_2Chl} + Cs^+MeO^- \rightleftharpoons \underset{\text{Enol form}}{HChl^-Cs^+} + MeOH, \qquad (6)$$

$$K_{KE} = \frac{[HChl^-Cs^+][MeOH]}{[H_2Chl][Cs^+MeO^-]}. \qquad (7)$$

The K_{KE} values for ethyl acetate–methanol–CsOH and ethyl acetate–ethanol–CsOH mixtures measured at 298 K are equal to $(3.2 \pm 0.3) \times 10^{-3}$ and $(8.2 \pm 1.2) \times 10^{-3}$, respectively. Obviously, the equilibrium (6) is strongly shifted towards the keto form H_2Chl, the enol form being stabilised by ethanol more effectively than by methanol. In this respect, it is of note that glycerol shifts the keto–enol equilibrium to the right more strongly than other alcohols as a result of additional stabilisation of the enol form of pheophytin by intermolecular hydrogen bonds.[26]

The effective rate constants for the opening of the cyclopentenone ring of pheophytin in the presence of alkali in some organic solvents were measured using spectrophotometry from the decrement in the intensity of the absorption band at 460 nm (Table 1).[24,25] The rate of the second step of reaction (5) is independent of the concentration of alkali, since it affects only the reaction equilibrium (6) (which is shifted to the right) and is not directly involved in the cleavage of the exocycle. The double bond C(10)=C(9) of the exocycle is oxidised by atmospheric oxygen present in the solution. The putative mechanism of reaction (5) has been discussed.[25]

The effective rate constant k_{eff} for the second step of reaction (5) is determined by the equation:

$$-\frac{dc_i}{dt} = k_{eff}c_i, \qquad (8)$$

where c_i is the concentration of the intermediate **5**.

Table 1. Effective rate constants for oxidative degradation (k_{eff}) of pheophytin *a* in mixed organic solvents in the presence of an alkali (298 K) (the operating wavelength $\lambda = 460$ nm, $c^0_{H_2Chl} = 2 \times 10^{-5}$ mol litre^{-1}, $c^0_{O_2} \approx 0.2$ ml cm^{-3}).[24, 25]

Solvent (volume ratio)	c_{CsOH} /mol litre^{-1}	k_{eff} /s^{-1}
$MeCO_2Et$ – MeOH (12 : 1)	$(1.5-80) \times 10^{-3}$	$(2.5 \pm 0.1) \times 10^{-4}$
$MeCO_2Et$ – EtOH (12 : 1)	4×10^{-2}	2.05×10^{-3}
$MeCO_2Et$ – n-$C_5H_{11}OH$ (12 : 1)	3.7×10^{-2}	1.3×10^{-3}
Et_2O – MeOH (12 : 1)	1.1×10^{-2}	6.9×10^{-4}
CCl_4 – MeOH (12 : 1)	1.1×10^{-2}	3.0×10^{-4}
MeOH [a]	0.4 – 0.9	5.4×10^{-4}
EtOH [b]	0.1 – 0.8	6.3×10^{-5}
n-C_3H_7OH [a]	0.4	8.0×10^{-5}
n-$C_5H_{11}OH$ [a]	0.01 – 0.4	9.5×10^{-5}

[a] $c^0_{H_2Chl} = 2.0 \times 10^{-4}$ mol litre^{-1}; [b] $c^0_{H_2Chl} = 2.2 \times 10^{-4}$ mol litre^{-1}.

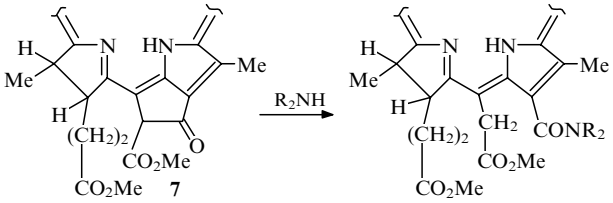
At the same time,

$$k_{eff} = k_v c_{O_2},$$

where k_v is the rate constant for the bimolecular reaction (5). With the molar concentration of O_2 in a saturated solution equal to 7×10^{-3} mol litre^{-1}, the rate constant for reaction (5) can be calculated by the formula:[24, 25]

$$k_v = \frac{k_{eff}}{c_{O_2}} = 1.4 \times 10^2 k_{eff}. \quad (9)$$

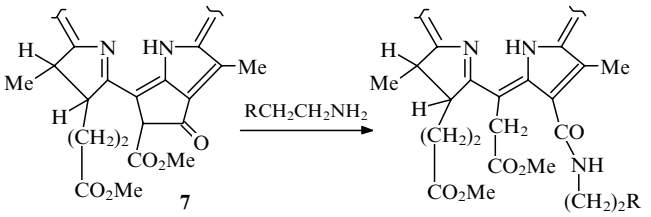
The opening of the cyclopentenone ring of methylpheophorbide *a* (**7**) under the action of amines has been studied.[27] These reactions result in the preferential amidation of one of the carboxy groups formed upon the opening of the exocycle to yield 6-monoamides of 7,γ-dimethyl ester of chlorin e_6.



R = Me, Et.

Analogously, the reaction of methylpheophorbide *a* with yet another nucleophilic reagent, *viz*., morpholine, results in the opening of the cyclopentenone ring. The amide groups of the chlorin derivatives manifest higher affinity for natural and synthetic polyamide fibres.

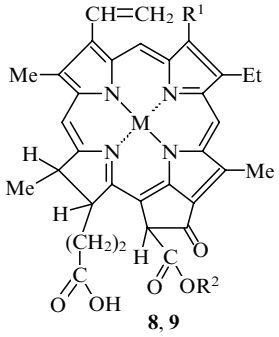
The aminolysis of methylpheophorbide (**7**) by ethylenediamine and ethanolamine is of considerable interest for the synthesis of chlorophyll dyes. In dilute aqueous solutions of carboxylic acids, monoamides of dimethyl ester of chlorin e_6 and their complexes with d-metals are converted into cationic dyes containing an active NH_3^+ group able to bind tightly to amide-type fibres containing terminal COOH groups.



R = NH_2, OH.

Reactions involving alkoxycarbonyl groups, *viz*., the phytyl propionate group in the pyrrole ring *IV* and the methoxycarbonyl group in the ring *V*, are extremely important for chlorophyll and pheophytin. Mild alkaline hydrolysis results in the splitting of phytol $C_{20}H_{39}OH$ and methanol, while the central metal ion is preserved; under these conditions, chlorophyll is transformed into chlorophyllin **8**. Acid hydrolysis leads to the loss of Mg^{2+} and the phytol residue resulting in the formation of pheophorbide **9**.

The extended size of the phytyl residue favours its incorporation into the solvation shell of chlorophyll and pheophytin and creates steric hindrance for the reagents; removal of phytol increases the rates of many chemical reactions.

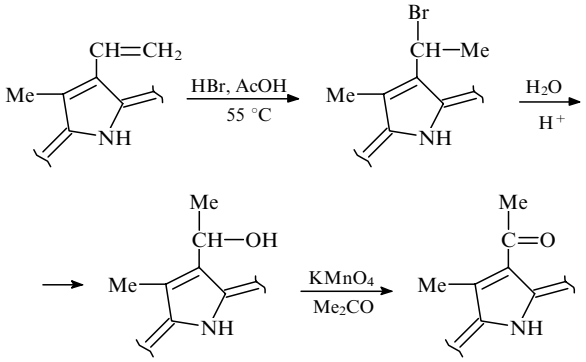


8, **9**

R^1 = Me, CHO; R^2 = H, M = Mg (**8**), R^2 = Me, M = 2 H (**9**).

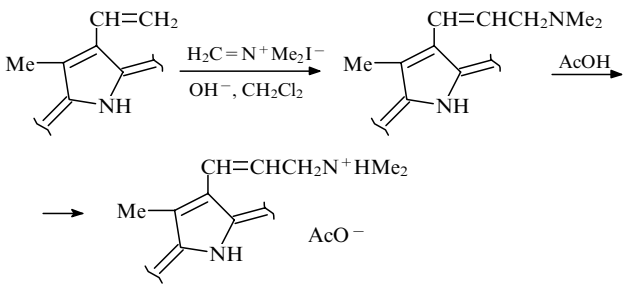
Free carboxy groups favour not only the solvation of pigment molecules in highly polar solvents, but also their association in weakly polar media. Therefore, prior to their chemical modification compounds **8** and **9** are methylated (5% methanolic H_2SO_4), resulting in their conversion into methylchlorophyllin and methylpheophorbide, commonly used in the synthesis of diverse chlorophyll derivatives.

The vinyl group of pheophytin, pheophorbide and other chlorophyll derivatives reacts easily with HBr in organic solvents.[28]

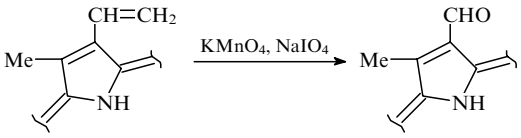


Bromine can be replaced by treatment with nucleophilic reagents,[29] which enables the preparation of chlorophyll derivatives with functional groups in position 2. For example, acid hydrolysis yields derivatives with an alcohol group which can be oxidised to the keto group by potassium permanganate.[30]

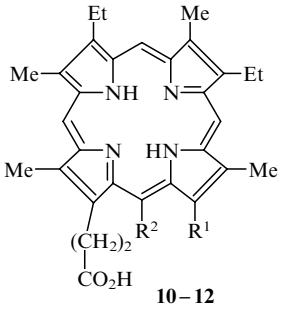
The reaction of chlorophyll with methylidenedimethylammonium iodide and subsequent treatment with acetic acid afford a cationic amino derivative [31] which is of interest in the chemistry of chlorophyll-based dyes due to its higher affinity for polyamide fibres. Quaternisation of tertiary amines affords chromophores that are readily soluble in water.



The oxidation of the vinyl group is an interesting approach to the modification of chlorophyll molecules. Treatment of chlorophyll *a* with $KMnO_4$ and then with $NaIO_4$ results in the incorporation of the aldehyde group into position 2 of the macrocycle which is not accompanied by the oxidation of the cyclopentenone ring. The formyl group can further be converted into a carboxy group.[32, 33]



Chlorophyll and its derivatives contain a chlorin macrocycle with a partially hydrogenated pyrrole ring. Chlorophyll derivatives can successfully be converted into porphyrins among which phylloporphyrin (**10**), pyrroporphyrin (**11**) and rhodoporphyrin (**12**) are of considerable practical interest by virtue of their peculiar structures, and high thermal and chemical stabilities. These compounds represent final products of chlorin conversions under the most drastic redox conditions. The preparation of pyrroporphyrin methyl ester from a mixture of pheophytins *a* and *b* by heating it in an autoclave with 30% KOH in methanol in the presence of a silver catalyst (8 h, 185 °C) has been described.[30, 34] Rhodoporphyrin dimethyl ester is synthesised from pheophytins *a* and *b* under similar conditions but at 145 °C. Phylloporphyrin is prepared from a mixture of pheophorbides *a* and *b* by heating it in pyridine in the presence of 30% methanolic KOH (138 – 140 °C).[34, 35] The reduction of the vinyl group is accompanied by simultaneous dehydrogenation of the C—C bond in the pyrrole ring *IV* of chlorin. It is noteworthy that the preparation of these porphyrins does not require any preliminary separation of a mixture of chlorophylls *a* and *b*.



10 – 12

R^1 = H: R^2 = Me (**10**), H (**11**); R^1 = CO_2H, R^2 = H (**12**).

Chemical modification of peripheral substituents of chlorophyll is possible owing to the extremely high stability of the aromatic porphyrin macroring in acidic, alkaline and various redox media.

III. Chromophore systems of chlorophyll, its derivatives and analogues

Electronic absorption spectra (EAS) provide valuable information about chromophore properties of molecules and the possibility of their use, in principle, as dyes. The electronic absorption spectra of tetrapyrrole aromatic macrocyclic compounds are considered comprehensively in monographs,[4, 18, 36] so there is no need to discuss them in detail. Suffice it to say that EAS of porphyrins, phthalocyanines and chlorophylls differ considerably.[36]

The electronic absorption spectra of porphyrins (Fig. 1) are characterised by low molar extinction coefficients (ε) in the visible region, high intensity of the Soret band at the boundary of visible and near-ultraviolet regions ($\lambda \approx 400$ nm), low sensitivity to the character of inert organic solvents and very high sensitivity to protonating and complex-forming reagents (acids, salts, *etc.*).[4, 36] The positions and intensities of bands in the EAS of porphyrins

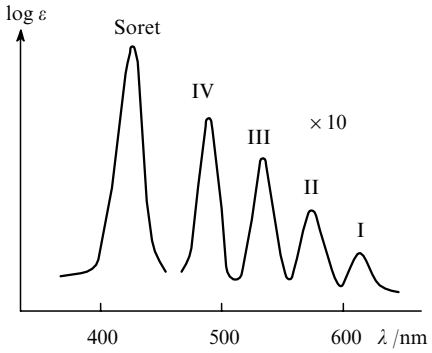


Figure 1. Electronic absorption spectrum of 1,3,5,7-tetramethyl-2,4,6,8-tetraethylporphin.

vary depending on the structures of the side substituents and their positions in the molecules.

In contrast to porphyrins, chlorins are characterised by a long-wave shift and high intensity of the first absorption band (Fig. 2), which enhances the chromophore properties of dyes.

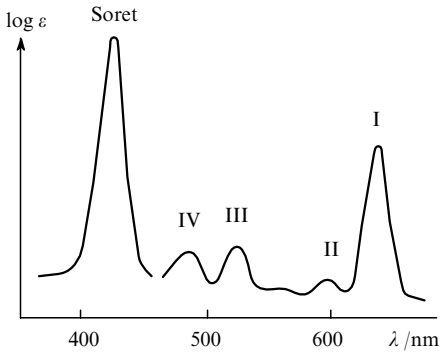

Figure 2. Electronic absorption spectrum of octaalkyl-7,8-dihydroporphin.

The intensities of the first absorption band of pheophytin (Table 2) and chlorophyll (Table 3) depend weakly on the nature of the solvent. In this case, its weak solvatochromic effect is determined by the symmetry of the macrocyclic chlorin chromophore, its atomic-electronic environment and, possibly, minor differences in the solvation of the ground and excited states of chlorophyll and pheophytin.

Special mention should be made of the relatively small dependence of the EAS of chlorins on the presence of substituents in the pyrrole fragments.

Incorporation of a metal atom into the centre of the chlorin molecule does not change the symmetry of the π-electron cloud of the chromophore. This is why EAS of metallochlorins do not differ significantly from that of pheophytin. In particular, the incorporation of Mg^{2+} or any other metal has little effect on the intensity of 'red' absorption bands of chlorins (see Tables 2, 3), since electron transitions in this band are permitted for both the ligand and the complexes.[36] However, the colour tones of crystalline chlorins, their complexes and solutions may vary widely, which is especially important for the chemistry of dyes.

In contrast, in the case of porphyrins the effects of metal cations on the electronic absorption spectra are very pronounced.[4] The complexation of metal ions with porphyrins results in degeneration of the energy levels for the electronic $\pi \rightarrow \pi^*$ transitions polarised along the coordination axes *x* and *y* in the plane of the macrocycle. The absorption bands I and III of free porphyrin corresponding to these transitions merge into one band (I) with an increase in the symmetry of metalloporphyrin mole-

cules. The intensity of this band increases, which is formally due to the fact that the corresponding electron transition becomes permitted, whereas the transitions I and III of free porphyrins are quasi-forbidden. The true reason for the increase in intensities of the absorption band I in the spectra of metalloporphyrins is that metalloporphyrins are more potent chromophores than the free porphyrins due to the rearrangements in their electronic and electronic-vibrational levels. The essence of these rearrangements is discussed in monographs.[36–38].

Coloured compounds are attributed to strong or weak chromophores based on the intensities of the absorption bands in the visible region of the spectrum. Of two coloured compounds with similar positions of the absorption bands, the one with a larger value of ε possesses more potent chromophore properties. The intensity of the absorption band I in the EAS of porphyrins increases 3–4-fold as a result of complexation, and a short-wave shift of this band by 40–60 nm occurs. In this respect, metalloporphyrins exhibit much more potent chromophore properties than the corresponding metal-free compounds (Tables 4 and 5).

IV. Photochemical stability of chlorophyll and its derivatives

Photochemical stability is a central problem in the design of novel dyes based on chlorophyll and related porphyrins. Chlorophyll and porphyrins are involved in diverse complex photochemical transformations; the theoretical aspects of these transformations are considered in detail in a monograph.[38] In this section, we shall discuss various problems connected with photochemical stabilities of chlorophyll and its derivatives in relation to their synthesis and application as dyes. Upon intense illumination, chlorophyll and porphyrins pass easily into singlet and triplet excited states characterised by high chemical activity and ability to generate singlet oxygen. Under these conditions, the macrocyclic chromophore passes into radical-cationic or radical-anionic forms in the presence of oxidants or reducing agents; their further conversions may lead to the cleavage of the macrocycle.[39] The cationic forms are generated in the presence of weak electron acceptors (O_2, quinones, Fe^{3+}, *etc.*), while stronger oxidants (H_2O_2, HNO_3, NO,

NO_2, $H_2S_2O_8$, *etc*.) result in the loss of chromophore properties. Abstraction of only two electrons from the binding π-orbitals of the porphyrin chromophore results in the disappearance of the absorption bands in the visible region of the spectrum. Thus, the absorption band I in the EAS of the radical cation of the magnesium octaethylporphyrin complex is characterised by lower intensity and has a bathochromic shift by 100 nm in comparison with its position in the spectrum of neutral porphyrin, whereas the corresponding dication is colourless. Pheophytin and its complexes manifest a similar behaviour. The alkyl groups, which represent σ-electron donors, favour the oxidation including photochemical oxidation. In contrast, protonation of porphyrins and chlorins prevents their oxidation. On the whole, chlorins are oxidised more easily than porphyrins. It should be remembered that the factors responsible for chemical and electrochemical oxidation can also influence photooxidation.[4,39]

Effects of metals on the oxidisability of complexes are of special interest. These metals can be divided into two groups that are different in principle. The metals of the first group (Mg, Cu, Zn, Cd, Ti) preserve their oxidation state in the transition of metalloporphyrins into radical-cationic and cationic forms. In this case, the electrons are abstracted from HOMO of the ligand, and the oxidation potential of the complex is lower than that of free porphyrin.[39]

The second group includes the metals (Mn, Fe, Co, Ni, Ag) the oxidation state of which changes upon transition into radical-cationic forms. As a result, the oxidation potentials of the complexes increase considerably.

The rate constants for photochemical destruction of metal analogues of chlorophyll are given in Table 6.[4]

Table 6. Rate constants (k_v) for the photochemical destruction of chlorophyll *a* and its metal complexes at different temperatures.[4]

Compound	Solvent	k_v /h^{-1}		
		20 °C	40 °C	60 °C
H_2Chl *a*	EtOH	very slow	very slow	very slow
	AcOH	0.019	0.039	0.081
MgChl *a*	EtOH	0.400	0.453	0.588
	AcOH	0.297	0.402	0.563
ZnChl *a*	EtOH	0.035	0.053	0.082
	AcOH	0.205	0.304	0.395
CdChl *a*	EtOH	0.460	0.466	0.493
HgChl *a*	EtOH	0.039	0.048	0.065
CoChl *a*	EtOH	–	–	0.025
	AcOH	–	–	0.006
CuChl *a*	AcOH	0.0101	0.015	0.024
PdChl *a*	AcOH	–	–	0.013
NiChl *a*	AcOH	–	–	0.0045
Fe(AcO)Chl *a*	AcOH	–	–	0.004

Ionic complexes with Cd and Mg and weakly covalent (Zn) complexes undergo photodestruction faster than pheophytin. The rate of photochemical oxidation of the covalent complexes with the metal ions (Cu, Co, Ni, Fe, Pd) that deactivate the triplet state and suppress the photogeneration of singlet oxygen is very low. This prompts an important practical conclusion that covalent metal-containing chlorin- and porphyrin-based dyes are much more resistant to photooxidation than free porphyrins.

V. Properties of chlorophyll and its derivatives in solutions. Solubility of porphyrins and energetics of solvation

Many natural porphyrins pass into a solution with difficulty. This is due to relatively high energies of their crystal lattices, low solvation energies of relatively non-polar chemical bonds and strong interactions of the π-systems of the neighbouring molecules. The solubility of porphyrins in organic solvents strongly depends on their structures.[40]

The structural and thermodynamic aspects of the solubilisation and solvation of the main types of porphyrins (chlorophyll, protoporphyrin and their derivatives, tetraphenylporphin, tetrabenzoporphin), their complexes and non-classical porphyrins (tetraazaporphyrins, phthalocyanines, chemical porphyrin dimers, *etc*.) have been investigated.[41–64] The main regularities of the thermodynamics of the solubilisation and solvation of porphyrins by various organic solvents and their binary mixtures have been established. The dependence of these processes on the conformational component of the free energy of solubilisation (ΔG_s), enthalpy (ΔH_s) and entropy (ΔS_s) of solubilisation caused by elimination of conformational strains in porphyrin molecules on phase transitions from the solid state to the solution has been established for the first time.

The energies of molecular lattices (ΔG_{lat}) for the majority of porphyrins are not determined. The contribution of the conformational component ΔG_{conf} for structurally similar porphyrins can be assessed only qualitatively. Therefore, a comparative analysis of experimental data on the solvation of porphyrins and their complexes is usually carried out based on the relative enthalpies of solubilisation of these compounds in a series of solvents with the least solvating one used as a standard.

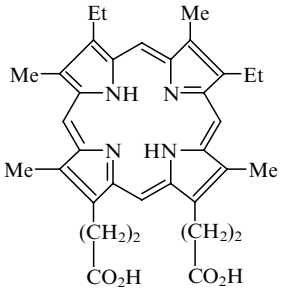
Chlorins are much more soluble in organic solvents than porphyrins. The enthalpies of the transfer from benzene to another organic solvent (Table 7) are negative and vary from -2.3 (for chlorin e_6 in pyridine) to -71 kJ mol^{-1} (for pheophorbide *a* in piperidine).

Table 7. Standard changes in the enthalpies of solubilisation (ΔH_s°) (±2%) and the transfer (ΔH_t°) of chlorins.[64]

Chlorin	Solvent	ΔH_s° /kJ mol^{-1}	ΔH_t° /kJ mol^{-1}
H_2Chl *a*	C_6H_6	30.6	0
	CCl_4	22.5	−8.1
	$C_6H_5NO_2$	20.3	−10.3
	$CHCl_3$	1.3	−29.3
	DMF	23.6	−7.0
	pyridine	16.4	−14.2
	piperidine	−35.9	−66.5
Pheophorbide *a*	C_6H_6	16.9	0
	CCl_4	11.9	−5.0
	$C_6H_5NO_2$	5.7	−11.2
	$CHCl_3$	−9.2	−26.1
	DMF	8.0	−8.9
	pyridine	8.6	−8.3
	piperidine	−53.8	−70.7
Chlorin e_6	C_6H_6	14.2	0
	$CHCl_3$	−2.2	−16.4
	DMF	−10.3	−24.5
	pyridine	11.9	−2.3
	piperidine	−25.8	−40.0
Pheophorbide *b*	C_6H_6	14.4	0
	$C_6H_5NO_2$	4.8	−9.6
	$CHCl_3$	−9.8	−24.2
	DMF	4.4	−10.0
	pyridine	3.8	−10.0

The data listed in Table 7 suggest that benzene is the worst solvent, especially for H_2Chl *a* the phytol residue in which prevents its solubilisation in all organic solvents studied. The difference in the ΔH_s° values for phytol-free and phytol-containing molecules in all solvents constitutes, on average, −15 kJ mol^{-1} (see Table 7). This suggests that the phytol residue creates conformational hindrances for the solubilisation (but not the solvation). Thus the ΔH_t° values for pheophytin *a* and pheophorbide *a* are virtually identical for each of the solvents chosen.

The energy characteristics of the solubilisation and solvation of methyl esters of porphyrins of the chlorophyll group, *viz.*, pyrroporphyrin (**11**), rhodoporphyrin (**12**) and mesoporphyrin (**13**), are given in Table 8.



13

The endothermic character of solubilisation of porphyrin methyl esters in benzene increases considerably in the following order: **11** < **12** < **13**. Presumably, the appearance of a second methoxycarbonyl group in the porphyrin molecule creates steric hindrance (the absolute value of ΔG_{conf} for compound **13** is also increased) and hinders the solvation (ΔG_{solv}) in benzene. This order of changes in ΔH_s is preserved in CCl_4. The ΔH_t values of porphyrins with alkoxycarbonyl groups become highly negative in $CHCl_3$. The latter, being a weak acid, forms solvates with these compounds through hydrogen bonds. The solvation of porphyrins dissolved in DMF, pyridine or piperidine is determined by a weak acid – base interaction of porphyrins with solvent molecules of the type N−H···Solv.

Table 8. Standard changes in the enthalpies of solubilisation (ΔH_s°) (± 5%) and transfer (ΔH_t°) of porphyrins of the chlorophyll group.[64]

Porphyrin	Solvent	ΔH_s° /kJ mol^{-1}	ΔH_t° /kJ mol^{-1}
Pyrroporphyrin	C_6H_6	22.5	0
	CCl_4	15.1	−7.4
	$CHCl_3$	8.1	−14.4
	DMF	12.8	−9.7
	pyridine	15.3	−7.2
	piperidine	10.3	−12.2
Rhodoporphyrin	C_6H_6	42.8	0
	CCl_4	29.4	−13.4
	$CHCl_3$	21.0	−21.8
	DMF	35.3	−7.5
	pyridine	40.2	−2.6
	piperidine	24.1	−18.7
Mesoporphyrin	C_6H_6	53.2	0
	CCl_4	40.4	−12.8
	$CHCl_3$	16.5	−36.7
	DMF	20.9	−32.3
	pyridine	31.5	−21.7

Metal ions coordinated to chlorins and porphyrins change strongly their abilities for solvation in organic solvents. Such ions as Zn^{2+}, Cd^{2+} and Co^{2+} in metalloporphyrins take part in the coordination of molecules of electron-donor solvents (alcohols, pyridine, piperidine, DMF, DMSO, *etc.*),[4,39,65] which strongly increases the solubility of metalloporphyrins and favours their solvation. In contrast, virtually no solvation of copper and nickel complexes through axial coordination takes place (Table 9).

Table 9. Enthalpies of axial coordination (ΔH_{ec}°) of the solvent molecules by porphyrin complexes at 298 K.[41–46,62]

Complex	ΔH_{ec}° /kJ mol^{-1}		
	DMF	Py	Pip[a]
MgChl	−17.5	−33.6	–
CdPhe *a* (see[b])	−17.2	−55	−38.7
ZnChl	−17.6	−30.3	–
ZnPhe	−13.0	−29.2	−15.5
ZnPir[c]	−12.2	−36.1	−33.8
ZnGp[d]	−23.0	−42.9	−51.8
CoChl	−25.6	−84.1	−172.2
CoPhe	−23.4	−29.5	−57.6
CoRp[e]	−25.1	−38.5	–
CuChl	1.8	−5.6	–
NiChl	−1.7	−27.7	−7.0
NiPir	−2.8	−6.3	–

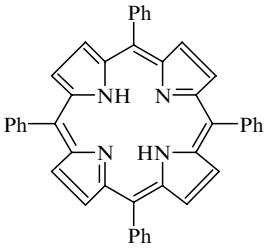
[a] Pip, piperidine; [b] Phe, pheophorbide; [c] Pir, pyrroporphyrin; [d] Gp, haematoporphyrin; [e] Rp, rhodoporphyrin.

The copper complex of tetraphenylporphin **14** is characterised by extremely low solubility in ethanol (Table 10).

Table 10. Solubilities of tetraphenylporphyrin and its complexes in ethanol at 298 K.[41–46, 62]

Compound	$10^3 S^{298}$ /mol litre^{-1}
H_2TPP [a]	0.018
	5.90 [b]
CoTPP	0.084
CuTPP	0.012
ZnTPP	0.682
CdTPP	0.802

[a] Tetraphenylporphyrin **14**; [b] in benzene.



14

At the same time, the solubility of Co, Zn and Cd complexes is increased 7–60-fold due to the axial coordination of the solvent molecules to the fifth and sixth coordination positions along the *z* axis orthogonal to the porphyrin ring as a result of which the solvation energy decreases (on average, by 20–40 kJ mol^{-1}) depending on the electron-donor properties of the solvent.

Thermodynamic, thermochemical and spectral methods have been developed for the study of solvation of metalloporphyrins through axial coordination of solvent molecules.[39, 41, 63]

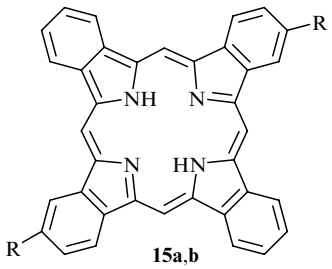
VI. Use of porphyrins and chlorins for dyeing textiles

The textile and light industries utilise an immense variety of synthetic dyes [66–72] many of which are toxic, irritate the skin and mucosa and cause otitis, laryngitis and various gastrointestinal disorders. Aniline dyes are especially hazardous in production and, possibly, application.[71, 72] Unfortunately, preventive measures are taken mostly during the production of synthetic dyes and, to a lesser degree, during colouration and utilisation of textiles. The effects of dyes on human skin in the course of wearing and laundering of dyed fabrics and their hazardous impact on living beings through waste waters have been little studied. One should not rule out the possibility that synthetic dyes of the arene series provoke cancerous and other severe diseases even in homeopathic doses. Therefore, in recent years the attention of investigators has been mainly focussed on natural dyes of plant origin.[73–76] A large body of literature data on this problem has been analysed.[75]

Chlorophyll, the most important natural dye, has a tetrapyrrole and not arene structure and is a component of foods consumed by warm-blooded animals. Therefore, chlorophyll itself, its derivatives and many porphyrins can be regarded as environmentally safe compounds. Dyes based on chlorophyll came into use as colouring matter for foodstuffs as early as the beginning of the 20th century and are currently widely used in medicine, perfumery and other areas.[34, 35] However, until recently the use of chlorophyll derivatives in the textile and light industries has been restrained due to the rapid progress in the chemistry of synthetic dyes and their ubiquitous application.

The necessity to find vast agricultural areas for growing plants as natural sources of dyes (*e.g.*, indigo) at the sacrifice of agricultural plants used as food for humans is the main obstacle to the transition to safe natural dyes.[73] No such problem exists for chlorophyll-based dyes, since chlorophyll is extracted from naturally abundant green plants (*e.g.*, nettle, conifers, algae, *etc.*). The annually renewable chlorophyll reserves on our planet constitute no less than 10^{12} tons.[11]

Several promising environmentally safe porphyrin dyes have been proposed,[77–81] and a simple, economic one-step procedure for the isolation of metallochlorophyll analogues from green plants has been developed.[82] Ni, Fe, Co, Cu, Mn complexes and complexes of other metals prepared by this method possess the entire set of characteristics required for them to be employed as dyes.



15a,**b**

R = CH_2N^+⟨pyridine⟩ Cl^- (**a**), $CH_2S^+{=}C(NMe_2)_2$ (**b**).

Pyridinium and thiouronium salts of tetrabenzoporphin **15a**,**b** were prepared in 98% yield by chloromethylation of tetrabenzoporphin [83–85] followed by heating of the reaction product with pyridine or tetramethylthiourea. These compounds are easily soluble in water and stable in weakly acidic solutions (1%–3% acetic acid). The derivatives **15a**,**b** impart an intensive bright green colouring to Nitron fibres in 40 min. Dyeing of cotton fibres with these salts also gave good results. Of substantial interest are active disperse porphyrin dyes for polyamide fibres based on tetra(*p*-chloromethylphenyl)porphin.[86, 87] The starting compounds for the synthesis of the latter are pyrrole, benzaldehyde and formaldehyde. The aforementioned porphyrin dyes can easily be converted into the corresponding metal complexes possessing enhanced chromophore properties.

Unique phthalocyanine pigments and dyes with a tetrabenzotetraazaporphin structure have been known for a very long time.[4, 88, 89] These compounds are prepared from phthalic acid derivatives and metal salts and are characterised by complete environmental safety owing to their extremely high chemical and photochemical stability which is not inherent in other classes of dyes.

The aforementioned properties of chlorophyll and the principles of its processing into chlorins and porphyrins enable its application as a potential source of environmentally safe dyes. Chlorophyll is isolated from green plant cells by extraction. In Russia, it is economically more effective to extract chlorophyll from nettle leaves.[4, 90] In the USA and European countries, food pigments have been prepared from chlorophyll extracted from finely ground alfalfa leaves since the early 1920's.[35] Acetone and light petroleum are used as extractants. Pheophytin is isolated by extraction with 96% ethanol and subsequent treatment with 6 M HCl. Treatment of plant tissues with acetone and 34% aqueous HCl yields a mixture of pheophorbides *a* and *b*.

Pheophorbide, chlorin e_6 and chlorin e_6 6-*N*-(2-aminoethyl)-amide dimethyl ester were tested as dyes for wool, cotton and acetate fibres in our laboratory.[91]

A wool specimen dyed with pheophorbide acquired a light green-brown colouring, while that dyed with chlorin e_6 was coloured bright green-brown. Dyeing with chlorin e_6 6-*N*-(2-aminoethyl)amide dimethyl ester gave the third specimen a khaki colour. Boiling of specimens dyed with chlorin e_6 and chlorin e_6 6-*N*-(2-aminoethyl)amide dimethyl ester with an aqueous solution of copper acetate resulted in complexation. In the former case, the colour of the specimen was bright blue-green, while in the latter it was green.

Chlorin e_6 6-*N*-(2-aminoethyl)amide dimethyl ester was used as a dye for conferring a khaki colour on acetate fibres. Subsequent boiling of the specimens with aqueous solutions of copper and nickel acetates gave the former an intensive light-green (lettuce) colour. After dyeing with chlorin e_6 and chlorin e_6 6-*N*-(2-aminoethyl)amide dimethyl ester by a pad-dry technique, which includes thermal treatment and steaming, the cotton specimens acquired green-yellow and khaki colouring, respectively. Subsequent boiling of the specimens with solutions of copper and nickel acetate gave dark-green and green colouring, respectively.

Chlorin e_6 was used for dyeing cotton fabrics by the colour-printing method which includes starch and cellulose thickening. The green-yellow coloured specimens appeared to be more sensitive to solar light than dyed wool specimens.

* * *

The state-of-the-art in chlorophyll chemistry allows gradual replacement of some environmentally unsafe classes of synthetic arene dyes by porphyrins and chlorophyll derivatives.

Chlorophyll and its derivatives, their cationic forms and metal complexes are potent chromophores characterised by purity of colour and photochemical stability. They can be used as direct, disperse, cationic and active dyes for regenerated protein (*e.g.*, wool, silk, *etc.*) and synthetic fibres giving stable and bright green tones. Chlorophyll-based porphyrins impart pink-red colouring to fabrics. The authors are currently engaged in the development of effective methods for extracting chlorophyll from natural raw materials (*e.g.*, nettle leaves, alfalfa powder, conifers, algae, *etc.*) and its modification into chemically stable and photostable derivatives possessing an ideal chromophore system and an affinity for textile fibres. The main practical results from their application give every reason to consider this class of chlorophyll dyes as promising industrially and operationally safe agents; their commercial production can be realised in the very near future.

Abstract. Attempts at using correlation analysis and the inductive constants for quantitative estimation of the reactivity of the solid surface and for predicting the character of surface reactions are discussed on the basis of the macromolecular concept of the structure of solids. The results of experimental studies of the reactivity of some solid oxides and single-crystal matrices, which confirm the good prospects of this approach, are presented. The bibliography includes 33 references.

I. Introduction

The active development of the chemistry and technology of a solid surface is associated with the prospects for using small-size surface structures in various fields of engineering, first of all, in micro- and nanoelectronics, heterogeneous catalysis and sorption techniques. Progress in the development of chemical methods for the synthesis of nanostructures is largely related to the possibility of predicting the pattern of surface reactions on the basis of a quantitative theory. An approach to quantitative estimation of the reactivity of the surface of solids is the use of correlation analysis, which underlies the quantitative theory of organic reactions [1, 2] based on the linear free energy (LFE) principle proposed by I Brønsted and M Polanyi. According to this principle, the reactivity of the members of a series of isostructural compounds having a reaction centre of the same type can be predicted using either empirical or experimentally determined constants. The numerical values of the constants can be used to compare and predict the equilibrium and kinetics of chemical processes involving these compounds. For example, compounds incorporating functional groups Y of the same type are combined into the reaction series

$$X_1-Y,\ X_2-Y,\ \ldots,\ X_n-Y;$$

for any member of this series, the rate constant of the reaction

$$X_i-Y + Z \longrightarrow X_i-Z + Y$$

depends unambiguously on the nature of X_i. The influence of X_i can be described by a set of dimensionless constants. This allows one to predict the behaviour of various compounds in chemical processes.

Qualitatively, the reactivity of X_i-Y molecules can be described by revealing the mechanism of interaction between the substituent X_i and the reaction centre Y. The major contributions to this interaction are made by inductive, steric, resonance, and some other effects. When a particular chemical reaction is considered, various types of interaction are postulated to be independent of each other and additive.[1, 2] The ability of a substituent to be involved in a particular type of interaction is described quantitatively by a constant which is expressed as a relative value, *i.e.*, describes the effect of a given substituent with respect to a reference one. For example, the effective electronegativity of the substituent is usually characterised by the constant σ_I, which reflects the inductive effect of this substituent. The qualitative views on the inductive interaction represent an integral part of the classical electronic theory of organic reactions. However, this does not mean that the nature of the inductive effect is now completely clear. The most widely used concept is intramolecular polarisation transmitted along the chain of bonds. This polarisation, induced by some charged or electronegative group, decreases with distance.

Quantitatively, the inductive effect of substituents as a formal type of interaction has been considered by Hammett and Taft.[2, 3] They proposed one-parameter correlation equations for various reaction series

$$\log K_i = \log K_0 + \rho\sigma_I, \qquad (1)$$

where K_i and K_0 are the equilibrium (or rate) constants for the reactions for substituted and unsubstituted members of the series, respectively; ρ is the proportionality coefficient reflecting the sensitivity of the reaction centre to the effect of the substituent in this reaction. The first term represents the part of the reaction free energy that does not depend on the nature of the substituent X.

In Taft's opinion, strict correlations between the inductive constants and the electronegativities can be established only for

monoatomic substituents. However, while developing a quantitative theory of organic reactions, Palm[1] made the inductive constants universal and assumed that any influence of the inductive effect can be described by the equation

$$A = A_{XY} + \rho_Y \sigma_X, \quad (2)$$

where A is any correlated value (for example, log$K$). According to Palm, this equation is valid for a variable substituent X_i of any complexity.

The experience of using structure–property relationships accumulated in organic and organoelement chemistry,[3–5] can be successfully applied to surface processes. This was promoted by the appearance of the core model of the structure of solids and development of the chemistry of supramolecular compounds.[6–8] An approach based on the use of the LFE principle and correlation analysis in the chemistry of the surface of solids can provide the basis for the development of a quantitative theory of surface reactions.

This review considers some results that demonstrate good prospects of using correlation analysis in the chemical investigations of solid surfaces, in particular, for quantitative estimation of the reactivity of functional groups on the surfaces of dispersed and single-crystal matrices on the basis of their inductive constants. This approach was verified in relation to dispersed silica, beryllia, titania and alumina and single-crystal silicon.

II. Macromolecular concept of surface chemical reactions and quantitative estimation of the reactivity of the solid surface from the inductive constants

In conformity with the main concept of the structure of solids,[6] any solid can be represented as a combination of a chemically inert core and reactive functional groups located on the surface (*e.g.*, OH groups). All surface reactions involving these groups and not affecting the core structure are considered as polymer analogous transformations.[7] Within the framework of a formal approach, this allows one to apply the LFE principle to solids containing similar functional groups and to use linear correlations of type (1) and (2). Usually, experimental results are represented as more or less complicated correlation equations. When the results deviate from dependences of types (1) and (2), the factors responsible for these deviations (steric, resonance, π-conjugation or hyperconjugation, *etc.*) should be taken into account using the stage-by-stage 'from simple to complex' procedures.

In a quantitative description of the inductive effect, a reaction series of solid matrices is not necessarily considered resorting to the X–Y system. If X is any substituent, in the X–Y series, one can distinguish the X–G–Y subseries where G is any divalent structural unit. If the inductive interaction has at least limited universality within a particular set of substituents X, the values for the considered characteristic A, present in Eqn (2), for the X–Y and X–G–Y series with the same range of substituents X should follow a linear correlation with each other. This means that the correlation equation (2) for the X–G–Y series can be written in two ways

$$A_{X-G-Y} = A_{X_0-G-Y} + \rho_{GY}\sigma_X$$

and

$$A_{X-G-Y} = A_{X_0-G-Y} + \rho_Y\sigma_{GX},$$

which implies inclusion of the fragment G in the reaction centre and in the substituent, respectively. For solids with hydroxylated surfaces that present a separate reaction series (for example, metal oxides), the electrophilic and nucleophilic substitution reactions can be presented in the following way:

$$X-OH + B \longrightarrow X-OB,$$

$$X-OH + B \longrightarrow X-B.$$

The type and the rate of the reaction are dictated by the effective electronegativity of the surface group (X or X–O). The reactivity of the hydroxyl groups is affected by all atoms that form the core; however, the effect of the nearest atoms that form the surface group is the most significant. The effective electronegativity of this group as a substituent in a surface compound can be evaluated from the inductive effect using one-parameter correlations. The value for the inductive effect (inductive constant) can be derived from any physicochemical process or phenomenon in which it is manifested to a sufficient extent. High sensitivity to electronic effects is typical of nuclear magnetic resonance; this is one of the best methods for determining the inductive constants.[1] However, strict requirements to investigation objects restrict the scope of its applicability. The bond force constants (and, hence, the stretching frequencies) depend on the electronic state of the system; therefore, with allowance for the LFE principle, one can use the relationships between the parameters σ_I and the spectral characteristics of the compounds of interest (for example, data of IR spectroscopy). These relationships have been used, for example, in a study of organosilicon compounds.[4,5]

Study of the influence of substituents on the spectroscopic characteristics of the Si–Cl, Si–F, Si–O–Si, and Si–H bonds in organosilicon compounds has shown that the shifts of the stretching frequencies of these bonds depend on the electronic state of the substituents present in the surroundings of the functional group and obey an equation of the form

$$\nu_i = \nu_0 + \alpha\sum \sigma^*, \quad (3)$$

where ν_i, ν_0 are the stretching frequencies of the bonds in this compound and in the methyl-substituted silane (or siloxane), respectively, α is a coefficient, $\sum\sigma^*$ is the sum of the Taft inductive constants of all substituents in this compound.

Relation (3) reflects a general feature of these compounds — the dependence of spectral characteristics on the electronic effects of substituents. The steric factors are insignificant in this case, and the inductive effect predominates.[4] This allows one to separate quantitatively the effects of different substituents by juxtaposing the data on chemical transformations of particular compounds with their spectral characteristics.

The linear dependence (3) was first established by Thompson,[4] who analysed the spectral characteristics of a small series of silanes R_3SiH with different substituents R. For compounds $R_{3-n}X_nSiH$, where X is halogen, a deviation from linear dependence (3) was observed and suggested [5] to be due to conjugation. The deviation can be quantitatively described by the difference between the calculated (ν_{cal}) and experimental (ν_{exp}) vibration frequencies of the Si–H group

$$\Delta\nu = \nu_{calc} - \nu_{exp}.$$

The ν_{calc} value was found using Eqn (3) taking into account the inductive constants for the corresponding substituents X [σ^*(X)] and R [σ^*(R)] and the relation

$$\sum\sigma^* = n\sigma^*(X) + (3-n)\sigma^*(R).$$

However, for a particular substituent X, the $\Delta\nu$ value was constant and did not change upon the variation of R. This allowed the researchers to separate quantitatively the effects of substituents.[5]

An IR-spectroscopic study of the ≡Si–Cl, ≡Si–F and ≡Si–H groups on the silica surface showed a shift of the characteristic absorption bands of these groups.[9] The authors interpreted these shifts as being due only to the effect of the surface. Meanwhile, the quantitative analysis of the changes in the spectral characteristics of chemisorbed (and, hence, substituted) silanes provides information on the electronic structure and the influence of all substituents that belong to the environment of silicon, including the surface group. To study the surface proper-

ties, it is most convenient to follow the characteristic absorption frequencies of the silicon hydride bond. First of all, this is due to the values of the Si—H stretching frequencies, which occur in the range of 2100–2300 cm^{-1}. Here, the absorption of the IR emission by the core of most solids is insignificant and the observed changes in $\Delta\nu$(Si—H) for various substituted silanes are fairly great, being equal to 100 to 150 cm^{-1} (see Refs 5, 9). This increases the accuracy and reliability of the results.

The surface compounds containing Si—H bonds are formed on hydroxylated surfaces of solid oxides when they are treated with chloro- or alkoxysilane vapours. By analysis of the changes in the chemical reactivity and spectroscopic characteristics, one can estimate quantitatively the influence of the surface groups or the whole core of the solid on the reaction centre.

The real surfaces of most metals and semiconductors contain oxide layers; therefore, the reactivity of such surfaces will be dictated, first of all, by the oxide microstructure and the type of hydroxyl groups. Studies of the hydroxyl cover of silicas and other oxides (for example, Al_2O_3, $xAl_2O_3 \cdot ySiO_2$, TiO_2, ZnO) which exhibit catalytic properties have shown [10] that, in terms of the number of coordination bonds formed by oxygen, three types of OH bonds can be distinguished, those attached to the metal of the oxide core by one (I), two (II) and three (III) bonds (all the M—O bonds are considered to be equivalent). The ratio of the concentrations of hydroxyl groups of each type to their total concentration is determined by both the oxide composition and the surface temperature. The formation of an additional coordination bond results in a lower stretching frequency of the OH groups. This underlies the identification of the type of hydroxy group based on its spectral characteristics.[10–12] For a particular oxide, the relation

$$\Delta\nu(\text{OH})\ (\text{III}) > \Delta\nu(\text{OH})\ (\text{II}) > \Delta\nu(\text{OH})\ (\text{I})$$

usually holds, which is due to a decrease in the electron density on the O—H bond and an increase in the positive charge on the hydrogen atom following an increase in the coordination number of oxygen in the corresponding OH groups. The involvement in surface reactions is determined by both the proton-donor capacity and the steric arrangement (steric factor) of the hydroxyl group. Also, for quantitative estimation of the reactivity of the surface hydroxyl groups, one can use the inductive effect of the matrix and calculate its inductive constant σ_s from the shift of the adsorption maximum for the Si—H stretching vibrations of the surface compounds formed upon the chemisorption of silanes.[12–15] As noted above, this bond is highly sensitive to the electronic effects of substituents. In this case, relation (3) has the form

$$\nu_I = \nu_0 + \alpha(\sum\sigma_I + \sigma_s). \quad (4)$$

When the Taft constants are used as σ_I, the σ_s value can be determined from the scale of these constants.

The fact that the spectral characteristics [ν(Si—H)] of chemisorbed silanes depend only on the electronic effects of substituents allows one to distinguish the influence of each of them; therefore, this method should be considered as legitimate. Evidently, the substituent effect of the core of a solid follows a complex pattern; therefore, experimental results can either obey or depart from Eqn (4), which will provide additional information on the object in question. The availability of Taft inductive constants for a large number of low-molecular-mass substituents [16] markedly simplifies the computational part of the procedure and makes this approach versatile.

III. Inductive effect of a silica matrix and regularities of its variation during dehydration

We tested the above approach in relation to silica samples (Aerosil A-175). The coefficients present in correlation equation (4) were determined for a reaction series of oxides. The concentration of the hydroxyl groups was determined by a reported procedure [17] and compared with the data of IR spectroscopy [18] obtained in the experiments described below.

The characteristic stretching frequencies of the Si—H bond of chemisorbed silanes were determined from the IR spectra recorded on UR-20 and Bruker spectrometers. The deviations of individual measurements from the statistical average values in the region of 2100–3800 cm^{-1} were smaller than 2 cm^{-1}.

For calculation of the coefficients for correlation equation (4), experimental ν_i values for a series of chemisorbed silanes are needed. The frequencies of the maxima of the stretching bands of the Si—H bonds incorporated in different functional groups of compounds synthesised on the Aerosil surface pretreated at 673 K *in vacuo* are listed in Table 1. On chemisorption of methyldichlorosilane and phenyldichlorosilane, surface compounds with different compositions can be obtained. This is due to the fact that these silanes mainly react with the Aerosil surface as monofunctional reagents (compound No. 3 or No. 8), which was confirmed by Tertykh *et al.*[19] During the subsequent treatment of these samples with water or alcohol vapour, the Si—Cl groups remaining intact were hydrolysed or alkoxylated. These processes were accompanied by the corresponding changes in the IR spectra (Fig. 1), namely, partial restoration of the absorption band due to the Si—OH groups (ν = 3750 cm^{-1}, spectrum *2*) in the case of hydrolysis or the change in the shape and intensity of the C—H bands (spectrum *5*) upon alkoxylation. In both cases, the introduction of a new substituent (OH, OCH_3 or OC_2H_5) in the environment of the silicon hydride bond was accompanied by displacement of the ν(Si—H) mode (see Table 1, compounds Nos. 3, 5, 6, 7 and 8, 10, 11, 12; Fig. 1). The subsequent maintenance of these samples at T = 673 K for 1 h resulted in some decrease in the intensity of the ν(Si—H) absorption bands and the appearance of new bands (2260 and 2270 cm^{-1}). This was accompanied by the

Table 1. Influence of the nature of the substituent on the stretching frequency of the silicon hydride bond.[14]

No.	Chemisorbed chlorosilane	Surface compound	ν(Si—H) /cm^{-1}	$\sum\sigma^*$ (see [14])	$\sigma^* + \sum\sigma_s^*$

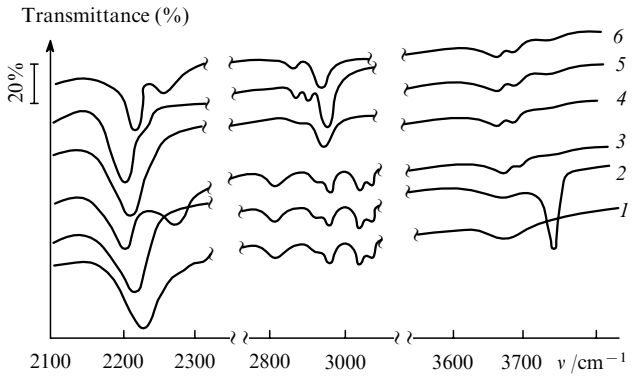

Figure 1. IR spectra of Aerosil treated with phenyldichlorosilane vapour at 473 K (*1*) with subsequent rehydration (*2*) and maintenance at 673 K for 60 min (*3*); and Aerosil treated with methyldichlorosilane vapour at 473 K (*4*) and then with ethanol vapour (*5*) and maintained at 673 K for 60 min (*6*).

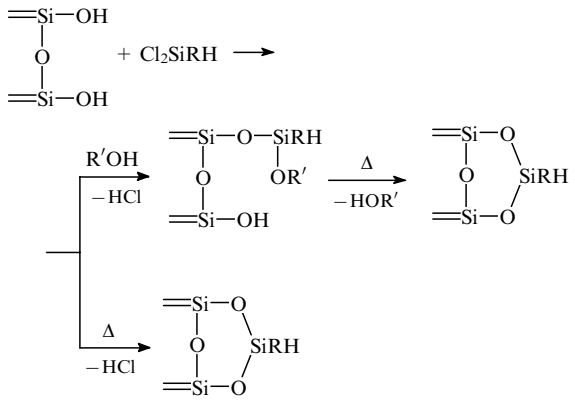
disappearance of the absorption bands due to the OH groups (3750 cm^{-1}) and the C–H bonds of the alkoxy groups (2850, 3070 cm^{-1}, Fig. 1, spectra *3* and *6*).

On the basis of these results, it was concluded that the reactions



R = Me, Ph; R′ = H, Me, Et

yield silicon hydride groups linked to the surface by two siloxane bonds. It is noteworthy that the characteristic vibration frequencies of the Si–H bonds of the $(\equiv Si-O)_2-SiRH$ groups do not depend on the way they were prepared and are determined only by the structure of the groups.

By mathematical processing of the experimental data given in Table 1 using the Taft inductive constants ($\sum\sigma^*$) for known substituents,[16] the coefficients of relation (4) were determined and the following expression was derived:

$$\nu_i = 2064 + 19.21(\sum\sigma^* + \sigma_s^*). \quad (5)$$

The value $\sigma_s^* = 5.05$, which was also obtained using these experimental data, serves as a measure of the inductive effect of the silicon–oxygen group on the reaction centre.

It can be seen from Table 1 that the surface functional groups can contain various substituents (for example, Cl, Ph); however, this does not cause a significant departure of the ν_i values from linear dependence (5). The presence of a linear correlation between ν_i and σ^* shows that the electronic effects are transmitted through the silicon atom by the inductive mechanism, while the conjugation effects do not play a significant role. The value $\sigma_s^* = 5.05$ serves as a quantitative measure of the electronic state of the silica surface under the experimental conditions.

Table 2. Influence of thermal treatment on the concentration of hydroxyl groups and the inductive constant of silica.[18]

Parameter	Temperature of the thermal treatment /K						
	473	573	673	773	873	973	1073
Concentration of the OH groups /μmol m^{-2}	7.8	5.6	3.4	3.0	2.6	2.3	1.5
ν (Si–H) /cm^{-1}	2152	2155	2161	2163	2165	2168	2170
σ_s^*	4.57	4.73	5.05	5.15	5.25	5.41	5.52

The data of spectroscopic investigations [20, 21] and quantum-chemical data [22, 23] showed that the reactivity of the surface silanol groups depends on their concentration, which, in turn, is a function of the temperature of dehydroxylation of the silica surface. This is due to an increase in the electronegativity of some surface silicon atoms caused by the removal of hydroxyl groups and/or water molecules from their coordination sphere and to electron density redistribution in the Si–O bonds. Thus, for samples with different degrees of hydration, the numerical σ_s^* values should be different. This was confirmed by experimental results. The experimental ν(Si–H) values for a series of Aerosil A-175 samples pre-evacuated at 473–1073 K were used to calculate, from Eqn (5), the σ_s^* values (Table 2) for samples with different concentrations of hydroxyl groups. Analysis of these results taking into account the high sensitivity of the Si–H bond to electronic effects of substituents showed that the relative shift of ν(Si–H) upon dehydration is rather small, namely, it does not exceed 20 cm^{-1} ($\sim$10% of the absolute value). This is due to the fact that the surface silicon atoms responsible for the change in the electronegativity of the [SiO_4] substituent are linked to the Si–H centre by a siloxane bond, which can suppress the inductive effect. The suppression coefficient (the transmission factor of the bond) Z can be derived from the ratio of the inductive constants for compounds with a chain of bonds

$$\sigma_{\equiv Si-(OSi\equiv)n} = \sigma_{(\equiv Si-)}Z^n. \quad (6)$$

The numerical value of Z was found from the values of σ_s^* for the following surface groups: (*1*) $\equiv$Si–H ($n = 0$); (*2*) $\equiv Si-O-Si(CH_3)_2H$ ($n = 1$) (see Table 2); and (*3*) $\equiv Si-O-Si(CH_3)_2-O-Si(CH_3)_2H$ ($n = 2$).

Compounds with type *1* and *3* fragments were synthesised by the reactions

$$\equiv Si-OH + CH_3OH \xrightarrow[-H_2O]{} \equiv Si-OCH_3 \xrightarrow{1023\ K} \equiv Si-H + CH_2O,$$

$$\equiv Si-OH + Cl_2Si(CH_3)_2 \xrightarrow[-HCl]{} \equiv Si-O-SiCl(CH_3)_2 \xrightarrow[-HCl]{H_2O} \equiv Si-O-Si(CH_3)_2-OH \xrightarrow[-HCl]{ClSi(CH_3)_2H} \equiv Si-O-Si(CH_3)_2-O-Si(CH_3)_2H.$$

These reactions were monitored by IR spectroscopy directly in the IR cell serving as the reaction vessel, by following the disappearance of the absorption band for isolated Si–OH groups (3750 cm^{-1}) and the appearance of bands for the methoxy group [ν(C–H) = 2930 and 2970 cm^{-1}]. During high-temperature treatment, the methoxy groups were detached as formaldehyde to give silica hydride [24] with ν(Si–H) = 2280 cm^{-1}. The last reaction was accompanied by the appearance of absorption bands for the methyl groups with ν(C–H) = 2920 cm^{-1}. Using the ν(Si–H) values for the $\equiv Si-O-$, $\equiv Si-O-Si(CH_3)-O-$ and $\equiv Si-O-Si(CH_3)_2-O-Si(CH_3)_2-$ substituents, which were 2280, 2161 and 2120 cm^{-1}, respectively, the inductive

constants σ_s^* were calculated from Eqn (5) ($\sigma_{0s}^* = 11.24$ for $n = 0$; $\sigma_{1s}^* = 5.05$ for $n = 1$; $\sigma_{2s}^* = 2.91$ for $n = 2$). The Z value was determined as the average of the three values obtained by substitution of pairs of values into Eqn (6):

$$Z_1 = \frac{\sigma_{1s}^*}{\sigma_{0s}^*} = 0.449,$$

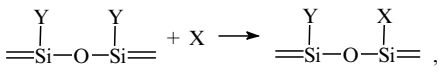
$$Z_2 = \frac{\sigma_{2s}^*}{\sigma_{1s}^*} = 0.576,$$

$$Z_3 = \left(\frac{\sigma_{2s}^*}{\sigma_{0s}^*}\right)^{0.5} = 0.509.$$

The resulting value, $Z = 0.51 \pm 0.04$, implies that the transmission ability of the siloxane bond in the synthesised surface compounds is rather great and does not differ much from that for linear siloxanes ($Z = 0.48$).[25] It can serve as a quantitative measure of the long-range effect of the silicon–oxygen core in the cases outlined below.

1. Variation of the reactivity of the functional group Y separated from the core by a chain of siloxane bonds, for example, $\equiv Si-(O-SiR_2-O)_n-Y$.

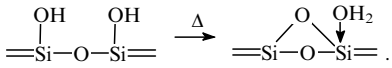
2. Variation of the reactivity of the functional group Y or X toward the reaction



for example, in the synthesis of silicas with functional groups of different types.

The parameters of the $\equiv Si-O-Si\equiv$ bond for silicas (the Si–O distance is 0.160–0.167 nm, the SiOSi angle is 150–170°) vary in the same range as those for linear or cyclic siloxanes.[25] This suggests that the transmission ability of siloxane bonds located on the silica surface should not differ much from that for silanes synthesised on the silica surface; this was confirmed by experimental data.

The relatively small shifts of ν(Si–H) during dehydration can also be attributed to the fact that dehydroxylation of the surface is usually accompanied by the formation of new aqua complexes



Therefore, the decrease in the coordination number of surface silicon atoms is partially compensated. The high sensitivity of the Si–H bond to the nature of the substituent allowed the researchers to detect the deviation of the dependence $\sigma_s^* = f(T)$ from the general linear dependence at $T < 600$ K ($c_{OH} > 5$ μmol m^{-2}) (Fig. 2). A substantial increase in the concentration of aqua complexes under these conditions and an increase in the coordination number of surface silicon atoms resulted in a decrease in their effective electronegativity, which told on the dependence $\sigma_s^* = f(T)$. The activation energy for dehydroxylation estimated based on the temperature dependence of the total concentration of the hydroxyl groups was ~160 kJ mol^{-1}; this value falls within the range reported by Gorlov *et al.*[26]

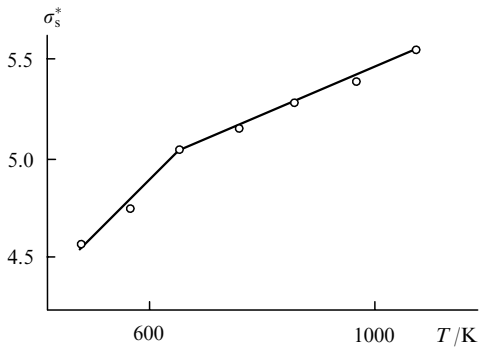


Figure 2. Influence of thermal treatment on the Taft inductive constant of silica.

IV. Estimation of the inductive effect of the core of some dispersed oxides

The good prospects of using correlation analysis for establishing the pattern of the electronic influence of a solid core were demonstrated for zinc, magnesium, beryllium, titanium and aluminium oxides, whose acidity constants vary over a rather broad range. Pelleted samples of these oxides were hydroxylated by water vapour and then treated with dimethylchlorosilane (DMCS) vapour at temperatures recommended for each oxide.[11,12]

For surface groups of the $MO-SiR_2H$ type, the ν(Si–H) values should depend not only on the metal of the surface but also on the type of OH groups involved in the formation of the silicon hydride group. In other words, the ν(Si–H) values should reflect the electron-withdrawing properties of the metal oxide surface fragment and, hence, the reactivity of the hydroxyl groups attached to it.

The IR spectra of these oxides treated with a DMCS vapour showed a number of specific features.[15] Figure 3 presents the IR spectra of the initial and DMCS-vapour treated samples of beryllia, titania and alumina. As a result of chemisorption, thermally stable compounds $MOSi(CH_3)_2H$ were formed on the

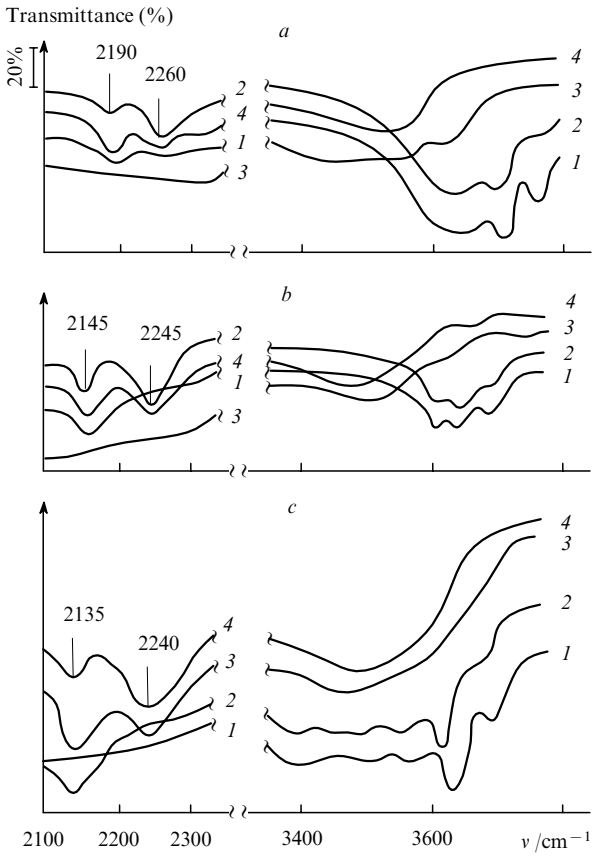

Figure 3. IR spectra of alumina (*a*), titania (*b*) and beryllia (*c*).[15] Samples: (*1*) initial; (*2*) treated with traces of DMCS at 473 K, $P = 1$ Pa, $\tau = 30$ min; (*3*) treated with traces of DMCS at 473 K, $P = 50$ Pa, $\tau = 30$ min; (*4*) evacuated while maintained at a constant temperature (523 K), $\tau = 60$ min.

oxide surface. For low pressures of DMCS vapour (~ 1 Pa), the spectrum of beryllia showed a decreased intensity of the band for the OH groups of type I (3720 cm^{-1}) and a new absorption band for the Si–H bond (2135 cm^{-1}, see Fig. 3 *c*; curves *1*, *2*). When the DMCS vapour pressure was increased to 50 Pa, the OH groups of type II (3630 cm^{-1}) entered into the reaction to give new silicon hydride groups [ν(Si–H) = 2240 cm^{-1}, see Fig. 3 *c*; curve *3*]. Similar changes were noted for TiO_2 (anatase) (see Fig. 3 *b*) and γ-Al_2O_3 samples (see Fig. 3 *a*).

It was found that the hydroxyl groups of type I were the first to react on the surfaces of all of the oxides. However, judging by the intensity of the Si–H absorption band and the thermal stability of the groups formed, type I hydroxyl groups are expected to be least reactive in electrophilic substitution. This contradiction can be explained by the influence of steric factors in heterogeneous chemical processes. The low concentration and the spatial positions of the 'sunk' OH groups of types II or III are unfavourable for surface reactions.

Treatment of the surfaces of zinc and magnesium oxides with DMCS vapour did not give thermally stable surface compounds of the $MOSiR_2H$ type. In this case, the absorption bands for type I and II hydroxyl groups were found to shift due to the presence of chlorosilane on the surface. The subsequent thermal treatment resulted in complete desorption, indicating the absence of chemical bonds with the surface. A possible reason is low electrophilicity of DMCS in surface reactions with the relatively inert hydroxyl groups of these matrices.

By comparison of the σ_s^* values calculated using the experimental ν(Si–H) frequencies for the $\equiv$SiH groups synthesised on reaction centres of the same type (Table 3), the oxides studied can be arranged in the following sequence according to increasing effective electronegativity of the core:

$$MgO \approx ZnO \ll BeO < TiO_2 < SiO_2 < \gamma\text{-}Al_2O_3.$$

No hydroxyl groups of type III were revealed in these experiments, probably, because they are present in a very low concentration if at all.

Table 3. Vibration frequencies of the OH and SiH groups and the Taft inductive constants of the oxide core ($T = 473$ K).[15]

Oxide	Type of OH groups	ν(OH) /cm^{-1}	ν(Si–H) /cm^{-1}	σ^*
BeO	I	3720	2135	3.70
	II	3630	2240	8.93
TiO_2	I	3700	2145	4.21
	II	3640	2245	9.42
γ-Al_2O_3	I	3780	2190	6.55
	II	3720	2260	10.20
SiO_2	I	3750	2152	4.57

The inductive effect is polarisation of σ bonds transferred along the chain of atoms; therefore, the inductive effect of the core would affect the electron density distribution in a hydroxyl group connected to this core. The above sequence reflects not only the effective electronegativity of the solid core; the particular value of σ_s^* of each member of the sequence can be used to estimate the reactivity of the surface hydroxyl groups. The data obtained using this approach are in good agreement with the results obtained by other procedures, for example, based on acidity constants.[10–12]

V. Quantitative estimation of the reactivity of hydroxylated surfaces of single-crystal matrices

The possibility of using the inductive effect to describe the surface phenomena demonstrated for dispersed oxide matrices opens up prospects for quantitative estimation of the reactivity of the surface hydroxyl groups on single-crystal, in particular semiconductor, matrices. Solution of this problem would allow one to predict the processes of template synthesis of nanostructures and promote the chemical nanotechnology for elaboration of the submicrometer component base for electronic engineering. As an example, one can consider the results obtained for silicon samples with (111) and (100) orientations by multiple attenuated total internal reflection (ATIR) IR spectroscopy.[27,28] In experiments, the angle of incidence of the beam θ was 45° and the number of reflections n was 28. The ATIR spectra were recorded directly in the cell-reaction vessel, which ensured treatment of the sample surfaces either in a vacuum (down to 10^{-3} Pa) or in a controlled medium in the temperature range of 20–600 °C.

Study of the hydroxylation of freshly etched silicon and the subsequent sorption of DMCS has shown[27,28] that the spectral pattern in the frequency region 3700–3750 cm^{-1} is similar to that observed for a dehydrated surface of narrow-pore silica gels.[29] The adsorption of DMCS resulted in the formation of tetramethyldisiloxane as a result of hydrolysis of the sorbed compound by the water molecules present on the surface as thermally stable aqua complexes. The tetramethyldisiloxane formed was not chemically bonded to the silicon surface and was completely desorbed upon temperature rise.[27,28]

On the basis of these data, it was concluded that silanol groups present on the silicon surface, like the hydroxyl groups of zinc and magnesium oxides, do not react with DMCS, whereas the OH groups on the silica surface are chemically reactive under similar conditions and form thermally stable surface compounds, $\equiv Si-O-Si(CH_3)_2H$ [ν(Si–H) = 2152 cm^{-1}]. This fact can be attributed either to low electrophilicity of DMCS or to different electronic structures of silicon and silica surface atoms. A surface of even freshly etched silicon contains an ultrafine (1.0–1.5 nm) oxide film;[30] therefore, on treatment with water vapour, in addition to silanol groups, one can also expect the formation of a hydration cover linked by coordination bonds. Presumably, the energy of the coordination bonds of aqua complexes is somewhat higher in this case, because the ultrafine oxide film on the surface of a single crystal is depleted in oxygen. In the depleted surface film, the probability of electron density displacement from silanol groups is much lower; therefore, they do not exhibit sufficient proton-donor capacity and do not react with DMCS.

The activation energy for the electrophilic replacement of the proton of silanol groups is known[31] to depend on the proton-acceptor properties of the attacking reagent; therefore, one can choose a substituted silane capable of reacting with relatively inert hydroxyl groups on the silicon surface. Triethoxysilane (TES) was chosen for this purpose. Its reaction with the silicon surface was studied at different temperatures ranging from room temperature

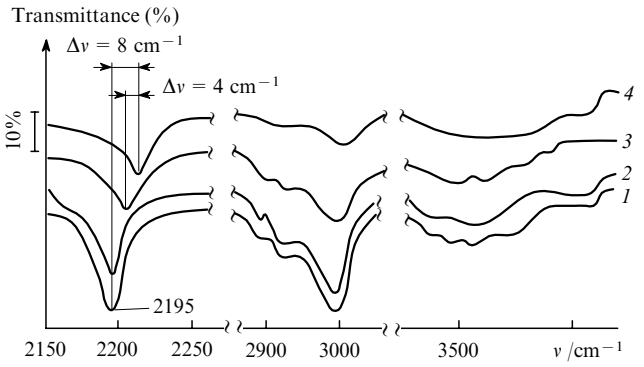

Figure 4. ATIR infrared spectra of a silicon surface;[28] (*1*) after hydration at 473 K and subsequent treatment with TES vapour at 300 K; (*2*, *3*) after evacuation at constant temperatures of 373 K and 473 K, respectively, for 30 min; (*4*) after rehydration in water vapour at 473 K.

to 673 K. Figure 4 shows the ATIR spectra of samples subjected to different types of thermochemical pretreatment. Stable surface compounds containing Si—H bonds were synthesised, and not only the inductive effect of the matrix but also the stoichiometry of the surface reaction was determined.

When samples evacuated for 1 h at 473 K are treated with water vapour at the same temperature, then cooled and treated with TES vapour at room temperature, the spectrum (see Fig. 4, spectrum *1*) exhibits an absorption band for the Si—H bond and a characteristic set of bands for the C—H bonds of the ethoxy groups. The ν(Si—H) frequency in this spectrum coincides with the Si—H stretching frequency for triethoxysilane (2195 cm^{-1}). This points to the absence of any chemical reactions in the system. After maintaining the sample for 30 min at 373 K, the spectrum (spectrum *2*) shows deformation of the low-frequency region of the Si—H band caused by the appearance on the silicon surface of adsorbed alkoxy-substituted disiloxane having formed in a reaction similar to the reaction with DMCS. Only after maintenance at 473 K for 1 h do the intensities of the Si—H and C—H absorption bands decrease. As this takes place, the band of the Si—H vibrations becomes symmetrical and its maximum shifts by 8 cm^{-1} to shorter wavelengths relative to the position of this band in the spectrum of sample *1* not kept at a constant temperature. The decrease in the intensity of the Si—H and C—H absorption bands is due to the thermal desorption of excess reagent and the disiloxane formed, while the observed shift of the ν(Si—H) absorption maximum is caused by the replacement of one or several alkoxy groups by more electronegative substituents. The above-listed changes in the spectral characteristics and the thermal stability of the product obtained at 473 K attest to its chemical bonding to the surface, which could result only from the reaction between the silanol groups and the ethoxy groups of the sorbed silane,

$$(\equiv Si-OH)_m + (C_2H_5O)_3SiH \longrightarrow$$
$$\longrightarrow (\equiv Si-O-)_mSi(OC_2H_5)_{3-m}H + m\,C_2H_5OH.$$

The alkoxy groups not involved in the reaction can be replaced by hydroxyl groups by treating the sample surface with water vapour. Indeed, when comparing spectra *2* and *3* (see Fig. 4), one can see that hydration entails an increase in the intensity of the C—H absorption band and substantial enhancement of the absorption in the OH stretching region (3600–3700 cm^{-1}). The ν(Si—H) mode shifts by 4 cm^{-1} to shorter wavelengths. The changes observed in spectra *3* and *4* are due to the reaction

$$(\equiv Si-O)_mSi(OC_2H_5)_{3-m}H + (3-m)\,H_2O \longrightarrow$$
$$\longrightarrow (\equiv Si-O)_mSi(OH)_{3-m}H + (3-m)\,C_2H_5OH.$$

The stoichiometry of the surface reactions, *i.e.*, the numerical value of the coefficient m, can be determined using correlation equation (5). By transforming this relation and replacing $(3-m)$ alkoxy groups with $\sigma^*(OC_2H_5) = 1.366$ (see Ref. 16) by an equivalent number of OH groups with $\sigma^*(OH) = 1.550$ (see Ref. 16), one can determine the shift of the stretching frequency of the Si—H bond

$$\Delta\nu(Si-H) = a(3-m)[\sigma^*(OH) - \sigma^*(OC_2H_5)];$$

hence,

$$m = 3 - \frac{\Delta\nu(SiH)}{a[\sigma^*(OH) - \sigma^*(OC_2H_5)]} =$$
$$= 3 - \frac{4}{19.21(1.550 - 1.366)} = 1.86 \approx 2.$$

Thus, the structure of the surface compounds formed in the reaction with TES can be represented as $(\equiv Si-O)_2Si(OC_2H_5)H$. By using Eqn (5) and substituting the value ν(Si—H) = 2203 cm^{-1} (see Fig. 4, spectrum *4*) for this compound into the equation, one can estimate the inductive effect of the silicon–oxygen groups present on the surface of single-crystal silicon against the scale of the Taft inductive constants

$$\sigma_s^* = \left[\frac{\nu_i - \nu_0}{a - \sigma^*(OC_2H_5)}\right]m^{-1} =$$
$$= \frac{(2203 - 2064)/19.21 - 1.366}{2} = 2.90.$$

For silica, this parameter is much higher. Thus for Aerosil dehydrated at the same temperature, $\sigma_s^* = 4.57$ (see Table 2). Comparison of the numerical values of these parameters showed that the silanol groups on the silicon surface are much weaker proton donors than the same groups on the silica surface. Most probably, this is due to the inhibitory inductive effect of the silicon core.

In addition, the hydration cover formed upon heating of the silicon surface in water vapour, was found to contain, apart from silanol groups, the OH groups of water molecules attached to the surface silicon atoms by coordination bonds. The results shown in Fig. 2 may suggest that quantitative dehydration of the surface of the oxidised single crystal would take place during evacuation only at $T > 600$ K. It is noteworthy that the observed changes in the spectral characteristics of silicon cells did not depend on the crystallographic orientation of the samples to within the sensitivity of the method. The lack of this dependence is due to the fact that the influence of the surface oxide layer is more significant than that of the single-crystal silicon core.

The inductive effect of the core of the GaAs binary semiconductor with orientation (100) was estimated for ATIR cells having $\theta = 30^\circ$ and $n = 28$. At temperatures of 423–523 K, active chemisorption of DMCS was observed on the GaAs surface containing a natural oxide layer [ν(Si—H) = 2165 cm^{-1}]; the calculated value is $\sigma^* = 5.25$. After etching of the surface of this semiconductor with a $CH_3OH : Br_2$ (100 : 1) mixture with subsequent washing with methanol and double-distilled water, the σ^* value decreased to 5.1 [ν(Si—H) = 2162 cm^{-1}], which is due to a decrease in the oxide layer thickness. However, in any case, the σ^* value is greater for the GaAs surface than for silicon or silica surfaces. The higher inductive effect of this matrix is caused by the fact that it incorporates a more electronegative component (arsenic) and its oxides. Therefore, there are grounds for believing that the hydroxyl groups on a real GaAs surface should exhibit rather high proton-donor capacity and hence, they can be used in surface chemical reactions with relatively weak electrophilic reagents. This fact is of certain interest for the production of surface nanostructures on this matrix.

VI. Effect of the thickness of the oxide layer on the activity of silanol groups on the silicon surface

On the basis of analysis of the experimental data concerning the inductive effect of silica, silicon and gallium arsenide cores, one can suggest that the reactivity of the hydroxyl groups occurring on the real surface of a semiconductor crystal would be determined by sample prehistory, namely, the thickness of the oxide layer formed during the pretreatment. From the inductive effect, this influence can be derived and the pattern of variation of the reactivity of the silanol groups present on the silicon surface with different degrees of oxidation can be elucidated. To this end, one merely has to analyse the spectral characteristics of chemisorbed silanes on matrices with different known thicknesses of the oxide. These experiments were carried out for silicon samples (ATIR cells) on which a specified oxide layer was synthesised by molecular layering,[27, 28, 31] *i.e.*, by alternating treatment of the surface with silicon tetrachloride and water vapours. The layer thickness was determined by ellipsometric measurements and calculated in the Drude–Tronston one-layer model approximation.[32] The measurements were carried out using an ellipsometer with a

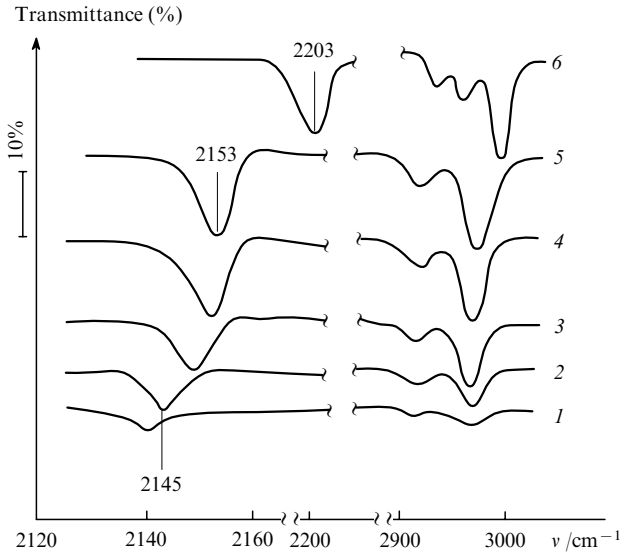

Figure 5. ATIR infrared spectra of the (111) silicon surface subjected to cyclic treatment with silicon tetrachloride and water vapours at 473 K with subsequent treatment with DMCS at the same temperature.[27,31]
The number of cycles is 4 (*1*), 10 (*2*), 20 (*3*), 30 (*4*), 40 (*5*); spectrum of the sample after etching and treatment with triethoxysilane (*6*).

fixed compensator and magnetic modulation of the light beam. The error of determination of these parameters did not exceed $\pm 0.01'$.

Figure 5 shows the IR spectra of ATIR silicon samples with a synthesised SiO_2 layer pretreated with DMCS vapour at 473 K, and Fig. 6 shows the dependence of the thickness of this layer (d) and the relative Si—H absorption intensity on the number of molecular layering cycles (N). Comparison of spectra *1–4* (see Fig. 5) showed that an increase in the thickness of the synthesised oxide layer entails a substantial increase in the absorption intensity in the region of the Si—H (2135–2150 cm^{-1}) and C—H (2900–3000 cm^{-1}) stretching frequencies and a noticeable shift of the ν(Si—H) bond to shorter wavelengths. This pointed unambiguously to an increase in the concentration of silanol groups capable of reacting with DMCS; moreover, up to $N \approx 15$ ($d \approx 3$ nm), the number of reactive centres increased in proportion to N and subsequently it changed only slightly (see Fig. 6).

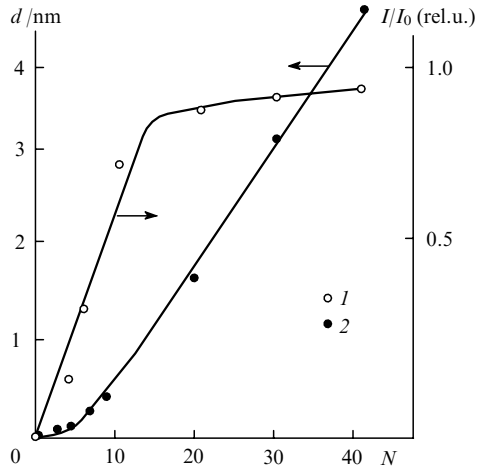

Figure 6. Relative intensity of the absorption bands for the Si—H bond (*1*) and thickness of the oxide layer (*2*) *vs.* the number of molecular layering cycles (N).[31]

As shown above, the silanol groups on a freshly etched silicon surface did not react with DMCS at all, but they did react with more active TES to give surface compounds. For comparison, Fig. 5 shows a fragment of the spectrum (curve *6*) of a freshly etched ATIR silicon cell pretreated with TES vapour. With an increase in the oxide thickness, the influence of the silicon core becomes less pronounced, while the role of the oxide with a large σ_s^* value is enhanced and, hence, the reactivity of the silanol groups increases. This appears to be also the reason for the retardation of the formation of the oxide layer upon chemisorption of $SiCl_4$, which is observed in the initial stages of the synthesis ($N < 10$) (see Fig. 6).

These results allowed the researchers to establish the quantitative relationship between the thickness of the oxide layer on the silicon matrix and its inductive effect and, hence, the activity of the hydroxyl groups (Fig. 7). As noted above, the most pronounced changes in σ_s^* were observed up to an oxide layer thickness of $\sim$3 nm. The inductive effect of the silicon core with thick oxide layers was almost the same as the effect of silica. In this case, as expected, active chemisorption of DMCS took place. It should be borne in mind that even a silicon surface freshly etched in aqueous solutions has a thin oxide layer ($\sim$1 nm, according to our estimates) and the σ_s^* value calculated from experimental ν(Si—H) to be 2.9, refers to such a surface.

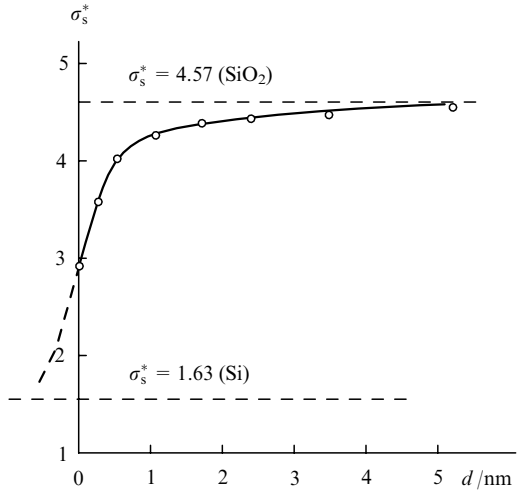

Figure 7. Influence of the thickness of the synthesised oxide layer on the inductive constant of silicon.[28]

The inductive constant estimated from the stretching frequency of the Si—H groups formed during etching of silicon with hydrofluoric acid [ν(Si—H) = 2096 cm^{-1}] amounts to 1.63. This value refers to a silicon surface almost deprived of the oxide layer and is indicative of a low reactivity of the silanol groups linked directly to the silicon core. If the surface contains a SiF group, the σ_s^* value can only increase; however extrapolation of the $\sigma_s^* = f(d)$ curve to $\sigma_s^* = 1.63$ (see Fig. 7) gives a real thickness of the residual oxide that coincides with ellipsometric estimates.

Thus, all real silicon matrices can be represented as a number of chemical compounds with the general formula $Si_m(SiO)_x.(SiO_2)_yOH$ where each particular composition (x and y values) is matched by a particular σ_s^*; at great y, this corresponds to the final member of the series, silica $(SiO_2)_yOH$.

The σ_s^* values obtained were indicative of relatively weak proton-donor properties of silanol groups both for a pure silicon surface and for a surface coated by a thin (< 3.0 nm) oxide layer. This means that for complete involvement of these groups in surface reactions, conditions should be provided for additional protonisation of hydroxyl groups. These conditions can be attained by raising the temperature (or by another activating

treatment) or by using proton-acceptor chemical reagents. For example, the use of triethylamine [27] as an exchange catalyst eliminates the latent period in the formation of silicon oxide layers (see Fig. 6) and allows the synthesis of silicon oxide nanostructures on hydroxylated surfaces of metals [33] in which the inductive effect of the core is relatively low for the same reasons as for silicon.

It should be noted that, judging by the transmission effect of the silicon–oxygen bond ($Z_{Si-O-Si} = 0.51$), the changes in $\Delta\sigma_s^*$ and, hence, the shift of ν(Si—H) should be much smaller for $N < 10$. If one oxide monolayer is synthesised per cycle of molecular layering, for N cycles, this should be

$$\Delta\sigma_s^* \sim Z^N = 0.51^N.$$

However, this relationship was not observed. Probably, in the initial stages of the molecular layering synthesis ($N < 10$), surface reactions involve only a part of hydroxyl groups and give rise to two-dimensional islet structures whose area increases upon further treatment. This is also indicated by the increase in the intensity of the bands for both Si—H and C—H bonds caused by the increase in the area occupied by the oxide.

An attempt to establish the general relationship between the inductive constants and the energetic characteristics of the studied matrices has revealed a linear correlation with the energy of the crystal core. For a gallium arsenide surface whose composition can be represented as a mixture of gallium and arsenic oxides, the experimental σ_s^* values fit well into the general linear dependence. The estimation of the presumptive σ_s^* values for MgO and ZnO using this dependence gave 2.8 and 2.2, respectively. These values could not be determined experimentally due to the low electrophilicity of DMCS.

VII. Conclusion

The material considered in this review shows good prospects for the use of the inductive effects and correlation analysis to study chemical transformations on the surface of solids. By comparison of inductive constants, it becomes possible not only to estimate quantitatively the influence of the core and the state of the surface for various solids on the processes taking place during thermal treatment but also to predict the pattern of surface reactions with various reagents. For this purpose, one should compare the σ_s^* and σ^* values for a substituent in a low-molecular-weight reagent. The reaction would proceed toward the replacement of the given substituent by a substituent with a greater inductive constant.

In a study of surface reactions on objects with small surface areas, for example, on single crystals, an important feature is the possibility of determining their stoichiometry when the use of direct chemical or analytical methods is difficult. The cited example of solving this problem for the silicon matrix convincingly demonstrates the utility of the parametric constants of the correlation equations.

Further development of the quantitative approach based on the use of inductive constants would involve selection of a standard surface reaction and determination of its characteristics (rate and equilibrium constants). This would enable quantitative prediction of the pathways and yields of surface reactions merely based on one-parameter correlation equations taking into account only the inductive effect. As a standard reaction, one can use the rearrangement [33] between chemisorbed chloro- and alkoxysilanes whose equilibrium constant can be found experimentally without much difficulty.

At the current stage of research, the inductive effect of substituents (including the core of a solid) can be estimated only as a certain approximation. Therefore, any task of exact determination of the inductive component in nonuniform surface phenomena is arbitrary and the result will depend on the choice of the standard process which underlies the scale of inductive constants used. However, this approach, which provides a quantitative description of surface processes, may prove useful for development of the routes of deliberate synthesis of surface nanostructures and development of chemical nanotechnology.

Abstract. The review surveys and generalises recent data on synthesis methods, physicochemical properties and crystal chemistry of silicate microporous materials containing transition elements (amphoterosilicates). The frameworks of these materials, unlike those of usual aluminosilicate zeolites, are built from tetrahedrally coordinated atoms along with atoms of various elements (Ti, Nb, Zr, Ta, Sn, W, Fe, Mn, Zn, *etc*.) with coordination numbers of 6 or 5. Many amphoterosilicates possess ion-exchange properties and can serve as catalysts for redox reactions, sorbents, *etc*. The structural diversity of synthetic and natural amphoterosilicates provides the basis for the preparation of microporous materials with different properties. The bibliography includes 195 references.

I. Introduction

Zeolites are finding increasing applications in industry and agriculture due primarily to their sorption, ion-exchange and catalytic properties.

Framework structures of traditional zeolites and zeolite materials, such as aluminosilicates, aluminophosphates, silicoaluminophosphates and silicas, are formed by four-coordinate elements (Si, Al, P, B, Be, Zn, *etc*.). However, studies performed in the last two – three decades demonstrated that many titano-, niobo- and zirconosilicates, tantalates, niobates, uranylphosphates, *etc*. are also able to be involved in ion exchange with solutions, supercritical fluids and electrolyte melts without destruction of the crystal structure. The classification (although incomplete) of the active exchange sites based on the differences in the character of charged polyanionic matrices was given by Chelishchev *et al*.[1] In the cited study, it was also noted that a number of solids which have non-aluminosilicate frameworks and do not exhibit ion-exchange properties at room temperature, begin to take on these properties under supercritical conditions.

Beginning in the 1990s, the synthesis of zeolite-like materials of a new type, primarily, of silicates whose frameworks contain five- and six-coordinate Ti, Nb, Zr, Al, V, Ga, *etc*. atoms along with tetrahedral fragments, has attracted growing interest. The first review devoted to such investigations (43 original studies were surveyed) was published in 1996.[2] Zeolite materials of this type whose frameworks generally contain transition elements are characterised by a considerable structural diversity, which allows one to prepare microporous materials with a broad spectrum of physical and chemical properties.

Data on the synthesis and ion-exchange properties of microporous titano-, zircono- and niobosilicates are scarce because of laborious and time-consuming procedures for the synthesis of these materials, the lack of reliable methods for predicting the structures and properties of the products and problems associated with studies of these compounds, which are prepared as fine powders and are often structurally disordered and inhomogeneous. Available abundant data on the structures, properties and conditions of formation of natural aqueous alkali silicates containing amphoteric transition elements (Ti, Nb, Zr, Fe, Mn, Zn, *etc*.), the so-called amphoterosilicates (the term was proposed by Khomyakov[3]), can be of great help in designing experiments on the synthesis of aqueous titano-, niobo- and zirconosilicates. Amphoterosilicates are rather diverse and often form large single crystals suitable for X-ray diffraction analysis. Unfortunately, investigations on synthetic titano-, niobo- and zirconosilicates and studies of their natural analogues (minerals) are not generalised. In this connection, one of the aims of the present review is to bridge the gap between these fields of investigations. Hence, considerable attention is given to the crystal-chemical features of amphoterosilicates of natural origin along with those of synthetic non-aluminosilicate zeolites.

II. Synthesis of microporous amphoterosilicates

Until recently, studies on the synthesis of alkali silicates containing transition elements were aimed primarily at modelling processes of mineral formation. In particular, analogues of a number of zeolite-type minerals were synthesised. For example, one of the most structurally complex zirconosilicates, *viz*., eudialyte, was synthesised[4] in a weakly alkaline aqueous medium from a $6\,SiO_2 + ZrO_2 + 6\,Na_2CO_3 + CaCO_3 + FeCl_2 + 4\,H_2O$ mixture in the presence of Na_2SiF_6 or K_2SiF_6 as catalysts (the temperature range was 450 – 550 °C, the water vapour pressure was 85 – 700 atm). In the presence of aluminium, eudialyte is unstable. Khibinskite $K_2ZrSi_2O_7$ was synthesised by fusing a mixture of

KOH, K_2CO_3, SiO_2 and $ZrSiO_4$ at 1250 °C followed by gradual cooling at a rate of 10 K h^{-1}.[5] A sodium analogue of khibinskite, *viz*., parakeldyshite, was synthesised[6] under hydrothermal conditions in the $ZrO_2-SiO_2-Na_2O-H_2O$ system. Even these examples demonstrate that zeolite-like amphoterosilicates, like aluminosilicate zeolites, crystallise in a wide temperature range.

The titanium-doped aluminium-free silicate called the material TS-1[7] is one of the first synthetic microporous titanosilicates which has no mineral analogues. In the structure of this material, the Ti^{4+} ions occupy tetrahedral positions. This material proved to be an active catalyst for oxidation reactions.

The microporous titanosilicate ETS-10 belongs to materials which hold most promise for practical applications (ion exchange, catalysis). In its structure, alternating corner-sharing SiO_4 tetrahedra and TiO_6 octahedra form a three-dimensional framework with broad channels.[8,9] In one of the two polymorphs of ETS-10, these channels are helical. In ETS-10, silicon is readily replaced by aluminium and gallium.[2,10] The material ETS-10 is most often prepared under hydrothermal conditions at 200–220 °C and pH ~10.5 from a mixture of $TiCl_3$ and/or $TiCl_4$ (and/or rutile or anatase, TiO_2) with silica in a molar ratio Si : Ti = 5–6.[11] In some cases, the synthesis is carried out in the presence of tetramethylammonium.[12] The synthesis can also be performed with the use of more stable TiF_4, including in the presence of tetramethylammonium.[13] Yet another procedure is based on the preparation of ETS-10 directly from titanosilicate gels with additives of another titanosilicate zeolite, *viz*., ETS-4, or organic matrices or without additives.[14] A Co-substituted analogue of ETS-10 containing cobalt in octahedral coordination was synthesised.[15] The presence of cobalt atoms in octahedral coordination leads to an increase in the unit cell parameters. In the study,[16] a 23-factor method of optimisation of the total composition of the reaction mixture was used for the rapid synthesis of ETS-10 and ETS-4, and a procedure was developed for the preparation of high-crystallinity ETS-10 in the presence of a large excess of water and moderate alkalinity of a solution for 18 h. In the cited study, the kinetics of crystallisation of ETS-10 was investigated (for the composition which was optimum from the viewpoint of the yield of the final product) and the activation energy of the process was evaluated at 66.8 kJ mol^{-1}. The enthalpies of formation of ETS-10 with composition $K_{0.61}Na_{1.09}Ti_{1.10}Si_{4.98}O_{13}\cdot 2.89\,H_2O$ from oxides or elements, which were determined from the heats of dissolution in lead borate at 974 K, are -262.2 ± 3.1 and -6995.2 ± 6.1 kJ mol^{-1}, respectively.[17]

In 1996, an analogue of minerals of the labuntsovite group was synthesised for the first time under hydrothermal conditions.[18,19] This synthesis afforded a series of specimens which have the nenadkevichite structure and Ti : Nb ratios from 0.8 to 12.3. A niobium-free phase corresponding to korobitsynite was also prepared. In physical properties and chemical composition (sodium as an extraframework cation) as well as based on powder X-ray diffraction patterns, these materials are analogous to natural minerals of the nenadkevichite subgroup (space group *Pbam*, $a = 7.41$, $b = 14.20$, $c = 7.15$ Å).

The titanosilicate material ETS-4 was also synthesised in 1996. This material was considered alternatively either as a thin intergrowth of zorite with nenadkevichite[20] or as an analogue of zorite and an intermediate for the synthesis of nenadkevichite[18] (by nenadkevichite was meant its titanium analogue, *viz*., korobitsynite). Subsequent studies[21,22] confirmed that ETS-4 is identical to zorite. Hence, it became apparent that korobitsynite is formed as a by-product in the synthesis of ETS-4.

The ease of isomorphous replacement of titanium by niobium in most silicates and in many oxides allows one to smoothly control the characteristics of microporous materials based on these elements. The replacement of titanium by zirconium provides even greater scope for these purposes. The synthesis under hydrothermal conditions afforded[23] a broad spectrum of mesoporous titano- and zirconosilicates Ti-MCM-41 and Zr-MCM-41 with Si : Ti and Si : Zr ratios varying from 11 to 96 as well as a series of zirconotitanosilicate zeolites with composition $(H,K)_2(Zr,Ti)Si_3O_9\cdot n\,H_2O$ containing a three-dimensional system of channels, whose sizes are smoothly varied in the course of the isomorphous replacement of titanium by zirconium.[24] The hydrothermal synthesis of a microporous material possessing ion-exchange properties, which is a structural analogue of penkvilksite-1*M*, was carried out[25] in the $SiO_2-TiO_2-Na_2O-H_2O-$ trimellitic anhydride system. The discovery of the natural mineral tumchaite,[26] which is a tin-containing zirconium analogue of penkvilksite, gives promise that the completely isomorphous system $Na_2(Zr,Ti,Sn)Si_4O_{11}\cdot 2\,H_2O$ with smoothly variable properties will be prepared for this structure type.

In addition to the commonly accepted hydrothermal method, the dry-gel conversion method is also used for the synthesis of microporous titanosilicates. In particular, based on spectroscopic data, it was suggested that the application of this method to the Ti-Nu-1 gel gives rise to microporous materials containing titanium in tetrahedral coordination.[27] In some cases, titanium-containing microporous materials were prepared by modifications of boro- or aluminosilicate zeolites.[28,29] The problems of the synthesis and modifications of microporous titano-, niobo- and zirconosilicates were also considered in the studies.[30–47] Noteworthy is the hydrothermal synthesis in the homogeneous $NbCl_5-SiO_2-NaOH$ (KOH) $-H_2O_2-H_2O$ systems giving rise to framework potassium and sodium niobosilicates, which possess ion-exchange activity with respect to a broad spectrum of cations in acidic media.[34] Methods for the synthesis of microporous silicates of rare-earth elements were described in the studies.[48,49]

The M : Si ratio (where M is a framework-forming transition element) in synthetic micro- and mesoporous materials can be varied over a very wide range. Silicon-free microporous niobates, tantalates, zirconates, stannates and titanates can be considered as limiting cases of zeolites with a purely octahedral framework. In particular, syntheses of materials which have structures of pyrochlore and some other niobates and possess various ion-exchange, transport and electromagnetic properties, were described in many publications.[50–55]

III. Crystal-chemical features of amphoterosilicates with zeolite properties

1. Crystal structures of synthetic microporous titanium, niobium and zirconium silicates

The zeolite properties of many alkali silicates containing Ti, Nb or Zr are determined by the difference in the force characteristics of their constituent cations. Having high force characteristics, transition elements play (along with silicon) the key role in structures of most of these compounds by forming three-dimensional frameworks, whereas elements possessing low force characteristics occupy cavities of the framework (along with water molecules). Hereinafter, the T atoms which are involved in complex anions and form covalent bonds with oxygen, are called (which is common practice in crystal chemistry) cations.

Unlike aluminosilicate zeolites containing cations of only two types, *viz*., tetrahedrally coordinated (Si, Al) and extraframework, zeolite-like materials with mixed-type frameworks involve a series of framework cations, which can be arranged in order of decreasing force characteristics (this decrease is manifested, in particular, in a decrease in the frequencies of the characteristic bands in IR spectra; see Table 1).[56] Various groups of cations play different roles in structure formation. The T, M and, generally, D cations are involved in the framework formation. The A cations are usually weakly bound to the framework and can be involved in ion-exchange processes in the absence of steric hindrance.

By analogy with zeolites, the framework density (FD) of non-aluminosilicate microporous materials can be calculated as the number of framework sites, *i.e*., the number of T, M and D cations, per 1000 $Å^3$. In zeolites, this value for aluminosilicate frameworks generally varies from 14 to 21. For example, FD = 14.5 for the large-pore zeolite shabazite, FD = 17 for

Table 1. Properties of cations in amphoterosilicates.

Type of position	Coordination number	Ionic radius /Å	Examples of cations [a]	Tendency to isomorphous substitution	Tendency to formation of vacant positions	Tendency to formation of split positions	Frequency range in IR spectra /cm^{-1} (see [b])
T	4	< 0.6	Si, Al, Zn, P [c]	–	–	–	900 – 1100
M	6	0.6 – 0.7	Ti, Nb, Zr, Fe^{3+}, Y, Mn^{3+}, Sn^{4+}	+	–	–	660 – 700
D	6	0.7 – 1.0	Mn^{2+}, Fe^{2+}, Mg, Zn, Ca	+	+	–	440 – 470
A	> 6	1.1 – 1.5	Na, K, Ca, Sr, Ba, Pb^{2+}, H_3O^+	+	+	+	< 400

[a] Charges are given only if elements can exist in different oxidation states; [b] the cation – oxygen stretching vibrations; [c] in microporous silicate materials devoid of transition elements, B and Be atoms also often serve as T cations.

clinoptilolite, which is widely used in practice, FD = 18.6 for the small-pore zeolite analcime, *etc*. For the framework aluminosilicate nepheline, which does not possess zeolite properties under normal conditions, FD = 22.1. For α-quartz, FD = 26.8. Apparently, the limiting framework densities, above which the zeolite properties are not observed, are in the range of FD = 21 – 22. This criterion can be used also (with minor reservations) for estimating zeolite properties of various amphoterosilicates (see below). Evidently, one should take into account that the ion-exchange and other properties characteristic of zeolites depend on the width and configuration of the channels and, consequently, are determined not only by the framework density but also by the sizes of the framework-forming polyhedra and their mutual arrangement, including the non-uniform distribution in the space.

As mentioned above, studies of the crystal structures of synthetic microporous materials present difficulties due to crystal imperfection and contamination by by-products of the synthesis. As a consequence, direct single-crystal X-ray methods are generally inapplicable for these purposes. In most cases, the structures of synthetic amphoterosilicates were studied either by analysing powder X-ray diffraction patterns (the Rietveld method) or indirectly based on the results of studies of local structures by IR, Raman, UV, ESR, NMR spectroscopy, *etc*.

The microporous titanosilicate ETS-10 has received the most study. The crystal structure of this material was established by both the Rietveld method [8,9] and single-crystal X-ray diffraction analysis.[57] It was found [8,9] that there are at least two polymorphs of ETS-10 and numerous types of this material, which differ in the degree of ordering. Both polymorphs (A, space group $P4_1$; B, space group $C2/c$) are characterised by large pores formed by twelve-membered rings of silicon – oxygen tetrahedra. The rings are linked in a mixed-type three-dimensional framework by sharing corners with Ti octahedra. In the structure of the modification A, the channels adopt a helical configuration. Generally, the synthesis of ETS-10 produces a mixture of the polymorphs A and B. The spatial distribution of extraframework cations in ETS-10 was determined.[58,59] In the studies,[60,61] the nature of the active sites and the configuration of the Ti octahedra were investigated by spectroscopic methods (ESR and X-ray spectral analysis).

The crystal structure of the titanosilicate AM-4 with composition $Na_3(Na,H)Ti_2O_2(Si_2O_6)\cdot 2.2\,H_2O$ can be described [62] as a quasilayered motif composed of chains of edge-sharing titanium – oxygen octahedra.

The relative amounts of T, M and D cations in amphoterosilicates can be varied virtually without limit. As mentioned above, microporous niobates and other complex oxides can be considered as the limiting case of zeolite-like materials whose frameworks are formed exclusively by MO_6 octahedra. However, these structures are beyond the scope of the present review. The mobility of cations in such materials and, as a consequence, their ability to be involved in ion exchange and exhibit ion conductivity are associated with structural disorder (see, for example, Refs 63 – 66).

2. Crystal structures of natural amphoterosilicates

In the last decade, considerable advances have been made in the crystal chemistry of minerals. This is associated with both an extension of instrumental capabilities (the use of synchrotron radiation and highly sensitive CCD detectors as well as an improvement of software) and a great interest in minerals as prototypes of materials with various technologically important properties. These materials are formed under conditions varying over a wide range (pressure, temperature, composition and viscosity of a medium, pH) and have different characteristic crystallisation times. It is often difficult or even impossible to use a combination of these conditions in laboratory practice. Suffice it to say that mineral formation in nature takes place over a geological period numbering in the millions of years.

Of the four thousand presently known mineral species, several hundred have zeolite-like structures, *i.e*., possess rigid three-dimensional frameworks. The cavities and channels in the frameworks are occupied by mobile cations, which are weakly bound to the framework (more rarely, additional anions are also involved), and water molecules. As mentioned above, only a minority of such minerals belong to zeolites in a classical sense of this term (*i.e*., framework aluminosilicates with a low framework density). Zeolite-like amphoterosilicates are most numerous and structurally and chemically diverse. Many such minerals occur in nature only in extremely hyperalkaline (the so-called hyperagpaitic) rocks characterised by an extremely high sodium and/or potassium content at a rather low activity of aluminium. These rocks are relatively rare in occurrence, but are characterised by a unique diversity of the mineral composition. Their mineralogy has been extensively studied in the last two decades, when many zeolite-like amphoterosilicates were discovered in such rocks and thoroughly studied. Most minerals of this type were discovered in the following four massifs of hyperalkaline rocks: the Lovozero and Khibiny massifs (the Kola Peninsula, Russia), Saint-Hilaire mountain (Quebec, Canada) and Ilimaussaq (Greenland, Denmark). The crystal-chemical features of natural microporous amphoterosilicates are briefly summarised in Table 2,[26,67 – 125] where these minerals are arranged in order of increasing framework density. As can be seen from this table, traskite, seidite-(Ce) and zorite have the most loose frameworks (*i.e*., are characterised by the lowest framework density) among natural amphoterosilicates. In this respect, traskite containing twelve-membered rings of silicon – oxygen tetrahedra, which are unique the structures of minerals, is analogous to ETS-10. Zorite is an analogue of synthetic titanosilicate ETS-4, which is also considered as a promising microporous material. The ion-exchange properties of the large-pore rare-earth titanosilicate seidite-(Ce) with the framework density of 14.05 were studied.[67] It was demonstrated that most sodium ions in the latter mineral can be readily replaced by Tl, K, Rb, Cs and Ba in the reactions with aqueous solutions of these metal salts and these replacements are accompanied by changes in the unit cell parameters and optical properties. For steenstrupine (FD = 14.6), leaching of sodium was studied experimentally.[68]

Table 2. Brief crystal-chemical characterisation of zeolite-like amphoterosilicate minerals.

[a] Framework cations are printed in bold type; [b] the framework density; [c] minerals with unknown structures are tentatively assigned to particular mineral groups by analogy with related minerals; [d] in these cases, the notation $(n-x)$ signifies that the position can be vacant ($0 \leqslant x < n$).

Minerals of the hilairite group [69] (FD varies from 15.0 to 15.9) are characterised by a constant T : M ratio of a mixed octahedral–tetrahedral framework, whereas the contents and ratio of extraframework cations (including oxonium) and the amount of molecular water can vary over wide ranges. There is evidence that ion exchange and decationation readily proceed in hilairite-like phases. The results of thermal analysis also provide unambiguous evidence for the zeolite character of hilairite-like minerals. For example, dehydration of hilairite on heating is completed already at 220 °C, after which the dehydrated material retains basically the hilairite structure up to at least 855 °C. The dehydration process is reversible. Thus, rehydration begins after cooling to 220 °C. At room temperature, the mineral absorbs about 95% of the initial amount of water during 15 h.[70] The major portion of water is eliminated from sazykinaite-(Y) at a temperature below 250 °C (more than 80% of the total mass loss as judged from the published thermogravimetric curve). After heating to 500 °C, the crystals, which turned white and lost transparency, gave a Debye powder pattern of sazykinaite with weak diffuse lines.[71] The zeolite nature of minerals of the hilairite group is also evidenced by the fact that additional Na^+ cations (compared to minerals of this group devoid of rare-earth elements) are easily incorporated into the channels of the frameworks of the sazykinaite and pyatenkoite structures. These additional cations are necessary for compensation of an excessive negative charge appearing upon heterovalent substitution

$$(Zr,Ti)^{4+} \longrightarrow Y^{3+}.$$

The idealised general scheme of isomorphism giving rise to cation-deficient calciohilairite can be represented as follows:

$$2\,Na^+ + H_2O \longrightarrow 0.5\,Ca^{2+} + 1.5\square + H_3O^+,$$

□ is a vacancy.

Taking into account the character of spatial inhomogeneity of the composition of calciohilairite crystals, it was suggested [69] that this scheme of isomorphism represents simultaneously the reaction scheme of the natural ion-exchange process responsible for the transformation of hilairite, which crystallised from highly alkaline solutions, into calciohilairite in the late-hydrothermal evolution stage.

Natural leaching of cations and ion-exchange processes, which occur without destruction of the crystal structure, were observed in many other amphoterosilicates: in minerals of the lovozerite group (elimination of sodium accompanied by the replacement of oxygen by OH groups), elpidite, gaidonnayite, eudialyte (substitution of Na for K, Ca, H_3O^+), *etc*.

In conclusion of this section, let us note that natural amphoterosilicates can not only serve as prototypes for the design of new microporous materials but are also of industrial interest in the case of their large deposits. For example, the Takhtarvumchorr deposit of keldyshite, which serves as a raw material for the production of zirconosilicate sorbents and ion-exchange materials, was included in the Cadaster of deposits of the Khibiny massif.[72] In the Lovozero and Ilimaussaq massifs, eudialyte serves as a rock-forming mineral and forms rich deposits with reserves of millions of tons. Economically important deposits in massifs of alkaline rocks were found for elpidite (Western Mongolia), steenstrupine (Greenland) and lovozerite (the Kola Peninsula). Deposits of microporous niobate pyrochlore and related minerals were discovered in many regions throughout the world.

3. Structures of labuntsovite and its analogues

Labuntsovite and its analogues belong to zeolite-like titano- and niobosilicates, which have been studied in depth.[126] These minerals are convenient to use for illustrating the general features concerning the composition, structure and properties of microporous amphoterosilicates.

All labuntsovite-like structures are based on a mixed framework, which involves infinite chains of corner-sharing M octahedra extended along the *a* axis. The M octahedra are occupied by titanium or niobium atoms. In two other directions, the chains are linked by the $[Si_4O_{12}]$ rings. In structures of some monoclinic representatives of the labuntsovite group, the chains are linked also by additional D octahedra. The SiO_4 tetrahedra share corners (O) with the M octahedra. The M octahedra are also linked to each other by sharing corners (O,OH). The M octahedra share edges (O–O) with the additional D octahedra.

The framework contains cavities and channels occupied by large alkali and alkaline-earth metal cations and water molecules. The extraframework positions are characterised by the presence of vacancies. These characteristic features of labuntsovite and related minerals make them similar to zeolite-type minerals (Figs 1 and 2).

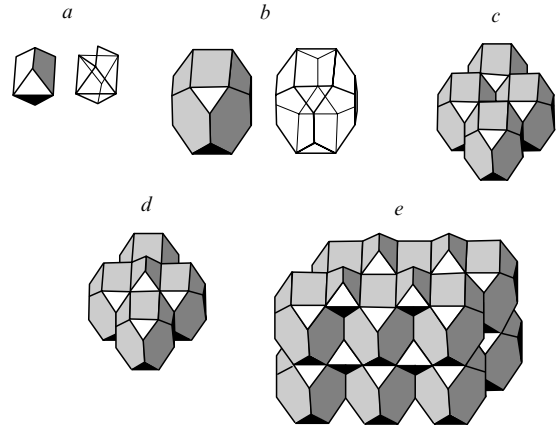

Figure 1. Zeolite polyhedra (*a*, *b*) and schemes of their arrangement (*c*, *d*, *e*) in the structures of minerals of the organovaite subgroup.[126]
The corners of the polyhedra are occupied by framework cations, and the oxygen atoms are located at the midpoint of the edges.

The minerals of the labuntsovite group can be divided into the following subgroups according to the symmetry and unit cell parameters:

— minerals with orthorhombic structures (the nenadkevichite subgroup), the space group *Pbam*;

— minerals with monoclinic structures and the unit cell parameter $c \approx 7$ Å (the labuntsovite, lemmleinite, kuzmenkoite, vuoriyarvite and gutkovaite subgroups), the space groups $C2/m$ or Cm;

— minerals with orthorhombic structures $c \approx 15$ Å (the paralabuntsovite and organovaite subgroups), the space group $C2/m$.

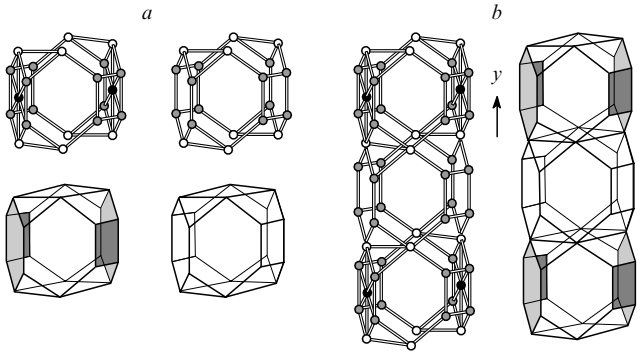

Figure 2. Zeolite polyhedra (*a*) and channels (*b*) in the structures of monoclinic minerals of the labuntsovite groups.[126] The D-octahedral, M-octahedral and tetrahedral sites are represented by solid, shaded and empty circles, respectively.

Minerals of the labuntsovite group are represented only by two topological types of the frameworks (*D*-occupied and *D*-vacant) as opposed to aluminosilicate zeolites characterised by several tens of topological types, which cannot be derived from one another by smooth transformations without cleavage of the chemical bonds. Each topological type of the labuntsovite group can be divided into two subtypes. In one of them, the adjacent octahedral layers are translationally equivalent, whereas in another one these layers are translationally non-equivalent. Nevertheless, minerals of the labuntsovite group are rather structurally diverse (10 structural types are known for this mineral group).

The crystal structures of nenadkevichite and its titanium analogue (korobitsynite) differ radically from those of all other (monoclinic) representatives of the labuntsovite group.[83–85] Both orthorhombic minerals belong to the space group *Pbam* and have similar unit cell parameters. This structural type is based on zigzag planar chains of corner-sharing Ti(Nb) octahedra extended along the *a* axis. The planes of the chains are parallel to the (001) plane. In labuntsovite and other monoclinic minerals of this group, the zigzag chains are parallel to the (010) plane and are strongly bent in the (001) plane in a wave-like fashion. In two other directions, the chains are linked by four-membered rings of Si tetrahedra to form a negatively charged framework with composition $[(Nb,Ti)_4(O,OH)_4(Si_4O_{12})_2]$ ($Z = 1$). The large cavities in the framework are occupied by Na^+ cations and crystallographically non-equivalent water molecules of three types. The possibility of the involvement of cations bulkier than Na^+ (such as K^+, Ba^{2+}, *etc*.) in these phases is limited due to steric hindrance.

In the structures of monoclinic minerals of the labuntsovite group, there are several non-equivalent positions occupied by extraframework cations (the most ordered structures have three such positions, *A*, *B* and *C*). The *D* position can be either vacant or occupied by divalent cations Q^{2+} (Q = Fe, Mn, Mg, Zn or, more rarely, Ca), which are involved in the D octahedron as the $[Q(H_2O)_2]^{2+}$ complex. The water molecules of this complex occupy the adjacent extraframework *C* positions. This is possible only if the latter positions are not occupied by cations. The simultaneous incorporation of K(Ba) into the *C* position and Q^{2+} into the *D* position would lead to a too short K(Ba)–Q^{2+} distance (~2.1 Å), which is unrealistic because of Coulombic repulsion. Hence, an interesting type of alternative isomorphism is observed in the labuntsovite structure:

$$\underset{C}{2(K,Ba)} + \underset{D}{\square} \longleftrightarrow \underset{C}{2H_2O} + \underset{D}{(Mn,Fe,Mg,Zn)}$$

In labuntsovites, continuous isomorphism according to this scheme occurs throughout the range of occupancies of the *C* and *D* positions by cations. This fact as well as the possibility of various mutual substitutions of cations in the *C* and *D* positions is responsible for a substantial compositional variability of labuntsovites. The general crystal-chemical formula for minerals of this group is as follows ($Z = 1$):

$$A_4B_4C_{4-2x}[D_x(H_2O)_{2x}][M_8(O,OH)_8][Si_4O_{12}]_4 \cdot n\,H_2O,$$

where $n \approx 8$; $x = 0–2$; A = Na, (Ca), □; B = K, Na, (H_3O), □; C = K, Ba, (H_3O), □; D = Mn^{2+}, Fe^{2+}, Mg, Zn, □; M = Ti, Nb, (Fe^{3+}); □ is vacancy.

Among monoclinic minerals of the labuntsovite group, representatives of the vuoriyarvite subgroup are characterised by the most disordered and loose structures.[86–88, 127–129] Some structural features of the framework of vuoriyarvite-K (Fig. 3) make it similar to nenadkevichite. In particular, both structures have no additional cross-linking D octahedra and are characterised by substantial displacements of the Nb and Ti atoms from the centres of octahedra toward one of the bridging corners. Distortions of the octahedral chains are manifested also in the fact that all (Nb,Ti)–O bonds in each tetrahedron have different lengths. In

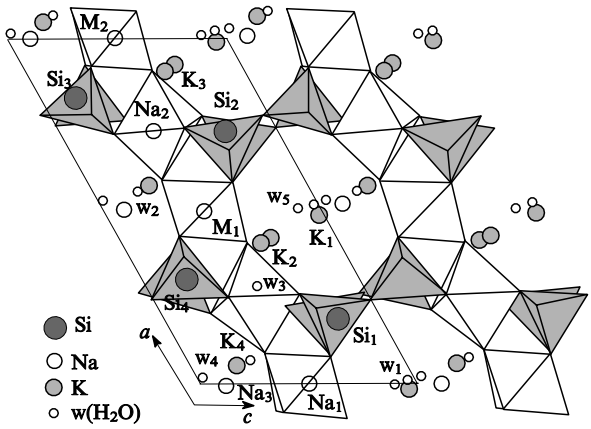

Figure 3. Crystal structure of vuoriyarvite-K, which is the *D*-vacant mineral of the labuntsovite group.[86]

the vuoriyarvite structure (unlike the nenadkevichite structure), the adjacent (Nb,Ti) octahedra are twisted about the axis of the chain (an analogous arrangement is observed in the labuntsovite structure) to form large cavities, which can be occupied by bulky potassium, barium and, probably, oxonium ions. Since the presence of these cations is very typical of monoclinic minerals of the labuntsovite group, this fact can be considered as an indication of a monoclinic symmetry.

The characteristic feature of the vuoriyarvite structure which distinguishes it from most other representatives of the labuntsovite group, is a large number of extraframework positions occupied by cations and water molecules, many of which are located at distances too close to be simultaneously occupied. As a result, most extraframework positions are predominantly vacant.

Vuoriyarvite-K is structurally similar to its analogues, *viz*., tsepinite-Na [128] and tsepinite-K, in which Na and Ti or K and Ti ions, respectively, prevail.[129]

The mixed framework in the kuzmenkoite structure [98–100] $K_4[(H_2O)_4(Mn,Zn)_2][(Ti,Nb)_8(O,OH)_8][Si_4O_{12}]_8 \cdot 8\,H_2O$ ($Z = 1$) is similar to the frameworks of minerals with labuntsovite-type structures. The only differences are the rotation and tilt angles of the adjacent polyhedra. The main distinguishing feature of the kuzmenkoite structure is that the *A* position is vacant due to a low sodium content. In addition to kuzmenkoites, this structural type includes their Fe,Nb-dominant analogue gjerdingenite-Fe.[130]

The organovaite subgroup,[95–97] which includes organovaite-Mn $K_2Mn(Nb,Ti)_4(Si_4O_{12})_2(O,OH)_4 \cdot 6\,H_2O$, organovaite-Zn $K_2Zn(Nb,Ti)_4(Si_4O_{12})_2(O,OH)_4 \cdot 6\,H_2O$ and parakuzmenkoite-Fe $(K,Ba)_2Fe(Ti,Nb)_4(Si_4O_{12})_2(O,OH)_4 \cdot 7\,H_2O$, is characterised by the space group $C2/m$ and the double (compared to labuntsovites) parameter *c* due to translational non-equivalence of the adjacent octahedral chains. Organovaites and parakuzmenkoite-Fe are isostructural to their *D*-deficient analogue paratsepinite-Ba,[129] in which extraframework positions are occupied predominantly by barium (Fig. 4).

In the structures of kuzmenkoites, organovaites and parakuzmenkoite, the *D* positions are completely or almost completely occupied by small divalent cations (Mn, Zn, Fe). Both extraframework positions are occupied primarily by large K and Ba cations. The sodium position is vacant. The excessive (with respect to the idealised formula of organovaite) Zn atoms can be incorporated into the potassium positions as the $[Zn(H_2O)_2]^{2+}$ complex.

The crystal structure of karupmøllerite-Ca,[94] which is a representative of the labuntsovite group characterised by the predominance of Ca and Nb [Ca > (Na, K, Ba, Sr), Nb > Ti], was studied by the Rietveld method.[93] In this structure, the D octahedra are occupied (by 70%) predominantly by Ca. Another distinguishing feature of karupmøllerite-Ca is that the *C* position is occupied by Ca and Na cations, unlike all other minerals of the

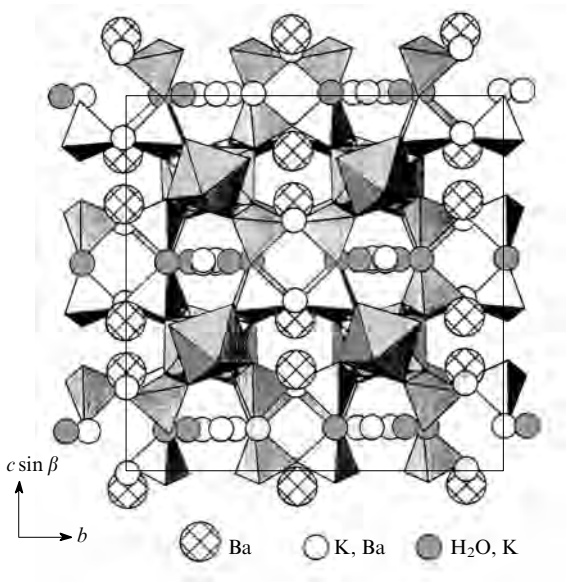

Figure 4. Crystal structure of paratsepinite-Ba, which is the *D*-vacant mineral of the labuntsovite group with the double unit cell parameter *c*.[126]

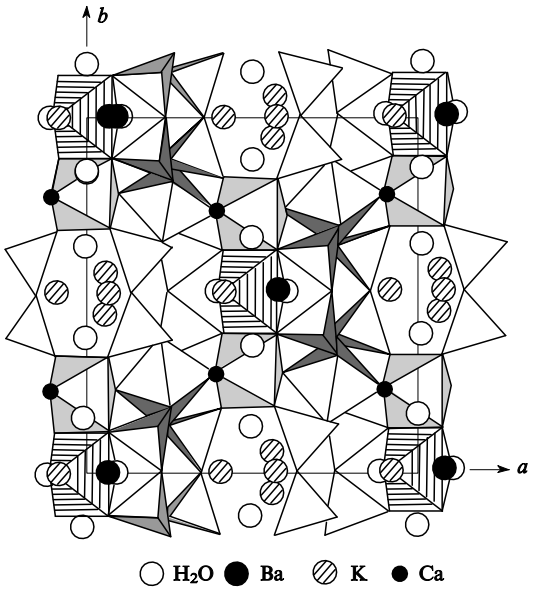

Figure 5. Crystal structure of gutkovaite-Mn, which is the *D*-occupied mineral of the labuntsovite group.[101]

labuntsovite group in which these positions are occupied by Ba and K. Therefore, calcium in the karupmøllerite-Ca structure serves both as a framework-forming cation (in the *D* position) and an extraframework cation (in the *C* position).

A radically different distribution of extraframework cations is observed in the gutkovaite structural type.[101–103] The structure of gutkovaite differs from that of labuntsovite primarily by splitting of the *A* position into two non-equivalent subpositions and a lowering of the symmetry to *Cm*. In addition to gutkovaite-Mn (Fig. 5), the gutkovaite structural type includes alsakharovite-Zn and neskevaaraite-Fe (Table 3).

It is noteworthy that all structurally studied crystals of minerals of the gutkovaite subgroup appeared to be microtwinned along the (001) and ($\bar{4}$01) planes of the true monoclinic lattice, which leads to a spurious increase in the symmetry to orthorhombic accompanied by an increase in the parameter *c* by a factor of four (c_{orthor} = 28.17 Å). An analogous twinning was revealed earlier in vuoriyarvite-K [86] and tsepinite-Na.[87]

The structural type of gutkovaite is of particular interest because it serves as a 'superefficient separator' of cations. The alsakharovite-Zn structure is the most prominent example. In this structure, Na + Ca, Sr, K, Ba and Zn ions occupy their own positions with good selectivity. The lemmleinite-Ba structure possesses a similar property. In this structure, the sodium, potassium, barium and manganese positions are strictly separated.

Due to non-rigid corner-sharing of octahedra in minerals of the labuntsovite group, the degree of deformation of the chains can vary depending on the type of the cations occupying the key *D* positions at the sites, where the chains approach each other. This is accompanied by a change in the parameter *a* along the axis of the chain and a smaller change in the parameter *b*. These changes are exemplified by several structurally studied representatives of the labuntsovite group.[87] In particular, the average distances in the D octahedron and the parameter *a* in labuntsovites are in the ranges of 2.0–2.1 and 14.2–14.3 Å, respectively. The corresponding characteristics for kuzmenkoite-Mn and vuoriyarvite-K (containing four-coordinate Na cations instead of D cations) are 2.2, 14.4 Å and 2.3, 14.7 Å, respectively, In monoclinic nenadkevichite (containing Ca in the 'cross-linking' position [107]) and tsepinite-Na (containing Sr and vacancies in the mixed *D* position), these parameters are 2.3, 14.75 Å and 2.35 (for Sr), 14.6 Å, respectively.

Among monoclinic minerals of the labuntsovite group, labuntsovites and lemmleinites (which are *D*-vacant analogues of labuntsovites) have the simplest and most ordered structures. Other structural types of this group can be derived from these simplest structures by shifting, splitting and varying the degree of occupancy of extraframework positions. For example, the gutkovaite structural type is derived by splitting the *A* position into two non-equivalent positions occupied by different cations, which leads to the disappearance of the centre of symmetry. The kuzmenkoite structure is characterised by the absence of A cations and the occupied *D* position. In this structure, the centre of symmetry is absent due to an unsymmetrical splitting of the *B* and *C* positions. The structures of organovaites and their titanium

Table 3. Comparative characteristics of minerals of the gutkovaite subgroup (the space group *Cm*).

Characteristics	Mineral		
	Gutkovaite-Mn	Neskevaaraite-Fe	Alsakharovite-Zn
Simplified formula	$CaK_2Mn(Ti,Nb)_4(Si_4O_{12})_2(O,OH)_4 \cdot 5H_2O$	$NaK_2Fe(Ti,Nb)_4(Si_4O_{12})_2(O,OH)_4 \cdot 6H_2O$	$NaSrKZn(Ti,Nb)_4(Si_4O_{12})_2(O,OH)_4 \cdot 7H_2O$
Composition of *A*(1) position	$Ca_{1.2}\square_{0.8}$	Na_2	$Na_{0.7}Ca_{0.7}\square_{0.6}$
Composition of *A*(2) position	$\square_2$	$K_{1.6}Na_{0.4}$	$\square_{1.0}Sr_{0.7}Na_{0.3}$
Composition of *B* position	$K_{3.0}\square_{1.0}$	$K_{2.2}\square_{1.0}(H_2O)_{0.8}$	$\square_{3.0}K_{1.0}$
Composition of *C* position	$(H_2O)_{3.6}K_{0.2}Ba_{0.2}$	$(H_2O)_{2.2}K_{0.72}Ba_{0.48}\square_{0.6}$	$(H_2O)_{3.6}Ba_{0.2}\square_{0.2}$
Composition of *D* position	$Mn_{1.7}Fe_{0.1}\square_{0.2}$	$Fe_{0.7}Mg_{0.4}\square_{0.9}$	$Zn_{1.6}Mn_{0.2}\square_{0.2}$
Composition of *M* position	$Ti_{7.8}Nb_{0.2}$	$Ti_{4.8}Nb_{3.2}$	$Ti_{5.7}Nb_{2.3}$

analogue parakuzmenkoite-Fe have the double (compared to kuzmenkoite) parameter *c*, which is associated with translational non-equivalence of the adjacent octahedral layers rather than with the ordered arrangement of the D cations, which takes place in paralabuntsovites with the space group $I2/m$.[84]

As mentioned above, minerals of the labuntsovite group can be divided into subgroups belonging to different structural types. These subgroups can be arranged according to changes in the physical properties of minerals (IR spectra, optical characteristics, behaviour on heating) and interplanar distances in powder X-ray diffraction patterns as follows: the labuntsovite, paralabuntsovite and lemmleinite subgroups → the gutkovaite subgroup → the kuzmenkoite and organovaite subgroups → the vuoriyarvite and paratsepinite subgroups → orthorhombic minerals (the nenadkevichite subgroup).

In most cases, this series correlates with the order of formation. Thus, the closer are the minerals to the end of the series, the later they crystallise, which is clearly manifested in intergrowths of different minerals of the labuntsovite group. Late minerals are characterised by weaker (according to IR spectroscopic data) hydrogen bonds formed by water molecules and lower dehydration temperatures, which is also indirect evidence for lower temperatures of formation.

It should be noted that in the structures of the first members of this series, the *D* positions are generally occupied, whereas the structures of the last members are characterised by the presence of *D*-deficient positions or do not have *D* positions at all (the vuoriyarvite, paratsepinite and nenadkevichite subgroups). The exceptions are lemmleinites, which, unlike other monoclinic *D*-deficient representatives of this group, are characterised by a high degree of cation ordering, which makes them similar to labuntsovites. The similarity of lemmleinites to labuntsovites is manifested also in the existence of continuous isomorphous series including minerals of these subgroups.

By contrast, isomorphism between representatives of other subgroups is often limited. This is confirmed, in particular, by the presence of sharp interfaces between intergrowth crystals of minerals belonging to different subgroups as well as by an essentially non-uniform distribution of various components (Na, Ca, Sr, Nb, the sum of D cations, *etc*.), which was established by a statistical analysis of the compositions using large specimen selections. In other words, minerals of each subgroup (structural type) possess an individual structurally-determined affinity for particular framework and extraframework cations.

The above-given series correlates also with the changes in the chemical composition of the minerals. This is most clearly reflected by the Ti : Nb ratio. For the labuntsovite, paralabuntsovite, lemmleinite and gutkovaite subgroups, high-niobium representatives are unknown, whereas virtually pure titanium specimens are usual for these minerals (except for members of the gutkovaite subgroup). By contrast, high-niobium specimens are known for the vuoriyarvite and nenadkevichite subgroups. Evidently, this fact is ralated to the condition of charge balance. Minerals of the vuoriyarvite, paratsepinite and nenadkevichite subgroups are characterised by the absence or deficiency of D-type cations and partial occupancies of the *A* positions resulting in the deficiency of the positive charge, which is compensated by the replacement of Ti^{4+} with Nb^{5+}. It should be emphasised that the framework density of minerals of the labuntsovite group is to a large extent determined by the presence of vacancies in the *D* positions.

4. Structures of eudialyte and its analogues

Minerals of the eudialyte group attract considerable interest not only because of their structural diversity, which leads to a wide range of physical and chemical properties and allows for their practical application, but also due to the fact that these minerals form giant and rich deposits. Two main fields of practical application of eudialytes hold promise. First, zirconium, hafnium, heavy rare-earth elements and other useful components can be extracted from these minerals. Second, ecologically harmful elements, such as radioactive isotopes of strontium, caesium, *etc*., can be incorporated into their decationated forms. Until recently, researchers attempted (rather unsuccessfully) to solve the former problem by technological approaches using total decomposition of eudialytes by inorganic acids. In these approaches, silicon goes into solution as polysilicic acids, which form filterable gels, thus hindering isolation and purification of valuable components. Recently, a new solvometallurgical method was developed[131,132] for the selective extraction of rare-earth elements and zirconium from mechanically activated minerals without their complete destruction.

The latter problem is associated with the ability of eudialytes to be involved in ion-exchange processes. Under natural conditions, the participation of these minerals in ion-exchange reactions is often accompanied by their hydration.[133]

Minerals of the eudialyte group, which are trigonal ring silicates with a complex and variable composition, belong to zeolite-like compounds. Their framework density calculated as the number of Si + (Zr,Ti) + Ca + Nb + (Fe,Mn) atoms per 1000 $Å^3$ varies from 18 to 21 and is comparable to the corresponding values for some aluminosilicate zeolites.

The framework of eudialyte contains three- and nine-membered rings of SiO_4 tetrahedra, which are linked to each other by Zr(Ti) octahedra and six-membered rings of edge-sharing Ca octahedra. The rings of the octahedra are linked to each other by Fe, Na, Zr, Mn, Ti atoms (more rarely, by Ta, *etc*. atoms) with coordination numbers of 4 (square planar), 5 (pyramid) or, more rarely, 6 (octahedron), which correspond to the *M*(2,1), *M*(2,2) and *M*(2,3) positions, respectively (see below). Sometimes, cations possessing high force characteristics are lacking in this microregion resulting in a decrease in the framework density. Based on abundant X-ray diffraction data,[122,134–159] the crystal-chemical formula of eudialytes in a typical unit cell ($c \approx 30$ Å) can be represented in the general form ($Z = 3$):

$$N_{12}A_3[M(1,1)M(1,2)]_3[M(2,1)M(2,2)M(2,3)]_{3-6}[M(3)M(4)].$$

$$.Z_3[Si_{24}O_{72}]\cdot OH_{2-6}X_{2-4},$$

where *N* are predominantly sodium ions occupying four types of extraframework positions (these positions can also involve substantial amounts of H_3O^+ ions and small amounts of other alkali and alkaline-earth metal ions); *A* = Na, K, Sr, Ln, Y, Ba, Mn, Ca, H_3O; *M*(1,1), *M*(1,2) = Ca, Mn, Y, Ln, Na, Sr, Fe; *M*(2,1) = Fe, Na, Zr, Ta; *M*(2,2), *M*(2,3) = Fe, Mn, Zr, Ti, Na, K, Ba, H_3O; *M*(3), *M*(4) = Si, Nb, Ti, W, Na; *Z* = Zr, Ti, Nb; *X* = Cl, F, H_2O, OH, CO_3, SO_4.

Therefore, the eudialyte structure incorporates almost all chemical elements present in a mineral-forming medium. The impurity cations in zeolite cavities can 'choose on their own' energetically favourable positions to compensate charges in the case of heterovalent substitutions. These cations are self-organised and occupy optimum positions in each particular case. Either additional SiO_4 tetrahedra or octahedra, which are most often occupied by Nb atoms (but in some cases, are occupied by W, Zr, Mn or Ti atoms), are located in the centres of the $[Si_9O_{27}]$ rings. Large cations (primarily, Na), additional *X* anions and water molecules are located in large cavities between these structural elements. Isomorphous substitutions in zeolite cavities are most often random. Relatively low-ordered minerals are most typical of the eudialyte group. The structures of these minerals are described by the hexagonal unit cell with the parameters $a \approx 14$ Å, $c \approx 30$ Å and the space group $R3m$ [eudialyte[122] $Na_{15}Ca_6Fe_3Zr_3.Si_{26}O_{72}(O,OH)_2Cl_2$ provides an example]. In some minerals, impurity cations are ordered. This ordering can occur both in the horizontal plane (in layers perpendicular to the threefold axis) and in the vertical direction (along the threefold axis). In the latter case, structures have the multiply larger period *c*.

Isomorphous substitutions, which are often accompanied by changes in the valence state and coordination number, can occur

in virtually all positions, both extraframework and framework (except for positions of the Si atoms in the silicon – oxygen rings). These processes most often lead to the disappearance of the centre of symmetry in the structure as a whole and give rise to cluster fragments composed of an octahedron located on a symmetry axis and three octahedra (or half-octahedra), which are arranged about the symmetry axis and share corners with the central octahedron. The structures of kentbrooksite [148] $(Na,Y,Ln)_{15}.Ca_6Mn_3Zr_3NbSi_{25}O_{73}(O,OH,H_2O)_3$ containing the $NbMn_3$ cluster and its analogue containing the $NbFe_3$ cluster [139] serve as such examples.

The octahedral positions in the six-membered rings are, as a rule, occupied predominantly by Ca atoms [for example, in feklichevite [134, 156] $Na_{11}Ca_9Fe_2Zr_3NbSi_{25}O_{73}(OH,H_2O,O,Cl)_5$]. In low-calcium minerals, other elements are also incorporated into these positions. In the case of their ordering, octahedrally coordinated sites of the six-membered ring break down into two groups consisting of three octahedra each, which are non-equivalent in both composition and size resulting in a lowering of the symmetry to $R3$. For example, Ca octahedra alternate with Mn octahedra in the oneillite structure [137, 143] (Fig. 6). Representatives containing ordered Ca and Fe [142] as well as ordered Mn and Na [146] were found.

An ordering along the main axis gives rise to superstructures, which are observed in a series of minerals of the eudialyte group. For example, half of Zr atoms in the octahedra of the framework in a high-titanium specimen [138] are replaced by Ti atoms in an ordered fashion. As a result, the octahedra containing predominantly either Zr or Ti atoms alternate along the threefold axis in the doubled unit cell.

The symmetry of structures with a doubled unit cell ($a \approx 14$ Å, $c \approx 60$ Å) can be either $R\bar{3}m$ (alluaivite [136]), $R3m$ or $R3$. In the lower-symmetry structures, an ordering along the threefold axis is accompanied by a horizontal ordering, including the positions in the six-membered rings.

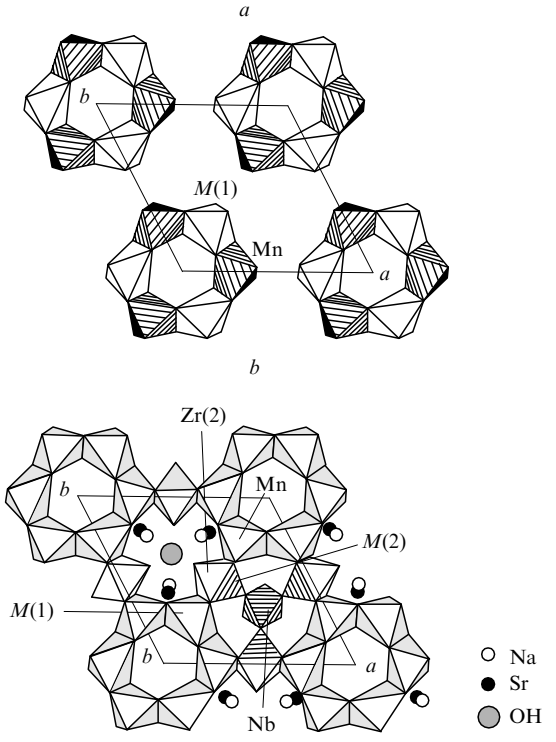

Figure 6. Ordering of the Mn and (Ca,Ce) ions in the rings of edge-sharing octahedra (*a*) and these rings linked by octahedra of *O*-coordinated transition metals (*b*) in oneillite, which is an analogue of eudialyte with the symmetry $R3$.[137]

The above examples do not exhaust the diversity of the structural features and chemical compositions of minerals of the eudialyte group. However, even these examples show that an analogous diversity is impossible for aluminosilicate zeolites, at least within the framework of one structural motif.

Decationation and cation substitution in eudialytes characterised by different degrees of hydration were studied [157] taking into account such structural features as occupancies of the framework positions, changes in the coordination numbers of the cations, the character of the complete and partial isomorphous substitution, the formation of vacancies, changes in the charges of the cations in particular positions, the lowering of the symmetry and/or doubling of the unit cell parameter c caused by ordering of the components over structural positions, *etc*.

Eudialytes, which were formed in hyperalkaline rocks in early evolution stages, contain large amounts of sodium ions, which can be involved in virtually all positions, except for silicon – oxygen rings and Zr octahedra. In the N and A positions, sodium ions can be replaced by equal-sized or larger cations. In the M positions, sodium ions are replaced by smaller cations. The exceptions are the $M(2,2)$ and $M(2,3)$ positions, which can be occupied by both smaller (compared to Na) and larger cations. In late stages of mineral formation involving a decrease in the temperature, the conditions are changed from hyperalkaline to less alkaline followed by the acid-leaching stage, where eudialytes sometimes almost completely lose sodium and are subjected to hydration.

The IR spectroscopic data provide evidence that the oxonium ions H_3O^+ can be incorporated into the cavities of the framework (Fig. 7) [the presence of larger single-charged groups, such as $(H_5O_2)^+$, is excluded for steric reasons].

The degree of hydration (*i.e*., the ratio of the number of oxonium groups and water molecules to the number of other extraframework cations) in structurally studied specimens varies from 0 (unaltered eudialyte) to ~ 2.2 (Na,Fe-decationated eudialyte [158]). Intermediate values for structurally studied specimens are 0.15, 0.6 and 1.4 (see Refs 157, 141 and 152, respectively).

A comparative analysis of the structures of six eudialytes, which differ in the degree of hydration,[157] revealed the following features.

1. Ion exchange in eudialytes occurs through the replacement of Na atoms by larger cations in all extraframework positions and, partially, in the $M(2,2)$ and $M(2,3)$ positions. Such substitutions in other M positions cannot take place.

2. The replacement of N and A cations by H_2O and H_3O^+ more often occurs in Zr- and Si-containing layers and, to a lesser degree, in layers containing Ca octahedra.

3. An increase in the degree of hydration is accompanied by an increase in the percentage of K, Sr, Ba, Ca and rare-earth cations, which stabilise the structure. Layers enriched in H_2O molecules

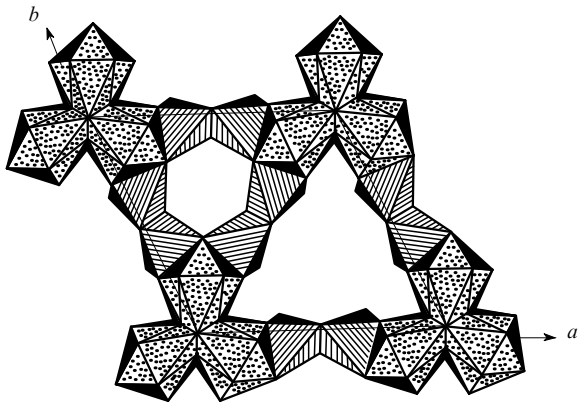

Figure 7. Fragment of the framework of the Fe,Sr-analogue of kentbrooksite.[140]
The rings of Ca octahedra are dashed and the $M(3)$ polyhedra are dotted.

and H_3O^+ ions are characterised by weaker bonds both within the layer and between the adjacent layers giving rise to cleavage perpendicular to the threefold axis. Apparently, the complete replacement of extraframework cations by H_3O^+ cannot occur because it would lead to destabilisation of the structure up to the transformation into the amorphous state. Under natural conditions, eudialyte is often replaced by amorphous aqueous zirconium silicate or an aggregate of water-containing zirconosilicates at low temperatures.

4. Because of the high mobility of H_3O^+ cations, their hydrogen atoms are not localised and the O atoms are characterised by high temperature parameters, random disorder, splitting and partial occupancies. A high content of oxonium groups generally leads to a symmetry lowering to *R*3. The limiting saturation can cause deformation of the unit cell accompanied by an increase in the parameter *c* by almost 1 Å and a decrease in the parameter *a* by 0.25 Å.

5. Isomorphous replacement of extraframework cations by H_3O^+ groups takes place either randomly in layers perpendicular to the threefold axis or in an ordered fashion along the threefold axis. In the latter case, modular structures with the double parameter *c* are formed. These structures are less stable (and the degree of their hydration is lower) compared to typical eudialytes (the parameter $c \approx 30$ Å).

Additional data on the crystal chemistry of natural amphoterosilicates were surveyed in the monographs by Pyatenko and co-workers.[80,160]

IV. Properties of microporous silicates containing transition elements

1. Ion-exchange and sorption properties

Studies of the ion-exchange properties of synthetic titanosilicates are rather scarce. It was demonstrated[34] that zeolite-like K and Na titanosilicates prepared by the hydrothermal synthesis efficiently adsorb Cs^+, Rb^+, Pb^{2+} and Hg^{2+} ions from solutions. In the patent,[161] nenadkevichite and the microporous aqueous titanosilicates ETS-10 and ETS-4 were described as sorbents of cations of radioactive isotopes of a number of metals (Cs, Sr, Co). It was also found that various cationic forms of synthetic titanosilicate having the pharmacosiderite structure remove trace amounts of ^{137}Cs and ^{89}Sr from aqueous solutions in a wide acidity range.[162] Complex oxides which contain Ti, Nb, Sb or W and have the pyrochlore structure, can also remove the above-mentioned isotopes from aqueous solutions.[52] A synthetic stibiosilicate and penkvilksite were used for extraction of ^{60}Co from aqueous solutions.[163]

In the microporous titanosilicate $K_2TiSi_3O_9 \cdot H_2O$, potassium ions can be replaced either completely by ammonium atoms or partially by other alkali metal cations through ion exchange with aqueous solutions. Due to high 'flexibility' of the framework, this cation substitution leads to a substantial change in the physicochemical properties of the material.[164]

Natural minerals of the labuntsovite group belong to zeolite-like titanosilicates. As mentioned above, these minerals are very structurally and compositionally diverse. The cation exchange was studied[165] under normal conditions for single-crystal grains of seven minerals of the labuntsovite group (korobitsynite, labuntsovite-Mn, lemmleinite-K, kuzmenkoite-Mn, organovaite-Mn, vuoriyarvite-K and tsepinite-Na) belonging to six structural types, which differ in the symmetry, the occupancies of the *D* positions and the character of ordering of extraframework A cations in the channels. In experiments, solutions of NaCl, Na_2CO_3, K_2CO_3, $CaCl_2$, $SrCl_2$, $BaCl_2$ and CsCl were used.

The cation exchange in aqueous solutions depends on the structural features and proceeds differently for various representatives of the labuntsovite group. Orthorhombic phases and minerals of the labuntsovite and lemmleinite subgroups, which are characterised by the maximum ordering of extraframework cations and high occupancies of their positions, do not exhibit cation-exchange properties under mild conditions. Representatives of the kuzmenkoite, organovaite and vuoriyarvite subgroups, which are characterised by relatively low occupancies of the cation positions in zeolite cavities and the low-ordered arrangement of cations in these cavities, possess pronounced cation-exchange properties. Minerals of the vuoriyarvite subgroup exhibit the strongest cation-exchange properties due to a combination of several factors: low saturation with extraframework (zeolite) cations, the maximum disordered distribution of these cations, the almost complete absence of D cations, which 'cut-off' some zeolite channels, weak hydrogen bonds involving water molecules in the channels and a high concentration of extended structural defects associated with microtwinning.

In each grain, the process occurs throughout the bulk, the intensity of saturation being dependent on local inhomogeneities of the crystal rather than on the distances of particular regions from the solution interface. In other words, the energy barrier which ions overcome at the crystal – solution interface, rather than diffusion in the crystal bulk is the rate-determining step. This suggests that the ion-exchange process can be accelerated by subjecting the solid particle surface to the corresponding modification.

The microporous silicates[24,166] $M_2TiSi_3O_9 \cdot 2.5\,H_2O$, where M are extraframework cations, and $K_2(Zr,Ti)Si_3O_9 \cdot H_2O$ as well as some perovskite-type[167] and pyrochlore-type[52] complex oxides exhibit pronounced ion-exchange properties.

Many amphoterosilicates serve not only as ion-exchange materials but also as sorbents due to their ability to absorb small molecules from gases and solutions. For example, ETS-10 efficiently adsorbs H_2, CO, N_2 and NO, Cu-modified ETS-10 adsorbs NO, CO, C_2H_4 and NH_3, and Mg-modified ETS-10 can adsorb CO and N_2. Sorption processes as well as the surface properties of modified ETS-10 and the states of adsorbed molecules were studied by IR spectroscopy and calorimetry.[168–170] It was demonstrated[171] that titanosilicate molecular sieves can adsorb various molecules with high selectivity.

2. Catalytic properties

In recent years, micro- and mesoporous silicates of transition elements as well as some niobates have found ever increasing application as catalysts and catalyst supports in various processes, primarily, in selective oxidation reactions. Titanosilicates are most commonly used for these purposes. For instance, ETS-10 was used to advantage as a catalyst for gas-phase oxidative dehydrogenation of cyclohexanol,[172] dehydration of n-butanol, isomerisation of *m*-xylene and 1,3,5-trimethylbenzene,[14] dehydration of *tert*-butanol,[173] acylation of alcohols[174] and polymerisation of alkynes.[175] By contrast, ETS-10 and ETS-4 do not generally exhibit catalytic activity in selective oxidation reactions with H_2O_2 because these materials are not prone to the formation of titanium hyperoxide complexes.[176] Modified forms of microporous titanosilicates containing various extraframework cations, *viz*., M-ETS-10 (M = Na + K, H, Li, Na, K, Ni^{II}, Cu^{II}, Co^{II}) and M-ETS-4 (M = Na, K), promote photoinduced charge transfer in methylphenothiazine at room temperature.[177] The catalysts Pt-ETS-10 and Pt-ETAS-10 appeared to be efficient in reforming of n-hexane.[178] The catalytic properties of ETS-10 containing various isomorphous impurities were also described in the study.[143] In the investigation,[179] the authors hypothesised that the catalytic properties of ETS-10 are associated with high basicity of this material.

In addition to ETS-10, the titanosilicates ETAS-10 and AM-6 also exhibit catalytic activity in dehydration of *tert*-butanol and show high selectivity for isobutene. Stability of these catalysts increases as the temperature increases from 200 to 300 °C.[173] In the above reaction, the catalytic activity of ETS-10, ETAS-10 and AM-6 is also determined by basic sites.

Epoxidation of *cis*-cyclooctene was carried out with a quantitative yield on the modified zeolite SSZ-33 containing extraframework tetrahedrally coordinated titanium atoms and on the Ti-beta

zeolite containing only framework titanium atoms.[28] Selective epoxidation of *cis*-cyclooctene was performed also on the titanium-containing zeolite TS-1.[28] Besides, TS-1 and, particularly, Ti-beta efficiently catalyse oxidation of dibutyl sulfoxide with dilute solutions of H_2O_2 in *tert*-butanol to form the corresponding sulfone.[180] In the latter study, the reaction kinetics was investigated and compared with that of catalytic oxidation of organic sulfides under analogous conditions.

The high catalytic activity of TS-1 and Ti-MCM-41 in selective oxidation reactions is associated with the formation of hydroperoxide complexes with titanium sites on the surface of the catalyst particles. In the presence of platinum, a mixture of hydrogen and oxygen can be used instead of H_2O_2 for the preparation of such complexes.[176] The catalytic sites in TS-1, Ti-MCM-41, ETS-10 and ETS-4 can also be modified in dry hydrogen at temperatures higher than 400 °C. Study by ESR spectroscopy [176] demonstrated that Ti^{3+} occurs in tetrahedral (in TS-1 and Ti-MCM-41) or octahedral (in ETS-10 and ETS-4) coordination, whereas reduction of TS-1 and Ti-MCM-4 at temperatures higher than 600 °C affords two types of non-equivalent Ti^{3+} positions.

Oxidation of various organic substrates with hydrogen peroxide in a three-phase system in the presence of TS-1 as the catalyst was described in the study.[181] In hydroxylation reactions of a series of aromatic compounds (benzene, toluene, anisole, benzyl chloride), the reaction rate increases by a factor of 3–10, the regioselectivity being also increased. The oxidative rearrangements of cyclohexanone and acetophenone (the Baeyer–Villiger reaction) afforded caprolactone and phenyl acetate, respectively; the selectivity was 70%–90%. Oxidation of benzyl chloride in this three-phase catalytic system gave rise to *p*- and *o*-hydroxybenzyl chlorides in a ratio of 85 : 15. In all such reactions, the activity and regioselectivity of catalysis are determined by the relative hydrophobicity and the pore size of titanosilicates used as catalysts as well as by their Brönsted acidity in the presence of H_2O and H_2O_2.

A broad spectrum of titanosilicate molecular sieves (TS-1, TS-2, Ti-beta, Ti-MCM-41, Ti-HMS, amorphous SiO_2–TiO_2) was examined in oxidation of propylamine with 30 mass % H_2O_2 to prepare a mixture of *syn*- and *anti*-propionaldoximes. Only TS-1, TS-2 and Ti-beta exhibit substantial catalytic activity. For these three catalysts, the influence of the conditions of oxidation on the reaction rate and selectivity was studied.[182] A series of studies devoted to the use of titanosilicates (primarily, TS-1) as catalysts for oxidation reactions were surveyed in the review;[36] in addition, different approaches to an increase in selectivity of oxidation reactions, mechanisms of these reactions and procedures for the synthesis of large-pore titanosilicate catalysts were considered.

The reactions of cyclohexanone and *m*-, *o*- and *p*-hydroxyacetophenones with NH_3 and H_2O_2 are catalysed by TS-1 and the Ti-modified zeolites Al-beta and ZSM-48.[183] In particular, *p*-hydroxyacetophenone is transformed in the presence of TS-1 into the corresponding oxime; the selectivity is 100% and the conversion is 50%. For other systems, high selectivity can also be achieved with the use of methanol as the solvent and in the presence of a large excess of NH_3.

Titanosilicate which was synthesised by the reaction of dealuminated ZSM-5 with $TiCl_4$ vapour, catalyses photochemical decomposition of NO.[29]

Soluble titanium complexes are widely used as homogeneous catalysts for redox reactions.[184] Apparently, the successful use of microporous titanosilicates as catalysts for selective oxidation of organic substrates is associated with the fact that these zeolite-like materials contain titanium catalytic sites directly in a microporous matrix.

Zirconosilicates are rarely used as catalysts in organic syntheses. In particular, in the study [23] the mesoporous molecular sieves Ti-MCM-41 and Zr-MCM-41 were demonstrated to catalyse hydroxylation of naphth-1-ol with an aqueous solution of H_2O_2 as well as epoxidation of norbornene.

Data on the use of niobosilicate catalysts are also relatively scarce.[44, 185, 186] The microporous niobosilicate AM-11, whose structure remains unknown, catalyses the synthesis of dimethyl ether from methanol in a flow reactor.[185] Under these conditions, the reaction proceeds primarily at the external active sites of the catalyst possessing high Brønsted acidity. In a closed reactor, the reaction of methanol in the presence of AM-1 affords primarily a mixture of hydrocarbons (from C_1 to C_5). In the latter case, catalysis occurs at the internal active sites. The compound AM-1 also catalyses the synthesis of methyl *tert*-butyl ether by the gas-phase reaction of methanol with *tert*-butanol in a flow reactor at 50–100 °C under atmospheric pressure.[186] In this reaction, high selectivity is achieved; the selectivity remains unchanged in the case of repeated use of the catalyst and only slightly decreases with increasing temperature.

The studies [187–193] were also concerned with the physicochemical properties of amphoterosilicates and the nature of their active sites.

In addition to titano- and niobosilicates, some microporous complex oxides, whose frameworks contain exclusively octahedrally coordinated atoms, also exhibit catalytic activity. For example, a ruthenium lead analogue of pyrochlore with composition $Pb_{2.25}Ru_{1.75}O_{7-y}$ catalyses electrochemical oxidation of formaldehyde and glucose.[194] Stannates with the pyrochlore structure $Ln_2Sn_2O_7$ (Ln = Y, La, Nd, Sm, Gd) catalyse decomposition of NO.[54] Catalysis of photochemical decomposition of water with caesium-doped potassium niobate was described in the study.[195]

* * *

To summarise, zeolite-like materials with mixed frameworks differ from aluminosilicate zeolites by having a wider diversity of chemical compositions, crystal structures and physicochemical properties. The fact that the configuration of the framework smoothly varies with composition makes it possible to synthesise zeolite materials possessing desired (ion-exchange, sorption, catalytic, *etc*.) properties. Additional advantages of zeolite materials containing transition elements are associated with the presence of various active sites. The available data on the crystal chemistry and mineralogy of natural microporous amphoterosilicates containing transition elements will, undoubtedly, be useful in preparing analogous synthetic materials.

Abstract. The state-of-the art in the study of three-dimensional radical copolymerisation of multifunctional vinyl compounds with various monomers has been analysed. The mechanisms of relationships between copolymerisation kinetics with structure-physical transformations of the reaction medium and structures of cross-linked polymers are discussed. The key role of spectroscopic monitoring methods in the *in situ* studies of structure – kinetics relationships in three-dimensional radical copolymerisation is demonstrated. New approaches to control over these processes based on the use of chain transfer catalysis and living radical polymerisation are considered. The bibliography includes 178 references.

I. Introduction

The use of three-dimensional radical copolymerisation (TRCP) of multifunctional compounds (M_1) containing several double bonds with monomers (M_2) significantly extends the capabilities of directed design of network polymeric structures by varying the structures of starting compounds and the compositions of oligomer – monomer mixtures. High-tech processes based on TRCP are currently employed in the production of polymeric sorbents, membranes, laser videodisks, contact lenses,[1] gradient optical materials,[2] elements of computer optics,[3] microelectronics [4] and a variety of composite materials for special technique.[5] Commercial production or, in essence, synthesis of such articles demands high level of integration of such diverse processes as chemical reactions involved in TRCP, formation of a copolymer structure, microsyneresis of reaction components, vitrification of the reaction medium and diffusion-controlled exchange of monomers in gel polymer systems. Therefore, studies of TRCP as an integral complex of interrelated chemical and structure-physical transformations is a topical problem.

The majority of papers published thus far are devoted to determination of copolymerisation constants for the comonomers M_1 and M_2, analysis of mechanisms of gel formation, elucidation of structures and properties of copolymers formed, theoretical description and computer simulation of various TRCP processes. Some of them are considered in reviews,[1,4,6] but structure – kinetics relationships, which play a key role in the control over TRCP processes have not been taken into consideration. The increasing number of publications on this problem suggests the advent of a qualitatively new stage of research which is characterised by *in situ* analysis of structure – kinetics relationships in TRCP using spectroscopic monitoring in a real-time mode and development of novel efficient methods for the control over these processes using chain transfer catalysts and reagents for living radical polymerisation.

This review is devoted to the analysis of the most recent trends in the study of mechanisms of TRCP and encompasses a broad range of reaction systems $M_1 + M_2$ with oligomers and monomers differing significantly in the structures and properties.These systems allowed an analysis of effects of chemical (*e.g.*, relative reactivities of the C = C bonds in M_1 and M_2) and physical factors (*e.g.*, the lengths of oligomeric fragments and alkyl substituents, the presence of sites of strong intermolecular interactions in M_1 and M_2, *etc.*) on the kinetics of TRCP and structures and properties of the network copolymers formed.

A comprehensive analysis of TRCP reactions in $M_1 + M_2$ systems demands knowledge of homopolymerisation of the corresponding multifunctional compounds M_1. The expediency of studies into both copolymerisation and homopolymerisation of compounds M_1 is dictated by the similarity of their topologies and formation of pendant double bonds which differ from the double bonds in the starting oligomers M_1 in effective reactivities.† A detailed description of the state-of-the-art in the study of three-dimensional radical homopolymerisation is given in a review. [7]

II. A microheterogeneous mechanism of three-dimensional radical copolymerisation and structures of copolymers

1. Topological features of three-dimensional radical copolymerisation

It is known [8] that radical copolymerisation of monomers M_1 and M_2 yields linear macromolecules. With the exception of special cases of distortions in the uniform distribution of reactants,[9–11]

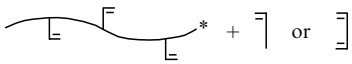
† Effective (as opposite to true) reactivities of monomer – polymer systems depend on external factors (*e.g.*, diffusional characteristics of the reaction medium, conformational mobility of the polymer network, cage effect, *etc.*) rather than on the electronic structures of the reacting bonds.

their compositions and alternation of the monomeric units in the polymer chain are determined by the composition of the initial monomer mixture and values of reactivity ratios of the monomers (r_1 and r_2, respectively). A totally different situation is observed on the transition to TRCP, where one of the components contains two (or more) reactive C=C bonds. In this case, the copolymerisation of a cross-linking reagent M_1 and a monomer M_2 is branched into different topological channels:[6]

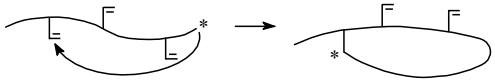
1. Growth of linear chains carrying pendant double bonds and terminal radicals:



(1)

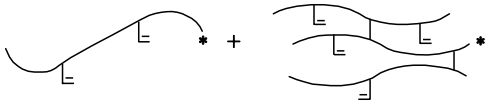
2. Primary intramolecular cyclisation:

(2a)



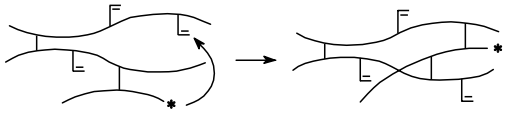
(2b)

3. Intermolecular chain cross-linking:



(3)

4. Secondary cyclisation in branched macromolecules, microgel particles and macrogel:



(4)

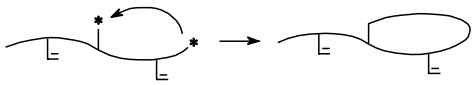
Primary intramolecular cyclisation (2a,b) is fairly inefficient as regards the formation of a network. This reaction results in a shift of the experimental gel point from a theoretical value calculated on the basis of the Flory–Stockmayer theory towards higher degrees of conversion.[6] Under these conditions, the formation of a microheterogeneous copolymer structure occurs at the topological level. Therefore, numerous papers deal with the analysis of factors determining the probability of this reaction.

The contribution of reactions (2a,b) is especially pronounced in early steps of TRCP where the probability of the bimolecular reaction (3) is very low because of a small concentration of the polymeric chains and growing macroradicals. In this step, effective reactivities of pendant C=C bonds in the vicinity of the terminal radical may exceed those of the C=C bonds of the oligomer M_1. Effective reactivities of the pendant double bonds also depend on the length and rigidity of the oligomeric fragment (spacer) which connects them with the main chain as well as on the flexibility of the main chain and the number of the rings formed.[1] The role of these factors is determined by the number and structure of the comonomer M_2 units which significantly influence the flexibility and conformation of chains in the growing macroradicals.[12, 13]

The feasibility of cyclisation during copolymerisation of ethylene glycol dimethacrylate (**1**) with styrene (**2**) has been established.[14] However, a completely soluble polymer devoid of double bonds and with rings in the main chain could be obtained only at low concentrations of the cross-linking reagent. Copolymerisation of dimethacrylate **1** and triethyleneglycol dimethacrylate (**3**) in highly dilute solutions resulted in cyclolinear polymers with M_w of $\sim$ 20 000.[15] An analysis of a hydrolysate of a polymer obtained from the dimethacrylate **3** revealed that the overwhelming majority of pendant double bonds are involved in intrachain cyclisation and the probability of formation of a ladder-type chain polymer is very low.

The dependence of the probability (DP) of intramolecular cyclisation on the length of the polymer chain of dimethacrylate **3** has been established.[16] The degree of polymerisation was controlled using a catalytic chain transfer agent and the number of double bonds was established by IR spectroscopy. It was found that only the products with DP < 9 had pendant methacrylate groups in each monomeric unit. With an increase in the DP to 15, the residual unsaturation of the products decreased to the level characteristic of the bulk polymer. This suggests that cyclisation in growing polymeric chains during polymerisation of dimethacrylate **3** occurs by route (2b).

The majority of papers devoted to cyclisation in TRCP consider only the reaction of the terminal radical and the pendant double bond. However, mathematical simulation of radical polymerisation reactions of oligomeric dimethacrylates on a cubic lattice[17] revealed that recombination of terminal and pendant radicals also contributes to cyclisation.

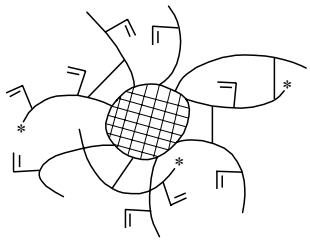


(5)

It was noted that at high initiator concentrations the intramolecular quadratic termination of radicals (5) is the main reason for cyclisation.

The probability of bimolecular intermolecular cross-linking (3) in the initial steps of (co)polymerisation is negligibly small, but increases rapidly with an increase in the concentration of primary polymeric chains. The interactions of growing macroradicals with the pendant double bonds of the polymeric chains result in the formation of branched macromolecules. The Monte Carlo simulation of topological structures of branched polymers in the pre-gelation step revealed[18] that the branching parameters strongly depend on the initiation rate of radical polymerisation of multifunctional monomers. Low initiation rates favour the formation of long-chain slightly branched polymers, whereas high initiation rates favour the formation of short-chain polymers with higher degrees of branching. The results of the simulation correlate qualitatively with the branching parameters of macromolecules isolated in the pre-gelation step of diallylic oligomers.[19, 20]

Favourable conditions for the reaction (4) between the radicals and pendant C=C bonds of different branching chains appear in branched macromolecules containing a large number of pendant double bonds. This process commonly referred to as secondary cyclisation[21] or intramolecular cross-linking[6] results in the formation of microgel particles, which consist of a dense nucleus and a loose shell.



The consumption of double bonds in the cross-linking and primary and secondary cyclisation during polymerisation reactions of multifunctional compounds can be calculated on the basis of a kinetic model of network formation.[21] These calculations showed (Fig. 1) that primary cyclisation prevails in the initial steps due to enhanced reactivities of pendant C=C bonds in the vicinity of growing radicals, which stimulates the formation of microgel particles. The contribution of intermolecular cross-linking and secondary cyclisation increases with an increase in the degree of conversion and polymer concentration, as a result of

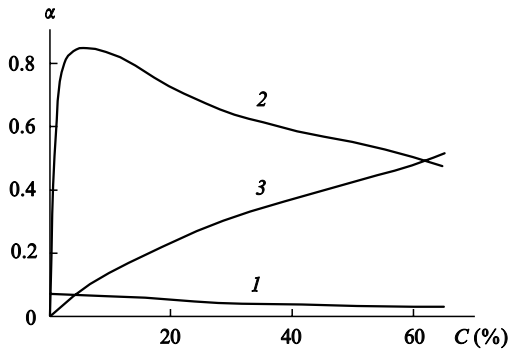


Figure 1. Dependence of the conversion of pendant double bonds (α) in cross-linking (*1*) and primary (*2*) and secondary cyclisation (*3*) on the overall conversion of the double bonds (C).[21]

which the macrogel is formed. Correspondingly, the homogeneity of the network increases with an increase in the contribution of secondary cyclisation and a simultaneous decrease in primary cyclisation.

2. Structural and kinetic heterogeneity of the reaction medium in three-dimensional radical copolymerisation

The true mechanism of three-dimensional (co)polymerisation is much more complicated than a model mechanism,[21] which takes into account only the topological peculiarities of network formation.[6,21] A crucial role in the formation of structures and properties of densely cross-linked polymers is assigned to microheterogeneous three-dimensional radical copolymerisation and structure-physical transformations, such as microsyneresis and vitrification of the reaction medium.[22–24]

From the moment of formation of microgel particles, the reaction medium becomes structurally and kinetically microheterogeneous due to lower mobility of the particles and a concomitant sharp decrease in the radical termination constant. As a result, the reaction is switched over to an autoacceleration mode (the gel effect).

Microgel particles can be regarded as microreactors consisting of two reaction zones, *viz*., an inner zone and a peripheral (near-surface) zone, which differ essentially in the effective reactivities and polymerisation rates of double bonds of a multifunctional oligomer.[23] The peripheral zone is characterised by higher rates of addition of double bonds of an oligomer to radicals localised on the surface of gel particles and thus unable to undergo recombination with analogous radicals of other particles. Slow polymerisation involving pendant double bonds occurs inside the microgel, its rate is limited by low mobility of the double bonds and steric hindrances, which prevents their addition to the radicals immobilised inside the microgel particles. Evidence for the existence of such limitations can be derived from the mode of attachment ('tail-to-tail'[25] or 'head-to-head'[26]) of the monomeric units, which is not typical of linear radical polymerisation. Steric constraints are important factors which control the stereoregularity of addition of the methacrylate groups and the topology of the netwok in the course of polymerisation of dimethacrylates.[27,28] They also determine the conformational state of network junctions, conformational dynamics and relaxation properties of the network itself.[27,29]

Pendant double bonds formed in a fast reaction of the radicals localised on the surface of microgel particles with one of the double bonds of the multifunctional oligomer M_1 are involved in a slow polymerisation inside the microgel particles. Consumption of the free oligomer and an increase in the size of a microgel particle result in a decrease in the effective size of the 'fast' reactor and an increase in the size of the 'slow' reactor to the size of a macrogel. As a result, the kinetics of three-dimensional polymerisation and copolymerisation of dimethacrylates switches over from an autoacceleration mode to an autoretardation mode.[23,30]

The structure–kinetic peculiarities of microheterogeneous three-dimensional radical polymerisation confer on it features of informal similarity with phase transition reactions, particularly crystallisation of polymers.[31] Based on this analogy, it was proposed to analyse the kinetic polymerisation curves conversion–time [$C(t)$] in the Avrami coordinates:[23]

$$C = 1 - \exp\left(-\sum_i k_i t^{n_i}\right), \qquad (6)$$

where k_i is the specific rate of polymerisation in the ith structural zone (*e.g*., in solution, on the surface or inside the microgel particle, *etc*.), which is proportional to the ratio of the rate constants for chain growth and chain termination (k_b) in this zone and n_i is the parameter which characterises the effect of the structure of the reaction medium on the rate of polymerisation in the ith zone.

Within the framework of this model, the value $n = 1$ corresponds to polymerisation under homogeneous conditions.[32,33] The value $n = 3$ entails total analogy to the polymerisation and phase transition where all the growing radicals are localised on the surface of polymer particles dispersed in the oligomer solution. In this case, $k_b = 0$ and the reaction proceeds in an autoacceleration regime. With an increase in the particle size, the particles merge and the contribution of the near-surface fast chain growth reaction diminishes and autoretardation of the polymerisation occurs. This structure–kinetic transition from near-surface to bulk polymerisation is manifested in a reduction of the parameter n due to diffusion-controlled constraints of the chain growth.

Studies into three-dimensional polymerisation of dimethacrylates have shown that, prior to autoretardation, the kinetic dependences plotted in the Avrami coordinates have one or two linear segments; their slopes yield the values of the parameter n in the range $1 \leqslant n \leqslant 3$ (see Refs 23 and 34). The autoretardation step is characterised by a gradual decrease of n to zero, which corresponds to termination of the reaction. The changes in the values of n are due to structural evolution of the reaction medium from a homogeneous solution of a polymer in an oligomer to the dispersion of microgel particles and the formation of a macrogel, which is accompanied by changes in the contributions of reactions occurring in different morphological zones to the overall reaction rate. The correctness of this statement was confirmed by *in situ* structural analysis of the reaction medium using light scattering techniques, NMR spectroscopy and dielectrometry.[22,35,36] The parameter n is highly sensitivite to changes in the structure-phase state of the reaction medium induced by solvents, precipitants, temperature, growth-limiting agents, *etc*.[23,34] Electron microscopic studies revealed a direct correlation between the numeric values of the parameter n and morphological characteristics of the polymers formed.[37] The validity of the use of the Avrami equation in the analysis of structure–kinetics relationships was confirmed by the fact that a similar equation was obtained with the help of an analytical method based on a kinetic scheme of three-dimensional radical polymerisation.[21]

In addition to topological and kinetic reasons, the microheterogeneous mechanism of three-dimensional radical polymerisation and copolymerisation has a thermodynamic reason which is related to the violation of the Flory–Rener[38] condition, *viz*., compatibility of a microgel with low-molecular-weight components of the reaction medium in the course of polymerisation. When the extent of the cross-linking inside microgel particles reaches a certain critical level, these components are displaced towards less densely cross-linked regions on the periphery of the microgel (syneresis). Because of diffusion-controlled limitations in macrogel formation, this process is not developed into separation of the system into two macroscopic phases, but is stopped in the microscopic level.[39] This process commonly referred to as microsyneresis results in structural and kinetic microheterogeneity of the reaction medium due to local vitrification in the central region

of microgel particles and violation of the homogeneous distribution of the reactants in the bulk of the reaction medium.

The redistribution of extrinsic molecular probes between zones with different network densities in the polymerisation of dimethacrylate **3** was established by the appearance of additional bands in the electronic absorption spectra of anthracene molecules localised in different zones of the polymeric matrix with different network densities.[27,28] The values of network densities calculated from absorption band frequencies of extrinsic anthracene molecules were equal to 1, 1.155 and 1.262 rel.u. The heterogeneity of molecular packing of the polymer of dimethacrylate **3**[28] was confirmed[40] by transmission electron microscopy, which revealed a bimodal distribution of heterogeneities according to their size (their diameters were 10 and 50–100 nm). These heterogeneities were related to the appearance of microgel particles preceding the macrogel formation.

Kinetic microheterogeneity of the initiation reaction can be due to involvement of initiator molecules in microsyneresis process[41] and increasing local concentrations of the initiator in less densely cross-linked areas. In this case kinetic heterogeneity can be further enhanced, since decomposition rates of radical polymerisation initiators increase with a decrease in the coefficient of molecular packing of the polymeric matrix.[42–44] Higher initiation rates of a monomer and pendant double bonds in areas with loose networks may result in homogenisation of network density over the bulk of the polymer. A significant improvement of the properties of network polymers after annealing and a relatively small increment in the conversion of the double bonds also suggest that in later polymerisation steps the reaction is predominantly localised in microzones with loosely cross-linked networks.[30]

In the case of three-dimensional copolymerisation, local relative concentrations of the comonomers M_1 and M_2 in the vicinity of growing radicals differ from their bulk-average concentrations due to microsyneresis.[12] This effect is manifested at higher effective reactivities of double bonds of the cross-linking reagent M_1 in comparison with the monomer M_2. It was shown[12,45] that microsyneresis observed in the copolymerisation of dimethacrylate **3** and butanediol dimethacrylate (**4**) with 2-methyl-5-vinyltetrazole (**5**) is accompanied by elimination of a less reactive compound **5** from the reaction zone of the microgel and a selective gel effect owing to consumption of double bonds of dimethacrylates **3** and **4** and pendant methacrylate groups. Specific heterogeneity of compositions of network copolymers formed is a natural consequence of microsyneresis and concomitant disturbances in the uniform distribution of comonomers.

The phenomenon of microphase separation of reaction components in the course of three-dimensional radical polymerisation and copolymerisation has found practical application in the production of liquid-crystal displays and synthesis of interpenetrating polymeric networks (IPN). One of the approaches to the production of such displays consists of polymerisation of diacrylates in solutions containing liquid-crystalline components.[46] The formation of a network induces phase separation and appearance of microdrops of a liquid-crystalline phase. By varying polymerisation conditions, one can control the degree of microphase separation and dispersity of liquid-crystalline inclusions into the network polymer matrix. Controlled microphase separation underlies the formation of structure and properties of interpenetrating polymeric networks one of which being formed by a three-dimensional radical (co)polymerisation mechanism, while the mechanism for the other is polycondensation (*e.g.*, urethane formation). Variation of relative rates of formation of these networks allows control over the degree of microphase separation of the reaction system components, phase morphology of IPN and their properties.[47,48]

3. Structures of network (co)polymers

In the context of this review, which is devoted to the analysis of structural and kinetic correlations in TRCP and their significance for the establishment of structure and properties of network copolymers, it seems expedient to highlight the role of reactivity ratios. If linear copolymerisation is carried out under homophasic conditions, the consumption of the monomers, the instantaneous composition of the copolymer formed and the distribution patterns of the monomeric units in the polymer chain are characterised by copolymerisation constants of the monomers r_1 and r_2.[49] Therefore, much attention is given to determination and refinement of these values for different comonomer pairs. The r_1 and r_2 values for many monomers are collected in reference books and are used in the design of experiments and simulation of copolymerisation processes.

In contrast to linear copolymerisation, three-dimensional copolymerisation cannot properly be described in terms of reactivity ratios of double bonds of a cross-linking reagent M_1 and a monomer M_2 because of the microheterogeneous mechanism of the three-dimensional copolymerisation, formation of pendant double bonds, microsyneresis of reaction components and vitrification of the reaction medium. These factors altogether largely determine effective reactivities of the double bonds in the starting oligomers M_1 and comonomers M_2 and pendant double bonds of the (co)polymer formed. The extent to which various factors affect the copolymerisation kinetics of individual reagents is different and depends on the composition of the original oligomer–monomer mixture and degree of conversion.[12,13,50]

Therefore, in order to minimise the specific effects of TRCP on r_1 and r_2 it is necessary that the values of the reactivity ratios of M_1 and M_2 were determined at low degrees of conversion ($< 1\%$) and at small concentrations of the cross-linking reagent ($< 1\%–3\%$). However, in this case, too, the differences in the reactivity ratios obtained by different authors are rather significant. Thus[51] the corresponding values for the copolymerisation of dimethacrylate **1** with methyl methacrylate (MMA, **6**) are as follows: $r_1 = 1.34$, $r_2 = 0.67$ (Ref. 51) or $r_1 = r_2 = 1$ (Ref. 52). Such discrepancies are due to the difficulty in isolation of the copolymer from the reaction mixture and different methods used for the determination of its composition and the content of pendant double bonds.

The ambiguity of the term 'monomer reactivity ratios', when speaking of the preparation of network copolymers, is spectacular as regards the differences in the values of r_1 and r_2 determined *in situ* in different steps of copolymerisation of *N*,*N*′-methylenebis(acrylamide) (**7**) and acrylamide (**8**) in D_2O using high-resolution ^{1}H NMR.[53] At a nearly zero conversion, $r_1 = 3.36$, $r_2 = 0.57$, whereas the corresponding values for the gel formation step ($C = 0.35$) are $r_1 = 1.77$ and $r_2 = 0.64$. It was suggested[53] that high reactivity of the double bonds in compound **7** at $C \approx 0$ favours the formation of microblocks of units **7** containing pendant double bonds as well as nonuniform distribution of the cross-links. The decrease in r_1 in the gelation step is attributed to microsyneresis and a decrease in effective reactivities of the double bonds.

It was suggested[12] that the ratio of copolymerisation rates of the cross-linking reagent and the monomer (w_1/w_2) was used as a parameter which takes into account all the structure-physical factors and characterises relative reactivities of double bonds. *In situ* determination of time dependences $w_1(t)$ and $w_2(t)$ throughout the whole polymerisation allows quantitative estimation of changes in the relative reactivities of the double bonds in the course of structural evolution of the reaction medium.

A comparison of experimental values of w_1/w_2 for different oligomer–monomer systems ($M_1 + M_2$) with those calculated from the Mayo–Lewis model (using experimental values of r_1 and r_2 for linear copolymerisation of the corresponding analogues) revealed their close fitting only for the very first reaction steps.[12,13,45] With an increase in the degree of conversion, both the experimental and calculated values diverge considerably. Thus in the copolymerisation of dimethacrylates **3** and **4** with deuterated methyl methacrylate (D-MMA) ($r_1 = r_2 = 1$ for linear copolymerisation of unlabelled and deuterated methyl methacrylate) this divergence amounts to 50% at high concentrations of the

cross-linking reagent. Obviously, in the three-dimensional copolymerisation the true reactivities of reagents determine the distribution of monomeric units in linear and branched macromolecules with pendant double bonds only in the initial steps of the reaction.[12] In turn, effective reactivities of M_1, M_2 and pendant double bonds begin to depend on the structure-physical state of the reaction medium with an increase in the degree of conversion, the appearance of microgel particles and the formation of a bulk polymer.

The topological, kinetic and thermodynamic factors altogether determine the microheterogeneous mechanism of three-dimensional copolymerisation and the structural heterogeneity of the network copolymer formed. It was found that the heterogeneity of moderately and strongly cross-linked networks increases with an increase in the density of the chemical cross-links.[54, 55] However, a specific type of non-homogeneity in a loosely cross-linked copolymer of methacrylate **6** with dimethacrylate **1** as a cross-linking reagent (0.1% – 0.5%) was observed.[56] Data from scanning near-field fluorescent microscopy suggest that local densities of segments within the copolymers under study exceed manyfold their average densities over the whole ensemble of chains. The segments vicinal to the cross-links form clusters ($\sim$ 10 nm) which merge to form heterogeneous structures the size of which amounts to several hundred nanometres. Presumably, the cross-links in such loose networks function as sites favouring supramolecular stacking of linear segments of polymer chains.

Convincing evidence in favour of microheterogeneity of network polymers was obtained by various methods which characterise different aspects of heterogeneity and differ in their resolution capacity. For example, microscopic methods allow revealing the microheterogeneity of polymer networks at the supramolecular level, whereas NMR and IR spectroscopy, at the molecular level.

High-resolution ^{1}H NMR provides direct information on the distribution of cross-links in model network copolymers prepared with involvement of a deuterated monomer M_2.[13] This method is based on the dependence of the width of the NMR line on the energy of magnetic dipole interactions between neighbouring H-containing units of the cross-linking reagent M_1. Since the units of deuterated M_2 function as non-magnetic diluents, the interaction of H-containing M_1 units and the width of the NMR line both depend on the distribution of the cross-links within the network. The efficiency of the method increases when network or linear copolymer analogues are analysed (Fig. 2).

The NMR line in linear copolymers prepared by copolymerisation of methyl methacrylate with a deuterated monomer (D-MMA) and containing up to 20% of H-MMA units remains narrow, which points to their statistical distribution among D-MMA units of the polymer chain. This is consistent with the values of their copolymerisation constants: $r_1 = r_2 = 1$. A further increase in the percentage of MMA units is accompanied by gradual broadening of the NMR line due to an increase in the number of MMA units constituting diads, triads and more lengthy sequences and the enhancement of their magnetic dipole interactions. In the case of network copolymers of triethylene glycol dimethacrylate with D-MMA, the broadening of the NMR line begins at dimethacrylate concentrations as low as < 5 mol.%. This points to a spatially heterogeneous distribution of cross-links in the bulk of the network copolymer. Apparently, such a heterogeneity can be accounted for by intramolecular cyclisation and microsyneresis, which results in the expulsion of D-MMA from microgel particles and a concomitant increase in the local concentration of the cross-links.

By virtue of their structural heterogeneity, network polymers and copolymers contain microzones which differ in local free volumes and mobilities of individual network elements. Using the polymer of dimethacrylate **3** as an example, it was shown [57, 58] that dynamic heterogeneity of network polymers causes the broadening of the time spectra of dielectric and mechanical α-relaxation. The microheterogeneity and the loss tangent a network increase

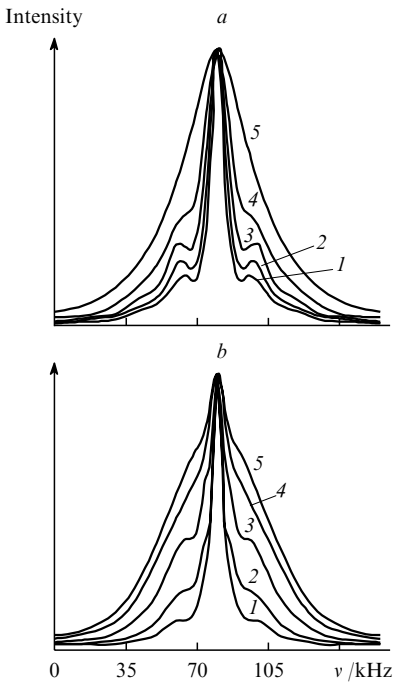

Figure 2. Dependence of linewidths in the NMR spectra of copolymers D-MMA with MMA (*a*) and with triethylene glycol dimethacrylate (*b*) on the concentrations of MMA and dimethacrylate.[13]
Concentrations of MMA (*a*) and dimethacrylate (*b*) /mol.%: (*1*) 1, (*2*) 5, (*3*) 20, (*4*) 50, (*5*) 100.

with an increase in its density.[58, 59] The width of the loss angle peak of a copolymer of **2** with divinylbenzene (**9**) prepared at 95 °C increases significantly with an increase in the concentration of compound **9** (from 5 mass % to 12 mass %). The glass-transition temperature of the copolymer (T_g) increases from 115 to 130 °C. The degree of deviation of T_g from the polymerisation temperature depends primarily on microheterogeneity of network polymers.[58] Synthesis of a microheterogeneous network polymer with T_g = 135 °C by polymerisation of diethylene glycol dimethacrylate (**10**) at room temperature supports this statement.

IR spectroscopy provides direct information about molecular structures of network polymers and copolymers. Studies of IR spectra of densely cross-linked polymers based on dimethacrylates

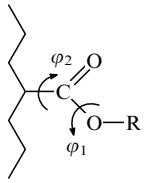
$$CH_2=C(CH_3)C(O)O-X-OC(O)C(CH_3)=CH_2$$

revealed that these spectra cannot be represented as a sum of the corresponding spectra of the linear poly(methyl methacrylate) (PMMA, **11**) and the oligomeric block X.[27, 28] The peculiarities of the IR spectra of poly(dimethacrylates) could be interpreted in terms of their cellular structure, which determines the conformation of atomic groups and stereoregularity of addition of methacrylate units.[27, 28] It was shown that syndiotactic addition of methacrylate units, which is thermodynamically more favourable than isotactic, is a more preferable route in linear radical polymerisation of the monomer **6** under ordinary conditions.[60] However, three-dimensional polymerisation of dimethacrylates shows a strong tendency of the probabilities of syndio- and isotactic addition of methacrylate groups to level off,[27, 28] which points to a greater contribution of thermodynamic factors responsible for the formation of the network structure in comparison with factors determining the stereospecificity of chain growth reactions in the linear polymer of **11**. In the case of three-dimensional polymerisation, the stereoregularity of the reaction of R* with C=C is controlled by steric factors and shrinkage stresses in the vicinity of the growing macroradicals.[16] When these stresses reach a certain critical level, the syndiotactic addition of methacrylate groups becomes thermodynamically less favourable and is replaced by

isotactic addition. The resulting changes in the packing conditions of atomic groups lead to alleviation of local stresses and a switchover of the chain growth reaction to a thermodynamically more favourable, *viz*., syndiotactic, route. Such a feedback between local stresses in network polymers and thermodynamics of a chemical reaction may bring about periodic switching of the chain growth reaction from one route of the addition of methacrylate groups to another. The microblock structure of polymethacrylate chains formed in this reaction seems to be the least significant (from the standpoint of structural hierarchy of network polymers) manifestation of the microheterogeneity of these processes.

The effects of steric hindrance and internal stresses on the stereoregularity of the addition of acrylate groups during the formation of network metallopolymers by radical polymerisation of zinc diacrylate have been established.[61]

The conformational state of methacrylate groups occupies a special place among characteristics of molecular structures of network (co)polymers based on oligodimethacrylates. These groups are localised in network nodes and their conformational dynamics determines largely the relaxation and physical-mechanical characteristics of poly(dimethacrylates).[29] The conformational states of methacrylate groups in network and linear polymers differ significantly [27, 28, 62] as can be evidenced from the differences in their IR spectra at the region of absorption bands of the C(O)O – R groups (1100 – 1300 cm^{-1}). Their frequencies depend on the values of the internal rotation angles φ_1 and φ_2.



The bands at 1197 and 1172 cm^{-1} in the absorption spectrum of the polymer **11** (Fig. 3) correspond to the vibrations of *cis*- and *gauche*-isomers which differ in the angle φ_1, whereas the bands at 1246 and 1275 cm^{-1} correspond to the oscillations of the ester group in conformations differing by the rotation angle φ_2 relative to the main chain.[62, 63, 64] Similar absorption bands are present in the IR spectrum of poly(dodecyl methacrylate) (**12**). However, in contrast to the polymer **11**, the intensity of the band corresponding to its *gauche*-isomer exceeds markedly that of the *trans*-isomer. This suggests that stabilities of ester-group isomers in linear polymers are determined by intermolecular interactions of alkyl substituents.

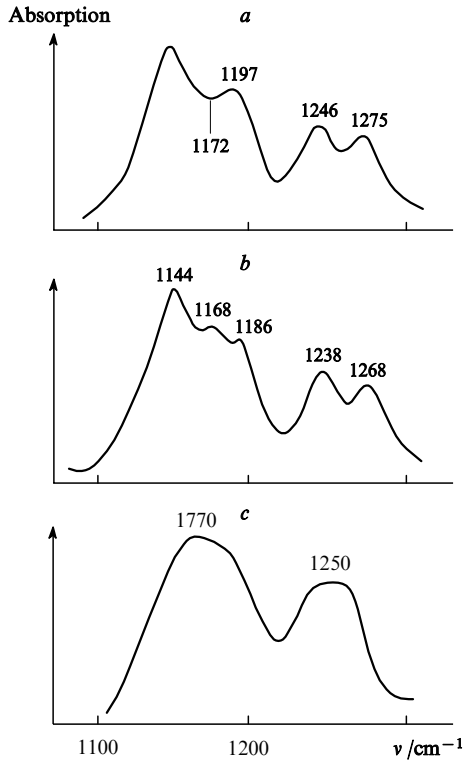


Figure 3. IR spectra of polymers of MMA (*a*), dodecyl methacrylate (*b*), butanediol dimethacrylate (*c*).[62]

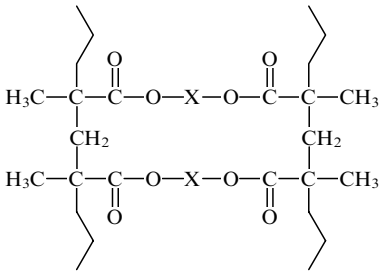
In contrast to linear polymers **11** and **12,** the IR spectrum of a network polymer of dimethacrylate **4** (Fig. 3 *c*) contains only one broad absorption band around 1200 – 1140 cm^{-1} instead of several bands corresponding to individual isomers. This suggests a broad distribution of ester group conformations in network nodes over all possible values of the angle φ_1. The change in relative intensities of a pair of bands corresponding to ester groups with different rotation angles φ_2 relative to the main chain is also noted. This situation is typical of many densely cross-linked polymers, although some of its manifestations depend on the length and flexibility of the oligomeric block X.[29] It may thus be concluded that the conformational state of ester groups in network polymers is determined by the packing of several adjacent nodes and the spatial architecture of the network cells rather than by local energy minimum of intermolecular interactions, as in linear polymers.



Obviously, such packing is provided by cooperative conformational dynamics and is limited by local free volume. The global energy minimum of the network cells is reached through variation of conformation energies of all of its constituent ester groups and the oligomeric blocks X.

The differences in the stereoregularity of the addition of methacrylate units and the conformation energies of ester groups in linear PMMA and in network polymers can be the reason for differences in specific heats of polymerisation of MMA and methacrylate groups in dimethacrylates.[16, 45, 62]

In some cases, chemical cross-links and the cellular structure of the network prevent approach of atomic groups to each other and intermolecular interactions in a rigid glassy matrix. This phenomenon commonly known as the loosening effect of chemical crosslinks [65] is manifested in a decrease in the molecular packing coefficient (MPC) for copolymers of **1** with MMA with an increase in the concentration of the cross-linking reagent.[66]

Concentration of **1** (mass %)	3	10	20
MPC	0.689	0.671	0.648

The copolymer with a maximum content of **1** manifests the highest compressibility in the glassy state due to the loosening of chemical cross-links. At the same time, a copolymer with a lower content of **1** manifests higher compressibility in a high-elasticity state.[66]

In densely cross-linked polymers of dimethacrylate, the loosening effect is manifested as higher amplitudes of torsional vibrations of atomic groups [65] and the dependence of the mechanism of water absorption on the network density.[67] It has been shown [30] that the loosening effect makes a significant contribution to physical-mechanical and sorption characteristics of a polymer of dimethacrylate **1** and copolymers of **1** with styrene.

Chemical shrinkage of the reaction medium has a strong impact on the structure and properties of network (co)polymers prepared by radical polymerisation of vinyl compounds.[4, 68–71] The reason should be sought in the fact that the distances between monomer molecules are determined by the sum of the van der Waals radii of outer atoms (~3.4 Å), while the distance between the monomeric units in the polymer chain depends on the length of the C–C bond (~ 1.5 Å). In turn, shrinkage depends on the size of the monomer molecule and decreases on going from MMA to butyl methacrylate (**13**) from 21.01 vol.% to 15.33 vol.%.[70]

In the linear polymerisation, shrinkage and polymerisation occur simultaneously, while in the case of three-dimensional polymerisation, shrinkage can lag behind as a result of which excess free volume can form in the polymer gel.[4, 69] In this case, the lag is caused by a virtually instantaneous addition of the double bond to the radical, while the relaxation of the excess free volume is limited by the low rate of cooperative rearrangements of the network. It was found that the higher the rate of photopolymerisation the greater the lag in shrinkage.[69] The maximum conversion of double bonds increases owing to the appearance of excess free volume and an increase in molecular mobilities of reaction components.

If three-dimensional polymerisation is accompanied by vitrification of the network polymer formed, the relaxation of the volume of the reaction medium to the equilibrium state is freezed virtually completely resulting in the appearance of internal stresses within the system.[16] These significantly deteriorate the quality of the articles prepared by TRCP and considerable attention is given to their analysis.[71, 72] It was found[72] that photopolymerisation of multifunctional (meth)acrylates is accompanied by the appearance of internal stresses following onset of vitrification, which increase monotonically and progressively throughout the reaction. The rates of stress appearance increase with an increase in the functionality of the monomer, a decrease in the length of the oligomeric chain and a decrease in the concentration of the plasticiser. These trends are much more pronounced for methacrylates than for acrylates. It was thus suggested that the level of internal stresses increases with an increase in the elasticity modulus of the polymer formed.[72]

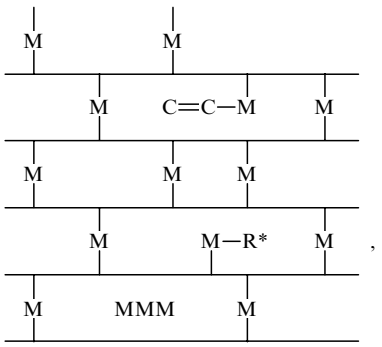
The total level of shrinkage stresses can be estimated as the energy of formation of an excess free volume ΔV in a network polymer with a bulk modulus K (see Ref. 16).

$$U \approx K\Delta V.$$

However, this expression is valid only for a model of a homogeneous network. In practice, the distribution of stresses in the bulk of a polymer is non-homogeneous due to the microheterogeneity of the three-dimensional polymerisation mechanism. Shrinkage stresses are usually concentrated in network zones at the junction of microgel particles. These particles can be regarded as microreactors where the chemical shrinkage occurs in a direction opposite to the propagation of the polymerisation front.[27] Therefore, the superposition of polymerisation fronts of several microreactors can bring about tensile stresses in the passing chains connecting different zones of the polymer formed in different microreactors. Quite probably, these stresses stimulate the cleavage of polymer chains and initiate the formation of microcracks in attempted synthesis of supercross-linked polymers of dimethacrylate.[68]

The heterogeneous distribution of stresses in the bulk of a polymer is the reason for specific features of thermal degradation of MMA copolymers with ethylene glycol, butanediol and hexanediol dimethacrylates where the content of the latter varies from 0.5 mol.% to 27 mol.%.[73] The degradation of copolymers occurs in two steps. In the first step, the degradation rate decreases progressively as the degree of cross-linking increases irrespective of the length of the cross-linking reagent, which is characteristic of moderately dense networks. In the second step, the degradation rate changes abnormally: it increases progressively with an increase in the degree of cross-linking and a decrease in the length of the spacer. Such a two-step degradation mechanism can be attributed to the presence of alternating loosely and densely cross-linked zones in the copolymer; cleavage of chemical bonds in the latter zones is induced by internal stresses.[73]

Considerable internal stresses can be developed in network polymers prepared by radical polymerisation of multifunctional metal-containing monomers of the type C=C–M–C=C, where M is an atom of a metal or a complex.[61, 74] Because of a small distance between the double bonds of organic ligands and their strict spatial fixation by a bridging atom M, the target polymer has a rigid small-meshed structure



which prevents chemical shrinkage and volume relaxation. As a result, growth of the polymer chains occurs under conditions of strong steric limitations and at higher internal stresses.

Direct evidence for the presence of internal stresses in a network polymer prepared from zinc diacrylate was obtained in the analysis of low-frequency IR spectra in the region of oscillations of the central fragment –O–M–O– (see Ref. 61). Instead of two narrow bands at 300 and 410 cm^{-1} characteristic of the monomer, the spectrum of this polymer contained one broad band at 340 cm^{-1}, which suggests distortions in the geometry of the bridging group induced by internal stresses. It was found[74] that internal stresses developed upon radical polymerisation of the $PdCl_2Y_2$ complex (Y is 2-methyl-5-vinyltetrazole) induce the cleavage of the metal–ligand bond and evolution of the inorganic microphase (MMM). An X-ray diffraction analysis of this complex has shown that the high level of internal stresses that appear upon polymerisation is due to strong steric shielding of the C=C bonds.[75] The inorganic microphase evolved in network polymers by virtue of internal stresses represents special manifestation of mechanochemical syneresis.

Since the reason for internal stresses in three-dimensional (co)polymerisation is incomplete shrinkage, total shrinkage can be reduced through the use of oligomers with a greater length of the spacer and plasticisers.[72] The total level of shrinkage and internal stresses can successfully be decreased using two-step synthesis of network (co)polymers. Its first step includes the synthesis of oligo(methacrylates) containing a large number of reactive double bonds from dimethacrylates.[28, 76] The use of such precursors in paint-and-varnish compositions employed as polymeric coatings improves their quality due to elimination of shrinkage stresses.[77] Slightly cross-linked gels based on dimethacrylates are used for the preparation of gradient light-focusing optical materials.[2] To do this, cylindrical gels are placed into a vessel filled with a solution of a monomer with a lower refraction index. A parabolic gradient of the monomer concentration is developed due to diffusion and is fixed by photopolymerisation. Non-shrinking spiroorthoester vinyl compounds proved to be valuable materials in the production of high-precision optics.[78] Radical polymerisation of these compounds at the double bonds is accompanied by the ring opening and the formation of a carbonyl group, which has larger size than that of the original ester ortho group. As a result, this reaction occurs without shrinking or is accompanied by a small increase in the volume. Non-shrinking compositions are prepared by copolymerisation of spiroorthoesters with ordinary vinyl monomers.[78]

Three-dimensional radical (co)polymerisation is widely employed for compression moulding of miscellaneous articles; therefore, much attention is given to the study of relationships between physical-mechanical properties of network copolymers and the structure of the starting oligomers and polymerisation conditions. An attempt has been made [24] to estimate the contribution of the structure of the starting oligoester methacrylates, intermolecular interactions and MPC into physical-mechanical characteristics of network polymers. The lack of a correlation between MPC and physical-mechanical characteristics of the polymers formed suggests that it is the distribution function of free volume rather than its absolute value that determines the properties of densely cross-linked polymers. Evidence for this assumption can be derived from the bimodal distribution of free volume in a polymer of triethylene glycol dimethacrylate as established by IR spectroscopy of adsorbed water.[67] It was found that the relative fractions of microvoids adsorbing small clusters $(H_2O)_n$ and of large pores absorbing water condensate depend on the polymerisation temperature.

Studies on physical-mechanical properties of network polymers based on oligocarbonate (meth)acrylates have shown [79] that the elasticity moduli determined from the initial portion of the deformation–stress diagram decrease with an increase in the spacer length and lowering of the energy barrier to internal rotation around the C–C bond. The elasticity modulus on compression is smaller than on stretching, which may be due to a greater contribution of the high-elasticity deformation component on compression. The differences in the chemical nature and lengths of oligomers and, correspondingly, molecular structures of polymer networks are especially apparent at initial portions of these diagrams. In regions of nonlinear dependence of stress *vs.* deformation, the differences in morphological characteristics of polymers predominate. A close relationship was found between the deformation-strength and relaxation characteristics of the polymers studied.[79] A similar correlation exists between thermomechanical and relaxation characteristics of network polymers based on oligomeric dimethacrylates.[57]

Studies of opticomechanical properties of model polymers based of diallyl and divinyl compounds of homologous series:

$$CH_2=CHCH_2OC(O)-(CH_2)_n-C(O)OCH_2CH=CH_2$$

$n = 2-8$, **14**

$$CH_2=CHC(O)O-(CH_2)_n-OC(O)CH=CH_2$$

$n = 2-6$, **15**

$$CH_2=C(CH_3)C(O)O-(CH_2)_n-OC(O)C(CH_3)=CH_2$$

$n = 2-6$, **16**

have been undertaken aimed at elucidation of the role of topological and morphological structures in the establishment of physical-mechanical characteristics of network polymers.[80]

Isochronic temperature dependences of the elasticity moduli $E = f(T)$ and optical sensitivity with respect to stress $D = f(T)$ have been determined [80] rather than deformation–tension dependences.[24, 79] Such a comprehensive approach has demonstrated non-additive changes in isothermic values of functions $E = f(n)_T$ and $D = f(n)_T$ on the number of the CH_2 groups in the homologous series of the polymers under study. There was no strict correlation between elastic and photoelastic characteristics and the length of the starting oligomers **14** and **15**.

The dependence of opticomechanical characteristics of densely cross-linked polymers on the structure of the starting oligomers is indirect rather than direct and is manifested as the peculiarities of topological structures of networks formed in three-dimensional polymerisation.[80] The differences in the properties of the polymers prepared from diallyl (**14**) and divinyl (**15**, **16**) oligomers are due to the fact that the former are prepared by cross-linking branched macromolecules, while the latter are synthesised by cross-linking primary microgel particles having colloidal sizes. A cage model of a network polymer was proposed [80] based on the established contributions of energy and entropic elasticities of deformed network polymers. According to this model, some interjunction chains have a rigid conformation, while the other undergo rotational-isomeric transitions and are responsible for the entropic elasticity of polymeric networks. This model has been rationalised taking into account the microtactic characteristics of polymeric chains and conformational structures of densely cross-linked polymers based on oligomeric dimethacrylates.[27, 28]

It was found [24, 79, 80] that the control of physicomechanical properties of network polymers by variation of the structures of the starting oligomers is inefficient due to microheterogeneity of the three-dimensional polymerisation mechanism, which determines topological and morphological structures of the final polymer. This stimulates a search for novel approaches to a control over topological and morphological structures of network polymers in the stage of their synthesis, *e.g.*, through the control over intramolecular cyclisation and intermolecular cross-linking reactions.[30]

III. Methods for *in situ* investigation of three-dimensional radical copolymerisation

Structural and kinetic studies of TRCP demand separate determination of the kinetics of consumption of double bonds of the cross-linking reagent M_1 and the monomer M_2 over the whole process. The sampling method and the analysis of the compositions of the copolymer and the monomer mixture in the course of the reaction applicable in linear copolymerisation cannot be used in this case, since insoluble network copolymers are formed in the earliest steps of TRCP. As for the calorimetric method widely used in the kinetic studies of three-dimensional homopolymerisation,[7] its application in TRCP is limited, since it allows one to measure the overall heat of the copolymerisation reaction and concomitant structural and physical transformations of the reaction medium.

The calorimetric method was used [81] for the study of copolymerisation of dimethacrylate **1** with styrene. By analogy with linear copolymerisation of styrene with MMA, the authors assumed that this reaction is azeotropic and used averaged values of molar heats to calculate the conversion:

$$Q = 0.5(Q_1 + Q_2),$$

where Q_1 and Q_2 are the known molar heats of homopolymerisation of styrene and MMA. However, these calculations did not take into account the fact that the heats of bond formation in the diads M_1M_2 in the copolymerisation of these monomers differ from those in the diads M_1M_1 and M_2M_2.[60, 82] One should also keep in mind that, apart from chemical reactions of the opening of C=C bonds, differences in the conformation energies of network polymers and its linear analogue and shrinkage stresses make significant contributions to the overall heat of three-dimensional copolymerisation.[83] The contribution of these structure-physical components to the heats of formation of network copolymers can apparently be ignored only in comparative studies of kinetics of copolymerisation of the same type of systems at the qualitative level.

Thus, the experimental base for the study of TRCP could not be formed by simple borrowing methods for investigations into linear copolymerisation, on the one hand, and the performance of three-dimensional homopolymerisation, on the other hand. Therefore, special methods of spectroscopic monitoring for *in situ* structure-and-kinetic investigation of TRCP have been developed to solve this problem.

1. IR spectroscopic monitoring

IR spectroscopic monitoring of TRCP is based on the construction of curves of double bonds consumption in the oligomer $[C_1(t)]$ and the monomer $[C_2(t)]$ from the decreage in the intensities of

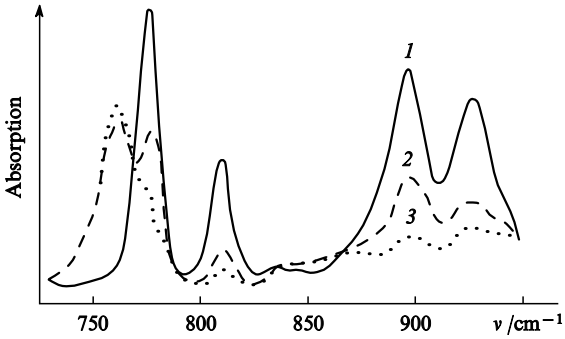


Figure 4. IR spectra of the original mixture (ethylene glycol dimethacrylate–styrene) (molar ratio, 1:2) (*1*), after 8 h polymerisation at 30 °C ([CPC] = 5 mass %) (*2*) and after 8 h annealing at 60 °C (*3*).[83]

absorption bands of the corresponding $C=CH_2$ groups. The main criterion in the choice of analytical bands is their minimum overlapping in the spectrum. In many oligomer–monomer systems, this criterion is met by the bands of deformation vibrations of hydrogen atoms in the region of 750–950 cm^{-1}. In the copolymerisation of ethylene glycol dimethacrylate with styrene and dicyclohexyl peroxydicarbonate (CPC) as an initiator, the intensities of all absorption bands related to deformation vibrations of $C=CH_2$ bonds of methacrylate groups (945, 812 cm^{-1}) and styrene (907, 780 cm^{-1}) shows a tendency to decrease reaching a constant level characteristic of residual unsaturation of the copolymer at a given temperature (Fig. 4).[83] Subsequent increase in the temperature results in 'thawing' of the mobilities of styrene, ethylene glycol dimethacrylate and pendant methacrylate groups, as a result of which copolymerisation continues up to the moment when the copolymer formed passes again into a glassy state (Fig. 4, curves *2* and *3*). Similar changes in the IR spectra are observed in the copolymerisation of triethylene glycol dimethacrylate with styrene.

The conversion curves of the methacrylate groups and styrene[83] are shown in Fig. 5. A decrease in the content of residual methacrylate groups on going from ethylene glycol dimethacrylate to triethylene glycol dimethacrylate suggests that the short oligomeric block significantly hinders the mobilities and decreases the effective reactivities of pendant methacrylate groups in comparison with a more lengthy oligomeric block.

Studies of TRCP of model systems based on monomers and multifunctional oligomers and carrying similar reactive groups (MMA with dimethacrylates, styrene with divinylbenzene) present considerable interest. However, the analytical bands of

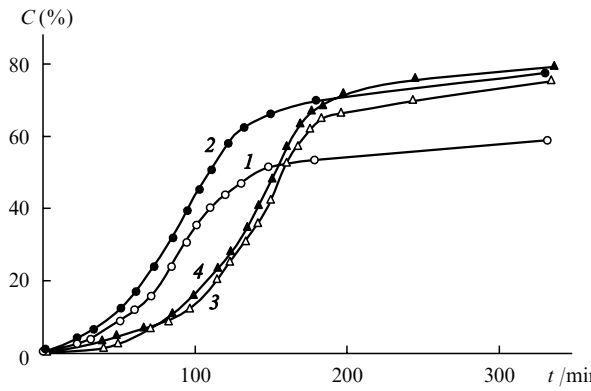

Figure 5. Copolymerisation kinetics of ethylene glycol dimethacrylate (*1*) with styrene (*2*) and triethylene glycol dimethacrylate (*3*) with styrene (*4*).[83]
Dimethacrylate : styrene ratio 2:1, T = 30 °C, [CPC] = 5 mass % (*1*, *2*) and 3 mass % (*3*, *4*).

the monomer and oligomer overlap completely. In this case, separate investigation of the copolymerisation kinetics can be carried out by replacing one of the comonomers by its deuterated analogue. Thus on going from MMA to D-MMA, the vibrational frequency of the C=C bond decreases from 1638 to 1592 cm^{-1}, which allows separate registration of copolymerisation rates of the double bonds of D-MMA and dimethacrylate.[13]

Monitoring of consumption of reactive groups using absorption bands of vibration overtones in the near IR region of the spectrum significantly expands the potential of the studies of (co)polymerisation in multicomponent systems. As the overtone frequences ν_{0-2} are associated with the main vibrational frequency ν_{0-1} by the ratio:

$$\nu_{0-2} \approx 2\,\nu_{0-1},$$

the absorption bands of the overtones are characterised by a better resolution than the neighbouring main vibration bands. Near-IR monitoring was used[48] in a study of two interpenetrating polymer networks one of which was prepared by radical copolymerisation of bisphenol A diglycidyl ether dimethacrylate (**17**) with styrene, while the other, by a reaction of diglycidyl ether of bisphenol A (**18**) with 4,4′-diaminodiphenylmethane (**19**). The kinetics of formation of each interpenetrating network could be studied by analysing overtones of vibration bands of the epoxy group, styrene and methacrylate groups at 6073, 6135 and 6166 cm^{-1}, respectively.

The achievements in the production of equipment for IR spectroscopy are so significant that they can meet virtually any demands of investigators in the field of three-dimensional (co)polymerisation. Modern Fourier spectrometers allow the registration of rates of superfast three-dimensional photopolymerisation reactions of acrylic and methacrylic compounds in microsecond time spans with time resolution of 10^{-3} s (see Ref. 84). Layer-by-layer scanning of polymeric coatings can be performed and the degree of conversion can be judged using real-time attenuated total reflectance-Fourier transform IR spectroscopy.[85] The use of optofibre connections permits one to conduct kinetic monitoring in polymerisation reactors located at a distance of up to 100 m from the spectrophotometer.[86]

An analysis of the kinetic data by spectroscopic monitoring is often confined to a discussion of the conversion *vs.* time dependences.[5,48,85] The presentation of experimental data in the copolymerisation rate–time coordinates makes it possible to increase the amount of information obtained by this method.[11–13] The ratio of copolymerisation rates in the oligomer M_1 and the monomer M_2 (υ_1/υ_2) is yet another important structure–kinetic feature of TRCP reactions which reflects the instantaneous composition of a copolymer. Valuable information about the state of a reaction system can be obtained from a comparison of experimental dependences of the rates *vs.* reaction time $(w_1/w_2)_{exp}$ with the dependences calculated on the basis of the Mayo–Lewis model according to the equation:

$$\left(\frac{w_1}{w_2}\right)_{cal} = \frac{r_1[M_1] + [M_2]}{r_2[M_2] + [M_1]}, \qquad (7)$$

where $[M_1]$ and $[M_2]$ are the current concentrations of the C=C bonds calculated on the basis of the experimental dependences $C(t)$.

IR spectroscopic monitoring allows one to follow the disturbances in the uniform distribution of reactants in TRCP. Such disturbances can be due to microsyneresis of the components from microgel particles (microreactors) and low molecular mobility of the medium in the vitrification step, as a result of which diffusional flows of the reactants to the active sites cannot compensate for the consumption of a more reactive monomer. Deviation of the experimental ratio of the reduced copolymerisation rates $(w_1/w_2)_{exp}$ from the values of $(w_1/w_2)_{cal}$ calculated by the Mayo–Lewis model is a criterion for the estimation of such disturbances.[12,45]

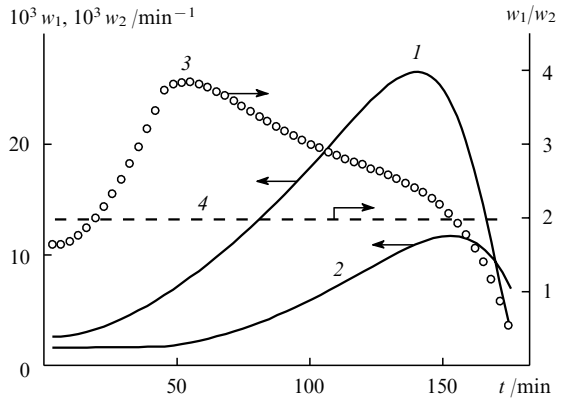

Figure 6. Copolymerisation kinetics of butanediol dimethacrylate (14.5 mass %) with 2-methyl-5-vinyltetrazole.[12]
(*1*, *2*) Copolymerisation rates (w_1 and w_2, respectively), (*3*) experimental values of w_1/w_2, (*4*) values of w_1/w_2 calculated from Eqn (7).

The TRCP of dimethacrylates with 2-methyl-5-vinyltetrazole is a special case of disturbances in the concentration homogeneity of the reaction medium.[12,45] Prerequisites for the appearance of concentration heterogeneities in such systems are significant differences in the reactivities of methacrylate groups of oligomers and vinyltetrazole (for linear copolymerisation of MMA with 2-methyl-5-vinyltetrazole $r_1 = 1.47$, $r_2 = 0.51$, respectively) and low content of the cross-linking reagent.

Figure 6 shows the experimental dependences of the reduced copolymerisation rates of butanediol dimethacrylate (**4**) and the monomer **5** as well as the experimental and calculated dependences of the ratios (w_1/w_2) *vs*. time. A comparison of curves *1* and *2* demonstrates that copolymerisation of methacrylate groups occurs as an autoaccelerating reaction from the very beginning, while the monomer **5** is polymerised initially at a constant rate. A possible reason for the selective gel effect in the polymerisation is disturbances in the initially uniform distribution of reagents in the vicinity of the growing macroradical due to the enrichment of the polymer chain with monomer units carrying pendant methacrylate groups due to low copolymerisation constant of vinyltetrazole.

As a result, the local concentration of methacrylate groups in the vicinity of the growing macroradical $[M_l]$ increases in comparison with their average concentration in a reactor $[M_m]$, the latter being determined by spectroscopic methods and used for the calculation of the reaction rates.

$$w = \frac{\upsilon}{[M_m]}.$$

This results in the overestimation of w values perceived as a selective gel effect. No such effect is observed at high concentrations of butanediol dimethacrylate. It was therefore concluded that high flexibility of the growing macroradical containing a large number of units of the monomer **5** is a prerequisite for its manifestation. Evidently, at high content of these units the macroradicals have a coil conformation, which favours intramolecular cyclisation. Selective gel effect can lead to the formation of a specific microheterogeneous network structure consisting of regions with higher concentration of the cross-links incorporated into a loosely cross-linked matrix enriched with units derived from 2-methyl-5-vinyltetrazole.[12]

The experimental values of w_1/w_2 significantly exceed the calculated values (see curves *3* and *4*, Fig. 6) over a broad range of conversions. This difference cannot be explained only by the increase in the local concentration of pendant methacrylate groups.[12] The exit of the monomer **5** from the reaction zone as a result of microsyneresis also seems to play a role in the concentration heterogeneity of the medium. Contrariwise, in the terminal step the experimental values of w_1/w_2, are much lower than the calculated ones.This can be due to higher mobility of the monomer **5** in comparison with dimethacrylate **4** and pendant methacrylate groups under conditions of vitrification of the reaction medium, as a result of which $[M_l]$ in the vicinity of the macroradicals becomes lower than $[M_m]$.

It was shown [12,13,45] that TRCP and the concomitant structure-physical transformations of the reaction medium may induce non-uniform distribution of the reactants in the vicinity of growing macroradicals and, as a consequence, compositional heterogeneity of copolymers. Thus topological peculiarities of TRCP play a role in the formation of compositional heterogeneity of network copolymers. These include cyclisation and selective gel effect in the initial steps of the process, microsyneresis of reactants, differences in the rates of diffusional transport of reactants to macroradicals in the step of vitrification of the reaction medium.

IR spectroscopic monitoring is a promising method for the *in situ* studies of structure–kinetic relationships in TRCP which consists of recording kinetic curves for the decomposition of initiators of the radical polymerisation $C_i(t)$.[50] The vibration bands of the C=O bonds of benzoyl peroxide and dicyclohexyl peroxydicarbonate lie in a convenient region for measurements (1770–1820 cm^{-1}) depending on the type of intermolecular interactions and do not overlap with the absorption bands of C=O in the decomposition products.[87] Their intensities are sufficiently high for registration of the dependences $C_1(t)$, $C_2(t)$ and $C_i(t)$ in one experiment. Combined analysis of these dependences enables the estimation of the contribution of a decrease in the decomposition rates of the initiator to inhibition of TRCP in the vitrification step.[50]

2. NMR studies of formation of network polymers

NMR spectroscopy is widely used for the *in situ* studies of copolymerisation kinetics and the structures of the copolymers formed. The conversion of the double bonds of comonomers is determined from the decrease in the intensities of signals for vinyl protons using high resolution ^{1}H NMR spectrometers.[88,89] Studies of ternary copolymerisation of hydroxyethyl methacrylate (**20**) with *N*-vinyl-2-pyrrolidone (**21**) and *tert*-butyl-2-hydroxycyclohexyl methacrylate (**22**) using this method made it possible to obtain conversion curves for each individual comonomer and to determine the instantaneous composition of the ternary copolymer at various degrees of conversion.[88]

The copolymerisation of acrylamide with bisacrylamide in D_2O has been studied in especially great detail.[26,53] This study revealed a nearly twofold decrease in effective reactivities of the double bonds of bisacrylamide with an increase in the depth of conversion due to accumulation of a great number of less mobile pendant acrylamide groups.[53] A large number of 'head-to-head' additions of the monomeric units testifies to the microheterogeneity of the copolymer structures at the molecular level.[26]

Pulse NMR was used [35,90,91] for the study of formation of network polymers during polymerisation of dimethacrylates. NMR data confirm the validity of the microheterogeneous mechanism of three-dimensional radical polymerisation [23,92] and enable more detailed investigations into formation of network polymers.

3. Dielectric relaxation spectroscopy

The effect of structure-physical transformations of the reaction medium on the kinetics of three-dimensional radical polymerisation is largely realised through changes in the molecular mobilities of the reactants.[36] On-line monitoring of three-dimensional polymerisation by dielectric relaxation spectroscopy in a broad frequency range (as a rule, from 1 to 10^5 Hz) provides comprehensive information about the evolution of structural and dynamic characteristics of the reaction medium. This allows one to follow *in situ* changes in the rotational mobilities of polar groups by changes in the dielectric conductivities ε and transla-

tional mobilities of impurity ions by changes in the electric conductivity σ and to observe microphase separation from the appearance of Maxwell–Wagner interlayer polarisation.[36, 57, 93–95] The informativity of this method increases appreciably when kinetic polymerisation studies are supplemented by calorimetry [36] and IR spectroscopy.[96]

The correlations between the features of molecular motion at different depths of polymerisation and kinetic characteristics of this process were established using a specially designed measuring cell [36] for simultaneous *in situ* registration of dielectric permittivity, conductivity of the reaction medium and heat evolution. It was found that a sharp decrease in the rate of linear polymerisation of MMA, which is due to the vitrification of the reaction medium, correlates with a sharp decrease in dielectric permittivity. This suggests that the freezing of the forward-rotational motion of MMA molecules over the whole bulk of the polymerisate is the main reason for autoretardation of the reaction.[36]

Three-dimensional polymerisation of oligomeric dimethacrylates, in contrast with polymerisation of MMA, is characterised by a broad range of autoretardation and an even broader (as regards conversion) zone of reduced dielectric permittivity.[36, 57] A broad range of dispersion of the dielectric permittivity testifies to the structural and dynamic heterogeneities of the polymerisates formed. Initial manifestations of a decrease in dielectric permittivity are due to the formation of fragments of a network with interjoint distances lower than the size of the kinetic segment (local vitrification). Further gradual decrease in dielectric permittivity down to maximum conversions suggests that fragments with a loose cross-linking where segmental mobility of the network components still remain in the polymer. This molecular mobility resource is used for enhancing the conversion in three-dimensional polymerisation and (co)polymerisation by increasing the temperature in the final step.[83]

The initial steps of three-dimensional polymerisation of dimethacrylates are often accompanied by abnormal increase in dielectric permittivity.[36, 57] The appearance of a positive increment $\Delta\varepsilon$ against the background of a general tendency of the dielectric permittivity to decrease owing to a decrease in the mobility of polar methacrylate groups included into the network is attributed to the formation of a microheterogeneous structure of the polymerisate, which restricts the mobilities of ionic impurities. An analysis of different models of microheterogeneous polymerisates revealed that these abnormalities can be explained by the 'reversal' of the matrix for the mechanism of interlayer polarisation and by using the theory of polarisation of the diffusion zone of the double electric layer.[97, 98]

A promising approach to the study of three-dimensional radical copolymerisation entails the use of complex techniques which include simultaneous monitoring of the reaction by dielectric relaxation and IR spectroscopy. The use of model oligomer–monomer systems allowing selective monitoring of molecular mobility of a polar cross-linking reagent (dimethacrylate) in a non-polar medium of the second monomer (styrene) seems to be a very informative approach.

4. Fluorescent probes

The use of fluorescent molecular probes for the study of polymerisation processes is based on high sensitivity of emission spectra parameters to intermolecular interactions and structure-physical state of the medium. The changes in the state of the nearest environment of luminophore molecules may bring about shifts in the maximum of the emission band, enhancement of the fluorescence intensity and changes in the anisotropy and fluorescence lifetime.[99] On-line measurements of these parameters in the course of polymerisation provide direct information about the structural evolution of the reaction medium.[100]

The fluorescence method was used for the study of the sol–gel transition in the copolymerisation of MMA with compound **1** [101–103] using pyrenemethyl pivalate as a probe. It was found that the intensity of fluorescence (I) at the moment of sol–gel transition (t_c) was sharply increased due to freezing of molecular mobility and an increase in the quantum yield of the fluorescence. A comparison of the experimental dependence t_c on the concentration of ethylene glycol dimethacrylate c_0 (see Ref. 101) with a calculated dependence obtained on the basis of a kinetic model of gel formation [104]

$$t_c = (kc_0)^{-1}, \tag{8}$$

where k is the combination of rate constants for all steps of the reaction, revealed that at the dimethacrylate concentrations above 0.5% the experimental values of t_c exceed manyfold the calculated values and are little dependent on the concentration of dimethacrylate in the reaction mixture (Fig. 7). These discrepancies are due to a decrease in the overall rate constant k caused by a decrease in the probability of involvement of pendant methacrylate groups in the molecular cross-linking.[101, 105]

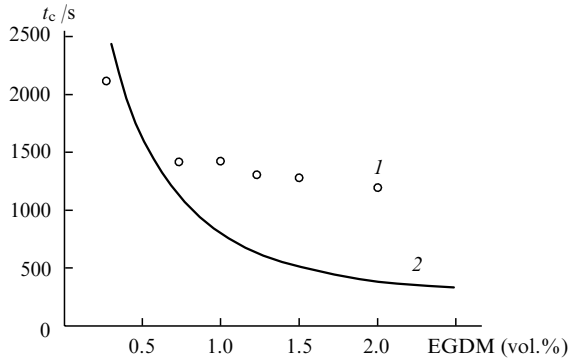

Figure 7. Dependence of the onset of gel formation in copolymerisation of MMA with ethylene glycol dimethacrylate (EGDM) at 75 °C on the concentration of dimethacrylate.[101]
(*1*) Experimental data, (*2*) curve calculated from Eqn (8).

The experimental dependences $I(t)$ were used [101–103] for determining the numerical value of a critical parameter β in the expression for the sol–gel transition in the framework of a percolation gel formation model:[106]

$$G = B(p - p_c)^{\beta}, \tag{9}$$

where G is the share of the gel fraction, B is the critical amplitude and p is the probability of formation of a bond between the adjacent junctions of the network. If $p = p_c$, this corresponds to the onset of formation of an infinite cluster, *viz*., the gel point. Assuming [101] that the reaction time t is proportional to the probability p, the time t_c corresponds to the gel point, and the fluorescence intensity corresponds to the amount of the gel formed, Eqn (9) can be converted into Eqn (10):

$$I = A(t - t_c)^{\beta}, \tag{10}$$

where A is a new critical amplitude. The values of β determined from the slope of the dependences:

$$\log I = \log A + \beta \log(t - t_c)$$

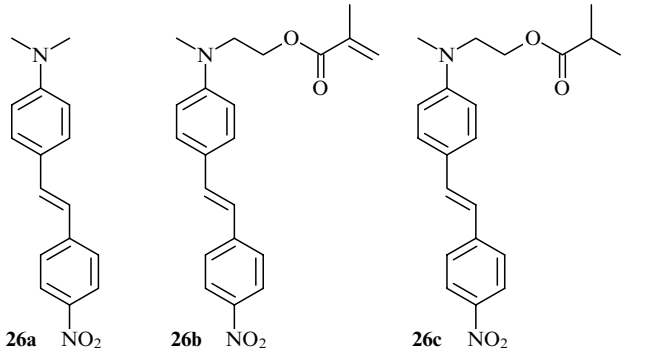
appeared to be the same for systems with different content of dimethacrylate; the average value of $\beta = 0.40 \pm 0.03$ was similar to that calculated on the basis of the percolation model.[106]

Copolymerisation of acrylamide with bisacrylamide in an aqueous solution was studied using 1-anilinonaphthalene-8-sulfonate (**23**) as a fluorescent probe.[99] The polymerisation was accompanied by a 20-fold increase in the fluorescence intensity with an increase in the volume fraction of the polymer in the hydrogel due to a decrease in the diffusion coefficient of the water molecules which play the role of fluorescence quenchers. There is a good correlation between the kinetic curves for the increment of I and the curves obtained using the dilatometric method. Both

methods gave similar values of rate constants for polymerisation and the reaction order with respect to the initiator.

An equipment for simultaneous *in situ* monitoring of conversion of double bonds and recording fluorescence spectra has been described.[100] In this equipment the differential scanning calorimeter and a spectrofluorimeter have a common measuring cell. 7-Nitro-2,1,3-oxadiazole dialkylamino derivatives (**24**, **25**) were used as fluorescent probes. That containing an acrylate group was incorporated into the network as a fluorescent label. Studies of photopolymerisation of dimethacrylates and other multifunctional oligomers revealed a good correlation between the increase in the fluorescence intensity and conversion of C=C bonds.

Both inert and reactive fluorescent probes (**26a**–**e**) based on 4-amino-4′-nitrostilbene were used for the study of microheterogeneity of the reaction medium in photopolymerisation of ethylene glycol, triethylene glycol, butanediol and hexanediol dimethacrylates.[107]



The inert probes **26a**, **26c** and **26e** simulated free oligomer molecules and participated in microsyneresis throughout the polymerisation; these concentrated in areas with a loose network and were surrounded by the oligomer molecules. The probes **26b** and **26d** containing methacrylate groups were incorporated into the network polymers formed and were distributed in the reaction medium more uniformly.[107]

The polymerisation of all dimethacrylates studied was accompanied by a shift of the maximum towards a short-wavelength region with a simultaneous broadening of the fluorescence band (λ_{max}); however, on reaching a $\sim 60\%$ conversion, the spectrum was slightly narrowed. In the authors' opinion,[107] the polymerisation results in the formation of a heterogeneous reaction medium in which the probe molecules are distributed between different microregions. As a consequence, the fluorescence spectrum represents a sum of spectra of probe molecules in different environments which vary from highly mobile regions enriched with the oligomer ($\lambda_{max} = 700-650$ nm) to regions consisting exclusively of rigid densely cross-linked polymer ($\lambda_{max} = 560-590$ nm). The changes in the spectral parameters of fluorescence are observed as a result of accumulation of a network polymer and the redistribution of probe molecules between different microregions. The probes **26a**, **26c** and **26e** are displaced from the areas with a high density of the network to more mobile loosely cross-linked areas. This can be evidenced from a smaller shift of λ_{max} in comparison with the shifts of λ_{max} in the case of probes **26b** and **26d**, which are immobilised in the network as a result of copolymerisation with dimethacrylates. A decrease in the width of the fluorescence band on reaching a $\sim 60\%$ conversion testifies to the tendency of the network density to equalise at greater depths of polymerisation. This tendency is consistent with the results of modelling and high-temperature annealing of network polymers.

IV. Control of three-dimensional radical copolymerisation and design of network macromolecular structures

Process control of three-dimensional radical copolymerisation and the formation of network copolymer structures entails control over growth, cyclisation and chain cross-linking reactions (1)–(5). Some authors (for bibliography, see Ref. 1) consider the intermolecular cross-linking reaction (3), responsible for the formation of macrogel, and secondary cyclisation (or intramolecular cross-linking) reaction (4), which results in the formation of microgel particles and a molecular network structure, as key objects for the control. However, the conventionality of such separation can be illustrated by the fact that the contribution of reactions (3) and (4) depends, in turn, on the lengths of the primary polymer chains formed in reaction (1).[6] Therefore, studies on three-dimensional radical (co)polymerisation are currently characterised by an intensive search for ways of control over the whole complex of reactions (1)–(5).

A characteristic feature of TRCP is the existence of tight structure–kinetic relationships realised at both topological and morphological levels of formation of the structure of the network polymer. Therefore, the studies devoted to the problem of control over TRCP processes can arbitrarily be divided into two groups depending on the factors (structure-physical or kinetic) used for this analysis. The conventionality of such division is determined by the fact that any changes in the structures of the starting monomers M_1 and M_2 and in the properties of the reaction medium (*e.g.*, type of solvent, nature of intermolecular interactions, *etc.*) determine the kinetics of the process. In turn, varying of the rates of initiation, growth and chain termination reactions is accompanied by changes in the structural and diffusional characteristics of the reaction medium, which influences the kinetics of the reaction in accordance with the feedback principle.

1. Structure-physical methods of control over three-dimensional radical copolymerisation

The structure-physical approach to the control over TRCP processes is based on variations of the types and intensities of intermolecular interactions in the reaction mixture. In practice, this approach is realised in several ways. Monomer units with bulky alkyl substituents, which create steric hindrance for the interaction of the growing radicals with pendant double bonds, are introduced into a copolymer chain in order to suppress cyclisation and intermolecular cross-linking. Monomers containing sites for strong intermolecular interactions resulting in the formation of a physical interaction network in the reaction medium are employed to stimulate intermolecular cross-linking and gel formation. And, finally, the contributions of cyclisation and intermolecular cross-linking can be controlled by varying the excluded volume factor through the use of solvents possessing different thermodynamic affinities for the copolymer formed.

Steric effects of alkyl substituents of methacrylate monomers on gel formation during their copolymerisation with multifunctional methacrylates have been studied.[108] It was shown that in copolymerisation of ethylene glycol dimethacrylate with dodecyl methacrylate (**27**) the intermolecular cross-linking can be completely suppressed due to steric hindrance created by the alkyl group of $C_{12}H_{25}$. This represents a new route to the preparation of reactive prepolymers carrying pendant methacrylate groups.

The effects of steric hindrance on the critical conversion (gel point) in the copolymerisation of allyl methacrylate (**28**) with MMA, dodecyl methacrylate, butyl methacrylate and hexadecyl methacrylate (**29**) have been studied.[109] The degree of polymerisation of the primary chains was maintained at the same level using a chain transfer agent, *viz*., dodecanethiol (**30**). A characteristic feature of the polymerisation of allyl methacrylate in comparison with dimethacrylates is that in the early steps of polymerisation a polymer is formed carrying only allyl pendant groups due to low reactivities of the allylic double bonds.[110, 111] Therefore, gel formation in the homopolymerisation of allyl methacrylate occurs later than in the polymerisation of dimethacrylates. In the copolymerisation of allyl methacrylate with MMA and butyl methacrylate, the experimental critical conversion corresponding to the gel point (C_c = 24.1%) coincided with that calculated with the use of the Stockmayer theory, whereas in the copolymerisation with methacrylates **27** and **29**, the gel point was shifted towards the critical conversion of 34.3% and 43.0%, respectively. It was shown [109] that as in copolymerisation of higher methacrylates with dimethacrylates, this shift is due to steric hindrance exerted by long-chain alkyl substituents, which prevents interaction of growing methacrylate radicals with pendant allyl groups.

The topology of the TRCP reaction strongly depends on the rigidity of the main chain of the copolymer macromolecule that is being formed.[6] This was established in comparative studies of gel formation during copolymerisation of dimethacrylates with MMA, on the one hand, and with *tert*-butyl methacrylate (**31**) and bornyl methacrylate (**32**), on the other hand. It was found that in copolymers prepared with involvement of the methacrylate units **31** and **32** cyclisation and inter- and intramolecular cross-linking are suppressed due to a decrease in the flexibility of the main chain and steric hindrance created by bulky substituents.

The effects of the physical network of the hydrogen bonds on intermolecular cross-linking and gel formation in three-dimensional copolymerisation have been studied.[112, 113] The copolymerisation of benzyl methacrylate (**33**) with 2 mol.% of hexanediol dimethacrylate was carried out in a solution of *tert*-butylbenzene in the absence and in the presence of 5 mol.% of (2-methacryloyloxyethyl) succinate (**34**).[112] The onset of gel formation occurred at conversions of 38.2% and 30.0%, respectively. The displacement of the gel point towards lower conversion values in the presence of the succinate **34** is due to the formation of hydrogen bonds between the carboxy groups of the succinate units **34** incorporated into the prepolymer and the growing macroradical. The presence of these bonds reduces the excluded volume effect thus favouring intermolecular cross-linking of the polymeric radicals with the pendant methacrylate groups of the prepolymer and the formation of macrogel.[112] A displacement of the gel point towards lower conversions under the influence of hydrogen binding of carboxy groups was also observed in ternary copolymerisation of hexanediol dimethacrylate with butyl methacrylate and the succinate **34**.

A combination of chemical and physical cross-linking makes it possible to realise the conditions of formation of network polymers which are consonant with the Flory–Stockmayer theory and to synthesise the networks close to ideal.[112] Copolymerisation of methacrylate **33** with 0.05 mol.% of poly(ethylene glycol) $(CH_2CH_2O)_{23}$ dimethacrylate (**35**) in *tert*-butylbenzene supplemented with 5 mol.% of the succinate **34** is an example. In the absence of the succinate **34**, no gel is formed even at maximum conversions of ~94%; however, in its presence, the network of hydrogen bonds favours the formation of a chemically cross-linked macrogel even at 58.4% conversion. The ratio of the experimental value of conversion, which corresponds to the gel point to the theoretical value is 1.9, which allows this network to be considered [112] as virtually ideal. The formation of such a network is favoured by the formation of a diphilic copolymer with a rigid non-polar primary chain built of units of methacrylate **33** and flexible polar pendant chains of dimethacrylate **35** in the pre-gel step.

Considerable attention is given to the study of three-dimensional copolymerisation of dimethacrylates with hydrophilic monomers containing hydroxy groups. The resulting hydrogels manifest good swelling properties in the presence of water. By virtue of their hydrophilic nature and good biocompatibility, such hydrogels find use in medicine and biology.[114]

Hydrogels based on hydroxyethyl methacrylate (**20**) are widely used in medicine. Large amounts of such hydrogels are used in the production of contact lenses,[115] while copolymers based on methacrylate **20** and dimethacrylates of ethylene glycol and diethylene glycol dimethacrylates are used as blood substitutes and drug depots.[116] Therefore, the regulation of processes of formation of the structure and properties of hydrogels based on methacrylate **20** should meet the most rigid criteria. Special attention is given to primary cyclisation, since it causes a significant deviation of mechanical properties, swelling index and diffusion characteristics of the copolymer from the corresponding parameters of an ideal network along with lower density of chain cross-linking. The effect of the composition of the monomeric mixture on primary cyclisation in photoinduced copolymerisation of methacrylate **20** with diethylene glycol dimethacrylate and poly[ethylene glycol(600) dimethacrylate] (**36**) has been studied.[114] A comparison of experimental results with the results of computer simulation of the reaction kinetics using a method developed by Elliot and Bowman [117] showed that the dependence of reactivities of pendant methacrylate groups on their spatial localisation, moment of 'generation' and length of the spacer as well as the differences in the local and averaged concentrations of polymeric radicals should be taken into consideration to fit the experimental data on the extent of cyclisation with the calculated values. The addition of a solvent increases the probability of cyclisation due to a decrease in the rate of the reaction of polymeric radicals with the monomer and an increase in the time of contact of the radical with the pendant methacrylate groups.[114]

The effects of the solvent on the formation of a network copolymer in the ternary copolymerisation of methacrylate **33**, ethylene glycol dimethacrylate and methoxytricosaethylene glycol methacrylate (**37**) have been studied.[6] The copolymer formed had a diphilic nature owing to a combination of a non-polar main chain and polar side chains of the comonomer **37**. As a result, the conformation of the copolymer depended on the nature of the solvent, which, in its turn, affected the cross-linking process. Thus the compression of the main chain and straightening of the side chain in a methanolic solution resulted in the formation of microgel particles.

Emulsion copolymerisation of styrene and MMA with divinylbenzene is used in the synthesis of reactive microgel particles having submicron sizes and carrying pendant C=C bonds.[118, 119] The microgels thus obtained are used in the production of polymeric coatings.

Three-dimensional radical copolymerisation in the presence of diluents is widely employed for the preparation of heterogeneous porous materials used as sorbents, membranes and materials for chromatography. Phase separation is the main driving force in the formation of a porous structure, while the morphology of the network polymer formed is determined by the microheterogeneous mechanism of copolymerisation.[1] Two-component mixtures consisting of a good solvent and a precipitant are often used for controlling the parameters of the porous structure of a copolymer in suspension copolymerisation.[120–122]

Hydrogen binding sites, which represent hydroxy groups localised in the oligomeric chain of dimethacrylate, have a pronounced effect on the TRCP processes and the structure and properties of the copolymers formed.[5] Studies of copolymerisation kinetics of such dimethacrylates by real-time IR spectroscopy revealed [5] that effective reactivities of methacrylate groups depend critically on the curing temperature. Thus in the initial steps, the rate of copolymerisation of methacrylate groups at 30 °C significantly exceeds that of styrene, whereas at 90 °C the difference is levelled off. A considerable effect of temperature on the relative

reactivities of the double bonds of comonomers can be explained [34] by the fact that low temperatures favour the formation of oligodimethacrylate associates stabilised by intermolecular hydrogen bonds and with methacrylate groups arranged favourably for the chain growth. An increase in temperature results in the dissociation of such associates and a decrease in effective reactivities of methacrylate groups.

Studies into mechanical properties of copolymers prepared at 30 and 90 °C and further cured to a state with identical conversion of the double bonds revealed that the strength and impact elasticity of the destruction of a low-temperature copolymer significantly exceed those of a high-temperature one. These differences correlate with the peculiarities of the microstructures of the copolymers as revealed in the analysis of the failure surface by atomic-force microscopy. Both copolymers have granular structures with the grain sizes of about 100 nm, the grain size in the low-temperature sample being larger. It was concluded [5] that the granular morphology of copolymers is due to the fact that TRCP occurs with the formation of microgel particles which then merge to form clusters. It was found also that microphase separation the early stages of which are temperature-dependent plays an important role in the formation of granular morphology.

Introduction of hydrogen-binding sites into network polymers based on dimethacrylates offers additional opportunities for modification of their properties owing to a combination of chemical physical networks. However, the problem of steric effects exerted by the rigid network of chemical bonds on the feasibility of realisation of an interpenetrating network of labile hydrogen bonds is still topical. Model hybrid networks based on triethylene glycol dimethylacrylate and containing COOH groups as potential junctions of a physical network were tested.[123] The carboxy groups were introduced in three different ways, *viz*., by copolymerisation of triethylene glycol dimethylacrylate with methacrylic acid, by polymerisation of dimethacrylate containing a solubilised copolymer of MMA with methacrylic acid and by thermal oxidation of residual double bonds in a homopolymer of triethylene glycol dimethacrylate. IR spectroscopic studies have shown that hydrogen bonds are formed both between the carboxy groups (dimers) and between the carboxy and ester groups; hydrogen bonds depleted by steric hindrance and a certain amount of free COOH groups are also present. The relative contents of different hydrogen bonds and free carboxy groups that cannot form H-bonds due to steric hindrance depend on the mode of introduction of these groups into the polymeric matrix.[123]

A significant effect on TRCP is produced by additives of various polymers introduced into the reaction medium in order to reduce shrinkage and modify the structure and properties of the network copolymers. A great number of papers are devoted to the effects of polymeric additives on curing of polyester resins which represent mixtures of unsaturated polyesters with styrene.[124–126] A characteristic feature of such processes is phase separation of the reaction mixture in the very early steps of the reaction and the formation of a biphasic structure where the components represent inclusions of the polymeric additives and the matrix represents a cured polyester resin.[126, 127] A polymeric additive can influence the topology and kinetics of network formation. The scope of this influence is determined by the concentration of the additive and its compatibility with the original reaction mixture and the network copolymer formed.[128]

A comprehensive structure–kinetic study of TRCP of a polyester and styrene in the presence of additives, *viz*., PMMA (**11**) and poly(vinyl acetate) (**38**) having a higher thermodynamic compatibility with the reaction medium has been carried out.[128] The reaction rate was recorded using differential scanning calorimetry; changes in the sizes of the microgel particles in the step preceding the formation of the macrogel were monitored by gel-permeating chromatography. It was found that the rate of copolymerisation decreases with an increase in the concentration of the additive, this effect being more pronounced for the polymer of **11**. The same factors determine the extent of reduction of microgel particles in early steps of the reaction. It was concluded [128] that poor compatibility of polymeric additives with the polyester results in compression of coils of polyester molecules in a mixture of styrene with the additive, which favours intramolecular cyclisation, reduction of the sizes of microgel particles and a shift of the onset of macrogel formation towards higher conversions.

2. Kinetic methods for the control over three-dimensional radical copolymerisation

The existence of a relationship between the kinetics of three-dimensional radical (co)polymerisation and structure formation of network (co)polymers has stimulated a search for efficient methods for the control over this process at different rates of initiation, growth and termination of polymeric chains.

The effect of the initiator concentration on the formation of microgel particles was studied for bulk polymerisation of ethylene glycol dimethacrylate.[129] This study included isolation and analysis of gel particles at different stages of the polymerisation process. The overall conversion of the double bonds was estimated using differential scannining calorimetry; the number of pendant methacrylate groups in gel particles was determined by IR spectroscopy. Dynamic light scattering studies have shown that a bimodal distribution of gel particles according to their size takes part in the reaction system in the very earliest steps of the reaction. It is of note that larger particles are formed upon aggregation of smaller particles.

The conversion of pendant double bonds in microgel particles increases in the course of polymerisation from 20% (at the overall conversion of double bonds of $\sim 1\%$) to 65% at the moment of formation of the macrogel (at the overall conversion of double bonds of 14%). An increase in the initiator concentration results in considerable broadening of the range of size distribution of macrogel particles: at the initiator concentration of 1%, the size of smaller particles ranges from 19 to 30 nm, whereas that of large particles is in the range 83–134 nm. If the initiator concentration increases to 5%, the ranges of the particle size increase to 11–32 and 44–154 nm, respectively, but the average size of larger particles diminishes from 105 to 80 nm, presumably at the expense of an increasing contribution of the quadratic radical termination reaction at invariably high rates of initiation and shortening of primary polymer chains involved in the formation of larger particles. The data obtained [129] suggest that the morphological structures of the polymers formed depend critically on the concentration of the initiator.

However, the experimental results reported by Chiu and Lee [129] do not correlate with the results obtained within the framework of a model of three-dimensional radical polymerisation.[24] According to this model, the reaction system contains, from the very beginning of polymerisation, only two components, *viz*., the starting oligomer and grains of a network polymer with the maximum possible degree of conversion. In the course of polymerisation, which occurs on the grain surface, the size of the grains increases and the latter begin to aggregate. Contrary to model concepts,[24] the degree of polymerisation of microgel particles increases gradually with time; the reaction of pendant methacrylate groups inside gel particles makes a significant contribution to the total conversion of the double bonds.[129]

It has been shown [130] that the experimental results obtained in the study cited [129] do not fit in kinetic and statistical network formation models, since they ignore the changes in structure–kinetic relations in polymerisation. However, it was found that these results can qualitatively be rationalised in the framework of a percolation model, which takes account of translational diffusion of monomeric and polymeric molecules, segmental diffusion of polymeric chains, excluded volume effect, formation of microgel particles and differences in effective reactivities of double bonds in the starting oligomer and pendant methacrylate groups. Presumably,[130] a more precise description of microheterogeneous

three-dimensional polymerisation should rely on a model which combines the advantages of the percolation model with those of the average field model.

The multimodal distribution of microgel particles according to their size [129] seems to be the most characteristic feature of three-dimensional radical polymerisation and copolymerisation. This was confirmed by the results of investigation of microgel particles obtained by copolymerisation of ethylene glycol dimethacrylate with MMA in toluene in which the cross-linking reagent was used at the concentrations of 9 mol.% and 15 mol.% (see Ref. 131). Data from exclusion chromatography suggest that in both cases the distribution of microgel particles according to their size changed gradually in the course of copolymerisation from monomodal to bimodal due to increasing fraction of larger particles. It was emphasised [131] that bimodal distribution of particles near the gel point provides conclusive evidence in favour of a coagulation macrogel-forming mechanism according to which small-sized (primary) particles aggregate to form larger particles. In earlier studies,[1] the formation of a macrogel in the course of TRCP was considered as a special manifestation of chemical aggregation of colloidal particles. The correlation between cross-linking and chain termination rate constants, on the one hand, and changes in the structures and sizes of reaction components, on the other hand, should be taken into consideration in describing the kinetics of gel formation as the interaction of microgel particles.[131]

IR spectroscopic monitoring was used [45] to study the effect of the initiator concentration on the copolymerisation kinetics of butanediol dimethacrylate with 2-methyl-5-vinyltetrazole (monomer **5**) over the whole range of conversion. It was found that the reduced copolymerisation rate of the methacrylate groups (w_1) in the initial steps of the reaction increases with the concentration of the initiator (dicyclohexyl peroxydicarbonate) (1 mass % – 3 mass %), this increase being more pronounced than that of the monomer **5** (w_2). This can be due to the fact that at high rates of initiation shrinkage lags behind copolymerisation in time, which leads to appearance of excess free volume in the vicinity of growing macroradicals. The mobilities and effective reactivities of pendant methacrylate groups increase correspondingly. The local concentration of the monomer **5** in the reaction zone may additionally decrease with an increase in the degree of cross-linking inside the microgel particles as a result of microsyneresis and a concomitant increase in the w_1/w_2 ratio. The differences in the effects of initiation rates on the copolymerisation kinetics of reaction components result in a significant effect of the initiator concentrations on the compositional and structural heterogeneities of network copolymers even if the compositions of original oligomer – monomer mixtures are identical.

An important role in the control over three-dimensional radical polymerisation is played by inhibitors and the polymer chain transfer agents. Their mechanisms of action are based on suppression of the intramolecular cyclisation reaction (2) by reduction of the lengths of primary polymeric chains. Trinitrotoluene (**39**) was found to be an effective regulator of structure formation in three-dimensional polymerisation of dimethacrylates.[23, 132] The addition of the polymerisation inhibitor **39** results in drastic changes in the kinetic and rheological characteristics of polymerisation of triethylene glycol dimethacrylate.[23] This is manifested in a shift in the onset of the gelation effect from the degree of conversion $\sim$ 1% to $\sim$ 15% with retention of fluidity of the polymerisate in this conversion range. In the Avrami coordinates, the polymerisation kinetics is characterised by the coefficient $n = 0.9$, which suggests homogeneity of polymerisation and the formation of short comb-like polymer chains with pendant methacrylate groups. Then, the system loses its fluidity, as a result of which the Avrami coefficient increases to 1.3 due to a decrease in the rate constant for quadratic termination of the macroradicals. The lack of the autoretardation step up to maximum conversions of $\sim$ 70% is a characteristic feature of the reaction carried out in the presence of 10 mol.% of the inhibitor **39.** Conventional microheterogeneous polymerisation of triethylene glycol dimethacrylate is described by a constant value of the Avrami index (1.6) even in the early steps up to a transition to the autoretardation mode at $\sim$ 40% conversion. The differences in the kinetics of ordinary and suppressed polymerisation of triethylene glycol dimethacrylate suggest that after addition of the inhibitor **39** the microheterogeneous formation of a network polymer can be replaced by a quasi-homogeneous one.

The effects of the inhibitor **39** on the copolymerisation kinetics of ethylene glycol and triethylene glycol dimethacrylates and oligocarbonate dimethacrylate as well as on the structures and properties of the polymers formed have been studied.[132] In this study, compound **39** suppressed the microheterogeneity of the reaction medium and favours the formation of polymers with more homogeneous structures. Compound **39** has an advantage over other, more rapidly consumed inhibitors in that it controls gel formation throughout the polymerisation time, since the value of the rate constant for the inhibition is $\sim$ 20 times lower than for chain growth.[132]

Chain transfer agents (alkanethiols and alkyl halides) are used to control three-dimensional (co)polymerisation much more frequently than inhibitors. Using chain transfer reactions, one can control successfully the degree of polymerisation of primary chains, prevent cyclisation and displace the gel point towards higher conversion values. Very often, this results in elimination of the gel effect. The main approaches to the use of chain transfer reactions for the control over three-dimensional thermally induced (co)polymerisation are discussed in a review.[6]

Considerable attention has recently been given to the role of the chain transfer reaction in three-dimensional photoinduced copolymerisation.[133, 134] The effect of initiation and chain transfer rates on the copolymerisation kinetics of hydroxyethyl methacrylate with 1 mass % of diethylene glycol dimethacrylate on the structure of the polymer chain was studied.[134] It was found that the lengths of the kinetic chains and the polymerisation rate decrease, while the rates of quadratic radical termination reactions increase in the presence of dodecane-1-thiol as the chain transfer agent. An increase in the initiation rate and a concomitant increase in the photoirradiation rate result in high concentration of short radicals, which also increases the probability of the chain termination reaction. Large number of short polymeric chains and the formation of a sol fraction significantly deteriorate the properties of network polymers of biomedical applications. Optimisation of conditions for their preparation demands selection of photoinitiation rates with account of the dependence of the chain termination reaction on the chain length.[134]

3. Chain transfer catalysts as regulators of three-dimensional radical (co)polymerisation and (co)polymer structures

The discovery of a catalytic chain transfer on a monomer in the linear polymerisation of MMA [135] has stimulated a search for possible applications of chain transfer catalysts in the control over three-dimensional polymerisation of oligodimethacrylates and the synthesis of soluble reactive polymers based on them.[28, 76, 136, 137] These and subsequent studies have demonstrated that the structure-forming role of chain transfer catalysts in linear and three-dimensional radical polymerisation differ substantially despite identical chemical mechanisms.

Low-spin cobalt(II) complexes with various macroligands proved to be highly efficient chain transfer catalysts in the polymerisation of methacrylates.[138] The type of ligand environment has a crucial effect on the rate constants of the catalytic chain transfer reaction, for the series of cobalt glyoximates these vary from 50 to 100 000. The steric factor, which determines the possibility of the interaction of cobalt with a growing polymeric radical, plays an important role. These data were taken into consideration in the design of catalysts that are efficient in the chain transfer from the methacrylate radicals, but completely inert with respect to styrene radicals.[138]

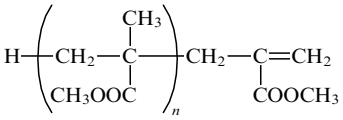
The pioneering study [135] was devoted to polymerisation of MMA in the presence of a cobalt – hematoporphyrin complex

[Co(II)P]. A two-step catalytic mechanism was proposed for the chain transfer from the growing radical R_n^* to the monomer M:

$$R_n^* + Co(II)P \longrightarrow Z_n + HCo(III)P, \quad (11)$$

$$HCo(III)P + M \longrightarrow Co(II)P + R_1^*. \quad (12)$$

According to IR spectroscopic data,[139] abstraction of the hydrogen atom from the terminal methyl group of the C-tertiary radical R_n^* in reaction (11) results in the formation of the unsaturated macromonomers Z_n:



40

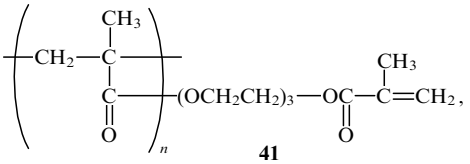
Because of the high value of the rate constant for the catalytic chain transfer (2.4×10^3), the Co(II)P added to the reaction medium in as low concentration as 6.6×10^{-4} mol litre^{-1} favours the formation of an oligomer P_n with a degree of polymerisation $n = 9$.[135] Preparation of an oligomer of the same degree of polymerisation in the presence of ordinary chain transfer agents of the thiol type demands $\sim$ 10 mass % of the latter, which is incorporated in the oligomer and thus presents serious technological problems.[140] The use of catalytic chain transfer agents not only eliminates these problems, but also enables access to reactive macromonomers of variable degrees of polymerisation which can be regulated by varying the concentration of the transfer agent.[138, 140]

Catalytic chain transfer reactions are widely used in the synthesis of macromonomers of the type **40** from various methacrylates.[141] Their reactivities differ significantly from those of ordinary unsubstituted methacrylates, since the radicals formed as a result of an attack on the vinyl group of the oligomers **40** have low growth rates due to steric shielding.[142] Therefore, the adducts formed in the reaction of the radicals R_n^* with macromonomers of the type **40** are prone to undergo reversible β-fragmentation, *i.e.,* elimination of the terminal fragment.[140, 143]

$$R_n^* + Z_k \rightleftharpoons Z_{n+1} + R_{k-1}^*. \quad (13)$$

Study of this reaction in a macromonomer **40**–butyl methacrylate mixture has led to suggestion [143] that macromonomers of the type **40** are involved neither in the copolymerisation with ordinary methacrylates nor in chain transfer catalysis through Co(II), but are themselves active participants of a catalytic chain transfer. A competition between catalytic chain transfer reactions through intermediacy of Co(II) and β-fragmentation is a characteristic feature of all reactions involving Co(II) complexes. Its role increases with an increase in the degree of conversion. Reaction (13) significantly extends the potential of radical polymerisation and allows one to perform synthesis of block and graft copolymers with acrylates, styrene and other monomers, which cannot normally be accomplished.[140, 143]

For the first time, the catalytic chain transfer reaction was used for the control over three-dimensional radical polymerisation of dimethacrylates.[28, 76] It was found that the polymerisation of triethylene glycol dimethacrylate in the presence of Co(II)P yields soluble linear oligo-*n*-methacrylates



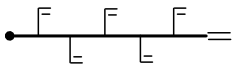
41

carrying a pendant methacryloyl group in each repeating unit. The degree of polymerisation of the oligomers **41** depends on the concentration of the chain transfer catalyst.

The oligomers **41** with degrees of polymerisation $n = 5-15$ manifest high reactivities. Substitution of oligomers **41** for dimethacrylates makes it possible to diminish chemical shrinkage and internal stresses within the polymer and to obtain networks with segmental structures made up of long and short polymethacrylate chains cross-linked with oligomeric chains. The polymers prepared from oligomers differ from ordinary triethylene glycol dimethacrylate-based polymers in syndiotactic attachment of their methacrylate groups and higher values of elastic moduli.[28] This testifies to gradual elimination of steric hindrances preventing the growth of polymethacrylate chains and alleviation of internal stresses associated with the two-step synthesis of the polymer. Possible applications of compounds **41** for improving the quality of paintwork materials based on oligoester acrylates are discussed.[77]

The addition of Co(II)P to triethylene glycol dimethacrylate in its bulk polymerisation strongly attenuates the gel effect which is shifted towards higher conversion values.[76] However, with an increase in the concentration of the catalyst up to the maximum limiting solubility values (5×10^{-3} mol litre^{-1}) the gel effect cannot totally be eliminated and insoluble network polymers are formed. Preparation of soluble products **41** and elimination of the gel effect can be achieved by polymerisation in DMF, which prevents aggregation of polymeric chains and the formation of a macrogel. In this context, degeneration of the gel effect can be regarded as a reliable test for the formation of multifunctional compounds **41**.[76]

The effect of the catalytic chain transfer reaction on polymerisation of ethylene glycol and diethylene glycol dimethacrylate with AIBN as the initiator has been studied.[29, 144] The addition of Co(II)P sharply decreases the polymerisation rate, diminishes the gel effect and changes the shapes of the kinetic curves (Figs 8 and 9). This suggests that Co(II)P significantly restricts the development of microheterogeneity of the reaction medium and the effect of the latter on the rates of chain growth and chain termination due to formation of multifunctional oligomers with pendant methacrylate groups.



42

The probability of intramolecular cyclisation decreases sharply after the formation of low-molecular-weight intermedi-

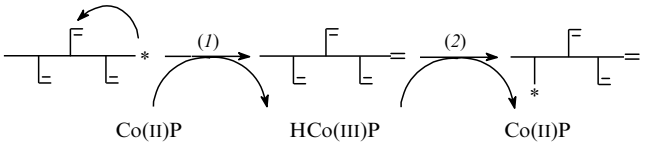
ates **42** and prerequisites appear for the formation of more homogeneous polymers.

The extent to which the chain transfer catalyst influences the rate of polymerisation of ethylene glycol and diethylene glycol dimethacrylates and the shapes of kinetic curves vary significantly (see Figs 8 and 9). As a consequence, the effective rate constant for the catalytic chain transfer and the structure–kinetic relationships in three-dimensional radical polymerisation strongly depend on the structures of the starting oligomer and the polymer and physical characteristics of the reaction medium.

It is known that this rate constant decreases in linear polymerisation of methacrylates with an increase in the length of the alkyl substituent.[145] However, in the polymerisation of dimethacrylates, similar doses of Co(II)P more strongly inhibit the polymerisation rate of diethylene glycol dimethacrylate, an oligomer with a greater chain length (see Figs. 8 and 9). Higher efficiency of the chain transfer catalyst in the polymerisation of diethylene glycol dimethylacrylate can be ascribed to structural peculiarities of the growing polymeric radical, *viz*., the probability of intramolecular transfer of chains to the pendant double bonds of diethylene glycol dimethacrylate is higher than in the case of ethyleneglycol dimethacrylate due to the greater length of the spacer.[144]

Obviously, the role of a catalytic chain transfer in the formation of a more homogeneous network structure is not confined to the inhibition of intramolecular cyclisation (*1*):



An important role is ascribed to the probability of intermolecular cross-linking of the intermediates **42**, which involve pendant radicals formed in the intramolecular chain transfer reaction (*2*).

Polymerisation of diethylene glycol dimethacrylate in the presence of high concentrations of Co(II)P is accompanied by an appearance of two maxima on the kinetic rate curve $w(C)$ which correspond to 6% and 53% conversion of the double bonds. The first maximum is unrelated to a classical gel effect and appears as a result of formation of multiple terminal C=C bonds in a fast catalytic chain transfer reaction. The formation of such bonds is accompanied by a reduction of the thermal effect of polymerisation (Q) depending on the number-averaged degree of polymerisation ($\bar{P}$) (see Ref. 141)

$$Q = \frac{Q_\infty (\bar{P} - 1)}{\bar{P}}, \qquad (14)$$

where Q_∞ is the specific heat of polymerisation in the absence of a chain transfer catalyst.

Thus, the first maximum (Fig. 9, curve *3*) corresponds to the apparent gel effect and is manifested if Q_∞ is used instead of Q in the processing of calorimetric data. A true gel effect is observed at the conversion $C > 30\%$ and develops in response to enhancement of diffusional control over the catalytic chain transfer reaction. This, in turn, is due to a decrease in the molecular mobilities of bulky Co(II)P complexes resulted from an increase in the concentration of the network polymer and vitrification of the reaction medium.

The effect of diffusion on the catalytic chain transfer reaction in the linear polymerisation of methacrylates were studied.[145] It was found that the structure–kinetic relationships can be expressed by an empirical equation:

$$C_k k \eta^\alpha \approx \text{const}, \qquad (15)$$

where C_k is the catalytic chain transfer constant, k is the rate constant for the chain growth and η is the viscosity of the reaction medium ($\alpha = 0.5-1$). From the expression (15), it follows that the efficiency of the chain transfer catalyst decreases with an increase in the viscosity of the reaction system. However in the case of three-dimensional bulk polymerisation of dimethacrylates the structure–kinetic relationships are more complicated, because the reaction occurs in a microheterogeneous medium.[29, 144]

When polymerisation of ethylene glycol and diethylene glycol dimethacrylates is carried out in DMF in the presence of high concentrations of Co(II)P, the gel effect is abolished completely, which points to elimination of the topological factors responsible for the microheterogeneity of the reaction medium.[144] The multimodal molecular-mass distribution of polymerisation products suggests the presence of dimeric and trimeric forms of the starting dimethacrylates and of the major high-molecular-weight fraction (Fig. 10). The average molecular masses of the polymerisation products depend substantially on the structure of the starting dimethacrylate, the concentrations of Co(II)P and the content of DMF. According to IR spectroscopic data, the products contain large amount of pendant methacrylate groups and can be related to compounds of the type **42**. High reactivities of these compounds were confirmed by separate determination of copolymerisation kinetics of pendant methacrylate groups with D-MMA (Fig. 11).[146]

In contrast to dimethacrylates, which are used exclusively in the synthesis of statistical polymers, the multifunctional compounds **42** can be used as starting reagents in the design of a new generation of polymeric materials having the structures of graft copolymers. Three-dimensional nanosized copolymers with controlled levels of microheterogeneities possessing entirely novel properties can be prepared by varying structural parameters of the precursors **42** and comonomers.[146]

The use of catalytic chain transfer agents for the control over three-dimensional copolymerisation was first proposed by the

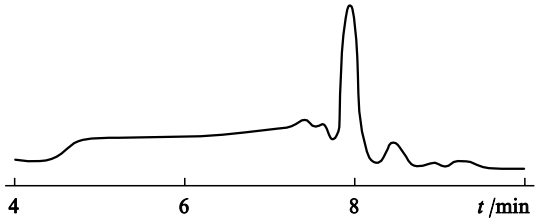


Figure 10. A gel-permeation chromatogram of polymerisation products of ethylene glycol dimethacrylate in the presence of 1×10^{-2} mol litre^{-1} Co(II)P and 40 mass % of DMF.[144]

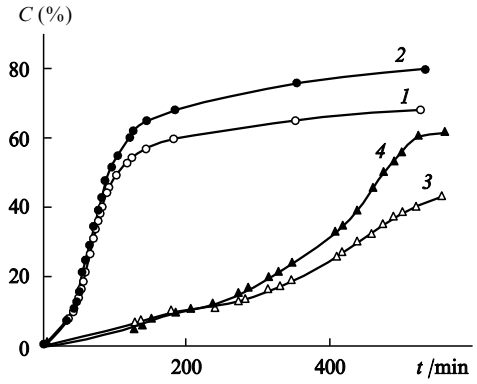

Figure 11. Copolymerisation kinetics of oligo-*n*-methacrylates based on ethylene glycol dimethacrylate (*1*, *3*) with D-MMA (*2*, *4*).[146]

present authors.[45] The use of oligomer – monomer systems, which differ considerably in the mechanisms of reactions of terminal radicals with chain transfer catalysts, seems to be especially promising in this respect. These systems include mixtures of dimethacrylates with styrene and acrylates, since reactions of catalytic transmitters with C-secondary styrene- and acrylate-derived radicals differ substantially from their reactions with tertiary methacrylate-derived radicals.[147–150]

It has been shown [147] that the coefficient of the chain transfer from the polymeric radical to the monomer in the polymerisation of styrene in the presence of Co(II)P is an order of magnitude lower than that in the polymerisation of MMA. In the authors' opinion, this is due to the involvement of the chain transmitter in the competing reactions of catalytic inhibition

$$HCo(III)P + R_m^* \longrightarrow P_m + Co(II)P \qquad (16)$$

and reversible inhibition due to the formation of a labile cobalt – carbon bond:

$$R_n^* + Co(II)P \longrightarrow R_n - Co(III)P. \qquad (17)$$

Reversible dissociation of the Co – C bond can lead to regeneration and further growth of the polystyrene radical, which corresponds to the passage of the reaction into a 'living' radical polymerisation mode.[148]

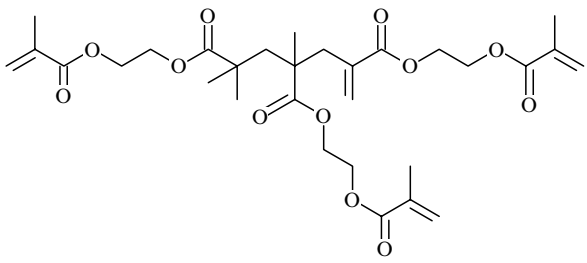
It has been shown [30, 151] that the addition of Co(II)P decreases drastically the rate of copolymerisation of ethylene glycol dimethacrylate with styrene in parallel with a shift of w_{max} towards higher degrees of conversion and an increase in the limiting conversion of the double bonds. An analysis of experimental results revealed that the formation of a network in the presence of Co(II)P is less subject to diffusion-controlled limitations in comparison with ordinary copolymerisation. As in the case of homopolymerisation of dimethacrylates,[29] the kinetic effects of Co(II)P are caused by a decrease in the microheterogeneity of the reaction medium due to the formation of intermediates of the type **42**. The sorption and physical-mechanical characteristics of the copolymers formed undergo significant modifications under the action of the chain transfer catalyst, which influences both the kinetics of copolymerisation and the formation of the network structure.[30]

In the bulk copolymerisation of dimethacrylate with styrene, the gel effect cannot completely be suppressed even by high concentrations of Co(II)P, which points to incomplete homogenisation of the reaction medium. The lack of the gel effect in the copolymerisation carried out in DMF suggests that the topological factors responsible for the microheterogeneity in the reaction of Co(II)P with macroradicals are eliminated virtually completely, as a result of which intramolecular cyclisation and cross-linking reactions are suppressed. The structures of reaction products obtained upon copolymerisation of an ethylene glycol dimethylacrylate – styrene mixture (1 : 1) in the presence of 20% of DMF provide supporting evidence. These reaction products represent multifunctional oligomers of the type **42** with M_n = 2270 and M_w = 14 350 (see Ref. 151).

The feasibility of preparation of soluble branched copolymers of MMA with tripropylene glycol diacrylate (**43**) in the presence of an ordinary (dodecanethiol) and a catalytic (cobalt difluoroboro dimethylglyoximate) chain transfer agents has been demonstrated.[152] This reaction was carried out in toluene (0.33 mol) with 0.15 mol of MMA and 5×10^{-3} mol of diacrylate (80 °C). The changes in the compositions and architectures of copolymers were recorded by NMR spectroscopy and chromatographic methods. It was found that linear copolymers with pendant acrylate groups are formed in the initial steps of the reaction. These groups react with the growing radicals to form branchings and loops. In turn, branched macromolecules can further be cross-linked through quadratic termination and recombination, which increases the molecular masses and polydispersities of the copolymers formed. Because of the differences in the reactivities of MMA ($r_1 \approx 2.0$) and diacrylate **43** ($r_2 \approx 0.5$), the concentration of the latter in branched copolymers increases with an increase in the degree of conversion, which favours further branching. The differences in the chain transfer constants for the reactions carried out in the presence of dodecanethiol for the methacrylate (~ 0.6) and acrylate (~ 1.7) radicals increase the probability of quadratic termination in the final period of the reaction due to consumption of the chain transfer agents and increasing concentrations of the growing acrylate radicals.

Although the persistent concentration of the catalytic chain transfer agents throughout the polymerisation reaction was noted [152] as its salient advantage, the problems of peculiarities of its interactions with acrylate and methacrylate were not touched upon. These include the possibility of formation of a cobalt – carbon bond between the terminal acrylate-derived radical of the copolymer and the transfer agents and the passage of the reaction into a living radical polymerisation mode upon reversible dissociation of this bond.[149, 150] The contribution of the aforementioned reaction should increase at higher conversions due to involvement of an increasing number of acrylate groups in copolymerisation. The β-fragmentation (13) resulting from the interaction of terminal C=C bonds in methacrylate branches of copolymers of the type **40** with various polymeric radicals [143] can also play a role in the character of the molecular-mass distribution and composition of branched copolymers.

The synthesis of superbranched polymers based on ethylene glycol dimethacrylate in the presence of cobalt glyoximate with a chain transfer constant of $\sim 10^3$ has been carried out.[153] By varying the concentration of the chain transfer catalyst, the author has succeeded in directing the polymerisation towards the formation of trimers of ethylene glycol dimethacrylate.



The reinitiation of terminal methacrylate groups of these trimers by a hydride transfer from the Co – H bond is accompanied by trimerisation and formation of new branching points. Cascade branching yields a soluble superbranched polymer with an average molecular mass ranging from several thousand to 40 000 Da. Soluble superbranched polymers are prepared by both bulk and solution polymerisation at dimethacrylate conversions

up to 70%. Special mention should be made of such remarkable characteristics of such superbranched polymers as high surface functionality and low viscosity, which is much lower than that of a linear poly(methyl methacrylate) of the same molecular mass.[153] Cascade radical polymerisation of dimethacrylates in the presence of a chain transfer catalyst can occupy a prominent place among more complex multistep procedures used in the synthesis of superbranched polymers and dendrimers.[154, 155]

Chain transfer catalysts based on triethylene glycol dimethacrylate can be used in the synthesis of linear polyesters.[156] However, the mechanism of their formation is still widely debated in the literature.[141] Note that linear polyesters can be prepared by catalytic chain transfer reactions (11) and (12) using hydride transfer to the pendant C=C bond of the terminal radical and the process occurs as alternating copolymerisation of these bonds with dimethacrylate molecules.

Studies on kinetics of three-dimensional radical (co)polymerisation of dimethacrylates in the presence of chain transfer catalysts [29, 30] have shown that the low-molecular-mass multifunctional intermediates **42** formed change dramatically the process of structure formation of network polymers in comparison with ordinary polymerisation where the role of transient species is played by microgel particles (Fig. 12 *a*). The formation of microgel particles in ordinary polymerisation of dimethacrylates and copolymerisation with styrene is the main reason for early manifestations of the gel effect, spatial heterogeneity of the network and formation of the microheterogeneous structure of the polymer. Using atomic-force microscopy, it was shown [157] that the degree of microheterogeneity of dimethacrylate–styrene copolymers increases with the concentration of the cross-linking reagent. This is accompanied by broadening of time relaxation spectra and an increase in fragility of the cross-linked copolymers.

The catalytic chain transfer reaction prevents the formation of microgel particles and development of the gel effect. In this case, the reaction medium represents a quasi-homogeneous solution of the intermediates **42** in the starting oligomer (Fig. 12 *b*).[151] The inhibition of intramolecular cyclisation sharply increases the probability of intermolecular cross-linking of the intermediates and favours the formation of a more uniform structure of the network (Fig. 12 *c*). It should be noted that not only the catalytic chain transfer reaction controls the morphology of the polymer by preventing the formation of large heterogeneous areas from microgel particles, but also stimulates the formation of a new in principle type of molecular networks consisting of short chains of the copolymer *1* cross-linked by the oligomeric chains *2*. By varying the concentration of a chain transfer catalyst, one can obtain chains *1* of any length and concentration and thus control the contribution of components *1* and *2* to the properties of the (co)polymers.

Comparative structure-physical studies of network polymers and copolymers prepared by conventional methods and in the presence of Co(II)P have shown that the structures and properties of the (co)polymers undergo significant modifications as a result of catalytic chain transfer reactions.[30, 151] The differences in the absorption kinetics of benzene and water induced by ethylene glycol dimethacrylate–styrene (4 : 1) copolymers synthesised by conventional methods and in the presence of Co(II)P provide an example (Fig. 13). The addition of Co(II)P also causes a ~ 10%

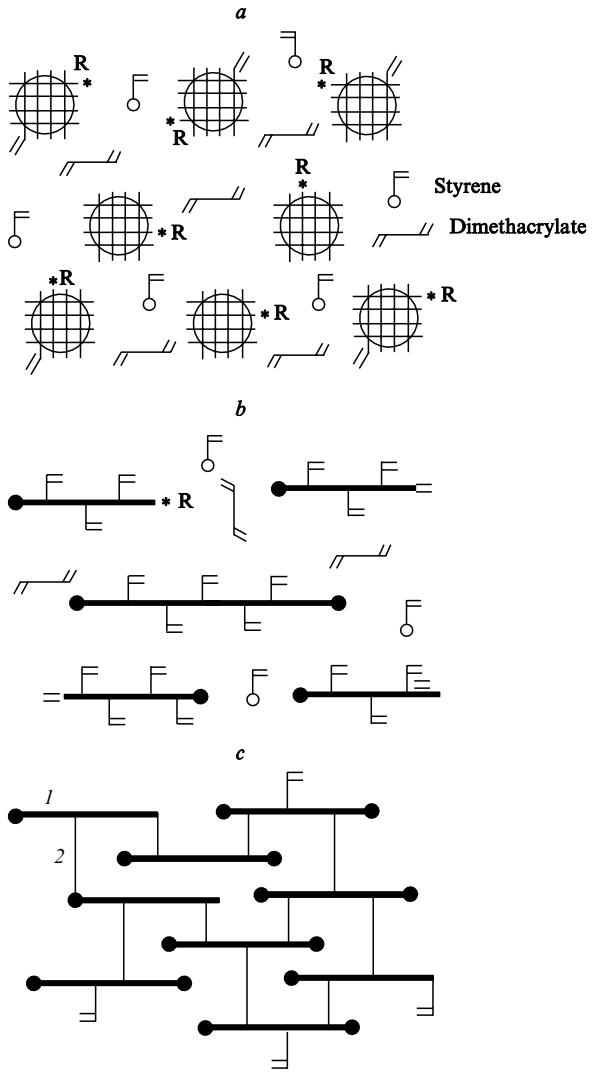


Figure 12. A scheme of synthesis of a network copolymer by conventional three-dimensional copolymerisation (*a*) and in the presence of a chain transfer catalyst (*b*, *c*).
For (*1*, *2*) see text.

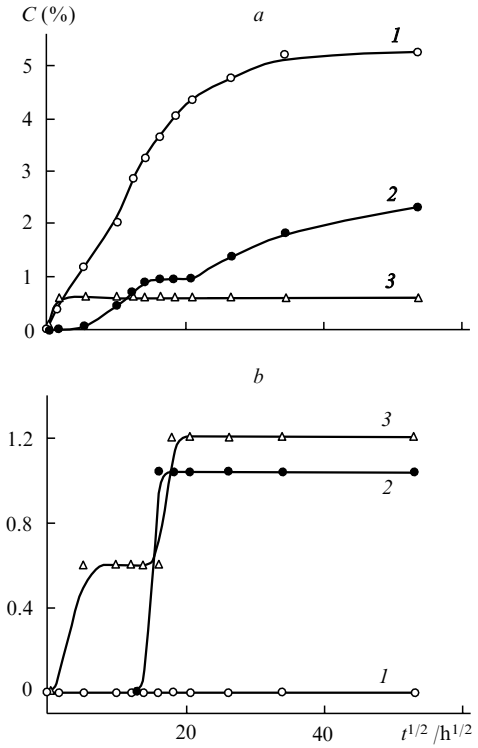

Figure 13. Kinetics of sorption of benzene (*a*) and water vapours (*b*) by copolymers of ethylene glycol dimethacrylate with styrene (4 : 1) prepared by ordinary copolymerisation (*1*) and in the presence of 3.4×10^{-4} (*2*) and 3.8×10^{-3} mol litre^{-1} Co(II)P (*3*).[30]

decrease in the elasticity modulus and a ~ 10% decrease in the forced elasticity modulus of copolymers. Homopolymerisation of ethylene glycol dimethacrylate in the presence of a chain transfer catalyst is accompanied by a ~ 30% decrease in the elasticity and forced elasticity moduli of the polymer. These data are at variance with the hypothesis [24] that a decrease in microheterogeneity of network polydimethacrylates will result in an increase in the elasticity modulus. Rather, they corroborate the hypothesis [158] that the microheterogeneities ('grains') play the role of reinforcing fillers in these polymers.

4. Three-dimensional radical (co)polymerisation in a 'living' chain growth mode

Significant achievements in the study of 'living' linear radical polymerisation in the past decade have paved the way to the synthesis of polymers with controllable structure and properties [159, 160] and stimulated attempts to use the 'living' polymerisation mode as a means of control over the formation of network (co)polymers. The agents of 'living' radical polymerisation influence substantially three-dimensional (co)polymerisation.[158] However, their efficiencies strongly depend on the structure-physical transformations of the reaction medium and can be brought to minimum through a decrease in the molecular mobilities of the reactants.[161]

The mechanism of 'living' radical (co)polymerisation is based on a reversible addition of growing polymeric radicals R* to low-molecular-mass radicals X* (see Refs 159 and 160).

$$R^* + X^* \rightleftharpoons R-X. \qquad (18)$$

Transition metal complexes, iminoxyl radicals and stable free radicals formed upon decomposition of the so-called iniferters (from Initiator Transfer Terminator Agent) can be used as polymerisation regulators X*.[159, 160] Owing to the high mobilities of the radicals X*, reaction (18) inhibits quadratic termination of polymeric radicals. Reiteration of decomposition and regeneration of a labile R–X bond induce the change in the fast chain growth mechanism into a slow step-by-step mechanism. The larger the number of steps in the chain growth mechanism the more completely the process meets the criteria of a true 'living' radical polymerisation, *i.e.*, the linear growth of the molecular mass of the polymer formed in parallel with the conversion of the monomer and narrow molecular mass distribution.[160]

There are hundreds of papers devoted to 'living' linear polymerisation of monofunctional compounds. The most recent advances are highlighted in several reviews [159, 160, 162, 163] which provide a detailed description of various types of compounds X and their applications as reagents for 'living' radical polymerisation and of mathematical models for predicting various parameters of the polymerisation reaction and the structures and properties of the reaction products. The use of polymers synthesised by ionic mechanisms, metathesis or polycondensation in 'living' radical polymerisation makes it possible to broaden the topology of the products (*e.g.*, linear, comb-like, superbranched, *etc.*, polymers) and compositions of copolymers (*e.g.*, statistical, regular, bulk, graft, *etc.*) and to ensure their controlled functionalisation.

However, the publications devoted to three-dimensional radical (co)polymerisation in a 'living' chain mode are not numerous due to the difficulties in conducting polymerisation in highly structured media. The main obstacle is that, in contrast to linear polymerisation, the mechanism of chain growth in three-dimensional polymerisation cannot be tested directly on the basis of such characteristics as molecular mass distribution, dependence of molecular masses of polymeric products on conversion, *etc.* Therefore, the contribution of the 'living' chain growth reaction to three-dimensional (co)polymerisation can be judged on the basis of indirect features, such as a critical conversion (gel point) shift,[164] suppression of autoacceleration of the reaction,[165] reduction of microheterogeneity of (co)polymerisation products and changes in their properties.[166] Some authors believe that these characteristics reflect the inhibition of intramolecular cyclisation due to a stepwise growth of the 'living' chains.[159] This hypothesis was corroborated in copolymerisation of styrene with 4,4′-divinylbiphenyl in the presence of an alkoxyamine, a 'living' radical polymerisation agent based on styrene and an iminoxyl radical 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO).[167, 168] The calculated experimental copolymerisation constants suggest that the cyclisation involving the pendant double bonds, which usually proceeds at high rates in ordinary polymerisation, is fully suppressed on going to the living polymerisation mode. The final product, *viz.*, cross-linked polystyrene, is virtually devoid of topological defects, such as small rings.

Significant differences were found [168] in the characteristics of polystyrenes cross-linked by 4,4′-divinylbiphenyl prepared upon conventional radical copolymerisation and in the presence of 'living' radical polymerisation agents. The copolymers synthesised in the 'living' chain mode were characterised by higher elasticity and swelling moduli than the former. These differences were interpreted within the framework of a microheterogeneous mechanism. The copolymers obtained by 'living' polymerisation possessed a nearly statistical distribution of network junctions and were characterised as homogeneous, whereas copolymers prepared by conventional three-dimensional polymerisation were made up of densely crosslinked microgel particles connected by a loose network typical of microheterogeneous polymerisation.

The efficacy of alkoxyamines for performing 'living' radical copolymerisation of dimethacrylates with styrene has been found.[166, 169] Three-dimensional radical copolymerisation of styrene with dimethacrylates in the presence of alkoxyamines based on TEMPO, benzoyl peroxide (dicyclohexyl peroxydicarbonate) and styrene was studied by high-precision isothermic calorimetry, EPR and rheokinetics.[169] A shift in the gel point towards higher conversion values (> 10%) and high concentrations of the iminoxyl radical throughout the polymerisation with sufficiently high rates of the reaction provide conclusive evidence in favour of a 'living' copolymerisation process. Detailed structure-physical studies using mechanical, thermomechanical and diffusion-sorption methods have shown [166] that copolymers obtained in 'living' polymerisation possess higher elasticities and lower effective densities of the macromolecular network in comparison with copolymers prepared by conventional polymerisation. These differences were attributed [166] to the decrease in the microheterogeneity of the reaction medium and granularity of the cross-linked copolymers on going from the chain growth to the stepwise growth mechanism.

The use of alkoxyamines and iminoxyl radicals as agents for 'living' radical polymerisation is limited to styrene-containing systems; in addition, polymerisation should be conducted at high temperatures (~ 120 °C).[159, 160] Therefore, controlled radical polymerisation of acrylates and methacrylates in a 'living' chain growth mode usually includes transfer of a halogen atom (the so-called Atom Transfer Radical Polymerisation, ATRP).[160] The possibility to perform polymerisation at lower temperatures (~ 70 °C) is an obvious advantage of this method. ATRP has found extensive application in linear (co)polymerisation and proved to be an efficient tool for the synthesis of polymers with controlled molecular masses, low polydispersities and diverse architectures.[159, 162, 170, 171] However, only a few examples are known where ATRP has been used for the control of three-dimensional radical (co)polymerisation reactions.[161, 172, 173]

The ATRP of diethylene glycol dimethacrylate induced by methyl α-bromophenyl acetate using a Cu(I)Br – 1,1,4,7,10,10-hexamethyltriethylenetetramine (HMTETA) complex as a catalyst has been studied.[161] This study included investigation of the time dependence of the conversion of double bonds by differential scanning calorimetry, *in situ* EPR spectroscopy and gel-permeation chromatography of the sol fraction isolated in different steps of polymerisation. An analysis of experimental results led the authors to the conclusion that this polymerisation proceeds in a 'living' mode and at persistent (low) concentrations of the growing

radicals only to conversions below 40%. Subsequent structurisation of the reaction medium and limitation of the diffusional mobility of the catalyst–ligand complexes disturb the equilibrium

$$R-M_n-Br + Cu(I)Br-HMTETA \rightleftharpoons$$
$$\rightleftharpoons R-M_n^* + Cu(II)Br_2-HMTETA$$

between growing and 'dormant' polymeric chains and direct the reaction to a conventional radical polymerisation route.[161]

The possibility of controlling three-dimensional radical bulk polymerisation of dimethacrylates by ATRP catalysts is limited due to a sharp decrease in their efficiencies with an increase in the viscosity of the reaction medium.[161] The use of solvents eliminates these limitations and opens up new opportunities for the design of network macromolecular structures in a 'living' radical copolymerisation mode. These possibilities were realised in the synthesis of star-shaped polymers with a functional microgel core.[172, 173] This approach [172] entails the addition of a bifunctional (cross-linking) reagent to a solution containing 'living' chains of a linear polymer. In the initial step, the molecules of the cross-linking reagent are attached to 'living' linear polymers; subsequent three-dimensional polymerisation yields microgel particles with chains of a linear polymer branching radially from its surface.

Star-shaped polymers with a microgel core were synthesised [172] by adding bis(acrylamides) containing spacers of different lengths and structures to a solution of 'living' PMMA chains prepared in the presence of an ATRP catalyst $RuCl_2(PPh_3)$. By varying the lengths of PMMA molecules and content of the divinyl compound, it was possible to obtain star-shaped polymers with molecular masses of 10^5-10^7 and macromolecular sizes ranging from 5 to 42 nm. This novel approach to the synthesis of star-shaped polymers enables incorporation of diverse functional groups (amide, ester, hydroxy, *etc*.) into the microgel core employing a cross-linking reagent with a spacer containing appropriate groups. This opens up new ways to the synthesis of star-shaped polymers attenuated to selective interactions of the 'guest–host' type. It was found [173] that biphilic star-shaped polymers with a diacrylamide core carrying ~ 70 radially branching PMMA chains with a degree of polymerisation of 100 can extract hydrophilic compounds, such as benzoic acid, benzyl alcohol and benzylamine from an aqueous solution to an organic phase. These polymers selectively interact with benzoic acid in the presence of ethyl benzoate (an equimolar mixture) by virtue of hydrogen bonding of the carboxy group to the $-NH-CO-$ groups.

Iniferters, which decompose upon UV irradiation or thermal treatment into two radicals, *viz*., an active R*, which initiates polymerisation of a monomer, and a passive radical X*, which is an active participant in linear termination of the macroradicals P_n^*, are widely used as initiators of 'living' radical polymerisation of vinyl monomers. The growth of 'living' chains is maintained owing to the fact that the rate of linear termination by a small mobile radical X* significantly exceeds that of diffusion-controlled quadratic termination of the macroradicals P_n^*, while the labile terminal bond in the adduct P_n-X dissociates with regeneration of the radical P_n^*, which ensures further chain growth up to the next chain termination.[160] Different types of iniferters and numerous examples of a macromolecular design based on them and their applications in linear radical polymerisation have been reviewed.[162]

The attempts to use iniferters to control three-dimensional radical copolymerisation are not numerous and confined to photopolymerisation of dimethacrylates.[58, 165, 174–176] *p*-Xylylenebis(*N*,*N*-diethyl dithiocarbamate), which dissociates irreversibly upon UV irradiation into an initiating C-radical and a carbamate-type S-radical terminating the growth of the polymeric chain, was used as an iniferter. The dependence of kinetics of 'living' three-dimensional (co)polymerisation of dimethacrylates on iniferter concentration, intensity of UV irradiation, temperature and spacer length has been studied.[165] It was found that the reaction is not autoaccelerated in the presence of the iniferter, and the polymerisation rate decreases 100-fold in comparison with ordinary photopolymerisation of dimethacrylates performed under identical conditions. A significant feature of this approach, which makes it different from conventional polymerisation, is that the polymerisation rate and the maximum conversion do not increase but rather decrease with an increase in the spacer length. This phenomenon is attributed [165] to the fact that the density of the cross-links increases in the presence of the iniferter much more slowly than in conventional polymerisation. Besides, the polymerisation rate is so low that the localisation of the methacrylate groups in the vicinity of the growing radical enhances their effective reactivities to a greater extent than the increase in their mobilities due to elongation of the spacer.

Poor reproducibility of the kinetic data obtained in the polymerisation reactions initiated by a photoiniferter ordinary photopolymerisation has been stressed.[165] This is attributed to the reversible chain termination in the presence of sulfo radicals; however, the contribution of this reaction to the overall heat of the process has not been taken into consideration in the calculation of conversions of double bonds on the basis of calorimetric data. It is therefore not surprising that the polymerisation kinetics of dimethacrylates measured by a spectroscopic method in the presence of the same iniferter [58] differs substantially from those results of calorimetric studies.[165] Studies of polymerisation kinetics of diethylene glycol and triethylene glycol dimethacrylates and of copolymerisation kinetics of divinylbenzene with styrene by the decrease in intensities of the absorption bands in the overtone vibrations of C–H bonds in the near IR revealed that the polymerisation rate decreases in the presence of a photoiniferter, although it does not eliminate the autoacceleration effect due to the diffusion control of quadratic termination of polymeric radicals.[58] Thus, the data available on the effects of iniferters on the kinetics of three-dimensional photopolymerisation of dimethacrylates are controversial. The mechanism whereby iniferters influence the kinetics of thermally induced three-dimensional polymerisation also needs to be further elucidated. The use of tetramethylthiuram disulfide as a free radical source imparts non-trivial kinetic features to the polymerisation of triethylene glycol dimethacrylate, which are manifested in particular in the appearance of two additional maxima on the polymerisation rate *vs*. time curve.[158]

Polymers synthesised in the presence of photoinifertes are convenient models for the study of dependences of their structures and properties on the degree of conversion, since they do not contain immobilised radicals able to initiate the polymerisation process at higher temperatures.[174–176] The heterogeneities of copolymers of poly[ethylene glycol(200) dimethacrylate] and poly[ethyleneglycol(200) acrylate] were established from the widths of the maxima on the temperature dependence curve of mechanical loss tangent.[165] The equality of this parameter in the copolymers prepared under ordinary conditions and in the presence of an iniferter prompted a conclusion that 'living' radical polymerisation of densely cross-linked networks neither influences the reactivities of pendant double bonds nor diminishes the microheterogeneity of the copolymer formed.[165]

Studies of temperature dependences of mechanical loss tangents revealed a high level of structural microheterogeneity of network polymers based on triethylene glycol dimethacrylate synthesised in the presence of a photoiniferter.[58] It is of note that the microheterogeneity of the polymer formed was not considered [58] as a structural defect,[24] but rather as a beneficial factor which enables the preparation of a polymeric material with the vitrification temperature exceeding the polymerisation temperature by ~ 100 °C. The feasibility of this synthesis is due to the coexistence of densely cross-linked microgel clusters with highly mobile loosely cross-linked network areas where further interactions of free radicals with pendant double bonds and oligomer molecules occur. As a consequence, at low curing temperatures a

heterogeneous system can produce a polymer with higher vitrification temperature than a homogeneous system.

It was found [160] that irreversible chain termination in linear radical polymerisation can be prevented through the use of both 'living' radical polymerisation agents and a structure-physical approach where 'living' chain mode is provided by restriction of translational mobilities of macroradicals. This approach was first realised in low-temperature polymerisation of butyl methacrylate in a glassy state induced by γ-irradiation.[177, 178] In this case, the mobilities of growing radicals appeared to be completely suppressed due to high viscosity of the reaction medium. When analysing the effects of chemical agents of 'living' radical polymerisation on three-dimensional polymerisation of multifunctional methacrylates, one should take into consideration the fact that this process has an intrinsic 'living' component of its own due to uninterrupted chain growth on radicals localised on the surface of microgel particles and immobilised in the network. This component, being an integral element of a microheterogeneous three-dimensional polymerisation mechanism, enhances the microheterogeneity of the polymer formed. 'Living' radical polymerisation agents suppress microgeterogeneity only in the step of growth of linear chains containing pendant methacrylate groups. With a decrease in the mobility and efficiency of these compounds (due to increased viscosity of the medium), the network formation goes under control of an ordinary microheterogeneity mechanism which retains some elements of 'living' polymerisation induced by structure-physical factors.

V. Conclusion

An analysis of literature data demonstrates significant achievements in the studies of kinetics and mechanisms of TRCP and the development of methods for the control over the structure and properties of network polymers. Progress in this area has been made owing to the use of IR spectroscopy and NMR monitoring based on separate registration of conversion curves of C=C bonds of the monomer and the cross-linking reagent. The use of *in situ* spectral monitoring allows one to measure instantaneous compositions of the copolymers formed in the course of copolymerisation, to follow changes in effective reactivity ratios induced by structure-physical transformations of the reaction medium and to detect violations in the homogeneous distribution of reaction components in the vicinity of macroradicals caused by microsyneresis and limitations in the molecular mobilities of the reaction components. Direct information about the redistribution of reactants due to microsyneresis and formation of a microheterogeneous structure of network copolymers can be obtained through the use of fluorescent probes and labels. The use of these tools has made it possible to establish the correlations between different parameters of the microheterogenous structure and characteristics of network copolymers.

The formation of structures of network copolymers occurs under conditions of superposition of chain growth, intermolecular cross-linking, cyclisation and intramolecular cross-linking involving pendant double bonds. Considerable attention has been given to experimental and theoretical studies of factors which influence the contribution of these reactions to the overall conversion of double bonds and, as a consequence, to the topological structure and microheterogeneity of the copolymer formed. It was found that the copolymerisation process can be controlled by varying the character of intermolecular interactions of growing polymeric radicals and macromolecules. Thus, the use of comonomers carrying carboxy groups favours intermolecular cross-linking due to the forward formation of hydrogen bonds in the reaction medium. Cross-linking and cyclisation can be suppressed by addition of comonomers containing bulky alkyl substituents, which create steric hindrance for the interaction of macroradicals with pendant double bonds. The control over the lengths of primary polymeric chains by chain transfer agents (thiols and alkyl halides) also limits the cyclisation and enables formation of a more homogeneous structure of a network polymer. However, these approaches have significant limitations: the range of copolymers obtainable is rather small in the former case and environmental safety requirements have not been met, in the latter case.

The discovery of catalytic chain transfer reactions and living' radical polymerisation reactions has revolutionised the situation in linear polymerisation and paved the way to the synthesis of copolymers of any architecture, which in turn gave a strong impetus to the development of versatile and environmentally safe methods for control over TRCP. Pioneering studies have shown that chain transfer catalysts inhibit cyclisation and the gel effect in bulk (co)polymerisation of multifunctional compounds and favour the formation of more homogeneous polymeric networks than upon conventional polymerisation. Data on the effects of the agents of 'living' radical polymerisation on microheterogeneity of the networks formed are scarce and controversial. The potential of these methods in the control over three-dimensional bulk polymerisation is limited, since at more advanced stages of the reaction the activities of chain transfer catalysts and agents of 'living' radical polymerisation decrease with a decrease in their mobilities on going to media with a higher degree of structurisation.

Diffusion-controlled restrictions in reactions of chain transfer catalysts and agents of 'living' radical polymerisation with polymeric radicals are eliminated when these reactions are carried out in solutions. This opens up broad prospects for the design of network macromolecular nanosized structures possessing complex architectures. The data cited in this review clearly demonstrate that these potentialities have partly been realised in the synthesis of a vast variety of superbranched reactive macromolecules and microgels, dendrimers and star-shaped copolymers with a functional microgel core.

Abstract. Mathematical methods of calculation of the critical conversion (gel point) in the formation of cross-linked polymers by polycondensation, cross-linking of macromolecules and three-dimensional polymerisation are considered. The results obtained using the statistical approach ('ideal' polycondensation), the concept of bond blocks (the 'non-ideal' or 'non-statistical' polycondensation) and kinetic calculations that allowed the determination of the gel point in three-dimensional polymerisation processes are discussed. The bibliography includes 105 references.

I. Introduction

The value of critical conversion in the formation of cross-linked polymers, the so-called gel point, characterises the transition of a system from a fluid state to a state with an equilibrium elastic modulus. It is a parameter of great importance both in applied and theoretical studies. At conversions smaller than the critical conversion, a polymer is characterised by a finite molecular mass. At higher conversions, the molecular mass becomes formally infinite, or, in mathematical terms, higher moments of molecular-mass distribution, starting from the second one, become infinite. The formation of an insoluble gel can result in complications in technological processes of polymer synthesis and, *vice versa*, finding the relationship between the critical conversion, on the one hand, and the structural and kinetic parameters of the process, on the other hand, makes it possible to state the conditions for forming a cross-linked polymer with required physico-mechanical characteristics.

The gel point determines the flow threshold in a polymeric system being formed, and finding the dependence of this value on kinetic and structural parameters is an important problem. For example, polymer properties in the critical point have recently become a subject of scientists' attention.[1] The relaxation properties of polymeric systems on transition from a sol to a gel have a distinctive feature due to the fact that macromolecules in this point are characterised by a specific structure shaped as fractal trees with an extraordinarily broad size distribution. The relaxation modulus has a power-law rather than exponential time dependence;[1–4] this is characteristic of pre-gel rather than post-gel regions. It follows that the real and imaginary components of the relaxation modulus are congruent and that the loss tangent is independent of frequency. Obviously, correct assessment of the critical conversion region in the formation of a three-dimensional polymeric system occurring by any mechanism can make it possible to determine conditions required to obtain a material with predefined properties.

The problem of determining the critical conversion for the polycondensation of *f*-functional monomers was solved by Flory [5] and Stockmayer [6] by statistical methods using combinatory analysis. The formulas they obtained were confirmed by kinetic calculations [7,8] and by experimental data.[5,8] They are applicable provided that intramolecular reactions (reactions between groups belonging to a single macromolecule) do not occur. It was later shown that probabilistic approaches are applicable only to those systems where the so-called substitution effect is absent, *i.e.*, where kinetic constants do not change during the process.[7,9,10] Otherwise, a strict kinetic calculation is required.

Three-dimensional polymerisation is usually described according to Flory [5] and Stockmayer [11] using the probabilistic approach,[12] which is of quite limited use for polymerisation processes. Monte Carlo computer simulation, which is also based on the probabilistic approach, was found to be more efficient.[13–15] Other approaches were also proposed, based on the analysis of infinite systems of differential equations describing different kinetic schemes of the polymerisation process: a method based on the calculation of the instantaneous value of molecular mass distribution;[11,16–20] approximation of a system of ordinary differential-difference equations by a continuous system of partial differential equations;[21–28] the method of moments;[29–35] the method of generating functions;[7,36,37] numeric inversion of *z*-[38] and Fourier transformations;[39] methods of discrete weighed residues;[40–42] numeric fractionation [43–45] and discrete population balance.[46,47] These methods were mainly used to evaluate the molecular mass distribution parameters in the formation of linear and branched polymers, and it is only in restricted cases (see, *e.g.*, Refs 7 and 48) that they were used to find critical conversion values.

The formulas obtained by any of these methods were not confirmed by experimental data. However, their validity was not disputed, because it is well known that intramolecular cyclisation occurs rather intensely under ordinary three-dimensional polymerisation conditions due to the fast chain growth in the case of

the radical mechanism and the low concentration of chains at early process stages.[8] Repeated cross-linking between a single pair of chains (formation of multiplet nodes and 'staircase' macromolecular structures) is also believed to be a factor that decreases the effective concentration of inter-chain cross-links and thus increases the critical conversion.[49] Because of this, radical polymerisation is a typical microheterogeneous process.[50] The combination of all these reasons makes it difficult to expect that any theoretical dependencies would be obeyed.

In this review, we intend to determine the applicability ranges of the statistic and kinetic approaches. Based on this, well-founded results on the calculation of critical conversion values with different mechanisms of formation of cross-linked polymers will be presented. The author has previously developed the bond blocks (BB) concept.[9, 51] This approach, which combines kinetic and probabilistic methods, makes it possible to simplify considerably the solution of problems that cannot be solved using the purely statistical method. In this review we consider the results of critical conversion calculations obtained by this method.

Thus, the review consists of three parts. The first part presents the results of statistical calculations ('ideal' polycondensation); the second part, the results obtained using the BB concept ('non-ideal' or 'nonstatistical' polycondensation); the third part, the kinetic calculations that allowed the determination of the gel point in three-dimensional polymerisation processes to be carried out.

II. Methods for the description of the kinetics of formation of cross-linked polymers

Unlike low-molecular compounds (not bodies!) that are defined almost unambiguously by their chemical formulas, the structures of polymers, and hence their properties, are not exhausted by their chemistry. Polymer structure is a multilevel characteristic, and the topological level is the most important.[8] In fact, the properties of linear polymers cannot be described if their molecular mass distribution is neglected. For cross-linked polymers, the concentration of nodes and the length distribution of internode chains are the most important structural parameters. Branched and star polymers and dendrimers differ principally both from each other and from linear polymers due to differences in their topological structures. Therefore, consideration of the polymer formation kinetics should not be limited to chemical reactions; it is also necessary to analyse how the polymeric chain is formed.

Taking the above considerations into account, we should discriminate at least two reaction types: polymerisation type and, tentatively speaking, polycondensation type (called 'Addition Polymerisation' and 'Stepwise Polymerisation' in English-language literature). Turning aside from chemistry, the reagents involved in these reactions can be described by vectors; in the former case, as R(m,n,p), where R is a macromolecule comprising m units, n functional groups (for vinyl polymers, n is the number of double bonds) and p active centres; m, n, p = 0, 1, 2, 3, ... *etc*., to infinity; in the latter case, as R(m,n).

This is certainly the easiest description method, which does not take certain details of the topological structure into account, but these characteristics suffice for the solution of the problem of interest, *viz*., determination of the gel point.

The former reaction type is described by the following scheme:

$$\mathrm{I} \xrightarrow{k_\mathrm{i}} f\mathrm{R}(0,0,1)$$

$$\mathrm{R}(i,j,l) + \mathrm{R}(m,n,p) \longrightarrow \begin{cases} \xrightarrow{k_\mathrm{p}} \mathrm{R}(i+m, j+n-l, l+p) \\ \xrightarrow{k_\mathrm{tr}} \mathrm{R}(i+m, j+n, l+p-2), \\ \xrightarrow{k_\mathrm{td}} \mathrm{R}(i,j,l-1) + \mathrm{R}(m,n,p-1) \end{cases} \quad (1)$$

$$\mathrm{R}(i,j,l) + \mathrm{X} \xrightarrow{k_\mathrm{X}} \mathrm{R}(i,j,l-1) + \mathrm{R}(0,0,1),$$

$$\mathrm{R}(i,j,l) + \mathrm{Y} \xrightarrow{k_\mathrm{Y}} \mathrm{R}(i,j,l-1).$$

where I is the initiator; f is the initiation efficiency (number of active centres formed in one initiation act); R(0,0,1) is a primary active centre; k_i, k_p, k_tr, k_td, k_X and k_Y are the rate constants of initiation, growth, square-law termination by recombination and disproportionation, chain transfer on transfer agent X and linear inhibition-type termination on agent Y.

For simplicity, it was assumed when developing this scheme that initiation occurs by monomolecular decomposition of initiator I and that the reactivity of functional groups does not depend on the complexity and size of the macromolecule that carries them (Flory's principle [5]). The reactivity of active centres in the chain growth, transfer and termination is also independent of this factor.

The second reaction type is described by the scheme (also with the use of Flory's principle)

$$\mathrm{R}(i,j) + \mathrm{R}(m,n) \xrightarrow{k} \mathrm{R}(i+m, j+n-2). \quad (2)$$

This is a simplified version where it is assumed that the reacting functional groups belong to a single type.

Schemes (1) and (2) result in infinite systems of differential equations. For scheme (1):

$$\frac{\mathrm{d}\mathrm{I}}{\mathrm{d}t} = -k_\mathrm{i}\mathrm{I},$$

$$\frac{\mathrm{d}\mathrm{R}(0,0,1)}{\mathrm{d}t} = fk_\mathrm{i}\mathrm{I} - \mathrm{R}(0,0,1)\,(k_\mathrm{p}\mathrm{F} + k_\mathrm{X}\mathrm{X} + k_\mathrm{t}\mathrm{R} + k_\mathrm{Y}\mathrm{Y}) + k_\mathrm{X}\mathrm{X}\mathrm{R},$$

$$\frac{\mathrm{d}\mathrm{R}(i,j,l)}{\mathrm{d}t} = -\mathrm{R}(i,j,l)\,[k_\mathrm{p}(l\mathrm{F} + j\mathrm{R}) + l(k_\mathrm{X}\mathrm{X} + k_\mathrm{t}\mathrm{R})] + \mathrm{R}(i,j,l+1) \times$$

$$\times (k_\mathrm{Y}\mathrm{Y} + k_\mathrm{X}\mathrm{X} + k_\mathrm{td}\mathrm{R}) + k_\mathrm{p} \sum_{m,n,p}^{i,j,l} \{[n(k-p)\mathrm{R}(i-m, j-n+1, l-p) +$$

$$+ p(j-n+1)\,\mathrm{R}(i-m, j-n+1, l-p)]\mathrm{R}(m,n,p)\} + \quad (3)$$

$$+ \frac{1}{2}k_\mathrm{tr} \sum_{m,n,p}^{i,j,l} [(l-p+1)\mathrm{R}(i-m, j-n+1, l-p+1)\,(p+1) \times$$

$$\times \mathrm{R}(m,n,p+1)].$$

In the above equations, I is the initiator concentration, $\mathrm{R} = \sum_{i,j,l}^{\infty} l\,\mathrm{R}(i,j,l)$ is the total concentration of active centres, X is the concentration of the chain transfer agent, Y is the concentration of the linear termination agent, F is the total concentration of reactive functional groups, and $k_\mathrm{t} = k_\mathrm{tr} + k_\mathrm{td}$ is the overall square-law termination constant.

For scheme (2)

$$\frac{\mathrm{d}\mathrm{R}(i,j)}{\mathrm{d}t} = -kj\mathrm{R}(i,j) \sum_{m,n=1}^{\infty} n\mathrm{R}(m,n) +$$

$$+ \frac{1}{2}k \sum_{m,n=1}^{i-1,j-1} (j-n)\mathrm{R}(i-m, j-n)\, n\mathrm{R}(m,n). \quad (4)$$

Infinite systems of differential equations can be solved only in convolute form. The simplest method involves the use of generating functions [7, 36, 37]

$$\Phi(q_1, q_2, q_3) = \sum_{i,j,l}^{\infty} q_1^i q_2^j q_3^l R(i,j,l), \quad (5)$$

where q_1, q_2, q_3 are arbitrary variables.

This procedure results in relatively simple partial equations that are principally soluble (in simplest cases, they can even be solved analytically).[52]

In generating function terms, system (3) gives a partial equation (its development can be found, *e.g*., in Refs 7 and 52) of the form:

$$\frac{\partial\Phi(\boldsymbol{q})}{\partial t} = fk_{\mathrm{i}}q_3\mathrm{I} + k_{\mathrm{p}}\left[q_3\frac{\partial\Phi(\boldsymbol{q})}{\partial q_2}\frac{\partial\Phi(\boldsymbol{q})}{\partial q_3} - q_3F\frac{\partial\Phi(\boldsymbol{q})}{\partial q_3} - q_2\mathrm{R}\frac{\partial\Phi(\boldsymbol{q})}{\partial q_2}\right] + (k_{\mathrm{Y}}\mathrm{Y} + k_{\mathrm{X}}\mathrm{X})(1-q_3)\frac{\partial\Phi(\boldsymbol{q})}{\partial q_3} + \frac{1}{2}k_{\mathrm{tr}}\left[\frac{\partial\Phi(\boldsymbol{q})}{\partial q_3}\right]^2 + (k_{\mathrm{td}} - q_3k_{\mathrm{t}})\frac{\partial\Phi(\boldsymbol{q})}{\partial q_3}\mathrm{R}, \quad (6)$$

where $\boldsymbol{q} \equiv (q_1,q_2,q_3)$.

A similar equation describing polycondensation has the form

$$\frac{\partial\Phi(\boldsymbol{q})}{\partial t} = -kq_2\frac{\partial\Phi(\boldsymbol{q})}{\partial q_2}\mathrm{F} + \frac{1}{2}k\left[\frac{\partial\Phi(\boldsymbol{q})}{\partial q_2}\right]^2, \quad (7)$$

where

$$\mathrm{F} = \sum_{i,j,l}^{\infty} j\,\mathrm{R}(i,j).$$

Equation (6) cannot be solved analytically even in its simplest version. Numeric solution encounters the problem of finding a general expression for critical conversion (for arbitrary values of kinetic constants). We shall try to answer this question below.

In the version presented above, Eqn (7) is much more simple than Eqn (6) and has an analytical solution. In any case, as shown in Ref. 53, the solution of Eqns (6) and (7) branches in some instant of time t_{c}, which corresponds to the gel point, and finding this point solves the problem. However, it is not possible to obtain such a simple analytical or even numerical solution in more complex cases, for example, if the reaction involves several types of functional group with different reactivity. Therefore, a method to solve the problem based on a statistical approach was suggested.[5,6]

III. Statistical methods

Flory was probably the first to suggest the use of the statistical approach to describe the polycondensation kinetics and the structure of polymers obtained by this method.[5,54] The molecular-mass distribution upon *f*-functional polycondensation was calculated using combinatorial analysis and the critical conversion condition was obtained. Later calculations were based on the use of a formalised and therefore simpler and more elegant method,[55,56] which is based on the theory of branching processes.[57]

Assuming that cyclisation reactions are excluded, the structure of a macromolecule is represented [8] as a branching tree; any chain unit or a whole fragment can be considered as the root. Reagent molecules are chosen as such fragments in order to link the macromolecule structure with the process of its formation. After that, the probabilities of transitions from generation to generation are considered (the root is taken as the zeroth generation). Probabilities are analysed in terms of generating functions. The kinetic parameters of the process, the depth of conversion by functional groups and their concentrations determine the probabilities of transitions.

The key point of the theory of branching processes [57] is that the generating functions for probabilities of transitions from generation to generation do not depend on the generation number (except the zeroth one), and their calculation requires that algebraic rather than differential (!) equations be solved.

Let us consider the principle of finding the critical conversion in a simple example, *viz*., *f*-functional polycondensation.

In each generation except the zeroth generation, an *f*-functional unit can derive a maximum of $f-1$ units; the probability of the event that each functional group reacts, *i.e*., derives a new unit, equals the conversion value (α). Thus, the generating function of probabilities is

$$Z(q) = \sum_{i=0}^{f-1} q^i\frac{(f-1)!}{i!(f-i-1)}\alpha^i(1-\alpha)^{f-i-1} = (1-\alpha+\alpha q)^{f-1}. \quad (8)$$

The gel formation condition is determined from the solution of the equation

$$u(q) = qZ[u(q)] = q[1-\alpha+\alpha u(q)]^{f-1}. \quad (9)$$

The generating function $u(q)$ characterises the molecular mass distribution of a polymer. The moments of this function correspond to distribution moments. For example, $u(1)$ is the first moment of distribution, and the first derivative on q at $q = 1$ is the second moment of molecular mass distribution.

The critical conversion equals the value α where the derivative $\partial u(1)/\partial q$ turns to infinity

$$\frac{\partial u(q)}{\partial q} = [1-\alpha+\alpha u(q)]^{f-1} + q(f-1)[1-\alpha+\alpha u(q)]^{f-2}\frac{\partial u(q)}{\partial q}. \quad (10)$$

At $q = 1$, we have $u(1) = 1$ and

$$\frac{\partial u(1)}{\partial q} = \frac{1}{1-\alpha(f-1)}. \quad (11)$$

Hence we obtain the gel formation condition (critical conversion):

$$\alpha_{\mathrm{c}}(f-1) = 1. \quad (12)$$

The equation for the first distribution moment $u(1)$ has only one root $u(1) = 1$ below the gel point. Starting from the time instant corresponding to critical conversion, the second root $u(1) < 1$ appears, which characterises the fraction of the soluble polymer (the sol fraction),

$$u(1) = \{1-\alpha[1-u(1)]\}^{f-1}, \quad (13)$$

$$1-u(1) = \alpha(f-1)[1-u(1)]\{1 - \frac{f-2}{2!}\alpha[1-u(1)] + \frac{(f-2)(f-3)}{3!}\alpha^2[1-u(1)]^2 - \ldots\}. \quad (13a)$$

Dividing both parts of this equation by $[1-u(1)]$ and equating the equation root to unity (gel point), we obtain the same expression (12) for critical conversion.

The conversion value is found by solving the differential equation for functional groups

$$\frac{\mathrm{dF}}{\mathrm{d}t} = -k\mathrm{F}^2,$$

$$\alpha = 1 - \frac{\mathrm{F}}{\mathrm{F}(0)}. \quad (14)$$

We present below formulas for determining the critical conversion for different cases of polycondensation.

1. Monomers with different functionality and single-type functional groups with equal reactivity (reactions between any groups are possible):

$$\alpha_{\mathrm{c}}(\langle f\rangle_{\mathrm{w}} - 1) = 1, \quad (15)$$

$$\langle f\rangle_{\mathrm{w}} = \sum_i in_i,$$

$$n_i = \frac{im_i}{\sum_j jm_j},$$

where m_i is the molar concentration of a monomer containing i functional groups. Thus, $\langle f\rangle_{\mathrm{w}}$ is the weight-average functionality.

2. Monomers with different functionality and different-type functional groups (A and B), in which single-type groups cannot

react with each other and the rate constant of the reaction between different-type groups is the same.

$$\alpha_{c\,A}\alpha_{c\,B}(\langle f_A\rangle_w - 1)(\langle f_B\rangle_w - 1) = 1. \quad (16)$$

Since

$$F_{A0} - F_A = F_{B0} - F_B,$$

hence

$$\alpha_A = \frac{F_{B0}}{F_{A0}}\alpha_B,$$

where F_{A0} and F_{B0} are the initial concentrations of the corresponding functional groups.

If the reactivities of functional groups are initially different, it is acceptable to use the statistical approach. For example, the secondary and primary hydroxy groups are non-equal in reactivity in the reaction of glycerol (B) with diisocyanate (A). Therefore, the formula for critical conversion will have the form

$$\frac{2}{3}\alpha_{c\,A}(2\alpha_{c\,B1} + \alpha_{c\,B2}) = 1, \quad (16a)$$

where the indices 1 and 2 correspond to the primary and secondary hydroxy groups of glycerol, respectively. The conversions of functional groups α_{B1} and α_{B2} are determined by solving the corresponding kinetic equations. If the reactivities are equal, *i.e.*, $\alpha_{c\,B1} = \alpha_{c\,B2}$, we obtain the formula (16).

In the case that the functional groups of reagents differ in reactivity, it is also necessary to modify formula (16). Assume that in the reaction

$$A_f + \sum_i B_i \rightarrow \text{products}$$

(the subscript indicates the number of reactive functional groups in a monomer molecule), the functional groups of each monomer B_i have different rate constants of the reaction with A. Therefore, each of them will have its own value of conversion α_i at any given instant in time. Hence, one can write:

$$(f-1)\alpha_{c\,A}\sum_i (i-1)n_i\alpha_{c\,i} = 1. \quad (16b)$$

It is obvious that we obtain Eqn (16) at $\alpha_i = \alpha$.

3. Cross-linking of polymeric chains with a bifunctional reagent. If each polymeric chain unit carries a functional group, then this is essentially the case described above, with the difference that the weight-average functionality of the polymeric reagent equals the weight-average degree of polymerisation ($\langle P\rangle_w$), which is generally much greater than unity. Furthermore, the concentration of the cross-linking agent m_A is usually much lower than the concentration of polymer functional groups. It hence follows that $\alpha_{c\,A} \approx 1$; therefore, Eqn (16) is transformed to the form

$$\alpha_{c\,B}\langle P\rangle_w = 1. \quad (16c)$$

Equations (16c) and (15) coincide formally.

If reactive functional groups are not contained in each unit and their molar fraction is $\rho < 1$, then $\langle f\rangle_w = \rho\langle P\rangle_w$, and, accordingly,

$$\alpha_{c\,B}\rho\langle P\rangle_w = 1. \quad (16d)$$

Simple relationships obtained by the statistical method are widely used in the analysis of various polycondensation processes. However, the so-called substitution effect is usual for polyfunctional reagents: the reactivity of functional groups changes after one group has reacted. In fact, the reaction rate constants for the primary (k_1) and secondary amino group (k_2), which appears as a result of the first reaction, are different in the reaction of epoxy compounds with an amine (Table 1).

The results of calculating the molecular mass distribution in linear polycondensation with the substitution effect depend on the calculation method.[7] Hence, the statistical approach is not suitable in this case. It has been shown[48,59] that a statistical calculation gives wrong results for critical conversion if the formation of a cross-linked polymer involves the substitution effect.

Table 1. Relative rate constants (k_2/k_1) of addition of the second epoxy group to the amine.[58]

T/°C	DDS [a]	MDA [b]	MDEA [c]	MCDA [d]
80	0.46	0.65	–	0.67
135	0.42	–	0.66	0.64
160	0.51	–	–	0.70

[a] DDS is 4,4′-diaminodiphenylsulfone, [b] MDA is 4,4′-methylenediamine, [c] MDEA is 4,4′-methylenebis(2,6-diethylaniline), [d] MCDA is 4,4′-methylenebis(3-chloro-2,6-diethylaniline).

It was found equally fruitless to use the statistical approach for solving the cyclisation problem.[60] It was shown[61] that, as in the previous case, only a kinetic solution can give correct results.

Later, a hypothesis on the applicability limits of the statistical calculation method was proposed.[62] Its applicability limits were fully established using the BBs concept.[9,63] However, attempts to use this method to describe the kinetics of polymer formation in the presence of the substitution effect were made previously[64] and were continuing until recently.[65,66]

IV. The bond block concept as a method to solve problems involving the substitution effect

The bond block concept[9,51,63,67] assumes a combination of kinetic and statistical methods. It is this concept that made it possible to develop a general approach for determining the gel point; the formulas resulting from statistical calculations are obtained as a special case if certain conditions are met. The 'bond block' concept is not yet widespread, therefore let us consider it in more detail.

A bond block is understood as a structure that can belong to any macromolecule or cross-linked polymer.[63] It is represented as a connected graph G, whose verges and nodes are bonds and atoms (units) connected by these bonds. The total set of concentrations of all bond blocks in a system characterises unambiguously its composition and structure. In this sense, the concentration $y(G)$ is analogous to the polymer molecular mass distribution function in terms of the information it contains. On the other hand, it is richer, as it not only describes the length distribution of chains but also characterises the molecular and topologic structure of a polymeric system.

When we speak of bonds, we mean those which result from the reaction under consideration. Hence, the BB concept is closely related to the process chemistry. Each bond is determined by the groups (units) connected by that bond: an a – a bond connects A units, an a – b bond connects A and B units, *etc*. In other words, identification of different units is meaningful only as an attribute (characteristics) of a bond. The total set of BBs unambiguously characterises the chain size and structure.

In the case of a linear homopolymer, BBs only differ in the number of bonds but not in their type, as in the example presented above. Therefore, the relationship between the concentrations of BBs and chains has a simple form in this case:

$$y_n = \sum_{i=n}^{\infty}(i-n)x_i, \quad (17)$$

where y_n and x_i are the concentrations of BBs and chains, respectively; their sizes are shown by the indices. The $(i-n)$ factor equals the number of ways to arrange a BB of n bonds in a chain containing i units.

The reverse relationship follows from Eqn (17)

$$x_i = y_{i-1} - 2y_i + y_{i+1}. \quad (18)$$

The condition (18) can be generalised for chains and BBs with any configuration if the terminal block (TB) concept is introduced. A TB is understood as a BB in which one of the units bordering the block is also a terminal unit of the chain (polymeric structure).

The TB concentration (z_i) is expressed through the BB concentration:

$$z_i = y_{i-1} - y_i = y_{i-1}(1 - y_1). \quad (19)$$

(For simplicity, here we used symbolic multiplication as addition of indices.)

If the number of terminal groups z_i^k (the superscript identifies the terminal member type) in a selected polymeric structure is more than unity, then

$$z_i^{k,m} = z_i^k(1 - y_1^m) = y_{i-1}(1 - y_1^k)(1 - y_1^m). \quad (20)$$

If there are several terminal groups (branched polymer), the numbers of multiplicands and superscripts in formula (20) increase accordingly.

A polymeric chain with any topology (excluding rings!) can be defined as a TB where the number of terminal groups equals the number of terminal groups of a macromolecule (all the block's bonds are broken). This number equals two for a linear chain. In this case, we come to the relationship (17). For an arbitrary number and type of terminal groups, we obtain

$$x_i = y_{i-1}\prod_{j=1}^{n}(1 - y_1^j). \quad (21)$$

Thus,

$$x_i = \begin{cases} y_{i-1} - y_i & \text{for terminal block} \\ y_{i-1} - y_i^1 - y_i^2 + y_{i+1}^{1,2} & \text{for linear chain with terminal groups of types 1 and 2} \\ y_{i-1} - \sum_{j=1}^{3} y_i^j + y_i^{1,2,3} & \text{for branched chain with three terminal groups} \end{cases} \quad (22)$$

and so on.

An example of the use of formulas similar to those presented above [(17)–(22)] was considered by Hsieh and Randall.[68] To calculate the number of sequences in ethylene and butene copolymers, they used NMR data that allowed the concentrations of short TBs (containing one, two, and three units) to be found.

The system of kinetic equations for BBs was obtained from a usual scheme of chain formation and a (17)-type relationship. Let us develop equations for linear polycondensation

$$\begin{aligned} &X_1 + X_1 \xrightarrow{k_1} X_2, \\ &X_1 + X_i \xrightarrow{k_2} X_{i+1},\ i = 2, 3, \ldots \\ &X_i + X_j \xrightarrow{k_3} X_{i+j},\ i, j = 2, 3, \ldots, \end{aligned} \quad (23)$$

where X_1, X_2, X_i, and X_j are reagents.

The corresponding system of differential equations has the form

$$\begin{aligned} \frac{dx_1}{dt} &= -2k_1x_1^2 - k_2x_1\sum_{j=2}^{\infty}x_j, \\ \frac{dx_2}{dt} &= k_1x_1^2 - k_2x_1x_2 - k_3x_2\sum_{j=2}^{\infty}x_j, \\ \frac{dx_3}{dt} &= k_2x_1(x_2 - x_3) - k_3x_3\sum_{j=2}^{\infty}x_j, \\ \frac{dx_i}{dt} &= k_2x_1(x_{i-1} - x_i) - k_3x_i\sum_{j=2}^{\infty}x_j + \frac{1}{2}k_3\sum_{j=2}^{i-2}x_jx_{i-j},\ i = 4, 5, \ldots, \end{aligned} \quad (24)$$

where x_1, x_2, x_3, x_i, x_j are the chain concentrations.

After substituting (17) into (24) we obtain

$$\begin{aligned} \frac{dy_0}{dt} &= 0, \\ \frac{dy_1}{dt} &= k_1(y_0 - y_1)^2 + (y_1 - y_2)[(k_2 - k_1)(y_0 - y_1) + \\ &\quad + \frac{1}{2}(k_1 - 2k_2 + k_3)(y_1 - y_2)], \\ \frac{dy_2}{dt} &= (k_2 - k_3)(y_1 - y_2)(y_0 - 2y_1 + y_2) + \\ &\quad + \frac{1}{2}k_3\sum_{j=0}^{2}(y_j - y_{j+1})(y_{2-j-1} - y_{2-j}), \\ \frac{dy_i}{dt} &= (k_2 - k_3)(y_{i-1} - y_i)(y_0 - 2y_1 + y_2) + \\ &\quad + \frac{1}{2}k_3\sum_{j=0}^{i}(y_j - y_{j+1})(y_{i-j-1} - y_{i-j}),\ i = 3, 4, \ldots \end{aligned} \quad (25)$$

where the concentration of bond blocks y_0 equals the total number of units in the system and is therefore a constant; y_1 is the total number of bonds; the y_1/y_0 ratio is the conversion depth.

System (25) is as infinite as system (24). However, the distinctive feature is that it is a closed system starting from the second term of the series (y_2), and can therefore be solved numerically by a sequential method: y_i can be calculated if all the preceding values, *viz.*, y_j, $j < i$, are known. The truncation of the system occurs naturally: there is no sense in calculating the variables whose concentrations cannot be measured. For example, if an experiment allows the determination of sequences consisting of a maximum of five units, why should the concentration of a six-unit sequence be determined? Thus, in this case the system to be solved will consist of five equations. A similar statement corresponds to chain concentrations obtained from (25) by substitution of y_i into Eqn (18).

Analysis of the structure of kinetic equations for BBs showed that a simple rule is observed: all the possible ways of formation of a given block are totalled. This simplifies considerably the formulation of kinetic equations for BBs. In this case, the TB concept becomes of key importance: in essence, the TB concept is a generalisation of the 'functional group' concept. In fact, a reaction between functional groups results in one bond, or a single BB (y_1). A terminal block is a functional group with units (one, two or more) bound to it. The formation of a TB results from reactions of simpler TBs with starting reagents; the structures of all the reaction participants are simpler than the structure of the starting block. Thus, the system of equations for any arbitrary complex structure appears to be closed, and the requirements of an experiment determine the blocks for which the kinetic problem should be solved.

Analysis of the system of differential equations for BBs showed [9, 51, 67] that it can be broken into groups of equations in such a way that the concentrations of BBs described by these equations can be calculated directly by solving that group of equations. The concentrations of larger BBs can be found using probabilistic methods. If such a group consists of a single block, *i.e.*, a block involving only one bond, the probabilistic approach is applicable to calculations of a polymeric structure of any complexity. In almost all cases it is possible to separate such structures of minimum size from which structures of arbitrary complexity and size can be combined. It was found [9, 51, 67] that the criterion of 'simplicity' consists of the absence of substitution effects on the reactivity of functional groups. Such effects can exist within a 'simple' block.

Thus, the use of the BB concept makes it possible to simplify the solution of kinetic problems, because it becomes unnecessary to formulate differential equations for all sizes of blocks. It is sufficient to solve these problems for elementary blocks and to use probabilistic calculations for larger blocks. In other words, the method based on the BB concept combines the advantages of both kinetic and probabilistic approaches.

Let us illustrate the application of the BB concept to the solution of the problem of critical conversion for a particular system, *viz*., epoxide bifunctional oligomer–pentafunctional amine.[69] The presence of primary and secondary hydrogen atoms in the latter creates prerequisites for the substitution effect. If BB concentrations are used, then, as in the statistical calculation, not molar concentrations of reagents are used but functional fractions of reactive groups (n_i) and probabilities of reactions of the corresponding groups, *i.e*., conversion degree (α_i).

The functional fractions of the corresponding groups n_i that are capable of reacting with the amine (the functional fraction of which equals n_A) can be represented as

$$n_i = \frac{N_i}{\sum_j N_j},$$

where N_i is the molar concentration of the corresponding groups at a given instant in time (at a given conversion); moreover,

$$N_i = i m_i,$$

where m is the molar concentration of a reagent containing i reactive functional groups. The balance condition is

$$\sum_i N_i \alpha_i = A\alpha_A,$$

where the i index corresponds to the epoxide reagents and the A index corresponds to the amine. The values of α_i and n_i are found by solving the corresponding systems of kinetic equations.

The structure of the network is determined by the concentration of nodes with different functionality; in this case, fragments of the amine-type hardening agent play the role of nodes. It is these structural elements that are bond blocks, whose concentration in this case should be calculated by the kinetic method, *i.e*., by solving the appropriate kinetic equations. The functionality of a node is determined by the number of oligomeric fragments bound to it.

In the case of the 'bifunctional epoxide oligomer–pentafunctional amine' system [*e.g*., diethylenetriamine (DETA) contains one secondary and two primary amino groups], it is necessary to distinguish primary and secondary amino groups from the very start of the reaction. If we designate the numbers of primary and secondary hydrogen atoms by digits (the first and second digit, respectively), the following groups are involved in the building of the network:

A(41) — original amine, node of zero functionality;

A(40) — amine with reacted secondary amino group; its functionality is 1, and it is a terminal fragment in the network;

A(22) — reaction product of a primary amino group; its functionality is 1, and it is a terminal fragment;

A(21) — functionality 2, intermediate fragment;

A(03) — functionality 2, intermediate fragment;

A(20) — trifunctional node;

A(02) — trifunctional node;

A(01) — tetrafunctional node;

A(00) — pentafunctional node.

If the ratio of reaction rate constants of secondary and primary amino groups is designated as

$$\beta = \frac{k_2}{k_1},$$

then the system of equations for all amino groups can be represented as follows:

$$\begin{aligned}
\frac{dB}{dt} &= -B\{4A(41) + 4A(40) + 2A(22) + 2A(21) + 2A(20) + \\
&\quad + \beta[A(41) + 2A(22) + A(21) + 3A(03) + \\
&\quad + 2A(02) + A(01)]\},\\
\frac{dA(41)}{dt} &= -(4+\beta)BA(41),\\
\frac{dA(40)}{dt} &= [\beta A(41) - 4A(40)]B,\\
\frac{dA(22)}{dt} &= [4A(41) - 2(1+\beta)A(22)]B,\\
\frac{dA(21)}{dt} &= [4A(40) + 2\beta A(22) - (2+\beta)A(21)]B,\\
\frac{dA(03)}{dt} &= [2A(22) - 3\beta A(03)]B,\\
\frac{dA(02)}{dt} &= [3\beta A(03) + 2A(21) - 2\beta A(02)]B,\\
\frac{dA(20)}{dt} &= [\beta A(21) - 2A(20)]B,\\
\frac{dA(01)}{dt} &= [2\beta A(02) + 2A(20) - \beta A(01)]B,\\
\frac{dA(00)}{dt} &= \beta A(01)B.
\end{aligned} \tag{26}$$

The concentrations of nodes with different functionality change in the course of a reaction (Fig. 1). Characteristically, the concentration–conversion curves for different β values are similar in appearance: the maximum concentration of nodes with a given functionality corresponds to a single value of conversion depth, irrespective of the relative rate constant of the reaction involving the secondary amino group. On the other hand, the maximum value varies as a function of the kinetic parameters of polycondensation.

Since it is assumed that the reactivity of epoxy groups is unchanged during the reaction, the network structure can be calculated using a statistical approach based on calculated node concentrations.

According to the theory of branching processes,

$$u(q) = x\left[1 - \alpha + \alpha\sum n_{Ai} u^{i-1}(q)\right], \tag{27}$$

where α is the conversion degree of epoxy groups; n_{Ai} is the functional fraction of i-functional nodes.

Differentiation of the equation results in an expression for the gel formation condition

$$\alpha\sum_i (i-1)n_{Ai} = 1. \tag{28}$$

Formally, Eqn (28) coincides with the critical condition for f-functional polycondensation (15); however, the difference is that the weight-average functionality $\langle f\rangle_w$ changes during the process, *i.e*., it is a function of the conversion α.

The plots

$$y(\alpha) = 1 - \alpha\sum_i (i-1)n_{Ai}$$

are presented in Fig. 2 for different β values. The α_c value is determined by the condition $y(\alpha) = 0$. The critical conversion values for the diepoxide–DETA system for different β values are presented below.

β	1.0	0.7	0.5	0.3	0.1	0.01
α_c	0.5	0.507	0.514	0.524	0.535	0.535

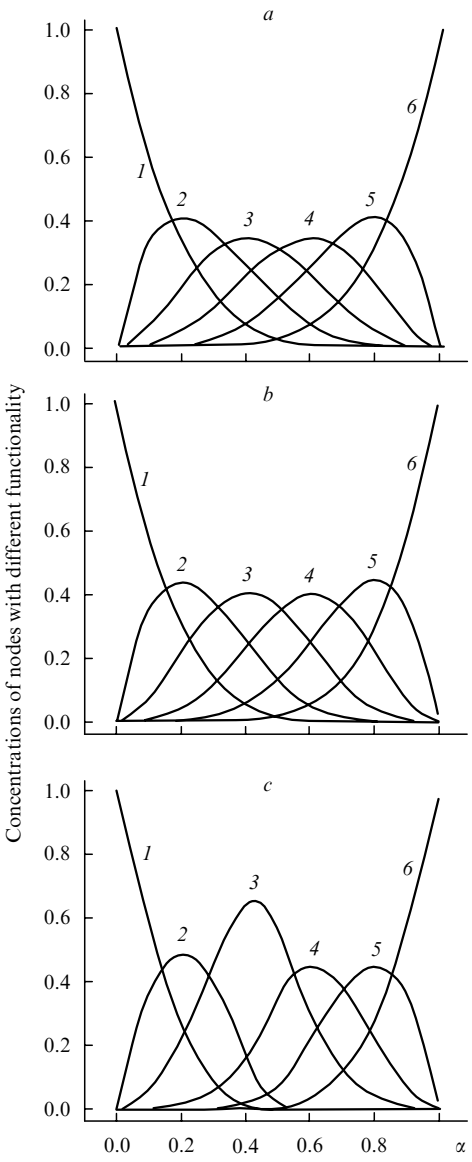

Figure 1. Dependencies of the concentrations of network nodes with different functionality on conversion for $\beta = 1$ (*a*), 0.5 (*b*), 0.1 (*c*).[69]
Node functionality: (*1*) 0, (*2*) 1, (*3*) 2, (*4*) 3, (*5*) 4, (*6*) 5.

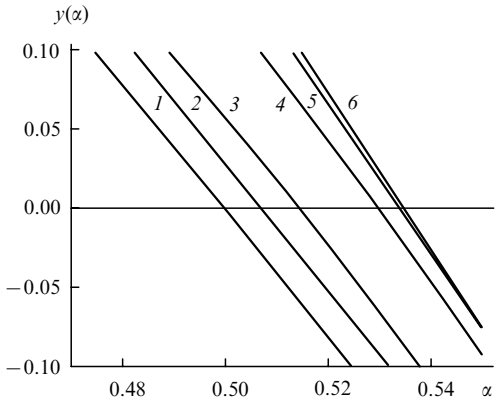

Figure 2. Graphical solution of the equation for finding the critical conversion at $\beta = 1$ (*1*), 0.7 (*2*), 0.5 (*3*), 0.2 (*4*), 0.1 (*5*), 0.01 (*6*).[69]

Thus, the solution result depends on the β value; this does not follow from the statistical theory at all. However, it can be shown easily that the known formula for the dependence of n_{Ai} on conversion is obtained if the applicability conditions of the statistical approach are met. In fact, according to statistics,

$$A_i = A\frac{f!}{i!(f-i)!}\alpha_A^i(1-\alpha_A)^{f-i}, \qquad (29)$$

where A_i is the concentration of the i-functional node and f is its maximum possible functionality ($f = 5$ for DETA).

Since

$$n_{Ai} = \frac{iA_i}{\sum_i iA_i},$$

substituting (29) into (28) we obtain

$$\alpha(f-1)\alpha_A = 1,$$

which coincides with Eqn (16) for a system of a bifunctional and an f-functional reagent.

The ratio of β constants affects considerably the gel point if the reagents are present in a non-equivalent ratio (Fig. 3).

When the scheme of a branching process is constructed (the statistical stage of solving the problem), the functionality of nodes that are formed should be taken into account. The presence of monofunctional reagents in the reaction mixture shifts the gel point towards higher conversions.[69] In this case, the gel formation condition has the form of Eqn (28); however, the presence of a monofunctional 'terminator' should be taken into account in the i index (as above, it means the node functionality). Here the functionality equals the number of added bifunctional oligomers rather than the number of hydrogen atoms that have reacted.

The strong dependence of the critical conversion on the concentration of the monofunctional modifier results from the decrease in the functionality of nodes (Table 2, Fig. 4). In comparison with the plots of changes in the concentrations of nodes with different functionality presented in Fig. 1, similar curves in Fig. 4 are shifted to the right along the x axis, the stronger the higher the content of the monofunctional modifier. While the final state of the system did not depend on the values of kinetic constants in the former case, in the latter case the presence of a monofunctional modifier strongly affects the structure of the

0.74	0.981	0.981	0.980	–	0.987

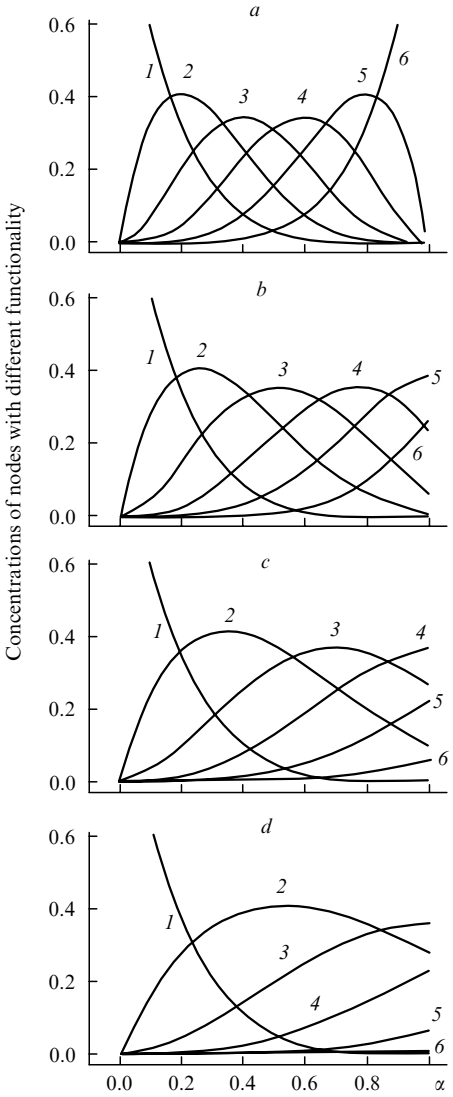

Figure 4. Dependencies of the concentrations of network nodes with different functionality on conversion for $\beta = 1$ at $n_1 = 0$ (*a*), 0.2 (*b*), 0.4 (*c*), 0.6 (*d*).
Node functionality: (*1*) 0, (*2*) 1, (*3*) 2, (*4*) 3, (*5*) 4, (*6*) 5.[69]

network formed, hence the gel point becomes unreachable at some concentration of the modifier.

Unlike a monofunctional modifier, a bifunctional modifier does not affect the critical conversion since neither of the components breaks network chains, hence the functionality of nodes does not depend on which of them is bound to an amine fragment. In this case, critical conversion is determined by the equation

$$(\alpha_b n_b + \alpha_2 n_2) \sum_i (i-1) n_{Ai} = 1, \tag{28a}$$

where the 'b' index corresponds to the main oligomer and the '2' index corresponds to the modifying one,

$$\alpha_b n_b + \alpha_2 n_2 \equiv \alpha_{ef}.$$

Both the difference of reaction rate constants of epoxy groups corresponding to different oligomers and the relative concentrations of oligomers affect the α_{ef} value but do not affect the gel point.

The use of the approach considered above for the solution of the problem of critical conversion values for other systems was considered by Deberdeev *et al.*[69,70].

V. Three-dimensional polymerisation

Polymerisation can be regarded as a process with a pronounced substitution effect. In fact, interaction of an active centre with a functional group recovers the active centre, *i.e.*, its reactivity changes. If there is no reagent with unchanged reactivity, the statistical approach to the description of such reactions is not applicable in any form (neither directly nor with the use of the BB concept). However, the statistical approach proposed long ago by Stockmayer [11,71] and improved by Gordon [72] is widely used even now.[18–20,73–76]

In essence, based on the statements of the statistical theory, the gel point condition for three-dimensional polymerisation consists of the requirement

$$\alpha_c = \frac{1}{\rho(\bar{P}_w - 1)}, \tag{16e}$$

i.e., this is considered as a cross-linking process. In this formula, α_c is the critical branching, a value introduced by Flory and Stockmayer;[5,71] ρ is the molar fraction of the bifunctional monomer if (as often happens) a mixture of mono- and bifunctional monomers is considered. The relationship between α_c and conversion was determined by solving kinetic equations describing the consumption of functional groups of monomers.[72]

Attempts were made to solve the problem kinetically. However, either the conditions used were not quite correct in some cases[77–79] or approximate and particular solutions were obtained.[7]

It should be noted that the question of experimental validation of theoretical calculations was non-topical for a long time, since it is well known that their feasibility conditions are not realised in three-dimensional polymerisation:[7,8,50] the fast chain growth by the radical mechanism and the low chain concentration at early stages of the process result in rather intense intramolecular cyclisation.[8,80–82] In this case, multiple cross-linking between a single pair of chains (formation of multiplet nodes and 'staircase'-type macromolecular structures) is also regarded as a factor decreasing the effective concentration of interchain cross-links and thus increasing the critical conversion. Because of that, microheterogeneous behaviour is typical of radical polymerisation.[8,50,83,84]

However, recent studies on living radical three-dimensional polymerisation (see, *e.g.*, Ref. 85) showed that the relationship (16e) is not fulfilled either,[86] though cyclisation does not play a significant role,[87] and the microheterogeneous character of the process does not manifest itself.[86,88]

It is convenient to solve Eqn (6) not in general form but by transforming it to a system of moments of the generating function.

Differentiation of Eqn (6) by all the q_i followed by equating them to 1 results in a system of differential equations for generating function moments and hence, moments of macromolecule distribution by length, chain functionality, and number of active centres. Obviously, all of these values are functions of time: $N = \Phi(\mathbf{1})$ is the total concentration of chains (zero moment);

first moments:

$$M = \frac{\partial \Phi(\mathbf{1})}{\partial q_1} = \sum_{i,j,l} i R(i,j,l)$$

is the total concentration of monomeric units in the system;

$$F = \frac{\partial \Phi(\mathbf{1})}{\partial q_2} = \sum_{i,j,l} j R(i,j,l)$$

is the total concentration of functional groups,

$$R = \frac{\partial \Phi(\mathbf{1})}{\partial q_3} = \sum_{i,j,l} l R(i,j,l)$$

is the total concentration of active centres;

second moments:

$$\Phi_{ij} \equiv \Phi_{ij}(\mathbf{1}) = \frac{\partial^2 \Phi(\bar{q})}{\partial q_i \partial q_j} \text{ at } \boldsymbol{q} = \mathbf{1}:$$

$$\Phi_{11} = \sum i(i-1)R(i,j,l),$$

$$\Phi_{12} = \sum ij R(i,j,l),$$

$$\Phi_{13} = \sum il R(i,j,l),$$

$$\Phi_{22} = \sum j(j-1)R(i,j,l),$$

$$F_{23} = \sum jl R(i,j,l),$$

$$\Phi_{33} = \sum l(l-1)R(i,j,l).$$

The system of differential equations for generating function moments has the form

$$\frac{dI}{dt} = -k_i I,$$

$$\frac{dN}{dt} = f k_i I - k_p FR - \frac{1}{2} k_t R^2 - k_Y Y,$$

$$\frac{dM}{dt} = 0,$$

$$\frac{dF}{dt} = -k_p FR,$$

$$\frac{dR}{dt} = f k_i I - k_t R^2 - k_Y Y,$$

$$\frac{dX}{dt} = -k_X XR,$$

$$\frac{d\Phi_{11}}{dt} = 2k_p \Phi_{12}\Phi_{13} + k_t(\Phi_{13})^2, \qquad (30)$$

$$\frac{d\Phi_{12}}{dt} = k_p(\Phi_{13}\Phi_{22} + \Phi_{12}\Phi_{23} - R\Phi_{12}) + k_t \Phi_{13}\Phi_{23},$$

$$\frac{d\Phi_{13}}{dt} = k_p(\Phi_{13}\Phi_{23} + \Phi_{12}\Phi_{33} + R\Phi_{12}) - (k_X X + k_Y Y)\Phi_{13} + k_t(\Phi_{33} - R)\Phi_{13},$$

$$\frac{d\Phi_{22}}{dt} = 2k_p(\Phi_{22}\Phi_{23} - R\Phi_{22}) + k_t(\Phi_{23})^2,$$

$$\frac{d\Phi_{23}}{dt} = k_p[(\Phi_{23})^2 + \Phi_{22}\Phi_{33} - R\Phi_{23} + R\Phi_{22}] - (k_Y Y + k_X X)\Phi_{23} + k_t(\Phi_{33} - R)\Phi_{23},$$

$$\frac{d\Phi_{33}}{dt} = 2k_p \Phi_{23}(\Phi_{33} + R) - 2(k_Y Y + k_X X)\Phi_{33} + k_t(\Phi_{33} - 2R)\Phi_{33}.$$

The solution of the system makes it possible to obtain comprehensive information about the course of polymerisation, including the value of critical conversion.

As noted above, the mathematical criterion of the formation of a cross-linked polymer is that the second moment of molecular mass distribution turns to infinity. However, it is the number of functional groups (as well as the number of active centres) that determines the chain growth rate during gel formation. Hence, distribution of macromolecules by functionality is the determining factor. In terms of generating function moments, it is the value of the second moment of the generating function by functionality

$$\Phi_{22}(t) = \sum_{i,j,l} j(j-1)R(i,j,l,t).$$

In a series of studies, Irzhak *et al.*[49,89–92] used the method considered above to study three-dimensional polymerisation processes involving different mechanisms: living polymerisation with instant and slow initiation, without and with chain transfer; polymerisation with square-law and linear termination. The main results of these studies are presented below.

The plots of $\Phi_{22}(t)$ during living polymerisation in the absence of chain transfer reactions under instant initiation conditions are presented in Fig. 5. One can see that $\Phi_{22}(t)$ increases by orders of magnitude (tends to infinity) in a very narrow range of conversions. Therefore, the critical conversion can be determined, without a considerable inaccuracy, as the x-axis intercept of the asymptote to the $\Phi_{22}(t)-\alpha$ curve. As calculations showed,[89] the critical conversion α_c obtained by this method is an unambiguous function of the starting $\Phi_{22}(0)$ value at a given concentration of active centres I_0 and does not depend on the starting concentration of functional groups, F(0).

The dependence of α_c on $\Phi_{22}(0)$ for living polymerisation with instantaneous initiation is presented in Fig. 6. It is evident that the square-root law is obeyed with good accuracy in this case; the

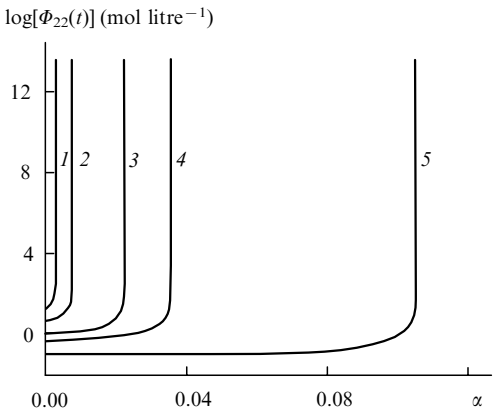

Figure 5. Kinetic curves of changes in the second moment of functionality distribution $\Phi_{22}(t)$ on instant initiation.
$I_0 = 10^{-3}$ mol litre^{-1}; $\Phi_{22}(0) = 20$ (*1*), 5 (*2*), 1 (*3*), 0.5 (*4*), 0.1 (*5*).[89]

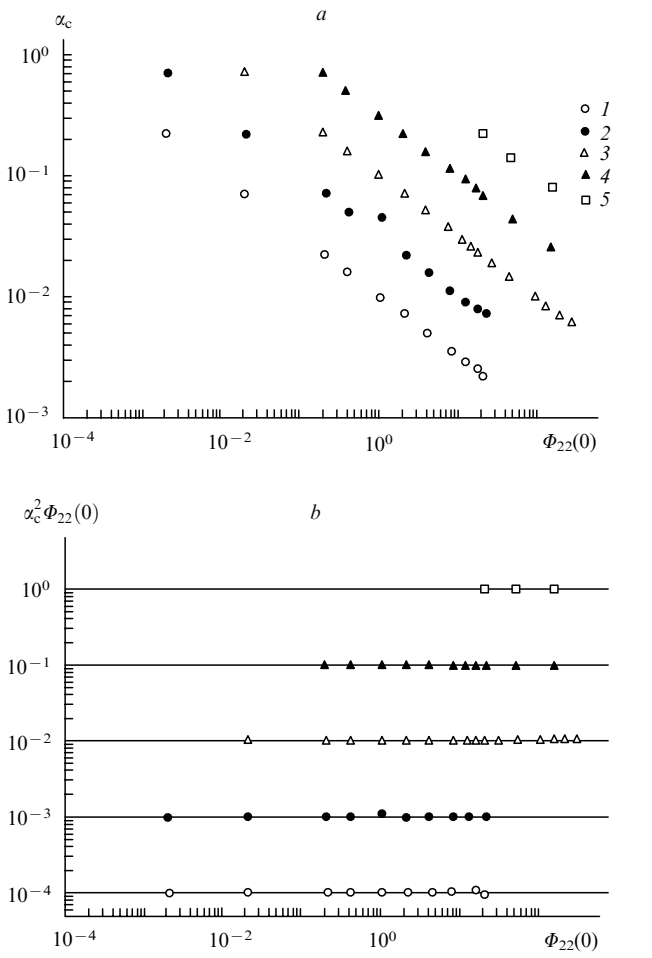

Figure 6. Dependencies of α_c on $\Phi_{22}(0)$ in the case of instant initiation. $I_0 = 10^{-4}$ (*1*), 10^{-3} (*2*), 10^{-2} (*3*), 10^{-1} (*4*), 1 mol litre^{-1} (*5*).[89]

straight lines corresponding to different concentrations of active centres are parallel to each other. Analysis showed that the critical conversion value is described by the formula

$$\frac{\alpha_c^2\Phi_{22}(0)}{I_0} = 1. \qquad (31)$$

The forms of the formulas (31) and (16) are similar. It fact, taking into account that

$$\frac{\Phi_{22}(0)}{F(0)} = \langle f\rangle_w - 1,$$

formula (31) can be converted to

$$\alpha_c^2 r(\bar{f_w} - 1) = 1. \qquad (31a)$$

However, this is just an outward similarity, since the r value, which is the ratio of concentrations of functional groups and active centres is much more than unity, whereas the F_{B0}/F_{A0} in formula (16) is close to unity. Furthermore, there is no multiplier characterising the distribution of the second reagent (active centres) by functionality. Anyway, it could not be present here because of the facts noted above, *i.e.*, that the starting molecules of active centres are monofunctional [R(0,0,1)/I_0 = 1] and that they are not consumed in polymerisation. Probably, the presence of the second power of α_c in formula (31) originates from the fact that the achievement of the critical point requires the reaction of at least two (per one chain) groups belonging to polyfunctional (branching) monomers, rather than the simultaneous reaction of two different functional groups, as is the case in Eqn (16).

Solution of the problem of radical copolymerisation of mono- and bifunctional monomers by the Monte Carlo method[93] resulted in an empirical relationship, whose form is similar to Eqn (31). The dependence of the critical conversion p_c on the inhibitor concentration C_I, the fraction of vacant lattice points C_V, and the molar fraction of bifunctional monomers f_{bif} was determined using the formula

$$p_c = \frac{C_I^{0.45}}{f_{bif}^{0.47}(1 - C_V)}.$$

As one can see, there are some differences, *viz.*, the index of power differs somewhat from 2 and the relative concentration of branching (bifunctional) comonomer appears in place of the second moment by functionality. The first difference is explained by the fact that cyclisation can be taken into account in the simulation of polymerisation. Therefore, the gel point should shift towards higher conversions in comparison with that calculated analytically. As regards the molar fraction of the branching comonomer, its use is not substantiated by any considerations.

Bansil *et al.*[93] reached the conclusion that the relationship obtained agreed with the ideas of Flory and Stockmayer. However, on the contrary, the calculation presented in that study suggests that there was no agreement.

Analysis of polymerisation processes with more complex mechanisms confirms the latter conclusion. Results for living polymerisation under slow initiation conditions are presented in Fig. 7. One can see that the α_c *vs.* $\Phi_{22}(0)$ plots in logarithmic

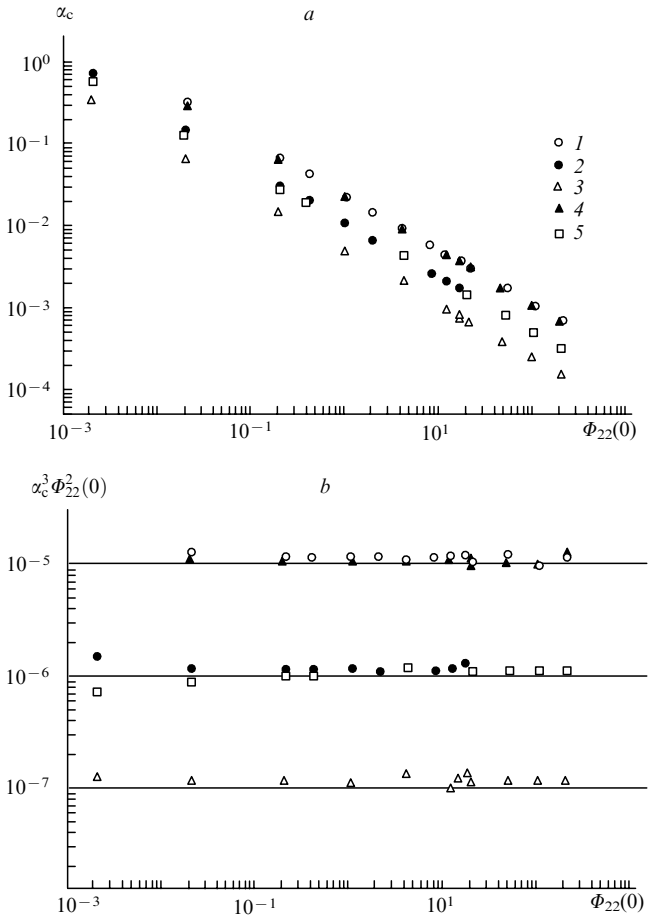

Figure 7. Dependencies of α_c on $\Phi_{22}(0)$ in the case of slow initiation. I_0 = 1 (*1*), 10^{-1} (*2*), 10^{-2} (*3*, *4*), 10^{-3} mol litre^{-1} (*5*); $k_i/k_p = 10^{-5}$ (*1–3*) and 10^{-3} (*4*, *5*).[89]

coordinates have the form of parallel straight lines demonstrating the relationship

$$\alpha_c \sim [\Phi_{22}(0)]^{-0.67},$$

shifted along the y-axis depending on the initiation rate. All the results are described with high accuracy by the following relationship:

$$\alpha_c^3 \frac{k_p \Phi_{22}^2(0)}{k_i I_0} = 1. \quad (32)$$

However, it is obvious that this result does not at all correlate with formulas provided by the statistical theory. On the other hand, both Eqns (31) and (32) relate the critical conversion value with the weight-average functionality of the starting monomer mixture referred to the concentration of chains [Eqn (31)] or to the rate of their accumulation [Eqn (32)].

It should be noted that the formulas (31) and (32) are some limiting cases that are obtained from a more general expression at $W_i \to \infty$ (instant initiation) or $W_i \to 0$ (slow initiation). The following formula can be an example:

$$\frac{\alpha_c^2 \Phi_{22}(0)}{I_0} = 1 - \exp\left[- \frac{k_i}{k_p \alpha_c \Phi_{22}(0)} \right] \longrightarrow$$

$$\longrightarrow \begin{cases} 1 & \text{at} \quad k_i \to \infty \\ \dfrac{k_i}{k_p \alpha_c \Phi_{22}(0)} & \text{at} \quad k_i \to 0 \end{cases}.$$

However, this result cannot be obtained in explicit form because the system (30) does not have an analytical solution. On the other hand, numeric calculation (Fig. 8) showed that the formula (31) is correct under the condition

$$\frac{k_i}{k_p \alpha_c \Phi_{22}(0)} \geqslant 6.$$

If

$$\frac{k_i}{k_p \alpha_c \Phi_{22}(0)} < 1,$$

then the critical conversion value is determined by the expression (32). The term 'instant initiation' should be used in the case $k_i/k_p > 0.1$ mol litre^{-1}.

Dusek and Somvarsky [94] gave a kinetic solution of the problem for living polymerisation with slow initiation. It was shown that the results given by the suggested approach differed from those of statistical calculations. Calculations carried out using the system (30) (taking into account that initiation occurs when an initiator reacts with a functional group) also give a somewhat different result (Table 3).

The difference between the critical conversion values is not high at a low inhibitor concentration and a low initiation constant, but it increases with an increase in these parameters.

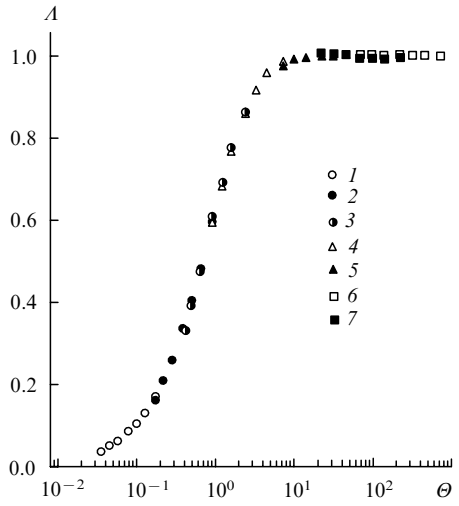

Figure 8. Dependence of α_c on the initiation rate in generalised coordinates $\Lambda - \Theta$.[49]
The curve shows the regions where the relationships (31) and (32) are obeyed.
$\Lambda = \alpha_c^2 \Phi_{22}(0)/I_0$, $\Theta = k_i/k_p \alpha_c \Phi_{22}(0)$; $\log(k_i/k_p) = -5$ (*1*), -4 (*2*), -3 (*3*), -2 (*4*), -1 (*5*), 0 (*6*), 1 (*7*).

Probably, the results of kinetic calculations differ because Dusek and Somvarsky [94] did not use the kinetic approach quite consistently: in order to take into account the interaction of active centres with 'dangling' functional groups, they derived a branching process and obtained the $G_1(z_a)$ probability generating function [see Eqns (14)–(16) in Ref. 94]. However, both variants give critical conversion values that differ considerably from those obtained using the statistical approach.

The significant dissimilarity between the results obtained and the statistical conclusions is also obtained if the concentration of chains is determined by a more complex mechanism, *viz*., chain transfer or chain termination.[89,90]

The relationships between the α_c, $\Phi_{22}(0)$ values and the chain transfer rate for instant and slow initiation are demonstrated in Fig. 9. In both cases, invariants characteristic of processes in the absence of chain transfer are plotted along the y axis. By selecting appropriate coordinates for the y axis it becomes possible to 'plot' the entire set of 'experimental' data on consolidated curves. The left branches of such curves correspond to the relationship

$$\alpha_c \approx \frac{1}{2} \frac{k_X X_0}{k_p \Phi_{22}(0)}, \quad (33)$$

i.e., critical conversion is determined by the ratio of the chain transfer rate to the growth rate on functional groups belonging to polyfunctional (branching) monomers.

The right branches of the curves for instant and slow initiation obey the relationships (31) and (32), respectively. The crossover points are described by the following relationships:

Table 3. Critical conversion calculation results: kinetic methods (I, II); statistical methods (III).

0.5	0.177	0.204	0.146	0.375	0.448	0.324	0.707	0.758	0.643	0.864	0.855	0.809

Note. I, III are data from Ref. 94, II is calculation using system (30); $F(0) = 10$, $\Phi_{22}(0) = 20$, monomer concentration $m_0 = 5$ mol litre^{-1}.

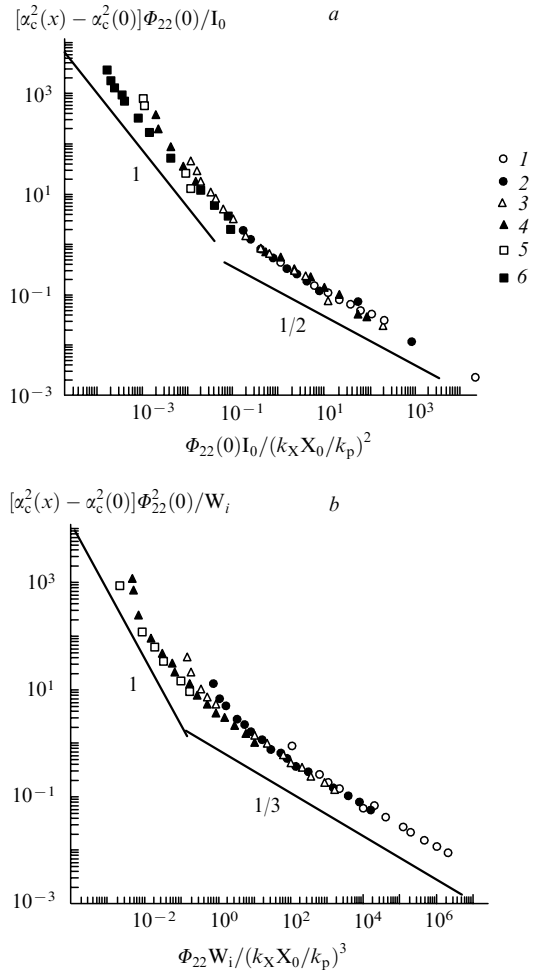

Figure 9. Dependencies of α_c on $\Phi_{22}(0)$ in the case of instant (*a*) and slow (*b*) initiation and chain transfer.[83]
$I_0 = 10^{-4}$ mol litre^{-1}: (*a*): $X_0 = 0$ (*1*), 1 (*2–4*, *6*); 10^{-1} mol litre^{-1} (*5*); $k_X/k_p = 10^{-3}$ (*1*, *2*), 10^{-2} (*3*), 10^{-1} (*4–6*); (*b*): $W_i = 10^{-4}$ (mol litre^{-1})^2 (see †). $X_0 = 0$ (*1*), 1 (*2–4*), 10^{-1} (*5*); $k_X/k_p = 10^{-3}$ (*1*, *2*), 10^{-2} (*3*), 10^{-1} (*4*, *5*). The numbers at the plots show the slopes of the straight lines.

$$\frac{k_p\Phi_{22}(0)}{k_X X_0} \approx \begin{cases} \dfrac{k_X X_0}{k_p I_0} & \text{(instant initiation)} \\ \dfrac{(k_X X_0)^2}{k_p k_i I_0} & \text{(slow initiation)} \end{cases} \qquad (34)$$

Therefore, if $k_X/k_p \approx 1$ and $X_0 \approx I_0$, one should use the formula (33) at $\Phi_{22}(0) < X_0$ and the relationships (31) and (32) at $\Phi_{22}(0) > X_0$. However, it is obvious that if $\Phi_{22}(0) < X_0$, then α_c exceeds 1, *i.e.*, the gel point cannot be reached. This means that it is the formulas (31) and (32) that make sense for practically important polymerisation conditions, *i.e.*, the chain transfer reaction and hence the actual length of the polymeric chain are not of importance in determining the critical conversion. In other words, the concentration of active centres in the former case and the initiation rate in the latter case are of importance not as factors determining the chain length but as those setting the concentration of the second reagent that participates in the formation of a macromolecule, which is an active centre.

Similar conclusions are obtained from analysis of polymerisation reactions with chain termination.[90, 92] The corresponding formulas are presented in Table 4.

† The initiation rate was attributed to the chain growth constant, therefore the (mol litre^{-1})^2 measurement units were obtained.

Table 4. Critical conversion calculation formulas.[89–92]

Process	small Φ_{22}	high Φ_{22}	Criterial conditions
Living polymerisation, instant initiation	$\frac{\alpha_c^2\Phi_{22}}{I_0} \approx 1$	$\frac{\alpha_c^2\Phi_{22}}{I_0} \approx 1$	$\frac{k_i}{k_p} > \sqrt{I_0\Phi_{22}}$
The same + chain transfer	$\alpha_c \approx \frac{1}{2}\frac{k_X X_0}{k_p\Phi_{22}}$	$\frac{\alpha_c^2\Phi_{22}}{I_0} \approx 1$	$\Phi_{22} >< \frac{(k_X X_0)^2}{k_p^2 I_0}$
Living polymerisation, slow initiation	$\frac{\alpha_c^3\Phi_{22}^2}{W_i} \approx 1$	$\frac{\alpha_c^3\Phi_{22}^2}{W_i} \approx 1$	$\frac{k_i}{k_p} < \sqrt{I_0\Phi_{22}}$
The same + chain transfer	$\alpha_c \approx \frac{1}{2}\frac{k_X X_0}{k_p\Phi_{22}}$	$\frac{\alpha_c^3\Phi_{22}^2}{W_i} \approx 1$	$\Phi_{22} >< \frac{(k_X X_0)^3}{k_p k_i^2 I_0}$
Slow initiation, termination by recombination	$\alpha_c \approx 0.33\frac{k_t R}{k_p\Phi_{22}}$	$\frac{\alpha_c^3\Phi_{22}^2}{W_i} \approx 1$	$\Phi_{22} >< \frac{\sqrt{k_1^3 W_i}}{k_p^2}$
Slow initiation, linear termination	$\alpha_c \approx \frac{1}{2}\frac{k_{tY} Y}{k_p\Phi_{22}(0)}$	–	–
'Substitution' effect, termination by disproportionation	$\alpha_c \approx \frac{1}{2}\frac{\sqrt{k_t W_i}}{k_{p2} Z_{22}}$	–	$\frac{k_{p1} Z_{22}}{\sqrt{k_t W_i}} < \frac{k_t}{k_{p2}}$

It is usual for three-dimensional radical polymerisation that a dilute solution of primary macromolecules in their own monomer is formed at early stages. Chain units carry functional ('dangling') groups; subsequent conversion of such groups is determined by two factors. On the one hand, the local concentration of these groups in the vicinity of a reactive end of a macroradical can be considerably higher than the mean bulk value, which results in their higher consumption with formation of intrachain rather than interchain cross-links. Because of that, both the apparent reactivity of 'dangling' groups and the critical conversion increase.[8] On the other hand, shielding of 'dangling' groups by the polymeric chain itself decreases the reactivity due to the steric factor, particularly if aggregation occurs. Finally, the substitution effect can manifest itself, *i.e.*, a change in the double bond reactivity, depending on whether it belongs to a monomer molecule or to a monomeric unit of a macromolecule. The combined effects of all these factors complicate the determination of the actual mechanism of the formation of cross-links in three-dimensional radical polymerisation.

In fact, conversion of double bonds (α_1) and 'dangling' groups (α_p) was observed separately in a number of studies [88, 95–97] on the kinetics of three-dimensional radical polymerisation. It was found that α_p reaches 0.2–0.4 at initial reaction stages where α_1 is close to zero. In terms of relative reactivity ε ($\varepsilon = k_{p2}/k_{p1}$, where k_{p1} and k_{p2} are reaction rate constants of chain growth on original and 'dangling' double bonds), this gives $\varepsilon \gg 1$.

The following copolymerisation systems were used: mixtures of styrene with 0.2 mol.%–2 mol.% of divinylbisphenol [88, 98–100] and mixtures of MMA with 1%–2% of ethylene glycol dimethacrylate.[98] In both cases, there are no reasons to believe that the reactivity of vinyl groups can increase when they are 'hung' on a polymeric chain. Probably, the increase in the local concentration of 'dangling' groups in the vicinity of the reactive macroradical end is the determining factor in both cases.

When three-dimensional radical polymerisation is carried out in the living chain mode,[86, 88] $k_{p2}/k_{p1} \approx 0.3$. This means that at the very start of the reaction, the concentration of macromolecules is high and the chain lengths are small, therefore the effect of local concentration of 'dangling' groups ceases and their decreased

reactivity in comparison with the original monomer is observed. It is likely that steric restrictions play a decisive role in this system.

On the other hand, it is obvious that the substitution effect can manifest itself in the three-dimensional radical polymerisation of diene monomers. This should primarily affect the structure of the cross-linked polymer:[101] a decrease in the reactivity of dangling groups in comparison with the original functional groups results in the formation of 'loose' interpenetrating clusters, while its increase results in compact, closely packed 'grains'.

Changes in the reactivity of functional groups within the suggested calculation scheme were taken into account by Korolev *et al.*[91] It was shown that it is necessary to separate original (monomeric) reagents from all polymeric chains and to introduce an own generating function for such chains

$$Z(\boldsymbol{q}) = \sum_i q_1 q_2^i m_i$$

(m_i is the concentration of the *i*-functional monomer). For example, in the case of bifunctional oligomers (*e.g.*, dimethacrylates)

$$Z(\boldsymbol{q}) = q_1 q_2^2 m_2.$$

The kinetic scheme of m_i consumption expressed by the equation

$$\frac{\mathrm{d}m_i}{\mathrm{d}t} = -k_{\mathrm{p}1} i m_i \mathrm{R}$$

($k_{\mathrm{p}1}$ is the growth rate constant on functional groups belonging to monomers) gives an ordinary differential partial equation for the generating function

$$\frac{\partial Z(\boldsymbol{q})}{\partial t} = -k_{\mathrm{p}1} q_2 \frac{\partial Z(\boldsymbol{q})}{\partial q_2} \mathrm{R}, \tag{35}$$

solution of which by the characteristics method gives

$$Z(\boldsymbol{q}) = \sum_i q_1 (q_2 \mathrm{e}^{-k_{\mathrm{p}1}\tau})^i m_i(0), \tag{36}$$

where

$$\tau = \int_0^t \mathrm{R}(\xi)\mathrm{d}\xi$$

(ξ is the variable of integration); $m_i(0)$ is the starting concentration of the *i*-functional monomer.

Equation (35) can be represented as a system for moments taking the distribution by functional groups (the '2' index) into account

$$\begin{aligned}
\frac{\mathrm{d}Z}{\mathrm{d}t} &= -k_{\mathrm{p}1}\mathrm{R}Z_2, \\
\frac{\mathrm{d}Z_2}{\mathrm{d}t} &= -k_{\mathrm{p}1}\mathrm{R}(Z_2 + Z_{22}), \\
\frac{\mathrm{d}Z_{22}}{\mathrm{d}t} &= -k_{\mathrm{p}1}\mathrm{R}(2Z_{22} + Z_{222}), \\
\frac{\mathrm{d}Z_{222}}{\mathrm{d}t} &= -k_{\mathrm{p}1}\mathrm{R}(3Z_{222} + Z_{2222}), \\
&\textit{etc.}
\end{aligned} \tag{37}$$

This system is not closed.

However, it should be taken into account that the initial reaction mixture consists of monomeric molecules with limited functionality. This fact makes it possible to truncate the system of equations. In fact, since

$$\begin{aligned}
Z_2(\boldsymbol{q}) &= q_1 \sum_{i=1}^n i q_2^{i-1} m_i, \\
Z_{22}(\boldsymbol{q}) &= q_1 \sum_{i=1}^n i(i-1) q_2^{i-2} m_i, \\
Z_{222}(\boldsymbol{q}) &= q_1 \sum_{i=1}^n i(i-1)(i-2) q_2^{i-3} m_i \\
&\textit{etc.},
\end{aligned} \tag{38}$$

$Z_{22}(1) = 0$ for linear polymerisation; $Z_{222}(1) = 0$ if the functionality does not exceed two ($n \leqslant 2$); $Z_{2222} = 0$ if n is no greater than three.

Naturally, the scheme describing radical polymerisation is more complex than Scheme (1). The system of differential equations for macromolecule concentrations and generating function moments changes accordingly. The initial conditions change as well: at $t = 0$ $m(1,i,0) = m_i(0)$, all $\mathrm{R}(i,j,l) = 0$.

Calculations showed[91] that the result obtained above is true with rather high precision, *viz.*, the critical conversion value depends only on the second distribution moment by functionality for initial molecules, $Z_{22}(0)$. Therefore, (31)- and (32)-type formulas are valid for living polymerisation. Results of calculations for radical polymerisation (with chain termination) are presented in Table 4.

As noted above, comparison of theoretical conclusions with experimental data for polymerisation processes is very difficult. Owing to the high distribution nonhomogeneity of reactive macromolecules in the reaction volume at early stages, intrachain cyclisation and aggregation of polymeric coils are highly probable at early stages. Therefore, assessment of the validity of particular formulas requires that the distribution nonhomogeneity of macromolecules be minimised. This can be achieved by minimising the degree of polymerisation by increasing the rates of chain transfer or chain termination reactions. When polymerisation occurs in the living chain mode, the steady-state concentration of active centres decreases by several orders in comparison with a similar value for polymerisation under ordinary conditions.[85,102] As a result, the concentration of chains is rather high even at small conversion levels. Therefore, the cyclisation probability decreases considerably in this case, too.[87] It can also be expected that cyclisation would contribute insignificantly to polymerisation if the content of the branching comonomer in the reaction mixture is decreased.

These approaches were used in a number of studies[75,86,87,90,98,103] on the determination of the critical conversion value in three-dimensional polymerisation processes.

Ide and Fukuda[86] carried out radical copolymerisation of styrene with certain bifunctional monomers in the presence of 2,2,6,6-tetramethylpiperidinyl 1-oxide, a stable radical that ensured the living polymerisation mode. The content of the bifunctional reagent

$$f_2 = \frac{m_2}{m_2 + m_1}$$

in the original mixture did not exceed two molar percent. As noted above, both factors (the living polymerisation mode and the small f_2 value) contribute to the insignificance of intrachain cyclisation. Some of the results obtained are presented in Table 5.

The fact that the calculation result obtained using formula (16e) exceeds the experimental critical conversion value suggests that this calculation is faulty; on the other hand, the overestimated values obtained using formula (31) can be due to the inaccuracy of determination of the number of chains, which may easily be smaller than I_0. Thus, experimental results can be regarded as evidence of the validity of the formula (31).

The use of dodecanethiol as the chain transfer agent in the polymerisation of neopentyl dimethacrylate[98] decreased the weight-average degree of polymerisation. As this value decreases from 142 to 49, the critical conversion value increases but remains higher than that calculated using formula (16e). Since formula (33) gives even lower values, it is not possible to assess the validity of the suggested approach. The cyclisation probability remains considerable even at such relatively low chain lengths.

Table 5. Critical conversion in living three-dimensional copolymerisation.[86]

f_2	I_0/m_1	$\langle P\rangle_w$	α_c		
			experiment	calculation using the formula	
				(16e)	(31) [a]
0.01	1/200	132	0.55	0.76	0.70
0.016	1/170	101	0.50	0.62	0.60
0.02	1/200	96	0.40	0.52	0.495

[a] In this case, formula (31) has the form

$$\alpha_c = \sqrt{\frac{I_0(1-f_2)}{f_2}}.$$

The effect of the number of branching links in a chain on the critical conversion value is demonstrated by data in Table 6.

Table 6. Critical conversion in three-dimensional copolymerisation of styrene with *m*-divinylbenzene (DVB).[75]

[DVN] (mol.%)	$10^{-3}\langle P\rangle_w$	$\Phi_{22}(0)$	α_c		
			experiment	calculation using the formula	
				(16e)	(see [a])
1	1.19	0.154	0.215	0.0425	0.032
0.5	0.79	0.077	0.333	0.133	0.065
0.25	0.74	0.039	0.488	0.271	0.128
0.17	0.67	0.026	0.549	0.435	0.192

[a] Calculation using the formula presented in Table 4.

Calculation gives lower critical conversion values in both versions. This suggests that cyclisation occurs at such a low content of the divinyl monomer. In fact, the molar fraction of the monomer was lower by an order of magnitude in the living polymerisation experiments described above; it is this factor that predefines the absence of cyclisation.

It is of note that statistical calculation gives overestimated gel point values. This may misguide researchers who assess the contributions of cyclisation to the polymerisation process. For example, the experimental gel point value in the polymerisation of triethylene glycol dimethacrylate in the presence of benzoquinone (0.05 mol litre^{-1}) as the inhibitor was found to be 0.19.[90] Statistical calculations gave a much higher value, *viz*., 0.72, which is physically unreasonable. Calculation with the use of formulas shown in Table 4 gave 0.18, which is very close to the experimental value. The corresponding values at the inhibitor concentration of 0.01 mol litre^{-1} are as follows: 0.135; 0.14; 0.036. In other words, cyclisation does not occur, judging by statistical calculation results. However, accurate calculation using the formulas in Table 4 indicates the opposite situation.

Thus, the statistical approach cannot be used to analyse three-dimensional polymerisation.

VI. Conclusion

In conclusion, it should be emphasised that calculation of critical conversion values in the case of the formation of network polymers can be regarded as a particular solution of a more general problem, *viz*., determination of molecular mass distribution parameters or, more exactly, distribution of macromolecules by functionality. Quite a few approaches have been proposed for this purpose; however, their physical substantiation is provided only in some cases. In this review we made an attempt to determine the applicability conditions of different solution methods, depending on the polymer formation mechanism. Calculation of molecular mass distributions is a problem of current interest for polymer technology, so the criteria formulated here appear to be quite significant.

In the review we summarise the achievements in the calculation methods for the critical sol–gel transition point during polymer formation. One can state with certainty that the principles underlying these methods are also applicable to the formation of physical gels.[104] In particular, the relationship between the temperature and the gel transition concentration of biopolymers discussed by Matveev[105] is determined, in essence, by general regularities of network structure formation, though in this case the nature of nodes is rather specific: the latter are formed due to phase separation rather than chemical reactions.

Abstract. Characteristic features of the catalytic synthesis of alternating copolymers of carbon monoxide with various olefins, dienes, styrene and its derivatives are considered. The diversity of catalyst systems used for the copolymerisation of carbon monoxide is demonstrated and their influence on the structure and the molecular mass of the resulting copolymers is analysed. The data on the structure and physicochemical and mechanical properties of this new generation of functional copolymers are generalised and described systematically for the first time. The bibliography includes 296 references.

I. Introduction

Alternating copolymers of carbon monoxide with acyclic and cyclic alkenes, dienes, styrene and its derivatives represent a new generation of functional low- and high-molecular-weight compounds.

$$n\,RCH{=}CH_2 + n\,CO \longrightarrow -(CH(R)-CH_2-C(=O))_n-$$

Systematic data on the synthesis, structure, and properties of these unusual copolymers have been appearing in the literature since the mid-1980s. Some of them (for example, copolymers of alkenes with carbon monoxide) have already found practical application.

The considerable interest of researchers in the problem of alternating copolymerisation of carbon monoxide with various monomers is indicated by the annual increase in the number of relevant publications. About 60% of these papers are devoted to the synthesis of alternating copolymers of carbon monoxide with alkenes, dienes, styrene and its derivatives. The European patent authority has now granted more than 300 patents for catalyst systems and methods for the preparation of alternating copolymers from carbon monoxide and alkene or diene monomers and for compositions of these copolymers with other polymers. A number of reviews have been devoted to the copolymerisation of carbon monoxide with olefins.[1–8]

The ready availability and low cost of carbon monoxide are important factors in the preparation of carbon monoxide copolymers.[9] The possibility of controlling the structure of copolymers by changing the order of connection of the CO groups to other monomer units allows one to prepare polymers with a set of new properties (high adhesion, high stability against photo- and biodestruction and so on).[2, 10, 11]

The purpose of this review is to analyse the key results obtained during the last decade in the field of catalytic alternating copolymerisation of carbon monoxide not only with olefins but also with dienes and functionalised olefins. Taking carbon monoxide copolymerisation with ethylene (the best studied pair of comonomers) as an example, the stepwise mechanism of copolymerisation is considered. The data on the structure and physicochemical and mechanical properties of a new generation of polyketones are described systematically for the first time.

II. Copolymers of carbon monoxide with olefins, dienes and other monomers

1. Carbon monoxide – ethylene

The alternating copolymers of carbon monoxide with ethylene were first synthesised under the action of $Ni(CN)_2$ in 1941.[12] Subsequently, $Pd(CN)_2$ [13] and its hydride form [14] have been used as the catalysts. The resulting ethylene – carbon monoxide copolymers have high molecular masses and melting points. The yield and the intrinsic viscosity ($[\eta]$) of the copolymers are markedly influenced by the nature of the solvent used as the reaction medium. In particular, the yield and the intrinsic viscosity increase in the sequence of solvents water < acetonitrile < *m*-cresol < chloroform < methyl ethyl ketone < ethyl acetate.

The data on the preparation of ethylene copolymers with carbon monoxide published in the patent literature before 1980 indicated that the synthesis had to be carried out at high temperature (100 – 200 °C) and that the product yields were low (see, for example, patents [12–14]). The activity of the catalysts (various Ni and Pd complexes) described in these publications was very low.

The possibility of copolymerisation of these monomers at room temperature was first reported in 1982.[15] As the catalyst, the researchers used the complex $[Pd(MeCN)(PPh_3)_3](BF_4)_2$. Copolymerisation was carried out in chloroform at a pressure of an equimolar monomer mixture of 5 MPa. The average copolymerisation rate did not exceed 10 $g\,g_{Pd}^{-1}\,h^{-1}$. Later, it has been shown [16–18] that the rate of alternating copolymerisation of

carbon monoxide and ethylene can reach 1000 g g_{Pd}^{-1} h^{-1} when the process is carried out in acetic acid in the presence of monodentate organophosphorus ligands. Ethylene copolymerisation with carbon monoxide in an acid medium has been considered.[19]

The use of bidentate organophosphorus ligands and acids with $pK_a \leqslant 2$ as components of Pd catalysts has initiated new vigorous research in this field.[20] A detailed study[21,22] of the kinetics of carbon monoxide copolymerisation with ethylene in the presence of $Pd(OAc)_2$–diphosphine–acid systems has shown that the reaction rate depends on the natures of the phosphine and the acid, the presence of an oxidant (for example, 1,4-benzoquinone), and also the amounts of these components with respect to palladium acetate.† These results have been supported by studies of Chinese researchers.[25]

As a rule, ethylene copolymerisation with carbon monoxide under the action of $Pd(OAc)_2$ and other Pd complexes is carried out in a rather polar medium (methanol is the best choice).[26,27] For increasing the catalytic activity of the Pd catalyst, the solvent must contain trace amounts (in some cases, several percent) of methanol or water.[27–29] The long induction period and low copolymerisation rate are due to the disregard of this requirement.[28]

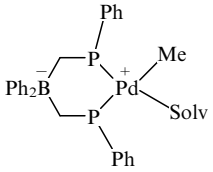
Copolymerisation of ethylene with carbon monoxide in the presence of the palladium complexes $[(L)Pd(MeCN)_2](BF_4)_2$, $[(L)Pd(H_2O)(TsO)](TsO)$ [L = $Ph_2P(CH_2)_3PPh_2$ (**1**)] and *trans*-$[(PCy_3)_2Pd(H)(H_2O)](BF_4)$ (Cy is cyclohexyl)[27–30] proceeds at a somewhat lower rate than that in the presence of the $Pd(OAc)_2$–diphosphine–acid system.

Usually, CF_3COOH or TsOH are employed as the acids in the $Pd(OAc)_2$–$Ph_2P(CH_2)_3PPh_2$–acid catalyst system (the copper salts of these acids can also be used).[16,31,32] Data on the activating effect of perchloric[33] and phosphoric[34] acids and nickel, copper, iron, zirconium or vanadium sulfates or perchlorates have been reported. It was shown[31,35] that the rate of ethylene copolymerisation with carbon monoxide depends on the type of the acid and decreases in the sequence CF_3SO_3H > *p*-$MeC_6H_4SO_3H$ > CF_3COOH > PhCOOH ≈ HBF_4 > CCl_3COOH > $C_6H_3Cl_2$.COOH > HCl. However, to establish a quantitative correlation between the copolymerisation rate and the acid pK_a, systematic studies are required.

The rate of ethylene–carbon monoxide copolymerisation in the presence of the $Pd(OAc)_2$–diphosphine–acid catalyst system depends also on the nature of the diphosphine. Patent data on the synthesis of ethylene–carbon monoxide copolymers indicate that $Pd(OAc)_2$–CF_3COOH–$(2\text{-}MeOC_6H_4)_2P(CH_2)_3P(C_6H_4OMe\text{-}2)$ (**2**) is the most active catalyst system.[36] In this case, copolymerisation rate can reach 33 000 g g_{Pd}^{-1} h^{-1} (with an overall pressure of 9 MPa). When the copolymerisation is performed at a low pressure and temperature, its rate and the yield of the copolymer decrease. For ethylene copolymerisation with CO in methanol in the presence of CF_3COOH used as the acid component, the reaction rate increases in the following sequence of diphosphines: bis(diphenylphosphino)methane (**3**) < 1,6-bis(diphenylphosphino)hexane (**4**) < 1,5-bis(diphenylphosphino)pentane < 1,4-bis(dibutylphosphino)butane (**5**) < 1,4-bis(butylphenylphosphino)butane (**6**) < 1,2-bis(diphenylphosphino)ethane (dppe) (**7**) < 2,3-bis(diphenylphosphino)butane (*meso*, *rac*) (**8**) < 2,4-bis(diphenylphosphino)pentane (*meso*, *rac*) (**9**) < 1,3-bis(di-n-butylphosphino)propane (dbpp) (**10**) < 1,4-bis(diphenylphosphino)butane (**11**) < 1,3-bis(diphenylphosphino)propane (**1**) < 1,3-bis[di(2-methoxyphenyl)phosphino]propane (**2**).[21,31,34,37–39] Comparison of the activities of various diphosphines with the activity of 1,3-bis(diphenylphosphino)propane used most often has shown that the introduction of alkyl substituents into the 2-position of propane barely influences the catalyst activity, whereas the introduction of alkyl groups into the 1,3-positions changes the activity of the palladium catalyst. This attests to the influence of the electronic and steric factors on the catalyst activity. It has been shown[40–43] that for copolymerisation of carbon monoxide with ethylene in the presence of the $[Pd(Me).(MeCN)(P\text{-}P)](PF_6)$ complexes (P-P are ligands **1** and **9** or **7** and **8**) in an aprotic solvent (CH_2Cl_2), the molecular mass of the copolymer increases in the sequences **1** > *meso*-**9** > *rac*-**9** and *meso*-**8** > *rac*-**8** > **7**. The presence of traces of water in the reaction medium results in the formation of μ-hydroxo complexes $[Pd(\mu\text{-}OH)(P\text{-}P)_2](PF_6)_2$ and in a higher yield of the copolymer, which increases in the sequence *rac*-**9** < *meso*-**9** < **1**. In the case of bischelate complexes, $[Pd(P\text{-}P)_2]^{2+}$, a different activity series is observed, namely, $[Pd(rac\text{-}\mathbf{9})_2]^{2+} < [Pd(\mathbf{1})_2]^{2+} < [Pd(meso\text{-}\mathbf{9})_2]^{2+}$. When bischelate palladium complexes are used and carbon monoxide–ethylene copolymerisation is carried out in methanol, the yield of the copolymer increases in the sequence **1** ≪ *rac*-**9** < *meso*-**9**.

Despite the fact that no quantitative data on the relationship between the copolymerisation rate and structural (or other) characteristics of diphosphines are currently available, presumably, the essential factors that determine the catalytic activity of palladium diphosphine complexes include the ligand conformation, the length of the methylene chain (*n*) between the P atoms and the rigidity of the complex. The P–Pd–P angle increases with an increase in *n* from 74° (for *n* = 1) to 175° (for *n* = 5). The palladium diphosphine complexes considered above have a planar square structure of the coordination unit with *cis*-arrangement of the phosphorus atoms for *n* = 1–4. As the methylene chain grows longer ($n \geqslant 5$), the formation of a dimer with *trans*-arrangement of the ligands becomes more favourable. The increase in the structural rigidity of the Pd complex resulting in a higher catalyst activity (by about an order of magnitude) in the copolymerisation of carbon monoxide with ethylene was shown for the 1,2,3,4-tetrakis(diphenylphosphino)cyclobutane complex of Pd(II).[44]

Worthy of note is the publication[45] concerning the possibility of alternating copolymerisation of carbon monoxide with ethylene induced by a zwitter-ionic palladium complex,



whose activity proved to be comparable with the activity of Pd complexes with 1,3-bis(diphenylphosphino)propane.

Some recent publications describe the use of palladium complexes with P-N and N-N bidentate ligands as catalysts of carbon monoxide copolymerisation with ethylene and the use of some aryl- and fluorine-containing arylboranes or their salts (Na, K or Li)[46–51] and alumoxanes,[52–55] instead of acids (CF_3COOH, *p*-$MeC_6H_5SO_3H$, *etc.*). Thus with the $Pd(OAc)_2$–$Ph_2P(CH_2)_3PPh_2$–$(Bu^t_2Al)_2O$ catalyst system, copolymerisation of ethylene with carbon monoxide in toluene proceeds at a rate of up to 2900 g g_{Pd}^{-1} h^{-1}.

It has been shown[56] that dicationic Pd complexes containing N-heterocyclic carbene ligands with the formula [*cis*-$CH_2\{N(H)C{=}C(H)N(R)C\}_2Pd(NCMe)_2](BF_4)_2$ (R = Me, 2,4,6-$Me_3C_6H_2$)‡ are active catalysts for ethylene copolymerisation with carbon monoxide. The reaction occurs at a rate of up to 810 g g_{Pd}^{-1} h^{-1}. Recently, a new family of P-N and P-P ligands based on 2-methyl-2-(2-pyridyl)-1,3-bis(diphenylphosphino)propane[57] and C_2-, C_3- and C_4-bridging bisphospholyl[58] ligands have been synthesised; their Pd complexes were shown to be active catalysts of the alternating copolymerisation of carbon monoxide

† The replacement of palladium acetate by nickel, cobalt, copper or silver acetate decreases the copolymerisation rate by a factor of several tens.[20,23,24]

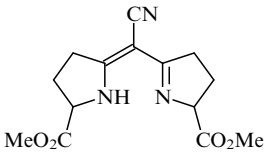
‡ These complexes proved to be inactive in carbon monoxide copolymerisation with propylene or styrene.

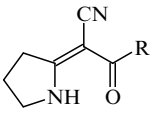
with ethylene. Palladium phosphineimine complexes [Pd(P-N)(Me)(MeCN)](BF$_4$) induce living copolymerisation and block copolymerisation of carbon monoxide with ethylene.[59]

The ruthenium(II) phosphine complexes, *cis*-[Ru(PPh$_2$CH$_2$CH$_2$PPh$_2$)$_2$](OTs)$_2$ and [Ru{PPh(CH$_2$CH$_2$CH$_2$.PPh$_2$)$_2$}$_2$](OTs)$_2$], exhibit a very low activity in the copolymerisation of carbon monoxide with ethylene. However, the addition of trifluoroacetic acid and 1,4-benzoquinone increases substantially the catalytic activity.[60] In this case, besides the high-molecular-mass copolymer, the reaction gives a low-molecular product soluble in methanol. A similar type of behaviour was found for 1,1′-palladium(II) bis(diphenylphosphino)ferrocene complexes, [Pd(H$_2$O)$_2${Fe(C$_5$R$_4$PPh$_2$)$_2$}](OTf)$_2$ (R = H, Me). The copolymerisation of carbon monoxide with ethylene in the presence of these complexes gives rise to oligoketone and methyl propionate (resulting from methoxycarbonylation of ethylene).[61] The following palladium complexes with diphosphine monoxide ligands have been synyhesised:[62] [(MeCN)(Me)Pd(κ^2-P,O-Ar$_2$P(CH$_2$)$_n$.P(O)Ar$_2$)]X (Ar = Ph, *p*-MeC$_6$H$_4$, n = 1–3, X = BF$_4$, SbF$_6$), [(η^3-C$_3$H$_5$)Pd{κ^2-P,O-Ar$_2$P(CH$_2$)$_n$P(O)Ar$_2$}]X (Ar = Ph: n = 2, 3, X = OTs, OTf; n = 1, X = SbF$_6$; Ar = *p*-MeC$_6$H$_4$: n = 1, X = SbF$_6$). Unfortunately, the catalytic activities of these complexes are lower than those of the catalyst systems described above.[20,36]

Due to the high cost of palladium, repeated attempts have been made at replacing it by cheaper nickel or copper. Nickel(II) phosphine complexes, [Ni{Ph$_2$PCH=C(Ph)O}(PEt$_3$)Ph], have been used[63] for copolymerisation of carbon monoxide with ethylene. A more recent study[62,64] reports the synthesis of nickel(II) complexes with N-O-bidentate ligands, [Ni(N-O).(*o*-MeC$_6$H$_4$)PPh$_3$] (N-O is 4-nitropyridine-2-carboxylate, pyrazine-2-carboxylate, 4-methoxypyridine-2-carboxylate) and with diphosphine monoxide ligands, [(η^3-CH$_2$C(Me)CH$_2$)Ni{κ^2-P,O-Ph$_2$PXP(O)Ph$_2$}]SbF$_6$ (X = *o*-C$_6$H$_4$, NH).

Recently, a series of [(L)Ni(*o*-MeC$_6$H$_4$)(PPh$_3$)] nickel complexes with bidentate N-N- and N-O-chelate ligands (L),



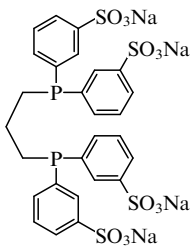


R = Me, OMe, Ph, CF$_3$, C$_3$F$_7$, C$_7$H$_{15}$.

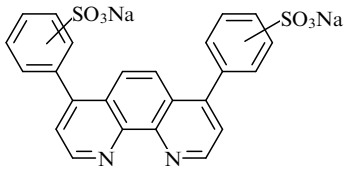
have been prepared. These complexes catalyse carbon monoxide–ethylene copolymerisation at a rate of up to 2300 g g_{Ni}^{-1} h^{-1}.[65] In 1998, it was reported that Ni(*o*-MeC$_6$H$_4$)(PPh$_3$)(Tp^{Ph}) [Tp^{Ph} is a tripodal tris(pyrazolyl)borate ligand] performs copolymerisation of carbon monoxide with ethylene giving rise to a high-molecular-weight product (T_m = 260 °C, M_w = 5770).[66] However, the rate of copolymerisation at 50 °C was low, 1.2 g g_{Ni}^{-1} h^{-1}.

The conduction of carbon monoxide–ethylene copolymerisation in methanol or in another polar solvent poses some difficulties associated with the process safety, environmental impact, the necessity of regenerating the solvent and so on. These aspects play a crucial role in the design of the industrial process. Therefore, in recent years, vigorous search for catalysts that would perform the copolymerisation in aqueous media has been carried out. This possibility was first mentioned in the 1990s.[67–69] Palladium complexes with sulfonated bidentate ligands have been used as the catalysts.

It was shown[68,69] that in the presence of a water-soluble diphosphine ligand, dppp-(SO$_3$Na)$_4$, and the palladium complex, Pd(TsO)$_2$(MeCN), copolymerisation of carbon monoxide with ethylene can be carried out in an aqueous medium at 90 °C to give copolymers with the molecular mass (6–8) × 10^3; the reaction rate reaches 4000 g g_{Pd}^{-1} h^{-1}.



dppp-(SO$_3$Na)$_4$

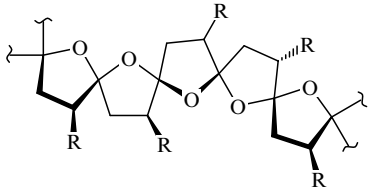


phen-(SO$_3$Na)$_2$

In the same years, data on conduction of the carbon monoxide–ethylene copolymerisation in the gas phase, appeared in the patent literature.[70–76] In this case, the Pd(OAc)$_2$–diphosphine–HBF$_4$ catalyst is applied onto a support (for example, the CO/C$_2$H$_4$ copolymer) impregnated with a nonpolymerising organic diluent. The gas phase should contain traces of methanol. The rate of this reaction is comparable with the rate of a similar process carried out in methanol.[35,77–79] Other polymers have also been used as catalyst supports, for example, porous polypropylene[79] or silica.[80] Although the first industrial process for the production of the alternating copolymer of carbon monoxide with ethylene was based on the reaction in solution,[81] subsequently, a pilot plant for gas-phase synthesis of polyketone has also been designed.[68] Copolymerisation of CO and C$_2$H$_4$ carried out in the gas phase would be noticeably more economic.

2. Carbon monoxide copolymers with propylene and higher olefins

When conducting copolymerisation of carbon monoxide with propylene and higher α-olefins (or with styrene or its derivatives), one should take into account a number of factors that influence the structure of the copolymer formed.[5] In addition to the major product with the 1,4-diketone structure [CHR–CH$_2$C(O)]$_n$, copolymerisation of carbon monoxide with α-olefins, styrene or its derivatives gives a copolymer with a spiroketal structure.[69,82]



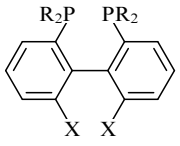
In the case of propylene, this copolymer is formed when the reaction is carried out at low temperature. In the copolymerisation of higher α-olefins (for example, hept-1-ene) with carbon monoxide, the spiroketal copolymer is formed at 50 °C.[83]

The activity of propylene in the reaction with carbon monoxide is about an order of magnitude lower than that of ethylene. The rates of copolymerisation of carbon monoxide with ethylene, propylene and but-1-ene under comparable conditions catalysed by the Pd(OAc)$_2$–CF$_3$COOH–Ph$_2$P(CH$_2$)$_3$PPh$_2$ system are 6000, 400 and 250 g g_{Pd}^{-1} h^{-1} (see Ref. 84). A similar dependence is observed with other catalyst systems, for example, heterogeneous and most of homogeneous Ziegler–Natta catalysts and the [(Ph$_2$P(CH$_2$)$_3$PPh$_2$)Pd(MeCN)$_2$](BF$_4$)$_2$ complex in a nitromethane–methanol medium.

The catalyst of choice for propylene–carbon monoxide copolymerisation is the [L$_2$PdX$_2$]$^{n+}$ complex (X is a weakly coordinating or non-coordinating anionic or neutral ligand, L is diphosphine) and an MeOH-containing solvent mixture is the best reaction medium.

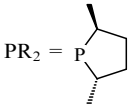
Until recently, the resulting copolymers of CO and propylene had low molecular masses. A detailed study[85] of carbon monoxide copolymerisation with propylene has revealed the reasons for the formation of low-molecular-weight polymers. The main reason is the lack of control of the contents of MeOH and H$_2$O in the reaction medium. Later, CO/MeCH=CH$_2$ copolymers with M_w = 43.2 × 10^4 have been obtained.[5,86,87] As in the case of

ethylene – carbon monoxide copolymerisation, the highest rate of carbon monoxide copolymerisation with olefins is observed in the presence of 1,ω-bis(diphenylphosphino)alkanes, $Ph_2P(CH_2)_nPPh_2$, with $n = 3$ and 4. The activity of the $Pd(OAc)_2$ – diphosphine – p-$MeC_6H_4SO_3H$ catalyst system in the copolymerisation of propylene and CO increases in the following series of diphosphines:[38] $Ph_2P(CH_2)_3PPh_2 < Bu_2P(CH_2)_3PBu_2 < Bu_2P(CH_2)_4PBu_2$. The copolymers of propylene and carbon monoxide obtained using bis(diphenylphosphino)alkanes are characterised by poor stereoregularity. It was shown[85] that by varying the nature of the diphosphine ligand, one can obtain fully iso- or atactic carbon monoxide – propylene copolymers. For example, *P*,*P*-(6,6′-dimethoxybiphenyl-2,2′-diyl)bis(2,5-dimethylphospholane) (**12**) has been used to prepare completely atactic copolymer, while using *P*,*P*-*o*-phenylenebis(2,5-dimethylphospholane) (Me-DUPHOS, **13**), a completely isotactic polymer was obtained. The use of enantiopure C_2-symmetrical diphosphine (**12**, **13**) and phosphine – phosphite (**14**) ligands gives copolymers with a higher stereoregularity.

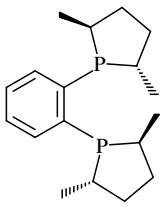


12

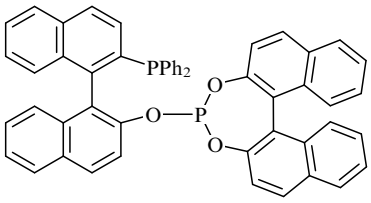
$PR_2 = PPh_2$: X = Me, OMe;
$PR_2 = PCy_2$: X = H, OMe;



, X = OMe.

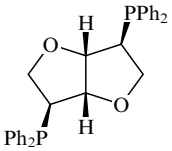


13 (Me-DUPHOS)



14 (BINAPHOS)

It is possible to prepare both dextro- and levorotatory stereoisomers.[88] The use of higher α-olefins (but-1-ene, hept-1-ene and oct-1-ene) in the copolymerisation with carbon monoxide in the presence of a Pd complex with diphosphine ligand **15** results in the formation of optically active copolymers.[89, 90]



15 (DDPPI)

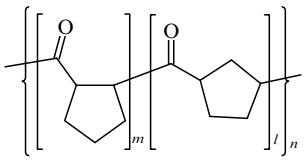
The alternating copolymerisation of α-olefins or styrene and its derivatives, dienes and some other monomers with carbon monoxide catalysed by chiral palladium complexes is a promising method for the preparation of optically active copolymers, mainly for two reasons: (i) the chirality of the backbone can be provided by using prochiral monomers; (ii) the presence of ketone groups in the backbone enables easy functionalisation of these polymers.

Olefins with internal double bonds can also be introduced in the copolymerisation with carbon monoxide. Thus it was shown[28] that in the presence of the $[Pd(Me\text{-}DUPHOS)(MeCN)_2](BF_4)_2$ catalyst, *cis*-but-2-ene copolymerises with CO to give an isotactic optically active oligomer with $M_n = 600$. The activity of *cis*-but-2-ene in this reaction is an order of magnitude lower than that of but-1-ene, which reacts with CO to give copolymer with $M_n = 4.0 \times 10^4$ and with both 1,4-ketone and the spiroketal structures in the backbone. The authors suggested that *cis*-but-2-ene isomerises into but-1-ene during copolymerisation. *trans*-But-2-ene does not copolymerise with carbon monoxide.

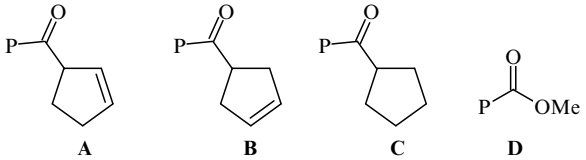
The synthesis of $C_2H_4/CO/MeCH=CH_2$ terpolymers with different contents of the CO/C_2H_4 and CO/C_3H_6 blocks in the polymer chain has been carried out in a hydrocarbon medium and the properties of the resulting copolymers have been studied.[85] Similar copolymers have been obtained in an aqueous medium[67] using water-soluble palladium complexes with dppp-$(SO_3Na)_4$ and phen-$(SO_3Na)_2$ as the catalysts. It is noteworthy that the rate of copolymerisation of propylene, ethylene and carbon monoxide in water was 4 – 22 g g_{Pd}^{-1} h^{-1}. These values are very low compared to those attained for the process carried out in methanol.[3] It was found that the rate of carbon monoxide copolymerisation with propylene in water is about 10 times as low as the rate of $CO/CH_2=CH_2$ copolymerisation under similar conditions. This is the main reason for the formation of a low-molecular-weight oily co-oligomer in the case of propylene. Co- and ter-polymerisation of ethylene, propylene and carbon monoxide in water catalysed by the $(NaO_3SC_6H_4CH_2)_2C(CH_2PPh_2)_2Pd(CF_3COO)_2 - TsOH - C_6H_4O_2$ system or by water-soluble palladium complexes with the $P(C_6H_4SO_3Na\text{-}m)_3$ and $(C_6H_4SO_3Na\text{-}m)_2P(CH_2)_3.P(C_6H_4SO_3Na\text{-}m)_2$ ligands have been reported.[91, 92] In the latter case, the product yield was $(2.6 - 7.2) \times 10^3$ g g_{Pd}^{-1} h^{-1}. Analysis of the structure of the resulting copolymers (at the terminal groups) by NMR shows that they have a diketone structure. When copolymerisation is carried out in methanol, the resulting copolymers have three types of terminal groups, namely, ketone, ketoester and ester groups.[92] Only low-molecular-weight terpolymers have been obtained in the aqueous medium.[92, 93] The possibility of copolymerisation in an aqueous emulsion in the presence of water-insoluble Pd complexes has been reported.[94]

3. Carbon monoxide – cyclic olefins

Copolymerisation of cyclopentene and carbon monoxide proceeds as 1,2- and 1,3-insertion of cyclopentene in the polymer chain.



Study of the influence of the natures of the solvent and the ligand, the temperature and carbon monoxide pressure on the rate of carbon monoxide – cyclopentene copolymerisation and on the molecular mass of the resulting copolymers revealed the optimal conditions (a temperature of 40 °C, a 4 MPa pressure of CO, Pd complexes with P-P- and N-N-bidentate ligands) for the synthesis of a high-molecular-weight isotactic copolymer (the ratio $l:m > 9$).[5, 95] It should be noted that irrespective of the reaction conditions, groups of types **A** – **D** are the major terminal groups of the copolymers.



A **B** **C** **D**

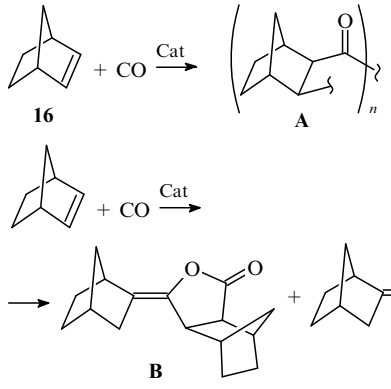
P is polymer.

The synthesis of a carbon monoxide – cyclohexene copolymer under the action of the $[Pd(MeCN)_4](BF_4)_2 - PPh_3$ complex has been reported.[96]

Of cyclic olefins used in copolymerisation with carbon monoxide, norbornene (**16**) is mentioned most often in the literature. Carbon monoxide copolymers with norbornene have been prepared in the presence of various Pd complexes, in particular,

$Pd(PPh_3)_4$, $PdCl_2-PPh_3-HCl$, and $[(bipy)Pd(MeCN)_2](BF_4)_2$, *etc.*[5,37,97–105]

It is known that norbornene can polymerise either with C—C bond cleavage, or with C—C bond cleavage and transfer of the reaction centre, or with ring opening. Depending on the catalyst used, copolymerisation can furnish polymers with a ketone (**A**) or lactone (**B**, **C**) structure.



The data on the influence of the nature of the ligands in the palladium complex on the copolymerisation rate and the glass transition temperature of the carbon monoxide copolymer with norbornene are summarised in Table 1.[106]

Copolymerisation of norbornene and carbon monoxide carried out with the $Pd(OAc)_2-Ph_2P(CH_2)_3PPh_2-p\text{-}MeC_6H_5SO_3H$ catalyst system in methanol in the presence of an oxidant (1,4-naphthoquinone or 1,4-benzoquinone) has been reported.[107] The researchers note that an increase in the *p*-toluenesulfonic acid to $Pd(OAc)_2$ molar ratio from 10 to 30 decreases the molecular mass of the co-oligomer with 8000 to 5000, while the replacement of 1,4-naphthoquinone by 1,4-benzoquinone decreases the copolymer yield and solubility in common organic solvents.

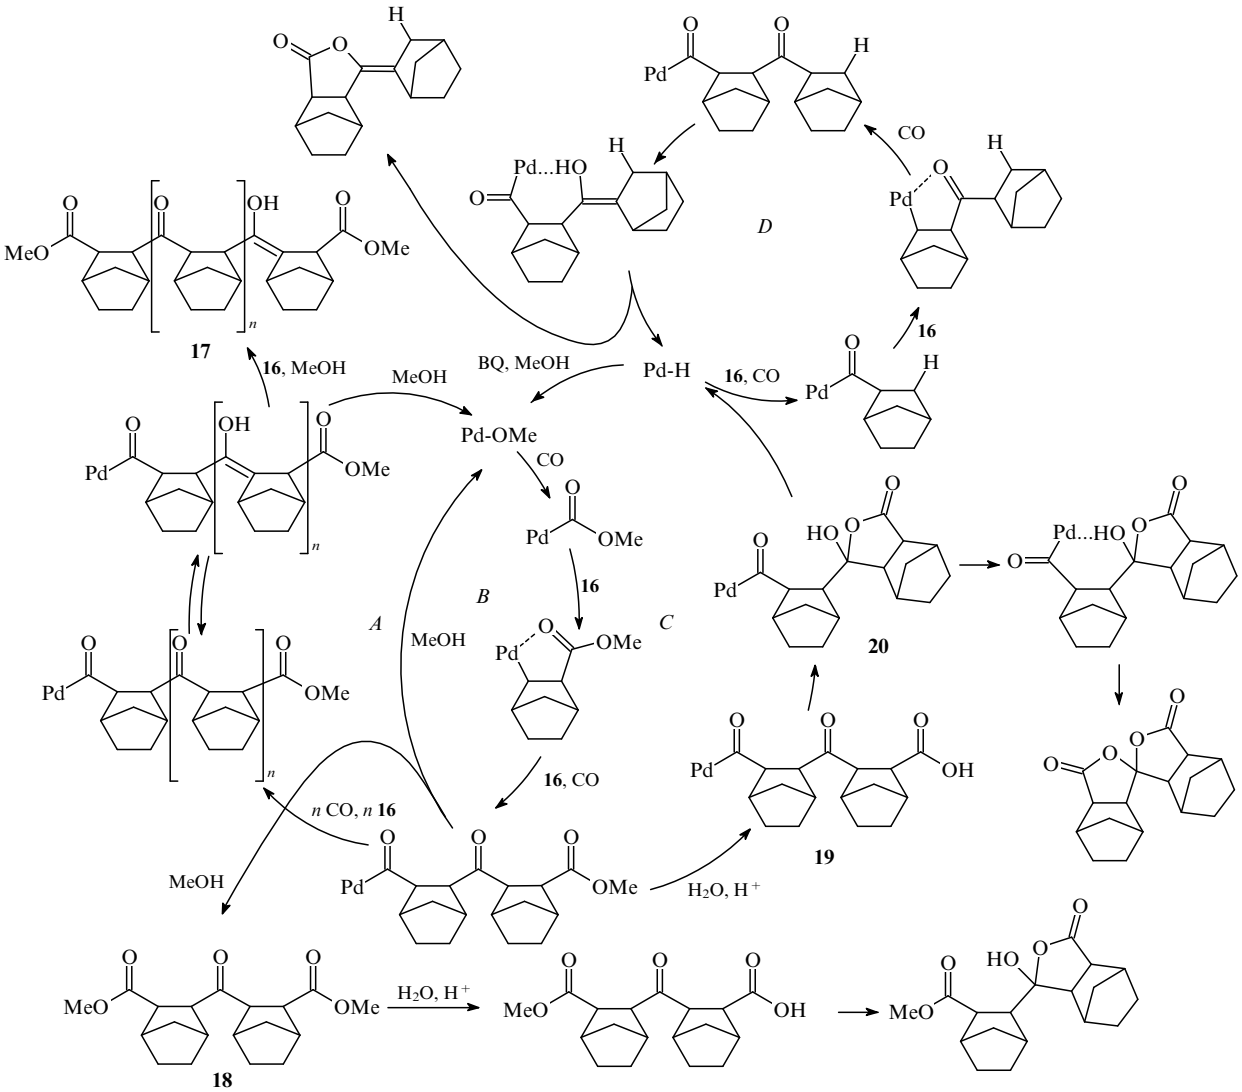
Table 1. Influence of the ligand nature on the rate of copolymerisation and glass transition temperature (T_g) of the CO – norbornene copolymer.

Ligand	Copolymerisation rate /g g_{Pd}^{-1} h^{-1}	T_g/°C
bipy	334	111
phen	371	113
5-NO_2-1,10-phen	282	112
$Ph_2P(CH_2)_3PPh_2$	58	126
PPh_3	31	120
$AsPh_3$	28	100
NPh_3	23	105

Note. Reaction conditions: $[Pd(OAc)_2] = 0.01$ mol litre^{-1}, [norbornene] = 10 mol litre^{-1}, temperature 90 °C.

Scheme 1 shows a reaction mechanism proposed on the basis of the data from ^{13}C and ^1H NMR and IR spectroscopy and the molecular-mass characteristics of the products of carbon monoxide co-oligomerisation with norbornene (**16**) under various

Scheme 1



BQ is 1,4-benzoquinone.

conditions.[107] The mechanism explains the formation of co-oligomers with different structures. Catalytic cycle *A* (the major cycle) affords high-molecular-weight and oligomeric structures (both ketone and spiroketal structures may appear). Chain termination (*via* methanolysis) results mainly in diester co-oligomers **17**.

Cycle *B* is analogous to cycle *A* but chain termination occurs after the formation of di- (**18**) and trimeric structures. The presence of trace amounts of water in the reaction medium (as a rule, methanol is used without dehydration and *p*-toluenesulfonic acid, often present as a component of the catalyst, contains water of crystallisation) initiates one more catalytic cycle *C*. In this cycle, hydrolysis affords monocarboxylic acid **19** and lactol **20** (due to tautometric transformations). When nitrogen-containing ligands are used (instead of phosphines), the reaction mixture must contain an oxidant, which facilitates the formation of catalytically active Pd-OMe sites. In this case, apart from catalytic cycles *A*, *B*, and *C*, one more cycle *D* is realised in which the Pd-H centres are the active sites.

The synthesis of block copolymers of norbornene with the $(CO/CH_2=CH_2)_n$ oligomer has been described.[108] The reaction was catalysed by time-stable complex *trans*-$Pd(PPh_3)_2.(Cl)(COC_6H_4Me\text{-}p)$ and carried out in an aprotic medium. This gave block copolymers containing long $(CO/C_2H_4)_n$ blocks alternating with norbornene.

Alternating copolymers of carbon monoxide with norbornene derivatives containing ester groups RC(O)O with different lengths of the hydrocarbon chain (acetate, pentanoate, octanoate, decanoate, dodecanoate) have been synthesised.[109] The reaction was carried out at 60 °C and at a carbon monoxide pressure of 3.4 MPa for 24 h in a $MeNO_2$–MeOH (5 : 1) mixture in the presence of the $[(bipy)Pd(MeCN)_2)](BF_4)_2$ catalyst. Table 2 presents some properties of the resulting copolymers. These copolymers were better soluble than those formed by carbon monoxide and norbornene (the former were soluble in DMSO, DMF, *N*,*N*-dimethylacetamide, pyridine and acetone but insoluble in benzene, toluene, chloroform, chlorobenzene or ether). An increase in the length of the hydrocarbon chain entailed a lower degree of crystallinity of the resulting copolymers and a higher solubility in organic solvents.

Table 2 Physicochemical properties of carbon monoxide copolymers with the ester derivatives of norbornene.

R	M_n	T_g /°C	T_m /°C	T^1_{dec} /°C	T^2_{dec} /°C
Me	3800	117	–	310	424
n-C_4H_9	4500	84	–	210	401
n-C_7H_{15}	5000	54	–	205	240
n-C_9H_{19}	4900	26	125	195	230
n-$C_{11}H_{23}$	5300	−32	99	180	230
Ph	4600	93	–	341	406

Note. T_g and T_m were determined by differential scanning calorimetry (DSC) at a heating rate of 20 °C min^{-1}. T^1_{dec} and T^2_{dec} are the temperatures of 10% loss of the polymer mass and the maximum decomposition, respectively determined by thermogravimetric analysis (TGA) at a heating rate of 10 °C min^{-1}.

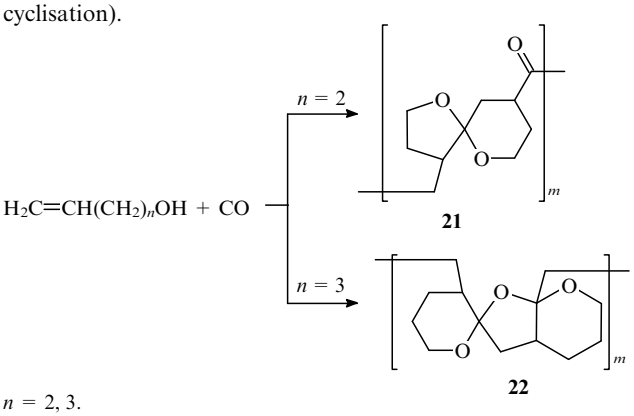
The data on the structure and properties of such copolymers are scarce. Photolysis of carbon monoxide copolymers with *exo*-norbornene having $M_n = 3200–4900$ and $M_w : M_n = 1.75–2.0$ has been studied by time-resolved EPR spectroscopy.[110] The EPR spectra of the copolymers exhibited weak signals for the *endo*-2-substituted norbornyl§ radicals, which attested to incomplete stereoregularity of this copolymer.

§ These radicals are produced by the Norrish-I mechanism on rupture of the polymer chain.

Copolymerisation of carbon monoxide with norbornene, cyclopentadiene or bicyclo[2.2.2]oct-2-ene in the presence of $[Pd(MeCN)_2(PPh_3)_2](BF_4)_2$ at 100 °C in acetonitrile yields low-molecular-weight polymers (M = 600–1000) containing lactone (**B** and **C**) and ketone (**A**) groups.[111] Copolymerisation of strained olefins with CO has been considered in detail in a review.[7]

4. Carbon monoxide – functional α-olefins and other monomers

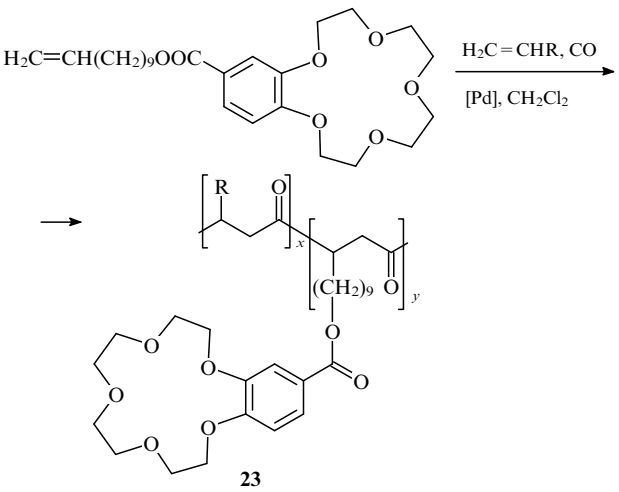
Of obvious scientific and practical interest are the products of alternating copolymerisation of carbon monoxide with various functionally substituted monomers. It has been reported [112] that carbon monoxide undergoes alternating copolymerisation with unsaturated alcohols $CH_2=CH(CH_2)_nOH$ (n = 2, 3, 5, 9) and acids $CH_2=CH(CH_2)_nCOOH$ (n = 1, 2, 4, 8) in the presence of $[Pd(Me\text{-}DUPHOS)(MeCN)_2](BF_4)_2$. The copolymers thus formed had molecular masses of $(10–45)\times10^3$ and $(12–100)\times10^4$, polydispersities of 1.5–2 and 2.9–5.8 for the alcohols and the acids, respectively. They exist as poly(1,4-ketone) and/or polyspiroketal structures and are optically active. Exceptions are provided by the copolymers based on but-3-en-1-ol (copolymer **21**) and pent-4-en-1-ol (copolymer **22**), which have an unusual polycyclic spiroketal structure. They are formed upon the interaction of the hydroxy group in the side chain with the nearest carbonyl group of the polymer chain (intramolecular cyclisation).



n = 2, 3.

The synthesis of the carbon monoxide copolymer with hepta-1,6-dien-4-ol ($M_w = 16\times10^3$ and T_g = 7 °C) has been reported.[113]

In the terpolymerisation of carbon monoxide with various α-olefins (C_3, C_6, C_{12} and C_{18}), a benzo-15-crown-5-functionalised α-olefin, undec-10-enyl[(benzo-15-crown-5)-4′-carboxylate], can be used as a comonomer.[114] It was found that an increase in the molecular mass of the α-olefin results in a decrease in the molecular mass of copolymer **23** from 12 800 (with C_6 α-olefin) to

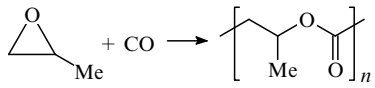


R = Me, Bu^n, n-$C_{10}H_{21}$, n-$C_{16}H_{33}$.

5 300 (for C_{18} α-olefin) and a decrease in T_g from 20 °C (for C_3) and −18 °C (for C_6) to −76 °C (for C_{12}). The polydispersities of the resulting terpolymers were 1.5–2.0. Despite the relatively low molecular mass of copolymers **23**, they were used to produce thin films suitable as ion selective membranes.

The synthesis of alternating copolymers of carbon monoxide with fluorinated alkenes $(C_nF_{2n+1})(CH_2)_mCH=CH_2$ ($m \geqslant 2$) has been described.[115] (see ¶). The resulting copolymers mainly had the spiroketal (rather than ketone) structure of the backbone.

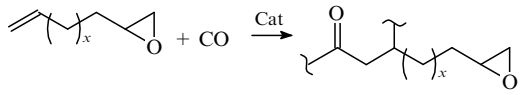
Copolymerisation of carbon monoxide with epoxides occurs with opening of the epoxide ring. The possibility of alternating copolymerisation of epoxides with carbon monoxide was first demonstrated in 1965.[117] Copolymerisation was carried out in the presence of the $Co(acac)_3$ – $AlEt_3$ catalyst system (acac is acetylacetonate). The alternating copolymerisation of carbon monoxide with epoxides induced by the $Co_2(CO)_8$ – pyridine catalyst system and resulting in polyesters **24** with a regular structure has been described.[118, 119]



24

The $Co_2(CO)_8$ – $Ru_3(CO)_{12}$ system has also been used to catalyse this reaction.[120] The researchers showed that the Ru : Co ratio affects the yield, the molecular mass and the structure of the product.

Polyketones containing epoxide groups in the side chain were obtained by copolymerisation of carbon monoxide with vinyl epoxides (for example, 1,2-epoxyhex-5-ene, 1,2-epoxyoct-7-ene, 1,2-epoxydec-9-ene) in the presence of the [Pd{(*R*,*R*)-Me-DUPHOS}$(MeCN)_2$]$(BF_4)_2$ – $C_{10}H_6O_2$ – HCOOH catalyst system (Table 3).[121]



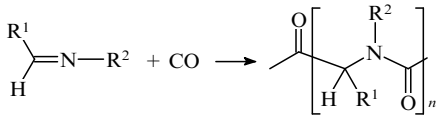
The copolymers formed have $M = (1-3) \times 10^4$ and a narrow molecular-mass distribution. They are soluble in CH_2Cl_2, THF, DMSO.

Table 3. Copolymerisation of CO with epoxides in the presence of the [Pd{(*R*,*R*)-Me-DUPHOS}$(MeCN)_2$]$(BF_4)_2$ – $C_{10}H_6O_2$ – HCOOH catalyst system.[121]

Epoxide	Time /h	Copolymer yield (%)	M_w	$M_w : M_n$
	40	3.58	30 500	1.97
	40	4.52	33 600	1.41
	18	5.41	28 500	3.40
	18	6.3	12 300	1.72
	48	6.77	3 350	1.28
	24	–	–	–

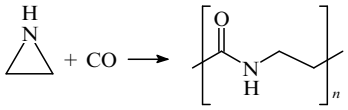
¶ The synthesis and study of the properties of alternating copolymers of carbon monoxide with fluorinated allylbenzenes have been considered in the literature.[116]

In 1998, it was shown that carbon monoxide copolymerisation with imines gives polypeptides, which can be of interest as biomimetic materials.[122, 123]



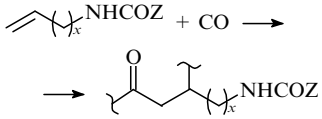
R^1, R^2 = H, Alk, Ar.

Later,[124] a crystalline polymer soluble in hot water, poly-β-alanine ($M = 14.1 \times 10^3$), has been prepared by copolymerisation of aziridine with carbon monoxide in the presence of the $CR_3C(O)Co(CO)_3PPh_3$ (R = H, D) and $HCo(CO)_3PPh_3$ complexes



It was found that, when the catalyst concentration is low, the polymer formed contains ethyleneimine units apart from β-alanine units.

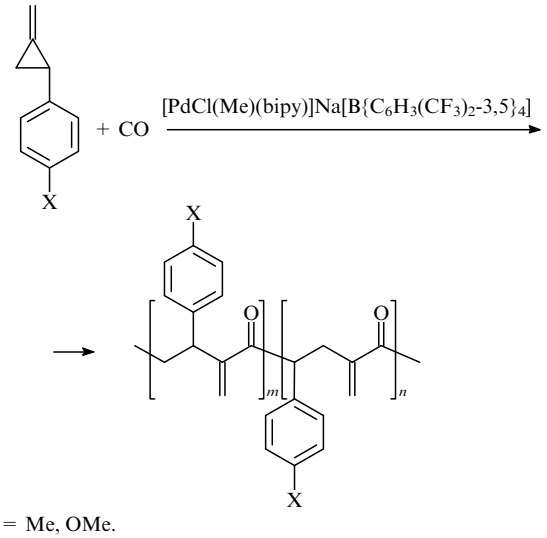
The synthesis of carbon monoxide copolymers with functionalised alkene monomers containing a carbamate or amide group has been described.[125] The [Pd(Me-DUPHOS)$(MeCN)_2$]$(BF_4)_2$ complex was used as the catalyst.



Z = OMe, OPh, Me, Ph; x = 1, 2.

This reaction carried out in CH_2Cl_2 or in a $MeNO_2$ – MeOH (2 : 1) solvent mixture gave copolymers with M_w ranging from 1×10^4 to 3×10^4, while in the absence of a solvent, $M_w = 6 \times 10^4$. Copolymerisation of carbon monoxide with *N*-(but-3-enyl)benzamide in CH_2Cl_2 or a $MeNO_2$ – MeOH (2 : 1) mixture gave two chiral copolymers, characterised by opposite signs of optical rotation.

The synthesis of alternating copolymers of carbon monoxide with cyclopropane derivatives has been described.[126–128] It has been proposed [127, 128] to carry out copolymerisation of 2-aryl-1-methylenecyclopropanes with CO in the presence of palladium diimine complexes such as [PdCl(R)(bipy)], [PdCl(R).(ArN=CHCH=NAr)] and [Pd(η^3-R′CHCHCH$_2$).(ArN=CHCH=NAr)] (R = Cl, Me; R′ = H, Ph; Ar = 4-MeC_6H_4, 4-$MeOC_6H_4$, 2,6-$Pr^i_2C_6H_3$).



X = Me, OMe.

The yields of copolymers obtained in the presence of π-allyl palladium complex are lower than the yields of copolymers synthesised using the [PdCl(R)(ArN=CHCH=NAr)] and [PdCl(R)(bipy)] complexes; however, in the presence of the π-allyl complex, regular copolymers are formed.

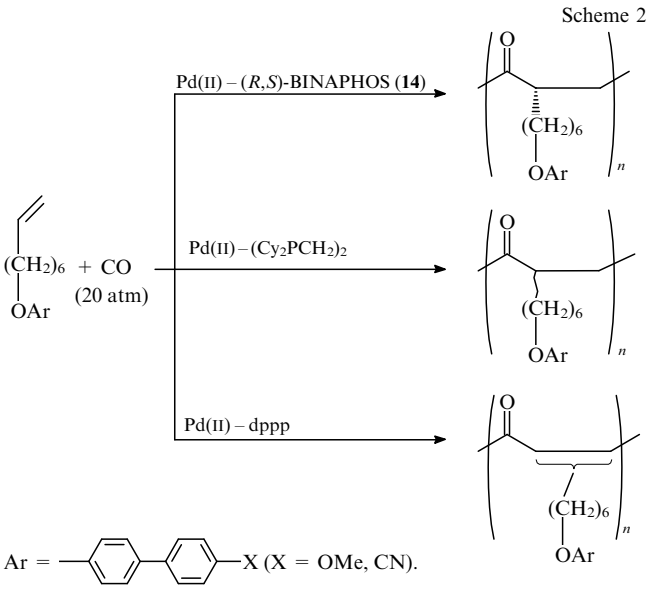
Recently, using copolymerisation of carbon monoxide, propylene and polyalcohol (polyethylene glycol, polyvinyl alcohol or monomethyl ether of ethylene glycol), the possibility of obtaining linear and branched poly(1,4-ketone)–polyalcohol block copolymers was demonstrated.[129]

Some vinyl monomers that cannot copolymerise with carbon monoxide can nevertheless be inserted as single units into the polymeric chain during terpolymerisation with ethylene and carbon monoxide. The content of these units in the product depends on the monomer concentration, the type of the catalyst used, temperature, *etc*. In particular, terpolymerisation proceeds rather vigorously when isobutylene,[130] methyl acrylate,[130,131] chlorohex-1-ene,[131] undec-10-enoic acid and its methyl ester, undec-10-enyl alcohol,[108] maleic acid anhydride,[132,133] allyl acetate[131,134] and vinyl acetate[131,135] are used as the third components.

Polymeric materials that possess anisotropic properties are valuable for practical purposes. One way of creating anisotropy in polymers during the synthesis is incorporation of mesogenic groups in the side chain. At present, copolymers and terpolymers (with hex-1-ene as the third component) of carbon monoxide with α-olefins containing methoxybiphenyl mesogenic groups have been prepared. These copolymers exist as smectic E-mesophases with a periodicity corresponding to S_A. Their thermal stability is comparable to that of the CO/MeCH=CH_2 alternating copolymer whose thermal decomposition starts at 270 °C. The isotropiosation temperature of copolymers decreases with an increase in the length of the spacer,† while that for terpolymers decreases with an increase in the content of hex-1-ene.[136]

The aliphatic α-alkenes containing mesogenic substituents enter into copolymerisation with carbon monoxide in the presence of Pd(II) complexes. Depending on the type of the ligand (L), products with different stereo- and regioregularities are formed in the palladium complex (Scheme 2).

Scheme 2



The properties of the resulting liquid-crystal polyketones[137] were studied by DSC and by polarisation optical microscopy.

† The length of the methylene chain that connects the polymer chain to the mesogenic group.

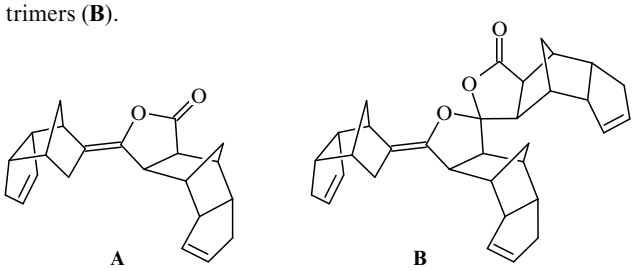
5. Carbon monoxide – linear dienes

Copolymerisation of carbon monoxide with butadiene in the presence of the $Pd(OAc)_2-Ph_2P(CH_2)_3PPh_2$ (or bipy)–CF_3COOH (or TsOH) catalyst system gives rise to low-molecular-mass copolymers in low yields.[5,138–140] On the basis of hexa-1,5-diene,[5,141,142] hepta-1,6-diene or octa-1,7-diene[5,113,142] and carbon monoxide, binary alternating copolyketones and terpolymers with ethylene have been synthesised. Hexa-1,5-diene[5,141,142] and hepta-1,6-diene react with carbon monoxide to give cyclic copolymers, whereas octa-1,7-diene copolymerises with CO to yield a linear alternating copolymer containing $CH_2CH=CH_2$ side groups.[5,113,141]

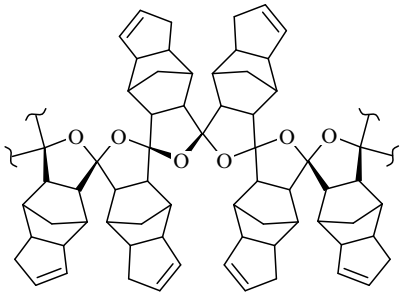
Data on the synthesis of the following terpolymers have been reported: hepta-1,6-dien-4-ol–carbon monoxide–propylene (T_g = 19 °C), propylene–carbon monoxide–methylenecyclopropane, propylene–carbon monoxide–octa-1,7-diene, hexa-1,5-diene–carbon monoxide–propylene,[113] ethylene–carbon monoxide–butadiene,[138–140] and ethylene–carbon monoxide–hexadiene.[141,142]

6. Carbon monoxide – cyclic dienes

The possibility of synthesis of an alternating copolymer of dicyclopentadiene (DCPD) with carbon monoxide was first mentioned in a patent.[98] Dicyclopentadiene is formed as a side product in the pyrolysis of petroleum products and represents a tricyclic hydrocarbon with two inequivalent C=C bonds, one highly reactive bond in the norbornene ring and one less reactive bond in the substituted cyclopentene ring. In the synthesis of DCPD/CO copolymers, the $Pd(OAc)_2$–bipy–TsOH–$C_6H_4O_2$ catalyst system was used. The copolymer is formed in a good yield even at room temperature, the presence of air in the reaction mixture being favourable for higher copolymer yield. When the $Pd(OAc)_2-Ph_2P(CH_2)_3PPh_2-CF_3COOH$ catalyst system is used, copolymerisation should be carried out at a temperature above 80–90 °C.[143] The synthesis of the CO copolymer with DCPD catalysed by $[Pd(MeCN)_2(PPh_3)_2](BF_4)_2$ (100 °C, carbon monoxide pressure of 1.0 MPa, 5 h) furnishes a solid white-coloured product, which is a mixture of CO/DCPD di- (**A**) and trimers (**B**).

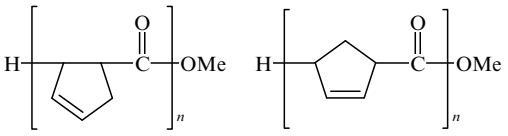


The copolymers of DCPD and carbon monoxide have, most often, a spiroketal structure, which is not tansformed into the ketone structure even on long-term heating.



Copolymerisation of carbon monoxide and cyclopentadiene in the presence of $[Pd(MeCN)_4](BF_4)_2$ (60 °C, pressure 5.6 MPa, 24 h) and various monodentate ligands [PPh_3, $AsPh_3$, NPh_3, $PMePh_2$, $P(OPh)_3$] has been described.[96] The process gives a partially crystalline copolymer with T_m > 180 °C, soluble in

THF. The M_n values of the copolymer increase from 570 to 2750 following an increase in the carbon monoxide pressure from 2.1 to 5.6 MPa. The highest yield of the copolymer is attained when PPh_3 is used as the ligand and MeOH is used as the reaction medium. According to ^1H NMR, the resulting copolymer consists of macromolecules having 1,2- and 1,4-structures,



1,2-structure 1,4-structure

the content of 1,2-structures markedly increasing for copolymerisation carried out in polar solvents (MeOH, MeCN). The resulting copolymer is thermally unstable: a partial mass loss is observed at 120 °C. The activity of cyclohexadiene in this reaction is about 60 times lower.

Using the $PdCl_2$ – 1,4:3,6-dianhydro-2,5-dideoxy-2,5-bis(diphenylphosphino)-L-idite – $CuCl_2$ – 2,6-$Me_2C_6H_2O_2$ – TsOH catalyst system (45 °C, 24 h, carbon monoxide pressure 6 MPa), alternating copolymers of carbon monoxide with DCPD and methylcyclopentadiene with an isotactic (1,4-ketone) structure and molecular masses of 1300 ($M_w : M_n = 1.7$ for DCPD) and 944 ($M_w : M_n = 2.88$ for methylcyclopentadiene) have been obtained.[144]

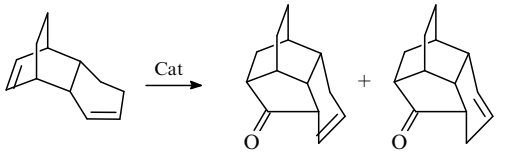
A study[145] of the influence of the solvent on the yield of carbon monoxide copolymer with 4-vinylcyclohexene obtained in the presence of the $[Pd(MeCN)_4](BF_4)_2$ – L catalyst system (L = PPh_3, bipy, phen or 5-NO_2-phen) (60 °C, carbon monoxide pressure 5.5 MPa, 12 h) has shown that copolymerisation rate is higher (1.45 and 0.82 g g_{Pd}^{-1} h^{-1}) in polar solvents (MeOH and $MeNO_2$) than in $CHCl_3$ (0.53 g g_{Pd}^{-1} h^{-1}). The copolymer thus formed had a relatively low molecular mass (1070 – 6910) and contained both ketone and cyclic (cyclohexyl and norbornane) structures in the chain. The copolymer was soluble in DMSO, *N*,*N*-dimethylacetamide, DMF, pyridine, acetonitrile, THF, nitromethane, acetone, chloroform and 1-methyl-2-pyrrolidone but insoluble in benzene, toluene, 1,2-dichloroethane, chlorobenzene, methanol, ether, 1,4-dioxane or ethyl acetate. According to DTG analysis, the loss of copolymer mass starts at 190 °C. Treatment of the copolymer with a solution of $LiAlH_4$ in THF results in polyalcohol, which is soluble in chloroform, THF, DMSO and methanol but insoluble in benzene, n-hexane or ether.

The first mention of the synthesis of the alternating copolymer of carbon monoxide and norbornadiene appeared more than 30 years ago.[146, 147] Palladium chloride was used as the catalyst. The copolymer formed had $M_n = 2900$, $T_m < 300$ °C; it was soluble in benzene, chloroform and THF. However, on storage in air, the solubility of the copolymer decreased, apparently, due to oxidation processes. The use of palladium complexes with bidentate P-P and N-N ligands as catalysts resulted in a higher yield of the copolymer.[98, 148] Copolymerisation carried out in the presence of $[Pd(MeCN)(PPh_3)_3](BF_4)_2$ at a temperature of 60 °C and a carbon monoxide pressure of 5.6 MPa gave a carbon monoxide – norbornadiene copolymer with $M_n = 3380$ soluble in $CHCl_3$ and C_6H_6,[97] while at 100 °C, a copolymer with $M_n = 800 – 1200$ was formed.[111] The IR spectra of the polymer exhibit characteristic bands at 1778, 1722 and 1702 cm^{-1}, indicating the presence of γ-lactone, ester, vinyl, and ketone groups in the polymer chain.

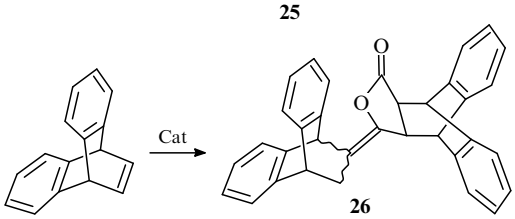
The influence of the nature of the catalyst, the temperature, the nature of the solvent and the concentrations of carbon monoxide, *p*-toluenesulfonic acid and 1,4-benzoquinone on the yield and the molecular mass of carbon monoxide – norbornadiene copolymer has been studied.[148] The highest catalytic activity in this reaction was found for $[Pd(MeCN)_4](BF_4)_2$ in the presence of bidentate N-N-ligands such as bipy or phen (in this case, copolymerisation rate reached 60 g g_{Pd}^{-1} h^{-1}). The presence of diphosphine $PPh_2(CH_2)_3PPh_2$ in the reaction medium decreases the catalyst activity about 1.5-fold and in the presence of monodentate ligands PPh_3, $AsPh_3$, NPh_3, or $P(OPh)_3$, the activity decreases 5 – 20 fold; simultaneously, the copolymer molecular mass decreases from 9000 to 1250. The replacement of polar protic solvents (for example, MeOH) by less polar solvents (THF or benzene) results, on the one hand, in a decrease in the catalyst activity and, on the other hand, in an increase in the copolymer molecular mass to 16 000, indicating the participation of the solvent in a chain termination reaction. An increase in the concentrations of carbon monoxide, TsOH or 1,4-benzoquinone results in a higher yield of the copolymer. Upon the increase in the carbon monoxide concentration, the molecular mass of the copolymer also increases (upon an increase in the TsOH or 1,4-benzoquinone concentration, the molecular mass decreases). The DTG data show that the copolymer starts to lose mass at 167 °C (at 356 °C, the mass loss is 24.5%). Hydrogenation of this copolymer affords polyalcohol, which is completely soluble in chloroform, THF, DMSO and *m*-cresol, partially soluble in acetone and methanol and insoluble in benzene, n-hexane or water.

The characteristic features of synthesis and the structure of alternating co-oligomers of carbon monoxide with norbornadiene and the mechanism of formation of various structural units in the polymer chain in the presence of the $Pd(MeC_6H_4PPh_3)(Tp^{Ph})$ catalyst in an aprotic medium and methanol have been considered.[149]

The copolymerisation of carbon monoxide with *endo*-tricyclo[6.2.2.$0^{2,7}$]dodeca-3,9-diene gives rise to oil-like dimers (mainly, dimer **25**) and that with dibenzobicyclo[2.2.2]octatriene affords solid dimer **26**.[111]

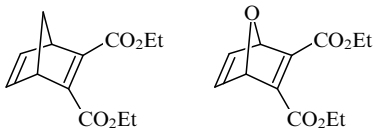


25



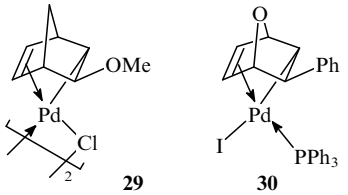
26

In the presence of Pd(II) complexes with σ,π-alkenyl ligands and a stabilising pyridine or triphenylphosphine ligand, alternating copolymers of carbon monoxide with diethylbicyclo-[2.2.1]hepta-2,5-diene-2,3-dicarboxylate (**27**) and diethyl 7-oxabicyclo[2.2.1]hepta-2,5-diene-2,3-dicarboxylate (**28**) have been obtained according to the living polymerisation mechanism.[150]



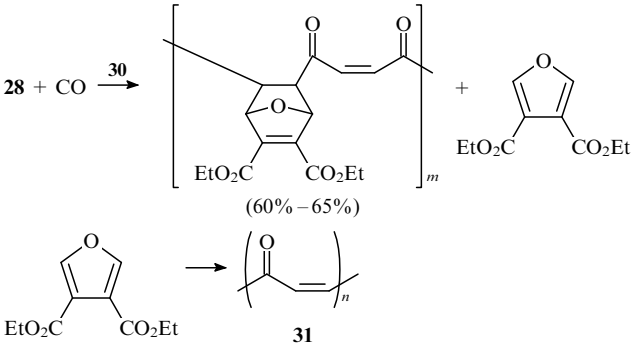
27 **28**

In the former case, dimeric palladium chloride complex was used as the catalyst (**29**), while in the latter case, this was triphenylphosphine complex **30**.

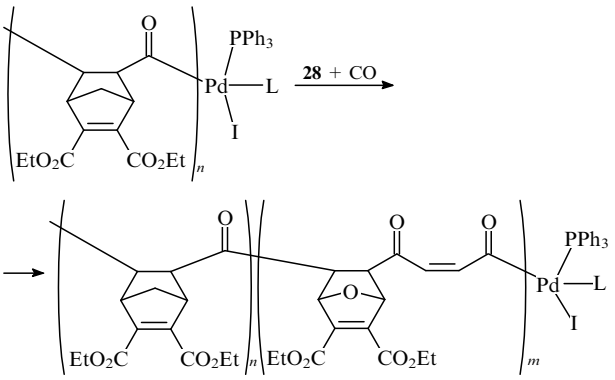


29 **30**

In the copolymerisation of carbon monoxide with diene **27**, the yield of the copolymer is nearly 100%, while in the copolymerisation with diene **28**, the yield was 60% – 65%. In the latter case, diethyl furan-3,4-dicarboxylate is formed as a side product. This side product can be isolated from the copolymer by heating at 70 °C. Diethyl furan-3,4-dicarboxylate is converted, in turn, into a polyconjugated polymer, polyketovinylene (**31**).



Study of the effect of the monomer and Pd complex concentrations on the kinetics of carbon monoxide copolymerisation with diene **27** has shown that the reaction is first order ($k = 8.2 \times 10^{-3}$ litre mol^{-1} s^{-1}) with respect to CO and Pd and a zero order with respect to diene. In all cases, the concentration of diene **27** was approximately two orders of magnitude higher than the carbon monoxide concentration. If monomer **28** is added to the CO/**27** copolymer, alternating block copolymer (CO/**27**)/(CO/**28**) can be obtained.



7. Carbon monoxide – allene derivatives

Although insertion of carbon mono- and dioxide and sulfur dioxide into the palladium – allyl bond has been mentioned in the literature,[151 – 155] no data on the synthesis of a binary copolymer of carbon monoxide with unsubstituted allene has been reported. Copolymers of carbon monoxide with 1,1-dimethylallene (1,2- and 2,3-isomers), 1,1,3,3-tetramethylallene [5, 156] and a large number of arylallenes *p*-$XC_6H_4CH=C=CH_2$ (X = H, Me, MeO, Cl, F, Bu^n, Bu^t) have now been prepared. The reaction with arylallenes was carried out at 25 °C, a CO pressure of 0.1 MPa (21 h) in the presence of a Rh complex, $Rh[\eta^3\text{-}CH(Ar)C\{C(=CHAr)CH_2C(=CHAr)CH_2CH_2CH=CHAr\}CH_2](PPh_3)_2$ (Ar = C_6H_4OMe-*p*).[5, 157] The reaction follows the living polymerisation mechanism. The alternating copolymers thus formed have $M = 10^4 – 10^5$, $M_w : M_n = 1.06 – 1.16$. Copolymerisation of phenylallene and carbon monoxide with subsequent addition of 4-methoxyphenylallene to the reaction mixture gives the block copolyketone $[CO-C(=CHPh)CH_2]_m/[CO-C(=CHC_6H_4OMe\text{-}p)CH_2]_n$; meanwhile, terpolymerisation of carbon monoxide with an equimolar mixture of phenylallene and 4-methoxyphenylallene yields a statistical copolymer. The same rhodium complex was used for terpolymerisation of carbon monoxide with 4-hexylphenylallene and 4-dodecylphenylallene. The T_m and T_g values of the $[CO/C(=CHC_6H_4Alk\text{-}p)CH_2]_n$ polyketones were found to increase in the series of alkyl radicals $C_{12}H_{25} < C_6H_{13} < Bu^n < Me < H$ from 65 to 170 °C and from 30 to 125 °C, respectively. By terpolymerisation of carbon monoxide with a mixture of phenylallene and 4-alkylphenylallene (Alk ≠ Me), statistical and block terpolymers were obtained, whereas the use of a mixture of 4-methylphenylallene and bisallenylbenzene results in cross-linked polyketones.[158, 159] The copolymerisation rate decreases in the sequence of comonomers: 1,1-dimethylallene > phenylallene > cyclohexylallene. Terpolymerisation of carbon monoxide with a mixture of 4-(allenyloxy)-azobenzene and 4-(methoxyphenyl)allene [or 4-(*tert*-butyl)-phenyloxyallene] resulted in statistical polyketones.[160]

The synthesis of new functional polyketones soluble in dichloromethane, THF and toluene was accomplished by terpolymerisation of propylene and carbon monoxide with 2-allylphenol, 2-allylmethoxybenzene, 4-allylmethoxybenzene and 4-allyl-2-methoxyphenol in the presence of the $[Pd(dppp)(MeCN)_2](BF_4)_2$ complex as the catalyst [160] and by carbon monoxide copolymerisation with 4-allylanisole catalysed by $[Pd\{(R,R)\text{-Me-DUPHOS}\}(MeCN)_2](BF_4)_2$.[5, 112]

Analysis of the state-of-the-art studies dealing with the synthesis of alternating copolymers of carbon monoxide with dienes shows that the search for effective catalysts is only at an early stage, unlike that for the synthesis of copolymers of carbon monoxide with alkenes. The obtained copolymers have a relatively low molecular mass ($10^3 – 10^4$) and only the use of some Pd complexes enables living copolymerisation mechanism; in this case, it is possible to obtain alternating copolymers with a molecular mass of $\sim 10^5$. Undoubtedly, effective catalysts for the synthesis of carbon monoxide copolymers with dienes would be found in the near future and these polymers would find extensive use.

8. Copolymers of carbon monoxide with styrene and its derivatives

Copolymerisation of carbon monoxide with styrene and its derivatives takes place only in the presence of nitrogen N-N- or hybrid P-X-ligands (X = N, O). In the presence of the $[(MeCO)Pd(MeCN)\{(R,S)\text{-BINAPHOS}\}][B\{3,5\text{-}(CF_3)_2C_6H_3\}_4]$ complex,[161] the chain initiation and propagation involved in the copolymerisation of carbon monoxide with *tert*-butylstyrene take place by the 1,2-inclusion mechanism.

Milani *et al.* [162] have studied the influence of the nature of the solvent [methanol or 2,2,2-trifluoroethanol (TFE)], the temperature, the carbon monoxide pressure and the concentration of 1,4-benzoquinone on the CO – styrene copolymerisation rate and on the molecular mass of the resulting copolymer. It was found that in TFE, the copolymerisation catalysed by the $[Pd(bipy)_2](PF_6)_2$ system is a quasi-steady-state process, whereas in methanol, the rate decreases with time. As the temperature is raised from 60 to 80 °C, the rate of copolymerisation increases from 271 to 1134 g g_{Pd}^{-1} h^{-1}, and the $[\eta]$ value decreases from 0.27 to 0.14 dl g^{-1}. The reaction time (7 – 48 h) and the carbon monoxide pressure have a little influence on the molecular mass of the resulting copolymer but influence the copolymerisation rate. Thus an increase in the carbon monoxide pressure from 1 to 4 MPa results in a sharp decrease in the reaction rate from 1081 to 290 g g_{Pd}^{-1} h^{-1}.

Interesting results have been obtained by Milani *et al.*,[163] who attained a rate of carbon monoxide – styrene copolymerisation equal to $\sim 17\,000$ g g_{Pd}^{-1} h^{-1} by using the $[Pd(bipy)_2](PF_6)_2 – C_6H_4O_2$ catalyst system, the reaction being conducted in TFE. The researchers noted that the catalyst system did not lose activity for at least 48 h. The presence of 1,4-benzoquinone influences not only the catalyst activity but also the molecular mass of the copolymer. With the molar ratio $C_6H_4O_2 : Pd = 5 : 1$, a copolymer with $M_w = 71\,710$ was obtained ($M_w : M_n = 2$), and in the absence of 1,4-benzoquinone, with $M_w = 84\,860$ ($M_w : M_n = 1.8$). It is noteworthy that this is the first example of synthesis of a carbon

monoxide copolymer with styrene with such a high molecular mass.

By varying the styrene : ethylene monomer ratio, one can prepare $C_2H_4/CO/H_2C=CHPh$ terpolymers in a high yield and with different contents of styrene. Recently, it has been shown [164] that the use of the palladium complex with the (*S*)-3-(1,2,2-$Me_3C_3H_4$)-1,10-phen ligand allows one to carry out carbon monoxide copolymerisation with styrene (or 4-methylstyrene) in TFE for 80 h almost without a decrease in the reaction rate and to obtain copolymers with a molecular mass of 20×10^4 (or 30×10^4). An increase in the styrene : Pd molar ratio (from 48 000 to 96 000) increases the yield and the molecular mass of product approximately twofold. The terminal groups present in the copolymers synthesised in TFE are PhCH=CH, Me(Ph)CH or CF_3CH_2O.[165] It has been shown [166] that the content of TFE should not exceed 3 mass % – 5 mass %.

The catalytic activity of the $[Pd(\eta^1,\eta^2\text{-}C_8H_{12}OMe).(bipy)]^+X^-$ complex [where $X = BPh_4$, CF_3SO_3, BF_4, PF_6, SbF_6, $B\{3,5\text{-}(CF_3)_2C_6H_3\}_4$] in the carbon monoxide copolymerisation with styrene in dichloromethane has been studied as a function of the activity of the counter-ion used.[167] The following activity series was elucidated: $BPh_4 \ll CF_3SO_3 < BF_4 < PF_6 < SbF_6 < B\{3,5\text{-}(CF_3)_2C_6H_3\}_4$. With an excess of the bipyridine ligand, the activity series changes to give $BPh_4 \ll CF_3SO_3 < BF_4 \approx B\{3,5\text{-}(CF_3)_2C_6H_3\}_4 \approx PF_6 \approx SbF_6$.

A new class of catalysts based on the Pd(II) bipyridyl complex containing $[B\{3,5\text{-}(CF_3)_2C_6H_3\}_4]^-$ as the counter-ion have been prepared. These catalysts were found to be more active in the carbon monoxide copolymerisation with styrene or *tert*-butylstyrene than catalysts with the PF_6 counter-ion.

A study [168, 169] of terpolymerisation in the $C_2H_4/CO/CH_2=CHPh$ system at high carbon monoxide pressures in the presence of various P-N-ligands as parts of the [Pd(COMe).(P-N)(solv)]O_3SCF_3 palladium complex [P-N is phosphino(dihydrooxazole) ligand, solv is solvent] has shown that a decrease in the carbon monoxide pressure from 29 to 14 MPa entails a decrease in the reaction rate from 27 to 12.9 mmol g_{Pd}^{-1} h^{-1}; simultaneously, the $(-C_2H_4-CO-):(-CH_2CHPh-CO-)$ ratio of copolymer units changes from 80 : 20 to 90 : 10. For $C_2H_4/CO/CH_2=CHPh$ terpolymers, the dependence of T_g on the composition $(C_2H_4/CO)/(CH_2=CHPh/CO)$ was determined. The copolymer containing 27 mol.% of the $-CH_2CHPhCO-$ units has $T_g = 37$ °C, a rupture resistance (σ_p) of 62 MPa, and a relative elongation at rupture (ε) of 270%.[170]

It was found that by varying the nature of the aryl substituent at the phosphorus atom in (*S*)-2-[2-(diarylphosphino)phenyl]-4-benzyl-4,5-dihydrooxazole (Ar = Ph, *p*-$MeOC_6H_4$, *o*-$MeOC_6H_4$, *o*-MeC_6H_4), one can affect the copolymerisation rate and the tacticity of the $CO/CH_2=CHPh$ copolymer.[171]

Ar	w /mmol g_{Pd}^{-1} h^{-1}	T_m /°C
Ph	81	228
p-$MeOC_6H_4$	28	175
o-$MeOC_6H_4$	71	127
o-MeC_6H_4	11.7	80

New homogeneous bismethoxycarbonyl complexes [Pd(L-L).$(MeOCO)_2$] (L-L are substituted phenanthroline ligands) have been used to synthesise the syndiotactic $CO/CH_2=CHPh$ copolymer.[172] In the $[Pd(L\text{-}L)(MeOCO)_2](X)_2$ – oxidant catalyst system, PF_6^- acts as the weakly coordinated counter-ion and 1,4-naphthoquinone acts as the oxidant. The rate of copolymerisation of carbon monoxide with styrene at 65 °C and at a carbon monoxide pressure of 4 MPa is ~194 g g_{Pd}^{-1} h^{-1}. The rate depends on the pK_a of the phenanthroline ligand. With an increase in the pK_a (caused by the introduction of substituents in the phenanthroline ring), the copolymerisation rate and the copolymer molecular mass decrease 2 – 6-fold with simultaneous decrease in the copolymer tacticity. A decrease in the copolymerisation rate following an increase in the pK_a of the N-N-ligand from 4.44 (bipy) to 6.31 (tetramethylphenanthroline) has also been reported in the study [46] describing styrene – carbon monoxide copolymerisation catalysed by the $[Pd(N\text{-}N)(MeCO_2)_2]$ and $[Pd(N\text{-}N)(CF_3CO_2)_2]$ complexes (N-N is bipy, 1,10-phenanthroline or their derivatives). The degree of polymerisation of the copolymer increases with time and after 6 h, it reaches 160. The copolymer thus obtained has $T_g = 99$ °C and $T_m = 273$ °C. On short-term (5 min) heating of the copolymer at temperatures of 200 °C and 220 °C, the number of terminal vinyl groups substantially increases, while the number of methoxycarbonyl groups decreases (their ratio in the initial copolymer is 1 : 1).

The syntheses of carbon monoxide – styrene and carbon monoxide – *p*-methylstyrene copolymers as well as styrene – carbon monoxide – ethylene, styrene – carbon monoxide – propylene, styrene – carbon monoxide – ω-undecyl alcohol and styrene – carbon monoxide – ω-methyl undecenecarboxylate terpolymers have been carried out using the $[Pd(5\text{-}Me\text{-}1,10\text{-}phen).(MeCN)_2](BF_4)_2 - C_6H_4O_2$ catalyst system.[173] The $CO/CH_2=CHPh$ copolymer is poorly soluble in 2-chlorophenol and in hexafluoroisopropyl alcohol and has $T_g = 94$ °C and $T_m = 290$ °C. The crystallinity of the copolymer sharply decreases after it has been dissolved and reprecipitated. For example, reprecipitation of the $CO/CH_2=CHC_6H_4Me\text{-}p$ copolymer from a solution in 2-chlorophenol by methanol gave an amorphous polymer, which was soluble in chloroform and dichloromethane.

The solubility of the $C_2H_4/CO/CH_2=CHPh$ and $CH_2=CHMe/CO/CH_2=CHPh$ terpolymers depends on the styrene : olefin ratio. For example, a terpolymer containing 11 mol.% – 12 mol.% of the $-C_2H_4CO-$ units is soluble in chloroform and dichloromethane but insoluble in acetone, whereas the material containing 80 mol.% of the $-C_2H_4CO-$ units is insoluble in common organic solvents but is soluble in 2-chlorophenol and hexafluoroisopropyl alcohol.

Japanese researchers ‡ have studied the asymmetric terpolymerisation of propylene and hex-1-ene with 4-(*tert*-butyl)styrene and carbon monoxide in the presence of the Pd complex with the phosphine phosphite ligand BINAPHOS (**14**). It was shown that the glass transition temperature of the copolymers depends on the olefin content in the copolymer.

In the copolymerisation of carbon monoxide and styrene in the presence of the $Pd(OAc)_2$ – bipy – TsOH catalyst system, the maximum copolymerisation rate (68 g g_{Pd}^{-1} h^{-1}) is observed at a bipy : Pd molar ratio of 15 : 1. The replacement of methanol used as the reaction medium by acetone, THF, DMSO, aniline or DMF results in a sharp decrease in the copolymerisation rate and the reduction of Pd(II) to Pd(0). When copolymerisation is carried out in petroleum ether, cyclohexane, nitrobenzene, ethyl acetate or phenyl ethyl ether, the rate decreases 3 – 4-fold compared to the copolymerisation rate in methanol.[174]

The effect of the nature of the bidentate N-N ligand on the structure of the resulting copolymer of carbon monoxide with styrene was demonstrated using two ligands: diazabutadiene and bioxazoline. It was found that in the former case, an isotactic copolymer is formed, while in the latter case, the product is a syndiotactic polymer.[175] When the Pd(II) acetonitrile complex with 2,2-bis[4-(*S*)-methyl-1,3-oxazolin-2-yl]propane [176] and (4*S*,4′*S*)-(−)-4,4′,5,5′-tetrahydro-4,4′-diisopropyl-2,2′-bioxazole,[177] which are ligands with C_2-symmetry, was used as the catalyst, the isotactic $CO/CH_2=CHPh$ copolymer and partially isotactic $CO/CH_2=CHC_6H_4Me\text{-}p$ copolymer with high optical activity were obtained. Using C_2-symmetric Pd complexes, (*R*,*R*/*S*,*S*)-*trans*-1,2-$[C_6H_{10}\{N=CH\text{-}2\text{-}C_5H_4N(PdMe(NCMe)_2)\}_2][B\{3,5\text{-}(CF_3)_2.C_6H_3\}_4]_2$ and $[C_2H_4\{N=CH\text{-}2\text{-}C_5H_4N(PdMe(NCMe)_2)\}_2].[B\{3,5\text{-}(CF_3)_2C_6H_3\}_4]_2$, syndiotactic copolymers of carbon monoxide with styrene and 4-methylstyrene were obtained.[178] Palladium complexes with C_s-symmetry with asymmetric chelating ligands on the basis of 2-(pyrazol-1-yl)pyridine, 2-(pyrazol-1-

‡ Y Kawashima, K Nozaki, T Hiyama *Inorg. Chim. Acta* **350** 577 (2003).

yl)pyrimidine and 2-[(3,5-dimethyl)pyrazol-1-yl]pyrimidine have been used for copolymerisation of carbon monoxide with 4-(*tert*-butyl)styrene. This gave syndiotactic copolymers.[179] The use of C_1-symmetric pyridinylimidazole ligands with different hydrocarbon substituents provides carbon monoxide–4-(*tert*-butyl)-styrene copolymers with different tacticities depending on the substituent.[180]

The synthesis of a stereoregular carbon monoxide–4-(*tert*-butyl)styrene block copolymer using the 2,2′-bipyridyl–bioxazoline Pd(II) complex catalyst system has been reported.[176] Bipyridyl is added to the palladium complex during the synthesis; as a result, fast ligand exchange takes place. The produced copolymer contains macromolecules of both isotactic and syndiotactic structures. Depending on the symmetry of the phosphino(dihydrooxazole) ligand used, both isotactic and atactic polymers were obtained.[181, 182] The synthesis of alternating copolymers of carbon monoxide with hydroxystyrene and its formate and acetate has been described.[183] It is noteworthy that $Pd(OAc)_2$ can be replaced by rare earth metal (Y, La, Nd, Sm, Dy) acetates or their mixtures with $Cu(OAc)_2$. For example, copolymerisation of carbon monoxide with styrene in the presence of rare earth metal acetates has been reported.[184]

III. The mechanism of alternating copolymerisation of carbon monoxide

In a study of the alternating copolymerisation of carbon monoxide with olefins, the ethylene–carbon monoxide system studied most comprehensively was chosen as the model system and the $Pd(OAc)_2$–diphosphine–acid system used most often was chosen as the catalyst.

When the catalyst is formed *in situ* under homogeneous conditions, depending on the nature of the solvent (alcohol, water or a less polar solvent), reactions (1)–(8) can take place between the catalyst components and the medium. If copolymerisation is carried out in methanol, L_2PdOMe^+ would act as the catalytically active species [reaction (2)].[185]

In water and in moist solvents, Pd hydride complexes may form [reactions (4), (8)]. In addition, palladium hydride species can be formed by reactions (3), (5) and (6).

$$Pd^{2+} + L_2 \longrightarrow L_2Pd^{2+} \text{ } (L_2 \text{ is a bidentate phosphine ligand}) \quad (1),$$

$$L_2Pd^{2+} + MeOH \longrightarrow L_2PdOMe^+ + H^+, \quad (2)$$

$$L_2PdOMe^+ \longrightarrow L_2PdH^+ + CH_2O, \quad (3)$$

$$L_2Pd^{2+} + CO + H_2O \longrightarrow L_2PdH^+ + CO_2 + H^+, \quad (4)$$

$$L_2Pd^{2+} + C_2H_4 + MeOH \longrightarrow L_2PdH^+ + CH_2{=}CHOMe + H^+, \quad (5)$$

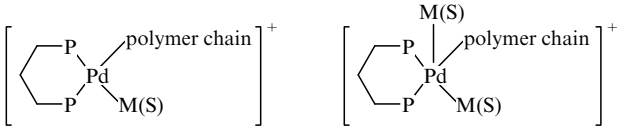
$$L_2Pd^{2+} + H_2 \longrightarrow L_2PdH^+ + H^+. \quad (6)$$

In an aqueous medium, apart from L_2PdH^+, the L_2PdOH^+ species are also present; they react with CO by reactions (7) and (8).

$$L_2PdOH^+ + CO \longrightarrow L_2PdCOOH^+, \quad (7)$$

$$L_2PdCOOH^+ \longrightarrow L_2PdH^+ + CO_2. \quad (8)$$

Initiation and propagation of the polymer chain. The chain initiation in a solution (*i.e.*, primary insertion of a CO or C_2H_4 molecule into a Pd–alkyl or Pd–acyl complex) has been studied rather comprehensively by various physicochemical and theoretical methods.[25, 185–202] In a number of studies,[25, 186, 187, 200–202] the structure of the catalytically active species that run the copolymerisation process has been proposed on the basis of data from EXAFS, UV, IR and ^1H and ^{31}P NMR spectroscopy and mass spectrometry. In particular, it was found that the monochelate complex of diphosphine and palladium acetate is the active site of the copolymerisation. As the diphosphine : palladium molar ratio increases to 2 or more, the monochelate complex is transformed into an inert bischelate complex, which is unable to participate in copolymerisation. When the inert palladium complex is exposed to atmospheric oxygen, the equilibrium shifts toward the formation of the catalytically active monochelate palladium complex. The relationship between the contents of these complexes in the catalyst system and the rate and the induction period of copolymerisation has been established.[185] On the basis of ^1H NMR data, it was shown that the $CO-C_2H_4$ copolymerisation in protic (alcohols) and aprotic solvents is initiated by the insertion of the CO and C_2H_4 molecules into the Pd–OMe and Pd–H bonds, respectively. It should be noted that protic solvents not only serve as the reaction medium; they are also involved in chain initiation and termination reactions and also stabilise the Pd^{2+} cation. It was found [25] that in addition to the catalytically active 16-electron four-coordinate square planar $Pd(d^8)$ species (**A**), a five-coordinate 18-electron pyramidal $Pd(d^8)$ species is also present in the reaction area (**B**).



A **B**

M is monomer (CO or C_2H_4), S is solvent.

Studies of the initiation and propagation of the polymer chain have been carried out using a heterogeneous single-centre Pd complex, $[\{Ph_2P(CH_2)_3PPh_2\}Pd(Me)(OSO_2CF_3)]$. The polarisation-modulated absorption IR spectroscopy technique has been used [186] to observe the changes taking place in the IR spectra on the successive insertion of the CO and C_2H_4 molecules into the Pd–OMe bond in the active catalytic species [reactions (9), (10)]. It was found that the hydride species L_2PdH^+, formed during the formation of the catalyst and in the subsequent chain termination and transfer steps, can be transformed again into catalytically active species by reaction (14).

$$L_2PdOMe^+ + CO \longrightarrow L_2PdCOOMe^+, \quad (9)$$

$$L_2PdOMe^+ + C_2H_4 \longrightarrow L_2PdCH_2CH_2OMe^+, \quad (10)$$

$$L_2PdH^+ + C_2H_4 \longrightarrow L_2PdC_2H_5^+, \quad (11)$$

$$L_2PdH^+ + CO + MeOH + \text{  } \longrightarrow \quad (12)$$

$$\longrightarrow L_2PdCOOMe^+ + \text{  }$$

$$L_2Pd^{2+} + CO \longrightarrow L_2PdCO^{2+}, \quad (13)$$

$$L_2PdCO^{2+} + MeOH \longrightarrow L_2PdCOOMe^+ + H^+, \quad (13')$$

$$L_2PdH^+ + MeOH + \text{  } \longrightarrow \quad (14)$$

$$\longrightarrow L_2PdOMe^+ + \text{  }$$

It should be noted that, depending on the nature of the initiating species (L_2PdOMe^+ or L_2PdH^+), the growing polymer chain would have a methoxyl or ethyl group at one end [reactions (15)–(17)].

$$L_2PdCOOMe^+ + C_2H_4 \longrightarrow L_2PdCH_2CH_2COOMe^+, \quad (15)$$

$$L_2PdCH_2CH_2OMe^+ + CO \longrightarrow L_2PdCOCH_2CH_2OMe^+, \quad (16)$$

$$L_2PdC_2H_5^+ + CO \longrightarrow L_2PdCOC_2H_5^+. \quad (17)$$

Chain restriction (termination and transfer). When the chain is transferred to the alcohol (by a protolysis or alcoholosis reaction), either methoxy or ethyl group is located at the end of the chain. In these cases, diester [reaction (18)], ketoester [reaction (19)] or diketone [reaction (20)] type copolymers are formed. Recently, it has been shown [203] that in a homogeneous medium (when the

length of the growing polymer chain does not exceed 500), chain termination and transfer occur mainly *via* protolysis of the active site, whereas in a heterogeneous medium (when the polymer chain is long and the polymer precipitates), both protolysis and alcoholysis reactions take place. (For determining the rates of these reactions depending on the type of catalyst and conditions of copolymerisation, further systematic research is required.)

$$L_2PdCO(CH_2CH_2CO)_nOMe^+ + MeOH \longrightarrow \quad (18)$$

$$\longrightarrow L_2PdH^+ + \underset{\text{diester}}{MeOCO(CH_2CH_2CO)_nOMe}$$

$$L_2PdCO(CH_2CH_2CO)_nOMe^+ + MeOH \longrightarrow \quad (19)$$

$$\longrightarrow L_2PdOMe^+ + \underset{\text{ketoester}}{HCO(CH_2CH_2CO)_nOMe}$$

$$L_2PdCO(CH_2CH_2CO)_nC_2H_5^+ + MeOH \longrightarrow \quad (20)$$

$$\longrightarrow L_2PdOMe^+ + \underset{\text{diketone}}{HCO(CH_2CH_2CO)_nC_2H_5}$$

During copolymerisation of CO and C_2H_4 in water or in water-containing solvents, the following reaction can take place:

$$L_2PdCO(CH_2CH_2CO)_nC_2H_5^+ + HOH \longrightarrow \quad (21)$$

$$\longrightarrow L_2PdOH^+ + \underset{\text{diketone}}{HCO(CH_2CH_2CO)_nC_2H_5}$$

Spontaneous chain termination. When copolymerisation is carried out in aprotic solvents, spontaneous chain termination takes place by β-elimination mechanism [reactions (22), (23)]. In this case, one end of the polymer chain would bear the vinyl group.

$$L_2Pd(CH_2CH_2CO)_nOMe^+ \longrightarrow$$

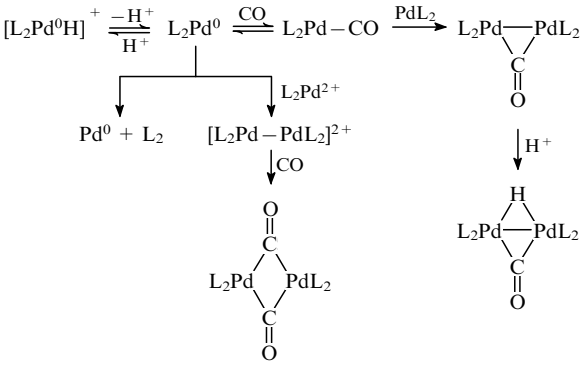
$$\longrightarrow L_2PdH^+ + CH_2{=}CHCO(CH_2CH_2CO)_{n-1}OMe, \quad (22)$$

$$L_2Pd(CH_2CH_2CO)_nC_2H_5^+ \longrightarrow$$

$$\longrightarrow L_2PdH^+ + CH_2{=}CHCO(CH_2CH_2CO)_{n-1}C_2H_5. \quad (23)$$

Irreversible destruction of the potential L_2PdH^+ active sites. The kinetic studies[21,22] show that, despite the steady-state copolymerisation character, the reaction rate decreases with time, due to the decrease in the concentration of catalytically active sites. Scheme 3 presents the most probable ways of destruction of the potentially active L_2PdH^+ sites.[7]

Scheme 3



In terms of the above kinetic scheme, the inverse kinetic problem was solved and the rate constants for individual copolymerisation steps were estimated. This model describes quantitatively the dependence of the initial process rate on the comonomer pressure, the kinetic curves for the consumption of comonomers and the molecular-mass characteristics of the copolymers at different pressures of the $CO/CH_2{=}CH_2$ monomer mixture.[203]

* * *

It is worth noting that although the Pd complexes used in the alternating copolymerisation of carbon monoxide with various monomers seem to differ from the known Ziegler–Natta catalysts (including metallocene type catalysts) used in the synthesis of polyolefins, they still have much in common with these catalysts (Table 4). Both the palladium complexes and the Ziegler–Natta catalysts contain an electrophilic metal cation and a weakly coordinated anion. In both types of catalyst, the metal cations have a coordination number equal to four. However, the metal cations in the Ziegler–Natta catalyst are most often tetravalent and contain four anionic ligands [two strongly coordinated (for example, Cp ligands) and two weakly coordinated Z^- anions], whereas in Pd complexes, the Pd cation is divalent and contains two neutral (L) and two weakly coordinated (Z^-) anionic ligand. The active sites in both types of catalyst have a *cis*-structure during the growth of the polymer chain and monomer coordination. In the d^0-metallocene complex, the *cis*-structure involves the pseudotetragonal coordination environment of the metal, while in the square planar Pd(d^8) complex, the *cis*-structure is ensured by the presence of neutral ligands.

Table 4. Comparison of the catalysts used in the synthesis of polyolefins (**A**) and polyketones (**B**).[3]

Catalyst structure	**A**	**B**
Metal ion	Ti^{IV}, Zr^{IV}, Hf^{IV}	Pd^{II}
Ligands	2 Cp^-, 2 Z^-	2 L, 2 Z^-
Anions	non-coordinated	weakly coordinated or non-coordinated
Geometry	tetrahedral	square planar
Active site structure		
Note. Cp is cyclopentadienyl.

IV. Structure and properties of polyketones

1. Study of the structure and properties of polyketones

Copolymers of ethylene with carbon monoxide were described by NMR and IR spectroscopy. The IR spectra of low-molecular-weight aliphatic polyketones exhibit an intense characteristic absorption band in the region of 1715–1720 cm^{-1} due to the CO group.[204] The IR spectra of random ethylene–carbon monoxide copolymers containing ~1 mol.% of carbon monoxide[205] also contain an absorption band in this region. However, in the IR spectrum of the alternating C_2H_4/CO copolymer, this band is shifted to 1695 cm^{-1}. The vibration frequencies of some functional groups of the CO/C_2H_4 copolymer at room temperature are lower than those observed for low-molecular-weight model analogues.

A study of the IR spectra of solid samples of model ketoesters $MeO(COCH_2CH_2)_nH$ ($n = 1-5$) has shown that the absorption band due to CO shifts from 1720 to 1700 cm^{-1} with an increase in n (see Ref. 206). The IR absorption bands of the alternating copolymer of carbon monoxide with ethylene are listed in Table 5.[207]

Table 5. Absorption bands in the IR spectra of the $CO/CH_2=CH_2$ copolymer (25 °C, KBr pellet).[207]

ν /cm^{-1}	Type of vibration [a]

A study of the temperature variation of the IR spectra of the carbon monoxide – ethylene copolymer has shown that in the temperature range of 20 – 260 °C, the CO vibration frequency shifts from 1692 to 1709 cm^{-1} (Fig. 1 *a*), and the band for the CH_2COCH_2 groups shifts from 1055 to 1062 cm^{-1} (Fig. 1 *b*). The vibrational spectra of thin films (60 μm) of the ethylene – carbon monoxide copolymer deposited on gold-coated silicon substrates have been reported.[208, 209]

Investigations of 5 – 12-nm thick films from CO/C_2H_4-based polyketones deposited on the surface of gold by Raman (120 – 3300 cm^{-1}), IR (10 – 3300 cm^{-1}), reflection absorption IR (500 – 3300 cm^{-1}) and surface electromagnetic wave absorption (1000 – 1450 cm^{-1}) spectra have shown that 8 – 12 nm thick films are predominantly lamellar crystals with a complex conformation of chains, while in the 5-nm thick films, crystals with stretched chains predominate.[210]

By using ^1H and ^{13}C NMR spectroscopy, not only the composition of the random CO/C_2H_4 copolymer but also the distribution of the monomer units along the chain, the terminal groups, branchings and conformational transitions have been determined.[211]

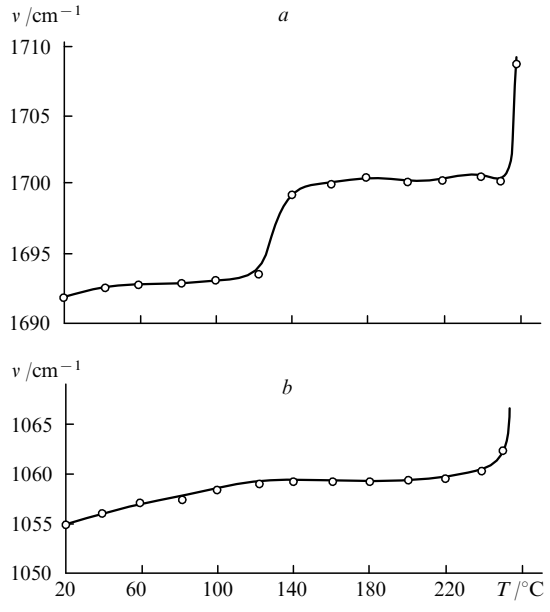

Figure 1. Effect of temperature on the shift of the absorption bands of the CO (*a*) and CH_2COCH_2 (*b*) groups in the IR spectra of the carbon monoxide – ethylene copolymer.

Belov *et al*.[212] reported the results of a ^1H and ^{13}C NMR study of the microsctructure of CO/C_2H_4 copolymers. The molecular-mass characteristics of the copolymers were determined by osmometry and gel permeation chromatography (GPC); in addition, the constants K and α of the Mark – Kuhn – Howink equation in the range of molecular mass from 10^3 to 10^6 were found.

The crystal structure of the ethylene – carbon monoxide copolymer with different ratios of the monomer units in the polymer chain has been studied.[213 – 215] In 1961, the crystal structure parameters of an alternating copolymer of ethylene and carbon monoxide (T_m = 175 – 185 °C), obtained by radiation copolymerisation were determined for the first time while studying the properties of oriented films.[213] More recently it has been shown [215] that this alternating copolymer has a β-structure, the *ab* projection of the orthorhombic cell of this structure being similar to that of polyethylene (PE). The alternating copolymer of ethylene and carbon monoxide obtained in a catalytic process has T_m = 250 – 260 °C and has the so-called α-structure. The conformations of the polymer backbone in these two structures are identical; however, the chain packings are different. This difference can be attributed to different orientations of the carbonyl groups relative to the chains arranged in the unit cell corners. The angles between the plane of the macromolecule and the *bc* plane are 26° and 40° in the α- and β-structures, respectively.

In the α-structure, the symmetry transformation that relates the corner and the central chains is $1/2-x$, $1/2+y$, z; while in the β-structure, this transformation is given by $1/2+x$, $1/2-y$, z. Thus, the difference between the two structures is described by rotation of the central chain through an angle of ~180° around the axis of this chain or by a translation of the central chain by half the unit cell dimension along the axis of the macromolecule. In the α-structure, the dipoles of all the carbonyl groups are oriented toward the same direction, whereas in the β-structure, the dipoles of the carbonyl groups of the corner and central chains point to different directions. As a consequence, the chain packing in the α-structure is less dense than that in the β-structure (the calculated densities are 1.383 and 1.297 g cm^{-3}, respectively). The cross section of the unit cell is perpendicular to the fiber axis and has an area of 35.2 Å^2, which is somewhat smaller than the area of the PE unit cell (36.2 Å^2). Table 6 presents data on the CO and CH_2 vibration frequencies for three forms [α, β and the amorphous form (or a melt)] of the co-polyketone based on $CH_2=CH_2$ and CO.

Table 6. Vibration frequencies of the main groups of the $CO/CH_2=CH_2$ copolymer in the IR spectrum.[208]

Table 7 contains the experimental densities of the alternating copolymer of ethylene and carbon monoxide (polyketone, POK), the unit cell parameters and T_m; the same characteristics for other polymers are given for comparison.

The α-form of POK has a greater density and a shorter $CH_2\cdots C=O$ distance (3 Å) than the β-form (3.41 Å). This is due

Table 7. Melting point, density and unit cell parameters for various polymers.[216]

Polymer	T_m /°C	d /g cm^{-3}	Sructure	a /Å	b /Å	c /Å

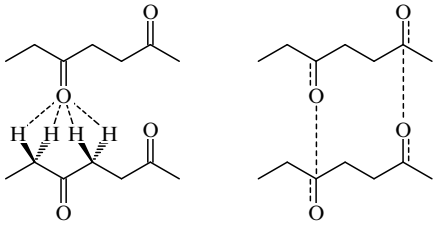
[a] The α-structure passes to the β-structure prior to the onset of melting of polyketone (at 110 – 130 °C). [b] Along the fibre axis. [c] PVA is poly(vinyl alcohol).

to the formation of intermolecular bonds between the CO and CH_2 groups. At room temperature, the α-form is more stable, whereas at a temperature of > 140 °C, only the β-form exists. The α→β temperature transition lies at about 113 °C (for the fibre) and 120 – 140 °C (for the film). The β→α transition takes place only upon drawing of POK samples. Thus, it can be concluded that the α- and β-forms of the copolymer are characterised by different strength of intermolecular cohesion caused by the presence of hydrogen bonds and dipole – dipole interactions.



A 3D computer model of polyketone was constructed using the molecular dynamics method. The calculated values for density and crystal lattice parameters coincided almost entirely with experimental data over a broad temperature range. Using the 3D model, it was shown that the crystal structure of the α- and β-phases is largely determined by the Coulomb interaction between the polar carbonyl groups.[217]

The ethylene – carbon monoxide – α-olefin terpolymers (α-olefin is propylene,[218, 219] but-1-ene or hex-1-ene [218]) were studied by

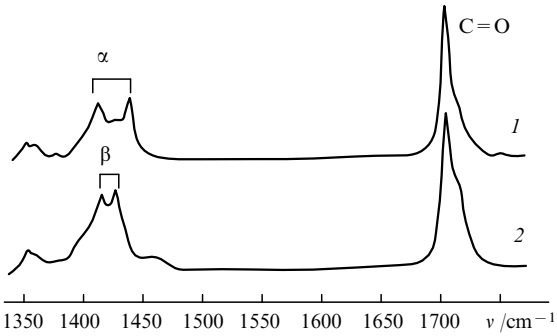


Figure 2. Raman spectra of the alternating ethylene – carbon monoxide – propylene terpolymers containing macromolecules of the α- (curve *1*) and β-form (curve *2*).

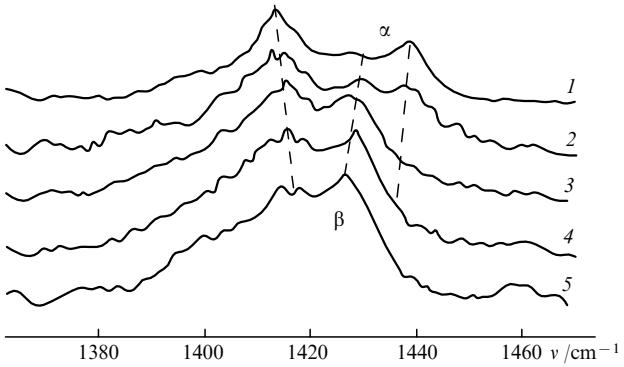

Figure 3. Raman spectra of the alternating ethylene – carbon monoxide – propylene terpolymers with different contents of propylene. [C_3H_6] (mol %): 0 (*1*), 1.2 (*2*), 2.9 (*3*), 4.6 (*4*), 7.2 (*5*).

wide-angle and small-angle X-ray diffraction, DSC and Raman spectroscopy. Copolymers containing hex-1-ene have a higher crystallinity than copolymers containing propylene and but-1-ene. The relative content of the α-form macromolecules in the terpolymers decreases in the sequence hex-1-ene > but-1-ene > propylene.[218] Figures 2 and 3 show the Raman spectra of the ethylene – carbon monoxide – propylene terpolymers which contain both α- and β-forms. It can be seen from Fig. 3 that the content of α-form macromolecules in the copolymer decreases with an increase in the propylene content.

The crystal structure of the CO/C_2H_4 copolymer and the $C_2H_4/CO/C_3H_6$ terpolymer (1.2 mol.%, 2.9 mol.%, 4.6 mol.% and 7.2 mol.% of propylene) was studied by DSC, Raman spectroscopy and wide-angle X-ray diffraction and the contents of α- and β-forms were determined.[220] The influence of the stereo- and regio-regularity of the propylene – carbon monoxide copolymer on its crystal structure and macroscopic properties was studied.[§]

Using X-ray examination and optical and electronic microscopy, the structure and morphology of the ethylene – carbon monoxide copolymer crystals prepared by crystallisation of the polymer from a mixture of hexafluoroisopropyl alcohol and hydroquinone have been studied.[221]

The crystal structure of iso- and syndiotactic copolymers of CO with styrene and some its derivatives has been studied.[222 – 224] The key crystallographic characteristics of these copolymers are listed in Table 8.

Table 8. Crystallographic parameters of copolymers of carbon monoxide with styrene or its derivatives.

Parameter	Copolymer $CO/CH_2=CHPh$		Copolymer $CO/CH_2=CHC_6H_4R$ (see [222])		
	isotactic [224]	syndiotactic [222]	R = *p*-F	R = *m*-Me	R = *p*-Me
a /Å	8.367	15.20	15.59	16.14	35.54

β /deg	100.0	102.5	98.8	100.3	96.0
d_{calc} /g cm^{-3}	1.347	1.262	1.388	–	–

The syndiotactic carbon monoxide copolymer with styrene (or *tert*-butylstyrene) can be converted into the atactic copolymer by heating in an organic base (for example, in a tertiary amine,

§ D V Anokhin, V M Neverov, S N Chvalun, N P Bessonova, Yu K Godovsky, F Hollmann, U Merer, B Rieger *Vysokomol. Soedin., Ser. A* **46** 69 (2004); [*Polym. Sci. (Engl. Transl.)*].

N-alkylamide or alkali metal phenoxide) at 40–200 °C [225] or by treatment of the copolymer in the NaOH–MeOH–THF medium.[226]

The IR spectra of carbon monoxide–DCPD copolymers exhibit high-intensity absorption bands in the regions of 1790 and 1721 cm^{-1} (for dimers **A**), indicating the presence of an enol lactone structure, and 1775, 1710–1735 cm^{-1} (for trimers **B**), indicating the presence of γ-lactone and ester vinyl groups.[111] The ^{13}C NMR spectra of these copolymers show signals at about 178–179 ppm (the carbonyl-group carbon atom in the lactone structure **A**), 147–149 (the carbon atoms of the ester vinyl group in structure **B**), 130–136 ppm (the C_{sp}^2 atoms of the cyclopentene ring) and 116–120 ppm (the carbon atom of the spiroketal structure **B**). The formation of terminal lactone groups can be regarded as intramolecular chain termination due to the reaction with methanol (methanolysis), usually resulting in the formation of terminal ester groups.

2. Thermal and thermodynamic properties

In a study of melting of ethylene–carbon monoxide copolymers, it was suggested that the increase in T_m for random carbon monoxide–ethylene copolymers with respect to PE is due to restriction of the rotation caused by the presence of carbonyl groups.[213] Determination of the heats of melting for random copolymers of ethylene and carbon monoxide has shown that the alternating copolymer has $T_m = 244$ °C and a low melting entropy.[227] Study of the melting of low- and high-molecular-weight alternating carbon monoxide–ethylene copolymers showed that their maximum melting points are 278 °C, the heats of melting are 4 and 6.2 kJ mol^{-1}, and the melting entropies are 7.3 and 11.3 J mol^{-1} K^{-1}, respectively.[214] In the case of $MeCH=CH_2/CO$ or $EtCH=CH_2/CO$ copolymers, the presence of side substituents in the position neighbouring to the carbonyl group promotes the formation of macromolecules with less regular structures. These copolymers have lower T_m values and lower solubilities in common solvents. The inclusion of propylene in the polymer chain on passing to the terpolymerisation of ethylene, propylene and carbon monoxide results in a noticeable decrease in T_m values of the terpolymer formed, which has a beneficial effect on the processing conditions. Figure 4 presents the dependences of the heat of melting (Fig. 4 *a*), the degree of crystallinity (Fig. 4 *b*) and T_m (Fig. 4 *c*) for the ethylene–carbon monoxide–α-olefin terpolymers (the α-olefin is propylene, but-1-ene, hex-1-ene) on the α-olefin concentration.[228]

As noted above, copolymerisation of propylene and α-olefins with carbon monoxide may yield macromolecules with the polyspiroketal structure. In the case of the propylene–carbon monoxide copolymer, the polyspiroketal structure is transformed into the usual ketone structure when the copolymer has been dissolved in hexafluoroiopropyl alcohol or heated to 70 °C (the process enthalpy is −11.8 to −10.5 kJ mol^{-1}). This value is close to the calculated enthalpy for the polymerisation of acetone (−10.0 kJ mol^{-1}).[229] The polyspiroketal structures of the but-1-ene–carbon monoxide and hept-1-ene–carbon monoxide copolymers are more stable than the polyspiroketal structure of the propylene–CO copolymer. The polyspiroketal structure of the hept-1-ene–carbon monoxide copolymer does not pass to the ketone structure even upon dissolution in chloroform. It is noteworthy that copolymers containing the spiroketal structure differ in physicochemical properties from copolymers with the ketone structure. For example, copolymers of carbon monoxide with but-1-ene and hept-1-ene having the ketone structure are completely soluble in acetone, while the same copolymers containing both spiroketal and ketone macromolecules are insoluble in acetone.[83]

The crystallisation kinetics of two samples of the ethylene–propylene–carbon monoxide terpolymer containing 3 mol.% and 6 mol.% of propylene has been studied.[230] In the epitaxial crystallisation of the ethylene–carbon monoxide copolymer carried out by the hypoeutectic growth technique on hydroquinone crystals, the axes of the polymeric chains are arranged parallel to the hydroquinone surface.[221] Tunnelling electron microscopy (TEM) has been used to study epitaxial crystallisation (at temperatures of 150–190 °C) of the carbon monoxide–ethylene copolymer on NaCl and KI crystals from a nitrobenzene solution. It was shown that the shape and orientation of macromolecular chains on the substrate surface depend on its nature.[231–233] The copolymer crystals grown under isothermal conditions (at 139 °C for 24 h) from a 0.01 mass % solution in nitrobenzene contained only macromolecules of the α-form (they were characterised by TEM and small-angle X-ray diffraction), whereas the copolymer crystals grown on the surface of alkali metals contained macromolecules of both (α and β) forms.[234]

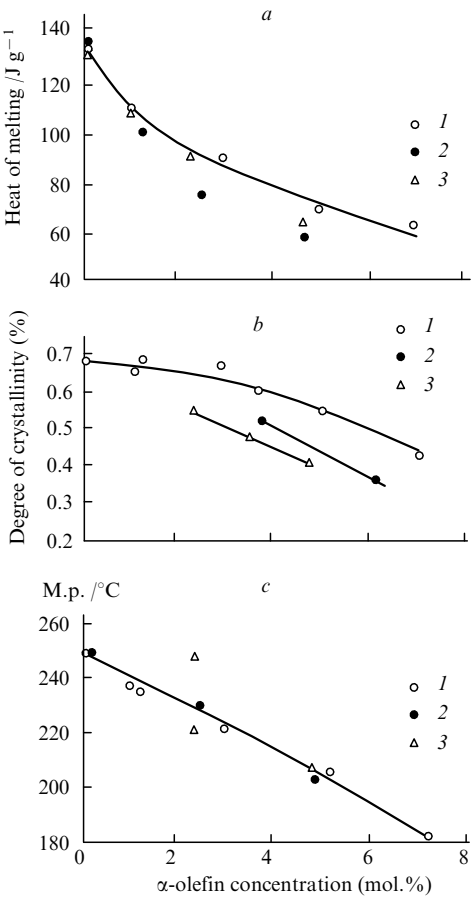

Figure 4. Effect of the α-olefin concentration on the heat of melting (*a*), degree of crystallinity (*b*) and T_m (*c*) of ethylene–CO–propylene (*1*), ethylene–CO–but-1-ene (*2*), ethylene–CO–hex-1-ene (*3*) terpolymers.[228]

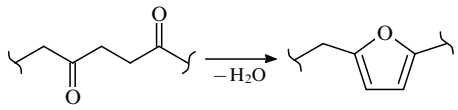
Detailed study of the characteristic features of the crystallisation and melting of three samples of the ethylene–carbon monoxide–propylene terpolymer (I–III) by DSC, wide-angle and small-angle X-ray and optical spectroscopies has been reported.[235]

Sample	$[C_3H_6]$ /mol.%	M_w	$M_w : M_n$
I	0	4×10^4	3.09
II	6	8×10^4	2.99
III	6	4×10^4	2.32

It was noted that T_m decreases by about 1 °C, the heats of melting decrease by 2 J g^{-1} and the sample crystallinity also decreases after every heating to T_m, which is due to cross-linking reactions. The heats of melting for the crystalline (100%) C_2H_4/CO copolymer (β-form) and $C_2H_4/CO/C_3H_6$ terpolymer (β-form) were determined to be 239±11 and 226±16 J g^{-1}, respectively. The thickness of the lamellae increases linearly with an increase in the

crystallisation temperature. The isothermal crystallisation of the copolymer proceeds faster than that for the terpolymer. On the basis of comprehensive analysis, it was concluded that the equilibrium T_m for the high-molecular mass copolymer and terpolymer and that for the low-molecular-mass copolymer are 278, 252 and 249.5 °C, respectively.

The high T_m values of ethylene–carbon monoxide copolymers bring about difficulties in the material processing into articles. This is due to the fact that at elevated temperatures, in addition to thermal destruction, condensation may take place, giving rise to furan structures in the polymer chain according to the following scheme:

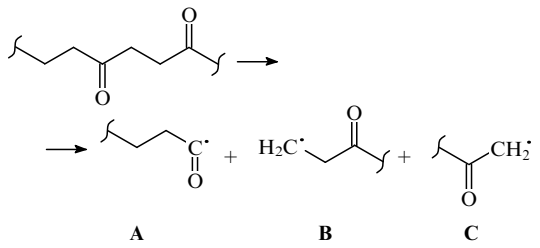


The thermal destruction of the carbon monoxide–ethylene copolymer at 500 °C to give linear polyketones, diketones and low-molecular-mass products has been studied.[236] A study of the thermal destruction of this polymer *in vacuo* at temperatures above T_m by flash pyrolysis–gas chromatography–mass spectrometry (FP-GCMS) has identified the formation of vinyl ketones with different molecular masses.[237]

The destruction of samples of the carbon monoxide–ethylene copolymers containing 70 ($[\eta] = 0.41$ dl g^{-1}) and 15 ppm Pd ($[\eta] = 2.5$ dl g^{-1}) has been studied by DTG, mass spectrometry, and UV and IR spectroscopy. The copolymer starts to lose mass at approximately 290 °C; the maximum mass loss is observed at 370–410 °C. The main decomposition products at temperatures of up to 215 °C are polyfuran structures and water. The residue obtained after the pyrolysis in an inert atmosphere and *in vacuo* amounts to 30 mass % and 10 mass %, respectively. After the pyrolysis, the polymer completely loses its solubility in hexafluoroisopropyl alcohol and crystallinity estimated based on the absorption bands in the region of 1082–1056 cm^{-1}. Cross-linking of polymer chains starts at 230 °C and is accompanied by the formation of ethylene, carbon monoxide and low-molecular-mass ketones. The rupture of polymer chains at this relatively low temperature affords macroradicals, which can be destroyed both upon intermolecular chain transfer and in bimolecular processes.

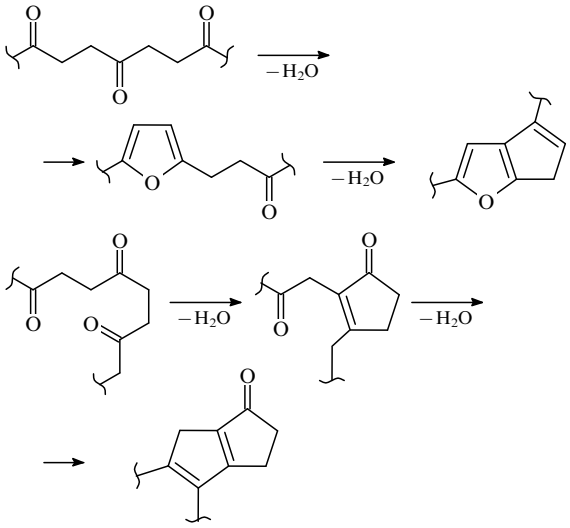
The pyrolysis products obtained at 500 °C were found to include CO, CO_2, water, linear low-molecular-mass polyketones, cyclopentanone derivatives, aromatic compounds (phenols, aromatic ketones and hydrocarbons having bi- and polycyclic structures). Pyrolysis of preliminarily 'aged' copolymer gives large amounts of water and CO_2 as well as furan, phenolic and aromatic derivatives, and linear polyketones. The thermal decomposition of the copolymer can be described as aldol condensation and/or dehydration to give furan structures at temperatures below 260 °C. On the basis of the DSC data, it was suggested that destruction starts in the amorphous regions of the copolymer.[238, 239]

The pyrolysis at 550 °C and thermal decomposition of the ethylene–carbon monoxide copolymer at 350 and 400 °C have been studied.[239] The volatile products of thermal decomposition were studied by GC and mass spectrometry, while the structural changes in the copolymer were examined by IR, UV and visible spectroscopy. It was found that all the volatile products are formed from **A**–**C** type radicals



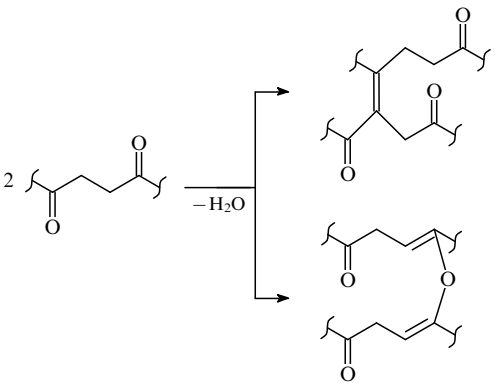
Depending on the temperature and duration of maintenance, the copolymer colour changes from while to pale yellow and dark brown; simultaneously, the polymer loses, either completely or partially, the solubility in hexafluoroisopropyl alcohol (due to cross-linking of polymer chains). Analysis of the IR spectra of thermally aged copolymers of carbon monoxide with ethylene shows that ageing is accompanied by the formation of new functional groups (Scheme 4).

Scheme 4

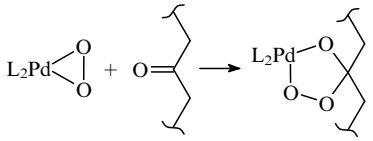


In addition, due to cross-linking of the polymer chains, copolymer loses crystallinity and becomes amorphous. The cross-linking of copolymer macromolecules can proceed according to Scheme 5.

Scheme 5



The influence of the remains of the Pd catalyst on the mass loss from the ethylene–carbon monoxide–propylene terpolymer in an inert atmosphere and in the presence of oxygen has been studied by TGA.[240, 241] On the basis of the DTG data, it was shown that under inert atmosphere, the maximum loss of mass (10%–30%) occurs at a Pd content of [Pd] ≈ 300 ppm (Fig. 5 *a*), while for the thermal destruction in air it barely depends on the Pd content up to 600–800 ppm and starts to decrease only at Pd > 800 ppm (Fig. 5 *b*). Thus, it was suggested that traces of palladium do not influence the temperature of the onset of thermal decomposition in the presence of oxygen, which is apparently related to the formation of stable palladium complexes with dioxygen, which subsequently react with the copolymer according to the following scheme:



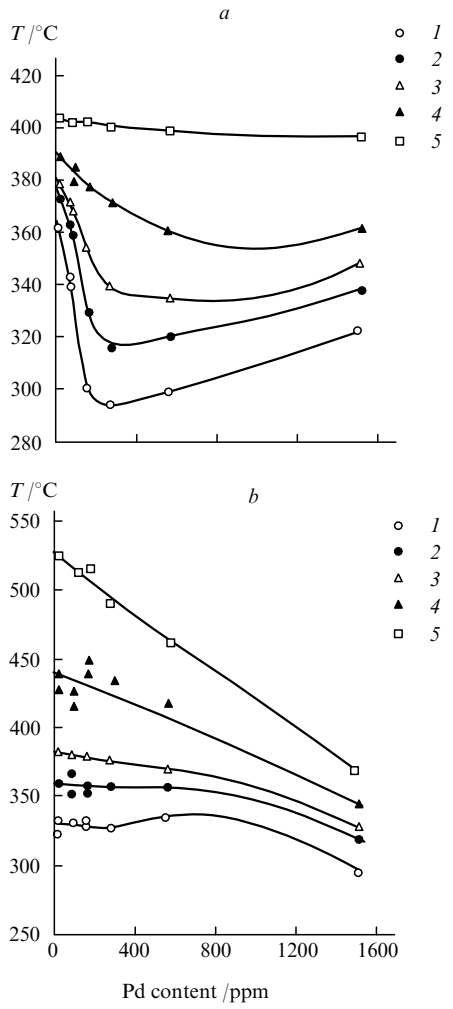


Figure 5. Effect of the palladium content in the ethylene–carbon monoxide–propylene terpolymer on the loss of its mass in an inert atmosphere (*a*) and in air (*b*).
Mass loss (%): 10 (*1*), 20 (*2*), 30 (*3*), 50 (*4*), 75 (*5*).

It was found that the oxidation state of palladium [Pd(II) or Pd(0)] has an influence on the destruction of copolymer. In the former case, destruction starts at a temperature lower by 60 °C than in the latter case.

Under an inert atmosphere, thermal decomposition is retarded with an increase in the palladium content (> 300 ppm). The higher the palladium content ¶ in the copolymer, the higher the degree of cross-linking.[240]

When the palladium content is less than 6 ppm, the ethylene–carbon monoxide–propylene terpolymer can be moulded to give transparent specimens which do not change their colour.[242]

A study of the uninhibited oxidation of the $CH_2=CH_2/CO$ copolymer (at 170–200 °C) and the $MeCH=CH_2/CO$ copolymer (at 80–180 °C) has shown that the patterns of oxidation of these copolymers are complex and differ considerably from each other.[243, 244] The kinetics of oxygen absorption during oxidation of the former copolymer shows two clear-cut steady-state sections with activation energies of 203 and 133 kJ mol^{-1}. For the second copolymer, the oxidation rate decreases with an increase in the temperature (> 140 °C) (negative temperature coefficient), the apparent activation energy being −59 kJ mol^{-1}. The mechanism of this phenomenon is related to switching from the standard oxidation mechanism [reactions (24), (25)] to a mechanism in which a significant role is played by decomposition of the $RO_2^{\bullet}$ radical [reaction (26)].

$$R^{\bullet} + O_2 \longrightarrow RO_2^{\bullet}, \quad (24)$$

$$RO_2^{\bullet} + RH \longrightarrow ROOH + R^{\bullet}, \quad (25)$$

$$RO_2^{\bullet} \longrightarrow R_1^{\bullet} + \text{products}. \quad (26)$$

In the search for compounds that could stabilise polyketones during processing to manufacture articles, the best results were obtained for aromatic carbodiimides, mono- and polyepoxy compounds, β-diketones and cellulose ethers in combination with hydroxyapatite. The key criteria used to estimate the efficiency of stabilisers in the processing of polyketones included the degree of crystallinity (DC), the shift of the crystallisation temperature in the second heating–cooling cycle (ΔT), the heat of crystallisation (C_2) in the second cycle and the ratio of the peak height in the second crystallisation cycle to the peak width at the half-height ($C_{h/w}$) (Table 9).

Table 9. Efficiency of various stabilisers (according to DSC).[245]

Stabiliser [a]	Degree of crystallinity	ΔT /°C	C_2 /J g^{-1}	$C_{h/w}$

Stabaxol P (2%)	0.38	53.0	−37.3	–

[a] **Notation**: Stabaxol P is 2,2′,6,6′-tetraisopropyldiphenylcarbodiimide, CaHA is hydroxyapatite, R50, R83 are β-diketones, ERL 4221, DEN 444 are epoxides, Naugard 445 is alkylated diphenylamine, Irganox 1425 is calcium bis[monoethyl(3,5-di-*tert*-butyl-4-hydroxybenzyl)]phosphonate.

The photodestruction of the $CH_2=CH_2/CO$ and $MeCH=CH_2/CO$ copolymers has been studied under anaerobic conditions. The rate of photooxidation at room temperature does not depend on the palladium content in the copolymer. The photostability of the $CO/MeCH=CH_2$ copolymer was found to be lower than that of the $CO/CH_2=CH_2$ copolymer due to oxidation reactions proceeding by the Norrish-I and Norrish-II mechanisms.[246] ($CO/CH_2=CH_2$ is oxidised only according to the Norrish-I mechanism.[247])

The photolysis and γ-radiolysis of the $CO/CH_2=CH_2$ copolymers and the subsequent thermal and chemical transformations of samples following an increase in the irradiation temperature (from

¶ Traces of transition metal ions are often used as catalysts for the destruction of polymeric materials both in the presence and in the absence of oxygen.[241]

−196 to 27 °C) have been studied.[248, 249] The main reaction in the photolysis is the rupture of the polymer chain to give alkyl and acyl radicals with the quantum yields $\varphi_R = 2 \times 10^{-4}$ at −196 °C and $\varphi_R = 2 \times 10^{-3}$ at 27 °C. The major products formed in the copolymer photolysis at 27 °C include ethane, ethylene and carbon monoxide. Radiolysis of the copolymer at −196 °C affords the same alkyl and acyl radicals as the photolysis. At a dose of $\leqslant 50$ kGy, these radicals account for ~50% of all paramagnetic centres.

The biodegradation of the $CO/CH_2=CH_2$ copolymer has been studied and the results have been compared with the data on biodegradation of PE and cellophane.[250] In terms of the susceptibility to biodestruction, the copolymer in question occupies an intermediate position between PE and cellophane.

The systematic research into the thermodynamic characteristics of alternating copolymers has been started. Using adiabatic vacuum and dynamic calorimetry, the temperature dependence of the heat capacity was determined and the temperatures and enthalpies of the physical transformations of carbon monoxide copolymers with ethylene,[251] propylene,[252] styrene,[253] *endo*-dicyclopentadiene[254] and norbornadiene† were found.

Of high practical value is the study of blends of polyketones with various polymers (as compatibilisers). It was found that the propylene–carbon monoxide copolymer forms homogeneous transparent blends with the styrene–acrylonitrile (SAN) copolymer containing 37 mass % of acrylonitrile.[86] As the content of SAN increases from 20 mass % to 90 mass %, the glass transition temperature increases from ~30 to 100 °C, which is in good agreement with the dependence of T_g on the composition of the polymer blend described by the Fox equation. However, blending of the propylene–carbon monoxide copolymer with polystyrene or the styrene–maleic anhydride copolymer gives brittle heterogeneous blends. The physicomechanical properties of the initial and glass fibre reinforced (30 mass %) ethylene–carbon monoxide–propylene terpolymer (with a propylene content of 5 mass %–6 mass %) obtained by injection moulding with controlled drawing have been compared.[255]

A TGA study of the thermal decomposition of syndiotactic carbon monoxide–styrene copolymer has shown that the process occurs in three stages. The activation energy of the fastest second stage of thermal decomposition, equal to 31 kcal mol^{-1}, is lower than the activation energy of the thermal decomposition of polystyrene (PS) (55 kcal mol^{-1}), which is indicative of a lower stability of $CO/CH_2=CHPh$. Photolysis of the copolymer entails a decrease in its molecular mass and loss of the sample mass. The macroradicals formed in the photolysis of the copolymer initiate polymerisation of methyl methacrylate (MMA) to give the CO–styrene block copolymer and poly(methyl methacrylate).[177] Photolysis of samples of the carbon monoxide–4-(*tert*-butyl)styrene copolymer (M_n = 44 000–53 000, $M_w : M_n$ = 1.2–1.4), in particular, a sample containing ^{13}CO, has been studied by time-resolved EPR spectroscopy at two frequencies, in the X (9.5 GHz) and Q (35.1 GHz) ranges.[97]

3. Mechanical and other properties of copolyketones

At present, the properties of terpolymers ($CH_2=CH_2/CO/MeCH=CH_2$) have been studied most comprehensively; the properties of alternating copolymers ($CH_2=CH_2/CO$) traded under the name Carilon (Shell Chemical Co) or Ketoneks (British Polymer Co) have been less studied.

Films of the $CH_2=CH_2/CO/MeCH=CH_2$ terpolymer containing 0 mol.%–14.6 mol.% of propylene before and after 3–6-fold drawing have been studied by X-ray diffraction and DSC. Drawing was found to promote the formation of units of the copolymer α-form; the lower the drawing velocity, the greater the number of the α-form units.[256] As the content of propylene in the copolymer increases from 0 to 14.6%, the temperature of the α → β transition decreases from 91 to 60 °C and simultaneously, the melting peak is broadened.

The effect of the temperature (0–80 °C) on the mechanical strength (tensile strength and the fracture pattern in uniaxial and biaxial tests) of solid and hollow cylindrical specimens of the $CH_2=CH_2/CO/MeCH=CH_2$ terpolymer containing 6 mol.% of propylene was studied. The data obtained in this study were compared with the results of calculations for a model anisotropic material.[257, 258]

Karttunen and Lesser[259] have studied the effect of extrusion conditions (shear rate, cooling rate) during moulding of hollow cylindrical specimens on the mechanical properties of the ethylene–carbon monoxide–propylene terpolymer containing 6 mol.% of propylene (T_m = 225 °C, T_g = 12 °C, molecular mass 1×10^5, degree of crystallinity 33%–35%, density 1.24 g cm^{-3}). The methods used included DSC, dynamic mechanical analysis (DMTA), IR spectroscopy, wide-angle X-ray diffraction and electron microscopy. The crystal structure and the morphology of this copolymer were studied by X-ray diffraction, DSC and TEM. It was found that T_m of the copolymer linearly decreases with an increase in the propylene content from 6 to 10 mol.%. Further increase in the content of propylene in the copolymer (10%–16%) barely influences its T_m.[260] The obtained results are in line with the data of other publications.[261, 262]

High-strength (1.1 GPa) and high-modulus (13 GPa) fibres of four specimens (I–IV) of the $CH_2=CH_2/CO/MeCH=CH_2$ terpolymer were produced by extrusion at temperatures of 250, 255 and 266 °C.

Specimen	$[C_3H_6]$ /mol.%	M_w	$M_w : M_n$
I	6.0	4×10^4	2.84
II	6.0	6×10^4	3.00
III	3.5	6×10^4	3.10
IV	0	4×10^4	3.10

The structure and morphology of the resulting fibres were studied by DSC, wide- and small-angle X-ray diffraction and scanning electron microscopy. It was found that in the $CH_2=CH_2/CO/MeCH=CH_2$ terpolymers, the crystalline phase is always represented by the β-form. In the $CH_2=CH_2/CO$ copolymer, depending on the cooling rate, α-form is also present in addition to the major β-form.[263] The dependences of the physicomechanical properties, the degree of crystallinity and T_m of the ethylene–CO–propylene terpolymers on the amount of propylene in specimens I–IV are shown in Figs 6, 7.

The morphological features and the mechanisms of crack formation in specimens of the $CH_2=CH_2/CO/MeCH=CH_2$ terpolymer (Carilon DP P1000) with a degree of crystallinity of

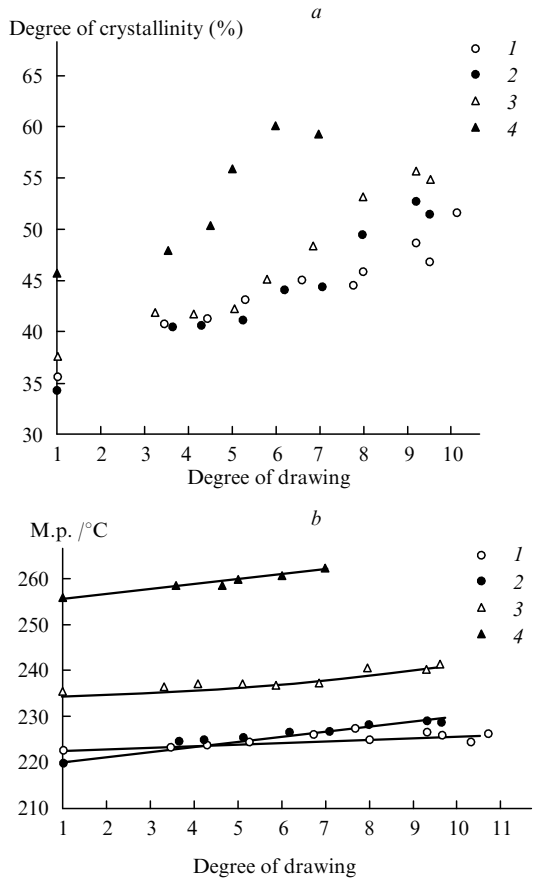

Figure 7. Degree of crystallinity (*a*) and T_m (*b*) of samples I–IV (points *1–4*, respectively) *vs.* degree of drawing.

38% obtained by injection moulding and mould pressing were studied by DSC, DMTA and optical microscopy.[264]

Studies of such copolymers carried out by thermoelastometry in the temperature range of 13–54 °C at pressures of 30–100 MPa have shown[265] that thermodynamic parameters of the terpolymers (specific volumes, thermal expansion and compression coefficients) are deteriorated with an increase in the content of the $(-C_2H_4CO-)_n$ blocks, whereas the thermal characteristics (heat and temperature conductivity, specific heat capacity) virtually do not depend on the polymer composition. The bell-shaped dependences of the Newton viscosity[266] and diamagnetic susceptibility[267] on the content of the $(-C_2H_4CO-)_n$ blocks in the ethylene–carbon monoxide–propylene terpolymer was described within the bounds of the classical copolymerisation theory taking the strictly alternating $CH_2=CH_2/CO$ and $MeCH=CH_2/CO$ copolymers as 'virtual homopolymers' and the strictly alternating $CH_2=CH_2/CO/MeCH=CH_2$ terpolymer, as a 'virtual copolymer.'

According to X-ray diffraction data,[266–268] the ethylene–CO–propylene terpolymers are amorphous to X-rays at room temperature; however, in the temperature range above the glass transition temperature ($T_g \approx 17$ °C), the heat capacity curves contain sections corresponding to slight endothermic effects. In the same temperature range, the intensity of the dielectric relaxation does not decrease with temperature but, conversely, increases. Moreover, hysteresis effects were found for the viscoelastic characteristics of the terpolymers in the melt on heating the specimens to 227 °C with subsequent cooling to 127 °C.[268] This set of data indicates that long-term storage of the terpolymers at room temperature promotes the formation of a network of $CH_2=CH_2/CO$ nanocrystallines with runs through the continuous phase of the noncrystalline $MeCH=CH_2/CO$ blocks. The low values of the shape parameter from the Kolmogorov–Avrami equation in combination with exceptionally long half-periods of nanocrystallisation[269] are consistent with the views stating that nanocrystallites are formed through lateral aggregation of the $CH_2=CH_2/CO$ blocks, which is retarded by the continuous $MeCH=CH_2/CO$ phase.

It was found that the activation energy of the relaxation processes at low temperatures equals 14 kcal mol^{-1}, while at elevated temperatures, this value is 38–61 kcal mol^{-1}. Young's modulus for the $CH_2=CH_2/CO/MeCH=CH_2$ terpolymer containing ~50% of the $-C_2H_4CO-$ units is three orders of magnitude lower than that of the $CH_2=CH_2/CO$ copolymer (1.6 GPa). As the content of the $-C_2H_4CO-$ units in the terpolymer increases, its melting heat increases, while T_g decreases from 22 °C (for the $MeCH=CH_2/CO$ copolymer) to 3 °C (for the terpolymer containing 80 mass % of the $-C_2H_4CO-$ units).[269]

Hollmann *et al.*[270] studied the dielectric (in the frequency range of 10^{-1}–10^6 Hz) and mechanical properties of terpolymers (with a content of the $-C_2H_4CO-$ units ranging from 0 mass % to 80 mass % and a molecular mass of 12×10^4–22.8×10^4) and determined their glass transition and melting temperatures. The structural changes taking place in the $CH_2=CH_2/CO/MeCH=CH_2$ specimens containing 47% and 69% of $-C_2H_4CO-$ units upon deformation were investigated by X-ray diffraction and DSC. It was shown that great reversible deformations are mainly due to the amorphous component of the terpolymer.[271]

The effect of the polyketone molecular mass and the conditions of surface formation (for example, during press moulding) on the energy characteristics of the surface has been studied.‡

Good adhesion of the alternating ethylene–CO copolymer to organic and inorganic materials allows the use of this copolymer in the production of composite materials without special adhesives. The properties of unfilled and glass fibre reinforced $CH_2=CH_2/CO$ copolymer are presented in Table 10. The influence of various types of surface treatment of glass fibre on the mechanical properties of the composites has been studied.§

Table 10. Properties of alternating $CO/CH_2=CH_2$ copolymer.[11]

Property	Unfilled copolymer	Glass fibre filled copolymer (30 mass %)
Density /g cm^{-3}	1.24	1.45
Melt index (240 °C, 2.16 kg) /g (10 min)$^{-1}$	6	5
Tensile strength /MPa	55	120
Elongation at rupture (%)	350	3
Vika softening temperature (5 kg) /°C	205	215
Shrinkage (%)	2	0.3–0.7

Owing to the specific structure of the polymer chain and the crystallinity (30%–50%), polyketones are not hydrolysed. Unlike other polymers such as PA, PC and polyesters, they are stable against aqueous solutions of weak acids and inorganic salts (Table 11).[272]

‡ S A Bogdanova, O R Shashkina, G P Belov, O N Golodkov, V P Barabanov, I A Starostina *Vysokomol. Soedin.* (2004) (in the press) [*Polym. Sci. (Engl. Transl.)*].

§ Yu N Smirnov, G P Belov, V V Barelko, O N Golodkov, E V Novikova, A D Pomogailo, K E Danilov *Plast. Massy*, (2004) (in the press).

Table 11. Effect of different media on the tensile strength of the alternating $CO/CH_2=CH_2$ copolymer [for comparison, data for polyamide (PA) are given].[272]

Medium	σ_p /MPa	
	polyketone	PA
Control run at 50% moisture content	57.7	57.2
Water	59.2	33.1
Sea water	60.0	33.1
Aqueous solutions		
MeCOOH (5 mass %)	57.9	33.8
$CaCl_2$ (5 mass %)	60.0	33.8
Antifreeze	59.2	35.8
H_2SO_4 (30 mass %)	59.3	dissolves
$ZnCl_2$ (50 mass %)	46.2	dissolves
HCl (10 mass %)	64.7	dissolves
NaOH (1 mass %)	58.6	28.2
NaOH (10 mass %)	60.0	28.9

Long-term keeping of polyketone in alcohols, ethyl acetate, benzene and methyl ethyl ketone has no effect on its properties, while keeping in chlorine-containing (trichloroethylene, dichloromethane, chloroform) and polar aprotic solvents (DMSO, *N*-methylpyrrolidone) results in swelling of the polymer (the gain in the mass is 8% to 35%) and a decrease in its strength (by up to 30%). The high hydrolytic and chemical stability of polyketone is combined with good barrier properties against hydrocarbons, oxygen and carbon dioxide (Table 12). Data on the permeability, diffusion coefficients and solubility of three gases (helium, oxygen and carbon dioxide) in the ethylene–propylene–carbon monoxide terpolymer (0.93 : 0.07 : 1) have been reported.[273]

The high crystallisation rate of polyketone ensures a short duration of the moulding cycle for articles based on this polymer (see Table 12) and eliminates the necessity for further conditioning, which substantially reduces the production costs.

V. Modification of polyketones

The chemical modification of polyketones at the carbonyl group allows one to create new classes of chiral and achiral polymers, which can serve themselves as the starting materials for the development of new low- and high-molecular-mass compounds *via* reactions in polymer chains.

The achiral $CH_2=CH_2/CO$ copolymer and atactic $MeCH=CH_2/CO$ copolymer can be converted into polyfurans,[275] polythiophenes,[275] polyoximes,[276–278] polycyanohydrins[1,276] and polyalcohols.[1,216,275–283] The reduction of isotactic $MeCH=CH_2/CO$ copolymer with lithium aluminium hydride gave polyalcohol whose stereochemistry has not been determined at that moment.[83] Later,[161] using tetrabutylammonium tetrahydroborate, the isotactic $MeCH=CH_2/CO$ copolymer was quantitatively reduced into the polyalcohol and the enantiomers present were identified by ^{13}C NMR spectroscopy ($S:R = 70:30$).

Other derivatives obtained include polyacetylenes,[284,285] polyamines,[1,286,287] poly(α-hydroxyphosphonic acids),[1,288] polythiols,[1,289] polyamides,[1,290] polyoximes,[1,290] polyketoesters,[291] polyketoximes,[278] dioxolane-containing derivatives,[292] nitrogen- and sulfur-containing heterocyclic derivatives of polyketone[293,294] and polymeric 1,2-diketones.[295] The molecular-topological structure of a polyketone modified by amines was studied.¶

VI. Applications

The alternating copolymers of olefins and CO can be used to manufacture high-strength fibres with a maximum strength of 3.8–3.9 GPa, which retain 85%–90% of their strength even at 140 °C. Due to the high polarity, these fibres possess a lower creep† than PE or PETF fibres. Highly oriented fibres have an elongation at rupture of 4%–5% and an initial modulus of 50–55 GPa.[216]

High-molecular-weight copolymers ($CO/MeCH=CH_2$) and terpolymers ($CH_2=CH_2/CO/MeCH=CH_2$) with the composition $(C_2H_4/CO):(C_3H_6/CO) = 1:1$ possess high elasticity and resemble poly(vinyl chloride) (PVC) in mechanical properties. As regards their barrier properties (N_2, O_2 and CO_2 permeability), they occupy an intermediate position between high-density polyethylene and PVC and in terms of water permeability, they are similar to polyurethane. Recently, the preparation of low-molecular-weight $CH_2=CH_2/CO/MeCH=CH_2$ terpolymers with $M_n = (1.5–5.0)\times10^3$ traded under the name Carilite Oligomer has been reported. These terpolymers can be cross-linked under the action of polyfunctional amines or converted into polyaminopyrroles by the reaction with asymmetrical diamines.[93]

As the chain length in the α-olefin increases, the glass transition temperature of α-olefin–carbon monoxide copolymers decreases from 25 °C (for $CO/MeCH=CH_2$) to −60 °C (for dodec-1-ene–carbon monoxide) and the contact angle increases from 65° (for $CO/MeCH=CH_2$) to 110° (for oct-1-ene–carbon monoxide); on further increase in the chain length in the α-olefin ($>C_6$), the contact angle almost does not change. In propylene–carbon monoxide–higher α-olefin terpolymerisation, a decrease

† Creep is building-up of the deformation in the course of time under a constant load.

Table 12. Permeability with respect to O_2, CO_2 and moisture and other characteristics of the polymers used for packing foodstuffs.[274]

Polymer[a]	Permeability			Extrudability	Crystallisation rate	Duration of moulding
	O_2	CO_2	90% moisture (38 °C)			
PA (amorphous)	4–19	39	59–79	poor	see[b]	medium
PA (crystalline)	–	–	98	–	–	–
PETP (amorphous)	31–97	78–295	20–28	medium	see[b]	high
PETP (crystalline)	8.9–19	39–58	4.7–4.9	good	low	very high
PP	1170	3100	2.08	"	high	low
PC	777–970	1170	1239	medium	see[b]	medium
$CH_2=CH_2/CO/MeCH=CH_2$	8–19	93	12–47	very good	high	very low
$CH_2=CH_2/CO$	8–19	93	44–67	the same	"	the same

[a] Abbreviations: PA is polyamide, PETP is poly(ethylene terephthalate), PP is polypropylene, PC is polycarbonate. [b] Amorphous polymer.

in T_g can be attained by increasing the content of the higher α-olefin.

The ever-growing demand for thermally stable and easily processable polymers having specific gas permeability properties is due to the increased requirements for packaging of foodstuffs. The alternating copolymers of olefins and carbon monoxide are especially attractive in this respect because they are thermally and chemically stable. They are distinguished by good barrier characteristics (with respect to gases) not inferior to nylon or PETP; good compatibility with other polymeric packaging materials (*e.g.*, nylon, PC, PVC). The combination of high chemical stability and low permeability makes polyketones attractive also for the use as protective coatings and chemical containers especially in those cases where it is necessary to prevent the escape of organic compounds into the environment. Polyketones can be used for the manufacture of pipes and hoses meant for transfer of chemicals. In this case, in addition to chemical stability and low permeability, the polymers should possess high mechanical and abrasive strengths.

Due to the high adhesion to organic and inorganic materials, alternating copolymers can be used to design structural materials with high mechanical strength. Due to the low friction coefficient, high strength and relatively low specific gravity, these polymers can be advised for the use in mechanical engineering (gear units and other similar structures).

Low-molecular-mass polyketones are of interest for preparative small-tonnage chemistry. For example, ethyl vinyl ketone and 1,4-diketones can be used for the production of substituted cyclopentanones, which are structural elements of natural aromatic compounds possessing the jasmine odour.[296]

* * *

This review is an attempt to survey and analyse the key aspects of a new line of research promising for both scientific and practical purposes, namely, the synthesis of alternating copolymers and terpolymers of carbon monoxide with various monomers. The attention is focussed on the search of new Pd(II), Ni(II), Cu(II) and Ru(II) catalysts and new ligands and modification of known catalysts used in the synthesis of alternating copolymers based on carbon monoxide and olefins, dienes, styrene and their derivatives. Some properties and applications of the copolymers are considered.

The alternating terpolymers based on carbon monoxide, ethylene and propylene (so-called aliphatic polyketones) manufactured in industry refer to a new class of structural polymers that combine high melting points (220–260 °C), good adhesion to organic and inorganic materials, high strength, high chemical stability and so on.

It is clear that the research and industrial projects executed during the last 10–15 years (after the beginning of studies of the effective copolymerisation of carbon monoxide with ethylene) represent only an early stage of the comprehensive investigation of the alternating copolymerisation of CO with various monomers.

The review was written with the financial support of the Russian Foundation for Basic Research (Project Nos 01-03-33248, 01-03-07004) and the INTAS (grant 00-00677).

V.	Conclusion	306

Abstract. A critical review of the published data on the mechanism of decomposition of secondary nitramines is presented. Based on the data available, it is concluded that the first step of decomposition always includes cleavage of the $N-NO_2$ bond, which is followed by various secondary reactions and sometimes by chain processes. The effects of structures of nitramines on their stabilities are considered. The bibliography includes 113 references.

I. Introduction

Thermal decomposition of secondary nitramines including potent explosives, such as tetryl (*N*-methyl-*N*,2,4,6-tetranitroaniline), hexogen (1,3,5-trinitro-1,3,5-triazacyclohexane), octogen (1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane), cyclotetramethylenetetranitramine, hexanitrohexaazaisowurtzitan (CL-20), *etc*.,[1] has been the subject of intensive studies over many decades. In addition to numerous original papers, this topic has been considered in several reviews.[2–8]. Elucidation of the mechanism of decomposition of secondary nitramines is one of the most complicated problems. The diversity of the decomposition products which depends on the reaction conditions suggests the existence of several competing channels of decomposition of secondary nitramines. More than 10 putative mechanisms for the first step of decomposition of hexogen and octogen have been proposed. These include abstraction of the oxygen atom from the nitro group, nitro – nitrite rearrangement, ring expansion and contraction, elimination of HNO_2 and heterolytic and homolytic dissociation of the $N-NO_2$ bond. All these mechanisms, with the exception of the latter, were rejected as being inconsistent with the thermochemical values of the thermal effects of the reactions or contradictory to the theoretical interpretation of the deuterium kinetic isotope effect (DKIE) or based on unreliable experimental data. The use of high-precision methods for kinetic measurements and analysis of the primary reaction products and calculation of the dissociation energy of the $N-NO_2$ bond have made it possible to establish a reliable reaction mechanism. By the late 1980's a definite conclusion could be drawn that the homolytic cleavage of the $N-NO_2$ bond is the only reaction characteristic of the first step of decomposition of secondary nitramines in both the melt and the solid state. This assumption was repetitively put forward in previous studies (see, *e.g.,* Refs 4 and 5). However, some of the results obtained in the study of secondary nitramines in solutions were at variance with a simple homolysis of the $N-NO_2$ bond. Thus the decomposition of hexogen in benzene is characterised by a DKIE of the solvent and in tetrahydrofuran this reaction has a negative activation volume, *i.e*., its rate does not decrease with an increase in the external pressure, which is typical of the bond cleavage, but shows a tendency to increase. It was not until the late 1990's that the decomposition of hexogen in certain solvents was shown to follow the chain mechanism; however, the first step of decomposition always includes the cleavage of the $N-NO_2$ bond.

The main attention in the study of the decomposition mechanism of secondary nitramines is given to three compounds, *viz*., *N*-nitrodimethylamine (dimethylnitramine, DMNA), the first member in the series of aliphatic nitramines and its typical representative, which is especially suitable for the study of the decomposition products; hexogen, a cyclic nitramine with pyramidal nitramine groups; and octogen, a hexogen analogue with planar nitramine groups. The nature of the decomposition products and the isotope effects have been established for these compounds and theoretical calculations of the rates of individual decomposition steps have been carried out. The kinetic parameters (the activation energies and preexponential factors) of decomposition reactions for several dozens of nitramines have been determined.

Analysis of the mechanism of thermal decomposition of nitramines (in the examples of the three aforementioned key compounds) is mainly based on the studies which contain information relevant to elucidation of the mechanism. The kinetic characteristics of initial decomposition steps of all nitramines studied are discussed and the correlation between the reaction rates, the structure of the starting compound and the specific decomposition mechanism is analysed.

We started our consideration of decomposition mechanism with the description of non-catalytic processes reflecting the thermal stabilities of concrete compounds. Other aspects of the decomposition of secondary nitramines, *e.g*., reactions on their combustion, are considered in detail in the review.[8]

II. The mechanism of thermal decomposition of dimethylnitramine

The first study devoted to the decomposition of DMNA was carried out by Flournoy[9] in 1962. It was found that the decomposition of this compound in vapour at pressures of 0.25–1.0 atm is first order, the reaction rate being independent of the addition of NO. The decomposition products include Me_2NNO (80%), $MeNO_2$, CO_2, CO, H_2O, N_2O, NO and N_2, the extent of decomposition at 165 °C being 1.6%. A comparison of the experimental value of the activation energy E_a (222 ± 21 kJ mol^{-1}) with the energy of the N–N bond cleavage [D(N–N)] calculated on the basis of approximate thermochemical data (230 kJ mol^{-1}) (see Ref. 10) prompted a conclusion that the decomposition of DMNA begins with the cleavage of the N–N bond and proceeds in accordance with the reactions (1)–(3).

$$Me_2NNO_2 \longrightarrow Me_2N^{\bullet} + NO_2, \quad (1)$$

$$NO_2 + Me_2NNO_2 \longrightarrow NO + \text{oxidation products}, \quad (2)$$

$$Me_2N^{\bullet} + NO \longrightarrow Me_2NNO. \quad (3)$$

It is noteworthy that the cited paper[9] does not provide any evidence for a direct reaction of NO_2 with DMNA. In all probability, the reaction (2) is an overall process of formation of light gases upon decomposition of DMNA. A more detailed description of the reaction (2) can be found in Refs 11 and 12. Using a manometric method, Korsounskii *et al.*[11,12] have demonstrated that at initial vapour pressures $p_0 = 0.08-0.5$ atm the reaction proceeds with acceleration by a two-step consecutive pathway. The rate constant for the initial step k_1 does not depend on p_0, while the rate constant for the second step k_2 increases with the increase in p_0. The Arrhenius parameters for k_1 [$E_a = 170.8$ kJ mol^{-1} and $\log A = 14.1$ (s^{-1})] were ascribed to the reaction (1). It was found that the decomposition rate of DMNA increases upon addition of NO_2, however, an increase in the decomposition rate was also observed after addition of formaldehyde which binds NO_2. In the presence of an excess of CH_2O, the decomposition of DMNA is described by a first-order equation; further addition of NO_2 does not influence the reaction rate. Thus, the increase in the reaction rate is limited by a factor of three.

To account for these facts, it was suggested that NO_2 plays a dual role in the decomposition of DMNA, namely, it reacts with nitramine by the reaction (2) and recombines with the radical $Me_2N^{\bullet}$ with regeneration of DMNA, *i.e.,* the reaction (–1) occurs, which is the reverse of the reaction (1).

$$Me_2N^{\bullet} + NO_2 \longrightarrow Me_2NNO_2. \quad (-1)$$

At NO_2 concentrations existing during decomposition of DMNA, the reaction (–1) prevails over the reaction (2). In the presence of CH_2O, the activation energy E_a is equal to 162.8 kJ mol^{-1} and $\log A = 13.7$ (s^{-1}). Probably, in this case the activation energy was determined not very accurately. Thus, the increase in the decomposition rate of DMNA in the presence of CH_2O should be due to an increase in the preexponential factor rather than to a decrease of the activation energy. In addition, it should be kept in mind that the values of $A < 10^{14}$ s^{-1} are not typical of the cleavage of the N–NO_2 bond. A more reliable value of E_a was obtained for pure DMNA, and this was identified with D(N–N).[11]

The decomposition rates and activation energies of other aliphatic and cyclic nitramines (*e.g.*, diethylnitramine, di-n-propylnitramine, nitromorpholine) and dinitropiperazine are similar to those for DMNA. Thermochemical calculations[2] give D(N–N) equal to 193.4 kJ mol^{-1}, which is inconsistent with that determined by a kinetic method; nevertheless, this is used in subsequent studies (see, *e.g.*, Ref. 13). Shaw and Walker[2] estimated D(N–N) in DMNA using the enthalpy of formation of the radical $Me_2N^{\bullet}$ (159 kJ mol^{-1}) calculated for the reaction:

$$Me_2NH \longrightarrow Me_2N^{\bullet} + H^{\bullet}$$

taking D(N–H) equal to 393.5 kJ mol^{-1}.

The last value was obtained in the study of high-vacuum pyrolysis (VLPP) of dimethylamine[14] and appeared to be erroneous. The use of a more precise value of D(N–H) (360 kJ mol^{-1}) and of $\Delta H_f^{\circ}(Me_2N)$ (123.4 kJ mol^{-1}) taken from the reference book[15] yields the magnitude of D(N–NO_2) in DMNA close to 167.5 kJ mol^{-1}.

In more recent studies,[16] the decomposition of DMNA was studied under static conditions at 193–251 °C and in a shock tube at 527–727 °C, the concentration of DMNA being determined by a spectral method. Over the whole temperature range, E_a was equal to 92 kJ mol^{-1}, which can most probably be explained by imperfection in the experimental procedure. Presumably,[16] the formation of Me_2NNO occurred in the reaction (3), whereas NO was formed in the reactions (4) and (5).

$$Me_2N^{\bullet} + NO_2 \longrightarrow 2\,MeNO, \quad (4)$$

$$MeNO \longrightarrow Me^{\bullet} + NO. \quad (5)$$

In 1989, Golden *et al.*,[17,18] who studied the pyrolysis of DMNA by the VLPP method, found the iminoxyl radical Me_2NO and NO among the reaction products. Assuming that these radicals are generated in the primary reaction, the authors proposed a decomposition mechanism for DMNA which involved the nitro–nitrite rearrangement, *i.e.*, an elementary reaction which proceeds *via* the formation of transition state **A**.

$$Me_2NNO_2 \longrightarrow \underset{\mathbf{A}}{(Me_2NONO)^{\neq}} \longrightarrow Me_2NO + NO.$$

However, the next year this conclusion was refuted. The decomposition of DMNA was studied by the multiphoton laser excitation method[13] at 1.3×10^{-7} atm using a CO_2-laser with $\nu = 971.9$ cm^{-1} close to the internal rotation frequency of the CH_3 group in DMNA (987 cm^{-1}). Mass spectrometric studies revealed Me_2NNO, $CH_2{=}NMe$, $CH_2{=}NOH$, NO, NO_2 and Me_2NNMe_2 to be the pyrolysis products. The effect of free radical scavengers, such as Cl_2, NOCl, NO and NO_2, on the composition of the reaction products was studied and the concentration ratios $Me_2NNO : Me_2NNO_2$, $Me_2NCl : Me_2NNO_2$, $CH_2{=}NOH : Me_2NNO_2$ and $NO_2 : Me_2NNO_2$ were determined quantitatively. The addition of Cl_2 and NOCl resulted in the formation of Me_2NCl; the yield of NO_2 increased and the yield of tetramethylhydrazine decreased. The yields of Me_2NNO, $CH_2{=}NOH$, Me_2NNMe_2 and NO_2 increased in the presence of NO. The addition of NO_2 had no effect on the yield of Me_2NNO, but increased the yield of $CH_2{=}NOH$. The addition of DMNA-d_6, which does not absorb the energy of the laser irradiation due to the lack of the resonance frequency and, correspondingly, does not dissociate, resulted in the formation of $(CD_3)_2NNO$ but not $(CD_3)_2NN(CD_3)_2$ or $Me_2NN(CD_3)_2$. The results obtained were rationalised[13] on the basis of occurrence of the following reactions:

$$Me_2NNO_2 \longrightarrow Me_2N^{\bullet} + NO_2, \quad (1)$$

$$Me_2N^{\bullet} + Cl_2 \longrightarrow Me_2NCl + Cl^{\bullet},$$

$$Me_2N^{\bullet} + Me_2NNO_2 \longrightarrow Me_2NO + Me_2NNO, \quad (6)$$

$$Me_2N^{\bullet} + Me_2N^{\bullet} \longrightarrow Me_2NNMe_2, \quad (7)$$

$$Me_2NO \longrightarrow MeNO + Me^{\bullet},$$

$$MeNO \longrightarrow CH_2{=}NOH,$$

$$Me_2N^{\bullet} + NO \longrightarrow Me_2NNO, \quad (3)$$

$$Me_2N^{\bullet} + NO_2 \longrightarrow Me_2NO + NO, \quad (8)$$

$$Me_2N^{\bullet} + NO_2 \longrightarrow Me_2NNO_2. \quad (-1)$$

Thus, it was concluded that the cleavage of the N–N bond is the primary step in the decomposition of DMNA. The reaction of

Table 1. Vibration frequencies of models of transition states for the reactions (1), (9) and (10).[13]

Bond or group	ν (ground state) /cm^{-1}	ν (transition state) /cm^{-1}		
		cleavage of N–N bond	elimination of HONO	rearrangement
C–H	2940(6)		2000

[a] Free rotation.

the radical $Me_2N^{\bullet}$ with the starting DMNA (6) was introduced into the scheme of secondary reactions.

The Reiss–Ramsperger–Kassel–Marcus (RRKM) theory was used [13] to calculate the rate constants for the reactions (1), (9) and (10) depending on the internal excitation energy (E^*) of the DMNA molecule in the range of 188–335 kJ mol^{-1}. The vibration frequencies of the models of transition states of these reactions are given in Table 1, the energy characteristics are listed in Table 2.

$$Me_2NNO_2 \xrightarrow{k_{N-N}} Me_2N^{\bullet} + NO_2, \quad (1)$$

$$Me_2NNO_2 \xrightarrow{k_{iso}} Me_2NONO, \quad (9)$$

$$Me_2NNO_2 \xrightarrow{k_{elim}} CH_2{=}NMe + HONO. \quad (10)$$

It was found that $k_{N-N}/k_{iso} = 10^{2.2}\exp(-6.5/RT)$. Hence, at 877 °C where the nitro–nitrite rearrangement was supposed to take place,[18] the contribution of this route does not exceed 10%, which is below the threshold sensitivity of the experiment. The rate constant for the elimination of HONO at $E^* = 188.4$ kJ mol^{-1} was nearly 100 times lower than k_{N-N}.

It was also found [13] that Me_2NH, which is formed in the disproportionation reaction of the radical $Me_2N^{\bullet}$

$$Me_2N^{\bullet} + Me_2N^{\bullet} \longrightarrow Me_2NH + MeN{=}CH_2,$$

undergoes decay on the wall upon interaction with NO_2.

Table 2. Energy characteristics of transition states and kinetic parameters of the reactions (1), (9) and (10).[13]

Parameter	Ground state	Reactions		
		(1)	(9)	(10)
E_z /kJ mol^{-1}	249	220.6	241	245.3
E_0 /kJ mol^{-1}	–	194.6	178	167.4
I^*/I	1	6	1	1.5
ΔH_0 /kJ mol^{-1}	–	194.6	11.7	119.3
log$A$ (s^{-1})	–	15.5	12.7	13.3

Note. E_z is the zero energy of a molecule; E_0 is the critical energy of the reaction; I^*/I is the ratio of the moments of inertia of a molecule in the transition and ground states.

The energy profiles for the cleavage of the N–N bond and other reactions were calculated using the MNDO and MNDO/3 methods. [19] It was shown that the radical $Me_2N^{\bullet}$ readily reacts with NO_2. A mechanism of decomposition of DMNA including the reactions (3)–(5) and (8) *inter alia* has been substantiated.

$$Me_2NNO_2 \longrightarrow Me_2N^{\bullet} + NO_2, \quad (1)$$

$$Me_2N^{\bullet} + NO_2 \longrightarrow Me_2NO + NO, \quad (8)$$

$$Me_2N^{\bullet} + NO_2 \longrightarrow (MeNO)_2 \longrightarrow 2\,MeNO, \quad (4)$$

$$MeNO \longrightarrow Me^{\bullet} + NO, \quad (5)$$

$$Me_2N^{\bullet} + NO \longrightarrow Me_2NNO, \quad (3)$$

$$Me^{\bullet} + NO_2 \longrightarrow MeO^{\bullet} + NO,$$

$$Me^{\bullet} + NO_2 \longrightarrow MeNO_2.$$

Summation of the reactions that have been proved in the experimental and theoretical studies cited above together with well-established oxidation reactions of the radical $Me^{\bullet}$ and methyl nitrite by nitrogen dioxide [20] yields a detailed scheme of decomposition of DMNA in vapour (Scheme 1).

Scheme 1

$$Me_2NNO_2 \longrightarrow Me_2N^{\bullet} + NO_2, \quad (1)$$

$$Me_2N^{\bullet} + NO_2 \longrightarrow Me_2NNO_2, \quad (-1)$$

$$Me_2N^{\bullet} \longrightarrow CH_2{=}NMe + H^{\bullet}, \quad (11)$$

$$Me_2N^{\bullet} + NO_2 \longrightarrow Me_2NO + NO, \quad (8)$$

$$Me_2N^{\bullet} + NO \longrightarrow Me_2NNO, \quad (3)$$

$$Me_2N^{\bullet} + Me_2NNO_2 \longrightarrow Me_2NO + Me_2NNO, \quad (6)$$

$$2\,Me_2N^{\bullet} \longrightarrow Me_2NNMe_2, \quad (7)$$

$$Me_2NO \longrightarrow MeNO + Me^{\bullet},$$

$$MeNO + NO_2 \longrightarrow MeNO_2 + NO,$$

$$MeNO \longrightarrow Me^{\bullet} + NO,$$

$$MeNO \longrightarrow CH_2{=}NOH,$$

$$MeNO + 2\,NO \longrightarrow MeO^{\bullet} + N_2 + NO_2,$$

$$Me^{\bullet} + NO_2 \longrightarrow CH_2O + HNO_2,$$

$$2\,HNO_2 \longrightarrow H_2O + NO + NO_2,$$

$$MeO^{\bullet} + NO_2 \longrightarrow CH_2O + NO,$$

$$CH_2O + NO_2 \longrightarrow CO + CO_2 + H_2O + NO.$$

In Scheme 1, the reaction (11) is characterised by a relatively high activation energy and may compete with the reactions (3) and (8) at very low pressures. Under normal conditions, the reaction (6) does not occur (otherwise, the inhibiting effect of NO would be apparent); the recombination reaction (7) is also related to secondary processes. Undoubtedly, the oxidation of DMNA by nitrogen dioxide occurs at high pressures of NO_2, the relative ease of oxidation seems to be due to the presence of a trivalent nitrogen atom in the DMNA molecule.

The kinetics of decomposition of DMNA at 240 °C in various solvents was studied at DMNA concentrations ranging from 0.01 mass % to 0.5 mass %. The first-order rate constants $10^4 k$ s^{-1} were determined using a chromatographic method [21] and were found to be equal to 11 (in cyclopentane), 9.3 (in cyclohexane), 9 (in isooctane), 3.2 (in n-butanol), 1.73 (in benzene) and 0.71 [in glycerol triacetate (triacetin)].

The effect of the solvent on the decomposition of DMNA was interpreted [21] in terms of the cage effect, which should have been manifested due to the reversibility of the initial step of dissociation of the N–N bond. Presumably, cleavage of the N–N bond is accompanied by an alternative decomposition route, *viz*., elimination of HONO.

The DKIE value equal to 1.56 observed in the decomposition of DMNA-d_6 in benzene at 240 °C is an argument in favour of a mechanism which involves elimination of HNO_2. However, as follows from the general theory of the kinetic isotope effect,[22] this value is too small for the primary isotope effect, but is rather consistent with the secondary isotope effect due to a decrease in the rocking vibration frequencies of the CH_3 groups in the radical $Me_2N^{\bullet}$ formed upon cleavage of the N–N bond. This conclusion was totally confirmed by calculations of the isotope effects carried out in 1997.[23]

There is additional evidence in favour of the above-mentioned mechanism.[21] The volume of activation ($\Delta V^{\neq}$) of DMNA decomposition in isooctane (227 °C, 2% solution, 10^3-10^4 atm) was equal to 30 $cm^3\ mol^{-1}$. Should elimination of $HONO^{\bullet}$ occurred, the value of $\Delta V^{\neq}$ would be negative. The decomposition of a 1 : 1 $Me_2{}^{14}N{}^{14}NO_2 - Me_2{}^{15}N{}^{15}NO_2$ mixture resulted in total redistribution of the label in the reaction products, such as Me_2NNO, NO and N_2. The decomposition of $Me_2N^{15}NO_2$ in the presence of $^{14}NO_2$ resulted in total redistribution of the label in Me_2NNO as well. It was also found[21] that the $^{15}NO_2$ group in $Me_2N^{15}NO_2$ is partly exchanged for free nitrogen dioxide $^{14}NO_2$. These data altogether clearly demonstrate that Scheme 1 involves the reactions (−1) and (3).

The formation of N_2 upon decomposition of DMNA was rationalised[21] by insertion of oxygen of the nitro group into the C–H bond

$$\begin{array}{l} MeN(CH_2OH)-N=O \longrightarrow MeN(CH_2OH)-N=O \longrightarrow MeN=NOH + CH_2O, \\ MeN=NOH \longrightarrow N_2 + MeOH, \end{array} \qquad (12)$$

or by elimination of HNO_2 with subsequent nitrosation of $MeN=CH_2$.

$$Me_2NNO_2 \longrightarrow MeN=CH_2 + HNO_2 \longrightarrow MeN=NOH + CH_2O.$$

Since neither CH_2O nor MeOH was detected among DMNA decomposition products, the formation of N_2 can be explained by occurrence of the reaction (13), which proceeds with extremely high efficiency despite its trimolecular character.[24]

$$MeNO + 2\,NO \longrightarrow Me^{\bullet} + N_2 + NO_3. \qquad (13)$$

It was assumed[21] that the formation of N_2 and acetone upon decomposition of diisopropylnitramine results from insertion or elimination reactions:

$$2\,(Me_2CH)_2NNO_2 \longrightarrow (Me_2CH)_2NNO + 2\,Me_2CO + N_2 + H_2O.$$

However, in this case, too, these products can be formed in ordinary reactions, since it is known that radicals $Me_2\dot{C}H$ and $Me_2CHO^{\bullet}$ yield acetone in oxidising media.[25]

$$(Me_2CH)_2NNO_2 \longrightarrow (Me_2CH)_2N^{\bullet} + NO_2,$$

$$(Me_2CH)_2N^{\bullet} + NO_2 \longrightarrow Me_2CHNO + Me_2\dot{C}H + NO,$$

$$(Me_2CH)_2N^{\bullet} + NO \longrightarrow (Me_2CH)_2NNO,$$

$$Me_2CHNO + 2\,NO \longrightarrow Me_2\dot{C}H + N_2 + NO_3,$$

$$Me_2\dot{C}H + NO_2 \longrightarrow Me_2CHO^{\bullet} + NO,$$

$$Me_2CHO^{\bullet} + NO_2 \longrightarrow Me_2C=O + HNO_2.$$

Thus, the data available on the secondary decomposition products do not contradict the cleavage of the N–N bond in the first step. It may thus be expected that the decomposition of other aliphatic secondary nitramines will also proceed in a similar fashion ($E_a \approx 170$ kJ mol^{-1}, $A \approx 10^{14.5}\ s^{-1}$) and will yield *N*-nitroso compounds, aldehydes, N_2 and H_2O as the main products.

III. The mechanism of decomposition of hexogen and octogen

Decomposition of hexogen and octogen follows the same regularities; therefore, these reactions are often studied simultaneously. The differences in the spatial structures of the nitramine groups[26] of these compounds affect only the initial rates, but not the reaction mechanism.

The first study of thermolysis of hexogen melts was carried out in 1944 (for a review, see Ref. 8). The presence of nitrogen dioxide in the decomposition products suggested that the initial step involved the cleavage of the $N-NO_2$ bond.

More detailed studies on the decomposition kinetics of hexogen and octogen were carried out in 1948–1949.[27,28] The decomposition rates of hexogen were measured in the gas phase, melts and solutions in dicyclohexyl phthalate and 2,4,6-trinitrotoluene. The decomposition of octogen was studied both in vapour and in the solid state. The decomposition products contained large amounts of CH_2O and H_2O as well as N_2, N_2O, NO, CO and H_2. Tables 3 and 4 illustrate quantitative data on the

decomposition products of hexogen and octogen [27–32] which are summarised in the review.[4] Later, minor decomposition products (H_2NCHO, $MeNHCHO$, Me_2NCHO, Me_2NNO, Me_2NNO_2) were identified.[33] The reliability of the results obtained [33] is doubtful due to ambiguity of the interpretation of mass-spectrometric data. Therefore, it is the products formed in high molar yields (CH_2O, N_2O, N_2, NO, CO, CO_2, HCN and H_2O) that can serve as the basis for an analysis of the decomposition mechanism. The non-volatile residue † of the polyamide type was also taken into consideration; its yield depended on the experimental conditions and could reach 10%.[33]

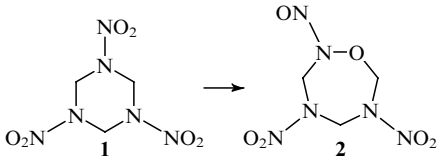
According to Robertson,[28] the major reaction products, *viz*., CH_2O and N_2O, are formed due to transfer of an oxygen atom from the nitro group of hexogen (**1**) to the neighbouring CH_2 group. The ring expansion product, *viz*., compound **2**, undergoes decomposition to give CH_2O and N_2O.

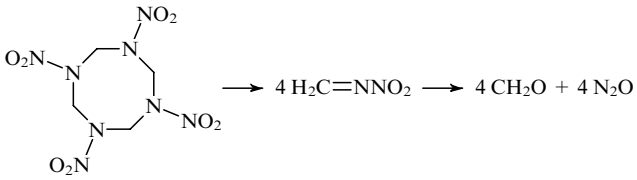


A typical methodological error has been made in the study [28] where the products of secondary reactions were ascribed to the first reaction step.[29]

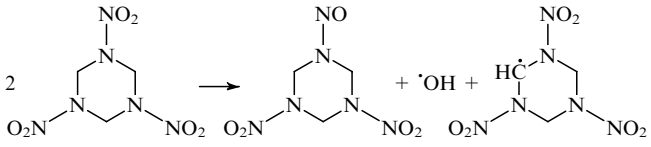
Studies of the solid-phase and solution (*m*-dinitrobenzene) decomposition of hexogen and octogen revealed a weak concentration dependence of the reaction rate.[34] The experimental values of activation energies coincided with those obtained by Robertson.[28] Cleavage of the N–NO_2 bond was postulated as the initial step of the reaction on the basis of approximate thermochemical estimates of D(N–N) in hydrazine derivatives.[35]

Valuable information for the interpretation of the mechanism was obtained using a tracer method.[30] Studies of the decomposition of octogen with a ^{15}N-labelled nitro group and a ^{14}N-labelled amino group revealed formation of $^{14}N^{15}NO$, $^{14}N^{15}N$, ^{15}NO and $HC^{14}N$ exclusively. The formation of products with such distribution of the label may occur by various routes, but cleavage of the C–N bond (rather than of the N–N bond) was thought to be predominant and a fragmentation mechanism with simultaneous cleavage of four C–N bonds was postulated.[30]

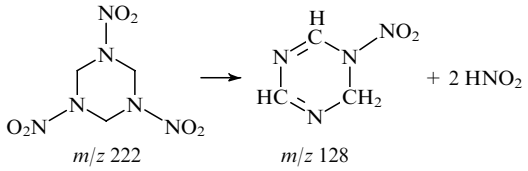
† The term 'non-volatile residue' was introduced [33] for the description of condensation products of the polyamide type which are always formed in small amounts upon decomposition of hexogen and octogen.



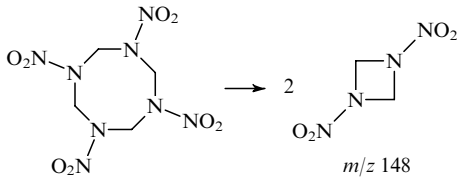
An X-ray diffraction analysis carried out in 1971 revealed [36] the existence of a very tight contact (smaller than the sum of the van der Waals radii of O and H atoms) between a nitro group of one hexogen molecule and a hydrogen atom of the other molecule. Based on these data, a bimolecular reaction was proposed which included direct interaction of two hexogen molecules. However, this hypothesis is untenable due to high endothermicity of this process.



The decomposition of hexogen and octogen was studied using mass spectrometric methods. Thus the decomposition of hexogen vapour in a flow reactor at 240–290 °C resulted in the appearance of species with m/z 128. This has made it possible to propose a mechanism for fast cleavage of two HONO molecules (for a review, see Ref. 8).



The decomposition of hexogen and octogen in vacuum (10^{-3}–10^{-5} atm) afforded species with m/z 148.[37,38] It was thus assumed that the decomposition of octogen involves opening and contraction of the ring and elimination of HNO_2.[38]



However, in these studies the vapours of the starting compounds and their decomposition products were not separated and their inlet into the chamber of the mass spectrometer occurred simultaneously. As a result, the ions generated upon fragmentation of the hexogen or octogen molecules under the electron impact might be mistaken for thermolysis products.

A significant contribution to the study of decomposition mechanisms of octogen was made in 1977 [2] when all the mechanisms postulated so far (with the exception of the cleavage of NO_2 and elimination of HNO_2 *via* a five-membered transition state) were abandoned based on the results of thermochemical estimates of thermal effects for different reactions. The equation for the calculation of the cleavage rate of the N–N bond appears as:

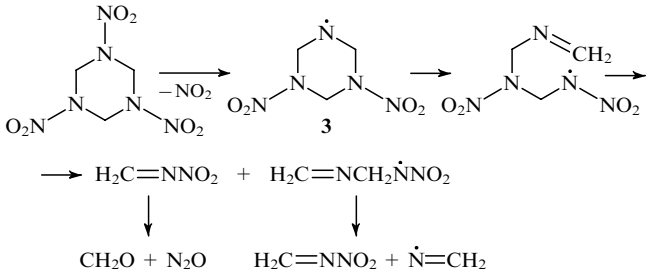
$$\log k_{N-N} = 16.4 - \frac{46\,200}{2.3\,RT}\ s^{-1},$$

and that for the elimination of HNO_2 as:

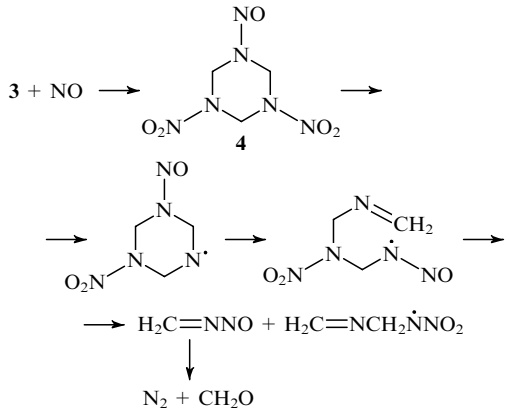
$$\log k_{elim} = 10.8 - \frac{38\,000}{2.3\,RT}\ s^{-1}.$$

It was found that a change in the decomposition mechanism occurred at 333 K.

A remarkably detailed analysis of the decomposition mechanism of hexogen and octogen was made by Schroeder [3,4] who has explained the formation of the major products by secondary reactions following cleavage of the $N-NO_2$ bond.[4]



This scheme was supplemented by an entrapment of the radical **3** by nitrogen oxide and dissociation of the $N-NO_2$ bond in nitroso derivative of RDX **4** formed.



EPR studies have shown [39] that pyrolysis products of hexogen at 260 °C contain large amounts of NO_2 and $H_2C=N^{\bullet}$ radicals, which is a direct proof of the Schroeder scheme.[4]

However, Schroeder noted that it is the elimination of HNO_2, rather than the abstraction of NO_2 that prevails in the gas phase at low temperatures. This statement was made on the basis of the rather low activation energy obtained for the decomposition of hexogen vapour ($\sim$ 125 kJ mol^{-1}). In our opinion, the data available are contradictory and the use of the activation energy measured with a large error is unreliable for an adequate explanation of the mechanism.

The kinetic isotope effect in the decomposition of HMX-d_8 in the solid phase was measured.[40] It was found that the ratio of the rate constants for normal and labelled HMX (k_H/k_d) was equal to 2 in the induction period and to 0.8 and 1.0 in the acceleration and deceleration steps, respectively. These measurements were performed using differential thermal analysis; therefore, it was correctly noted that the data obtained were more relevant to the overall process rather than to its first elementary step, particularly to heat liberation reactions.[23] For example, the products of oxidation of formaldehyde by nitrogen dioxide were often found in early decomposition steps of octogen.[5,7,8]

The formal kinetic regularities of decomposition of hexogen and octogen in the solid phase and the effects of gaseous decomposition products on the reaction rates have been studied.[36,41–44] It was found that the solid-phase reaction is complicated by several factors, *e.g.*, evaporation of the sample and fast reaction occurring in the gas phase, melting of the sample on the decomposition products, autocatalysis and a cage effect. Thus, the decomposition rate depends on the degree of filling of the reaction vessel with the substance, pressure of extraneous gases, mass and even the shape of the sample. Some products, *e.g.*, N_2, CO and CO_2, inhibit the decomposition by preventing the evaporation of the substance and, as a consequence, the course of the gas-phase process. The addition of NO_2 and O_2 produces an even stronger effect, most probably due to reversibility of the first step of decomposition.

The rate and activation energy measured in the decomposition of solid samples do not fit into the mechanism of monomolecular radical cleavage of the N–N bond, since this reaction is superimposed by numerous secondary processes. All these side factors were taken into consideration and the lowest values of the rate constant were obtained in the solid phase (k_{solid}).[26]

Significant progress has been made in the past decade in the development of highly sensitive dynamic methods for monitoring the decomposition of hexogen and octogen. One of them, *viz.*, FT-IR spectroscopy, was used for monitoring the decomposition of solid hexogen and octogen in a nitrogen atmosphere at heating rates up to 200 K s^{-1} (see Refs 45 and 46). The main reaction products are NO_2, N_2O, CH_2O and HCN. The concentrations of NO_2 and CH_2O decrease with time, while that of NO increases, which suggests that formaldehyde is oxidised by nitrogen dioxide. These results fit well into the Schroeder scheme.[4]

A procedure for studying the primary step in the decomposition of hexogen in the solid phase has been developed.[47,48] A thin film of the sample is placed onto a massive support and irradiated *in vacuo* by short (35 μs) pulses of a CO_2 laser at 77 K. This leads to instantaneous heating of the support to 1200 K and cooling to 400 K within 3×10^{-3} s. The decomposition products were analysed by IR spectroscopy directly in the solid phase which remained after partial evaporation of the sample. The dimer N_2O_4 was identified as the only primary decomposition product. Further analysis based on the use of the tracer method revealed that NO_2 molecules forming the dimer originate from different hexogen molecules, *i.e.*, one hexogen molecule always yields only one NO_2 species. This can be regarded as a direct proof that the cleavage of the $N-NO_2$ bond is the only initial step in the decomposition of solid hexogen.

A more complicated situation was observed when the decomposition of hexogen was studied in solutions. An analysis of hexogen and its decomposition products in benzene and benzene-d_6 by liquid chromatography quite unexpectedly revealed [49] that the rate of this reaction is higher in solutions than in the melts. A kinetic isotope effect of the solvent was observed at 180 °C (k_H/k_d = 1.6). This was accounted for by a direct reaction of hexogen with a solvent:

$$>NNO_2 + RH \longrightarrow ROH + >NNO.$$

Actually, this reaction is hardly possible, since its endothermic thermal effect is no less than 250 kJ mol^{-1}, while the activation energy of hexogen decomposition does not exceed 170 kJ mol^{-1}. Besides, these data were not confirmed experimentally in further studies.[50] However, the possibility of the interaction of hexogen with solvents first postulated in 1985 [49] was corroborated by an analysis of their effects on the decomposition rate constant. The results of early studies suggest that such solvents as dicyclohexyl phthalate and *m*-dinitrobenzene are inert in the decomposition of hexogen.[28,34] However, subsequent studies have shown that the reaction rates strongly depend on the nature of the solvent in dilute solutions (Table 5).

It was found [52] that the decomposition of hexogen in THF has a negative activation volume ($\Delta V^{\neq} = -11$ cm^3 mol^{-1}). Thus, it was suggested that it is the elimination of HNO_2, rather than the homolytic cleavage of the N–N bond that is predominant in polar solvents. In this case, the transition state is polar and stabilised by the solvent. No additional evidence was given in favour of this pathway that was rejected earlier in the studies of DMNA decomposition in polar solvents and decomposition of hexogen in the melts and the solid state. As for elimination of HNO_2, it does not provide any adequate explanation for the fact that some hexogen analogues including octogen are characterised

Table 5. Effect of the solvent on the decomposition rate of hexogen at 180 °C.

by positive values of activation volumes in the decomposition in more polar solvents, *e.g.,* acetonitrile.[52]

The decomposition of 0.05% solutions of hexogen in benzene, acetone and isooctane was studied using a chromatographic method.[50] In this study, mononitrosohexogen, the yield of which in solution exceeded severalfold that in the melt, was identified as an intermediate product. This fact did not receive any adequate interpretation either, although it is evident that the solvent does influence the yields of nitroso derivative of RDX in one way or another. Unfortunately, the range of solvents used for the study of hexogen decomposition by chromatographic methods could not be expanded.

Clues to the problems related to decomposition of hexogen in solutions were obtained through the use of a highly efficient manometric technique which permits one to measure pressures up to 100 atm directly in glass reaction vessels.[53–55] The rate constants for the decomposition of hexogen at 180 °C were measured systematically in various solvents differing in their structures and properties. These studies included the measurements of DKIE of the solvents and an analysis of the effects of chain reaction inhibitors on the decomposition rate. The main results of these studies are summarised in Table 6.

The solvents from 1,2,4-trichlorobenzene to acetonitrile (Table 6) are inert with respect to hexogen, at least they do not cause any appreciable increase in the decomposition rate in comparison with the melt. This group includes structurally diverse compounds, *e.g.*, aliphatic and aromatic hydrocarbons, fluorinated alkanes, chloro- and nitro-derivatives of benzene. In benzene, naphthalene, isooctane and acetonitrile, the decomposition rates are similar within the limits of the experimental error and exceed only slightly that in the melt. However, in other solvents of this group they are lower than in the melt, which can be attributed to the cage effect characteristic of viscous media. A similar effect was observed for DMNA,[21] the first decomposition step for which, *viz*., the cleavage of the N—N bond, is reversible.

Acetonitrile and nitrobenzene manifest the highest values of dielectric permeability in comparison with other solvents, naphthalene being the most potent π-donor. However, all these compounds are inert with respect to hexogen. As a consequence, such

factors as polarity or tendency of a solvent to form charge-transfer complexes do not influence the decomposition rate of hexogen.

The second group includes solvents where decomposition occurs at higher rates in comparison with the melt. This group includes alkylaromatic hydrocarbons, alcohols, ketones, aldehydes, chloroform and some other compounds. Their common property is the presence of labile hydrogen atoms, *i.e.*, unstable C–H bonds (in the case of non-polar compounds, *e.g.*, toluene) or relatively stable, but polarised and therefore highly reactive C–H bonds as, *e.g.*, chloroform and alcohols. These solvents always manifest DKIE, which suggests involvement of the cleavage of the C–H bond.

The curve for the dependence of the decomposition rate constant of hexogen (k_1) on the bond dissociation energy D(C–H) of the solvent has a maximum. The data on D(C–H) are scarce; therefore, a regularity can be established only approximately using the D(C–H) values (in kJ mol^{-1}) as reference points for the following solvents: aliphatic hydrocarbons, toluene (356), *m*-xylene (325), *p*-xylene (322), diphenylmethane (262) and triphenylmethane ($\sim$ 255).[15] The rate constants measured in aliphatic hydrocarbons, *e.g.*, isooctane, are nearly the same as in the melt. In toluene, this increases threefold, whereas in *m*- and *p*-xylene the difference between k_1 values in the melt and in solution is as high as five- to sevenfold. For diphenylmethane, the k_1 value is higher than for benzene, but lower than for xylenes and even for toluene. Triphenylmethane inhibits the decomposition. The solvents containing polar C–H bonds ($CHCl_3$, alcohols) strongly affect reaction rates at D(C–H) > 360 kJ mol^{-1}.

At 180 °C, the maximum increment in k_1 (11-fold when compared with the melt) is observed for glycerol. With a decrease in temperature, the difference between k_1 values in the melt and in solution is expected to increase due to lower activation energy in solutions. The activation energy E_a in inert benzene is equal to 169 and in toluene and butane-1,4-diol it is equal to 158 and 135 kJ mol^{-1}, respectively.

The decomposition products of hexogen in the gas phase contain N_2, N_2O, CO, CO_2, trace amounts of NO and small amounts of formaldehyde and water. Lower molar yields of gaseous products with a decrease in the concentration of hexogen is characteristic of decomposition in solutions. In the melt, the total yield of gaseous products is about 5 mol per mol of hexogen, whereas in 0.5% solution in benzene it is as low as 0.5 mol. It was found that the decomposition of 1% hexogen in toluene affords benzaldehyde, benzonitrile and benzyl alcohol in 0.43, 0.32 and 0.43 mol yields per mol of hexogen, respectively. Phenylnitromethane and benzoic acid are also present in small amounts. These findings provide supporting evidence for the involvement of the solvent in the reaction.

The DKIE was observed in all solvents that accelerate the decomposition, and typical inhibitors of chain reactions (*e.g.*, NO, NO_2, *p*-dinitrosobenzene) bring the rate constant down to a level characteristic of inert solvents. These data altogether led to a hypothesis [53] on a chain decomposition mechanism of hexogen in solvents containing reactive C–H bonds and a monomolecular mechanism for this decomposition in inert media. Detailed kinetic schemes for both mechanisms were developed and rationalised; it was shown that they are consistent with the experimental data.[53, 55]

An example of a non-chain decomposition mechanism of hexogen in solutions is given in Scheme 2.

The reactions (14)–(18) reproduce the basic decomposition mechanism proposed by Schroeder.[4] Other reactions are common to the reactions of NO and NO_2 with free radicals of the C- and N-types as well as for polymerisation and oxidation of unsaturated compounds, isomerisation of nitroso compounds and some other reactions.

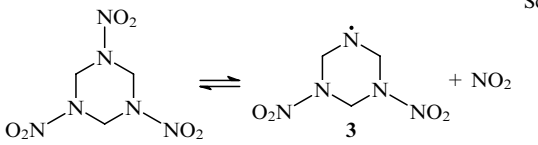
The decomposition begins with the dissociation of the N–N bond [reaction (14)]. Like any other dissociation of a molecule into radicals, this reaction is reversible and a cage effect can be observed in viscous media. The radical **3** undergoes isomerisation into the radical **5** which is then decomposed by the reaction (16) to yield an inactive radical $CH_2=N^{\cdot}$. The radical **3** reacts also with NO and NO_2. The reversible formation of mononitroso derivative of RDX **4** proceeds *via* the reaction (18). In contrast to unsubstituted aliphatic *N*-nitroso compounds, which are more stable than the corresponding secondary nitramines,[56, 57] nitroso compounds containing electronegative substituents (including diazacyclohexane derivatives) are less stable [58, 59] than their nitramine analogues. Compound **4** is formed as an intermediate product; its decomposition occurs 10 times faster than that of hexogen.[52] According to a theoretically rationalised mechanism of the reaction of aminyl radicals with NO_2 (see Ref. 60), the reaction (19) of the radical **3** with NO_2 should result in ring opening and the formation of a highly reactive dinitroso compound **8** and then of dioxime **9**. Polymerisation with the formation of a non-volatile residue [reaction (20)] is the most probable route to the conversion of the oxime **9**. Polymerisation of the unsaturated compound **7** [reaction (21)], which competes with its decomposition [reaction (17)], is yet another source of a non-volatile residue. Like nitroethylene, compound **7** is stable but prone to polymerisation. In the presence of NO_2, the unsaturated compounds **9** and **7** are easily oxidised to form gaseous products. It is noteworthy that the reactions (14) and (15) occur only with the radicals **3** and **5** containing a labile (75 kJ mol^{-1}) H_2C-NNO_2 bond in the β-position relative to the free valence.[61] The radical **6** contains no such bond.

The yield of N_2O is 1–1.5 molecules per molecule of hexogen rather than 2 as should follow from Scheme 2.[3] It is possible that the dissociation of the radical **6** into $CH_2=N^{\cdot}$ and compound **7** does not take place at all (the probability of such reaction in the

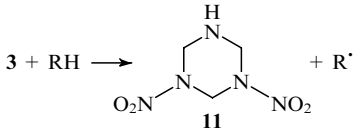
gas phase was first put in doubt [33]). Instead, the nitraminyl radical **6** is converted into the radical **10** in the presence of nitrogen oxides in the reactions (24) and (25).[62] The latter radical is easily oxidised to yield $HOCH_2NHCHO$, one of the decomposition products of hexogen,[3] and gaseous compounds.

The concentration of nitrogen dioxide in a solution depends on the partial pressure in the gas phase much more strongly than the concentration of NO. Therefore, the ratio of the rates of the reactions (19) and (18) will decrease with hexogen concentration, all other conditions being the same. The yield of the intermediate nitroso derivative **4** will increase correspondingly (*cf.* Refs 49 and 50). Similarly, the polymerisation reactions (20) and (21) will occur faster than the oxidation reactions (22) and (23) due to a sharp decrease in NO_2 concentration in very dilute solutions. This accounts for a significant decrease in the yields of gaseous products and an increase in the yield of the non-volatile residue at hexogen concentrations < 5%. Chain decomposition of hexogen in solution (RH is the solvent) is presented in Scheme 3.[55]

Scheme 3



(14)



(26)

$$NO_2 + RH \longrightarrow HNO_2 + R^{\bullet}, \quad (27)$$

$$R^{\bullet} + \mathbf{1} \longrightarrow \mathbf{4} + RO^{\bullet}, \quad (28)$$

$$RO^{\bullet} + RH \longrightarrow ROH + R^{\bullet},$$

$$\mathbf{4} \longrightarrow \mathbf{3} + NO,$$

$$R^{\bullet} + NO_2 \longrightarrow RO^{\bullet} + NO,$$

$$RO^{\bullet} + NO_2 \longrightarrow R'CHO + HNO_2,$$

$$R^{\bullet} + NO_2 \longrightarrow RNO_2,$$

$$R^{\bullet} + NO \longrightarrow RNO \longrightarrow R'CH{=}NOH \longrightarrow R'CN + H_2O,$$

$$RNO + 2\,NO \longrightarrow RO^{\bullet} + N_2 + NO_2.$$

R′ is R containing one CH_2 unit less.

The chain reaction begins with the reactions of the free radical **3** and NO_2, which are generated in the first step of decomposition, with the solvent [reactions (26) and (27)]. The reaction (26) is preferable, since it is more exothermic than the reaction (27) by nearly 40 kJ mol^{-1}. As a source of free radicals, the latter reaction can be neglected, since the addition of NO_2 decelerates rather than accelerates the process.

By virtue of the reaction (26) free radicals are not extinguished, and N-centred radicals inactive with respect to the nitro group are converted into C-centred radicals of the solvent. The isotope effect of the solvent is manifested in this step. The maximum rate of the reaction of the radical **3** with the solvent [reaction (26)] is reached at those $D(C-H)$ values which enable the competition of the reaction with the rearrangement of the radical **3** [reaction (15)]. For non-polar solvents, this value is equal to 360 kJ mol^{-1}. In solvents containing polar C–H bonds adjacent to heteroatoms (chloroform, alcohols), the reaction (26) proceeds at a sufficiently high rate even at $D(C-H) >$ 360 kJ mol^{-1}. The reaction (28) occurs only in the solvents in which the radical $R^{\bullet}$ retains its activity and the chain propagates. A combination of the reactions (26) and (28) results in the appearance of an extremum on the experimental curve for the dependence of k_1 on $D(C-H)$.

Extinction of the radicals $R^{\bullet}$ occurs in their reactions with NO_2 and NO, these are consumed in the reaction (28) with hexogen. The reaction of the radical $R^{\bullet}$ with hexogen occurs only where the concentration of the inhibitor (NO, NO_2, *etc.*) is four orders of magnitude lower than that of hexogen. This condition is usually fulfilled, since NO is poorly soluble in the liquid phase where other non-volatile inhibitors are virtually absent.

The rates of bimolecular reactions of the chain generation and propagation [reactions (26) and (28)] increase with pressure; therefore, the stability of hexogen in non-inert solvents will decrease at high pressures used for the determination of the activation volume. Hence, the negative activation volume of decomposition of hexogen in THF, one of the most active solvents,[52] can easily be explained. Many structural analogues of hexogen, *e.g.*, trinitrosohexogen and 1,3,3,5,5-pentanitropiperazine, are also characterised by negative activation volumes in THF.[52] Other hexogen analogues, including octogen, that were studied in acetonitrile (but not in THF), which was inert in this concrete case,[55] have positive activation volumes.

Despite their obvious incompleteness, the schemes of monomolecular (see Scheme 2) and chain decomposition of hexogen (see Scheme 3) in solutions [53, 55] provide an explanation for the principal experimental results, *e.g.*, the dependence of the yields of gaseous products on the concentration of hexogen, high yields of mononitrosohexogen in very dilute solutions of inert solvents, cage effects and, what is even more important, enhancing effects of some solvents and the negative activation volumes in the decomposition of hexogen in THF.

Further chain propagation is provided by the reaction of the radicals **3** with the solvent. This is favoured by low concentrations of gaseous inhibitors (NO and NO_2) in solutions and the absence of non-volatile free radical scavengers which cannot be formed from the methylene groups of hexogen. Apparently, this factor is the most important. Thus the final decomposition products of DMNA contain stable dimethylnitrosamine, while the intermediate products contain nitrosomethane and formaldoxime,[13] both of which are efficient free radical acceptors. Therefore, no chain reactions occur in the case of DMNA. All the solvents including alcohols are inert with respect to DMNA. The solvents listed in Table 6 appeared to be inert with respect to hexanitrohexaazaisowurtzitan (CL-20) as well.[54] Although the nitramine groups of this compound are structurally similar to those of hexogen, CL-20 cannot be regarded as its complete analogue. Owing to the presence in CL-20 of a stable carbon backbone, its decomposition affords numerous reactive products which remain in the condensed phase and prevent the onset of the chain reaction.[63, 64]

In contrast, the chain decomposition of octogen is very well-expressed.[54] As in hexogen, the nitramine groups are separated only by methylene groups, therefore, the formation of condensed products possessing inhibitory properties is prevented.

The chain mechanism described above eliminates all contradictions in the interpretation of decomposition reactions of hexogen and octogen. In solutions as well as in the melt and in the solid state, homolysis of the N–NO_2 bond is the first decomposition step.

IV. Structures and stabilities of secondary nitramines. Kinetic data

Unlike studies on DMNA, hexogen and octogen that have been the subjects of comprehensive examination (both theoretical and experimental), studies on the thermal decomposition of other secondary nitramines were largely confined to measurements of reaction rates and determination of kinetic parameters under various experimental conditions. Since the kinetic parameters of decomposition reflect its mechanism, it is appropriate to consider the correspondence of the kinetic data with the mechanism involving dissociation of the N–NO_2 bond. The known formal

kinetic characteristics of the decomposition of secondary nitramines are given in Table 7.

The maximum difference in the decomposition rates of nitramines is three orders of magnitude, data on decomposition of nitramines in the solid phase being set aside, since the rates here are determined not only by their structures, but also by their physical properties. This difference is only partly due to the errors in the determination of activation energies used for extrapolation of rate constants to reference temperature. In general terms, the differences in the decomposition rates are determined by the dependence of the energy of the N—N bond on the structure of the nitramine. It has been shown for the first time [26] that stability of a nitramine depends critically on the spatial structure of its nitramine groups. The activation energies for the decomposition

Table 7. Kinetic characteristics of decomposition reactions of secondary nitramines.

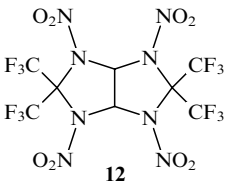
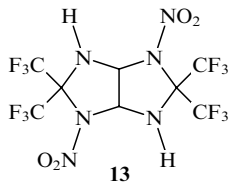
of planar nitramine groups are, on average, 172 kJ mol^{-1}, whereas that for the pyramidal group does not exceed 160 kJ mol^{-1}. In the case of hexogen, two of three nitramine groups are pyramidal, and it is 100 times less stable than octogen with all of the four groups planar. Low stability is also characteristic of 1,3-dinitro-1,3-diazacyclopentane (see Table 7) with pyramidal nitramine groups. At the same time, all the nitramines containing planar groups are decomposed at approximately the same rates. The frequencies of anti-symmetrical oscillations of the nitro groups (ν_{as}) are determined by the extent of the deviation of the nitramine groups from the planar structure.[103] The dependence of ν_{as} on the length of the N–N bond is linear. In its turn, the elongation of the bond is accompanied by a decrease in its strength. The maximum values of ν_{as} around 1600 cm^{-1} are observed for the nitramine groups attached to a five-membered ring or to even more strained rings as, *e.g.,* in CL-20 (see Table 7) or in compounds **12** and **13**.[103]



12



13

The frequency of anti-symmetrical oscillations of the nitro group ν_{as} of hexogen is 1570 (see Ref. 103) (*cf.* 1605 cm^{-1} for CL-20) (see Ref. 100). Therefore, CL-20 is 10 times less stable than hexogen.

There is a correlation between ^{13}C and ^{15}N chemical shifts in the NMR spectra and the kinetic parameters of the decomposition reactions.[104, 105] This correlation provides additional support in favour of a decomposition mechanism of secondary nitramines which involves cleavage of the N–NO_2 bond. This can also be used for predicting the stabilities of novel nitramines.

Resonance conjugation of the nitramine group with a phenyl substituent or another system of π-bonds is yet another factor which determines the stabilities of nitramines. For example, the activation energy for the decomposition of tetryl is 21 kJ mol^{-1} lower than that of dimethylnitramine and the reaction rate is 200 times higher. Nevertheless, the effect of conjugation on the D(N–NO_2) is rather weak. Similar structural changes, *i.e.*, passage from MeX to $PhCH_2X$, decrease the energies of the C–X bonds (X = H, NO_2, Hal) by 60 kJ mol^{-1} (see Ref. 15). The induction effects of substituents in the α- or β-positions on D(N–NO_2) and the decomposition rates of nitramines are very small.[90] This explains why virtually all secondary nitramines manifest high thermal stabilities and are widely used as explosives. The reduction of stabilities of secondary nitramines to a level which makes impossible their practical application requires a combination of two adverse factors, *viz*., the presence of two substituents that can manifest resonance conjugation (*e.g*., heterocycles) or a combined effect of the pyramidal structure of the nitramine group and one such substituent.

Thus, the formal kinetic parameters and the dependence of the decomposition rates on nitramine structures can be explained within the framework of an integral mechanism which postulates the cleavage of the N–NO_2 bond. It may be expected that other nitramines will manifest a decomposition mechanism similar to that of DMNA, hexogen or octogen and the decomposition rates will obey the regularities described above. For example, the decomposition rate in the liquid phase of a popular novel high-energy compound CL-20, which contains four pyramidal nitramine groups, is higher than that of hexogen or 1,3-dinitro-1,3-diazacyclopentane each containing two groups of the same structure.[54, 63, 64, 100–102, 106–108] This prognosis is fully corroborated by experimental results (see Table 7). Extrapolation of a detailed scheme of the non-chain decomposition of hexogen to CL-20 prompts an unambiguous conclusion about the formation of low-volatile nitroso compounds, aldehydes, unsaturated com-

pounds, and stable iminoxyl radicals. Determination of the functional groups in condensed products corroborates this conclusion.[63,64] The chain decomposition of CL-20 in solutions is impossible due to the formation of products able to scavenge free radicals. Indeed, all the solvents studied are inert with respect to CL-20.[54] Yet another novel promising explosive reagent, *viz.*, 1,3,3-trinitroazetidine (see Table 7), contains two functional groups that can undergo decomposition, *viz.*, a nitramine group and a dinitromethylene group. A comparison of parameters of decomposition of compounds containing such groups [109] suggests that the cleavage of the $N-NO_2$ bond at temperatures below 200 °C occurs several times faster than that of the $C-NO_2$ bond, whereas at 240 °C the rates of these reactions become similar. A conclusion about the existence of two parallel channels for decomposition of 1,3,3-trinitroazetidine with approximately the same rates was drawn on the basis of direct kinetic measurements and identification of the decomposition products.[68]

V. Conclusion

Significant progress has been achieved in the study of the mechanism of the first step of thermal decomposition of nitramines. Thus it has become possible to predict the rate of this step, which determines the thermal stability of a compound. Contrariwise, secondary reactions including those of the starting compound have been rather poorly studied. Reactions of nitramines with nitrogen dioxide have not been investigated; as yet, little is known about the autocatalysis of decomposition of nitramines in liquid and solid phases and the mechanism of autocatalysis also remains to be elucidated. Studies along these lines will be continued in the near future. A quantitative description of detailed decomposition schemes for the simplest molecules [110,111] can be used for the calculation of combustion rates.

The problem of decomposition of nitramines in the solid phase is closely related to the general problem of chemical kinetics, *viz.*, the development of a physical model of solid-phase monomolecular reactions. Analysis of effects of various factors, such as defects of a crystal lattice and phase transitions,[112] on the decomposition of hexogen and octogen have given a strong impetus to the further progress of these studies.[82,83,88] A search for nitramines that decompose in a non-localised manner, *i.e.*, uniformly over the whole crystal, presents special interest for investigators. Verification of semi-empirical models [113] allowing estimation of decomposition rate constants in the solid phase k_{solid}, requires comprehensive investigations which will include determination of the main characteristics of a crystal and study of a relationship between k_{solid} and melting temperature, structure and specific properties of a crystal, *e.g.*, compressibility, free volume, density and their temperature dependences. The immense diversity of secondary nitramines which differ in both decomposition rates and physical properties, leaves hope that compounds for such investigations will be found.

This review has been written with the financial support of the International Science and Technology Centre (Project No. 2324p).

VIII.	Conclusion	345

Abstract. The review considers methods of synthesis of cyclopalladated compounds of the PC- and PCP-type including intramolecular activation of the C–H bonds in the P-donor ligands, oxidative addition of preliminarily functionalised substrates to palladium(0), transmetallation of lithiated compounds, chelation of phosphine-substituted phosphorus ylides, and some non-standard processes resulting in a new ligand formation on a metal template. Particular attention has been given to the structural factors and experimental conditions that determine the feasibility of direct cyclopalladation of mono- and bidentate phosphines, phosphites and phosphinites. The bibliography includes 384 references.

I. Introduction

A driving force for writing of this review was the impressive progress achieved in the modern homogeneous metal complex catalysis due to the use of metallacycles as catalysts or precatalysts.[1–5] A pronounced increase in the catalytic activity due to *ortho*-metallation (for phosphites) was first detected by Lewis in 1986.[6,7] The unique role of phosphine complexes of palladium in classical homogeneous catalysis is known; therefore, it is not surprising that phosphapalladacycles occupy a central place in the new branch of catalysis.[1,5,8–12]

Some data concerning the chemistry of mono- and bicyclic compounds of this class, including their dendrimeric forms,[13] can be found in recent reviews dealing with cyclometallation (involving all metals [14–20] or only palladium [21]) and organopalladium compounds.[22] Among the survey papers devoted to cyclometallated structures each with one particular heterodonor atom,[19,23–28] only one publication [19] is known dealing with complexes of various metals with P-donor ligands (up to mid-1979). The monograph by Omae,[18] which summarises his earlier reviews is largely a compilation (as noted in a book review [29]).

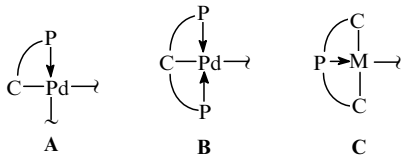
Uspekhi Khimii **73** (4) 339 – 382 (2004); translated by Z P Bobkova

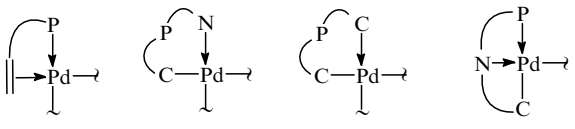
The intensive development of this field seen in recent years calls for a deliberate consideration of the existing routes to phosphapalladacycles known to date (up to the end of 2002) and elucidation of the specific features of the process of their formation.

The purpose of this review is to analyse the methods of synthesis of cyclopalladated complexes with P-donor atoms with the emphasis on the factors that determine the feasibility of this process. The reactions of phosphapalladacycles will be considered elsewhere. Compounds in which the metal is linked directly to one or two phosphorus(III) atoms and to one carbanionic centre incorporated in an anionic bi- or tridentate chelating ligand (mono- or bicyclic structures of kind **A** or **B**) were chosen as the objects. Optically active compounds of this type constitute the subject of a special review. Type **C** structures for palladium have not been obtained as yet, although for other transition metals (for example, Rh, Ir and Pt), not only CPC- [30,31] but also PCPC- [32] and PCCP-type complexes are known.[33]



A **B** **C**

Compounds of structural types **D** – **G** are beyond the scope of this review, because their properties differ appreciably from those typical of classical mono- or dianionic phosphapalladacyclic systems. These include compounds with phosphines chelated to the metal due to additional π-coordination through their double bonds (**D**);[34–39] metallacycles of other types, for example, CN- (**E**) [40,41] or CC-types (**F**),[41–45] containing a non-donor phosphorus atom; and bicyclic structures with the Pd–C and Pd←P bonds located in two different metallacycles (*e.g.*, those of **G** type).[46,47]



D **E** **F** **G**

† The first review in a series of publications devoted to the chemistry and stereochemistry of phosphapalladacycles.

Conversely, PC-chelated phosphine-substituted phosphorus ylides are covered in the review, despite the formally neutral character of these ligands (actually, they are zwitter-ionic), because their C-donor atom shows carbanionic properties. Dendrimers containing phosphapalladacycles[13] are not discussed, but their precursors[48–50] are included in Tables 1–4 (see Supplement).

The basic difference between metallacyclic systems with P-heterodonor atoms and their CN- or NCN-analogues is that the phosphorus atom can act not only as a σ-donor but also as a π-acceptor.[51–54] Many other properties of phosphapalladacyclic systems account for the fact that they are considered separately. These include the higher atomic radius of phosphorus, the lower basicity and greater 'softness' of this atom (the latter is especially important for the complexation with the 'soft' palladium atom) and much higher strength of the P → Pd bonds compared to the N → Pd bonds. Since the possibility of structural modification aimed at the optimisation of electronic and steric characteristics of the metal and its environment is extremely important for almost any field of application of cyclopalladated complexes, the demand for information on the synthetic routes to these compounds is evident.

An idea of the diversity of known phosphapalladacyclic compounds can be gained from Tables 1–4 given in the Supplement, which summarise methods for the synthesis of complexes classified in terms of structural features. Monochelate compounds of the PC-type (**A**) and their bicyclic or 'pincer' PCP analogues (**B**) are included in Tables 1 and 4, respectively; the bis(chelate) spiro complexes and derivatives of PC-coordinated phosphine-substituted phosphorus ylides are considered in Tables 2 and 3, respectively. The Tables give only the structures of primary cyclometallation products arranged according to the type of hybridisation of the metal-bound carbon atom (sp^3 or sp^2) and to the size of the chelate ring formed (six-, five- or four-membered). The reaction conditions, the types of intermediates (for multistage processes), the yields in the stage of cyclometallation itself and the total yield (for multistage routes) are also presented.

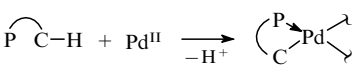
In the text and in the Tables, the ordinal number of the complex corresponds to the superscript in the designation of the cyclopalladated ligand HL^n, while letters designate all compounds derived from this ligand; the numbers of similar complexes of other metals are primed.

While Tables 1–4 can be useful for the synthesis of known complexes, the main goal of the discussion of published data is to elucidate the regular trends which could be useful for the design of new phosphapalladacycles and in the search for methods for their synthesis.

The routes to cyclopalladated complexes with P-donor atoms are diverse, the most important being direct activation of C–H bonds (Section II) and oxidative addition of a C–H or C–Hal bond of the ligand to a low-valence metal (Section III). Other possible approaches include complexation of Pd(II) with a prelithiated ligand (transmetallation, Section IV) or its simple chelation by formally neutral phosphine-substituted phosphorus ylide ligands (Section V). Some exotic transformations resulting in closure of phosphapalladacycles are considered in Section VI.

II. Direct intramolecular cyclopalladation

Direct intramolecular activation of C–H bonds in P-donor ligands seems to be the most attractive route to phosphapalladacycles.



The efficiency of this method is determined, first of all, by the ligand structure; if necessary, it can be increased by optimisation of the reaction conditions. This Section is devoted to consideration of these factors.

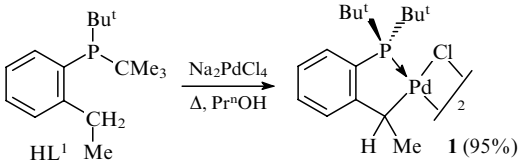
1. Structural factors

The ease of cyclopalladation of a P-donor ligand depends, first of all, on its structural features including the position of the C–H bond to be activated (this dictates the size of the phosphapalladacycle formed) and hybridisation of the carbon atom involved, the steric conditions near the P-donor atom and near the metallation site, the basicity of phosphorus atom, *etc*.

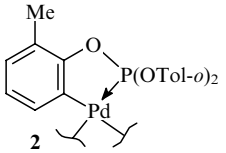
a. Localisation of the C–H bond to be activated

The position of the C–H bond being activated with respect to the P-donor atom largely determines the ease of cyclopalladation: the tendency for the formation of five-membered PC-palladacycles is as pronounced as in the case of ligands with other donor atoms.[21]

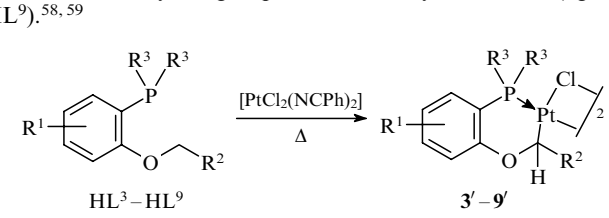
For example, phosphine HL^1 forms only a five-membered metallacycle in complex **1** due to the activation of the C–H bond of the methylene group in the *o*-Et substituent,[55] despite the presence of aliphatic C–H bonds in sterically less hindered methyl groups of the *o*-Et and PBu^t substituents and an aromatic C–H bond whose activation could have resulted in six- or four-membered metallacycles. The reactions with other aryl-, benzyl- and alkyl-phosphines with PBu^t substituents also always lead to the closure of five-membered palladacycles (see Table 1).



The same trend becomes apparent in Pd(II) reactions with phosphites. Cyclopalladation of tri(*o*-tolyl) phosphite (HL^2) both *via* the standard coordination precursor, $[Pd(\kappa^1\text{-}HL^2)_2Cl_2]$,[56] and *via* the organometallic compound, $[PdCl(\eta^5\text{-}Cp)(HL^2)]$,[57] affords only the five-membered palladacycle **2** due to the attack by palladium on the benzene ring, although the formation of a six-membered metal ring is also possible in principle through activation of the *o*-Me group of the tolyl substituent.



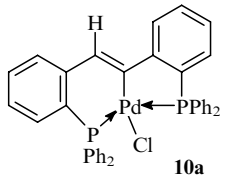
The six-membered metallacycles are rather uncommon; their formation is hampered and becomes possible only when there are no alternatives. For instance, all attempts to close six-membered PC-palladacycles upon activation of the $C(sp^3)$–H bond in the *o*-AlkO group of the phosphines HL^3–HL^9 failed, even in the case of sterically hindered HL^4, HL^6 and HL^8 ligands. It is noteworthy that the corresponding platinacycles **3′**–**9′** are formed upon metallation of not only the methyl group (ligands HL^3–HL^8) but also the methylene group of the *o*-alkoxy substituent (ligand HL^9).[58, 59]



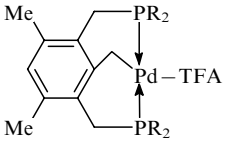
$R^1 = R^2 = H$: $R^3 = Ph$ (HL^3, **3′**), Bu^t (HL^4, **4′**);
$R^1 = 3\text{-MeO}$, $R^2 = H$: $R^3 = Ph$ (HL^5, **5′**), Bu^t (HL^6, **6′**);
$R^1 = 6\text{-MeO}$, $R^2 = H$: $R^3 = Ph$ (HL^7, **7′**), Bu^t (HL^8, **8′**);
$R^1 = H$, $R^2 = Me$, $R^3 = Ph$ (HL^9, **9′**).

As rare examples of six-membered phosphapalladacycles, one can mention bicyclic PCP structures **10a**, **11** and **12**, prepared from

2,2′-bis(diphenylphosphino)stilbene (HL^{10})[60,61] and 1,3-bis-(phosphinomethyl)-2,4,6-trimethylbenzenes (HL^{11} and HL^{12}).[62] In the case of complex **10a** and related derivatives of diphosphines with the dibenzyl skeleton (see Table 4), the unfavourableness of the formation of a six-membered chelate ring is partially compensated by the simultaneous closure of the optimal five-membered phosphapalladacycle.



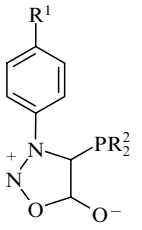
10a



11 (R = Pr^i), **12** (R = Bu^t)

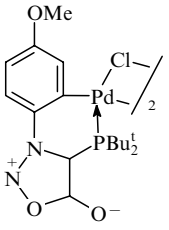
TFA is trifluoroacetate.

The only example of formation of a six-membered PC-palladacycle by a monodentate ligand is *ortho*-palladation of 4-(di-*tert*-butylphosphino)-3-(4-methoxyphenyl)sydnone (HL^{13}). The structure of dimer **13** was confirmed by X-ray diffraction.[63]



HL^{13}–HL^{16}

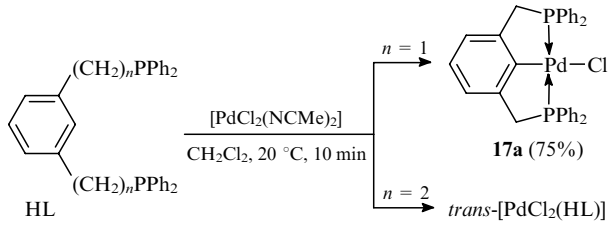
Ligand	R^1	R^2
HL^{13}	MeO	Bu^t
HL^{14}	H	Bu^t
HL^{15}	MeO	Ph
HL^{16}	H	Ph



13

The *ortho*-palladation of sydnonylphosphine HL^{13} is possible only under simultaneous assistance of steric and electronic factors. Studies of other ligands of this class have shown that in the absence of the electron-donating 4-MeO group in the aromatic ring but with retention of the bulky substituents at phosphorus (HL^{14})[64] and, especially, upon replacement of the bulky PBu^t_2 group by the less bulky PPh_2 fragment in ligands HL^{15} (see Ref. 65) and HL^{16} (see Ref. 64), the reaction under the same conditions ($PdCl_2$–HCl, EtOH–H_2O, 80 °C, 4 h) gives simple coordination complexes of the type *trans*-[$PdCl_2(HL)_2$], instead of *ortho*-palladated compounds.

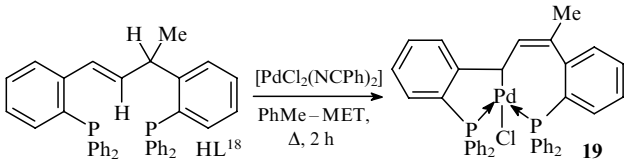
It is equally obvious that the formation of five-membered metallacycles in the case of PCP-complexes is facilitated. Unlike *m*-xylylene-α,α′-diphosphine (HL^{17}, $n = 1$), which is easily cyclopalladated under mild conditions (CH_2Cl_2, 20 °C) to give bicyclic structure **17a** with five-membered metallacycles,[66] its homologue with longer diatomic ($n = 2$) bridges between the PPh_2 groups and the phenylene skeleton cannot be involved in this process. Under the same and even under more rigorous conditions, it affords only a coordination complex of the *trans*-[$PdCl_2(HL)$] type with P,P-chelated diphosphine.[67]



HL

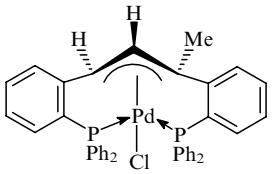
$n = 1$ (HL^{17}), 2.

A forcible argument in favour of the preferred formation of five-membered phosphapalladacycles may be derived from the results of palladation of diphosphine HL^{18}. Despite the potential possibility of closure of two six-membered metal rings with participation of the C(sp^2)–H vinyl bond, a PCP-structure **19** with five- and seven-membered palladacycles is formed upon the formal 1,2-migration of the double bond in the ligand (as confirmed by X-ray diffraction).[68]



MET is 2-methoxyethanol.

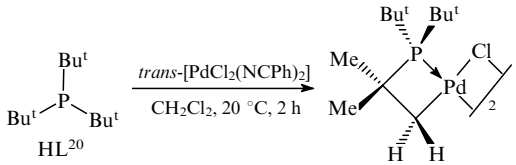
Presumably, the reaction includes the formation of cationic η^3-allylic intermediate **A** upon deprotonation of the tertiary carbon atom of the ArC(Me)H fragment whose C–H bond is most 'acidified', due to its simultaneously benzylic and allylic positions.



A

The formation of intermediate **A** was confirmed by isolation of its tetrafluoroborate upon dehalogenation of complex **19** under the action of $AgBF_4$. The driving force of subsequent rearrangement of intermediate **A** to the η^1-allylic structure **19** is minimisation of steric strain in the tetracyclic system consisting of two metallacycles and two aromatic rings.[68] This factor appears to be even more important in view of the fact that in the case of diphosphine ligands, the activation of the C(sp^2)–H bonds is usually preferred over the activation of the C(sp^3)–H bond and occurs much more easily (see below).

The closure of the four-membered metallacycle upon cyclopalladation of tri-*tert*-butylphosphine (HL^{20}) is also forced, as this ligand does not contain any C–H bonds suitable for the formation of five-membered rings.[69–74]



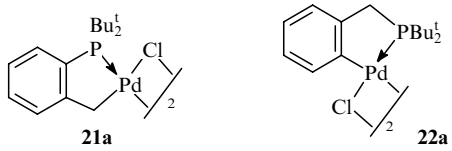
20a (70%)

Probably, the formation of these sterically 'inconvenient' metallacycles is facilitated by the rather large bulk of the phosphorus atom; to some extent, this is also stimulated by steric effects of P-substituents[75] (see below). It should be noted that, in spite of the smaller atomic radius of nitrogen, compounds with four-membered CN-palladacycles are also encountered, although rather seldom;[40,76–78] they are mainly formed with dianionic ligands[77,78] and are prone to ring expansion.[79]

b. Hybridisation of the metallated carbon

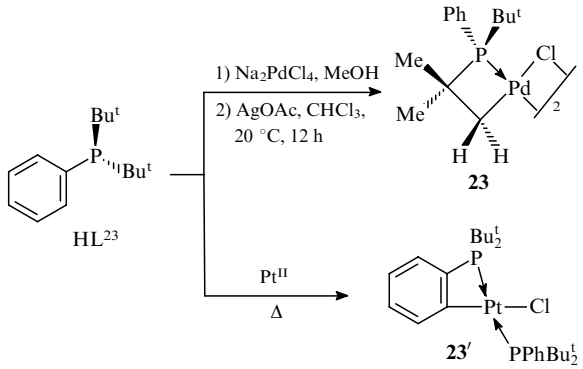
The hybridisation of the carbon atom in the C–H bond being metallated undoubtedly influences the ease of cyclometallation. Formal considerations concerning different strengths of aromatic and aliphatic C–H bonds (with an energy of ~110 and ~100 kcal mol^{-1}, respectively[80]) are of little utility due to the complex combination of various factors determining the course of this process (thermodynamics and kinetics, mechanistic features, steric effects, and so on). However, analysis of the available experimental results indicates that the hybridisation of carbon in the C–H bond that is metallated plays different roles in PC- and PCP-systems.

Comparison of the formation conditions of five-membered PC-palladacycles **21a** and **22a** from di-*tert*-butyl-substituted phosphines P(Tol-*o*)Bu^t_2 (HL^{21}) (Na_2PdCl_4, MeOH – PrOH, ~60 °C, 5 min, 90%) and $PBnBu^t_2$ (HL^{22}) (Na_2PdCl_4, MET, 125 °C, 5 days, 64%) shows that the C(sp^3) – H bond in the former ligand [81] is activated more readily than the C(sp^2) – H bond in the latter ligand,[82] as in the first case the reaction requires much less time and occurs at a lower temperature, the dimer being formed in a higher yield.



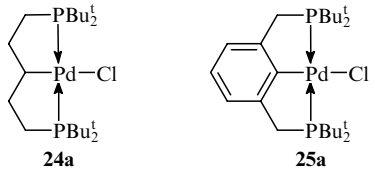
21a **22a**

This regularity is also retained in systems with four-membered metallacycles. Indeed, the bond to be activated during the cyclopalladation of the phosphine $PPhBu^t_2$ (HL^{23}) is the aliphatic C – H bond of the *tert*-butyl group [83,84] rather than the aromatic *o*-C – H bond of the P-phenyl substituent. The lower steric promotion required the use of silver acetate for halide abstraction in this process.



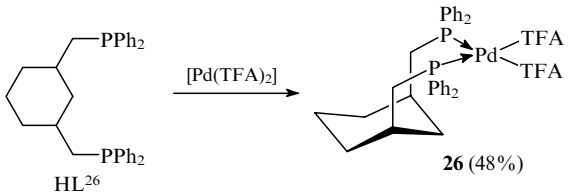
It should be noted that cycloplatination of the HL^{23} ligand and related phosphines follows an opposite trend, *i.e.*, the aromatic C – H bond is attacked preferably to give *ortho*-metallated platinum complex **23′**.[85–87] Moreover, measurements of the H/D exchange kinetics showed that in the presence of platinum(II), the exchange rate of *ortho*-protons in the PPh substituent of phosphine HL^{23} is 50 times as high as the exchange rate of protons in the PBu^t groups.[88] Palladium(II) compounds with four-membered phosphametallacycles, like complex **23′**, have been prepared by a different method (see Section III).

The opposite trend is observed in the formation of two related PCP-complexes, **24a** (260 °C, sublimation, 64%) [89] and **25a** (MET, 125 °C, 25 min, 75%),[90] in the reaction of diphosphines with the same reagent, [$PdCl_2(NCPh)_2$]. Namely, the activation of the aliphatic C – H bond requires higher temperature [or the use of a more efficient reagent, palladium(II) trifluoroacetate [91]] than the palladation involving the aromatic C – H bond.

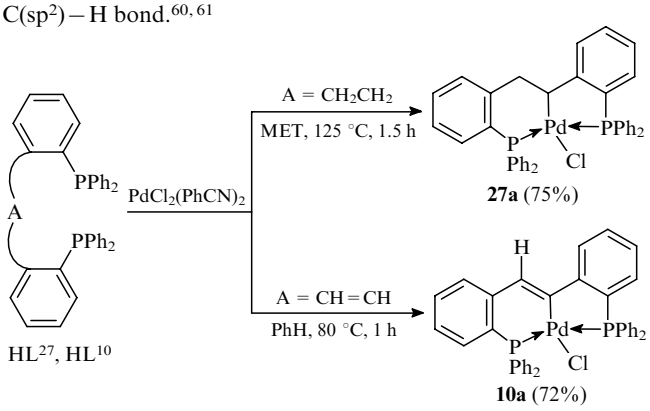


24a **25a**

This difference is even more pronounced in similar, but sterically non-crowded systems with PPh_2 donor groups. Of two diphosphines, one with a *m*-xylylene (HL^{17}) [66] and one with a fully hydrogenated *cis*-cyclohexane-1,3-dimethylene skeleton (HL^{26}),[92] only the former can be effectively palladated at the C(sp^2) – H bond under very mild conditions under the action of a mild reagent, [$PdCl_2(NCMe)_2$], whereas the latter forms only the coordination complex **26** even when treated with the more electrophilic palladium(II) trifluoroacetate.



A similar, although less pronounced trend is found in cyclopalladation of the pair of diphosphines with dibenzyl (HL^{27}) or stilbene (HL^{10}) bridges: the activation of the C – H aliphatic bond in the former one requires longer-term refluxing in a more basic solvent (MET) than metallation of the latter HL^{10} ligand at the C(sp^2) – H bond.[60,61]



A = CH_2CH_2 (HL^{27}), *trans*-CH=CH (HL^{10}).

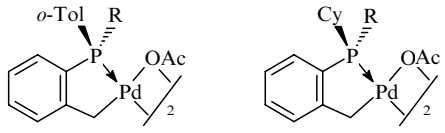
In support of the structure of the complex **10a**, X-ray data for the platinum analogue can be mentioned.[60,93] The mechanism of cyclometallation of two related ligands, HL^{27} and HL^{10}, has not been studied; however, it was suggested that activation of the C(sp^2) – H bond in diphosphine HL^{10} can be facilitated due to the formation of an ionic intermediate with a π-coordinated double bond.[61]

Cyclopalladation involving the C(sp^3) – H bond does not take place for diphosphine (2-$Ph_2PC_6H_4)_2CH_2$ (HL^{28}) with the diphenylmethane skeleton containing PPh_2 donor groups. Refluxing of the HL^{28} ligand with [$PdCl_2(NCPh)_2$] furnishes only the coordination complex *cis*-[$PdCl_2(HL^{28})$], despite the potential possibility of the closure of two optimal five-membered phosphapalladacycles.[94]

Thus, for mono- and diphosphine ligands, the ease of cyclopalladation follows opposite patterns of dependence on the type of hybridisation of the carbon atom in the C – H bond that is activated. This suggests that the reaction routes, resulting in the PC- and PCP-structures may be different.

c. The basicity of the phosphorus donor atom

Theoretically, the process rate can also be influenced by the basicity and the coordination ability of the donor atom of phosphorus [51–53] due to the change in the electron density on the metal atom in the coordination precursors. However, comparison of the results of cyclopalladation with palladium(II) acetate of two pairs of *o*-tolylphosphines (HL^{29}, HL^{30} and HL^{31}, HL^{32}) differing in the nature of two other substituents at the phosphorus atoms shows that these factors are relatively insignificant.



29a, **30a** **31**, **32**

Compound	R	θ /deg	Reaction conditions	Yield (%)
29a	*o*-Tol	194	50 °C, 3 min	93
30a	Bu^t	190	60 °C, 5 min	94
31	*o*-Tol	186	20 °C, 6 h	42
32	Cy	178	20 °C, 12 h	41

Indeed, when the aromatic *o*-tolyl group at the phosphorus atom is replaced by an aliphatic group [Bu^t or cyclohexyl (Cy)], the ligand basicity should substantially increase; this follows from the fact that aliphatic phosphines PBu^t_3 and PCy_3 are much more basic (pK_a 11.4 and 9.70, respectively) than the analogous aromatic phosphine P(Tol-*o*)$_3$ (pK_a 3.08).[52,53] Nevertheless, the activation of the C–H bond is hampered only slightly within any of the above pairs with similar steric characteristics, and the yields of complexes remain almost the same.[10] A decrease in the yield of the cyclopalladated complex on passing from the first pair of complexes to the second one (~90% and ~40%) may be related to both the lower temperatures used in the synthesis and, to some extent, to steric effects, which are measured in terms of the Tolman cone angles (θ) ‡ of the starting phosphines.[95]

d. Steric promotion

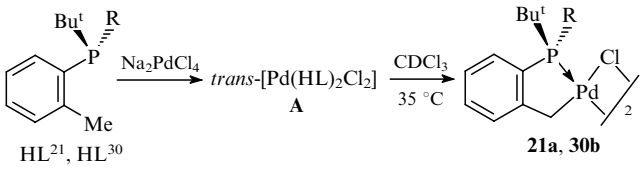
It is in phosphine substrates that the steric promotion of the activation of C–H bonds was first observed by Shaw and coworkers.[85,96,97] This phenomenon has developed into a potent tool in cyclometallation chemistry, which is actively applied to ligands with other heteroatoms, for example, to N-donors.[98–101] Since a phosphorus atom is larger than a nitrogen atom, the steric promotion of reactions of P-donor substrates requires the introduction of more bulky substituents: for example, *tert*-butyl or *o*-tolyl groups are desirable for phosphines, whereas for cyclometallation of benzylamines, it is sufficient to introduce *N*-methyl groups.[21,102] This effect has acquired the name of the *gem*-di-*tert*-butyl effect,[97] by analogy with the Thorpe–Ingold *gem*-dimethyl effect, known from the organic chemistry of small carbocycles.[103–105]

The nature of the steric promotion of cyclometallation processes is rather complex (see Section II.3) and the result is not always predictable. The steric crowding of the P-donor ligands ensures acceleration of the process only for some types of substrate and only for a definite location of bulky substituents.

Most often, bulky substituents at phosphorus markedly facilitate the activation of aromatic and aliphatic C–H bonds in monodentate phosphines, these effects being usually correlated with the Tolman angles of the ligands.[95,106,107] A classical example is the extremely easy closure of a strained four-membered metallacycle in complex **20a** in the reaction of bulky tri(*tert*-butyl)phosphine (HL^{20}) with weak palladating reagents, K_2PdCl_4 or *trans*-[$PdCl_2(NCPh)_2$], at room temperature.[69–71]

The accumulation of *tert*-butyl groups at phosphorus facilitates also the closure of five-membered PC-palladacycles. Spectroscopic (^{1}H NMR) monitoring of formation of cyclopalladated complexes **21a** and **30b** from the corresponding coordination compounds *trans*-[$PdCl_2(HL)_2$] with *o*-tolylphosphines HL^{21} and HL^{30} has shown that in the case of the di-*tert*-butyl-substituted ligand HL^{21}, the reaction is complete in 85 min (yield 100%), whereas with the mono-*tert*-butyl-substituted ligand HL^{30}, one-third of the intermediate coordination complex **A** remain intact even after 5 h.[81]

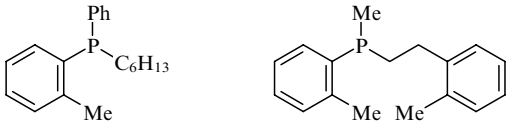
‡ Here and below, the θ values were taken from Ref. 95.



HL^{21}, HL^{30} **A** **21a**, **30b**

R = Bu^t (HL^{21}, **21a**), *o*-Tol (HL^{30}, **30b**).

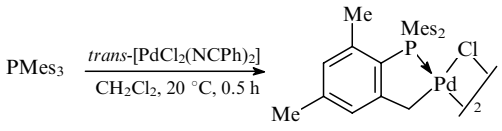
Ligands of the $PRBu^t_2$ type incorporated in coordination precursors such as [$PdCl_2(HL)_2$] often undergo spontaneous cyclometallation even when the latter are kept at room temperature in solution (R = Bu^t)[70] or on attempted recrystallisation (R = 2-EtC_6H_4).[55] Thus, it is quite clear why all attempts at cyclopalladation of the *o*-tolylphosphines HL^{33} and HL^{34} with small substituents at the phosphorus atom have failed.[108]



HL^{33} ($\theta \approx 157°$) HL^{34} ($\theta \approx 148°$)

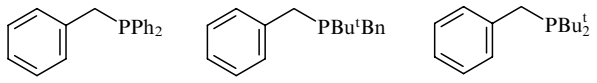
Neither the use of Li_2PdCl_4 and $Pd(OAc)_2$ as palladating agents in the presence of bases (AcONa or K_2CO_3) or without any bases, nor thermolysis (up to 160 °C) of the intermediate coordination complexes [$Pd(HL^{33})_2Hal_2$] or [{$Pd(HL^{34})Hal(\mu$-Hal)}$_2$], nor even generation of a vacant coordination site in the latter complex on treatment with $AgBF_4$ (see Ref. 108) have led to the desired palladacycles.

Perhaps, steric effects are the most pronounced in the cyclometallation of trimesitylphosphine (HL^{35}).[10,109–111] X-Ray diffraction studies of this bulky ligand (θ = 212 °) have shown that repulsion of the three encumbered mesityl groups results in substantial flattening of the pyramidal configuration at phosphorus, in particular, the angles between the P–C bonds are increased to 108–111 ° compared to the typical values for acyclic phosphines being equal to 90–104 °.[112] Cyclopalladation of this phosphine proceeds under mild conditions, the contribution of the steric promotion being so high that variation of reaction conditions including the solvent (CH_2Cl_2, PhH, $CHCl_3$ or EtOH) and the metal : ligand ratio (1 : 2 or 1 : 1) has virtually no influence on the yields of dimer **35a**, which remain nearly quantitative (87%–98%) in reactions carried out at ~20 °C.[110] The ^{1}H NMR monitoring of the reaction presented below has shown that the process is really over after as soon as 5 min.[109]



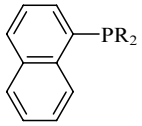
35a (98%)

A similar dependence on the bulk of the P-substituents is also observed in activation of the C(sp^2)–H bonds in benzylphosphines.[82,113,114] The HL^{36} ligand could be cyclometallated with moderate success only using highly electrophilic $Pd(OAc)_2$ (the yield of the dimer was 19%).[114] The intramolecular metallation with a weak electrophile such as Na_2PdCl_4 (AcONa, MET, 130 °C) becomes possible with appearance of the first Bu^t group and is essentially facilitated after the introduction of the second Bu^t group. Thus, the *ortho*-palladated derivatives of the phosphines HL^{37} and HL^{22} are formed in 12% and 75% yields over periods of 24 and 0.5 h, respectively.[82]



HL^{36} (θ = 151°) HL^{37} (θ = 161°) HL^{22} (θ = 177°)

Apparently, it is due to the lack of bulky P-substituents that the attempts to prepare phosphapalladacycles from dimethylnaphthalen-1-ylphosphine (HL^{38}) have not met with success. Neither pyrolysis of the intermediate coordination complexes of the *cis*-$[Pd(HL^{38})_2X_2]$ type (X = Cl, Br) nor long-term refluxing of their solutions in the presence of bases resulted in activation of the $C(sp^2)-H$ bond.[115]

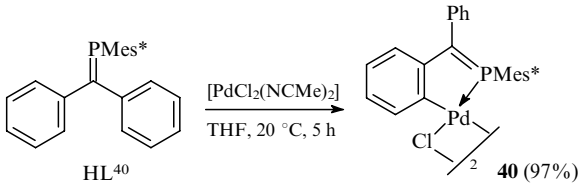


R = Me (HL^{38}), 1-Np (HL^{39});
Np is naphthyl.

HL^{38}, HL^{39}

However, a similar but more bulky tri(naphthalen-2-yl)phosphine (HL^{39}) is cyclometallated on treatment with a more electrophilic reagent, $Pd(OAc)_2$.[116] A certain contribution to increasing the reactivity may also be made by the lower basicity of the P-donor centre in HL^{39} compared to that in HL^{38}.

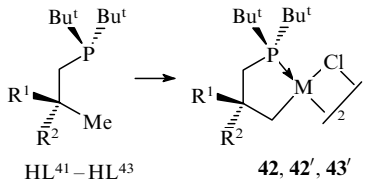
In substrates with P-donor atoms of other types, *ortho*-palladation also proceeds more readily when steric stimulation is involved. For instance, monodentate phosphaalkenes with an extremely bulky 'supermesityl' substituent (Mes* = 2,4,6-$Bu^t_3C_6H_2$) form phosphapalladocycles at room temperature on treatment with a moderately electrophilic palladating agent:[117]



HL^{40} **40** (97%)

Thus, it is clear that cyclopalladation of monodentate phosphines is stimulated by the increase in the size of the P-substituents (*e.g.*, in the series Me < Ph < Bu^t).

It is likely that the activation of the aliphatic C–H bonds can be promoted by an increase in the number of substituents at the carbon atom adjacent to the metallation site. Using platinum analogues as examples, it was found that cyclometallation is markedly accelerated with an increase in the number of β-methyl groups in the $CH_2CR^1R^2Me$ alkyl substituent at phosphorus. Indeed, n-propylphosphine HL^{41} does not form a phosphametallacycle; cycloplatination of isobutylphosphine HL^{42} proceeds only on heating; and neopentylphosphine HL^{43} forms dimer **43′** over a period of several minutes at room temperature.[118, 119] The cyclopalladated derivative **42** is known only for phosphine HL^{42} (see Ref. 119).



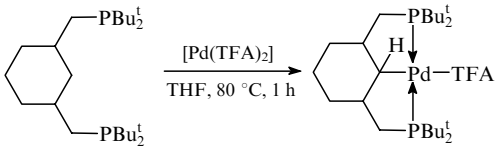
HL^{41}–HL^{43} **42**, **42′**, **43′**

M = Pt: $R^1 = R^2 = H$ (HL^{41}); R^1 = Me, R^2 = H (HL^{42}, **42′**);
$R^1 = R^2$ = Me (HL^{43}, **43′**); M = Pd: R^1 = Me, R^2 = H (**42**).

It is assumed that easier cyclometallation of sterically overcrowded ligands is determined by both the entropy and conformation effects [118, 119] (see Section II.3.a).

It may seem unexpected at first glance that steric stimulation of cyclopalladation of diphosphine ligands by bulky P-substituents is not always observed, the effect being appreciably dependent on the hybridisation of carbon in the C–H bond subject to metallation and perhaps also on the conformational features of the ligand.

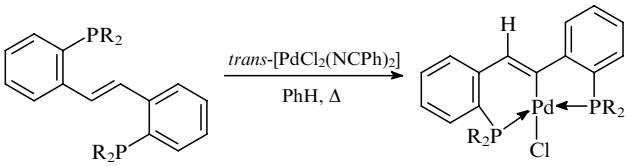
As an example of normal steric promotion, one can mention successful cyclopalladation at the $C(sp^3)-H$ bond of diphosphine HL^{44}, containing PBu^t_2 donor groups. When $Pd(TFA)_2$ is used as the metallating agent, the reaction is completed over a short period and gives the product in a nearly quantitative yield.[91]



HL^{44} **44** (91%)

Recall that a similar ligand, HL^{26}, with PPh_2 donor groups forms only the *cis*-$[Pd(\kappa^2\text{-}HL^{26})(TFA)_2]$ (**26**) coordination complex under the same conditions.[92]

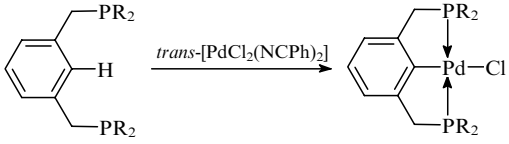
Conversely, in the activation of $C(sp^2)-H$ bonds, an increase in the steric demands of the P-substituents not only does not promote, but hampers this process. For example, cyclopalladation is substantially retarded when the Ph_2P groups in diphosphine HL^{10} are replaced by more bulky $(o\text{-Tol})_2P$ groups to form the HL^{45} ligand [for PPh_3 and $PPh(o\text{-Tol})_2$, the θ values are 145 and 178°, respectively]. The conversion of HL^{10} and HL^{45} into cyclopalladated complexes **10a** and **45a** in comparable yields required heating for 1 and 16 h, respectively.[60, 61]



HL^{10}, HL^{45} **10a** (72%), **45a** (62%)

R = Ph (HL^{10}, **10a**), *o*-Tol (HL^{45}, **45a**).

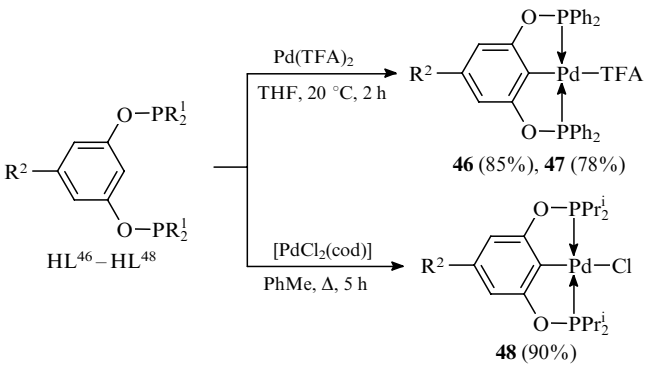
The transformation of steric stimulation into steric impediment is even more obvious from comparison of the metallation conditions of two *m*-xylylene-α,α′-diphosphines HL^{17} and HL^{25}. The HL^{25} ligand with PBu^t_2 groups reacts at much higher temperature and in a more basic solvent (MET, 130 °C, 25 min)[90] than the PPh_2-analogue HL^{17} (CH_2Cl_2, 20 °C, 10 min),[66] despite the much greater cone angles of the P-donor fragments in the former compound (for the monophosphines $BnPBu^t_2$ and $BnPPh_2$, the θ values are 176 and 152°, respectively). The reasons why Milstein and coworkers[120] used much more rigorous conditions (MET, 150 °C) to prepare complex **17a** remain obscure (the yield of the complex is not documented). Presumably, the ease of cyclometallation in these systems is mainly determined by the geometry of the coordination precursors of the *trans*-$[PdCl_2(\kappa^2\text{-}HL)]$ type, in particular, by the degree of proximity of the C–H bond to be activated to the metal.[66]



HL^{17}, HL^{25} **17a** (75%), **25a** (75%)

R = Ph (HL^{17}, **17a**), Bu^t (HL^{25}, **25a**).

The activation of the C–H bond in bis(phosphinites) HL^{46} and HL^{47} based on resorcinols containing the PPh_2 donor groups does not require steric stimulation either: on treatment with palladium(II) trifluoroacetate at 20 °C, PCP-complexes **46** and **47** are formed rather fast (2 h) and in high yields (78%–85%).[121]

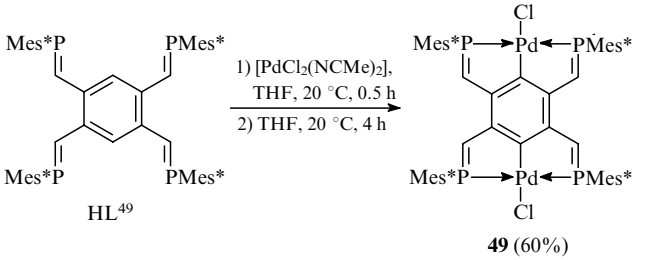


R^1 = Ph: R^2 = H (HL[46], **46**), Me (HL[47], **47**);

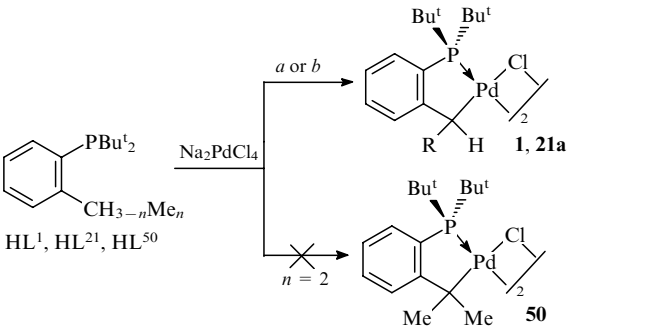
R^1 = Pr^i, R^2 = H (HL[48], **48**); cod is cycloocta-1,5-diene.

Conversely, cyclopalladation of sterically more hindered bis(phosphinite) ligand HL[48] with Pr^i_2P donor groups (for the phosphinites $PhOPPh_2$ and $PhOPPr^i_2$, the θ angles are 139 and 149 °, respectively) is obviously hampered and requires more drastic conditions: high yields in the reaction of HL[48] with $[PdCl_2(cod)]$ were attained after refluxing in toluene for 5 h.[122] This difference in the behaviours of bidentate ligands with PPh_2 and Pr^i_2P donor groups becomes even more significant if one takes into account the fact that the palladating agents used should tend[123] (or do tend[124]) to form mononuclear coordination intermediates (see Section II.3.a).

Apparently, the optimal structure of the coordination precursor makes a certain contribution (apart from the steric assistance from bulky supermesityl P-substituents) to the easy cyclopalladation of bis-*m*-diphosphaethene ligand HL[49] (see Ref. 117) and a number of related substrates.[125–127]



Whereas bulky substituents at the phosphorus atom or in the side chain promote activation of the C–H bonds in monophosphines, the substituents at the carbon atom subjected to metallation appreciably hamper this process.[55,81] This can be illustrated by the conditions of synthesis of PC-palladacycles from (*o*-alkylphenyl)di(*tert*-butyl)phosphines on treatment with Na_2PdCl_4 in alcohols.



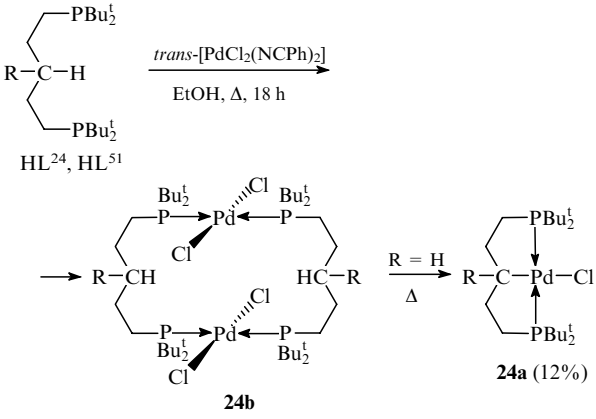
n = 0, R = H (HL[21], **21a**, 90%); n = 1, R = Me (HL[1], **1**, 95%);

n = 2 (HL[50], **50**);

(*a*) ~65 °C, 5 min; (*b*) ~97 °C, 20 min.

The metallation of the secondary C–H bond in the phosphine HL[1] requires a higher temperature and longer time than the metallation of the primary C–H bond in HL[21] analogue, while attempts at activation of the tertiary C–H bond in the phosphine HL[50] have failed at all.[55]

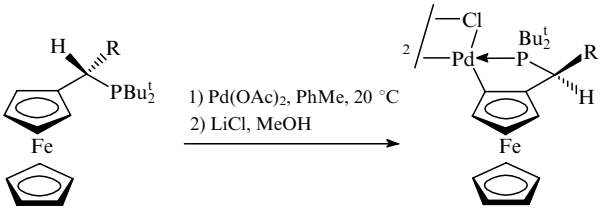
Similar results have also been obtained for reactions of aliphatic diphosphines. For instance, cyclometallation involving the secondary C–H bond in the HL[24] ligand was accomplished in a low yield (12%) by long-term thermolysis of the macrocyclic coordination precursor $[\{PdCl_2(\mu\text{-HL}^{24})\}_2]$ (**24b**) in alcohol;[128] by sublimation of intermediate **24b** *in vacuo* (10^{-2} mm Hg), the yield of the PCP-complex **24a** can be increased to 64%.[89] However, the tertiary C–H bond in the diphosphine HL[51] cannot be metallated under the same conditions.[129]



R = H (HL[24], **24a**,**b**); Me (HL[51]).

It is known from the chemistry of benzylaminate CN-systems that the introduction of any α-substituent (even a small Me group[98,130] and, especially, a bulky group[99–101]) into the side chain near the heterodonor atom promotes appreciably the activation of the aromatic C–H bond. Unfortunately, the possibility of estimating the influence of this factor on the activity of P-donor ligands is limited and the available data are rather contradictory.

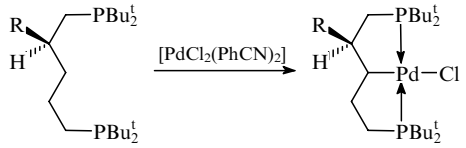
On the one hand, comparison of the reaction conditions and the yields of the products of cyclopalladation of α-ferrocenylalkylphosphines HL[52] and HL[53] with palladium(II) acetate prompts the conclusion that the activation of the aromatic $C(sp^2)$–H bond is accelerated upon the introduction of a substituent into the side chain.[131,132] The reaction with the α-Me-substituted HL[53] ligand proceeds much faster and gives complex **53** in a higher yield (93% in 1 h) than that with the α-unsubstituted analogue **52** (70% in 8 h). Actually, this effect is even stronger, as it is manifested against the background of an additional steric stimulation by the bulky PBu^t_2 donor groups.



R = H (HL[52], **52**), Me (HL[53], **53**).

Signs of same assistance to the activation of the aliphatic $C(sp^3)$–H bond as a result of similar modification of the ligand structure can be found by comparing the cyclopalladation conditions for two aliphatic diphosphines, $Bu^t_2PCH_2CH(R).(CH_2)_3PBu^t_2$ with R = H (HL[24]) and R = Me (HL[54]), on treatment with *trans*-$[PdCl_2(NCPh)_2]$. The PCP-complex derived from the former ligand, **24a**, was isolated in a very low yield (12%) after long-term (18 h) refluxing in ethanol,[128] whereas the synthesis of

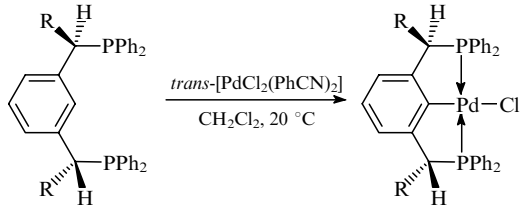
2-methyl-substituted analogue **54** in a moderate yield (36%) required only a 15-minute heating in MET.[133]



HL[24], HL[54] **24a** (12%), **54** (36%)

R = H (HL[24], **24a**), Me (HL[54], **54**).

On the other hand, an adverse influence of α-substituents can be inferred from comparison of reaction durations of *trans*-[$PdCl_2(NCPh)_2$] with the diphosphines HL[17] and HL[55] possessing aromatic core, under identical conditions (CH_2Cl_2, 20 °C) resulting in two related PCP-complexes **17a**[66,134] and **55a**[135]. The palladation of the HL[17] ligand unsubstituted in the benzylic positions required only 10 min, whereas for the cyclopalladation of its α,α′-dimethyl-substituted analogue HL[55], a 24 h period was required.

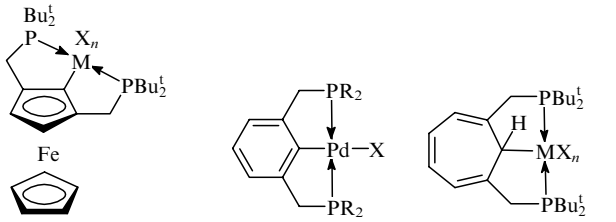


HL[17], HL[55] **17a** (75%), **55a** (85%)

R = H (HL[17], **17a**), Me (HL[55], **55a**).

This anomaly in the behaviour of diphosphine ligands can be due either to the entropy effects [which account for the fact that bulky substituents at phosphorus do not 'work' in these systems (see above)] or to the change in the ligand conformation in the stage of the formation of coordination intermediates. However, it cannot be ruled out that the mechanism of activation of the C—H bonds changes on passing from N- to P-donor ligands, from monodentate to bidentate phosphines, and from $C(sp^3)$—H to $C(sp^2)$—H bonds.

In conclusion, one more parameter important for the cyclopalladation of diphosphines should be mentioned, namely, the P,P-chelate bite angle essential for the formation of the coordination precursor. This parameter is mainly governed by the geometry of the bridging fragment between two P-donor atoms. Apparently, the too large funnel between the side chains in the HL[56] ligand with 1,3-ferrocenedimethylene skeleton (caused by the geometric demands of the five-membered Cp ring) precluded its cyclopalladation to give complex **56** (MX_n = PdCl),[136] whereas analogous 'pincer' complexes of type **A** (for example, **17a**, **25a**, *etc*., see Table 4) with the six-membered *m*-xylylene skeleton are quite accessible.



56′ (MX_n = RhHCl) **A** **57′** (MX_n = IrH(CO)Cl)

However, in this case, some mechanistic restrictions cannot be ruled out, because the formation of the hydride PCP-complex **56′** (MX_n = RhHCl) proved to be possible *via* oxidative addition of the HL[56] ligand to the [{Rh(η²-C_2H_4)$_2$(μ-Cl)}$_2$] dimer.[136] A PCP-complex with a bridge incorporating a seven-membered cycloheptatrienyl ring is unknown for palladium(II), although a similar iridium complex **57′** [MX_n = IrH(CO)Cl] has been obtained by the reaction of HL[57] with iridium(I).[137]

Apparently, the true role of the geometric requirements of five-, six- and seven-membered rings in the bridge connecting two donor phosphorus atoms in diphosphines in the intramolecular palladation giving PCP-structures of types **56**, **A** and **57** would be properly evaluated only after the synthesis (or attempts at the synthesis) of the last representative of this series, complex **57** (M = Pd) using this method.

2. Conditions of direct intramolecular cyclopalladation

From the previous section, it is evident that the ease of activation of the C—H bonds in P-donor ligands largely depends on their structural features. With a specified ligand structure, the success of cyclopalladation is determined to a large extent by the conditions chosen, including the type of the palladating agent and the base, the reactant ratio, the nature of the solvent and the temperature regime. Therefore, two equally important problems are to be solved: ensuring the ligand coordination to palladium through the phosphorus atom(s) and creating conditions for the subsequent intramolecular activation of the C—H bond in the resulting coordination precursor.

a. Standard routes and classical reagents

The set of palladating reagents suitable for the direct activation of the C—H bonds in phosphines, phosphites and phosphinites is rather broad (see Tables 1, 4). It includes simple salts ($PdCl_2$), carboxylates [$Pd(OAc)_2$ and $Pd(TFA)_2$] and palladium(II) complexes: anionic ($[PdHal_4]^{2-}$), neutral {$[PdCl_2(Q)_2]$, where Q = MeCN, PhCN or (Q_2) = cod} and cationic ($[Pd(NCMe)_4]^{2+}$) ones. However, the relative efficiency of the reagents is often not correlated with the efficiency characteristic of the reactions of substrates with more rigid donor atoms.[21]

The activity of the palladating agent depends on the nature of the anionic and neutral ligands bound to the metal and on the charge on the metal atom.

1. The electron density on the metal centre determines its electrophilic or nucleophilic behaviour.

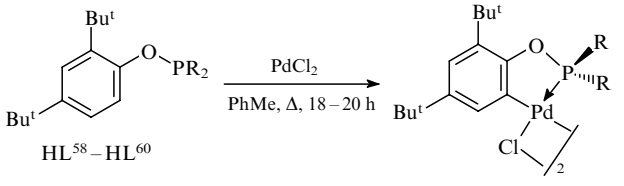
2. The dissociative lability of the ligands bound to the metal is important for the creation of the coordination vacancy.

3. The nature of the ligands bound to Pd controls the steric effects in the coordination sphere.

Depending on the reagent used, both the structure of the coordination precursor formed in the first stage and the reaction route as a whole may vary (see Section II.3.a).

The solubility of the palladating agent in organic media is also important for practical use.

The simplest and the most readily available reagent, the insoluble $\{PdCl_2\}_n$ polymer, is applied rather rarely but in some cases, this reagent works quite satisfactorily. Thus in the *ortho*-palladation of the phosphinites HL[58] and HL[59], the yields of dimers **58** and **59** are 50%—52%, irrespective of the electronic properties of the substituents at the phosphorus atoms (aromatic or aliphatic ones),[138] and an increase in the substituent bulk (for example, for R = 2,4-Bu$^t_2$$C_6H_3O$) results in a nearly quantitative yield of the PC-complex **60**.[139]



HL[58]—HL[60] **58** (52%), **59** (50%), **60** (96%)

R = Ph (HL[58], **58**), Pr^i (HL[59], **59**), 2,4-Bu$^t_2$$C_6H_3O$ (HL[60], **60**).

The $\{PdCl_2\}_n$ reagent is also able to activate the aliphatic C—H bonds provided that an additional steric stimulation is

involved. In the cyclopalladation of trimesitylphosphine HL^{35} on treatment with $PdCl_2$, good yields (70% – 80%) are attained even at 20 °C, although the process is much slower (8 – 10 h) than that with the soluble $[PdCl_2(NCPh)_2]$ complex (0.5 h).[110] Most likely, the lower activity of palladium chloride is due to retardation of the preliminary P-coordination of the ligand under heterogeneous conditions. Nevertheless, the excellent P-donor properties of the ligands (*e.g.*, HL^{58} – HL^{60}) ensure cleavage of the chloride bridges in the polymeric palladating reagent, while their rich hydrocarbon framing allows performing the reactions in nonpolar solvents (toluene, dichloromethane).

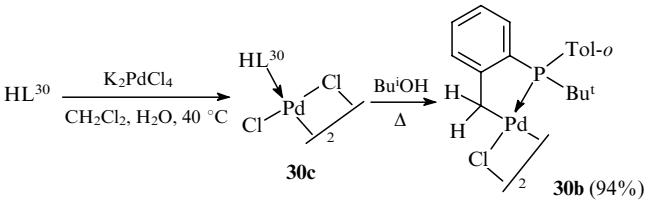
It should be noted that palladium(II) chloride is sometimes used to convert mononuclear bis(phosphine) intermediates into more reactive binuclear complexes in experiments carried out in three stages.[56, 140 – 142]

$$HL \longrightarrow [PdCl_2(\kappa^1\text{-}HL)_2] \longrightarrow \textit{trans}\text{-}[\{PdCl(\kappa^1\text{-}HL)(\mu\text{-}Cl)\}_2] \longrightarrow [\{Pd(\eta^2\text{-}L)(\mu\text{-}Cl)\}_2].$$

The differences caused by the nature of the donor atom are illustrated by the fact that tetrachloropalladates, which are relatively inert in cyclopalladation of N-donor ligands,[21] often ensure almost quantitative yields of the cyclopalladated complexes of the PC-type (mainly, when steric stimulation is involved). Most often, Na_2PdCl_4 is used, and the reaction is carried out in alcohols (MeOH, EtOH, Pr^nOH or MET). In some cases, the stages of monodentate P-coordination and C – H bond activation are carried out separately. Under these conditions, cyclopalladation involving the Me groups of bulky *o*-tolylphosphines ensures good yields of five-membered PC-palladacycles (76% – 97%,[55, 81] see Table 1); they decrease to 60% when the reagent is generated *in situ*.[57] The efficiency of Na_2PdCl_4 is lower in reactions with less bulky ligands ($Bu^iPBu^t_2$,[119] $PhPBu^t_2$,[84] the yields are 40% – 43%) and in the case of activation of aromatic C – H bonds both in phosphines (for $BnPBu^t_2$, the yield is 49%,[82] while for less bulky Bn_2PBu^t, the yield is 13%[82]) and in triaryl phosphites $P(OAr)_3$ (yields 40% – 64%).[143, 144] The decrease in the yields might be partly due to the use of the metal : ligand ratio of 1 : 2; in this case, thermolysis of the coordination precursor in high-boiling solvents is required (MET or decalin).

The drawbacks of sodium tetrachloropalladate include its amorphous structure, which brings about some problems in its purification, while the satisfactory solubility in alcohols is an advantage of this reagent. Strange as it may seem, the lithium salt Li_2PdCl_4, readily soluble in alcohols, which is the most popular reagent (despite its hygroscopicity) in the cyclopalladation of N-donor ligands,[21] has not yet been used for the synthesis of PC-palladacycles.

The crystalline potassium tetrachloropalladate is free from this drawback, however, it is virtually insoluble in alcohols, which has markedly restricted, until recently, the use of this reagent in cyclopalladation. Only one example of the use of K_2PdCl_4 is its reaction with PBu^t_3, which had to be performed in DMF (yield 72%).[69, 70] However, this problem can be solved successfully by passing to a two-phase system at the stage of formation of the coordination intermediate, because potassium tetrachloropalladate is perfectly soluble in water. This approach is illustrated by cyclopalladation of the phosphine $PBu^t(Tol\text{-}o)_2$ (HL^{30}), which includes *in situ* generation of the binuclear coordination precursor **30c** in the $CH_2Cl_2 - H_2O$ two-phase system.[145]

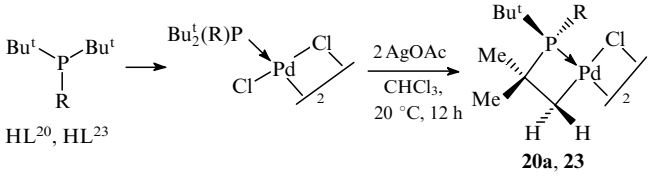


Note for comparison that cyclopalladation of *tert*-butyldi(*o*-tolyl)phosphine by Na_2PdCl_4 in alcohols (see Table 1) afforded dimer **30b** in 84% – 97% yields.[81]

For the formation of PCP-structures, tetrachloropalladates are not used at all and the examples of using the corresponding bromides (K_2PdBr_4) and iodides (Na_2PdI_4) are very scarce (see below).[60, 61]

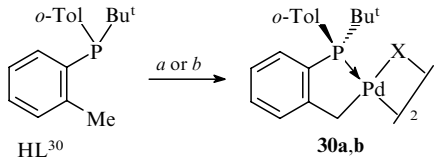
The activation of the $C(sp^3) - H$ bonds in monodentate P-donor substrates is often performed by palladium(II) acetate, which has a macrocyclic trinuclear structure.[146] However, in this case, too, the outcome depends appreciably on the steric demands of the ligand. With thermal promotion of the process (50 – 60 °C), excellent yields of cyclopalladated complexes (> 90%) can be obtained in the reactions of bulky di-*o*-tolylphosphines $(o\text{-}Tol)_2PR$ with R = *o*-Tol, Bu^t (θ = 194 and 190°, respectively) proceeding in 3 – 5 min.[10, 147, 148] Moreover, the reaction can also be carried out at 20 °C; in this case, its duration has to be increased to 6 – 12 h. The yields are correlated with the steric demands of P-substituents, varying from ~40% in the reactions with $P(Tol\text{-}o)Cy_2$ or $P(Tol\text{-}o)_2Cy$ (θ = 178 and 186°, respectively) to 80% – 90% for $P(Tol\text{-}o)Bu^t_2$ or $PMes_3$ (θ = 186 and 212°, respectively).[10]

The cyclopalladation involving aliphatic fragments proceeds more easily when the chloride ligands in the intermediate coordination complexes are replaced by acetate anions on treatment with silver acetate. This method was used to obtain dimeric PC-complexes **20a** and **23** with strained four-membered phosphapalladacycles from the phosphines PBu^t_2R under mild conditions (20 °C). The yields of cyclopalladated complexes increased with increasing steric stimulation of the process from 55% for R = Ph (θ = 170°) to 100% for R = Bu^t (θ = 182°).[84]



R = Bu^t (HL^{20}, **20a**), Ph (HL^{23}, **23**).

However, in the reactions with monodentate phosphines, palladium(II) acetate does not always show noticeable advantages over halides. Reagents of both classes are equally suitable for sterically hindered substrates, for example, for the *o*-tolylphosphines HL^{21} and HL^{30} (see Refs 10 and 81).



X = OAc (**a**), Cl (**b**); (*a*) $Pd(OAc)_2$, PhMe, 60 °C, 5 min, 90%; (*b*) Na_2PdCl_4, Pr^nOH – MeOH, 3 min, Δ, 96%.

Strange as it may seem, until recently, the electrophilic palladium(II) acetate has been seldom used to activate the aromatic $C(sp^2) - H$ bonds in monodentate phosphines. The rare examples of successful use of this reagent refer to cyclopalladation of the bulky α-ferrocenylalkylphosphines HL^{52} and HL^{53} (in yields ranging from 70% to 93%).[132, 149] In the absence of steric promotion, this reagent is of low utility: *ortho*-palladation of the benzylphosphine $PBnPh_2$ (HL^{36}, θ = 152°) in MeOH with heating (60 °C, 3 h) gave the PC-dimer $[\{Pd(\eta^2\text{-}L^{36})(\mu\text{-}OAc)\}_2]$ (**36b**) in a yield of only 19%.[114] A higher yield (85%) was attained in the reaction with more bulky PBn_2Ph ligand (θ = 158°), but this required longer heating (50 °C, 16 h).[150]

Palladium(II) acetate has not yet been used in reactions with diphosphines, although the more electrophilic trifluoroacetate is often used to create PCP-structures. The latter reagent activates

fairly efficiently both aliphatic [62, 91] and aromatic [151, 152] C–H bonds, thus ensuring the yields of cyclopalladated compounds ranging from 75% to 100%; however, in this case, thermal activation is required (70–130 °C). An exception is provided by the bis(phosphinites) HL[46] and HL[47], which react with $Pd(TFA)_2$ at 20 °C without steric promotion giving rise to PCP-complexes in 78%–85% yields over a period of 2 h.[121]

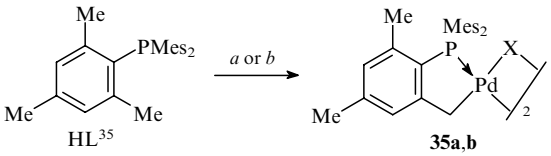
The next group of reagents is comprised by neutral mononuclear palladium(II) complexes with auxiliary ligands. The coordination compounds like *trans*-$[PdCl_2(NCR)_2]$ (R = Ph, Me) are most popular; the benzonitrile complex is known as the Karash reagent.[153] Reagents of this type are convenient from the practical standpoint, as they are readily soluble in organic solvents, both in alcohols or tetrahydrofuran and hydrocarbons (benzene, toluene, dichloromethane). It is more important that nitriles incorporated in these complexes are classified as weakly bound [154] ligands; therefore, they are replaced by P-donor substrates without any difficulty.

Despite the relatively low electrophilicity of the metal centre in the nitrile reagents, they are traditionally used for the synthesis of PCP-complexes (see Table 4); in the activation of the aromatic C–H bonds, they ensure yields of 60%–90% (with rare exceptions [155]). Their efficiency may be illustrated by the fact that some diphosphine and bis(phosphaalkene) ligands can be introduced in the reaction even at 20 °C;[66, 117, 125–127, 134, 135] nearly quantitative yields (75%–90%) of cyclopalladated compounds can be attained in 10–30 min.[66, 126] Nevertheless, in most cases, the activation of the $C(sp^2)$–H bonds is thermally stimulated (80–150 °C).[90, 120, 155, 156] The high efficiency of nitrile reagents with respect to bifunctional substrates with a rigid, aromatic skeleton is due, most likely, to the forced character of cyclometallation caused by the proximity of the C–H bond (subject to activation) to the metal in the coordination precursor if it has the *trans*-P,P-geometry.[66]

Perhaps, this accounts for the lower efficiency of *trans*-$[PdCl_2(NCPh)_2]$ in the activation of aliphatic $C(sp^3)$–H bonds in conformationally flexible diphosphines with a polymethylene bridge.[89, 128, 133, 157] Even upon high-temperature thermolysis (>260 °C) [128] or sublimation *in vacuo*,[89, 157] the yields of cyclopalladated compounds obtained from the pentamethylene-1,5-diphosphines HL[24] and HL[54] do not exceed 40%. However, in the cyclopalladation of the diphosphine HL[27] with the more rigid dibenzyl skeleton by treatment with the same reagent, a high yield of the PCP-complex **27a** (75%) is attained under milder conditions.[60, 61]

Nitrile palladating agents are used somewhat more rarely to prepare monocyclic PC-complexes, although they are rather effective (with rare exceptions [140]) towards the activation of the $C(sp^2)$–H and $C(sp^3)$–H bonds (see Table 1). To attain high yields in the *ortho*-palladation of monodentate benzylphosphines (83%–85%) [113] and phosphites (70%–90%),[56, 138, 141, 142] heating is usually required; however, cyclopalladation of the phosphaalkene HL[40] with the supermesityl substituent proceeds even at 20 °C (the yield of **40** is 97%).[117]

Under equally mild conditions (20 °C, 0.5–2 h), the aliphatic C–H bonds in the bulky phosphines PBu^t_3 and $PMes_3$ are usually activated (the yields are >80% [70, 71] and 98%,[109, 110] respectively). The (benzonitrile)chloride complex competes quite successfully with a powerful metallating agent such as $Pd(OAc)_2$: trimesitylphosphine HL[35] is cyclopalladated by this complex faster and with a higher yield [109] than by $Pd(OAc)_2$ (see Ref. 10).



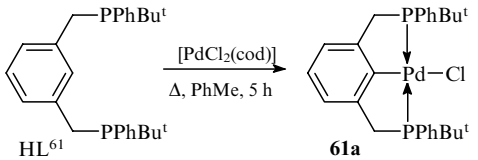
X = OAc (**35a**, 81%), Cl (**35b**, 98%); (*a*) $Pd(OAc)_2$, PhMe, 60 °C, 12 h; (*b*) *trans*-$[PdCl_2(NCPh)_2]$, 20 °C, 30 min.

The efficiency of reagents such as *trans*-$[PdCl_2(NCR)_2]$ is determined, first of all, by the easy replacement of the weakly coordinated nitrile by P- or P,P-donor ligand. Actually, these nitrile complexes can be regarded as solvation-stabilised forms of mononuclear palladium(II) chloride. When the nitrile in these complexes is replaced by a $\eta^2{:}\eta^2$-bound diene in the $[PdCl_2(cod)]$ reagent, restrictions apparently arise already in the stage of ligand coordination to the metal through phosphorus atoms due to both stronger binding of the diene to the metal and steric factors.

For example, all attempts at the intramolecular activation of the $C(sp^3)$–H bond of the trimesitylphosphine HL[35] (θ = 212°) [95] by the diene reagent even under conditions of long-term thermolysis in high-boiling solvents (toluene, xylene) failed, although the use of the benzonitrile reagent furnishes cyclopalladated complex **35a** in a quantitative yield at 20 °C.

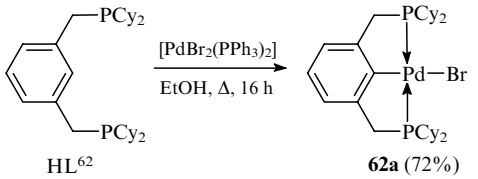
The reason for the lack of success is the fact that the sterically crowded phosphine is unable to displace the diene from the starting $[PdCl_2(cod)]$ complex.[110] The diene reagent is markedly inferior to the benzonitrile analogue also in the reaction with the bulky phosphine PBu^t_3, whose cyclopalladation required 8 days (the yield was not reported),[69] whereas with the use of *trans*-$[PdCl_2(NCPh)_2]$, 70% yield was attained in 2 h.[71]

The activation of aromatic C–H bonds in the bidentate P,P-donor ligands by $[PdCl_2(cod)]$ is somewhat more efficient. Although cyclopalladation of diphosphinite HL[48] with the *meta*-phenylene skeleton [122, 158] and *m*-xylylene-α,α'-diphosphine HL[61] (see Ref. 159) gives PCP-complexes **48** and **61a** in almost quantitative yields (90%–98%), this still requires long-term (5 h) heating in toluene.



Note for comparison that the use of other reagents [the acetonitrile complex [66] or palladium(II) [121] trifluoroacetate] in reactions with related P,P-ligands allows one to attain rather high yields (75%–85%) at 20 °C over short periods of time (10 min to 2 h, see Table 4).

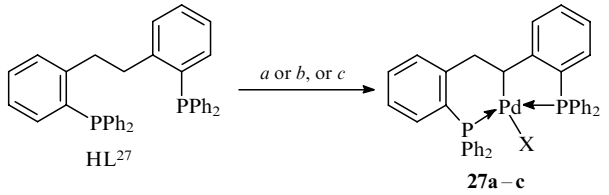
Assuming that the efficiency of nitrile reagents is mainly determined by the ease of replacement of the auxiliary neutral ligand, one should expect that the appearance of phosphines (that are held more tightly by the metal centre) in the palladating reagent would complicate the stage of formation of the coordination intermediate. From this standpoint, the results of cyclopalladation of the HL[62] ligand with a phosphine reagent, *trans*-$[PdBr_2(PPh_3)_2]$, appear rather unexpected: the PCP-complex **62a** has been obtained in a quite satisfactory yield.[155]



Conversely, the reaction of the same HL[62] ligand with the nitrile reagent $[PdCl_2(NCPh)_2]$ gave polymeric coordination complex *trans*,*trans*-$[\{PdCl_2(\mu\text{-HL}^{62})\}_n]$ as the major product; the C–H bond in this complex was activated with moderate success only upon long-term thermolysis (MET, 48 h, yield 31%).[155]

It could be suggested that in the above example, a positive role is played by the replacement of the chloride in the nitrile metallating agent by the bromide in the phosphine analogue. However, this appears unlikely in view of the behaviour of diphosphines with dibenzyl (HL[27]) and stilbene skeletons (HL[10] and HL[45]) with respect to various palladating reagents (see Table 4). For instance, the activation of the aliphatic C–H bond in the diphosphine HL[27]

is obviously hampered upon the replacement of the chloride reagent $[PdCl_2(NCPh)_2]$ by the bromide $K_2[PdBr_4]$ and, the more so, by the iodide $Na_2[PdI_4]$. Under similar conditions, the yield of the PCP-complexes **27** either sharply decreases (X = Cl, 75%; X = Br, 26%), or remains comparable (X = I, 86%) provided that the reaction duration is increased five- to seven-fold.[60,61]



X = Cl (**a**), Br (**b**), I (**c**); (*a*) $[PdCl_2(NCPh)_2]$, MET, Δ, 1.5 h, 75%; (*b*) K_2PdBr_4, MET, Δ, 2 h, 26%; (*c*) $[PdI_2(PPh_3)_2]$, MET, Δ, 10 h, 86%.

Similar effects are also observed in the cyclopalladation of the vinyl fragment in the diphosphines HL[10] and HL[45] with the stilbene skeleton. On passing from $[PdCl_2(NCPh)_2]$ to K_2PdBr_4 and then to $[PdI_2(PPh_3)_2]$, the temperature regime become more drastic and the reaction duration increases; simultaneously, the yield of the cyclopalladated compound decreases (see Table 4).[60,61]

A similar halide-induced effect has been found in a study of *ortho*-metallation of phosphites of the $P(OAr)_3$ type (Ar = Ph, *o*-, *m*-, *p*-Tol, *p*-ClC_6H_4).[143,144] The thermal activation of the $C(sp^2)-H$ bond in the coordination complexes $[Pd(HL)_2Hal_2]$ is substantially hampered upon the variation of the halide in the series Cl < Br < I: under the same conditions (decalin, Δ, 3 h), the yield at this stage decreases 2.5-fold on the replacement of Cl^- by Br^-, and in the case of the iodide analogue, only traces of the PC-palladacycle are formed.

Unfortunately, such comparison has not been carried out for monodentate phosphines, although a process acceleration could be expected upon the replacement of Cl^- by Br^- and then by I^-. This assumption follows from several considerations, which are outlined below.

1. Cycloplatination of phosphines in the $[Pt(HL)_2Hal_2]$ type coordination complexes[86,160] is accelerated in the series Cl < Br < I, whereas for phosphites, the opposite order was found.[144]

2. In the complexation of the phosphine $PPhBu^t_2$ (HL^{23}) with palladium(II), this sequence (Cl < Br < I) reflects the increase in the tendency to form binuclear complexes in which the subsequent cyclopalladation proceeds more easily due to appearance of a coordination vacancy through cleavage of halide bridges. For example, the $[Pd(HL^{23})_2Cl_2]$ complex reacts with LiI being converted into the binuclear intermediate $[\{Pd(HL^{23})I(\mu\text{-}I)\}_2]$.[83]

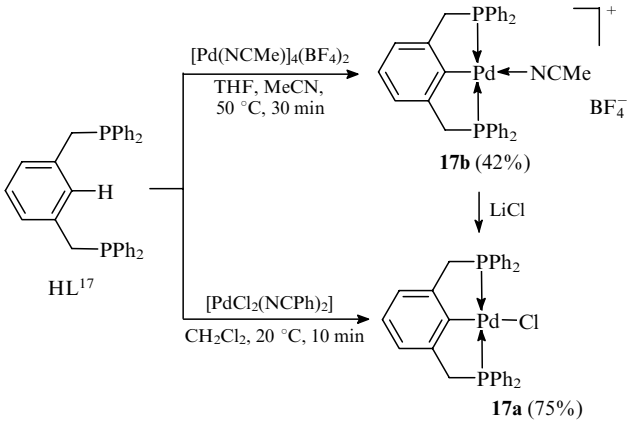
3. The same dependence on the nature of the halide (Cl < Br < I) was observed in the case of intermolecular activation of C–H bonds by $[Pd(PPh_3)_2Hal_2]$ type complexes.[161,162]

Unfortunately, systematic investigations of the role of the anions in the palladating reagents of the similar structure or in the coordination intermediates of the same type are scarce. The true reasons for the halide effects remain obscure; in all probability, the final outcome depends on a complex combination of the electronegativity and the size of the halide atoms, their leaving-group properties and the tendency to accomplish the bridging function. All this is superimposed onto the steric effects stemming from the ligand subjected to metallation. A significant contribution to the slowing of cyclopalladation following the change in the nature of the halide (Cl < Br ≪ I) can be made by the increase in the strength of their binding to the metal (Lewis acid of class *b*).[154]

At first glance, cationic reagents of the $[Pd(NCR)_4]^{2+}$ type[163] free from halides and containing easily dissociating nitrile ligands appear especially attractive. The positive charge of the metal centre should ensure its high electrophilicity in the activation of the aromatic C–H bonds. However, analysis of the available published data shows that the situation is not that unambiguous.

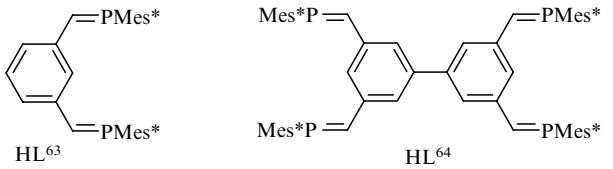
The use of reagents of this class has been limited so far to cyclopalladation of only bidentate substrates with an aromatic skeleton, mainly *m*-xylylene-α,α′-diphosphines and their dendrimer analogues.[48–50,164,165] Most often, the preliminarily obtained $[Pd(NCMe)_4](BF_4)_2$ complex is used;[163,166,167] however, it can be generated *in situ*, for example, by treatment of a suspension of palladium chloride in acetonitrile with a stoichiometric amount of $AgBF_4$ with heating.[49]

The advantages of this approach include the possibility of isolation of the intermediate acetonitrile solvate **17b**, which is especially useful for the subsequent introduction of weakly coordinated ligands. However, most often, this solvate is converted without isolation into standard chloride PCP-complex, for example, **17a**.



Unfortunately, the efficiency of this highly electrophilic cationic reagent is evidently lower than expected (see Table 4). In most cases, the PCP-complexes are isolated in moderate (42%–67%)[48,49,164] or even in low yields (15%–20%);[50,165] in some cases, the reaction does not proceed at 20 °C[48,127,165] and requires refluxing in acetonitrile.[49,50,164] The best results were obtained with generation of the solvated $[Pd(NCMe)_4](BF_4)_2$ reagent *in situ*. In this case, the acetonitrile derivative **17b** was isolated in 90% yield.[49]

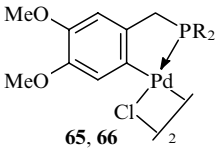
The cationic complex $[Pd(NCMe)_4](BF_4)_2$ is far inferior in activity to the neutral chloride analogue, $[PdCl_2(NCPh)_2]$. The yield of the PCP-complex **17a** is lower with the former reagent[164] than with the latter,[66] despite a longer reaction time and a higher temperature. The same conclusion follows from comparison of the outcome of cyclopalladation of bis(phosphaalkenes) HL[63] (Ref. 125) and H_2L[64] (Ref. 126) (see Table 4). The reason for the lower efficiency of the cationic reagent is not clear, although a possible main reason is reduction of the reagent (extensive isolation of palladium black during the reaction has been noted[165]).



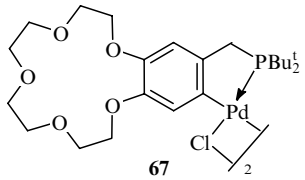
The role of the bases in cyclopalladation of P-donor substrates also differs from that observed for the N-analogues.[21] Phosphines and phosphites have lower basicities than N-donor ligands with a similar structure, but it varies over a fairly broad range depending on the nature of the substituents at the phosphorus atom. According to the pK_a values for the corresponding conjugate acids $[HPR_3]^+$ (see Refs 52–54), the basicity of aliphatic tertiary phosphines $PAlk_3$ is rather high (pK_a 8.0–11.4); but it markedly decreases on passing to triarylphosphines (pK_a 2.7–5.3) and sharply decreases for phosphites (pK_a from −1.8 to −2.0).

Nevertheless, P-donor substrates can often be cyclopalladated without introduction of an additional base. This function can be performed by phosphine ligands themselves; thus the isolation of the corresponding phosphonium salts as the chloride, $[HPBu^t_3]^+Cl^-$,[70] the tetrafluoroborate, $[HPBu^t_2(C_6H_4Et\text{-}2)]^+BPh^-_4$,[55] and the tetrachloropalladate, $[HPBu^t_3]^+_2[PdCl_4]^{2-}$,[69] from the reaction mixture (after cyclopalladation) has been reported.

The necessity of adding a base arises in the case of low-reactivity ligands. Usually, sodium acetate is used as the base; triethylamine[82] or potassium carbonate[140] are less effective and are used less often. Examples of substantial acceleration of the process following the introduction of a proton acceptor are few and mainly refer to reactions of benzylphosphines. Thus the metallation of PBu^t_2Bn (HL^{22}) on treatment with $[PdCl_4]^{2-}$ in boiling MET in the presence of AcONa proceeds much faster (0.5 h, 75%) than without a base (5 days, 64%).[82] *ortho*-Palladation of a less bulky substrate, PBu^tBn_2 (HL^{37}), was accomplished (in a yield of only 12%) only upon the addition of AcONa.[82] The base effect is most pronounced in the case of dialkoxy-substituted benzylphosphines; the C–H-bond activation in the HL^{65} and HL^{66} ligands under the action of *trans*-$[PdCl_2(NCPh)_2]$ is totally impossible without a base, and that in the case of HL^{67} occurs only by 10%. The same reactions carried out in the presence of AcONa in boiling MET ensure high yields of *ortho*-palladated dimers **65** and **66** (81%–84%), the reaction time (2 and 0.5 h) being dependent on the degree of steric assistance from the P-substituents (θ = 152 and 176°, respectively).[113]



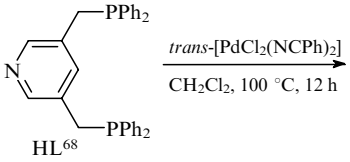
65, **66**



67

R = Ph (**65**), Bu^t (**66**).

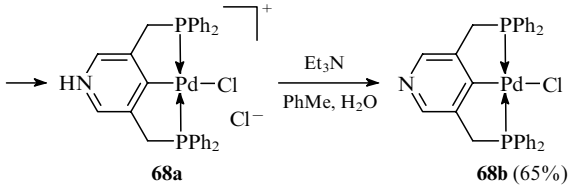
In the cyclopalladation of the diphosphine HL^{68} with the lutidine skeleton, the pyridine ring of the ligand serves itself as the acceptor of liberated protons; hence, the reaction yields first the ionic PCP-complex **68a**, which is converted into neutral compound **68b** under the action of a base.[168]



HL^{68}

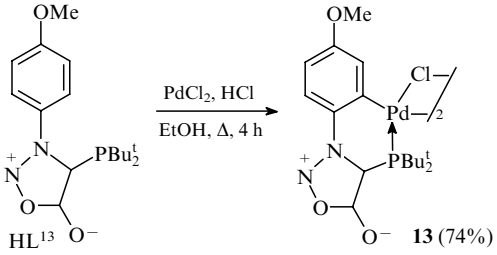
trans-$[PdCl_2(NCPh)_2]$

CH_2Cl_2, 100 °C, 12 h



68a **68b** (65%)

However, under certain conditions, a base does not facilitate cyclometallation and, moreover, it can even inhibit the process. In addition to the known acid-catalysed cyclopalladation of $HPMes_2$ (see Section II.2.b),[169] noteworthy is the activation of the C(sp^2)–H bond in (3-arylsydnonyl)phosphine HL^{13}, which takes place in acid medium (EtOH, conc. HCl), to give the unfavourable six-membered PC-metallacycle in dimer **13**.[63]



HL^{13} **13** (74%)

The possibility of stimulating the cyclopalladation by changing the nature of the solvent has not been studied in systematic mode; the choice of the medium was dictated first of all by the structure of the palladating reagent and the desire to conduct the reaction under homogeneous conditions. It can be suggested from general considerations that highly solvating polar and protic solvents should be favourable for the creation of a coordination vacancy. Perhaps, it is for this reason that alcohols (a MeOH–EtOH mixture,[81] Pr^nOH,[55] Bu^iOH,[145] MET[82,119]) are used for the transformation of chloride coordination precursors into cyclopalladated complexes using alcohols .

When choosing the solvent, one should take into account its ability to compete with the substrate for the site at the metallic centre. Thus cyclopalladation of the secondary phosphine $HPMes_2$ proceeds faster in THF or CH_2Cl_2 than in acetone and becomes impossible in a readily coordinating solvent, acetonitrile.[169] Apparently, for the same reason, cyclopalladation of tri(*tert*-butyl)phosphine under the action of potassium tetrachloropalladate in DMF requires 12 h, whereas the reaction of the same phosphine with $[PdCl_2(NCPh)_2]$ in CH_2Cl_2 is over after 2 h under the same conditions (20 °C, reactant ratio 2 : 1).[70]

The reactant ratio in cyclopalladation is among the most important factors determining the reaction rate, most of all, in 'halide' routes. The metal-to-ligand ratio influences the efficiency of vacation of the coordination site needed for the activation of the C–H bond. This goal is difficult to attain for Pd : HL = 1 : 2 due to the strong binding to the metal of all ligands in the bis(phosphine) intermediate of the $[Pd(HL)_2Hal_2]$ type. Therefore, it comes as no surprise that reactions with this stoichiometry often require rather drastic conditions (up to refluxing in decalin),[143,144] while the yields of cyclopalladated compounds leave much to be desired[82,143,144] (see Table 1). In addition, under these conditions, the reactions often do not give the dimeric complex, but instead, result in its adduct with the starting P-donor ligand.[69,143,144,170]

When equimolar amounts of reactants are used, the problem of generation of a coordination vacancy can be easily solved due to the cleavage of the halide bridges in the binuclear intermediate of the $[\{PdHal(HL)(\mu\text{-}Hal)\}_2]$ type, which allows this reaction to be carried out under milder conditions with good product yields.[57,81]

The reactant ratio becomes almost insignificant only when the process is efficiently sterically stimulated, for example, in reactions of phosphines such as PBu^t_3,[70,71] $PMes_3$,[109,110] and $P(Tol\text{-}o)_2Bu^t$.[81]

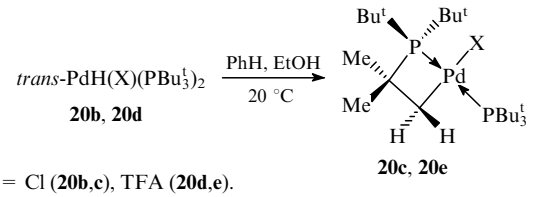
b. Organometallic reagents in cyclopalladation

A special group of cyclometallation processes is comprised by reactions involving organometallic or hydride reagents or intermediates. As a rule, these synthetic protocols show clear advantages over the classical methods considered above, possibly, due to different in kind mechanisms of transformations.

The C–H bonds of monodentate phosphines can be activated within hydride intermediates, $[PdH(X)(HL)_2]$. This approach has been mainly developed using di- and tri(*tert*-butyl)phosphine ligands as substrates.[71,171] The standard route to these hydrides[71,172,173] includes oxidative addition of the acid HX to a palladium(0) complex with the corresponding phosphine, $[Pd^0(HL)_2]$;[174] the existing alternative ways are based on the reduction of Pd(II) bis(phosphine) complexes, for example, by sodium borohydride.[175] The method including a short-term (0.5 h) heating of $PdCl_2$ with PBu^t_3 in DMF at 115 °C is more efficient and practically convenient (the yield of the hydride complex is 90%).[73]

Although hydride complexes of this type are rather stable in the solid state, in solutions, their phosphine ligands are cyclometallated rather easily (at 20 °C).[73] This process depends appreciably on the solvent and on the nature of the anion. In

dichloromethane, the reaction proceeds more rapidly than in benzene and it is markedly accelerated upon the addition of alcohol.[71, 171] The effect of the anion nature is clear-cut and differs from that observed for classical reagents (see Section II.2.a). For example, the hydrido chloride complex **20b** is converted into the phosphine adduct **20c** six times as fast (0.5 h) as the trifluoroacetate analogue **20d** (2 – 3 h), and the hydrido bromide precursor provides instantaneously the phosphapalladacycle, which is formed as the dimer **20a** (apparently, for steric reasons) rather than its mononuclear phosphine derivative.[71, 171]



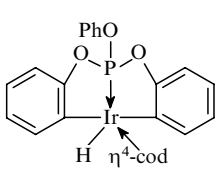
X = Cl (**20b**,**c**), TFA (**20d**,**e**).

Cyclometallation of mono- and dihydride platinum phosphine complexes proceeds equally easily and obeys the same type of dependence on the nature of the anion.[176] The [PdH(Cl)(AsBu$^t_3$)$_2$] hydride with bulky arsine ligands also readily forms a palladacycle (as an unusual dimeric compound with two hydride bridges),[177] whereas the standard coordination complexes cannot be involved in this process.[178]

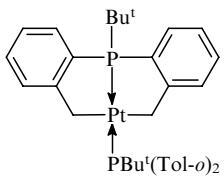
The high efficiency of hydride complexes can be illustrated by closure of an additional four-membered palladacycle due to intramolecular activation of the C – H bonds of the PBu^t group in the iridium(III) PCP-complex [(η^3-HL′)IrH(Cl)] (H_2L' is the 4-MeO-substituted analogue of the HL[25] ligand), resulting in the formation of the [5.5.4]-tricyclic PCPC-complex, [(η^4-L′)Ir(Cl)].[32] No transformations of this type have been described in the chemistry of pincer palladium complexes, although their hydride derivatives are known.

The electronic state of the metal in the coordination precursors changes crucially following the appearance of C-bound ligands, which can serve as efficient acceptors for the proton liberated during cyclometallation or participate in the reductive elimination together with the hydride ligand formed upon the oxidative addition of the phosphine C – H bond. An alternative interpretation of the role of these ligands is easy generation of a vacant coordination position due to protolysis of the Pd – C bond.

The high activity of intermediates with M – Me bonds is well known. One can mention *ortho*-metallation of triphenylphosphine in the [MeRh(PPh$_3$)$_3$] complex, resulting in a strained four-membered PC-metallacycle and liberation of methane,[179] and double *ortho*-metallation of the simple phosphite P(OPh)$_3$ (H_2L^{69}) through the coordination intermediate [MeIr(cod)(H_2L^{69})], which furnishes bicyclic CPC-structure **69′**.[31]



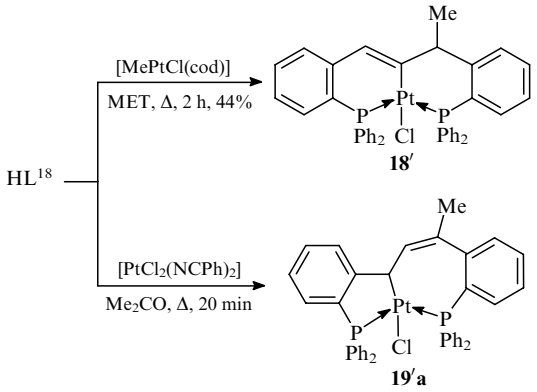
69′



30′

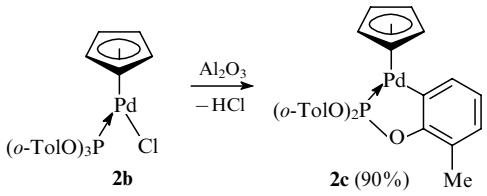
The efficiency of replacement of halides by Me groups in the coordination intermediates of the [M(HL)$_2$X$_2$] type (X = Cl, Me) has been demonstrated with platinum(II) compounds.[115] The activity of organometallic intermediates can be illustrated by the formation of the [Pt(η^2-L)$_2$] bis(chelate) complexes from phosphine adducts of the [MePt(η^2-L)(κ^1-HL)] type [HL = PBu^t_n.(Tol-*o*)$_{3-n}$, where *n* = 1, 2] due to the activation of the C – H bond in the monodentatate phosphine ligand [30, 180] and by double cyclometallation of PBu^t(Tol-*o*)$_2$ at both *o*-tolyl fragments, giving rise to the CPC-structure **30′**.[30] Unfortunately, transformations of this type have not been studied for palladium analogues; palladium spiro complexes are available only through *ortho*-lithiated ligands (see Section IV), while the palladium(II) CPC-complexes are still unknown. This difference between the reactivities of compounds of the two d^8 metals might serve as indirect evidence pointing to different mechanisms of C – H bond activation.

The passage from classical to organometallic reagents can result in switching to another metallation site due to the modification of the reaction mechanism. Two different platinacycles obtained from the same HL[18] ligand can serve as examples.[68]



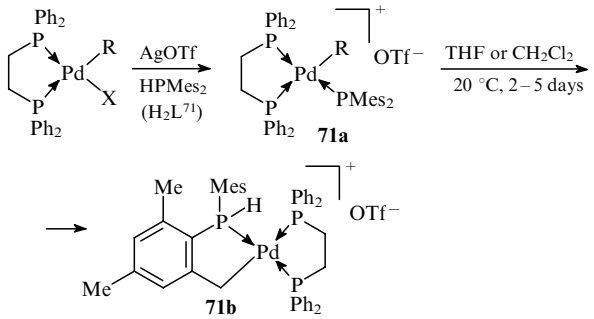
Although no comparison of the behaviours of the two types of reagent in the cyclopalladation of the HL[18] ligand has been carried out, it can still be suggested that this approach can be useful not only for facilitating the process but also for modification of the reaction pathways in systems that contain several alternative reaction sites.

One can only regret that organometallic reagents are seldom used for cyclopalladation. One of the few examples is easy activation of the C(sp^2) – H bond in the phosphite HL[2] in the [Pd(η^5-Cp){P(OTol-*o*)$_3$}Cl] complex, which takes place under unusual conditions — during chromatography of this compound on neutral alumina.[57] The regularities typical of classical systems (see Section II.2.a) are retained; these include the 'halide' effect (the iodide analogue of **2b** is inactive)[57] and the preferred formation of the five-membered PC-metallacycle {a four-membered ring is not formed from the [Pd(η^5-Cp)(PBu$^t_2$Ph)Cl] complex}.[84]



As yet another example of C – H bond activation with participation of a support, one can mention the quantitative formation of the cyclopalladated compound [{(η^2-L[70])Pd(μ-Cl)}$_2$] (**70**) on passage of the [{(κ^1-HL[70])PdCl(μ-Cl)}$_2$] coordination complex with the AsMes$_3$ ligand (HL[70]) through silica gel. The effect appears even more impressive in view of the fact that cyclopalladation of the HL[70] ligand could not be accomplished by the reaction with [PdCl$_2$(NCPh)$_2$] even in boiling benzene.[109]

An absolutely different role is played by the aryl or alkyl groups (Ph, Me) attached to palladium in the cyclometallation of the secondary dimesitylphosphine HPMes$_2$ (H_2L^{71}). The monodentate P-coordination of this bulky ligand giving cationic intermediates of the [(dppe)PdR(κ^1-H_2L^{71})]OTf (**71a**) type [dppe is 1,2-bis(diphenylphosphino)ethane, OTf is trifluoromethanesulfonate] is possible only after the removal of the halide ion from the reagent. A C(sp^3) – H bond of one of the *o*-Me groups of the mesityl substituent is activated on long-term keeping of solutions of these coordination precursors in CH_2Cl_2 or THF at 20 °C to give cationic complex **71b**.[169]



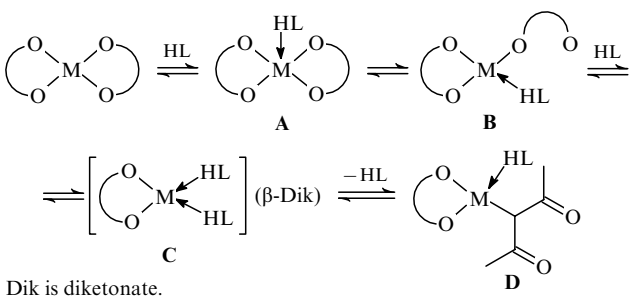
R = Me, Ph.

High activity of the intermediates containing alkyl or aryl groups bound to the metal is indicated by the fact that cyclopalladation of the secondary phosphine H_2L^{71} could not be accomplished using Pd(II) acetate. Detailed studies of the reactions of $HPMes_2$ with palladium(II) showed that cyclopalladation is catalysed by acids (presumably present as impurities in the solvents or reactants used) and inhibited by bases. Protolysis of the Pd–R bond needed for generation of the coordinatively unsaturated 14-electron species $\{(dppe)Pd^{II}(H_2L^{71})\}$ was confirmed by identification of the corresponding hydrocarbons RH (by spectroscopy and using ^{13}C-labelled model compounds). However, the researchers cited do not rule out the possibility of alternative pathways including oxidative addition of the P–H bond or benzyl C–H bond to palladium(II) followed by the reductive elimination of the hydrocarbon RH.[169]

Cases of acid catalysis (through organometallic intermediates) are also known in cycloplatination chemistry. Thus only in the presence of catalytic amounts of HCl, does the phosphine PPr^i_3 (HL^{72}) in the intermediate $[MePt(\kappa^1\text{-}HL^{72})_2(OTf)]$ complex form a four-membered metallacycle.[181]

The selectivity of the $PHMes_2$ (H_2L^{71}) → **71a** → **71b** transformation is remarkable due to the presence of two other potential reaction sites in the ligand molecule: activation can involve both the P–H bond of the secondary dimesitylphosphine H_2L^{71} (*via* deprotonation or oxidative addition) and the P–C(Mes) bond (processes of the latter type are known in the chemistry of arylphosphine complexes of transition metals [182]). It is noteworthy that both reaction directions are realised for the phosphine H_2L^{71} on the platinum(0) centre, giving rise to the phosphide complexes, [(dppe)PtH($PMes_2$)] and [(dppe)Pt(Mes)(PHMes)], respectively.[183]

Interesting possibilities appear when palladium(II) bis(β-diketonate) complexes are used as palladating agents. The synthetic routes to reagents of this class are simple and well-known,[184] and their complexation with N-[185–189] and P-donor ligands [185–187,190–194] have been the subject of detailed research for many years. The set of transformations of β-diketonates on palladium centres caused by the introduction of the additional ligand is fairly diverse.[195] On the basis of kinetic studies,[188,192] it was suggested that the reaction gives first five-coordinate species **A** with O,O′-chelated β-dicarbonyl ligands, one of which then partly undergoes dechelation (**B**). With excess Lewis base (HL), the β-diketonate ligand can be displaced from the metal coordination sphere (**C**) and returns there again after the rerarrangement

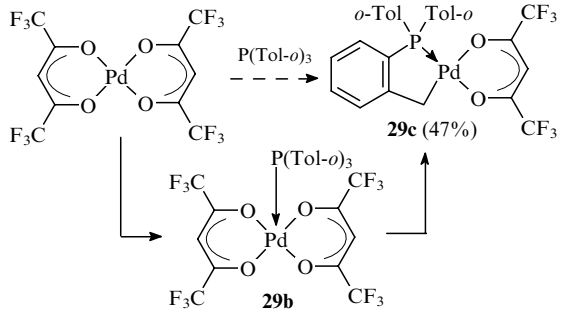


Dik is diketonate.

into the γ-C-bound state (**D**). The structures of the species involved in these multistage processes have been convincingly confirmed by both spectroscopic methods (*in situ* or after isolation) and X-ray diffraction, for example, for five-coordinate adducts of the $[Pd(hfac)_2(PR_3)]$ type ($hfac^-$ is hexafluoroacetylacetonate; R = *o*-Tol [191,196] or Ph [197]).

As regards the use of β-diketonate complexes for cyclometallation, species of type **A** and **D** seem to be the most valuable. In the former type of species, the monodentate O-coordinated β-diketonate with the hard donor atom is weakly bound to the metal and can easily depart, thus leaving a free coordination site needed for the activation of the C–H bond. In organometallic species of type **D**, the γ-C-bound diacylmethyl group $(RCO)_2CH^-$ can not only serve as a good acceptor for the protons being liberated but should also decrease substantially the electron density at the metallic centre due to conjugation and thus enhance its electrophilic properties. In this respect, the hexafluoroacetylacetonate reagent should be more reactive than the acetylacetonate analogue.

The efficiency of the β-diketonate reagents in the cyclometallation was first demonstrated for the *ortho*-palladation of primary benzylamine,[189,198] which had long been considered to be absolutely impossible.[21] Unfortunately, the use of this approach for the cyclopalladation of phosphines is limited to two examples,[116,196] and only one of these studies gives quantitative data.[196] The activation of the C–H bond in tri(*o*-tolyl)phosphine on treatment with palladium(II) bis(hexafluoroacetylacetonate) occurs with moderate success (the yield is 47%), but the reaction proceeds under mild conditions (20 °C), the transformation of the intermediate five-coordinate $[Pd(hfac)_2P(o\text{-}Tol)_3]$ (**29b**) adduct into the cyclopalladated compound **29c** being possible even in the solid phase during long-term storage of the sample.[196]

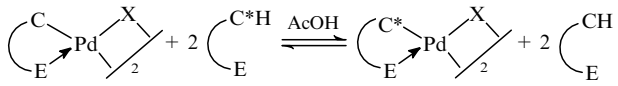


A certain role in this process may be performed by steric promotion: the large bulk of the phosphine ligand (θ = 194°)[95] hinders the rotation about the P→Pd bond in the five-coordinate precursor **29b**, which is manifested as non-equivalence of the three *o*-methyl groups in the ^1H NMR spectra recorded at −55 °C (δ 1.72, 2.10 and 2.94 ppm).[196] The substantial dispersion of these signals ($\Delta\delta$ > 2.2 ppm) may be related to the effect of the paramagnetic anisotropy of the metal on the protons of one of these groups located in the apical position near palladium. Thus, the stereochemistry of the coordination intermediate is favourable for the activation of the phosphine C–H bond.

Mention should be made of the synthetic pathway provided by the use of more readily available cyclopalladated complexes as metallating agents. This is the exchange of cyclopalladated ligands (ECL).[199,200] Recently,[201,202] the term 'transcyclometallation' has been proposed for these reactions.§ Detailed investigations of this process for N-donor ligands [99,200,203,204] have shown that it is

§ Although this concise term may seem attractive, it is not quite adequate to the process in question, because a similar term, 'transmetallation' is used to describe the processes based on replacement of one metal by another (rather than one ligand by another). Perhaps, it would be more appropriate to introduce the term 'transligandation' of palladacycles, which would describe the exchange of ligands at the same metallic centre.

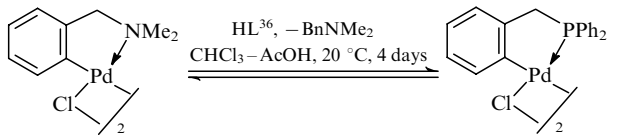
fairly efficient with respect to 'difficult' N-donor substrates and can be useful for the preparation of palladacycles that are inaccessible or accessible with difficulty by other, simpler methods. In the simplified form, the ECL can be represented as follows:



E is the heterodonor atom.

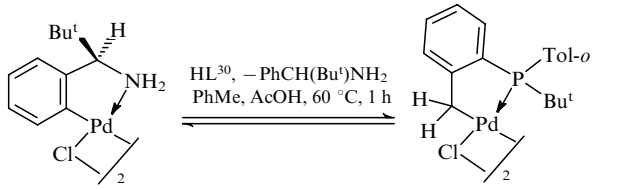
The views on the mechanism of the exchange of cyclopalladated ligands are rather contradictory. Both a dissociative route, which implies the destruction of the initial palladacycle as far as to the closure of a new ring,[199,200] and an associative route with a bis(chelate) intermediate containing both the initial and the new palladacycles have been considered.[203] Irrespective of the views on the mechanism, reactions of this type are carried out in protic media, most often, in acetic acid or its mixtures with aprotic organic solvents.

One can only regret that the use of this approach to phosphapalladacycles is limited to single examples. The use of the simplest CN-palladacycle (**A**) based on *N,N*-dimethylbenzylamine for the activation of the aromatic C–H bond of diphenylbenzylphosphine (HL^{36}) has been reported.[205] However, the cyclopalladated CN-complex proved to be inefficient in this process, like simpler but highly electrophilic $Pd(OAc)_2$. The dimer **36a** has been obtained in a yield of only 21%,[205] while its μ-acetate analogue (**36b**), in 19% yield.[114]



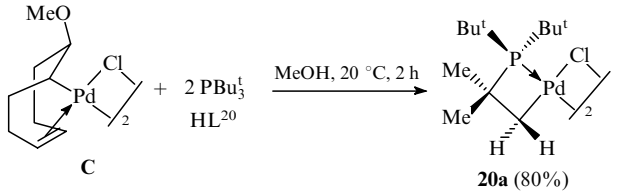
A **36a** (21%)

Some progress along this line has been attained due to the structural modification of the CN-reagent. When the cyclopalladated derivative of primary benzylamine (**B**) was introduced in the reaction with the phosphine $P(o\text{-Tol})_2Bu^t$ (HL^{30}) in the presence of acetic acid with heating, the dimer **30b** was obtained in 71% yield.[206,207]



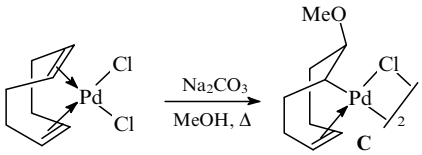
B (R_P,S_P)-**30b** (71%)

Formally, cyclopalladation of the tri-*tert*-butylphosphine HL^{20} under the action of the organometallic dimer **C** should be attributed to the same type of processes.[74] This reagent can be regarded as a specific analogue of a cyclopalladated complex in which the double bond of the alkene fragment replaces the heterodonor centre.



C **20a** (80%)

Unfortunately, this reaction is not discussed by the authors, but the data presented in the Experimental clearly indicate that it smoothly proceeds under mild conditions to give dimer **20a** in a high yield. The type **C** reagents are quite accessible through methoxypalladation[208] of the metal-bound cycloocta-1,5-diene in the commercially available $[PdCl_2(cod)]$ complex, which can also be generated *in situ*.[209,210]



C

The data considered in this Section demonstrate that organometallic reagents possess high (and in some cases, unusual) activities in cyclopalladation. Although this field has not been adequately explored as yet, further progress along this line can provide valuable results.

3. Mechanistic aspects of the direct intramolecular cyclopalladation of P-donor ligands

Two features distinguish the cyclopalladation processes of P-donor ligands from those of substrates with harder donor atoms: first, the pronounced steric effects and, second, high stability of the intermediate coordination compounds. The latter feature is exceptionally convenient from a practical standpoint, because the problem of oxidative instability of phosphine ligands is eliminated when they are coordinated through heteroatom(s). In addition, even this preliminary stage largely determines the possibility (and ease) of the subsequent activation of the C–H bond. Therefore, analysis of the structural peculiarities of coordination precursors deserves attention, first of all, as a way of estimating the true causes of steric promotion of cyclopalladation processes.

a. Coordination intermediates

Usually, three factors are considered as underlying the steric effects involved in cyclopalladation: the entropy (a substantial portion of the inner rotation entropy is lost even in coordination precursors), enthalpy (the number of unfavourable interactions decreases upon cyclisation) and conformational factors (the conformational mobility of the ligand coordinated through the heteroatom decreases or the ligand is fixed in a rotamer that ensures proximity of the C–H bond suitable for activation with the metallic centre).[68,96,97,118,119] With fairly high steric crowding of the phosphine ligands, the barriers to rotation around the P→Pd and P–C bonds in the coordination complexes may increase, so that the rotamers can be detected by spectroscopy,[55,81,180,211–214] in some cases, even at 20 °C.

For the coordination intermediate to be perfectly prepared for the subsequent proper cyclometallation step, its structure should ensure not only the proximate positions of the C–H bond to be activated and the metal, but also the possibility of formation of a free coordination site in the equatorial plane. Presumably, effective solution of the last-mentioned problem in sterically overcrowded systems makes a substantial contribution to the steric assistance to the C–H bond activation.

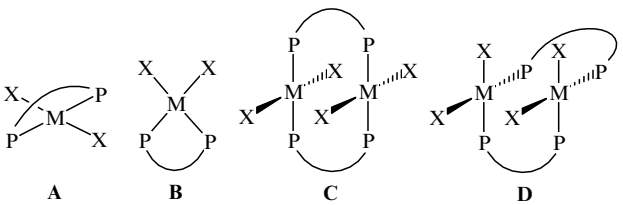
The reactions of monodentate P-donor ligands with halide-containing palladating agents are often (especially in early publications) carried out in two or even in three stages with isolation of intermediate mono- or binuclear complexes of the $[Pd(\kappa^1\text{-}HL)_2Hal_2]$ or $[\{Pd(\kappa^1\text{-}HL)Hal(\mu\text{-}Hal)\}_2]$ type depending on the reactant ratio. The problem of formation of a coordination vacancy in these precursors can be solved in several ways. In complexes with bulky P-donor ligands, the P→Pd bonds are weakened,[215] which have to facilitate the phosphine dissociation. Indeed, a partial dissociation of *tert*-butyldi(*o*-tolyl)phosphine (HL^{30}) from the intermediate coordination complex, $[Pd(\kappa^1\text{-}HL^{30})_2Cl_2]$, was confirmed by molecular mass measurements (508 against the calculated value of 718).[81] In palladium(0) phosphine complexes, the coordination number of the metal decreases from four to two following an increase in the steric requirements of the ligands,[174,215–218] irrespective of their basicities.[216]

It is also assumed [97] that bulky ligands can stabilise coordinatively unsaturated species resulting from elimination of one of the ligands through steric shielding of the vacant site. A certain stabilising role can also be played by secondary interactions with the metal.[174, 217] Under these conditions, the structure of the initial intermediate (mono- or binuclear) is virtually insignificant. Apparently, this is why cyclometallation of sterically crowded ligands depends only slightly on the reaction conditions (see Section II.1).

In addition, due to the large number of unfavourable interactions between bulky substituents of the phosphine and *cis*-arranged ligands (usually halides) in bis(phosphine) complexes, they tend to be transformed into binuclear halide-bridged compounds [55, 219] (they are formed even at a metal : ligand ratio of 1 : 2 [55]). These binuclear complexes readily dissociate owing to cleavage of the halide bridges to give coordinatively unsaturated species. The tendency for the monomer → dimer transformation is known to increase with an increase in the size of the halide ion or its ability to perform the bridging function in the sequence $Cl^- < Br^- < I^-$. Thus upon the replacement of the chloride in *trans*-$[Pd(PPhBu^t_2)_2Cl_2]$ by iodide, the binuclear $[\{PdI(PPhBu^t_2)(\mu\text{-}I)\}_2]$ complex is formed instead of the expected mononuclear analogue, *trans*-$[Pd(PPhBu^t_2)_2I_2]$.[83] However, the dependence of the ease of cyclometallation on the nature of the halide follows the opposite order, indicating the predominant role of other factors at subsequent stages.

In the absence of steric promotion, the advantage of binuclear coordination precursors for the subsequent cyclopalladation becomes more pronounced. This can be confirmed by the results of a study of the H/D-exchange in mono- and binuclear complexes, $[Pd(HL)_2Cl_2]$ and $[\{Pd(HL)Cl(\mu\text{-}Cl)\}_2]$ [HL = (*o*-Tol)P(Ph)Hex (HL[33]) and (*o*-Tol)P(Me)CH_2CH_2Tol-*o* (HL[34])].[108] Only for binuclear compounds, was the H/D-exchange detected for the *o*-methyl group of the P-tolyl substituent upon prolonged storage of the compounds as solutions in d_4-methanol at 20 °C, which was indicative of reversible C–H bond activation. Although the corresponding phosphapalladacycles have not been synthesised (due to insufficient steric stimulation), their formation was detected in mass spectroscopic studies of the same binuclear coordination precursors. However, in the case of mononuclear bis(phosphine) intermediates, no activation of the C–H bond was observed.[108]

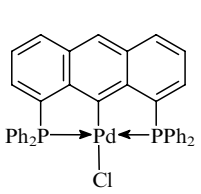
The structure of the coordination intermediates is also important for the cyclopalladation of diphosphine ligands. Unfortunately, purposeful studies of such intermediate complexes are scanty. The types of coordination of diphosphines are diverse and include both mononuclear structures with a P,P-chelating ligand with either *trans*- (**A**) or *cis*-geometry (**B**) and binuclear complexes with a bridging P,P-ligand linking two metal centres in either *trans*- (**C**) or *cis*-configuration (**D**).[123] The formation of coordination polymers cannot be ruled out either.



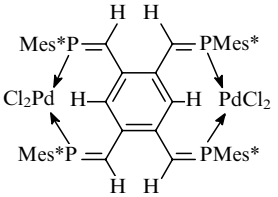
A **B** **C** **D**

It is reasonable to suggest that the optimal geometry of the coordination precursor should be largely determined by the structure of the fragment connecting two P-donor atoms. In the general case, *trans*-P,P-chelation is preferred for the subsequent cyclopalladation. This geometry ensures the closest proximity of the metal and the C–H bond to be activated, which is located in the middle of the bridging fragment in the vast majority of known ligands. However, the structure of such coordination intermediates has been convincingly confirmed only in a few cases.

In the coordination of a diphosphine having a rigid anthracene-1,8-diyl skeleton (HL[73]), the central C–H bond and Pd are forced to approach each other. The interaction of the ligand with the metal cannot be limited to only *trans*-P,P-chelation (despite the quite acceptable distance between the two phosphorus donor atoms equal to 5 Å) due to steric hindrance created by the C(9)–H bond of the anthracene skeleton; therefore, the formal insertion of the metal into this bond to give PCP-complex **73** becomes inevitable.[156]



73



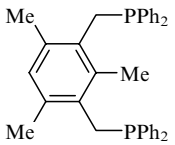
49b

The forced character of proximity of the metal atom and the C–H bond to be activated in the coordination precursor **49b** (detected by spectroscopy) was suggested for cyclopalladation of the H_2L[49] ligand.[117] This spatial proximity can be partly responsible (together with steric assistance of bulky supermesityl P-substituents) for the subsequent exceptionally easy cyclometallation of this and other similar ligands [125–127] (see Table 4).

The necessity of a mononuclear *trans*-chelate structure for the coordination intermediate of type **A** has also been assumed for cyclopalladation of diphosphines with relatively rigid *m*-xylylene skeletons.[66, 67, 155] However, no data on the isolation or reliable spectroscopic identification of such complexes have been reported as yet.

The possibility of controlling the types of ligand pre-coordination appears fairly attractive; however, studies of this type are scarce.[123, 155] For example, a study of cyclopalladation of *m*-xylylene-α,α′-diphosphine HL[62] by $[PdCl_2(PhCN)_2]$ has revealed predominant formation of an inactive polymeric coordination complex, *trans*,*trans*-$[\{PdCl_2(\mu\text{-}HL^{62})\}_n]$, whereas with the use of the phosphine-containing reagent $[PdBr_2(PPh_3)_2]$, cyclopalladation proceeds rather smoothly. While discussing the role of the phosphine ligand in the $[PdBr_2(PPh_3)_2]$ reagent, the researchers suggest that it can catalyse the rearrangement of the polymeric coordination intermediate into a mononuclear species with the *trans*-P,P-geometry, needed to bring together the C–H bond to be activated and the metal.[155]

A more detailed study [123] of the influence of neutral ligands in palladating agents on the structure of the coordination intermediates has been carried out using complexation with the diphosphine HL[74] as the example.



HL[74]

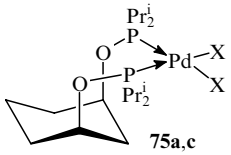
The cyclopalladated derivative of this diphosphine is unknown; however, the synthesis of its analogues **11** and **12** with two six-membered metal rings has been reported.[62]

The requirements of the structure of an optimal coordination precursor can vary depending on the position of the C–H bond subject to activation relative to the metal. This is the case on passing from *m*-xylylenediphosphine HL[17] to its homologue HL[74]. In the researchers' opinion,[123] of the three possible structural types of coordination complexes **B**–**D** (mononuclear *trans*-structures of type **A** are not considered in this work), the closest position of the specified $C(sp^3)$–H bond to the metal can be ensured only in the mononuclear species **B** having the *cis*-P,P-geometry.

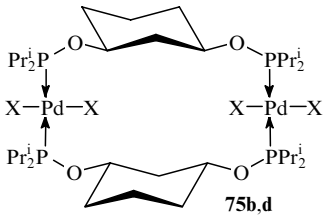
An important result of this study is the established relationship between the type of coordination and the nature of the palladating reagent. Thus the reaction of the HL[74] ligand with

the nitrile reagents $[MCl_2(NCR)_2]$ (M = Pd, Pt; R = Ph, Me) at 20 °C gives selectively and quantitatively only binuclear macrocyclic compounds of the *trans*, *trans*-configuration with a bridging diphosphine (type **C**). The structure of the complex *trans*,*trans*-$[\{PdCl_2(\mu\text{-}HL^{74})\}_2]$ was confirmed by X-ray diffraction. However, the complexation of HL^{74} with the diene reagent $[PtCl_2(cod)]$ gives, equally selectively, the mononuclear complex *cis*-$[PtCl_2(\kappa^2\text{-}HL^{74})]$ with P,P-chelating diphosphine of type **B** with an eight-membered ring.[123] Although the reasons for these differences remained unknown, the possibility of controlling the process at the stage of coordination precursors is undoubtedly useful. For the subsequent cyclometallation, which is often carried out at elevated temperatures, it is also important that the binuclear platinum(II) complex of type **C** is converted into thermally more stable mononuclear compound of type **B** under relatively drastic conditions (CH_2Cl_2, 140 °C, autoclave).[123]

Possibly, type **A** or **B** mononuclear complexes are also formed intermediately in the reactions with palladium(II) trifluoroacetate. First, using this reagent, cyclopalladated derivatives of the PCP-type (complexes **11** and **12**) have been prepared from diphosphines similar to the ligand HL^{74} but containing PBu^t_2 and PPr^i_2 donor groups.[62] Second, mononuclear complex **75a** with the *cis*-P,P-configuration (type **B**) was the major product (72%) in the reaction of $Pd(TFA)_2$ with bis(phosphinite) HL^{75}, whereas the binuclear macrocyclic compound **75b** with the *trans*,*trans*-geometry is only a minor product under these conditions (8%). The structures of both coordination complexes isolated as iodides **75c** and **75d** were confirmed by X-ray diffraction.[124]



75a,c

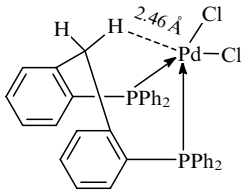


75b,d

X = TFA (**75a**,**b**), I (**75c**,**d**).

Probably, the efficiency of palladium(II) trifluoroacetate in the cyclopalladation of P,P-donor ligands is due, among other factors, to its tendency towards the formation of mononuclear (rather than binuclear or polymeric) coordination intermediates. An unsuccessful attempt at cyclopalladation of the bis(phosphinite) HL^{75} through the precursor **75a** with the *cis*-P,P-geometry [124] suggests that the activation of the C(sp^3)—H bond in ligands of this type should be preceded by a rearrangement of the mononuclear coordination intermediate from the *cis*-P,P- into the *trans*-P,P-configuration, which is hampered due to conformational features of the cyclohexane fragment. Indeed, the structural parameters of the complex **75a** clearly show that the *endo*-hydrogen of the central methylene group is removed away from the metal by a distance (CH···Pd = 3.725 Å),¶ longer than the sum of the van der Waals radii of these atoms (3.1 Å [220,221]). The activation of this C—H bond would require an essential structural reorganisation.

However, even when the structure of the coordination precursor appears optimal, this still does not guarantee the success of the subsequent activation of the C—H bond. The unsuccessful attempt to cyclopalladate the diphosphine HL^{28} can serve as an example of such restrictions. Even long-term (3 h) refluxing of this diphosphine with $[PdCl_2(NCPh)_2]$ gives only the coordination complex *cis*-$[PdCl_2(\kappa^2\text{-}HL^{28})]$ (**28**), despite the potential possibility of the formation of two optimal five-membered phosphapalladacycles.[94]



28

This seems even more surprising in view of the fact that an X-ray diffraction study of the coordination precursor **28** showed the occurrence of a close contact between the *endo*-hydrogen atom of the methylene group of the diphosphine and the metal (the distance is 2.46 Å). The substantial downfield shift of the ^{1}H NMR signal of this proton with respect to the signal of the *exo*-proton ($\Delta\delta$ = 2.7 ppm) confirms that the boat conformation is retained in solutions. Thus, the close geometric proximity of the metal and the C—H bond potentially suitable for activation is a necessary but not a sufficient condition.

The formation of mononuclear complexes with a *trans*-P,P-chelated ligand (type **A**) seems to be more realistic in the case of diphosphines with a flexible and rather long polymethylene bridge. The structure of these complexes has been the subject of keen attention at an early stage of research into their cyclometallation.[222–224]

It is believed that the preferableness of *trans*-P,P-chelation for long-chain diphosphines at the stage of coordination intermediates is determined by the presence of bulky PBu^t_2 groups (as opposed to the PPh_2 analogues, which usually form linear polynuclear species at this stage). The bulky donor groups restrict the freedom of rotation not only about the P→Pd and P—C bonds but also about the C(α)—C(β) and C(β)—C(γ) bonds of the polymethylene bridge, thus predetermining its conformation.[96,128,222–224] This type of pre-coordination should result in localisation of one of the central methylene groups in the axial position above the metal, thus ensuring the necessary proximity of one C—H bond with the metal. However, the coordination complex of type **A** — *trans*-P,P-$[Pd(HL^{76})Cl_2]$ — was isolated only upon the reaction with the decamethylenediphosphine $Bu^t_2P(CH_2)_{10}PBu^t_2$ (HL^{76}), whereas in the case of its pentamethylene analogue, HL^{24}, no signs of formation of mononuclear species were detected.[224] The most typical coordination complexes formed by these ligands are bimetallic macrocycles with the bridging diphosphine (type **C**).[128,129,222,224] The structures of *trans*, *trans*-$[\{Pd(\mu\text{-}HL)Cl_2\}_2]$ complexes with pentamethylenediphosphines HL^{24} (see Ref. 128) and HL^{44} (see Ref. 129) were confirmed by X-ray diffraction.

To conclude this Section, we can make some assumptions concerning the causes for the difference between the behaviours of mono- and diphosphines in cyclopalladation (see Section II.1). Most likely, the difference between them is due to entropy effects. Whereas the formation of a PC-palladacycle from the coordination intermediate with a monodentate phosphine is usually accompanied by a substantial decrease in the system entropy, in the case of diphosphines, the entropy has markedly decreased already upon their bridging P,P-coordination and, even more so, in the case of P,P-chelation.

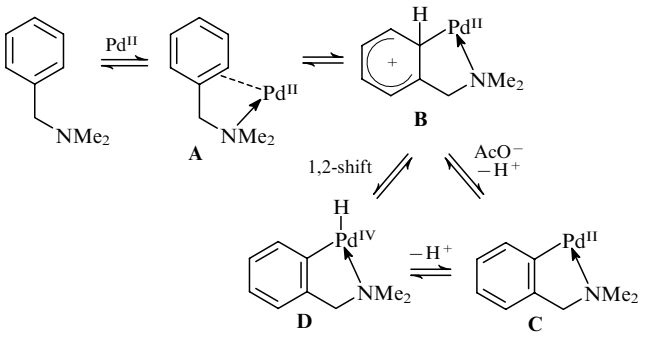
b. The stage of activation of the C—H bonds

The importance of the processes of the C—H bond activation involving transition metal complexes (especially, in the catalytic regime [225–227]) dictates the permanent interest in experimental [80,162,228] and theoretical [229–234] studies in this field. However, most of the known relevant reviews consider intermolecular processes.[80,226,235,236] Only a few studies deal with analysis of the specific features of the intramolecular activation of C—H bonds by various transition metals,[14,237–241] and only some of these studies touch upon the mechanisms of reactions involving palladium.[238–240] Some general views on the mechanisms of

¶ Data from the Cambridge Structural Database; code MEXRID.

intramolecular activation of C—H bonds can be found in reviews on cyclometallation.[15, 17, 19]

It is generally believed that the activation of aromatic C—H bonds occurs *via* preliminary η^2-coordination of the arene fragment to the metal, which allows the reaction to follow a lower-energy pathway.[14, 80, 240] This accounts for the apparent anomaly: many metals are capable of even intermolecular activation of strong aromatic C—H bonds ($\sim$110 kcal mol^{-1}), but for weaker aliphatic C—H bonds (96– 102 kcal mol^{-1}), this process is impossible or substantially hampered.[80] A similar mechanism has been assumed for cyclopalladation.[240]



The intramolecular activation of the C(sp^2)—H bond in dimethylbenzylamine includes the preliminary η^2-coordination of the metal to the aromatic ring of the N-bound ligand and subsequent transformation of intermediate **A** into arenonium species **B**. In the classical versions of electrophilic cyclometallation,[14, 238] the process of formation of metallacycle **C** from **B** ends with proton elimination under the action of a base. However, the possibility of a 1,2-shift of hydrogen from the *ipso*-carbon atom of the arenonium species **B** to the metal with the intermediate formation of a Pd(IV)-containing hydride derivative of metallacycle **D** also cannot be ruled out.[240]

This version of the reaction seems even more likely if one recalls that Pd(IV) complexes[242–245] have ceased to be exotic compounds during the last decade. An extensive series of organometallic Pd(IV) derivatives has been prepared, including compounds with phosphine ligands[246, 247] and structures with CC-[248] and CN-palladacycles.[249] In the presence of stabilising ligands, Pd(IV) compounds become rather stable and can be isolated;[248–252] some of these are stable in solutions even at elevated temperatures.[240] The structures of most of these complexes were confirmed by X-ray diffraction.[248, 249, 251, 252]

η^2-Arene complexes which model intermediate **A** are also known, many of them have been studied not only by spectroscopy but also by X-ray diffraction.[253–257] Detailed analysis of their structural parameters[256] resulted in the suggestion that the mode of coordination of the arene fragment to palladium should rather be interpreted as being intermediate between η^2- and η^1-modes,[258] because the *ipso*-carbon of the arene ring is the main donor of π-electron density. In addition, in a recent study, direct transformation of such complexes into CC-palladacycles has been observed.[259, 260]

In most of the generally accepted mechanistic schemes proposed for cyclopalladation, an essential role is assigned to agostic interactions between the metal and the C—H bonds to be activated, both aliphatic[261, 262] and aromatic[263, 264] ones. It is believed that the oxidative addition of alkanes is preceded by η^1-, η^2- or η^3-coordination of the CH_n fragments to the metal.[235] The ease of this process depends on the degree of substitution of the carbon atom to be metallated both from purely statistical considerations ($CH_3 > CH_2 \gg CH$) and for steric reasons, because the access of the metal to the C—H bond becomes more complicated with an increase in the number of substituents in its surroundings.[241] An argument in favour of the possibility of subsequent oxidative addition of the aliphatic C—H bond to the palladium centre is provided by spectral identification of the hydrido(alkyl) [PdH(Cy)Br$_2$(PPh$_3$)$_2$] species in the intermolecular activation of cyclohexane by the [PdBr$_2$(PPh$_3$)$_2$] complex.[162]

Contacts of the Pd$\cdots$H type were detected by crystallography in many palladium compounds with bulky phosphines.[174, 217, 265, 266] For instance, in the structure of *trans*-[PdI$_2$(PMe$_2$Ph)$_2$], the Pd$\cdots$H distance between the Pd atom and the *o*-hydrogen atom of the benzene ring (in the axial position) is shortened to $\sim$2.8 Å (see Ref. 265). The substantial downfield shift of the ^{1}H NMR signal for the *o*-protons ($\delta > 9$ ppm) indicates that these axial contacts are also retained in solution.[174, 217] However, the direction of this shift is opposite to that expected of true agostic interactions, which impart a hydride nature to the hydrogen atom.

It has been assumed that the interaction of Pd with the C—H bond located in the axial position (even at distances shortened to 2.1 Å) is destabilising, but it can become attractive when the bond shifts to the coordination plane.[237] Therefore, bringing the Pd atom closer to the axial hydrogen atom can be a useful step in the overall process of C—H bond activation. This can be considered as a desirable condition but it does not ensure the success of cyclometallation. For example, the *trans*-[PdI$_2$(PMe$_2$Ph)$_2$] complex mentioned above[265] does not form a four-membered phosphapalladacycle, although the corresponding platinum analogues are known.[85]

Although agostic complexes with a two-electron three-centre C—H$\rightarrow$M bond are regarded as intermediates or transition states in the metallation of aromatic substrates,[267] cases where they have been isolated are rare. Recently,[264] such complexes have been synthesised by the reaction of a cationic Rh(I) reagent with the diphosphine HL^{25} and its 4,5,6-trimethoxy-substituted analogue. The structure of the former product, [Rh(HL^{25})CO]$^+$, was confirmed by X-ray diffraction. Moreover, an increase in the acidity of the aromatic proton involved in the agostic interaction was noted: its ^{1}H NMR signal is shifted to δ 4.13 ppm. The deprotonation of the agostic precursor giving rise to the PCP-complex [Rh(η^3-L^{25})(CO)] is easily induced by the action of weak bases (triethylamine or collidine). This process models the last stage of the electrophilic cyclometallation of diphosphines at the arene fragment. It has been suggested[264] that in this case, the contribution of the pathway involving the classical arenonium intermediate is small, if present at all.

These results are of interest as an illustration of the extensive potential for changing individual steps of the overall mechanism of C—H bond activation by varying not only the structures of the process participants but also the reaction conditions. For example, a decrease in the electron density on the metallic centre of the reagent proved to be sufficient to make Rh(I), known for its nucleophilic properties,[238, 239] react with the highly basic diphosphine HL^{25} by an electrophilic mechanism. Presumably, this pathway could also be realised in intramolecular activation of C—H aromatic bonds by palladium(II), which is more prone to electrophilic behaviour.

Comparative analysis of the available experimental data on the cyclopalladation of P-donor ligands with participation of both aromatic and aliphatic fragments (see Section II.1) has shown that mono- and bidentate ligands behave differently: the activation of aromatic C(sp^2)—H bonds is facilitated only for diphosphines and diphosphites (see Table 4), whereas for monodentate phosphines, it is rather hampered. If the role of the η^2-arene or agostic intermediate is assumed to reduce to bringing the metal closer to the C—H bond being activated, then the difference between mono- and diphosphines can be related to the fact that in the latter case, the tight contact is attained automatically even upon *trans*-P,P-coordination of the ligand, whereas in the case of monodentate ligands, conformational reorganisation is required.

The information on the mechanisms of direct intramolecular activation of C—H bonds in P-donor ligands by palladium is extremely sparse. It can only be suggested from general considerations that the reaction pathway should depend on a number of factors: the nature of the central metal atom and the donor atom

of the ligand [14, 15] (in particular, the ratio of its σ-donor to π-acceptor properties);[51, 53] hybridisation of and the electron density on the carbon atom in the C−H bond being metallated and the steric factors in its surroundings; the possibility of agostic or other secondary interactions between this bond and the metal, or η^2-coordination of the metal to the double bond of the aromatic ring.[14]

Apparently, the electron density on the metallic centre in the intermediate coordination complexes is one of the most important factors, because it determines the metal susceptibility to oxidative addition or to electrophilic attack. The former pathway is typical of electron-enriched metals; for Pd(II), electrophilic behaviour is assumed most often, whereas Pt(II) occupies an intermediate position.[15, 237, 238]

In the absence of experimental data, assumptions concerning the cyclometallation mechanism are often made on the basis of the influence of the nature of the metal on the ease of the process. This criterion is justified by the easier oxidative addition to Pt(II) compared to that to Pd(II) and by the lower stability of Pd(IV) complexes. Indeed, direct activation of the C−H bonds in phosphines and phosphites under the action of Pt(II) compounds often occurs much more easily than that with Pd(II)-containing reagents.[15, 59, 69, 81, 82, 86, 129, 143] However, numerous exceptions to this rule can be found. For example, cycloplatination of bulky ligands such as trimesitylphosphine [110] and *tert*-butyldi(*o*-tolyl)-phosphine [81] proceeds at higher temperatures than cyclopalladation. This points indirectly to the possibility of changing of the process mechanism. Similar anomalies can also be found among reactions of diphosphines. For example, attempts at cycloplatination of *m*-xylylene-α,α′-diphosphine HL[62] have not met with success, while it can be cyclopalladated quite readily by the action of *trans*-[$PdBr_2(PPh_3)_2$].[155] These contradictions can be due to the change in the mechanism of the proper C−H bond activation stage. However, difficulties in the stage of the coordination through heterodonor atoms caused by steric factors [268] or by kinetic intertness of Pt(II), which is several orders of magnitude higher than that of Pd(II), also cannot be ruled out.

The electron density on the metallic centre is largely determined by the nature of the attached organic ligands, in particular, the nucleophilic behaviour becomes more probable on passing from N- to P-donor substrates.[14] This assumption is supported by the increase in the activity of Ni(0) complexes with respect to the oxidative addition following the introduction of phosphines into the Ni(0) coordination sphere and the subsequent increase in the phosphine basicity [241] (for PPh_3 and PEt_3, the pK_a values are 2.73 and 8.69, respectively [53]).

$$[Ni(cod)(bipy)] < [Ni(PPh_3)_4] < [Ni(PEt_3)_4]$$

bipy is 2,2′-bipyridyl.

The increase in the electron density on the metal atom with an increase in the basicity of the coordinated phosphines was convincingly confirmed by calorimetric measurements of the protonation enthalpies of complexes ($-\Delta H_{HM}$). For example, upon replacement of PPh_3 by PMe_3 (pK_a 2.73 and 8.65, respectively), the basicity of complexes increases by 3−7 kcal mol^{-1} (see Ref. 269).

However, in view of the predominant influence of steric effects in the cyclopalladation of P-donor ligands, this criterion should be treated with caution. Indeed, from the standpoint of electronic effects and with the assumption of the electrophilic mechanism, one cannot interpret the failure [82] or the difficulty [114, 205] of the *ortho*-palladation of the benzylphosphine $PhCH_2PPh_2$ against the background of the brilliant results attained in the *ortho*-palladation of more bulky $PhCH_2PBu^t_2$.[82] An idea of the relative basicities of these two ligands can be gained from comparison of this parameter for phosphines PPh_3 and PBu^t_3 (pK_a 2.73 and 11.4, respectively).[53] If we assume that the considerable increase in the basicity of the metallic centre caused by the coordination of trialkylphosphine is responsible for the success of the reaction, this prompts the idea that the reaction has a nucleophilic mechanism. However, this conclusion is faulty, as indicated by the pronounced acceleration of the reaction upon the introduction of MeO substituents into the aromatic ring,[113] which attests in favour of an electrophilic pathway.

The attempts to predict the reaction mechanism on the basis of the effect of substituents in the triarylphosphine cannot be considered legitimate: in addition to the expected influence of substituents in the aromatic ring on the C−H bond being metallated, the electronic effects can be transferred to the metal through the donor phosphorus atom. The introduction of electron-donating substituents increases the electron density in the aromatic ring (and thus increases its susceptibility for the electrophilic attack), but the electron density on the metal also increases and this enhances its tendency for the oxidative addition.[14, 86] For example, the protonation enthalpy of [$Fe(CO)_3(PAr_3)_2$] type complexes (Ar = Ph, *p*-$MeOC_6H_4$) increases from 14.1 to 16.2 kcal mol^{-1} upon the introduction of *p*-MeO substituents into the triphenylphosphine ligand (the pK_a values for these ligands are 2.73 and 4.59, respectively).[269] This transfer of electronic effects makes problematic the choice between alternative mechanisms on the basis of this criterion and for the given class of ligands.

The formal charge of the metal is considerably affected by the anions linked directly to the metal. The measured protonation enthalpies of the complexes with different halides [269] provided a paradoxical outcome: their basicity increases along the sequence $I^- < Br^- < Cl^-$, opposite to that expected on the basis of electronegativities (but consistent with the proton affinity of these anions in the gas phase). A similar conclusion was drawn from detailed X-ray diffraction and ^{13}C, ^{19}F and ^{31}P NMR studies of organometallic complexes of the *trans*-[$(PPh_3)_2Pd(Ph)Hal$] type: the affinity of halides to palladium(II) in nonpolar media increases in the series $I^- < Br^- < Cl^- < F^-$ (see Ref. 270). This 'halide anomaly' is at variance with the standard views on the greater affinity of soft bases (here, I^-) for soft acids such as Pd(II). Presumably, for complexes of the type mentioned above and for other compounds of d^8 metals, this anomaly can be interpreted in terms of the concept of repulsion of filled orbitals (two-orbital four-electron destabilisation).[270] A certain contribution might be made by the change in the ratio of the σ- to π-donor properties of the anions.[269]

From the studies of cycloplatination of the P-donor ligands through the coordination precursors [$Pt(HL)_2X_2$], it is known that in the case of phosphines, the reaction rate decreases depending on the nature of the halide in the series I > Br > Cl,[85, 86] whereas on passing to phosphites, the order of reactivity is reversed (Cl > Br > I).[143, 144] On the basis of these data, it is usually assumed that reactions with phosphines proceed by a nucleophilic mechanism, while those with phosphites follow an electrophilic mechanism.[17]

For coordination complexes of palladium(II) with phosphites [143, 144] and phosphines, similar patterns of dependence of the reaction rate on the nature of the anions are obeyed, namely, Cl > Br > I (see Section II.2.a).

Examples of a similar dependence of the ease of cyclopalladation on the nature of the halide (Cl > Br > I) can also be found in the processes of formation of PCP-structures from diphosphines (see Table 4 and Section II.2.a). For instance, metallation of the aliphatic (in the HL[27] ligand) and vinylic fragments (in the diphosphines HL[10] and HL[45]) is markedly hampered as the chloride-containing palladating reagent is replaced by bromide- and then by iodide-containing analogues.[60, 61]

The observed halide effects may suggest a similar electrophilic mechanism for cyclopalladation of both phosphites and phosphines. However, assuming that the overall reaction rate is determined by the stage of C−H bond activation in the coordination precursors with similar structures and taking into account the increase in the basicity of the metallic centre in the series $I^- < Br^- < Cl^-$,[269] one can conclude that the halide effect

observed experimentally attests to the nucleophilic rather than electrophilic behaviour of the metal. An alternative interpretation of the halide effect is the increase in the *trans* influence of halides in the sequence $Br^- < Cl^-$;[270] as a result, the coordination site becomes vacant more readily due to weakening of the bond with the *trans*-ligand.

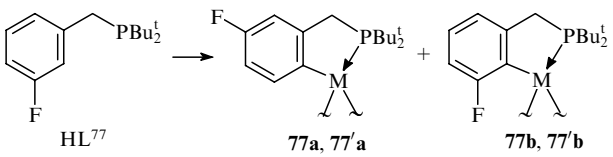
This criterion cannot be accepted as being perfect either, because the electronic and steric factors can influence the reaction mechanism in different ways, depending on the nature of P-donor ligands. With lower steric requirements of the ligands (phosphites are usually characterised by smaller Tolman cone angles[95, 107, 271]), electronic effects acquire primary importance, whereas for bulky phosphines, steric effects are more significant. In this case, the size and the leaving-group properties of the halide ion become more important and dissociation of one of the ligands with the formation of a coordination vacancy may become the rate-determining step.[272]

From determination of the protonation enthalpy for metal complexes, it is known that the appearance of the hydride ligand in the coordination sphere results in a sharp increase in the metal basicity: it can be 20 kcal mol^{-1} higher than that for analogous halide complexes.[269] During cyclopalladation through hydride intermediates, the opposite pattern of dependence of the reaction rate on the nature of the anions is observed: the formation of palladacycles from the $[PdH(X)(PBu^t_3)_2]$ precursors (X = Cl, Br, CF_3COO) is substantially accelerated in the sequence $CF_3COO^- < Cl^- < Br^-$.[71, 171] This type of dependence can be interpreted as indicating a nucleophilic pathway. It is assumed that in these reactions, direct intramolecular elimination of a hydrogen molecule (rather than an HX molecule) formed from the hydride ligand and one of the phosphine hydrogen atoms (forcibly located close to the metal) can take place.[71]

A similar dependence on the nature of the halides has been observed in the intermolecular activation of aliphatic C–H bonds of cyclohexane by the $[Pd(PPh_3)_2Hal_2]$ complexes.[161, 162] The hydride species $[CyPd^{IV}(H)(PPh_3)_2Hal_2]$ formed upon the oxidative addition were identified by spectroscopy; upon the subsequent reductive elimination of HHal, they were transformed into more stable $[CyPd^{II}(PPh_3)_2Hal]$ complexes.[162] The feasibility of this pathway in intermolecular processes has been confirmed by calculations.[229, 234]

The probability of the nucleophilic pathway should also increase in the cyclometallation with organoelement reagents containing Pd–R bonds[14] (see Section II.2.b). The fact that the hydride intermediate containing Pd(IV) (the product of oxidative addition of the C–H bond) has not been detected does not eliminate the possibility of such pathway, because these compounds are highly reactive and should easily undergo the reductive elimination of the hydrocarbon.

A convenient criterion for elucidation of the mechanism is the regiochemistry of reactions of substrates containing several alternative sites.[238] The only study of this kind known in the chemistry of cyclopalladation of P-donor ligands is the analysis of the isomeric composition of the phosphametallacycles formed by *m*-fluorobenzylphosphine HL^{77} (see Ref. 272). Upon the introduction of an electron-withdrawing substituent (in this particular case, fluorine) into the aromatic ring, the electron density in the ring markedly decreases, especially in the *ortho*-positions, one of which is to be attacked predominantly by a nucleophilic metal ion (for example, Ir^I, Rh^I). Conversely, in the case of an electrophilic mechanism, the C–H bond located in the *para*-position to the electronegative substituent should be attacked predominantly; exactly this outcome (the formation of only the *para*-isomer **77a**) was obtained in the reaction of the phosphine HL^{77} with Na tetrachloropalladate. When phosphines are metallated by compounds of electron-enriched monovalent iridium and rhodium, mixtures of *ortho*- and *para*-isomers (*o*-**77′b** and *p*-**77′a**) are formed in a 4 : 1 ratio.[272]



M = Pd (**77a**, 100%; **77b**, 0%); M = Ir (**77′a**, 20%; **77′b**, 80%)

Indirect evidence for the electrophilic mechanism of *ortho*-palladation of other benzylphosphines is provided by acceleration of the process upon the introduction of electron-donating substituents into the aromatic ring of the ligand.[14] For example, the formation of a phosphapalladacycle from benzyldi(*tert*-butyl)-phosphine (HL^{22}), with the unsubstituted aromatic ring, without assistance by a base requires long-term (5 days) refluxing of the intermediate chloride coordination complex in MET.[82] If the aromatic ring is modified by a crown-ether fragment (with electron-donating alkoxy groups in positions 3 and 4), the reaction becomes possible even at 20 °C.[113] The introduction of electron-donating substituents into the aromatic ring is especially efficient in the case of sterically non-crowded phosphines. For example, attempts to accomplish *ortho*-palladation of the phosphine $PhCH_2PPh_2$ (HL^{36}) failed during a long period,[82] whereas the 3,4-dimethoxy-substituted analogue HL^{65} reacts with an almost quantitative yield (91% in the step of C–H bond activation).[113]

It has been assumed[272] that substituents in the aromatic ring of benzylphosphines can also influence the charge and, hence, the reactivity of the metal; however, the transfer of electronic effects through the methylene group appears rather problematic. It can be considered that their influence is mainly limited to the aromatic C–H bond subjected to activation.

As opposed to cyclopalladation of benzylphosphines, *ortho*-palladation of phosphites of the type $4\text{-}RC_6H_4OP(OEt)_2$ (R = MeO, Me, NO_2) virtually does not depend on the electronic properties of the *para*-substituent in the aromatic ring: the product yields in the activation step of the C–H bond under comparable conditions remain unchanged (90% – 97%)[56] (see Table 1).

It can be suggested that this lack of sensitivity to the nature of the substituent in the aromatic ring can be related to the π-acceptor properties of the phosphites,[51, 53] whose P-coordination results in a sharp decrease in the electron density on the metal centre, thus facilitating the electrophilic attack. Indeed, the phosphites $P(OPh)_3$ and $P(OTol\text{-}o)_3$ have very low basicities (pK_a values are −2.00 and −1.83, respectively[53]). No data for $P(CH_2Ph)_3$ are available, but it follows from the pK_a values for $P(OPr^i)_3$ and $P(CH_2Pr^i)_3$ (4.08 and 7.97, respectively[53]) that the basicity decreases by four orders of magnitude upon the replacement of the methylene group present in the phosphine by the oxygen atom (in the phosphite ligand). Recall that the electrophilic mechanism is also assumed for the cycloplatination of phosphites.[17, 237]

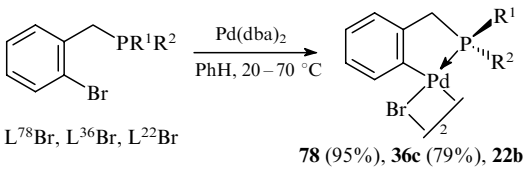
In conclusion, it should be noted that the mechanisms of cyclopalladation of P-donor ligands have not been adequately studied and further research along this line can provide a lot of interesting results.

III. Synthesis of phosphapalladacycles by oxidative addition

An alternative way for the construction of phosphapalladacycles is oxidative addition of the C–Hal bonds of preliminarily functionalised substrates to zerovalent palladium. This method is less attractive due to the necessity of preparing these substrates; therefore, the number of relevant publications is moderate.

A classical example of this approach is the reaction of the $Pd(dba)_2$ complex (dba is dibenzylideneacetone) with *o*-bromobenzylphosphines $(o\text{-}BrC_6H_4CH_2)PR^1R^2$, resulting in the cyclopalladated complexes as μ-bromide dimers.[273, 274] In this case (unlike direct intramolecular activation of the C–H bonds), the

enhancement of the steric requirements of the P-donor fragment of the $L^{78}Br$, $L^{36}Br$ and $L^{22}Br$ ligands in the series PMePh ($\theta' = 96°$)† < PPh_2 ($\theta' = 97°$) < PBu^t_2 ($\theta' = 121°$) entails a decrease in the yields of cyclopalladated complexes from nearly quantitative to moderate.[273]

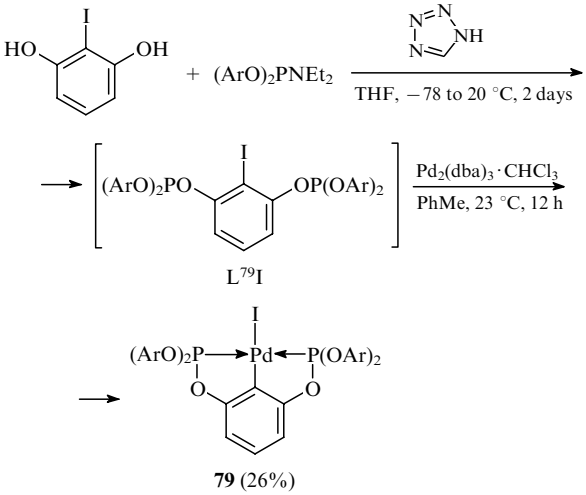


$L^{78}Br$, $L^{36}Br$, $L^{22}Br$ **78** (95%), **36c** (79%), **22b** (68%)

$R^1 = Me$, $R^2 = Ph$ ($L^{78}Br$, **78**); $R^1 = R^2 = Ph$ ($L^{36}Br$, **36c**); $R^1 = R^2 = Bu^t$ ($L^{22}Br$, **22b**).

This route to PC-palladacycles can be considered justified if the synthesis by direct activation of the C–H bond is either difficult (the μ-AcO analogue of the complex **36c** was obtained in ~20% yield) or impossible (for example, in the case of compound **78**).[114, 205]

The efficiency of the method based on oxidative addition for the creation of PCP-structures is difficult to estimate as the available information is sparse but, most likely, it is rather low. For example, in the synthesis of bis(phosphite) complex **79** by treatment of the 2-iodinated $L^{79}I$ ligand with $Pd_2(dba)_3 \cdot CHCl_3$, the overall yield over several steps (including generation of the ligand *in situ* from 2-iodoresorcinol) was only 26%.[275]



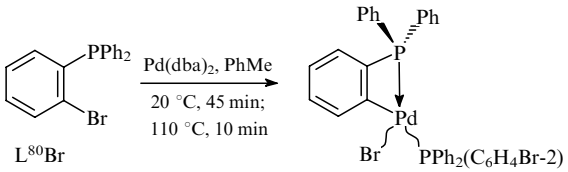
79 (26%)

Ar = 4-$MeOC_6H_4$.

This approach was even less efficient as applied to the synthesis of the bromide analogue of the PCP-complex **61a** from the diphosphine $L^{61}Br$: the yield in the proper oxidative addition step was only 19%.[165]

A rare example of direct activation of the C–H bond in triphenylphosphine with the assistance by fluoride ions in the cycloplatination has been reported.[276] A similar formation of a four-membered PC-palladacycle has been proposed earlier [170] for the reactions catalysed by the Pd(0)–PPh_3 system. However, the cyclopalladated structure of the resulting complex can hardly be considered established for the following reasons: (i) its alternative synthesis by direct activation of the *o*-C–H-bond in the coordination complex $[PdCl_2(PPh_3)_2]$ has been carried out under too mild conditions (AcOLi, DMF, 20 °C); (ii) the isolated compound was characterised only by elemental analysis and IR spectra.

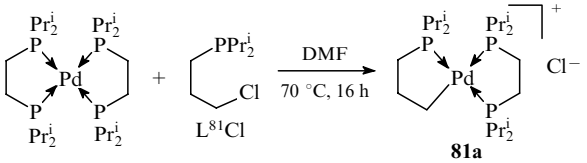
A four-membered PC-palladacycle sterically strained due to annelation to a benzene ring has been prepared only by using the oxidative addition of the *o*-bromo-substituted phosphine $L^{80}Br$ to Pd(0); the product structure was confirmed by X-ray diffraction analysis of the adduct *trans*-(P,P)-**80a**.[277]



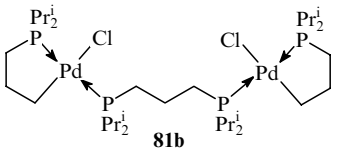
$L^{80}Br$ *cis*,*trans*-**80a** (53%)

The strained character of the metallacycle in **80a** is evident from the fact that in the absence of excess $L^{80}Br$ ligand, the reaction gives a macrocyclic tetranuclear compound with bridging (rather than chelating) PC-ligands — $[\{Pd(\mu\text{-}L^{80})(\mu\text{-}Br)\}_4]$, whose structure was confirmed by X-ray diffraction. Species of two types, those with μ- and η^2-bound ligand $(L^{80})^-$, exist in solutions in an equilibrium, whose position can be controlled by varying the auxiliary monodentate phosphines, in particular, bulky ligands stabilise the phosphapalladacycle, whereas in the presence of small-size phosphines (PMe_3, PMe_2Ph), the PC-palladacycle is cleaved giving rise to bi- or tetranuclear species.[277, 278] An attempt to elucidate the reaction mechanism by spectroscopic monitoring has shown only the intermediate formation of the coordination complex $[Pd(dba)(\kappa^1\text{-}L^{80}Br)_2]$.[277]

The scope of the method considered in this Section is not limited to reactions of aromatic $C(sp^2)$–Hal bonds. At least one example is known where the aliphatic PC-palladacycle is formed through oxidative addition of the $C(sp^3)$–Cl bond of the γ-chloropropylphosphine $L^{81}Cl$ to Pd(0) stabilised by 1,2-bis(diisopropylphosphino)ethane (dippe).[279]



Initially, compound **81a** was detected as a side product in attempted preparation of the $[Pd^0(dippp)_2]$ catalyst [280] from 1,3-bis(diisopropylphosphino)propane (dippp) contaminated by γ-chloropropylphosphine $L^{81}Cl$. The structure of the isolated binuclear complex **81b** with a bridging diphosphine was confirmed by X-ray diffraction.



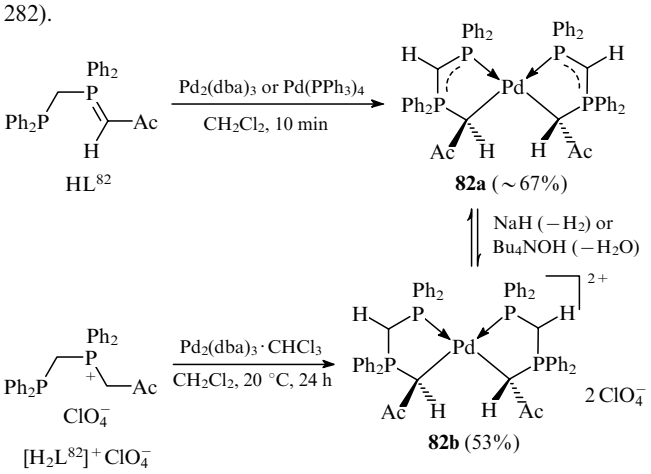
The researchers cited reasonably believe [279] that activation of the aliphatic C–Cl bond is promoted by the preliminary P-coordination of the substrate to the metal, because the rate of the intermolecular oxidative addition of butyl chloride to the same Pd(0) complex is lower by several orders of magnitude (even with excess alkyl halide and when the reaction is conducted under more drastic conditions, at 100 °C). This process may be additionally stimulated by the bulky diphosphines (dippp and dippe).

Thus, the method for the synthesis of PC (but not PCP) complexes by activation of the C–Hal bonds by palladium(0) is rather efficient, but the necessity of preliminary functionalisation of the phosphorus-containing substrate should be regarded as its drawback. The complication of the synthetic protocols could be avoided in the case of direct activation of the C–H bond by Pd(0) compounds.[281]

However, to the best of our knowledge, only one example of reaction of this type is known in the chemistry of complexes of zerovalent palladium, namely, the oxidative addition to Pd(0)

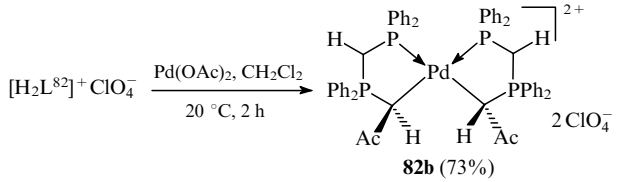
† From here on, the θ' value designates the contribution from the PR^1R^2 fragment to the Tolman θ angle.

complexes of the α-stabilised phosphino-P-ylide HL^{82} or its synthetic precursor, the phosphonium salt $[H_2L^{82}]^+$ (see Ref. 282).



In both processes, *cis*-bis(chelate) complexes are formed and molecular hydrogen is evolved, which was confirmed by gas chromatography. A significant distinctive feature of the former reaction is additional deprotonation of the phosphino-P-ylide ligand in complex **82a** compared to its formally neutral state in the analogue **82b** formed according to the latter pathway. The structural characteristics of the spiro complex **82a** obtained by X-ray diffraction analysis confirm both the methanide nature of the $\{PC(H)P\}^-$ fragment with the central sp^2-hybridised carbon atom and the substantial delocalisation of the electron density in this fragment. The transoid arrangement of two acetyl groups at the ylide carbon atoms (in the axial positions on opposite sides of the coordinate plane) points to a high diastereoselectivity of the formation of C* stereocentres, which are fixed in identical (*S*,*S*)- or (*R*,*R*)-configurations.

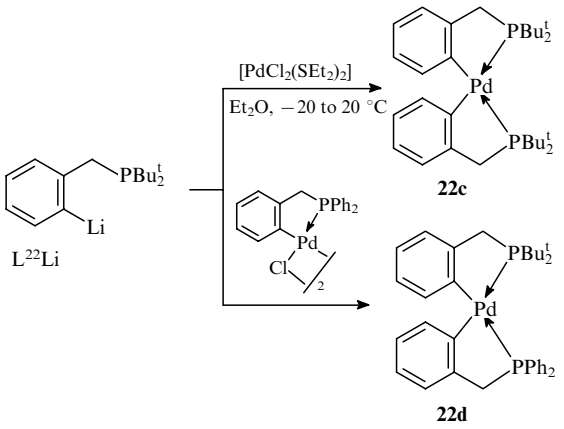
The true mechanism of these transformations is unknown, but a rough estimation of the reactivities of the two forms of the ligand used on the basis of the yields and reaction durations shows that the free phosphino-P-ylide HL^{82} is much more reactive in the oxidative addition than the phosphonium salt $[H_2L^{82}]^+ClO_4^-$. Note for comparison that direct activation of the C−H bond in the latter ligand under the action of $Pd(OAc)_2$ to give complex **82b** is more efficient (yield 73%).[282]



IV. Transmetallation

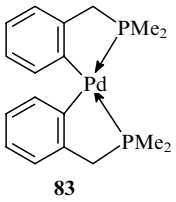
The transmetallation of lithiated phosphines on treatment with palladium(II) coordination complexes is a unique method for the synthesis of phosphapalladacycles as bis(chelate) compounds of the spiro structure.[16,283,284] Recall that direct intramolecular activation of the C−H bonds results in PC-palladacycles as μ-halide or μ-carboxylate dimers or their mononuclear derivatives (see Section II and Table 1).

The $[PdCl_2(SEt_2)_2]$ coordination complex serves usually as the source of palladium(II) in the stage of metal exchange; for example, it is used in the synthesis of spiro complex **22c** from the *ortho*-lithiated ligand HL^{22} (see Refs 283, 285).



The introduction of standard μ-chloride dimeric cyclopalladated complexes into the reactions with lithiated phosphines opens up the way to asymmetrical spiro structures both with identical (*e.g.*, complex **22d**) and with different donor atoms (P and N; see Table 2).[284,286,287] It has been assumed that mixed-ligand bis(chelate) compounds containing both soft and hard donor atoms at the same metallic centre can be of interest for catalysis.[287] However, as far as we know, their potential as (pre)catalysts has not been evaluated as yet.

Usually, reactions of this type proceed under mild conditions with rather high yields (60%−90%) and do not require steric stimulation.[283,284] For instance, this method was used to prepare complex **83** with the smallest donor groups, PMe_2,[283] whereas, attempts at direct activation of the aromatic C−H bond in dimethylbenzylphosphine (HL^{83}, $\theta = 134°$) have been unsuccessful.[288]



83

The practical value of these bis(chelate) PC-complexes increases due to the fact that they can be easily converted in high yields into standard dimeric cyclopalladated compounds with halide or acetate bridges.

In this version, transmetallation has been applied only to tertiary benzylphosphines, the preparation of *ortho*-lithiated ligands being the key problem. As opposed to tertiary benzylamines where (provided that no steric contraindications are involved)[289,290] direct activation of the $C(sp^2)-H$ bond in the benzene ring is possible and is widely used,[291−295] in the case of phosphorus analogues, direct *ortho*-lithiation proved to be impossible.[296,297] Therefore, a standard method for the synthesis of *ortho*-lithiated benzylphosphines is replacement of bromine by lithium,[298,299] which requires preliminary *ortho*-functionalisation of phosphine. However, in this case, too, the reactions of *ortho*-halogenated benzylphosphines with organolithium reagents can be complicated by at least two side reactions, namely, α-metallation and nucleophilic substitution at phosphorus (depending on the nature of the P-substituents, the nature of the halide, and the reaction conditions).[298,300] For example, *o*-chlorobenzylphosphines are metallated predominantly at the α-benzyl position, while the bromine atom in the *ortho*-position of the aromatic ring can be replaced by lithium almost quantitatively under appropriate conditions.[300−302] The susceptibility for α-lithiation can be illustrated by the replacement of the α-benzyl protons of all three

benzyl groups of the phosphonium salt $[PhP(CH_2Ph)_3]Cl$ in the reaction with BuLi.[303]
