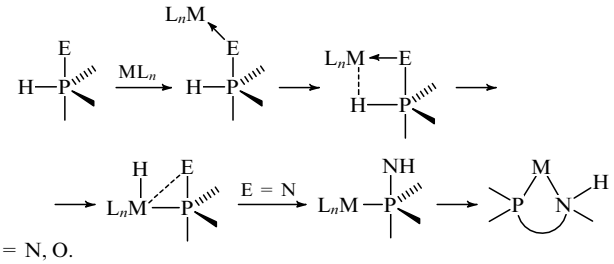
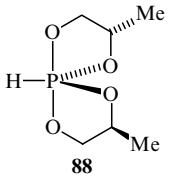
Of considerable interest is to study the complexation mechanism of HPs. Here, two mechanisms are possible, one with and one without involvement of the P(III) tautomers of HPs.[130] In the former case, the role of the transition metal is in essence to shift the tautomeric equilibrium P(V) ⇄ P(III) by bonding to the structure with the tricoordinate phosphorus atom. The latter case is in fact a kind of metal complex catalysis of the opening of the hydrophosphorane structure. The first stage involves complexation at the apical donor atom of HPs (for BF_3 and $ZnCl_2$ this stage is simultaneously the last one, resulting in compounds **83a**,**b**). An important argument in favour of this stage is provided by a direct correlation between the Lewis basicity of HPs and their coordination activity.[133] This stage can be followed by oxidative addition – reductive elimination proceeding *via* agostic and metal hydride intermediates.[133, 135]



From this standpoint compounds **86a**,**c** can be treated as relatively stable intermediates that can be isolated at elevated temperature.[137, 139] Replacement of chloride counterion by non-nucleophilic tetrafluoroborate anion permits the synthesis of rather stable complexes **86b**,**d**, which were studied by various methods including X-ray analysis.[134, 139]

The choice between both complexation mechanisms of HPs and the structures of corresponding products depend first of all on the nature of the phosphorane and the Lewis acid. For instance, coordination of tetraoxohydrospirophosphorane **88** to rhodium(I) and palladium(II) involves a P(III) tautomer.[133]



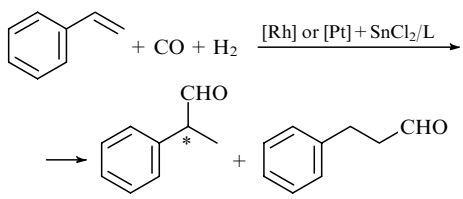
Compared to HSPs, tricyclic hydrophosphoranes are much more prone to retention of the phosphorane frame. At the same time, rhodium(I) and platinum(II) assist the opening of TCHPs more actively than palladium(II).

Hydrophosphoranes **78c** and **82a**,**b** were studied taking Pd-catalysed alkylation of substrate **43** by dimethyl malonate [reaction (8)] as an example.[135] Ligands **78c** and **82a** were found to be inefficient stereoselectors (the enantiomeric excess was 34% and 27%, respectively). A much higher optical yield (up to 74%) was achieved using compound **82b**. At present, this is the best result in asymmetric catalysis involving phosphorane ligands. Noteworthy is that the use of a catalytic system based on $[Pd(All)Cl]_2$ and ligands **82a**,**b** results in the formation of complexes **85a**,**b** with P-monodentate bonding of the 'open' forms of TCHPs. In contrast to this, complexation of $[PdCl_2(R'CN)_2]$ (R′ = Me, Ph) with ligand **82b** affords a mixture of compounds **83d** and **84b** with retention of the phosphorane structure of the ligand. Nevertheless, this system also provides a rather high enantioselectivity (*ee* up to 60%). We believe that these facts point to the great potential of tricyclic hydrophosphoranes as a specific group of chiral phosphorus-containing ligands.

IV. P,P-Bidentate phosphites

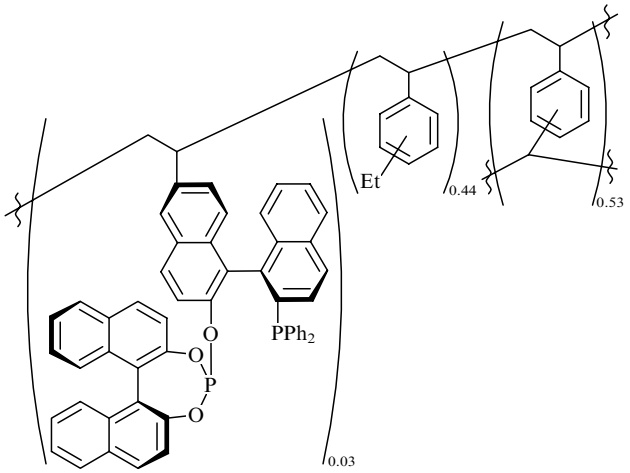
1. Phosphine-phosphites and phosphine-phosphoramidites

We begin this Section with consideration of these systems because the presence of two donor centres of different nature in such molecules makes them similar to the P,N-bidentate ligands considered above. Interest in these compounds is also due to the fact that they combine the two most important classes of chiral phosphorus-containing ligands, *viz*., phosphines and phosphites. First of all, studies aimed at unveiling the potential of the highly efficient ligand BINAPHOS (**2**) are noteworthy. Here, the research avenues are as follows: preparation of polymer-immobilised catalysts, the use of particularly valuable or 'hard-to-access' substrates and operation in supercritical CO_2.



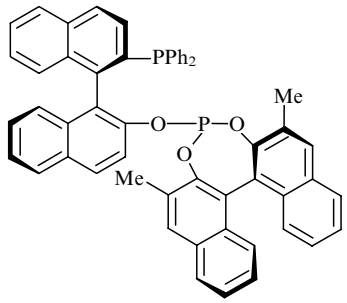
(13)

For instance, polymer-immobilised BINAPHOS provides an *ee* of 89% in Rh-catalysed hydroformylation of styrene [reaction (13)] at high conversion and regioselectivity (the mole fractions of different monomer units are shown in the Scheme).[140, 141]



This polymeric ligand was also successfully used in hydroformylation of (*Z*)-but-2-ene, 3,3,3-trifluoropropene and vinyl acetate with optical yields of 89%–93% including solvent-free processes in the synthesis gas.[142]

BINAPHOS (**2**) has found new fields of application, namely, Rh-catalysed hydroformylation of (i) conjugated dienes, which provides a synthetic route to hard-to-access β,γ-unsaturated aldehydes (*ee* up to 97%),[143] and (ii) allylic alcohols followed by oxidation of intermediate lactols to lactones (*ee* up to 87%).[144] An *ortho*-substituted derivative of BINAPHOS was found to be appropriate for treating heterocyclic olefins (optimisaton of hydroformylation conditions for these substrates faces severe problems).



(*R*,*S*)-3,3′-Me-BINAPHOS

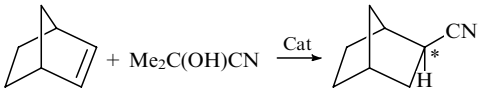
The use of this compound in the reaction shown below provided the enantiomeric excesses in the range 64% to 76%.[145]

X = O, NBoc, NAc.

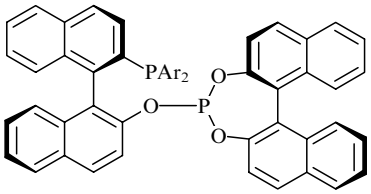
New studies on the mechanism of catalytic hydroformylation involving BINAPHOS,[146] including quantum-chemical calculations[147] have been reported.

Pd-Catalysed copolymerisation of alkenes with CO has been improved;[148] the corresponding metal complex intermediates were studied by spectral methods.[149]

Compounds [M(BINAPHOS)$_2$] [M = Ni(0), Pd(0)] were synthesised and studied by ^{31}P NMR spectroscopy and FAB mass spectrometry.[150] Hydrocyanation of norbornene catalysed by a palladium complex results in an *exo*-nitrile with the highest enantioselectivity achieved so far (48%).



Recently, supercritical CO_2 has became popular as an ecologically safe and non-toxic medium for performing catalytic reactions. However, it has severe limitations due to the poor solubility of many phosphorus-containing ligands in CO_2. To enhance the solubility of BINAPHOS (**2**), a fluorinated derivative, (*R*,*S*)-3-H^{2}F^6-BINAPHOS, was synthesised.[151, 152]

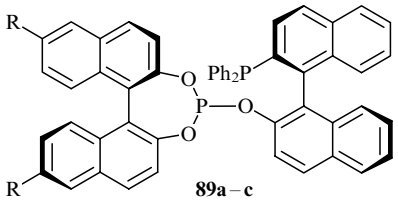


(*R*,*S*)-3-H^{2}F^6-BINAPHOS

Ar = $C_6H_4(CH_2)_2(CF_2)_6$-*m*.

A study on this ligand involved in Rh-catalysed hydroformylation in supercritical CO_2 showed that it demonstrates a high enantioselectivity (*ee* 88%–94%), conversion (>98%) and regioselectivity (branched : linear product ratio from 93 : 7 to 96 : 4) in reactions with different substrates, thus being highly competitive with (*R*,*S*)-BINAPHOS (**2**). Using multinuclear NMR spectroscopy, it was shown that supercritical CO_2 has no effect on the formation of the hydroformylation catalyst, [RhH(CO)$_2$L], and that the catalytic reaction in this medium proceeds by the same mechanism as reactions in organic solvents. (*R*,*S*)-3-H^{2}F^6-BINAPHOS was also found to be highly efficient in hydrogenation processes proceeding in supercritical CO_2 [an *ee* of 97% at 99% conversion was achieved for substrates **4a**,**b** in reaction (2)].

Fluorinated derivatives of BINAPHOS **89a**–**c** were obtained to be used in hydroformylation of styrene [reaction (13)] in supercritical CO_2 or in fluorine-containing solvents.

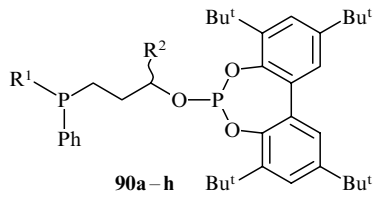


89a–**c**

R = n-$C_4F_9(CH_2)_3$ (**a**), n-$C_6F_{13}(CH_2)_3$ (**b**), n-$C_8F_{17}(CH_2)_3$ (**c**).

Ligand (*S*,*R*)-**89b** provided an *ee* up to 74% at 90 : 10 regioselectivity (branched : linear product) in supercritical CO_2.[153] Unfortunately, reactions in perfluorinated solvents were characterised by low (at most 11%) conversion of olefins at enantioselectivities of up to 94%.

Another interesting group of phosphine-phosphites comprises a series of ligands **90**–**93** containing both C*- and P*-stereocentres. These compounds were synthesised by van Leeuwen *et al.*[154–157]



90a–h

(S_{ax})-**d**	Ph	H

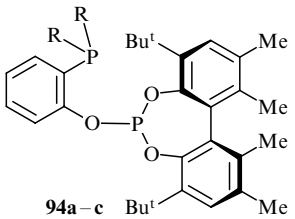
By varying positions and configurations of stereogenic centres it was established how these factors affect the enantioselectivity in catalytic processes.[154–157] Intermediates in the Rh-catalysed hydroformylation of styrene [reaction (13)] were also comprehensively studied by IR spectroscopy and ^{1}H and ^{31}P NMR spectroscopy. It was shown[154] that in trigonal-bipyramidal complexes [RhH(CO)$_2$L] the σ-donor phosphine centre occupies an apical position while the π-acceptor phosphite centre is in an equatorial position. The latter feature as well as manifestation of the so-called co-operative effect (the presence of chiral centres on the phosphine phosphorus atom and on atoms of the bridging group connecting two donor centres) are of great importance for achieving high enantioselectivity. Ligand **90a** used in reaction (13) provided an *ee* of up to 63%.

Cu-Catalysed addition of Et$_2$Zn and Et$_3$Al to cyclic enone **9a** [reaction (4)] in the presence of compounds **90**–**93** was also studied.[155] All reactions showed excellent conversions and regioselectivities at moderate optical yields (22% to 62%).

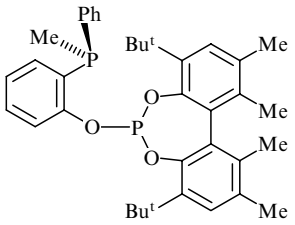
In addition, ligands **90**–**93** were studied in the alkylation of substrate **43** by dimethyl malonate [reaction (8)].[156] The best stereoselector, compound **90b**, provided an *ee* of 83%. The structure of one catalytically active complex, [Pd(All)(**92a**)], was refined by X-ray analysis. It was found that the Pd–C$_{All}$ bond in the *trans*-position relative to the phosphite phosphorus atom is 0.05 Å shorter than the bond in the *trans*-position relative to the phosphine phosphorus atom because of the greater π-acceptor ability of the phosphite centre. In the catalytic cycle, the nucleophile attacks the carbon atom of the allylic ligand in the *trans*-position relative to the phosphine P atom. Thus, a general trend is as follows: intermediates of allylic substitution containing heterobidentate ligands are attacked by nucleophiles at the *trans*-position with respect to the 'softer' (according to Pearson's HSAB principle) donor atom, namely, the phosphine centre in phosphine-phosphites or the phosphorus centre in P,N-bidentate compounds. It was shown that the enantioselectivity provided by compounds **90**–**93** depends on the structural parameters of the phosphite fragment of the ligand including the cone angle.[158]

Phosphine-phosphites **90**–**92** were also used in the asymmetric hydrogenation of substrates **4b**,**d** [reaction (2)] and gave an *ee* of up to 99% at nearly 100% conversion.[157] Similarly to allylic alkylation, the enantioselectivity is controlled by the structural parameters of the phosphite centre and of the C*-stereocentre present in the linker. Catalytically active complexes [Rh(cod)L]$^+$BF$_4^-$ were studied by multinuclear NMR spectroscopy. A double set of signals with similar values of the ^1J(P,Rh) spin–spin coupling constant was explained by either atropoisomerism of the phosphite centre or conformational isomerism of the chelate metallacycle. The joint action of both factors cannot also be ruled out. Note that this presents no obstacles to hydrogenation with excellent optical yields.

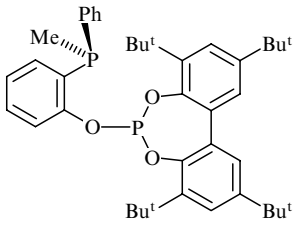
A series of phosphine-phosphite ligands **94** containing chiral phosphite and(or) phosphine fragments was synthesised.[159,160]



94a–c R = Ph (**a**), Me (**b**), Pr^i (**c**).



(S_{ax})-**94e**, (R_{ax})-**94f**

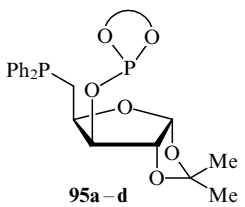


94d

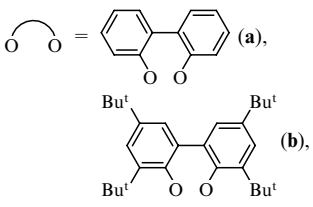
The electronic properties of the donor centres were assessed by analysing the ^1J(P,Se) spin–spin coupling constants of corresponding diselenides. The weaker σ-donor ability of the phosphite moiety compared to the phosphine fragment was confirmed. This is also indicated by the magnitude of the ^1J(P,Rh) spin–spin coupling constant, which for the phosphine centre of complexes [RhCl(CO)L] is 120 Hz lower than for the phosphite centre. X-Ray diffraction studies revealed a *trans*-disposition of the phosphine centre and the carbonyl ligand.

Cationic complexes [Rh(cod)L]$^+$BF$_4^-$ were used in the asymmetric hydrogenation of esters **4a**,**d** [reaction (2)]. It was found that high enantioselectivity requires the presence of an axially chiral phosphite moiety and bulky substituents in the phosphine fragment. For instance, compounds **94a** and **94f** provide an *ee* of 99% (*cf.* at most 49% for ligand **94d**).

A group of phosphine-phosphite derivatives of D-xylose **95a–d** is noteworthy.[161]



95a–d

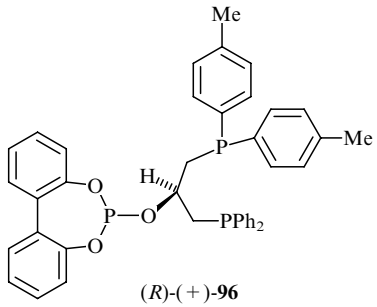


(R_{ax})-BNaph(O)$_2$ (**c**),
(S_{ax})-BNaph(O)$_2$ (**d**).

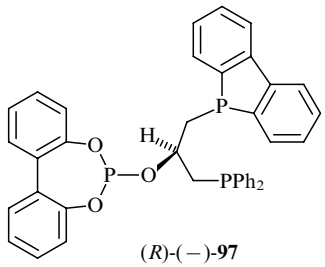
Using these compounds, a Rh-catalysed hydroformylation of styrene [reaction (13)] resulted in a product with a regioselectivity of up to 95 : 5 (branched : linear product) at moderate optical yields (*ee* up to 49%). The best stereoselector was ligand **95b** containing bulky *tert*-butyl substituents. The efficiency of phosphine-phosphites **95** in asymmetric addition of Et_2Zn to enone **9a** [reaction (4)] under the action of copper salts was even lower (the enantioselectivity was at most 19%).[162]

In contrast to this, compounds **95** were successfully used in the Rh-catalysed hydrogenation of substrates **4b**,**d** [reaction (2)] and ligand **95b** provided an *ee* of greater than 99%.[163] Similarly to phosphine-phosphites **90**–**92** (and for the same reasons), spectral analysis of rhodium complexes of compounds **95**, $[Rh(cod)L]^+BF_4^-$, revealed a double set of signals. The stereoinduction was also high.

An original approach is to increase the denticity of phosphine-phosphites by, *e.g.*, incorporating an additional phosphine centre.[164] In this case, Rh-catalysed hydrogenation of esters **4a**,**b** in the presence of ligands **96** and **97** resulted in racemic products. However, one must keep in mind that this is the first step in studies of tridentate phosphine-phosphite ligands.

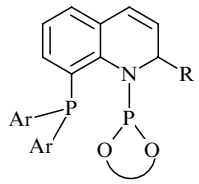


(*R*)-(+)-**96**



(*R*)-(−)-**97**

Yet another promising research avenue is the synthesis of phosphine-phosphoramidites. In particular, a series of quinoline derivatives **98a**–**d** was proposed.[165]



98a–**d** [(R_C) and/or (S_C)]

Compound **98**	Ar	R	
a	Ph	Bu^n	(R_{ax})-BNaph(O)$_2$
b	Ph	Bu^t	(R_{ax})-BNaph(O)$_2$
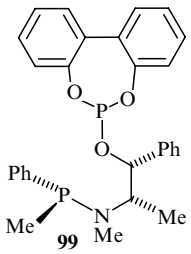
c	Ph	Bu^n	d	*m*-$F(CF_2)_6(CH_2)_2C_6H_4$	Bu^n	(R_{ax})-BNaph(O)$_2$

Mixtures of diastereomers were resolved by column chromatography. The first experiments revealed the efficiency of these systems in asymmetric catalysis. Ligand (R_{ax},S_C)-**98a** provided an *ee* of up to 74% at 96 : 4 (branched : linear product) regioselectivity and 79% conversion in hydroformylation of styrene [reaction (13)]. The use of its epimer, (R_{ax},R_C)-**98**, leads to a dramatic decrease in the enantioselectivity down to 5%. In contrast to this, epimer (R_{ax},R_C)-**98a** appeared to be more efficient in hydrogenation of unsaturated acid esters **4a**,**d** [reaction (2)] and provided an *ee* of 98%–99%.

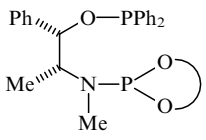
The enantioselectivity of hydroformylation in the presence of aminophosphonite-phosphite **99** was somewhat lower (*ee* 58%).[166]



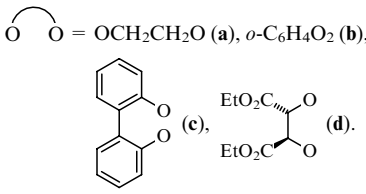
99

NMR and IR spectroscopy studies of catalytically active complexes $[RhH(CO)_2L]$ revealed that the amidophosphonite centre occupies an apical position while the phosphite centre is in an equatorial position. Summing up the results reported in Refs 154, 161 and 166, note that in complexes $[RhH(CO)_2L]$ with dissymmetric P,P-bidentate compounds the equatorial position is occupied by the phosphorus centre, which possesses more pronounced π-acceptor properties. The exception is BINAPHOS (**2**); however, this is due to steric reasons.[7]

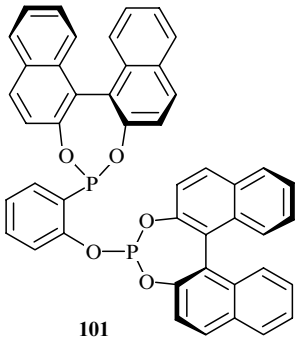
Only one series of aminophosphonite-phosphite ligands **100a**–**d** based on the ephedrine moiety has been reported to date.[167]



100a–**d**



However, the enantioselectivity of Rh-catalysed hydroformylation of styrene [reaction (13)] in the presence of compounds **100a**–**d** was at most 20%. Mention may also be made of phosphonite-phosphite **101** providing an *ee* of up to 80% in Rh-catalysed hydrogenation of ester **4a** [reaction (2)].[168]

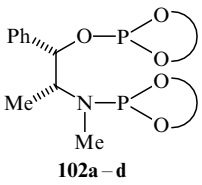


101

2. Phosphite-phosphoramidite and diphosphoramidites

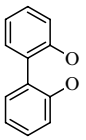
Moving to phosphite-phosphoramidites makes it possible to have two different phosphorus centres in the ligand structure in the

absence of a fragment containing P–C bonds. This approach was realised taking ligands **102a–d** as examples.[167]

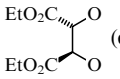


102a–d

O O = OCH_2CH_2O (**a**), *o*-$C_6H_4O_2$ (**b**),



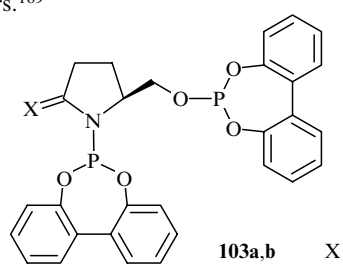
(**c**),



(**d**).

A chelate mononuclear complex $[PtCl_2(L)]$ with phosphite-phosphoramidite **102a** was obtained. However, ligands **102a–d** provided low enantioselectivities in Rh-catalysed hydroformylation of styrene [reaction (13)].

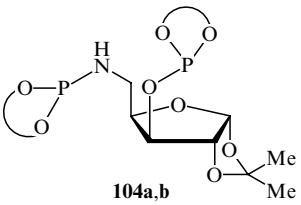
Phosphite derivatives **103** of available (*S*)-prolinol and (*S*)-oxyprolinol appeared to be somewhat better stereoselectors.[169]



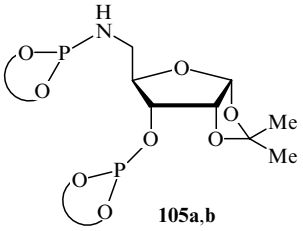
103a,**b** X = 2 H (**a**), O (**b**).

Platinum complexes of these compounds catalyse hydroformylation of styrene [reaction (13)] with an optical yield of up to 44%.

Even higher enantioselectivity (*ee* up to 65%) is provided by rhodium complexes of phosphite-phosphoramidites **104** and **105** based on D-xylose and D-ribose:[170]



104a,**b**

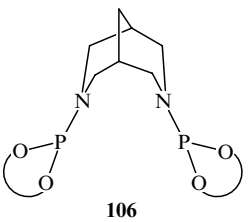


105a,**b**

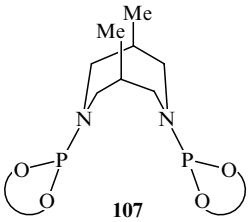
O O =  ; R^1 = Bu^t: R^2 = Bu^t (**a**), OMe (**b**).

Besides, compounds $[Rh(cod)L]^+BF_4^-$ (L = **104** and **104**) were used in asymmetric hydrogenation of substrates **4a**,**b**,**d** [reaction (2)].[171] They provided an *ee* of up to 99% at nearly 100% conversion. Similarly to hydroformylation, the chemical and optical yields depend on the absolute configuration of the C*(3)-stereocentre and on the nature of the *ortho*-substituents in the biphenyl fragment of the ligands.

Symmetrical (C_2) diphosphoramidites **106** and **107** have been reported recently.[172]



106

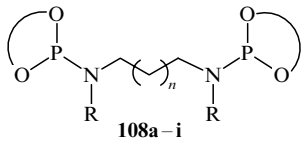


107

O O = (R_{ax})-BNaph(O)$_2$.

They provided an *ee* of up to 82% in Cu-catalysed addition of Et_2Zn to enones **9a**,**b** [reaction (4)] and up to 90% in Rh-catalysed hydrogenation of esters **4a**,**d** [reaction (2)].

A series of phosphoramidite derivatives of acyclic diamines comprises the following compounds:[173]



108a–i

Compound **108**	R	*n*	O O
a	Me	0	b	Me	1	
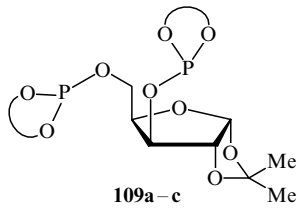
c	Me	0	(R_{ax})-BNaph(O)$_2$
d	Me	1	
e	Pr^i	1	
f		1	
g		1	
h		0	(S_{ax})-BNaph(O)$_2$
i		1	

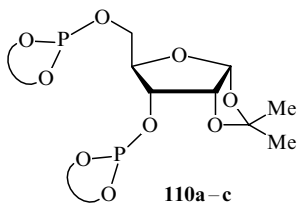
Cu-Catalysed tandem 1,4-addition of Et_2Zn to cyclopentenone **9b** and aldol condensation with benzaldehyde proceed with optical yields of up to 83%. The best ligand is compound **108h**. Conjugate addition of Et_2Zn to enone **9a** [reaction (4)] showed an *ee* of up to 89% with the most efficient diamide ligand **108f** . Ligands **108a**,**b** containing no BINOL moiety are inefficient.

3. Diphosphites based on carbohydrates and their derivatives

We begin consideration of this type of ligands with diphosphites derived from D-xylofuranose **109** and D-ribofuranose **110**.[174–176]



109a–c

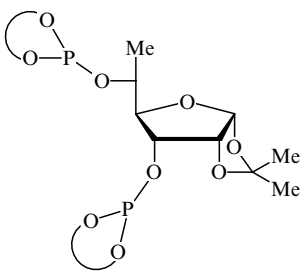


110a–c

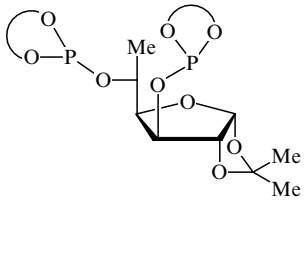
O O =  ; R^1 = R^2 = H (**a**); R^1 = Bu^t: R^2 = OMe (**b**), Bu^t (**c**).

Rh-Catalysed hydrogenation of itaconic acid, hydroformylation of styrene [reaction (13)], Cu-catalysed addition of Et_2Zn to cyclohexenone **9a** [reaction (4)] and Ir-catalysed hydrogenation of imines involving ligands **109** and **110** proceed with optical yields ranging between 50% and 60%. The best results were obtained [177] for allylic substitution of substrate **43** [reaction (8)] for dimethyl malonate (*ee* up to 90%) and benzylamine (*ee* up to 97%); both values were obtained in the presence of diphosphite **109c**). It was established that the stereoinduction is controlled by the configuration of the C*(3)-stereocentre of the furanose ring, while the nucleophile attacks the allylic carbon atom of the intermediate palladium complex, which is in the *trans*-position relative to the phosphite centre at the C(5) atom. Because of this, an increase in the size of substituents at the phosphite centre at the C(5) atom favours enhancement of enantioselectivity.

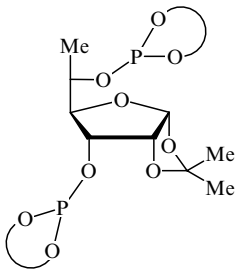
More efficient is a group of phosphite derivatives of 6-deoxy-D-allose, 6-deoxy-D-glucose, 6-deoxy-L-talose and 6-deoxy-L-idose **111**–**114**, which contain an additional C*-stereocentre.[178, 179]



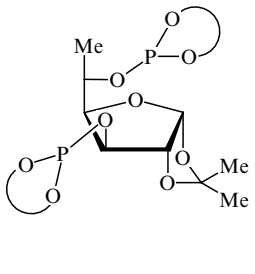
(1*R*,2*R*,3*R*,4*R*,5*R*)-**111a**–**h**



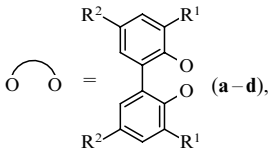
(1*R*,2*R*,3*S*,4*R*,5*R*)-**112a**–**h**



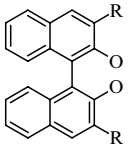
(1*R*,2*R*,3*R*,4*R*,5*S*)-**113a**–**h**



(1*R*,2*R*,3*S*,4*R*,5*S*)-**114a**–**h**



(**a**–**d**),



(**e**–**h**).

Compounds **111**–**114**	R^1	R^2
a	H	H
b	Bu^t	Bu^t
c	Bu^t	OMe
d	$SiMe_3$	H

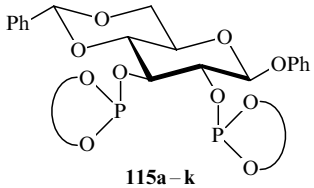
Compounds **111**–**114**	R
(S_{ax})-**e**	H
(R_{ax})-**f**	H
(S_{ax})-**g**	$SiMe_3$
(R_{ax})-**h**	$SiMe_3$

These ligands provided an *ee* of up to 91% in the hydroformylation of styrene [reaction (13)] at amazingly high regioselectivity 99 : 1 (branched : linear products), which is comparable with the efficiency of the BINAPHOS (**2**) ligand. It was shown that the absolute configuration of the product depends on the configuration of the C*(3)-stereocentre while the enantioselectivity is controlled by the co-operative effect of the C*(3)- and C*(5)-stereocentres. NMR and IR spectroscopy studies of intermediates [$RhH(CO)_2L$] revealed that the best stereoselectors are those ligands which occupy two equatorial positions in the coordination sphere of the Rh atom. The dynamic equilibrium between the equatorial and equatorial-axial bonding reduces the enantioselectivity.

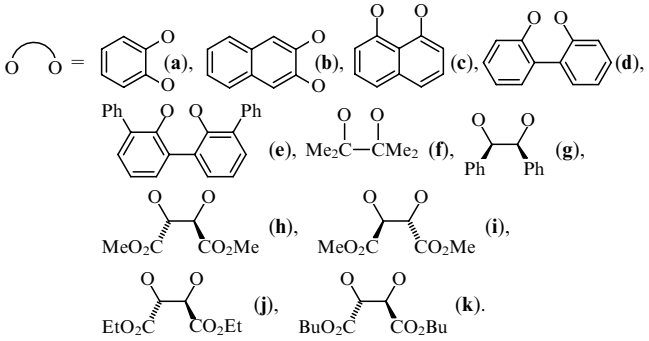
Rh-catalysed hydrogenation of substrates **4a**,**b**,**d** [reaction (2)] in the presence of diphosphite **111d** with bulky trimethylsilyl substituents showed an *ee* of greater than 99% at 100% conversion.[180] Compounds **111**–**113** provide an *ee* of up to 84% in Cu-catalysed addition of Et_2Zn to enone **9a** [reaction (4)].[181] The optical yields in Rh-catalysed hydrosilylation of acetophenone [reaction (5)] involving diphosphites **111**–**114** were lower (*ee* less than 51%).[182] However, trends common to this series of ligands can also be revealed. These are control of the configuration of the product by the stereochemistry of the C*(3) centre and favourable influence of both the co-operative effect of the C*(3) and C*(5) stereocentres and an increase in the size of the *ortho*- and *para*-substituents in the aromatic rings on the enantioselectivity.

The use of ligands **111**–**113** in the Pd-catalysed alkylation of substrate **43** by dimethyl malonate [reaction (8)] should be emphasised. A 100% conversion and an optical yield of 95% were achieved under standard experimental conditions in the presence of diphosphite **112c** and took only 10 min.[183] At present, this is the best result in Pd-catalysed allylic alkylation using P,P-bidentate phosphites.

A series of diphosphite ligands based on phenyl-β-D-glucopyranoside **115a**–**k** and their rhodium and platinum complexes were synthesised.[184] They were studied in hydroformylation of various substrates.

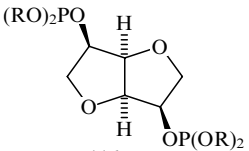


115a–**k**

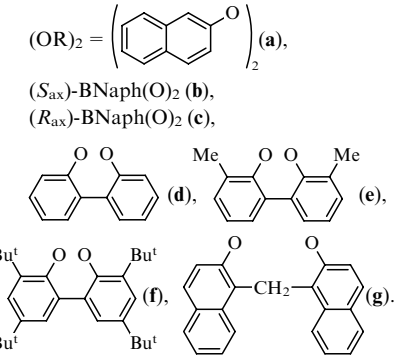


However, the asymmetric induction was low (*ee* 36% with allyl acetate as substrate).

The best stereoselectors in this group of ligands are diphosphite derivatives of dianhydro-D-mannite **116**.[185]



116a–**g**

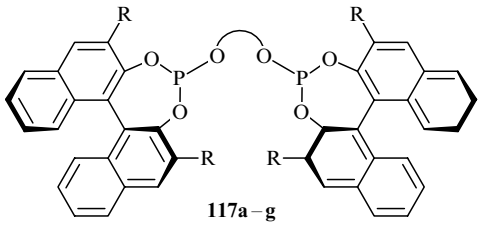


In particular, ligands **116e** and **116c** provide enantiomeric excesses of up to 98% and 96%, respectively, in Rh-catalysed hydrogenation of ester **4a** [reaction (2)]. In both cases the product has the same absolute configuration. A feature of ligands **116a**–**g** is that, in contrast to the general trend, an increase in the size of substituents in the *ortho*- and *para*-positions of the aromatic rings causes a dramatic decrease in enantioselectivity. For instance, the reaction in the presence of a catalyst based on compound **116f** results in a nearly racemic product.

4. Diphosphites based on BINOL and chiral diols

Chan *et al.*[186] proposed a series of aryl phosphite structures based on BINOL (**1**).†

† Ligand **117a** was described earlier (see Ref. 7 and references cited therein).



117a–g

Compound **117**	R	O O
a	H	(R_{ax})-BNaph(O)$_2$
b	Me	(R_{ax})-BNaph(O)$_2$
c	H	(R_{ax})-3,3′-Me$_2$-BNaph(O)$_2$
d	H	e	H	f	H	*o*-C$_6$H$_4$O$_2$
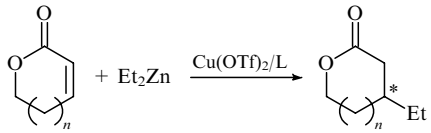
g	H	
These compounds were studied in the Ni-catalysed hydrocyanation of alkenes. In particular, ligand **117d** provides an *ee* of 65% for styrene and an *ee* of 73% for vinyl acetate.

Cu-Catalysed addition of Et_2Zn to cyclic enone **9a** [reaction (4)] and to enone **9b** proceeds with optical yields of up to 90% and 89%, respectively. Diphosphites **117d**,**f** were found to be the best in both reactions.[187] α,β-Unsaturated lactones **118a**,**b** were also used as substrates.[188] The enantioselectivity of the reaction with lactone **118a** was as high as 92% at 100% conversion. Here, diphosphite **117d** also exhibited the best efficiency. However, passage to the five-membered ring in lactone **118b** was accompanied by a marked decrease in the stereoinduction (*ee* up to 56%). It should be noted that the structure of the catalytically active complex [Cu(MeCN)$_2$(**117d**)]$^+$OTf$^-$ was established by X-ray analysis.[188]

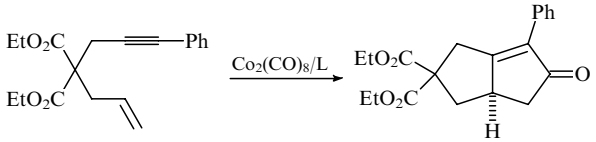


118a,**b**

n = 1 (**a**), 0 (**b**).

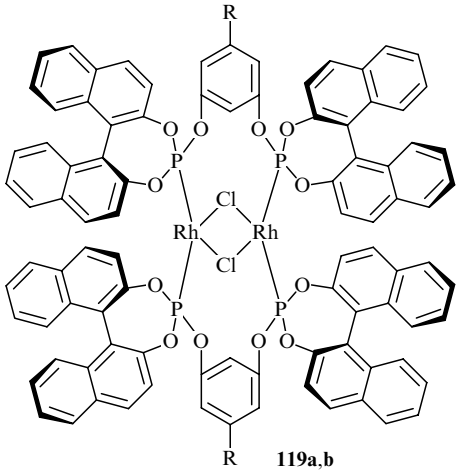
The conversion and enantioselectivity (*ee* up to 28%) provided by a complex [Rh(cod)L]$^+$BF$_4^-$ based on diphosphite **117a** (see Ref. 189) in hydroformylation of styrene [reaction (13)] were similar to those of the catalytic system [Rh(acac)(CO)$_2$]/**117a**. According to IR spectroscopy and ^{31}P and ^{1}H NMR data, this is due to the formation of the same intermediate [RhH(CO)$_2$L] in the catalytic cycle.

Ligand **117a** was also used in the Ir-catalysed hydrogenation of prochiral arylimines (*ee* up to 12%) [190] and in the Co-catalysed intramolecular Pauson–Khand reaction.[191]



The cobalt-phosphite precatalyst and the cobalt-phosphite-alkyl intermediate of the catalytic process were detected by electrospray mass spectrometry and ^{31}P NMR spectroscopy. The best results (*ee* up to 75%) in reactions with various substrates were achieved using aryl-substituted 1,6-alkynes.

Two original dimeric rhodium complexes **119a**,**b** based on the ligands related to diphosphites **117a–g** are noteworthy.[192]

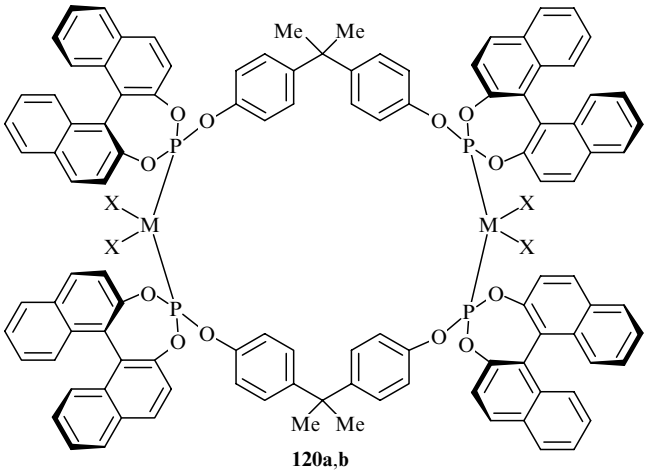


119a,**b**

R = H (**a**), OMe (**b**).

The structure of compound **119a** was established by X-ray analysis. Complexes **119a**,**b** showed low enantioselectivities (*ee* at most 20%) in the hydrosilylation of acetophenone [reaction (5)].

Unusual binuclear metal complexes **120a**,**b** containing twenty-eight-membered macrocycles [193] should also be pointed out.

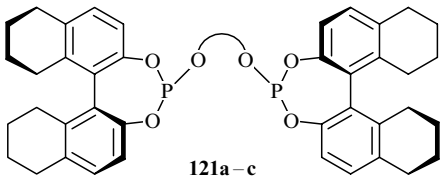


120a,**b**

M = Pd, X = Cl (**a**); M = Pt, X = I (**b**).

The synthesis of such compounds is closely related to the synthesis of chiral supramolecular structures.

Diphosphites **121a–c** based on H$_8$-BINOL (**13**) appeared to be excellent stereoselectors.[194] They provided an *ee* of 97%–99% at 92%–99% conversion in the Cu-catalysed addition of Et_2Zn to enones **9a–c** [reaction (4)].

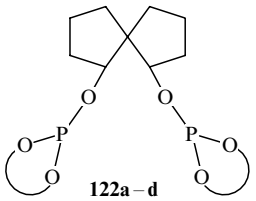


121a–c

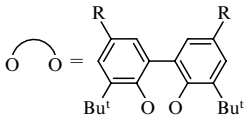
O O = (R_{ax})-BNaph(O)$_2$ (**a**), (R_{ax})-H$_8$-BNaph(O)$_2$ (**b**), (S_{ax})-BNaph(O)$_2$ (**c**).

It was found that the configuration of reaction products and the enantioselectivity remain unchanged as the configuration of the bridging fragment of ligands changes. The optical and chemical yields are rather sensitive to the nature of the solvent. Namely, they increase after replacement of toluene and methylene chloride by diethyl ether possessing more pronounced electron-donor properties. Phosphite **121a** was also used in the addition of Me_2Zn to cyclic enone **9c** [reaction (4)], the optical yield being as high as 99%. This is the best result obtained for this reaction, which is the key stage of the synthesis of anticancer drug clavularin B. Ligand **121a** also exhibited a high efficiency in the reaction of Me_3Al with substrate **9a** (an *ee* of 96% was obtained at high conversion).[195]

The synthesis of diphosphites **122a**–**d** based on *cis*, *trans*-spiro[4.4]nonane-1,6-diol has been reported.[196]



122a–**d**

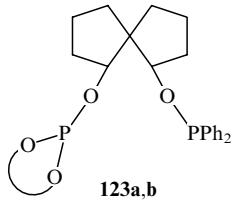


: R = Bu^t (**a**), OMe (**b**),

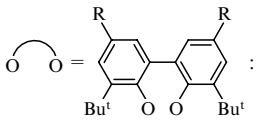
(S_{ax})-BNaph(O)$_2$ (**c**),

(R_{ax})-BNaph(O)$_2$ (**d**).

An attempt at obtaining their diastereomers based on *cis*,*cis*-spiro[4.4]nonane-1,6-diol failed because of steric hindrance (close disposition of bulky substituents). Therefore, only less sterically hindered phosphine-phosphite ligands **123a**,**b** were synthesised. Compounds **122a**–**d** and **123a**,**b** were studied in Rh-catalysed hydroformylation of styrene [reaction (13)] and showed a moderate enantioselectivity (*ee* up to 65%).

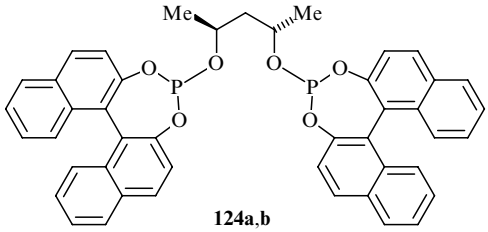


123a,**b**



R = Bu^t (**a**), OMe (**b**).

At the same time one of the two ligands based on (2*R*,4*R*)-pentadiol **124a**,**b** provides an *ee* of up to 91% in Pt-catalysed hydroformylation of styrene [reaction (13)].[197]

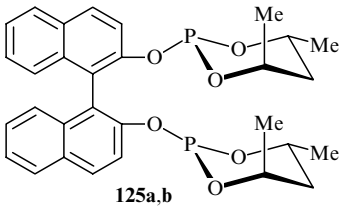


124a,**b**

(2*R*,4*R*)-bis(R_{ax}) (**a**), (2*R*,4*R*)-bis(S_{ax}) (**b**).

Noteworthy is that only diastereomer **124a** is efficient. Here we deal with the co-operative effect of the axial and central chiralities. Catalytically active *cis*-chelate complexes [$PtCl_2$(**124a**)] and [$PtCl(SnCl_3)$(**124a**)] were isolated and studied.

Diphosphites based on BINOL or atropoisomeric diphenyldiols and containing phosphorus centres were considered earlier. However, systems with cyclic phosphite moieties which are based on optically active aliphatic diols are also known. Two examples are provided by ligands **125a**,**b**.[198]

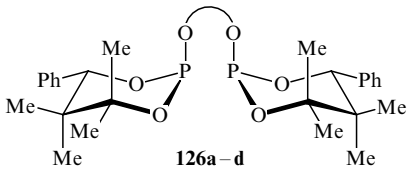


125a,**b**

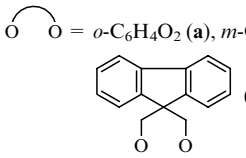
(R_{ax})-bis(4*R*,6*R*) (**a**), (S_{ax})-bis(4*R*,6*R*) (**b**).

The corresponding *cis*-chelate complexes [$PtCl_2$(L)] and [$PtCl(SnCl_3)$L] were obtained and studied by multinuclear NMR spectroscopy and X-ray analysis. Both Pt- and Rh-catalysed hydroformylations of styrene [reaction (13)] in the presence of compounds **125a**,**b** show moderate regioselectivities and optical yields of at most 39%.

Diphosphite derivatives of sterically hindered chiral diols **126**, **127** are noteworthy. They contain, in particular, the dioxaphosphorinane rings in the hindered chair conformation.[199, 200]

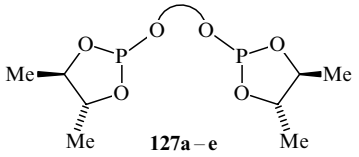


126a–**d**

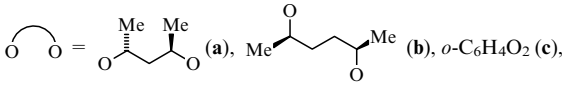


= *o*-$C_6H_4O_2$ (**a**), *m*-$C_6H_4O_2$ (**b**), $OCH_2CMe_2CH_2O$ (**c**),

(**d**).



127a–**e**



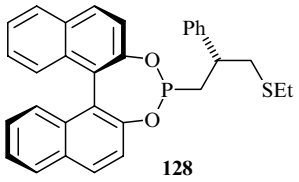
(**a**), (**b**), *o*-$C_6H_4O_2$ (**c**),

(R_{ax})-BNaph(O)$_2$ (**d**), (S_{ax})-BNaph(O)$_2$ (**e**).

The structures of compounds **126a** and **127d** were refined by X-ray analysis. Based on ligands **126a**–**d**, complexes [$Mo(CO)_4$L] and [$(BH_3)_2$L] were synthesised, which can be used in asymmetric catalysis, *e.g.*, hydroformylation and conjugate addition.

V. Other groups of chiral phosphite ligands

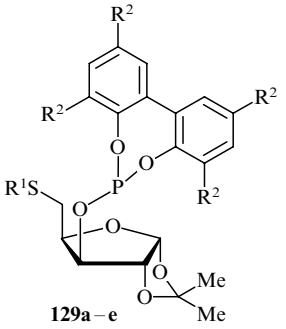
First of all, P,S-bidentate phosphites are of interest. The syntheses of ligand **128** and its complexes of compositions [Pd(alkene)L] (L = fumaronitrile, maleic anhydride, pentadienone)[201] and [Rh(cod)L]$^+$ BF_4^- (see Ref. 202) were reported. These compounds were thoroughly studied by multinuclear NMR spectroscopy, mass spectrometry and X-ray analysis.



128

2D NMR (NOESY) studies revealed that [Pd(alkene)L] exists in solution in the form of two stereoisomers due to the relatively unhindered rotation of the alkene ligands. Phosphite **128** was used in the allylic substitution of unsymmetrical substrate **39a** for dimethyl malonate [reaction (7)] with $[RhCl(cod)]_2$, $[IrCl(cod)]_2$ and $[Pd(1,3\text{-}Ph_2All)Cl]_2$ as precatalysts. The highest stereoinduction was achieved using the rhodium complex (*ee* up to 81%) while the iridium and palladium compounds provided an *ee* of 68% – 70%.

A series of thioether-phosphite ligands **129a – e** based on xylofuranose was applied [162] in the Cu-catalysed conjugate addition of Et_2Zn to enone **9a** [reaction (4)].

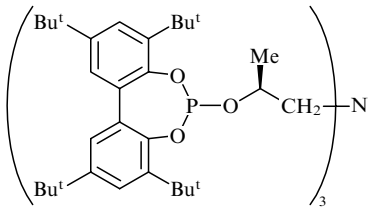


129a – e

Compound **129**	R^1	R^2
a	Me	Bu^i
b	Pr^i	Bu^t
c	Ph	Bu^t
d	Pr^i	H
e	Ph	H

In contrast to the P,P-bidentate systems, the optical yields achieved using ligands **129** appeared to be rather low (at most 41%). Ir-Catalysed hydrogenation of itaconic acid showed an enantioselectivity of up to 51%. Rh-Catalysed hydroformylation of styrene resulted in a racemic product. Probably, the reason is that the ligands are coordinated to the rhodium atom in a monodentate fashion (through the P atom).[203]

A formally P,P,P,N-tetradentate ligand **130** was successfully employed in the Rh-catalysed hydrosilylation of acetophenone [reaction (5) and provided an *ee* of up to 81%].[204]



130

It should be emphasised that phosphite **130** coordinated to $[RhCl(cod)]_2$ behaves as a P,P-bidentate ligand. By and large there are a few phosphites that do not belong to the three major classes considered above.

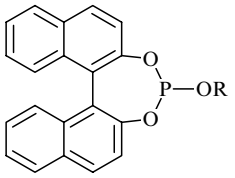
VI. Conclusion

The material presented in this review shows that research on chiral phosphites is progressing rapidly. Over four hundred chiral phosphite compounds are used in asymmetric catalysis, in particular, hydrogenation of C=C and C=N bonds, hydroformylation, hydrosilylation of C=C and C=O bonds, hydroboronation – oxidation, allylic substitution, conjugate addition, hydrovinylation, hydrocyanation and in the Heck, Diels – Alder and Pauson – Khand reactions.

The most important results obtained in enantioselective catalysis using optically active phosphites are summarised in Table 2. As can be seen, considerable advances have been made in hydrogenation, conjugate addition and allylic substitution. On the other hand, the wide use of P-monodentate systems in hydroformylation of ketones and of P,P-bidentate systems in hydrosilylation of ketones seems to be appropriate. Processes in which chiral phosphites are of limited use as yet, namely, hydrosilylation – oxidation and hydroboronation – oxidation of C=C bonds, hydrovinylation and the named reactions mentioned above, deserve much greater attention. Finally, there are also reasons to pay attention to such asymmetric catalytic transformations that were performed up to now exclusively without using chiral phosphite ligands. To start with, examples are proton transfer, cross-coupling and enantioselective rearrangements.

There are a number of unsolved topical problems and potential 'growth points' of the chemistry of chiral phosphite ligands. In particular, studies on the mechanisms of catalytic reactions should be developed more intensively. The results obtained in this field will serve as a basis for recommendations concerned with the choice of experimental conditions and targeted synthesis of the most efficient ligands. Up to now, most of these problems are attacked empirically. Progress towards an understanding of the mechanism of hydroformylation and, to a lesser extent, of allylic substitution in the presence of P,P-bidentate phosphites has been made. Information on other reactions and other ligand groups is scarce. This especially holds for the popular class of P-monodentate phosphites. For instance, there is no theoretical understanding of the reasons for the high asymmetrising activity of these compounds in hydrogenation (earlier, P,P-bidentate chelation was assumed to be a necessary condition). The corresponding studies are in the early stage of development.[206]

At present, P-monodentate chiral phosphites are most widely used. However, different groups of ligands belonging to this class of compounds have been studied in different ways. Emphasis has been placed on compounds derived from BINOL (**1**) and TADDOL (**19**). For instance, the synthesis of a new group of esters and amidoesters of BINOL, **131** and **132**, was reported very recently.



131a – f [(S_{ax}) and/or (R_{ax})]

R = Et (**a**), cyclo-C_6H_{11} (**b**), Bu^t (**c**), 9-fluorenyl (**d**),

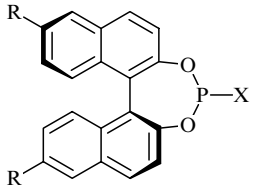
(**f**).



132a – c

Compound **132**	X	R
a	$N(CH_2)_4$	H
b	NMe(OMe)	H
c	NMe_2	Br

Ligands **131a – d** are used in Rh-catalysed combinatorial hydrogenation [207] while compounds **132a**,**b** are employed in the interesting reaction of conjugate addition of arylboronic acids to α,β-unsaturated substrates {with $[Rh(acac)(C_2H_4)_2]$ as precatalyst}.[208] Comparative studies of these systems and classical diphosphine ligands are in progress. In particular, the advantages of phosphoramidites not only in enantioselectivity but also in the catalytic activity in Rh-catalysed hydrogenation [reaction (2)] are revealed.[209] For instance, a 100% conversion of substrate **4d** in the

Table 2. Relative enantioselectivity of chiral phosphites in the most important catalytic reactions [listed are the maximum *ee* values (%)].

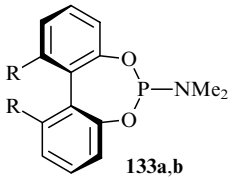
[a] For the formally P,P,P,N-tetradentate ligand **130**.

presense of phosphoramidite **132c** at an optical yield of the product of 94% takes less than 30 min.

The field of application of these ligands is extending continuously. Phosphoramidite (R_{ax},R_C)-**7n** was successfully (enantioselectivity up to 97%) used in a novel Ir-catalysed reaction of allylic etherification of achiral allylic carbonates with alkali metal phenolates.[210] It is of great importance that recent investigations in the field of Cu-catalysed addition of Me_2Zn to acyclic nitroalkenes (*ee* up to 98%)[211] opened novel routes to valuable bioactive compounds (Cyclamenol A, cryptophycins and β-methyl carbopenem antibiotics).

At the same time, increasing the number of phosphite (phosphoramidite) derivatives of BINOL and TADDOL obtained by varying the nature of exocyclic substituents is an extensive approach whose potential has been to a great extent exhausted. For instance, the enantioselectivity achieved in the Cu-catalysed addition of Et_2Zn to acyclic enones in the presence of phosphites **131e**,**f** (see Ref. 212) appeared to be lower (78%) than the enantioselectivity provided by the simpler ligands **3t**,**u**. We believe that it is more useful to extend the range of P-monodentate systems based on substituted diphenyldiols and, probably, on various mononuclear phenols. Here, two examples are provided by phosphoramidites **133a**,**b** based on axially chiral biphenyldiols.[208]



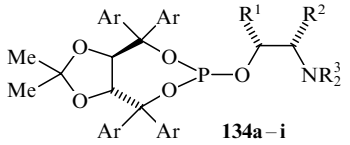
133a,**b** R = OMe (**a**), Ph (**b**).

The use of achiral phenols as, *e.g.*, in the synthesis of ligands **16** and **17** seems to be even more promising. These compounds, provided that BINOL and TADDOL are synthetically accessible ligands, undoubtedly are a step towards the synthesis of much simpler and inexpensive P-monodentate ligands.

A few monodentate systems containing P-stereocentres have been reported to date. However, it was established that ligands containing asymmetric donor atoms are of particular value for asymmetric induction. Therefore, synthesis of such ligands is a quite promising avenue of research in this field of catalysis.

Among P,N-bidentate phosphites, considerable attention should be paid to structures with oxazoline fragments and to phosphite derivatives of Schiff bases. This group of compounds can comprise convenient and efficient systems based on biphenyldiols as well as structures containing stereogenic phosphorus atoms.

We believe that relevant areas of catalytic applications should be found for a variety of aminophosphites. A recent example is provided by the use of ligands **134a–i** in Rh-catalysed hydrosilylation of prochiral ketones.[205]



134a–i

Compound **134**	Ar	R^1	R^2	R^3
a	Ph	Ph	Me	H
b	Ph	Ph	Me	Me
c	Ph	H	H	Me
d	Ph	H	Me	Me
e	Ph	Ph	H	Me
f	Ph	Ph	Me	$(CH_2)_4$ (see [a])
g	Ph	Ph	Me	$(CH_2)_5$ (see [a])
h	Ph	Ph	Ph	Me
i	2-naphthyl	Ph	Me	Me

[a] Here, R^3-R^3.

The best results were obtained using aminophosphite **134b**. The enantiomeric excess was 80% and 94% for the reduction of acetophenone and β-naphthyl methyl ketone, respectively.

As mentioned above, phosphine-phosphites form one of the most efficient groups of P,P-bidentate ligands. Undoubtedly, studies on applications of these compounds in asymmetric catalysis will continue. However, we believe that the synthesis of ligands containing phosphorus centres of different natures and no fragments with P–C bonds is at least equally important. These compounds (phosphite-phosphoramidite, unsymmetrical bisphosphoramidites) can be obtained with ease by phosphorylation of the corresponding amino alcohols and diamines. The data listed in Table 2 point to considerable advances made in applications of these ligands in catalytic reactions.

No planar chiral phosphite ligands have been reported as yet, though this type of chiral phosphines has long been known and comprises a variety of compounds that are excellent stereoselectors.[1,5] Therefore, there are grounds to expect the synthesis of planar chiral phosphites, the more so since the procedure for the synthesis of appropriate starting compounds (*e.g.*, ferrocene series) has already been developed.[213]

In the field of coordination chemistry one can expect a continuation of research into complexation of the most important groups of ligands with catalytically active metals. At present, there are a large number of catalytically efficient phosphites whose complexes with transition metals have not been isolated and studied in detail. This particularly concerns the P-monodentate compounds. Their coordination behaviour was studied much less thoroughly than that of the P,P- and P,N-bidentate systems. The structure of rhodium, palladium and iridium compounds has been studied in more detail, while information on copper complexes is scarce. Obviously, for each group of ligands it is important to combine catalytic experiments and studies on the structure of catalytically active complexes and intermediates of the catalytic cycle.

Is seems appropriate to synthesise a series of related complexes with different ligands for each class of chiral phosphites. Based on their spectral characteristics, the electron-donor properties of ligands will be assessed, which is of great importance for the prediction of catalytic efficiency. Interest in the optically active phosphites continuously increases. This is also indicated by the recently published reviews concerned with the problems of asymmetric synthesis.[214,215] We can with certainty say that application of chiral phosphites has brought coordination chemistry and asymmetric catalysis into a novel epoch.

Nucleosides and oligonucleotides containing 2′-reactive groups: synthesis and applications

T S Zatsepin, E A Romanova, T S Oretskaya

Contents

I.	Introduction	701
II.	Synthesis of modified nucleosides containing reactive groups in the 2′-position	701
III.	Synthesis of conjugates based on 2′-modified nucleosides and oligonucleotides	710
IV.	The use of nucleosides, nucleotides and oligonucleotides containing reactive groups in the 2′-position	722
V.	Conclusion	727

Abstract. The known methods for the synthesis of 2′-functionalised nucleosides, oligonucleotides and their conjugates are systematised. The applications of 2′-modified nucleosides and oligonucleotides are discussed. The bibliography includes 451 references.

I. Introduction

At present, the use of synthetic (including modified) oligonucleotides is unavoidable for progress in molecular biology and medicine. The interest in oligonucleotides and their derivatives as potential therapeutics able to influence, in one way or another, intracellular transformations of nucleic acids (NA) has been steadily increasing in the past decade. In addition, oligonucleotides are applied in antisense [1] and anti-gene [2] biotechnologies. The use of NA-based ribozymes [3] and aptamers [4] as well as RNA interference [5, 6] are no less promising trends.

Treatment of fragments of native NA with various chemical reagents usually results in statistical intrachain or terminal modifications. Incorporation of a modified fragment into a predetermined position of the oligomeric chain in the course of oligonucleotide synthesis is a more versatile approach which enables the introduction of reactive groups into heterocyclic bases, internucleotide phosphate groups or carbohydrate fragments. Obviously, nucleic acids should preserve their ability for complementary interactions. In this context, modification of functional groups involved in complementary interactions is undesirable, since it causes significant destabilisation of an NA duplex formed by the modified oligomer and complementary NA template.[7, 8] The C(5) atom of pyrimidine [9, 10] and the C(7) [11] or the C(8) atom [12] of purine nucleosides are sites of choice for the modification of heterocyclic bases, primarily because of minimum disturbances in the structures of the modified NA fragments obtained. The introduction of substituents into internucleotide phosphate groups results in the apperance of chiral centres and, as a consequence, the existence of two stereoisomers. Modification at the C(2′) atom of nucleosides seems to be especially promising, since the disturbances in the structures of DNA duplexes upon incorporation of thus modified fragments into the oligonucleotide structure are minimum. Besides, the introduction of reactive groups into the 2′-position allows the synthesis of nucleosides with both C(2′)-*exo*- and C(2′)-*endo*-conformations of the carbohydrate residue, directing the substituent to both minor and major grooves of the NA duplex.[13] The synthesis of 2′-modified oligonucleotides is reduced to the preparation of nucleoside phosphoramidite derivatives containing protected reactive groups with subsequent incorporation of the unit formed into the oligonucleotide chain by automated synthesis.

This review deals with the analysis of published papers devoted to the synthesis of nucleosides containing a reactive group in the 2′-position; this group is linked to the C(2′) atom either directly or through various linkers. Main attention is given to derivatives which can be incorporated into the oligonucleotide chain. The groups, which differ in reactivity from that of the functional groups of the natural nucleosides, will be referred to as the reactive groups. Here we do not consider modified nucleosides containing a single or a double C—C bond at the C(2′) atom, since these nucleosides, with only few exceptions, are not potential objects for conjugation with other compounds and incorporation into oligonucleotides.

The application of nucleosides and oligonucleotides containing reactive groups at the C(2′) atom is also discussed.

II. Synthesis of modified nucleosides containing reactive groups in the 2′-position

Numerous methods for the synthesis of nucleosides containing nucleophilic (amino or thio groups) and electrophilic (carboxy, aldehyde, *etc.*) groups in the 2′-position are known to date.

1. Synthesis of nucleosides containing nucleophilic groups

a. Synthesis of 2′-amino-2′-deoxynucleosides

Nucleophilic substitution at the C(2′) atom of activated nucleoside derivatives under the action of the azide ion and subsequent reduction of the azide to the amine is the most popular approach to the introduction of the amino group into the 2′-position of a nucleoside. The synthesis of nucleosides containing an azido group in the sugar moiety has been reviewed.[14] Here we shall consider only those papers which were not cited in that review [14] or were considered only briefly.

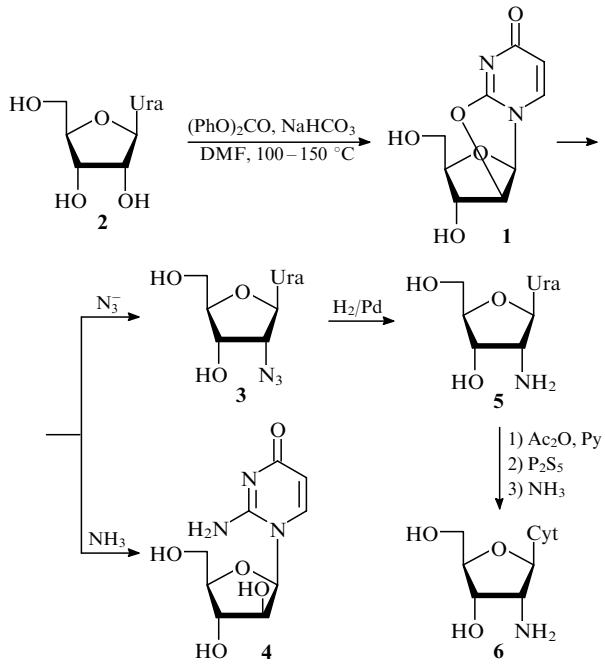
Uspekhi Khimii **73** (7) 757 – 791 (2004); translated by R L Birnova

$O^2,2'$-Anhydrouridine (**1**) is most frequently used as an activated derivative for the synthesis of pyrimidine 2′-amino-2′-deoxyribonucleosides. The anhydronucleoside **1** can be prepared by different methods among which the reaction of uridine (**2**) with diphenyl carbonate in the presence of sodium hydrogencarbonate as a base is the most popular.[15,16] The reaction of compound **1** with a weak nucleophile (*e.g.*, the azide ion) yields the 2′-substituted nucleoside **3**. If a stronger nucleophilic agent, *e.g.*, ammonia, is used, the reaction involves the heterocyclic base and yields arabinoisocytidine (**4**).

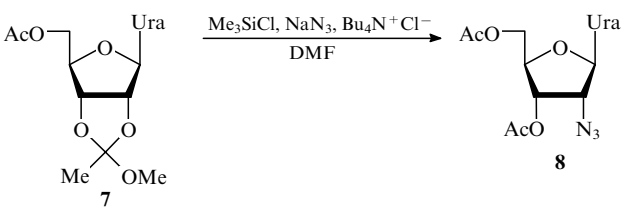
The reduction of 2′-azido-2′-deoxyuridine (**3**) was used for the preparation of 2′-amino-2′-deoxyuridine (**5**) in 50% yield.[17] Subsequent modification of the heterocyclic base in compound **5** yields the analogous cytidine derivative **6**.



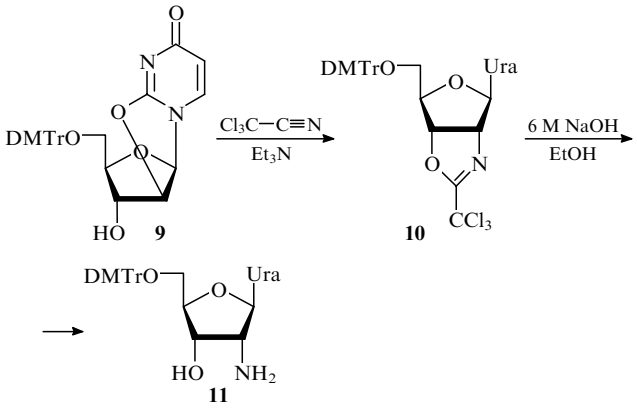
A similar procedure for the synthesis of pyrimidine 2′-amino-2′-deoxyribonucleosides starting from 5′-*O*-trityl- (see Ref. 18) and 3′,5′-di-*O*-benzoyl-$O^2,2'$-anhydrouridine was developed later.[19] In the latter case, partial deprotection of the 3′-hydroxy group took place.

The yield of compound **3** can be increased to 70% through *in situ* generation of lithium azide in the reaction of lithium fluoride with trimethylsilyl azide.[20,21] The addition of tetramethylethylenediamine to the reaction mixture favours the solubilisation of lithium azide in DMF due to its complexation with lithium ions, which increases the yield of the azido derivative **3** up to 80%. A similar effect was observed when a system Me_3SiN_3 – KF – 18-crown-6 was used.[20]

5′-*O*-Acetyl-2′,3′-*O*-(1-methoxyethylidene)uridine (**7**) was used as a starting compound in the synthesis of protected azidouridine **8**.[22] The generation of anhydrouridine occurs *in situ*. Nucleophilic substitution under the action of sodium azide in the presence of Me_3SiCl and Bu_4NCl results in compound **8** in 80% yield.

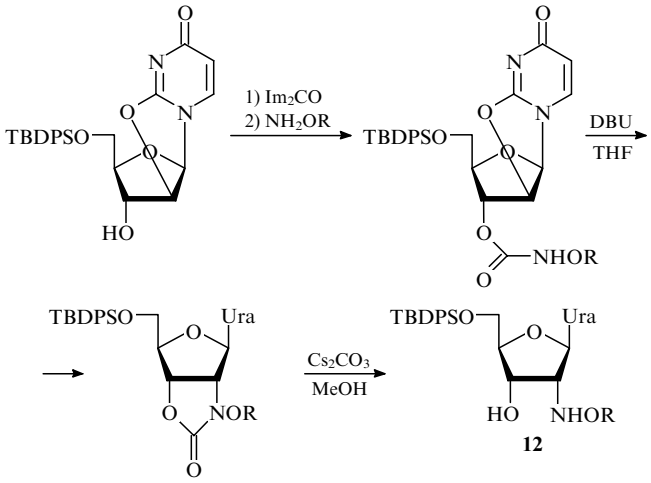


An alternative approach to the synthesis of 2′-amino-2′-deoxyribonucleosides has been developed.[23] The reaction of 5′-protected anhydrouridine **9** with trichloroacetonitrile affords trichloroacetimidate **10**; its subsequent hydrolysis with an ethanolic alkali yields the target product, *viz.*, 2′-amino-2′-deoxyuridine **11**.

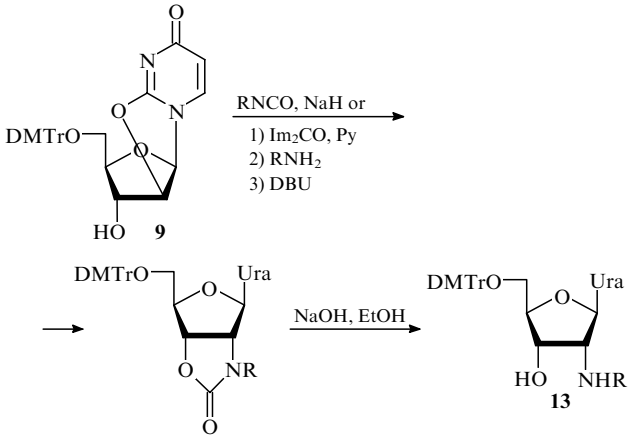


DMTr = $(4\text{-MeOC}_6H_4)_2PhC$.

This methodology gives access to pyrimidine 2′-alkoxyaminonucleosides **12**[24,25] and 2′-alkylaminonucleosides **13**[26,27] as well as 2′-hydroxyaminonucleosides.[28–30] The use of the *tert*-butyldiphenylsilyl protecting group for the 5′-hydroxy function allows the preparation of easily crystallisable products.

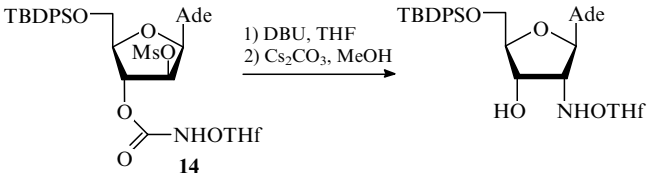


TBDPS = Bu^tPh_2Si; Im is imidazolyl; R = Me, Et, Bn, $(CH_2)_2OH$; DBU is 1,8-diazabicyclo[5.4.0]undec-7-ene.



R = Et, $(CH_2)_7Me$, 2-$PyCH_2$, 2-$Py(CH_2)_2$.

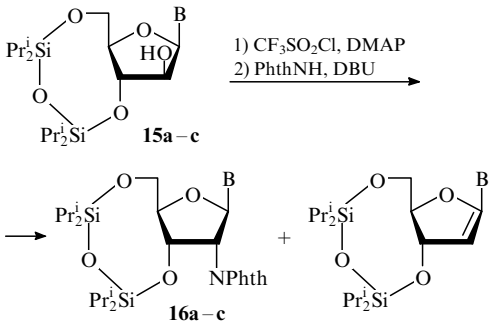
5′-*O*-*tert*-Butyldiphenylsilyl-2′-tetrahydrofuranyloxyamino-2′-deoxyadenosine was prepared starting from mesylated arabinoadenosine **14** using a similar approach.[29]



14

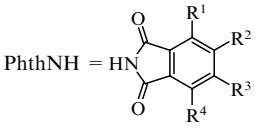
Ms = $MeSO_2$, THf is tetrahydrofuranyl.

Recently, Beigelman and co-workers [31] have developed an efficient scheme for the synthesis of protected 2′-amino-2′-deoxyribonucleosides. The starting arabinonucleosides **15a**–**c** with the tetraisopropyldisiloxane-1,3-diyl (TIPDS) [32] protecting group for 3′- and 5′-OH-groups were activated by treatment with trifluoromethanesulfonyl chloride. Nucleophilic substitution of the triflate group in the derivatives formed by treatment with phthalimides containing various substituents in the benzene ring resulted in 2′-phthalimido-2′-deoxynucleosides **16a**–**c** in 35%–70% yields. 4,5-Dichlorophthalimide proved to be the nucleophile of choice; its application did not result in the formation of side products such as 2′-deoxy-1′,2′-didehydronucleosides. This is a preparative and versatile method for the synthesis of purine and pyrimidine nucleosides.



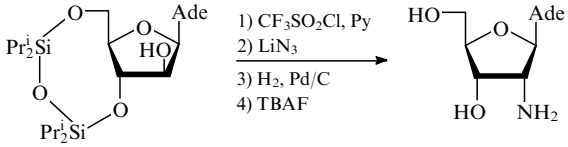
15a–**c** → **16a**–**c** +

B = Ura (**a**), Ade^{Bz} (**b**), Cyt^{Ac} (**c**); DMAP = 4-Me_2NPy;



R^1	R^2	R^3	R^4
H	H	H	H
Cl	Cl	Cl	Cl
H	Cl	Cl	H
NO_2	H	H	H
H	NO_2	H	H

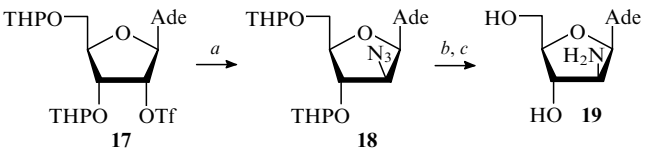
Realisation of a similar method has been described.[33,34] In this case, the triflate of the protected arabinoadenosine obtained in the first step was introduced in the reaction with lithium azide with subsequent reduction of the azido group.



TBAF = $Bu_4N^+F^-$.

The nucleophilic substitution of 2′-*O*-sulfonyl groups in ribonucleoside derivatives, which also occurs with reversal of the configuration at the C(2′)-atom, is used for the synthesis of 2′-amino-2′-deoxyarabinonucleosides. Of this type of nucleoside, purine nucleosides are synthetically more accessible.

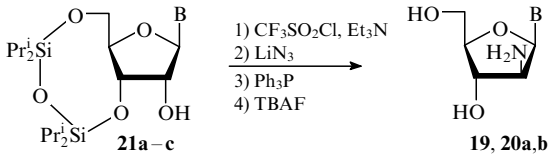
Starting from 3′,5′-di-*O*-tetrahydropyranyl-2′-*O*-trifluoromethylsulfonyladenosine (**17**), 2′-azido-2′-deoxy-β-D-arabinoadenosine **18** was prepared, which was reduced to the target nucleoside **19** after deprotection.[35]



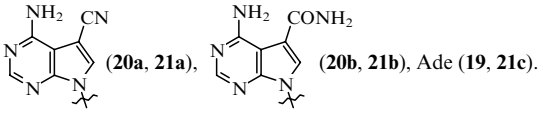
17 **18**

THP is tetrahydropyranyl, Tf = CF_3SO_2.
(*a*) NaN_3, (*b*) H^+, (*c*) Ph_3P, H_2O.

The same strategy was used in the synthesis of 2′-amino-2′-deoxy-β-D-arabinoadenosine (**19**) [36] and its analogues **20a**,**b** [37] from protected ribonucleosides **21a**–**c**.



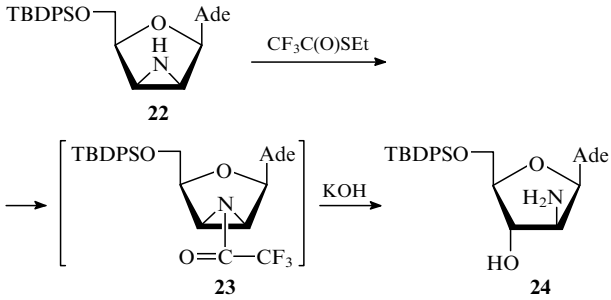
21a–**c** → **19**, **20a**,**b**



(**20a**, **21a**), (**20b**, **21b**), Ade (**19**, **21c**).

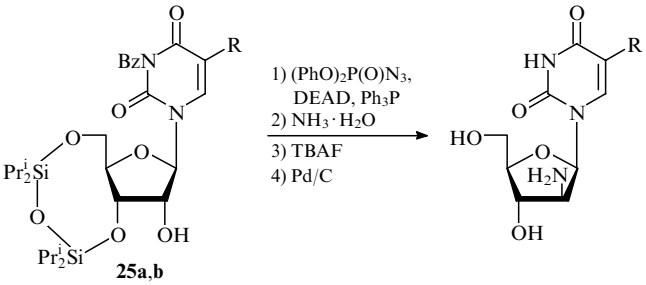
It should be noted that the glycosidic bond in the 2′-*O*-tosyl adenosine derivative is cleaved under the action of nucleophilic agents in DMF resulting in the liberation of adenine.[38] The nucleophilic substitution of the tosyloxy group under the action of NaN_3 in hexamethylphosphoramide has been carried out, however, with low yields [46% and 11% for 2′-*O*-(toluene-*p*-sulfonyl)adenosine and -guanosine, respectively].[39]

A scheme for the preparation of 2′-amino-2′-deoxyarabinoadenosine from the β-D-lyxoadenosine derivative **22** has been proposed.[40] The opening of the aziridine ring in the *N*-trifluoroacetyl derivative **23** occurred in a virtually regioselective manner; the yield of compound **24** was 49%.



22 → **23** → **24**

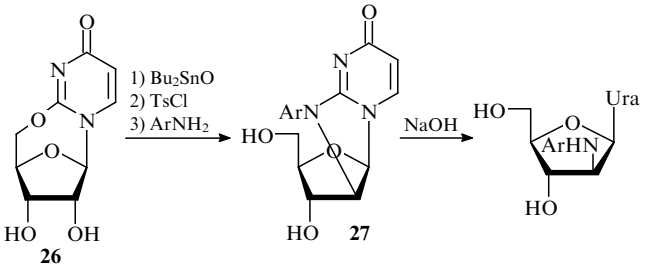
Pyrimidine 2′-amino-2′-deoxyarabinonucleosides are synthetically less accessible and were prepared for the first time as late as 1989 using the reaction of protected ribouridine **25a** and ribothymidine **25b** with diphenyl phosphorazidate in the presence of diethyl azodicarboxylate (DEAD) and triphenylphosphine with subsequent reduction of the azido group. The presence of a benzoyl protecting group at the N^3-atom of the heterocyclic base is necessary for preventing the closure of the O^2,2′-anhydro ring, which yields 2′-amino derivatives with a ribo-configuration.[41,42]



25a,**b**

R = H (**a**), Me (**b**).

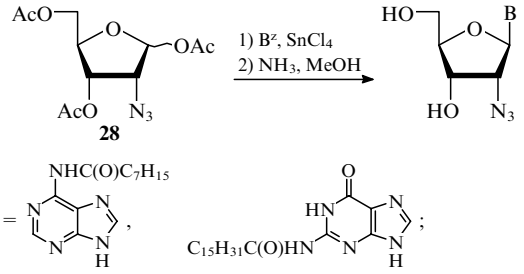
An original scheme for the synthesis of 2′-arylamino-2′-deoxy-β-D-arabinouridines from the O^2,5′-anhydroderivative **26** has been developed.[43] Selective tosylation of the 2′-hydroxy group and subsequent treatment with aromatic amines yielded tricyclic compounds **27**, which were further hydrolysed with aqueous alkali. If aliphatic amines were used, the intermediate tricyclic compounds underwent degradation.



Ts = 4-$MeC_6H_4SO_2$; Ar = Ph, 4-MeC_6H_4.

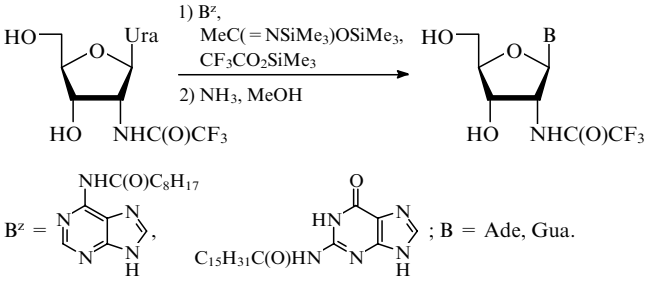
The synthesis of 2′-amino-2′-deoxyadenosine from 9-(2,3-anhydro-D-lyxofuranosyl)adenine has been described.[44]

In all the methods for the synthesis of 2′-amino-2′-deoxynucleosides, the amino group was introduced using modification of activated derivatives of preformed nucleosides. An alternative strategy consists of glycosylation of heterocyclic bases by premodified sugars. First attempts to synthesise 2′-amino-2′-deoxyderivatives of purine nucleosides starting from D-altrose[45] and glucosamine[46] were unsuccessful. Glycosylation of purines by protected 2-azido-2-deoxyribose **28** was more successful; however, a mixture of α and β-anomers of the target 2′-azido-2′-deoxyribonucleosides was obtained (7- and 9-isomers are formed in the case of guanosine).[47]



B = Ade (38%), Gua (21%).

Later, purine 2′-amino-2′-deoxynucleosides were synthesised by transglycosylation of protected adenine and guanine with 2′-trifluoroacetamido-2′-deoxyuridine.[48]



; B = Ade, Gua.

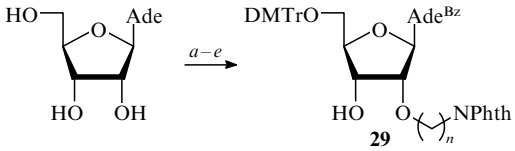
The condensation of 3-*O*-acetyl-2-azido-5-*O*-benzoyl-2-deoxy-D-arabinofuranosyl chloride, prepared from D-glucose by a multistep synthesis, with silylated cytosine afforded 1-(2-azido-2-deoxy-β-D-arabinofuranosyl)cytosine in 37% yield. This reaction was also accompanied by the formation of the α-anomer (yield 10%).[41]

Some examples are known of chemoenzymatic synthesis of modified nucleosides which combines classical methods of organic synthesis with the use of enzymes[49] and cell cultures.[50] Thus 2′-amino-2′-deoxyadenosine is produced by the bacteria *Actinomadura*.[51,52] Transglycosylation of hypoxanthine[53] and adenine[54] by 2′-amino-2′-deoxyuridine in a cell culture of *Ervinia herbicola* with a degree of conversion of up to 50% has been carried out. 2′-Amino-2′-deoxy-β-D-arabinoadenosine was converted into the corresponding inosine derivative under the action of adenosine deaminase.[55]

Synthesis of 2′-*O*-aminoalkylnucleosides

The preparation of 2′-*O*-aminoalkylnucleosides can be regarded as a special case of alkylation of the 2′-hydroxy group. The methods for the synthesis of 2′-*O*-alkylnucleosides have been reviewed.[56] In this Section, special attention will be given to the introduction and protection of the amino group.

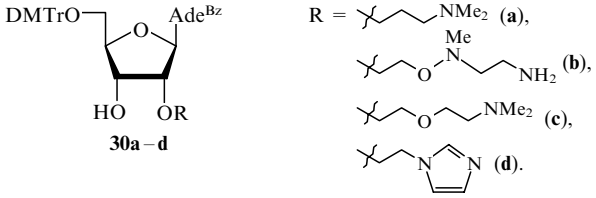
2′-*O*-Aminoalkyl nucleosides **29** were first obtained in 1991 by Cook and co-workers[57] Free adenosine was alkylated with phthalimidoalkyl bromides in the presence of sodium hydride.[57–61]



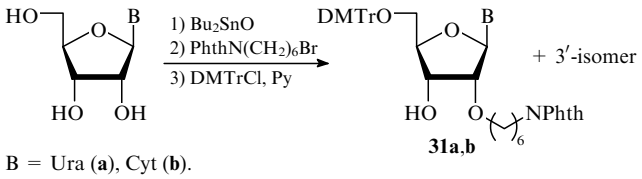
(*a*) $PhthN(CH_2)_nBr$, NaH, DMF; (*b*) Me_3SiCl, Py; (*c*) BzCl; (*d*) NH_4OH; (*e*) DMTrCl, Py; *n* = 2–6.

This reaction yields a mixture of 2′- and 3′-isomers which can be separated only after benzoylation of the exocyclic amino group of adenine and tritylation of the 5′-hydroxy group. Although the total yields of nucleosides **29** are low (10%–20%), the advantage of this method is that it does not require additional protection/deprotection steps and eliminates multiple chromatography of intermediates. In addition, the aminoalkyl group is introduced in one step, while the phthaloyl protecting group is stable under the conditions of the oligonucleotide synthesis and is removed by standard post-synthetic treatments with concentrated aqueous ammonia on heating. Trifluoroacetyl[62] or 2-cyanoethoxycarbonyl groups can be used instead of the phthaloyl protecting group.[63]

Nucleosides **30a–d** in which the amino groups are linked to the O(2′) atom through more complex linkers have also been used in oligonucleotide synthesis.[64]



Unfortunately, direct alkylation of non-protected nucleosides is possible only in the case of adenosine and its analogues. Metal-directed alkylation of the *cis*-diol group permits one to increase the total yield of pyrimidine nucleosides **31a**,**b** to 46% (no base alkylation is observed), but the regiospecificity of the substitution is still low (a mixture of 2′- and 3′-isomers is formed in a 55 : 45 ratio).[65]



B = Ura (**a**), Cyt (**b**).

A method for the alkylation of O^2,2′-anhydrouridine **1** and thymidine **32** by boric acid esters has been developed.[63,66–69] The yields of compounds **33** and **34** are 15%–20%. The opening of the

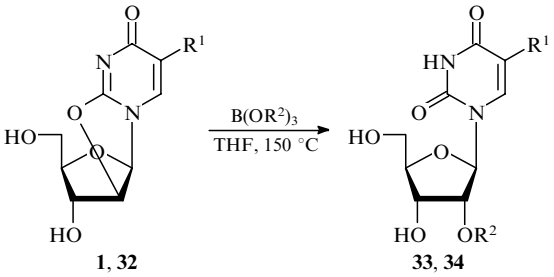
ring in compound **32** was achieved by treatment with phthalimidoethanol in the presence of titanium tetraisopropoxide.[70]

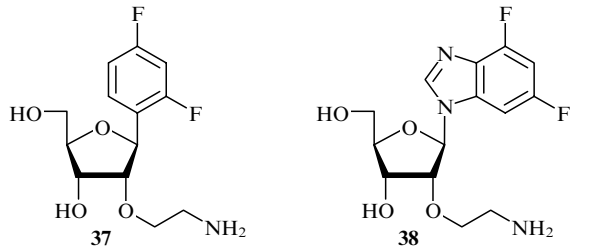


1, **32** **33**, **34**

1, **33**: R^1 = H; **32**, **34**: R^1 = Me; $R^2 = (CH_2)_n$NPhth; n = 2, 3.

A more standard version of the synthesis of 2′-*O*-aminoalkylnucleosides **35** and **36** based on protection of all the reaction centres with the exception of that to be modified has been published.[71,72] Here, all the synthetic steps are high-yielding, but the total yield is only 10%–25% due to the large number of steps (Scheme 1).

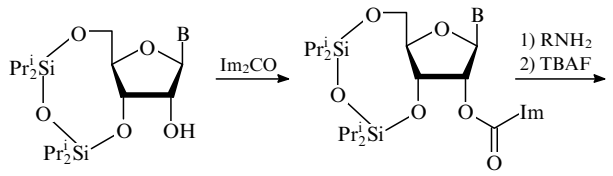
A similar synthesis of modified glycosides **37** and **38** with non-native aglycons has been carried out.[73]



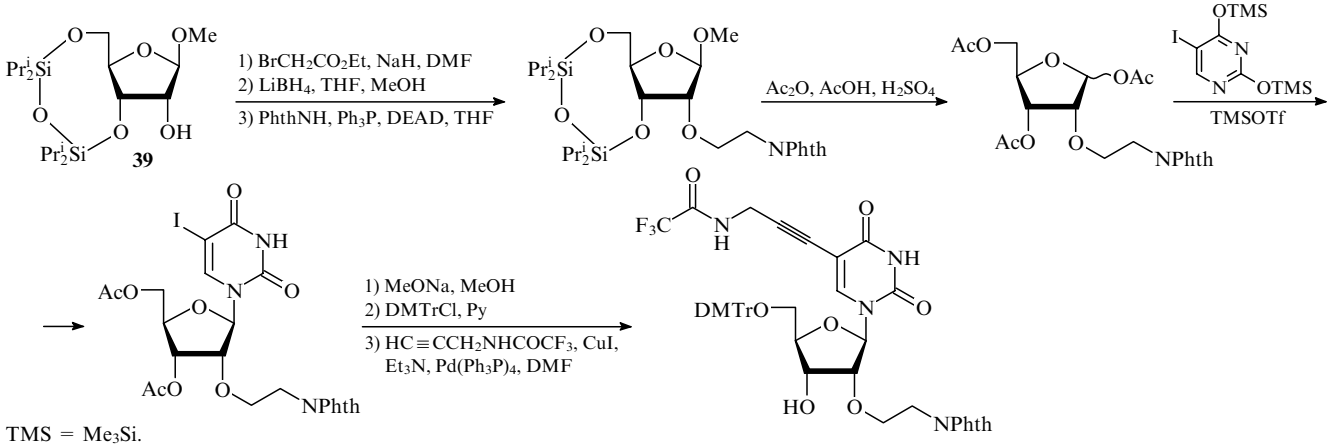
37 **38**

Sollogoub *et al.*[74] have performed alkylation of the protected riboside **39** with subsequent introduction of an amino group under conditions of the Mitsunobu reaction; glycosylation was carried out in the later steps of the synthesis (Scheme 2).

The aminoalkyl groups were attached to the O(2′) atom through a carbamoyl linker.[75–77] This approach provides high yields of the aminoalkylated derivatives **40**.



Scheme 2



TMS = Me_3Si.

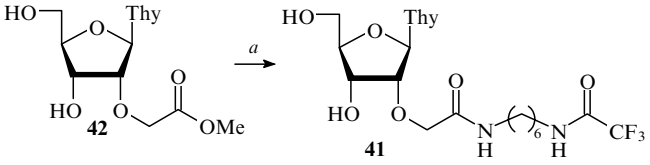
B = Cyt^{Bz}: R = $(CH_2)_6NHC(O)CF_3$;
B = Ura: R = $(CH_2)_2NPhth$, $CH_2(CH_2CH_2O)_3(CH_2)_2NH_2$, $CH_2(CH_2CH_2NH)_2(CH_2)_2NH_2$, $(CH_2)_3NH(CH_2)_2NH_2$, Leu-PheNH_2.

The carbamate of 3′,5′-protected arabinouridine was prepared in a similar way.[78]

Keller and Haner[79] have synthesised *N*-acylated 2′-*O*-(9-amino-2-oxo-3-azanonyl)thymidine **41** starting from the nucleoside **42** containing a glycolic acid fragment in the 2′-position.



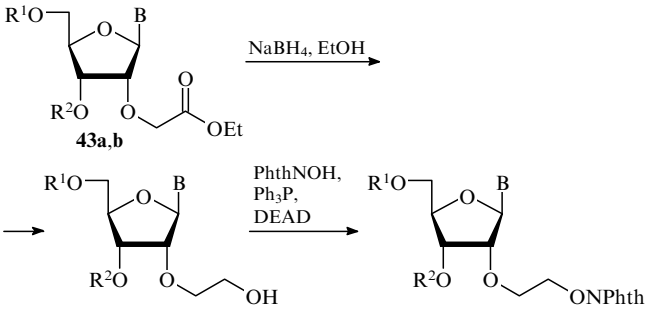
42 **41**

(*a*) $H_2N(CH_2)_6NHC(O)CF_3$.

c. Synthesis of nucleosides containing an aminooxy group

Treatment of nucleosides with *N*-hydroxyphthalimide under conditions of the Mitsunobu reaction is an optimum method for the introduction of an aminooxy group.[80] This method is well developed and the phthaloyl protecting group meets all the requirements for the automated oligonucleotide synthesis.

A possible approach to the introduction of the aminooxyethyl group into the 2′-position of protected thymidine **43a** and adenosine **43b** has been described.[81,82]

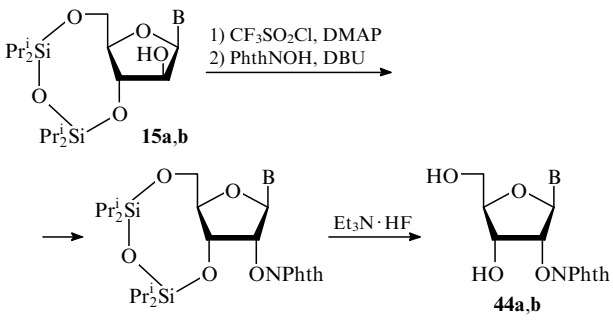


43a,**b**

B = Thy: $R^1 = R^2 = 2,4\text{-}Cl_2C_6H_3CH_2$ (**a**);
B = Ade: $R^1 - R^2 = (Pr^i_2Si)_2O$ (**b**).

Recently, a shorter route to the synthesis of pyrimidine 2′-*O*-(2-hydroxyethyl)nucleosides by alkylation of O^2,2′-anhydronucleosides by boric acid esters has been proposed.[83–85] The nucleosides thus prepared are intermediate compounds in the synthesis of protected 2′-*O*-(2-aminooxyethyl)nucleosides.

In an attempt to introduce the phthalimido group directly into the 2′-position of 3′,5′-*O*-protected nucleosides, the yields of the target products did not exceed 10% because of the low reactivity of the secondary hydroxy group under conditions of the Mitsunobu reaction. Nevertheless, the desired products **44a**,**b** were prepared by substitution of the 2′-*O*-trifluoromethylsulfonyl group in the arabinouridine derivatives **15a** and the arabinoadenosine derivatives **15b**.[86] This reaction occurs with inversion of the configuration of the C(2′) atom.



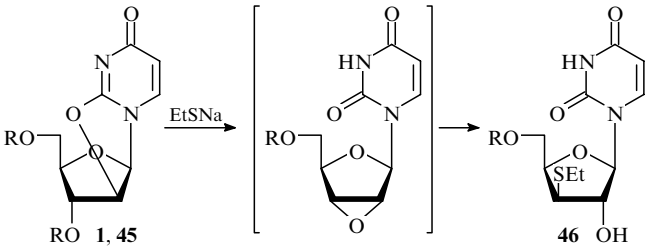
15a,**b** **44a**,**b**

B = Ura (**a**), Ade (**b**).

d. Synthesis of nucleosides containing a thiol group

In this subsection, we shall consider the synthesis of 2′-thionucleosides and 2′-*O*-mercaptoalkylnucleosides. A review[87] devoted to the synthesis of various thionucleosides has been published recently; however, methods for the synthesis of C(2′)-derivatives are not considered there.

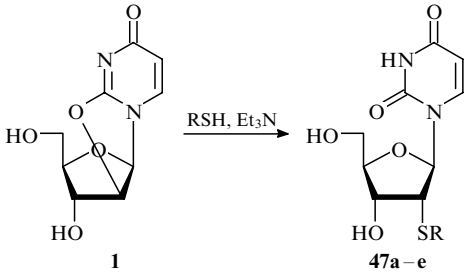
The first attempts to carry out the reaction of free O^2,2′-anhydrouridine **1**[88] or its protected derivative **45**[89] with sodium ethanethiolate resulted in 3′-*S*-ethylthio-3′-deoxyxylouridine **46** as the main product.



1, **45** **46**

1: R = H; **45**: R = Ac.

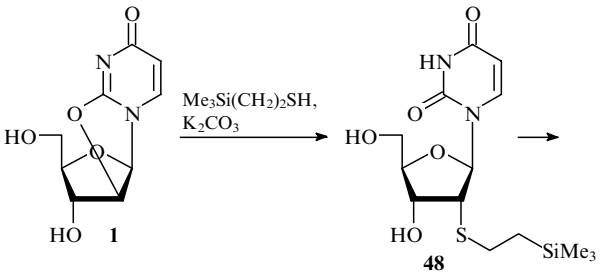
Later, it was found that preparation of the nucleoside 2′-thioderivatives **47a**–**e** by nucleophilic substitution at the C(2′) atom of the anhydronucleoside **1** requires the use of weaker nucleophiles, *e.g.*, thioacetic acid[90,91] and various thiols[92] and that the reaction was carried out in the presence of triethylamine or N^1,N^1,N^3,N^3-tetramethylguanidine. This approach was repeatedly used later.[93–96]



1 **47a**–**e**

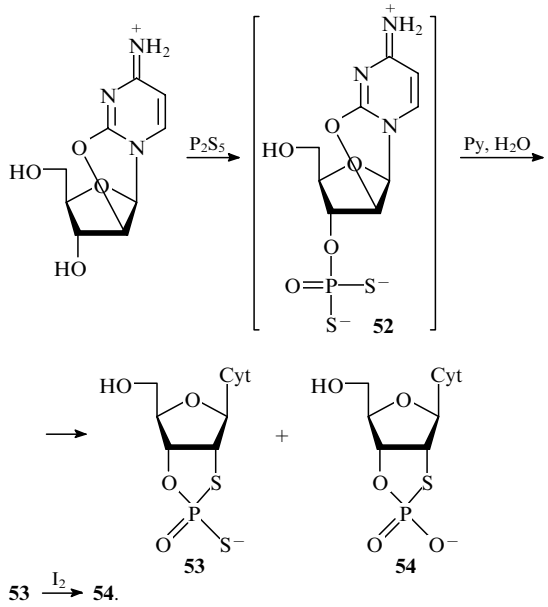
R = Ac (**a**), Me (**b**), Et (**c**), Bn (**d**), 4-$MeOC_6H_4$ (**e**).

Recently, it was proposed that 2-(trimethylsilyl)ethanethiol in the presence of potassium carbonate can be used for the synthesis of pyrimidine 2′-thionucleosides.[97] The uridine **48** thus modified can be easily converted into the mixed disulfide **49** and the analogous cytidine derivatives **50** and **51**. The high cost of reagents is the main disadvantage of this method. An attempt to deprotect the thiol group in compound **48** with tetrabutylammonium fluoride yielded a complex mixture of reaction products.



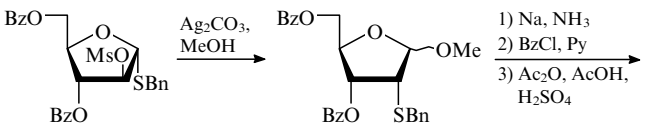
(*a*) Ac_2O, Py; (*b*) , $POCl_3$, Et_3N; (*c*) NH_3.

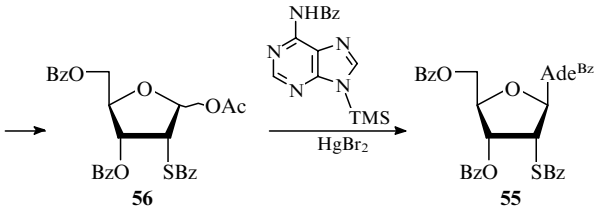
2′-Thiocytidine derivatives can be prepared not only by transamination of uridine,[93,97] but also by opening of the O^2,2′-anhydrocytidine ring.[98] An intramolecular attack of the 3′-*O*-dithiophosphate group at the C(2′) atom of substituted O^2,2′-anhydrocytidine **52** has been described.[98] This yields a mixture of 2′,3′-cyclodithiophosphate **53** and 2′,3′-cyclothiophosphate **54** which can be prepared from compound **53** by treatment with iodine.



53 $\xrightarrow{I_2}$ **54**.

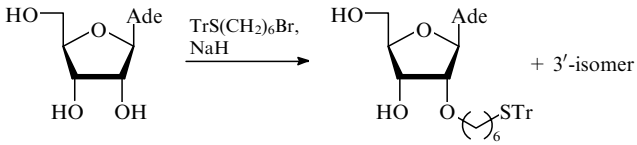
The synthesis of 2′-benzoylthioadenosine **55** by glycosylation of protected adenine with the ribose thioanalogue **56** has been described.[99]



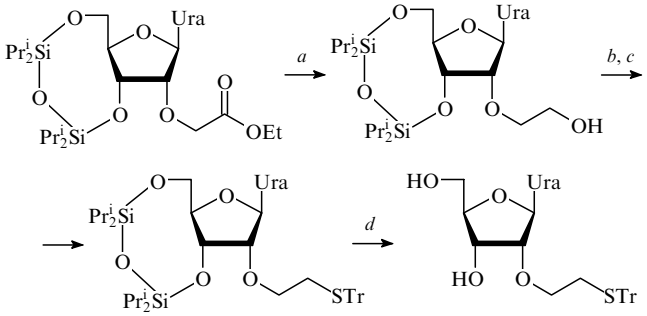


Although 2′-thionucleosides were first described about 25 years ago, they came into the routine practice of oligonucleotide synthesis only very recently.[93,100]

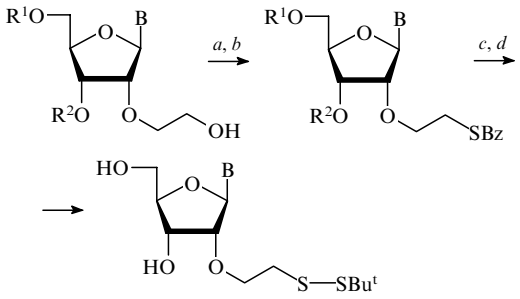
Two strategies are feasible for the synthesis of 2′-*O*-mercaptoalkylnucleosides, *viz*., the reaction of nucleosides with alkyl halides containing a protected thiol group,[101–103] or the preparation of 2′-*O*-hydroxyalkyl nucleosides with subsequent conversion of the hydroxy group into the thiol group.[104–107]



Tr = Ph_3C.



(*a*) $NaBH_4$, MeOH, Bu^tOH; (*b*) Ph_3P, CBr_4, MeCN; (*c*) TrSH, DBU, C_6H_6; (*d*) TBAF, THF.



B = Ura, Cyt^{Bz}, $Gua^{Bu^iC(O)}$; $R^1 - R^2 = (Pr^i_2Si)_2O$, $R^1 = R^2 = Bu^tMe_2Si$.
(*a*) $MeSO_2Cl$, Py, CH_2Cl_2; (*b*) BzSH, Et_3N, DMF; (*c*) HF, MeCN; (*d*) 1-(*tert*-butylthio)hydrazine-1,2-dicarboxymorpholide, LiOH, MeOH, THF.

Moreover, target 2′-*O*-mercaptoalkyl nucleosides can be prepared *via* intermediate bromoalkyl nucleosides.[108]

2. Synthesis of nucleosides containing electrophilic groups

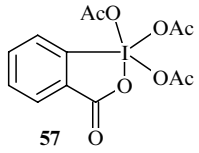
In contrast to nucleophilic groups, electrophilic groups (with the exception of monosubstituted phosphate and keto groups) cannot be directly introduced at the C(2′) atom of the nucleoside. This is due to the fact that such nucleosides are highly unstable and prone to β-elimination. Therefore, the use of linkers is the only possible approach to the attachment of electrophilic groups at the C(2′) atom of the nucleoside. A recently published review [109] devoted to the preparation of modified oligonucleotides containing electrophilic groups describes the synthesis of nucleosides containing

aldehyde and carboxy groups. Here we thought it expedient to highlight some aspects of the problem not touched upon in the above-cited review.

a. Synthesis of 2′-oxonucleosides

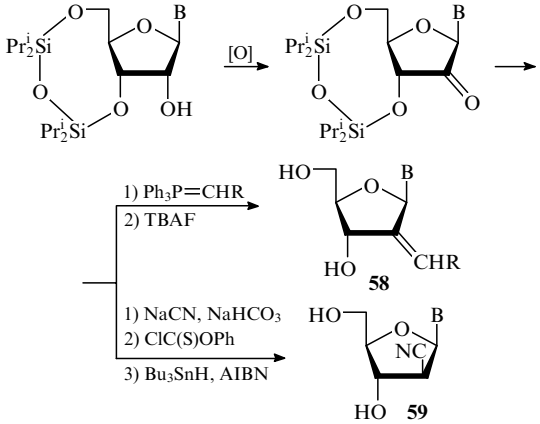
It has long been thought that 2′-oxo derivatives of nucleosides are highly unstable and undergo decomposition due to the high lability of the *N*-glycosidic bond.[110] Nevertheless, Robins and co-workers[111,112] succeeded in the oxidation of 3′,5′-protected uridine by CrO_3. Later, this approach was used by other authors.[113,114] Matsuda *et al.*[115–120] have performed the synthesis of protected 2′-oxonucleosides using the Swern oxidation by the oxalyl chloride–DMSO–triethylamine system.[121,122] This reaction requires protection of the heterocyclic base.[123,124] A recently published paper[125] deals with a comparison of various acylating reagents used in the Swern oxidation of 3′,5′-protected cytidine. It was shown that the use of trifluoroacetic anhydride provides the maximum yield of 2′-oxocytidine.

In 1990, Robins *et al.*[126] used the Dess–Martin 'periodinane' {1,1,1-triacetoxybenzo[*d*]-1,2-iodoxol-3(1*H*)-one} **57** for the oxidation of the 2′-hydroxy group.[127] At present, this is the method of choice,[128,129] since the reaction is selective and the product formed can be used in subsequent transformations without additional purification.



57

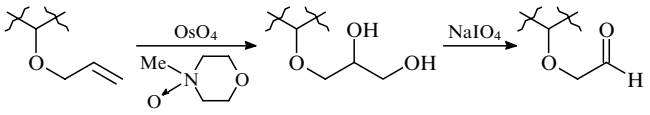
2′-Oxonucleosides are further used in the synthesis of the 2′-deoxy-2′-methylidene derivatives **58** by the Wittig reaction[130–133] or of the cyano derivatives **59**.[134,135] The modified nucleosides **58** and **59** are extensively employed in the therapy of cancer and viral diseases.[136,137] However, the introduction of these derivatives into the oligonucleotide chain results in significant destabilisation of the NA duplex;[138] therefore, their use in the synthesis of modified oligonucleotides is hardly justified.



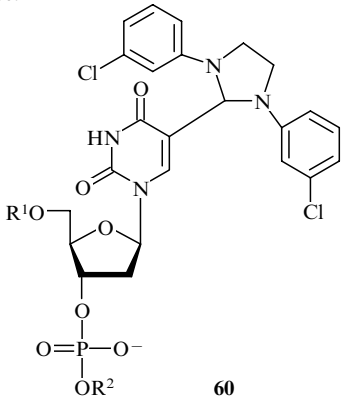
B is a free or protected heterocyclic base,
R = Alk.

b. Synthesis of nucleosides containing an aldehyde group

Synthesis of nucleosides containing an aldehyde group in the 2′-position is usually carried out by oxidative cleavage of their precursors (*vic*-diol derivatives) by sodium periodate.



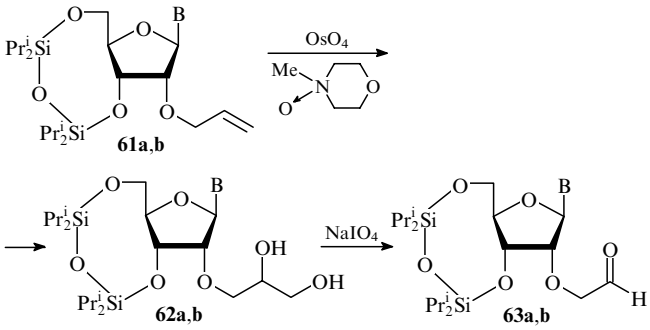
The choice of this strategy is determined by a number of factors. First, the oxidation of the vinyl group to the aldehyde group occurs under milder conditions than that of the primary hydroxy group. Second, if a nucleoside to be introduced into the oligonucleotide chain already contains an aldehyde group, the latter should be protected to prevent its reaction with the amino groups of heterocyclic bases and phosphorus(III) derivatives and oxidation by iodine. Unfortunately, no suitable protecting group has been found so far. Thus the *N*,*N*′-bis(3-chlorophenyl)imidazolidine protecting group[139] recommended for the protection of the aldehyde group of 5-formyl-2′-deoxyuridine has not found wide application, because its removal requires long-term treatment of the oligonucleotide **60** with 80% acetic acid, which leads to the degradation of even the most stable homothymidine oligonucleotides.



60

R^1 and R^2 are fragments of an oligodeoxyribonucleotide chain.

Studies by Glick and co-workers[105,106] who first performed the synthesis of the 2′-*O*-allyl pyrimidine nucleoside derivatives **61a**,**b**, their subsequent oxidation to the *vic*-diols **62a**,**b** and then cleavage to the aldehydes **63a**,**b**, represent an example of this methodology.

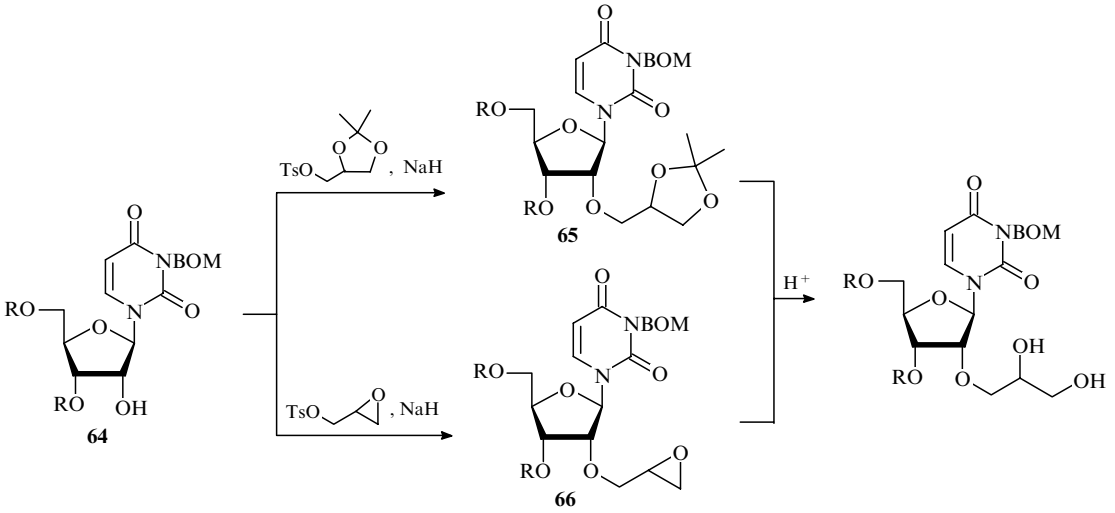


B = Ura (**a**), Cyt^{Bz} (**b**).

A similar approach was used in other studies[140,141] with the only exception that the *vic*-diol group of protected uridine **62a** was benzoylated into a 3′-phosphoroamidite derivative, which was then used in automated oligonucleotide synthesis. The aldehyde group was generated at the oligonucleotide level.

Martin[71] proposed the use of isopropylideneglycerol and glycidol toluene-*p*-sulfonates for the alkylation of the 2′-hydroxy group of the protected nucleoside **64**. The *vic*-diol fragment was generated upon acid hydrolysis of the isopropylidene protecting group in the modified uridine **65** or of the oxirane **66** (Scheme 3).

Scheme 3



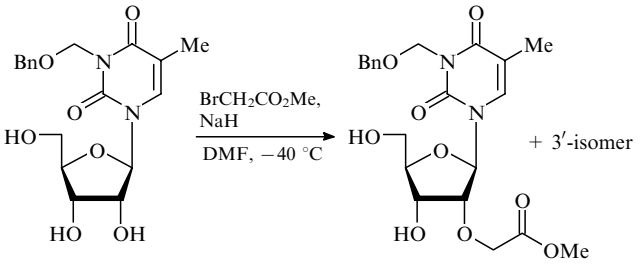
R = 2,4-$Cl_2C_6H_3CH_2$.

Mention should also be made of the recently published reviews [142–144] devoted to the synthesis and applications of nucleoside and oligonucleotide dialdehyde derivatives.

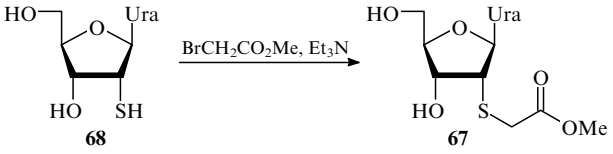
c. Synthesis of nucleosides containing a carboxy group

Studies devoted to the synthesis of 2′-*O*-alkoxycarbonyl methylnucleosides are generalised in the review.[109] Here, we shall consider only those publications which have not been included in that review [109] or demand additional discussion.

Alkylation of 3-*N*-(benzyloxymethyl)ribothymidine containing free hydroxy groups [145] occurred with high regiospecificity (the isomer ratio 2′ : 3′ was 9 : 1) (however, the yield of the 2′-isomer is not indicated).



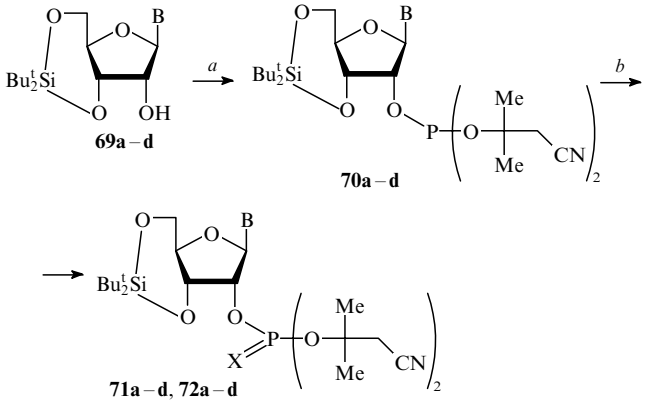
The preparation of 2′-methoxycarbonylmethylthio-2′-deoxyuridine **67** has been described.[94,95] The alkylation of the nonprotected derivative **68** by methyl bromoacetate partly involved the N(3) atom of the heterocyclic base.



According to literature data,[146] the 2′-*S*-alkyl group is exposed to the major groove of the DNA duplex contrary to the 2′-*O*-alkyl group, which is exposed to the minor groove.[147] The difference in the arrangement of reactive groups in the NA duplexes allows preparation of conjugates with different properties from modified oligonucleotides and other molecules.

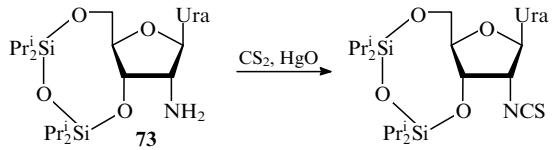
d. Synthesis of nucleosides containing other electrophilic groups

Studies by Sekine *et al.*[148,149] describe the synthesis of nucleosides and oligonucleotides containing a 2′-phosphate or a 2′-thiophosphate group. The 3′- and 5′-protected nucleosides **69a–d** were converted into the trivalent phosphorus derivatives **70a–d**; their subsequent oxidation with *tert*-butyl hydrogen peroxide or sulfur yielded 2′-phosphates **71a–d** and thiophosphates **72a–d**, respectively.



B = Ura^{Bz} (**a**), $Cyt^{Bu^tC(O)}$ (**b**), Ade^{Bz} (**c**);  (**d**);
71a–d: X = O; **72a–d**: X = S;
(*a*) $Pr^i_2NP(OCMe_2CH_2CN)_2$, TetrH; (*b*) Bu^tO_2H or S_8;
TetrH is tetrazole.

The conversion of the 2′-amino group of modified uridine **73** into the isothiocyanate group, which can further be introduced into reactions with various nucleophiles, has been described.[150]



These data suggest that the methodology for synthesis of modified nucleosides containing free or protected reactive groups in the 2-position of the carbohydrate fragment is fairly well developed. The former are used for the preparation of conjugates with various compounds, whereas the latter are employed for the preparation of protected phosphoramidite derivatives for oligonucleotide synthesis.

III. Synthesis of conjugates based on 2′-modified nucleosides and oligonucleotides

Two, different in principle, approaches to the synthesis of NA, *viz*., chemical and enzymatic, are known. The overwhelming majority of 2′-modified oligonucleotides have been synthesised using the chemical approach. The latter implies initial preparation of protected nucleoside derivatives for automatic oligonucleotide synthesis. Natural $3' \rightarrow 5'$ internucleotide bonds are usually formed using 3′-phosphoramidite nucleoside derivatives, although some exceptions are possible. The dimethoxytrityl protecting group is widely used for the protection of the 5′-hydroxy group, whereas amino groups of heterocyclic bases are protected by groups that are labile in alkaline media. This approach enables the synthesis of oligomers containing up to 80 – 100 nucleotides. NA with longer chains are synthesised using chemical [151] or enzymatic [152] ligation.

The use of the enzymatic approach, which entails the incorporation of nucleoside 5′-triphosphates into NA using DNA and RNA polymerases, is confined to 2′-amino-2′-deoxy- [153] and 2′-alkoxyaminonucleosides.[154, 155] In addition, the substrate properties of pyrimidine 2′-amino-2′-deoxynucleoside triphosphates are inferior to the natural nucleoside triphosphates.[156]

Oligonucleotide 2′-conjugates can be prepared using three different approaches. The first of them includes the preparation of nucleoside conjugates with other compounds and their subsequent introduction into the automated oligonucleotide synthesis. The stability of phosphoramidite derivatives of conjugates in the course of the oligonucleotide synthesis and post-synthetic treatments is a prerequisite. The possibility of selective conjugation and no need for post-synthetic modifications of oligonucleotides are considered as advantages of this method. However, this requires considerable amounts of modified nucleosides, which significantly restricts the potential of this method.

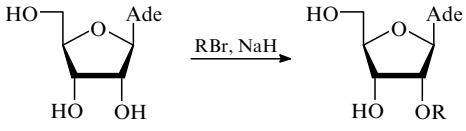
The second approach consists of the conjugation of 2′-modified oligonucleotides immobilised on a polymeric support. To achieve this, a modified fragment containing a 2′-protected reactive group is incorporated into the oligonucleotide chain in the course of solid-phase chemical synthesis. The protecting group in this fragment should retain stability throughout the oligonucleotide synthesis and be selectively removed on its termination without any effect on the newly formed bonds in the protected oligonucleotide. 2′-Hydroxy and amino groups are protected either by the allyloxycarbonyl group, which is removed by palladium(0) complexes, or by the fluorenylmethoxycarbonyl group, which is removed upon treatment with morpholine or piperidine. The levulinoyl and phthaloyl groups are used for the protection of hydroxy and amino groups, respectively, and are removed by hydrazinolysis. Fluorenylmethyl protection, which is removed by treatment with morpholine or piperidine, is used for the carboxy group. Various photolabile protecting groups are also used for this purpose. The use of *tert*-butyldimethylsilyl and *tert*-butyldiphenylsilyl protecting groups is limited to automated synthesis on polystyrene carriers, since controlled-pore glass (CPG) support is destroyed upon removal of protecting groups under the action of the fluoride anion.

Conjugation is carried out after deprotection of the reactive group. Oligonucleotide conjugates immobilised on a polymeric support are washed to remove excess reagents, deprotected, and the product is split from the solid phase. The conjugation is usually carried out in anhydrous organic solvents, especially in the case of conjugates with hydrophobic compounds that are poorly soluble in aqueous and aqueous-organic media. Selective removal of 2-cyanoethyl protecting groups from phosphate groups by treatment with morpholine increases the hydrophilicity of the protected oligonucleotide and favours its conjugation in aqueous – organic media. The fact that protection of heterocyclic bases increases the lability of the *N*-glycosidic bond should also be taken into consideration.

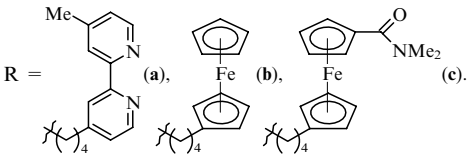
The third approach entails the synthesis of oligonucleotide conjugates in solution. In this case, the protection of the reactive group in the 2′-position should be stable under conditions of oligonucleotide synthesis and be easily removed in the course of standard post-synthetic treatments. Side reactions with the imino and amino groups of heterocyclic bases, *e.g*., during the amide bond formation in compounds containing carboxy groups, can occur, which is a limitation of this method.

1. Synthesis of nucleoside 2′-conjugates

Three different approaches to the synthesis of nucleoside 2′-conjugates with various compounds are possible. The first of them entails direct attachment of various molecules to the 2′-hydroxy groups of nucleosides with formation of ether,[56] carbamate [76] or phosphotriester [157] bonds. The second approach consists of preliminary attachment, to the C(2′)-atom, of a linker containing an amino [57] or a carboxy group,[79] which is then made to react with another compound to form an amide bond. Acylation of 2′-amino-2′-deoxynucleosides is yet another route.

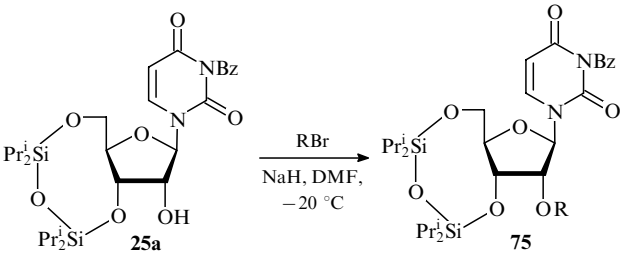


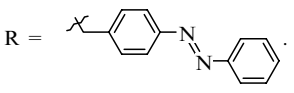
74a – c



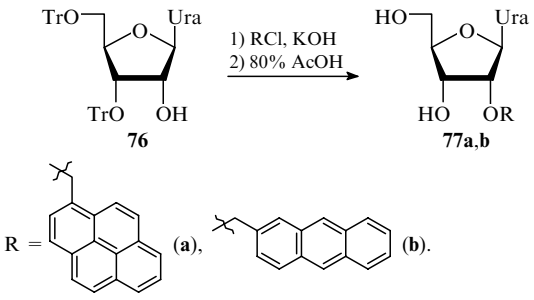
The preparation of the adenosine derivatives **74a – c** containing 2,2′-bipyridine and ferrocene residues linked to the O(2′) atom through a butylene bridge has been described.[158 – 160] The alkylation of adenosine occurs regiospecifically, the yields of 3′-derivatives are insignificant.

A similar alkylation procedure was used [161] for the introduction of an azobenzene fragment at the O(2′)-atom of protected uridine **25a**. The resulting derivative **75** was deprotected and incorporated into an oligonucleotide.

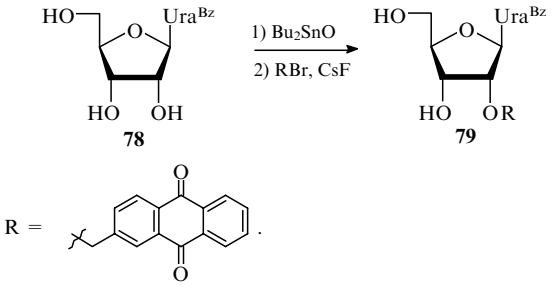




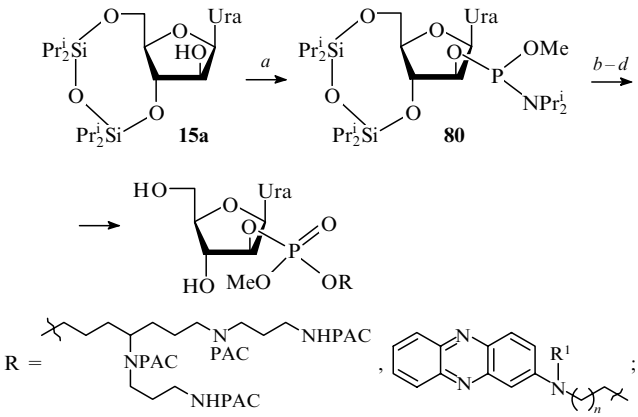
The alkylation of 3′,5′-protected uridine **76** by substituted methyl chlorides in the presence of potassium hydroxide was used for the introduction of polyaromatic molecules into the carbohydrate fragment of the nucleoside.[162, 163] It is of note that the heterocyclic base was not affected, compounds **77a**,**b** being the only reaction products.



The metal-directed alkylation of uridine has been described.[164, 165] Prior to the reaction, the *vic*-diol system of N^3-benzoyluridine (**78**) was activated by dibutyltin oxide and the intermediate formed was introduced into the reaction with 2-bromomethylanthraquinone. The addition of caesium fluoride to the reaction mixture increases the proportion of the 2′-isomer **79**.

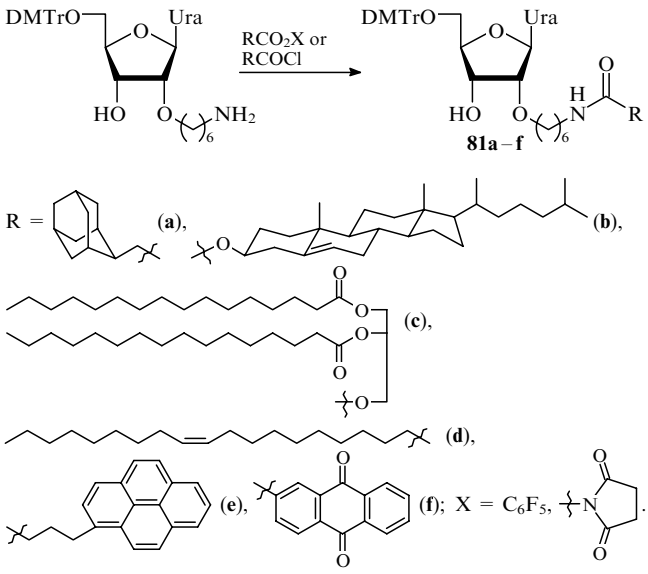


Chattopadhyaya and co-workers[166, 167] have developed a simple and convenient scheme for the attachment of a spermine C-homologue to a nucleoside through a 2′-phosphate group. The 2′-phosphoramidite **80** formed from the protected arabinouridine **15a** was made to react with the hydroxy derivative of the spermine analogue with subsequent oxidation of the phosphorus-containing fragment and deprotection of the hydroxy groups. In these studies, spermine was considered as a cationic constituent able to increase the stability of the NA duplex due to interaction with the phosphate groups of the opposite chain. Similarly, phenazine derivatives were attached to the O(2′)-atom of arabinouridine through a phosphate group.[157]

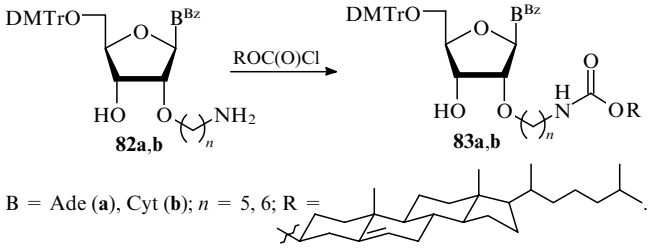


PAC = $PhOCH_2C(O)$; R^1 = PAC, Me; n = 2, 4, 6.
(*a*) $Pr^i_2NP(Cl)OMe$, Pr^i_2NEt; (*b*) ROH, TetrH;
(*c*) I_2, THF, Py, H_2O; (*d*) TBAF.

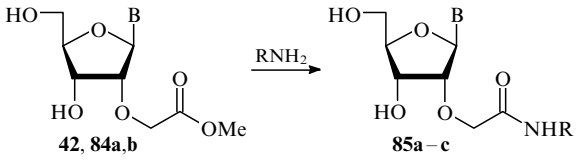
Yet another approach to the synthesis of nucleoside 2′-conjugates has been developed by Cook and co-workers.[168, 169] This included the introduction of fragments of various compounds into the 2′-position of uridine through an aminohexyl linker. This method was used in the synthesis, from one modified nucleoside, of hydrophobic derivatives **81a**–**d**[168, 169] as well as compounds with fluorescent (**81e**[170]) and electrochemical (**81f**[171]) labels suitable for incorporation into the oligonucleotide chain.



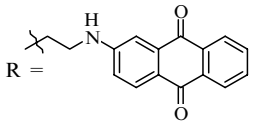
Cholesterol was attached to the modified nucleosides **82a**,**b**.[172] The resulting derivatives **83a**,**b** were introduced into a standard automated oligonucleotide synthesis. The presence of a cholesterol residue in the modified oligonucleotides strongly affects their pharmacodynamic properties.



Keller and Haner[79, 173] have carried out reactions of 2′-*O*-(methoxycarbonylmethyl)nucleosides **42** and **84a**,**b** with 2-[(2-aminoethyl)amino]anthraquinone, octylamine and 6-(*N*,*N*-dimethylamino)hexylamine. The resulting nucleoside conjugates **85a**–**c** were first converted into phosphoramidite derivatives and then incorporated into the oligonucleotide chain. The presence of such modifications in oligonucleotide molecules increases the thermal stabilities of the respective NA duplexes in comparison with native analogues.



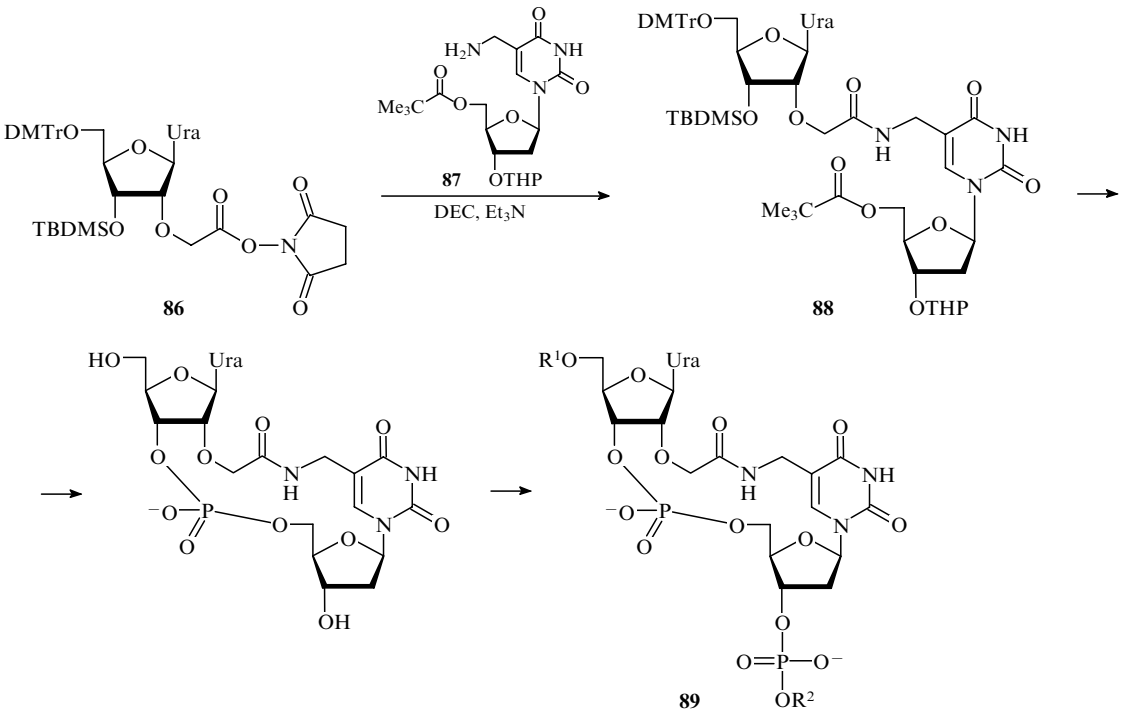
B = Cyt^{Bz} (**84a**, **85a**), Ade^{Bz} (**84b**, **85b**), Thy (**42**, **85c**);



Starting from protected uridine **86** containing an activated 2′-carboxy group and protected 5-aminomethyl-2′-deoxyuridine **87**, Sekine and co-workers[174, 175] have synthesised the dinucleoside **88;** this was converted into a dinucleoside phosphate having a fixed conformation[174] and incorporated into the oligonucleotide **89** (Scheme 4).[175]

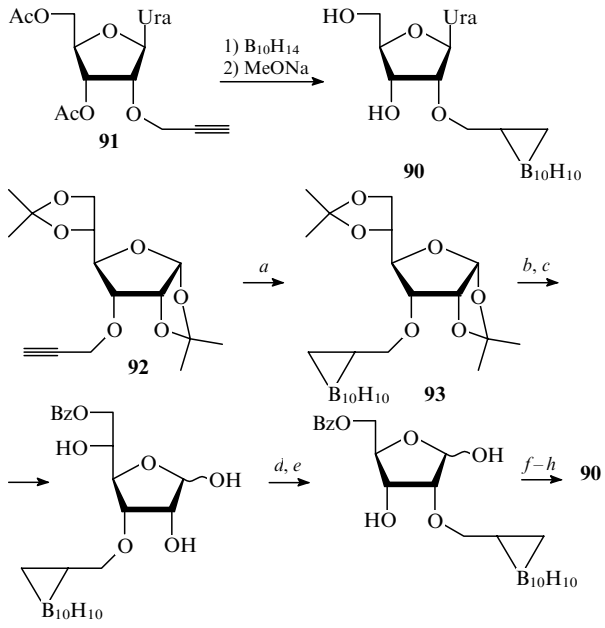
The synthesis of 2′-*O*-carboranylmethyluridine **90** starting from the propargyluridine derivative **91**[176, 177] or protected allofuranose **92** has been carried out.[178] In the latter case, the attach-

Scheme 4



TBDMS = Bu^{t}Me$_2$Si; DEC = Me$_2$N(CH$_2$)$_3$N=C=NEt; R^1 and R^2 are fragments of an oligonucleotide chain.

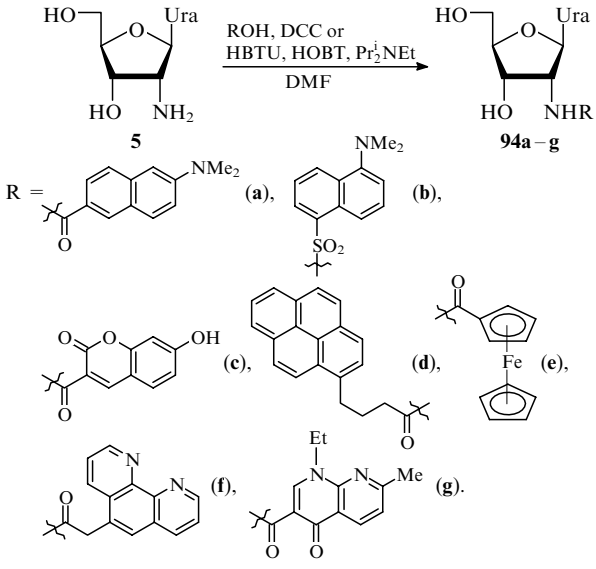
ment of decaborane to the carbohydrate **92** gave first the 3′-isomer **93**; after removal of isopropylidene protecting groups and cleavage of the *cis*-diol system, this was transformed into a ribofuranose derivative and used for glycosylation.



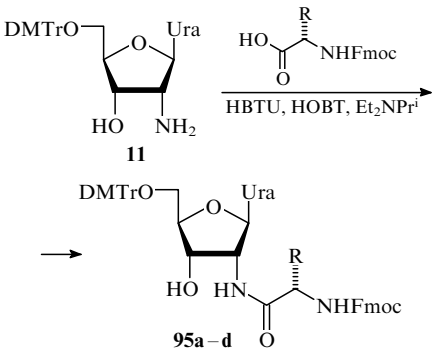
(*a*) $B_{10}H_{14}$; (*b*) H^+; (*c*) BzCl; (*d*) $NaIO_4$; (*e*) Py, H_2O, Δ; (*f*) Ac_2O, Py; (*g*) Ura^{TMS}, TMSOTf; (*h*) MeONa.

Carboranyl nucleosides are used in boron neutron-capture therapy of malignant tumours.[179,180] *In vivo* studies have shown[181] that the nucleoside **90** effectively penetrates into cells, but is not phosphorylated. The intracellular boron concentration varies from 5 to 35 μg g^{-1}, *i.e.*, is sufficient for the implementation of efficient boron neutron-capture therapy. Further studies have shown[182] that the incorporation of the nucleoside **90** into the oligonucleotide chain significantly decreases the stability of the DNA duplex, most probably due to the formation of a negatively charged *nido*-form of carborane under the action of ammonia upon standard post-synthetic treatments.

Synthesis of conjugates based on 2′-amino-2′-deoxyuridine **5** included the acylation of the amino group with acids activated by dicyclohexylcarbodiimide (DCC) or a mixture of 1-hydroxybenzotriazole (HOBT) with *O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium (HBTU) hexafluorophosphate. This approach was used for the introduction, into the 2′-position of the nucleoside, of various fluorescent labels, such as 6-dimethylamino-2-naphthalene (**94a**),[183,184] the dansyl group (**94b**),[185] coumarin (**94c**)[186] and pyrene (**94d**),[187] of the electrochemical label ferrocene (**94e**),[188–190] of phenanthroline (**94f**)[191] (chemical nuclease in the presence of multicharged metal ions) and of nalidixic acid **94g**;[192] the attachment of the latter to the 3′-end of an oligonucleotide significantly increases the thermal stability of the duplex formed.

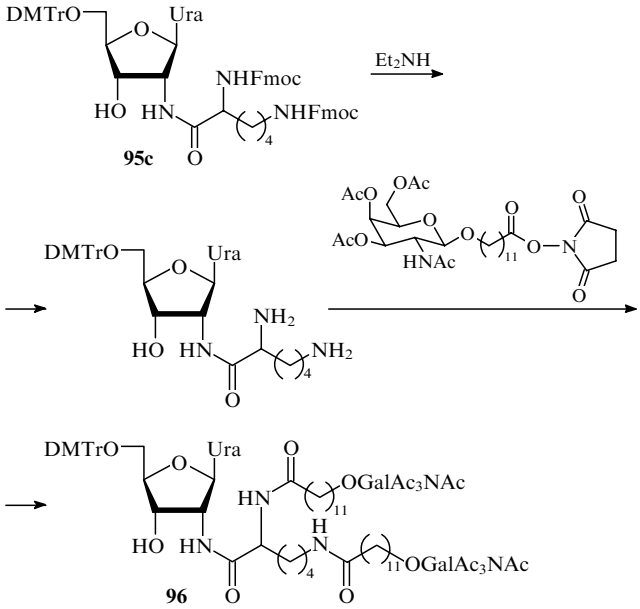


Protected 2′-amino-2′-deoxyuridine **11** was acylated with amino acids.[193] The derivatives **95a–d** obtained were converted into phosphoramidites and incorporated into ribozymes to increase catalytic activity and stability against nucleases.



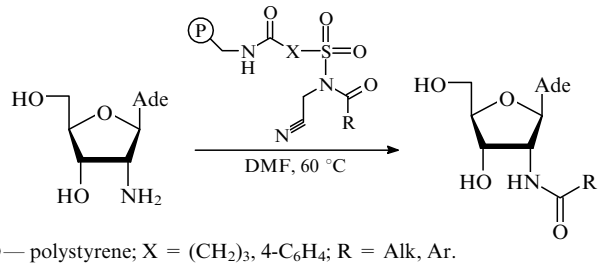
R = Me (**a**), Bn (**b**), $(CH_2)_4NHFmoc$ (**c**), CH_2CO_2Bn (**d**);

Fmoc = 
The protected 2′-amino-2′-deoxyuridine **95c** acylated with *N*-protected lysine served as a basis for the preparation of the bisconjugate **96** containing peracetylgalactosamine residues.[194] Unfortunately, subsequent reactions of the nucleoside phosphoramidite derivative **96** were strongly hampered due to steric hindrances.



Acylation of free and protected 2′-amino-2′-deoxyadenosine with various aromatic acids in the presence of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide has been described.[34, 195]

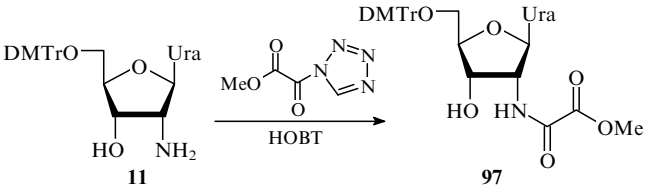
An unusual version of the acylation of 2′-amino-2′-deoxyadenosine has been proposed.[196] Here, the role of acylating agents is played by activated *N*-sulfo-*N*-cyanomethylamides of carboxylic acids immobilised on a solid phase (safety catch linker).[197] Aminomethylated polystyrene containing 4-substituted benzoic or butyric acid residues were used as polymeric supports. The yields in this reaction are more than 95%.



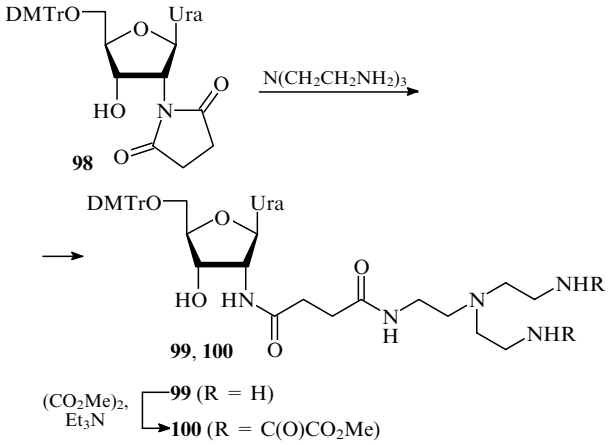
Ⓟ — polystyrene; X = $(CH_2)_3$, 4-C_6H_4; R = Alk, Ar.

This approach was used for the preparation of various 2′-aroyl derivatives of N^6-substituted 2′-amino-2′-deoxyadenosine and 2′,5′-diamino-2′,5′-dideoxyadenosine.[198–201]

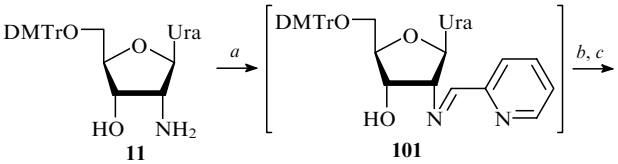
An original procedure for the synthesis of the nucleoside **97** having a methoxalylamido fragment in the 2′-position by the reaction of protected 2′-amino-2′-deoxyuridine **11** with methoxalyltetrazole has been developed by Polushin.[202]

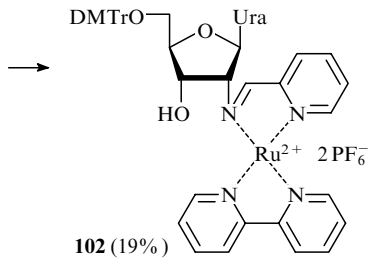


Later[203] 2′-succinimido-2′-deoxyuridine **98** and the dendrimers **99**, **100**[204] based on it were synthesised.



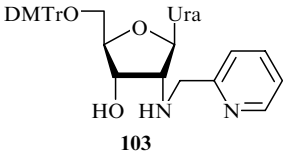
The imino derivative **101** synthesised starting from 2′-amino-2′-deoxyuridine **11** reacted *in situ* with bis(bipyridine)ruthenium(II) chloride.[205, 206] The resulting nucleoside **102** was converted into a phosphoramidite derivative and incorporated into the oligonucleotide chain; however, the yield in the condensation step was extremely low.[27] The yield in the immobilisation of the nucleoside **102** on a polymeric support using a succinate linker was comparable to those for non-modified nucleosides.[206] The complex **102** within the oligonucleotide is stable under the conditions of the post-synthetic treatments with saturated ammonia. Derivatives of the type **102** are the optimum reagents for modification of 3′- (see Ref. 206) and 5′-ends[207] of oligonucleotides, since they cause minimum changes in the structure of the DNA duplex.





(*a*)  ; (*b*) $Ru(bpy)_2Cl_2$; (*c*) KPF_6; bpy is 2,2′-bipyridine.

The nucleoside **103** containing a picolylamino group in the 2′-position has recently been synthesised.[27] The introduction of such a modified fragment into the oligonucleotide chain decreases the thermal stability of the DNA duplex by 2–4 °C. These oligonucleotides can also be used for ruthenium chelation.



103

2. Solid-phase synthesis of oligonucleotide conjugates

The publications on this subject are few in number, although in some cases, *e.g.*, for incorporation of hydrophobic molecules, this method is the optimum and is the only possible solution for the construction of combinatorial libraries. The term 'combinatorial libraries' is used to encompass a set of conjugates containing identical cores (*e.g.*, oligonucleotides), but differing in the fragments of molecules attached to them. It is of note that such sets of conjugates are prepared simultaneously, *e.g.*, by treatment of an oligonucleotide containing the amino group with a mixture of activated carboxylic acids with subsequent separation of the reaction products. Combinatorial oligonucleotide libraries are extensively used in bioorganic chemistry and molecular biology, particularly, in the search for compounds that are highly resistant to nucleases.[208]

An alternative approach to the synthesis of conjugates based on immobilised oligonucleotides **104** containing a protected 2′-*O*-(6-aminohexyl)nucleoside has been described by Manoharan and co-workers [209] Selective removal of the allyloxycarbonyl protecting group by a palladium(0) complex and subsequent reaction of pyrenylbutyric acid ester with *N*-hydroxysuccinimide give compound **105a.** The internucleotide bonds and protecting groups of heterocyclic bases and internucleotide phosphates remained intact. Later, the same authors [210] carried out the synthesis of oligonucleotides **105b** containing a guanidine group attached to a 2′-*O*-aminohexyl linker (Scheme 5).

A recently published paper [211] describes the synthesis of the oligonucleotide conjugates **106a**,**b** with 3′-terminal 2′-acylamido groups. A nucleoside with an *N*-protected phenylalanylamide residue in the 2′-position was immobilised on a polymeric support through a standard succinate linker. The allyloxycarbonyl protecting group in compound **107** was selectively removed and the immobilised nucleoside was acylated and introduced into the standard oligonucleotide synthesis (Scheme 6).

Yet another approach to the attachment of an amino group to the 3′-end of an oligonucleotide entails the use of a 5′-phosphor-

Scheme 5

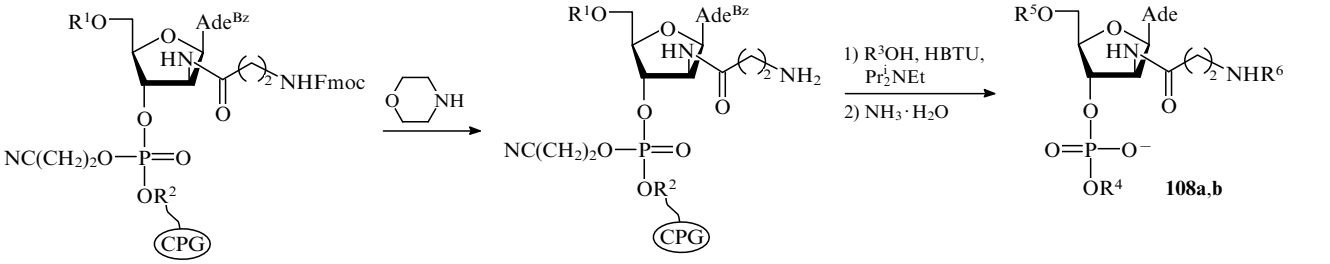
R^1 =  (**a**),  (**b**); R^2 is a fragment of an oligonucleotide chain.

Scheme 7



R^1 and R^2 are fragments of a protected oligonucleotide chain; R^3 = –Gly-LeuNHFmoc, –Gly-Phe-D-Ala-TyrNHFmoc; R^4 and R^5 are fragments of a deprotected oligonucleotide chain; R^6 = –Gly-LeuNH$_2$ (**a**), –Gly-Phe-D-Ala-TyrNH$_2$ (**b**).

amidite derivative of a modified nucleoside that is incorporated into the oligonucleotide chain by reversed (5′→ 3′) automated oligonucleotide synthesis.[211] High yields in the *N*-acylation step enable the construction of a combinatorial library and investigation of the resistance of 3′-oligonucleotide conjugates against nucleases.[208]

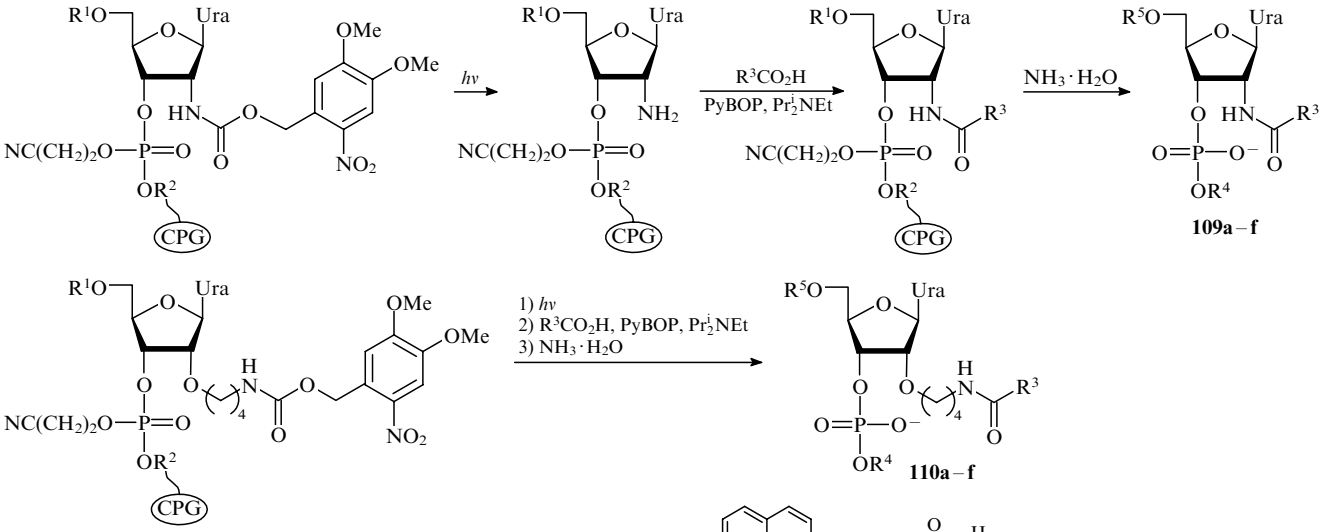
Synthesis of peptide–oligonucleotide conjugates has been described by Oretskaya and co-workers[212] The protected amino group of 2′-(β-alanyl)amido-2′-deoxyarabinoadenosine incorporated into oligonucleotides was selectively deprotected by morpholine or piperidine. Subsequent acylation with *N*-protected peptides and removal of protecting groups afforded the target conjugates **108a**,**b** with a degree of conversion of 80%–90% (Scheme 7).

Hwang and Greenberg[213, 214] have recommended the use of photo-removable 4,5-dimethoxy-2-nitrobenzyloxycarbonyl protection for the 2′-amino group of modified nucleosides. The reactivities of 2′-amino-2′-deoxy- and 2′-*O*-(4-aminobutyl)uridine groups of oligonucleotides in acylation reactions have been studied. In some cases, the yields of the products **109** and **110** were rather low (*e.g.*, the yield of the oligonucleotide–peptide conjugate **110b** was 30%) (Scheme 8).

Manoharan and co-workers[215] used phthaloyl protection (which is selectively removable by hydrazinolysis) of aminooxy groups of modified nucleosides. The aminooxy group is extremely reactive with respect to carbonyl compounds. This type of conjugation is extensively used in peptide chemistry.[216] The oximes thus prepared are stable over a broad pH range and can be reduced to *N*,*O*-disubstituted hydroxylamines which are even more stable under drastic conditions (Scheme 9).

Sawai and co-workers[94, 95] have proposed to simultaneously remove protecting groups and convert the ester group in a modified fragment into an amide group. In this way, dinucleoside monophosphates were prepared containing non-substituted (**111a**), *N*-alkyl (**111b**), *N*-aminoalkyl (**111c**) carbamoyl groups and a dendrimer (**111d**) in the 2′-position. It is of note that the yields of the target products were smaller in the case of more complex amines. When *N*-protected adenosine, cytidine and guanosine were used instead of thymidine and uridine, side transamination occurred.

Scheme 8



R^1 and R^2 are fragments of a protected oligonucleotide chain; R^3 =  (**a**),  (**b**),  (**c**),  (**d**),  (**e**),  (**f**); R^4 and R^5 are fragments of a deprotected oligonucleotide chain;

PyBOP is benzotriazol-1-yloxytris(pyrollidino)phosphonium hexafluorophosphate.

Scheme 9

R^1 and R^2 are fragments of a protected oligonucleotide chain; R^3 = R^4 and R^5 are fragments of a deprotected oligonucleotide chain.

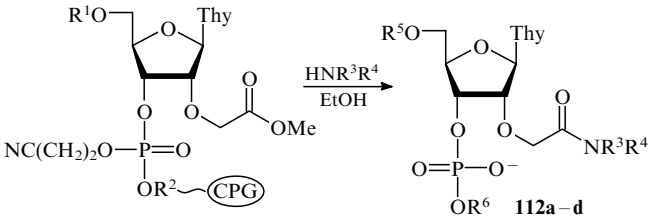
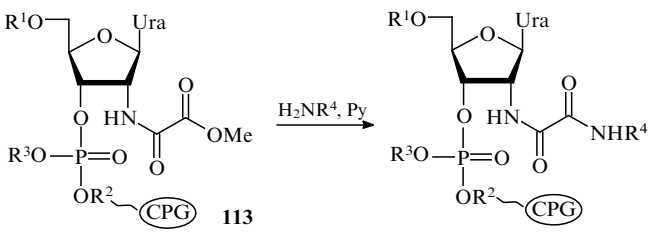
R = H (**a**), $(CH_2)_6Me$ (**b**), $(CH_2)_2NH_2$ (**c**), $(CH_2)_2N(CH_2CH_2NH_2)_2$ (**d**); Alk = Me, Et.

This methodology was further developed by Manoharan and co-workers [145] If primary amines were used, high yields of compounds **112a**–**c** were achieved within 24 h at room temperature, but the yield of compound **112d** in the reaction with dimethylamine was as low as 50%; at higher temperature, side products were formed.



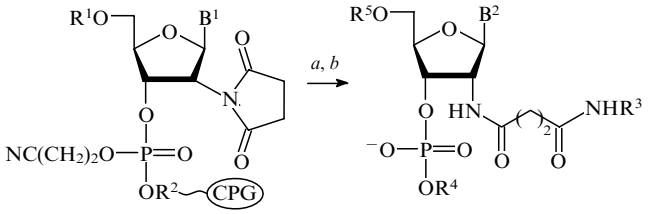
R^1 and R^2 are fragments of a protected oligonucleotide chain;
R^3 = H: R^4 = H (**a**), Me (**b**), $(CH_2)_2NMe_2$ (**c**); R^3 = R^4 = Me (**d**);
R^5 and R^6 are fragments of a deprotected oligonucleotide chain.

Polushin [202] has prepared a series of oligonucleotides **113** containing a methoxalylamido group in the 2′-position. This group is more electrophilic in comparison with ordinary ester group, which permits one to carry out reactions with amines under milder conditions without simultaneous splitting of the oligonucleotide from the polymer.



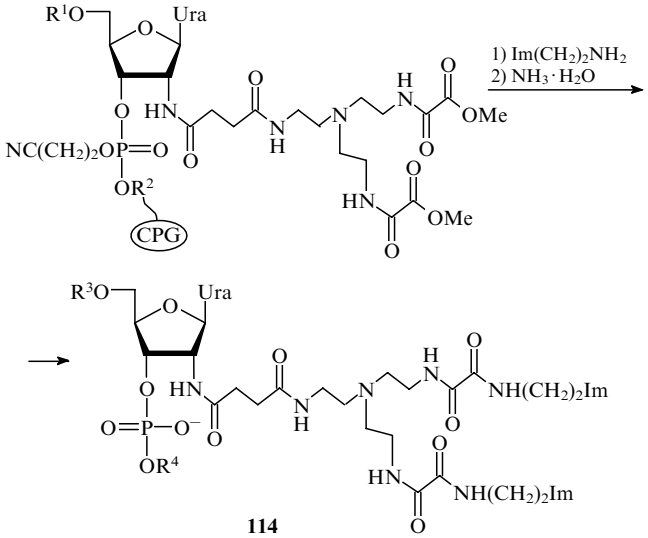
R^1 and R^2 are fragments of a protected oligonucleotide chain;
$R^3 = (CH_2)_2CN$; $R^4 = (CH_2)_{12}NH_2$.

In 2′-succinimido derivatives of 2′-deoxyuridine and -cytidine, the five-membered imide ring is opened upon reactions with various amines. [203, 204, 217]



B^1 = Ura, Cyt^{Bz}; B^2 = Ura, Cyt; R^1 and R^2 are fragments of a protected oligonucleotide chain; R^3 = Me, $(CH_2)_2OH$, $(CH_2)_6OH$, $(CH_2)_3NMe_2$, $(CH_2)_n$Im; n = 2, 3; R^4 and R^5 are fragments of a deprotected oligonucleotide chain; (*a*) R^3NH_2; (*b*) $NH_3 \cdot H_2O$.

The same authors [204, 217] have described the synthesis of dendrimeric derivatives based on 2′-succinimido-2′-deoxyuridine incorporated into the oligonucleotide chain. The attachment of branched polyamines to a modified nucleoside fragment was followed by acylation of free amino groups with methoxalyltetrazole. Treatment of the dendrimer formed with histamine affords the conjugate **114** which is a potential chemical nuclease.

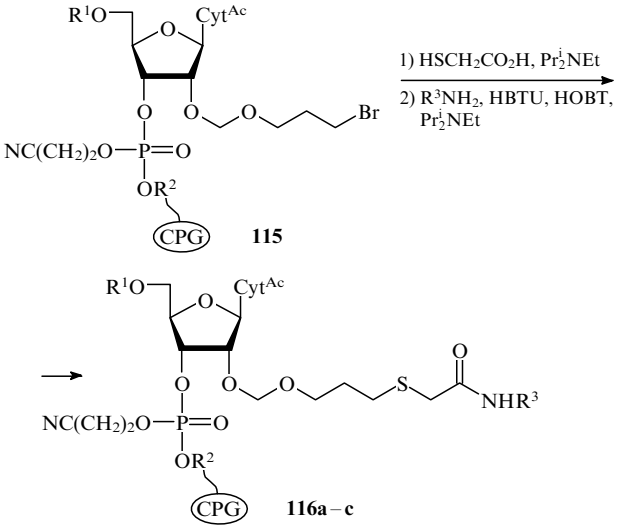


114

R^1 and R^2 are fragments of a protected oligonucleotide chain;
R^3 and R^4 are fragments of a deprotected oligonucleotide chain.

The incorporation of a bromoalkyl group into an oligonucleotide enables conjugation with nucleophiles, such as thiols and sodium azide. [108, 218] Thus the preparation of oligonucleotide conjugates with amines included initial synthesis of modified

oligonucleotides **115** immobilised on a polymeric support containing a ω-bromoalkyl group at the O(2′) atom.[219] These were treated with thioglycolic acid in the presence of a base. After the activation of the carboxy group in the acids formed, the latter reacted with various amines to yield compounds **116a–c**.



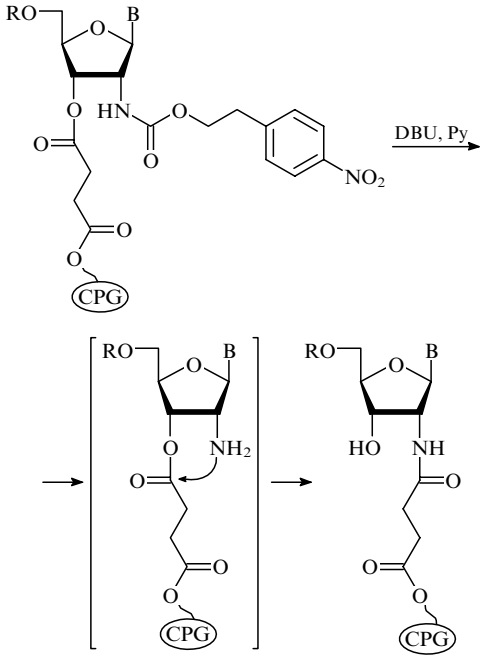
R[1] and R[2] are fragments of a protected oligonucleotide chain;

R[3] =  (**a**), Me (**b**),  (**c**).

3. Solution synthesis of oligonucleotide conjugates

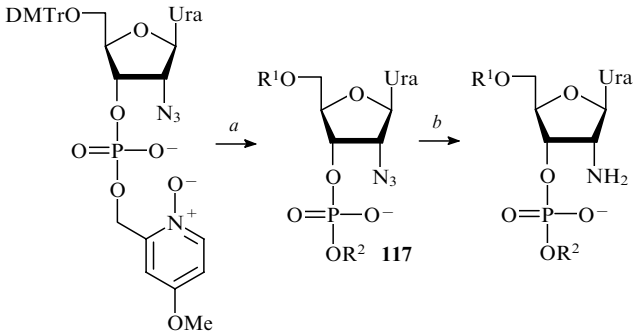
Oligonucleotides containing pyrimidine 2′-amino-2′-deoxyribonucleoside fragments have been especially extensively used for conjugation in solution. The amino group in the 2′-position has pK_a = 6.2,[220] which was confirmed by ^{1}H NMR (see Ref. 221) and ^{13}C NMR (see Ref. 222) spectroscopic data. This enables its selective acylation at appropriate pH precluding the involvement of amino groups of heterocyclic bases with pK_a from 3 to 5. The significant decrease in the melting temperature of the duplexes formed by 2′-amino-2′-deoxyribooligonucleotides with non-modified NA is the main disadvantage of this modification. Thus the melting temperature of a 15-membered duplex decreases by 2.7–13.8 °C depending on the structure of the duplex and the position of the modified fragment in the chain.[223]

The choice of a protecting group for the amino group of a modified fragment for the incorporation of 2′-amino-2′-deoxyribonucleosides into the oligonucleotide chain presents a problem. The use of trifluoroacetyl protection for this purpose was suggested, but the condensation of a commercially available 2′-trifluoroacetamido-2′-deoxyuridine phosphoramidite with a growing oligonucleotide chain occurs in a relatively low yield (~ 90% in 10 min),[224] which can be attributed to the high electronegativity of the trifluoroacetyl protecting group. This problem can be overcome by increasing the condensation time;[225] however, side reactions thus occur, which diminish the total yield of the oligonucleotide.[226] The trifluoroacetyl protecting group was also used for the protection of the amino group of 2′-amino-2′-deoxyguanosine.[227] The fluorenylmethoxycarbonyl protecting group meets all the requirements of oligonucleotide synthesis, but the thus protected 2′-amino-2′-deoxyuridine phosphoramidite derivative was unstable in an acetonitrile solution and was destroyed even in a solid state at −20 °C.[224, 228] Nevertheless, this group was used for protection.[229] The use of the phthalimide group was also proposed;[224] the latter was introduced with high yields and could be completely removed with standard post-synthetic treatments, but in this case the condensation efficiency could be increased by only 3%–5%. The use of the 2-(4-nitrophenyl)ethoxycarbonyl protecting group[230, 231] can hardly be called successful, since its removal demands preliminary 12-h treatment of the protected oligonucleotide with a 1 M solution of DBU in pyridine. The thus protected 2′-amino-2′-deoxynucleoside cannot be immobilised on a polymeric support using a succinate linker due to intramolecular $O \rightarrow N$ migration of the acyl group upon deprotection. The stability of the amide bond in the 2′-succinamide formed prevents the removal of the modified oligonucleotide from the polymeric support.



R is a fragment of a protected oligonucleotide chain;
B is a protected heterocyclic base.

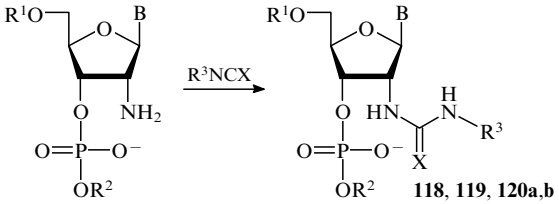
A new approach, in principle, to the synthesis of oligonucleotides with 2′-amino-2′-deoxyribonucleoside fragments has been developed by Polushin *et al.*[232] The oligonucleotides **117** containing a 2′-azido-2′-deoxyuridine fragment were prepared using the phosphotriester method. The azido group was further reduced to the amino group by treatment with triphenylphosphine or tris(2-carboxyethyl)phosphine (TCEP) in the presence of water. However, this approach has not received wide application, since the solid-phase phosphotriester method is no longer used in oligonucleotide synthesis due to the lengthy reaction cycle and lower yields in the condensation step in comparison with the phosphoramidite method. Nevertheless, today it is the only approach which enables the synthesis of oligonucleotides containing 2′-amino-2′-deoxyribonucleoside fragments in the middle of the chain.



(*a*) is oligonucleotide synthesis; (*b*) Ph_3P or TCEP, H_2O, MeCN;
R[1] and R[2] are fragments of an oligonucleotide chain.

Synthesis of conjugates based on oligonucleotides containing 2′-amino groups is carried out using *N*-acylation in a borate, phosphate or carbonate buffer at pH 8–8.5. Under these con-

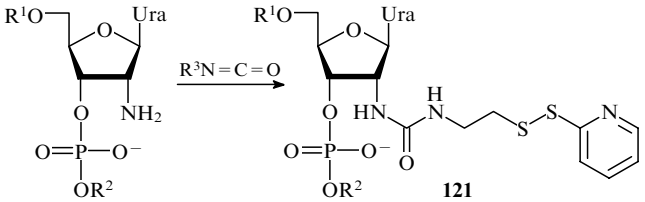
ditions, the amino groups of heterocyclic bases are protonated, which allows selective involvement of the 2′-amino group of the modified fragment. Activated carboxylic acids, isocyanates or isothiocyanates are used as acylating reagents. This approach was used for the preparation of conjugates (**118**–**120a**,**b**) with fluorescein isothiocyanate,[233–235] rhodamine 5-isocyanate,[222] a photochemically active diazirine derivative **120a**[236] and a spin label **120b**.[237]



R^1 and R^2 are fragments of an oligonucleotide chain;
118: R^3 is fluorescein, X = S, B = Ura;
119: R^3 is rhodamine, X = O, B = Cyt.

120: R^3 =  (**a**), (**b**); X = O, S; B = Ura.

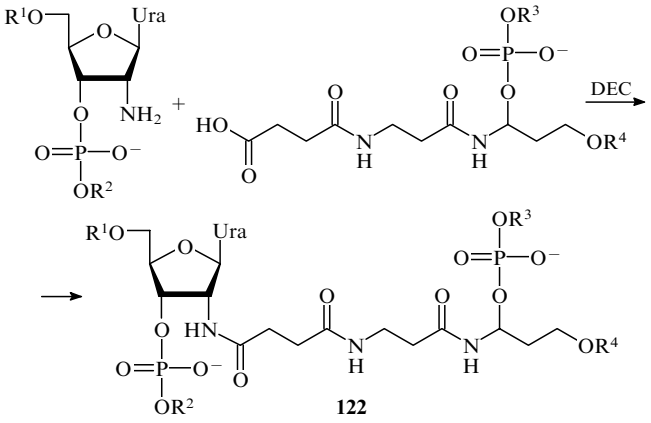
Sigurdsson *et al.*[238–240] have prepared the conjugates **121** by the reaction of a 2′-amino-2′-deoxyuridine fragment of an oligonucleotide with 2-isothiocyanatoethyl 2-pyridyl disulfide.

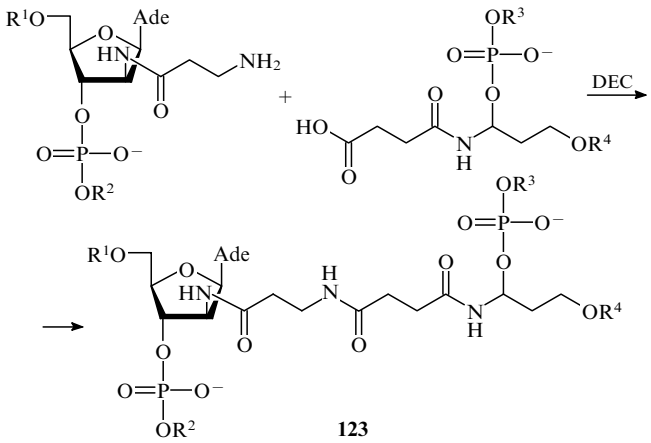


R^1 and R^2 are fragments of an oligonucleotide chain;

$R^3N{=}C{=}O$ =  .

The oligonucleotides containing 2′-amino-2′-deoxyuridine[241–244] or 2′-(β-alanylamido-2′-deoxyarabinoadenosine[245,246] were used by Shabarova *et al.* in the synthesis of covalently bound duplexes **122** and **123**. In this case, a nonnucleoside fragment containing a carboxy group at the end of an extended linker was introduced into the complementary chain.



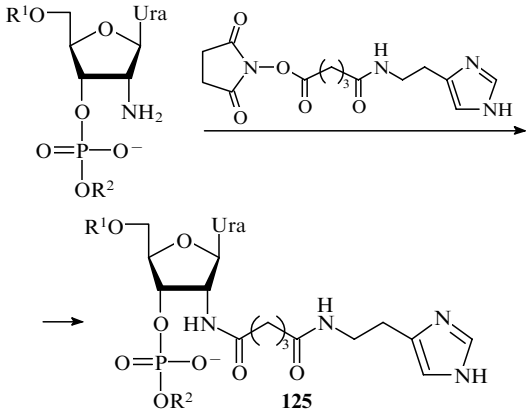


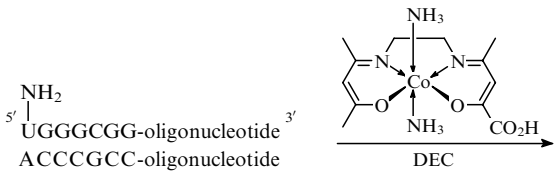
R^1, R^2, R^3 and R^4 are fragments of oligonucleotide chains.

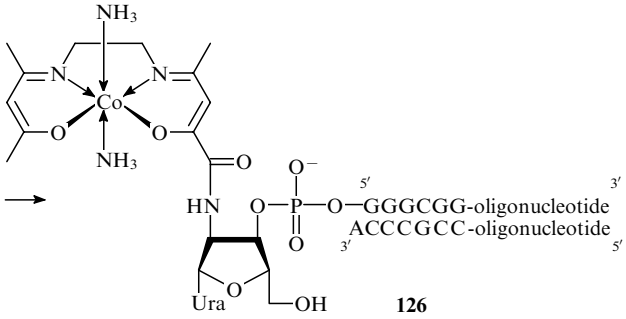
Oligonucleotides **124**, where the chain units are linked by amide bonds in addition to phosphodiester bonds through linkers attached to the C(2′) atoms, have been synthesised.[247] The spatial proximity of carboxy and amino groups determined the high regioselectivity of this reaction, the yield of the target product **124** being 78%; the formation of side products was not observed (Scheme 10).

Substituted carboxylic acid esters of *N*-hydroxysuccinimide are often used as activated acylating agents. Silverman and Cech[248] have performed the acylation of oligonucleotides containing 2′-amino-2′-deoxyuridine using pyrenylacetic and pyrenylbutyric acid esters of *N*-hydroxysuccinimide; Weeks and coworkers[249–251] used biotinylbutyric ester for this purpose.

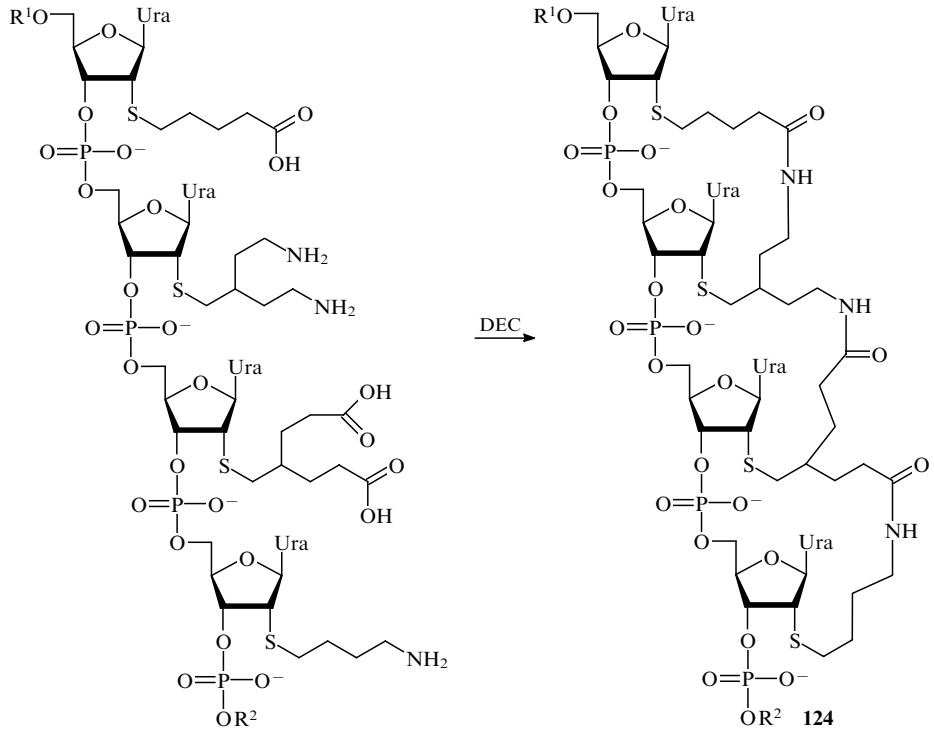
Conjugates of modified oligonucleotides containing 2′-amino-2′-deoxyuridine with histamine **125**[252] and the cobalt complex **126** have been synthesised.[253] In the latter case, the acylation was







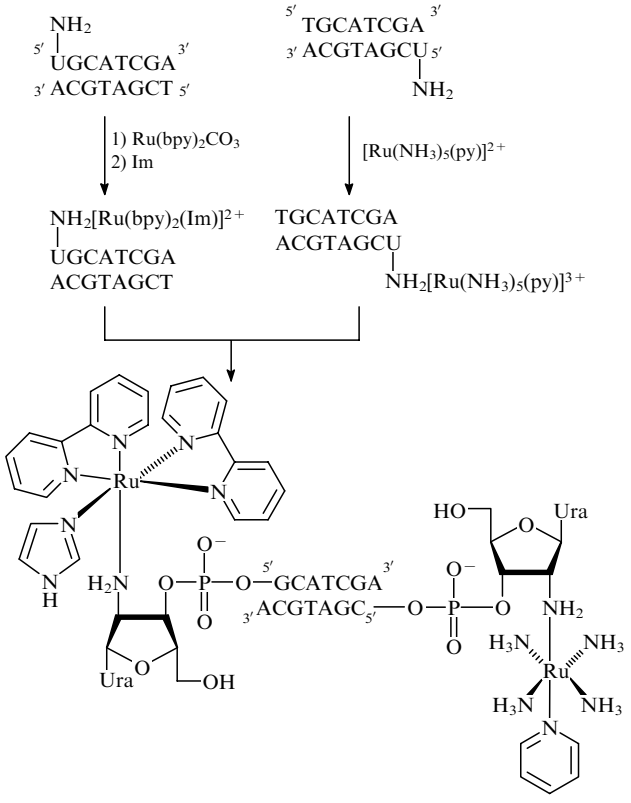
Scheme 10



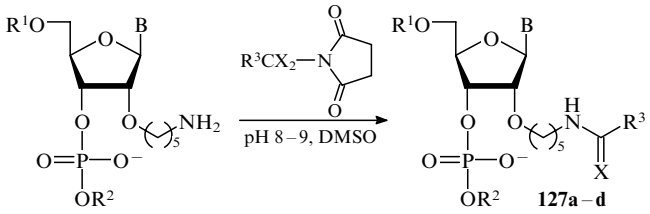
R^1 and R^2 are fragments of an oligonucleotide chain.

performed in the duplex in order to prevent the interaction of the carboxy group of the ligand with the amino groups of the heterocyclic bases.

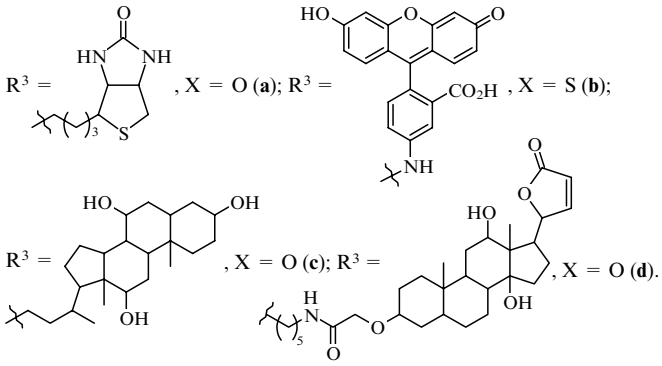
Studies by Meade *et al.*[254, 255] are devoted to the synthesis of ruthenium complexes of 2′-amino-2′-deoxyribooligonucleotides. Complementary oligonucleotides containing 2′-amino-2′-deoxyuridine at the 5′-ends were modified by two ruthenium complexes differing in degree of oxidation. The complex formation was carried out within the DNA duplexes to prevent interaction of the ruthenium complexes with exocyclic amino groups of the heterocyclic bases. The modified DNA duplex was used for the study of photoinduced electron transfer along the DNA chain which plays an essential role in the damage and repair of DNA.[256, 257]



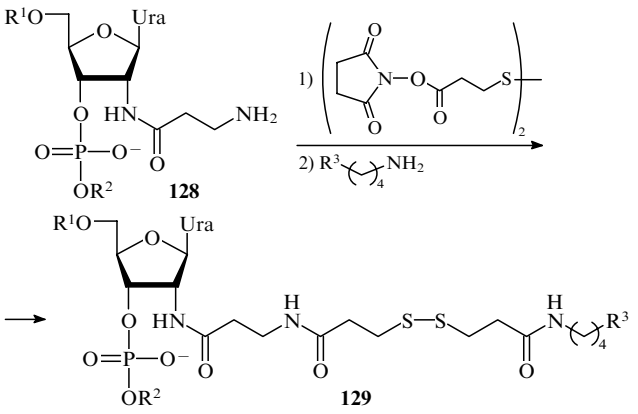
A series of conjugates **127a**–**d** were prepared by reactions of modified oligonucleotides containing 2′-*O*-(5-aminopentyl)uridine[65] and -adenosine[57] with various *N*-hydroxysuccinimide esters.



R^1 and R^2 are fragments of an oligonucleotide chain; B = Ade, Ura;

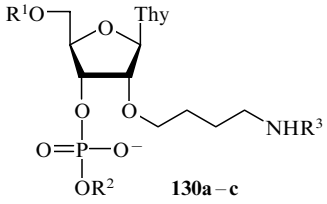


Acylation of the oligoribonucleotide **128** containing 2′-(β-alanylamido)-2′-deoxyuridine with a bifunctional reagent [3,3′-dithiobis(propionic) acid ester of *N*-hydroxysuccinimide] eventually allowed preparation of conjugate **129** containing a peptide linked to the C(2′) atom through a disulfide linker.[258] The disulfide bond can be cleaved by thiols, which simplifies the mass-spectrometric analysis of the conjugates with peptides.

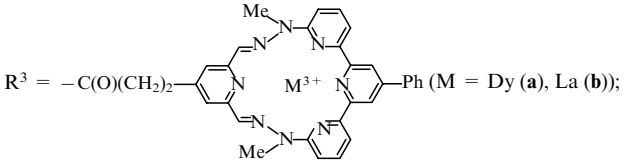


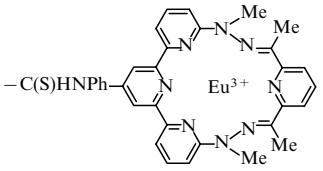
R^1 and R^2 are fragments of an oligonucleotide chain; R^3 is a fragment of the Tat-protein.

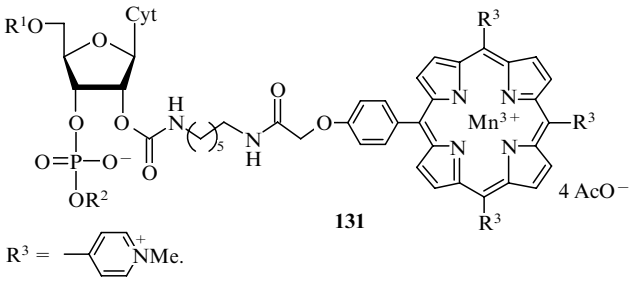
Conjugates of oligonucleotides containing 2′-*O*-(4-aminobutyl)ribothymidine with lanthanide complexes **130a**–**c**,[259] and conjugates of oligonucleotides containing 2′-*O*-(6-aminohexylcarbamoyl)cytidine linked with a porphyrin manganese complex (**131**) were synthesised in a similar way.[75]



R^1 and R^2 are fragments of an oligonucleotide chain;

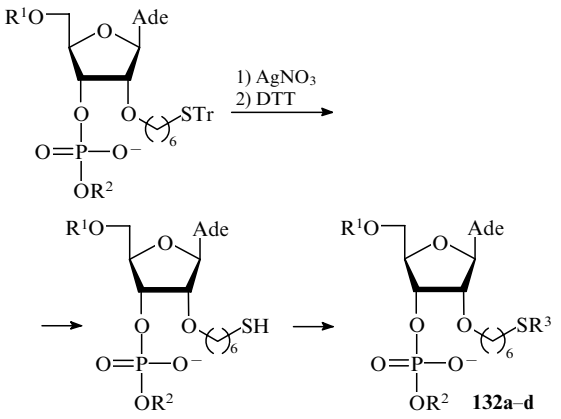




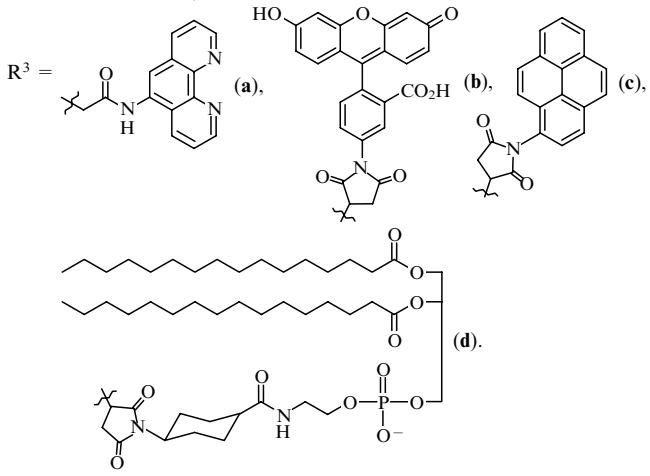


The presence, in modified oligonucleotides, of a thiol group, which can be involved in the formation of disulfide bonds, thioethers and thioesters offers broad opportunities for conjugation.[260]

2′-*O*-(6-Mercaptohexyl)adenosine incorporated into the oligomeric chain was converted into the conjugates **132a**–**d** using *S*-alkylation by iodoacetamidophenanthroline or addition of maleimide derivatives of fluorescein, pyrene and a phospholipid.

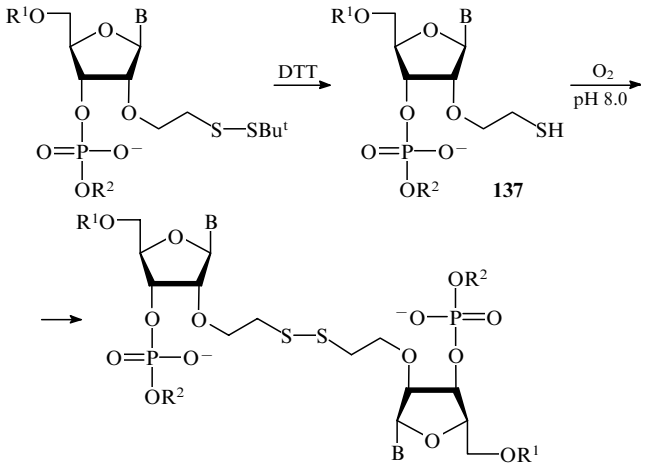


R^1 and R^2 are fragments of an oligonucleotide chain; DTT is dithiothreitol;



Sigurdsson *et al.*[238,240] have succeeded in synthesising cross-linked duplexes **133** and conjugates with the fluorescent label bimane **134**[239] starting from oligonucleotides **135** containing a thiol group as well as conjugates with glutathione **136** based on oligomers **121** containing an activated thiol group (Scheme 11).[239]

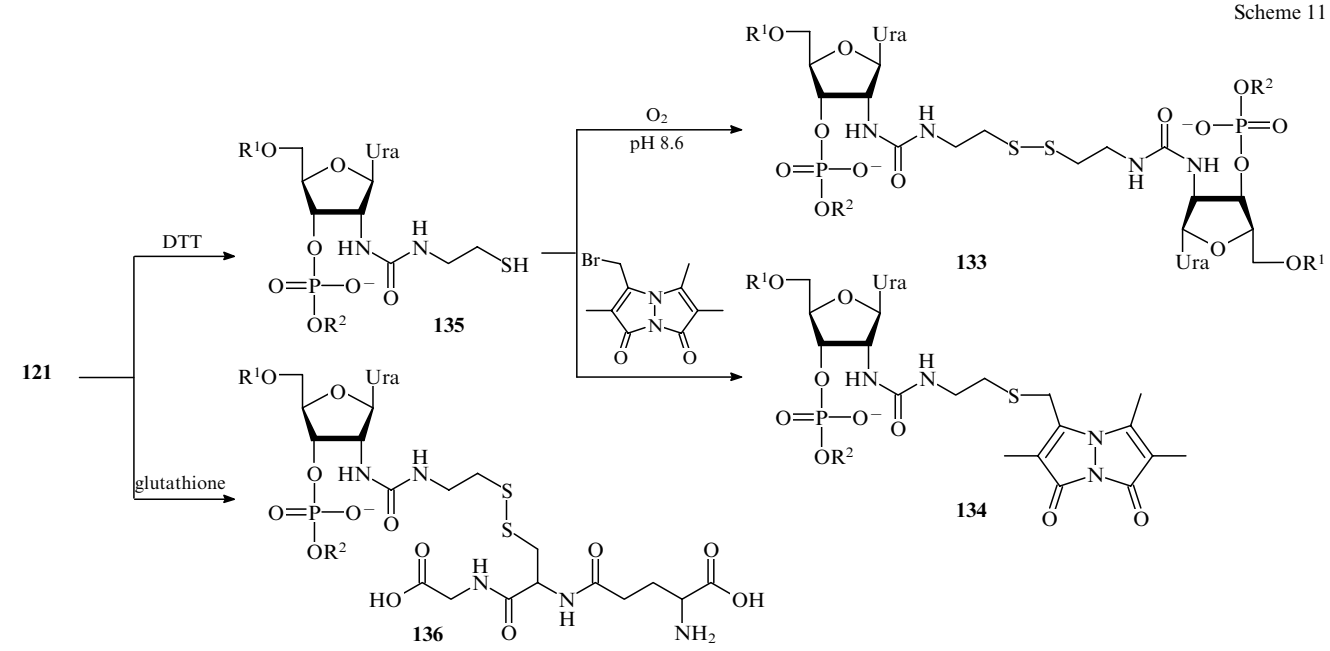
Covalent ‘homocross-linking’ of thiols **137** has been carried out; the duplexes formed were used for the study of the spatial structure of $tRNA^{Phe}$.[105,106]



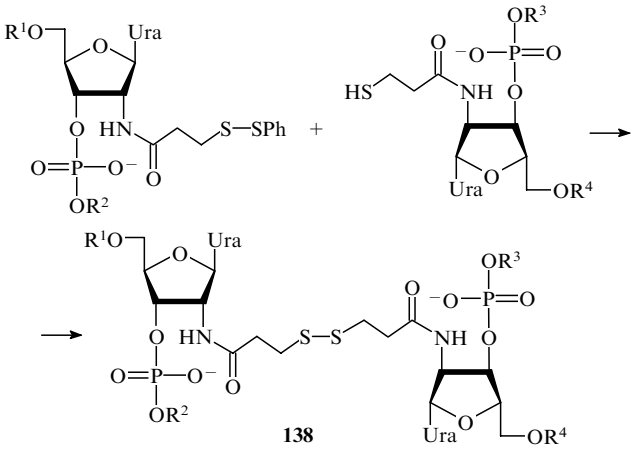
R^1 and R^2 are fragments of $tRNA^{Phe}$; B = Ura, Cyt.

The conjugates **138** containing a disulfide bond were formed in the thiol–disulfide exchange reaction.[261]

Scheme 11

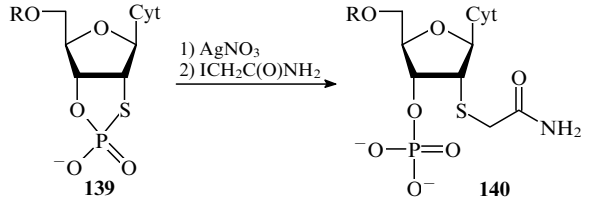


R^1 and R^2 are fragments of an oligonucleotide chain.



R^1, R^2, R^3 and R^4 are fragments of an oligonucleotide chain.

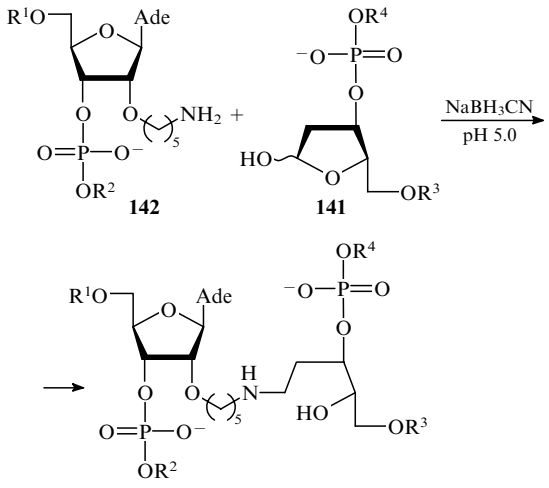
Hamm and Piccirilly [262] have synthesised oligonucleotides **139** containing 2′-*S*,3′-*O*-cyclophosphate at the 3′-end. The free 2′-thiol group was generated by treatment of the oligomers **139** with silver nitrate; subsequent reaction with iodoacetamide yielded the derivatives **140**. This approach can be used for modification of 2′-thionucleosides localised in the middle of the oligonucleotide chain.



R is a fragment of an oligonucleotide chain.

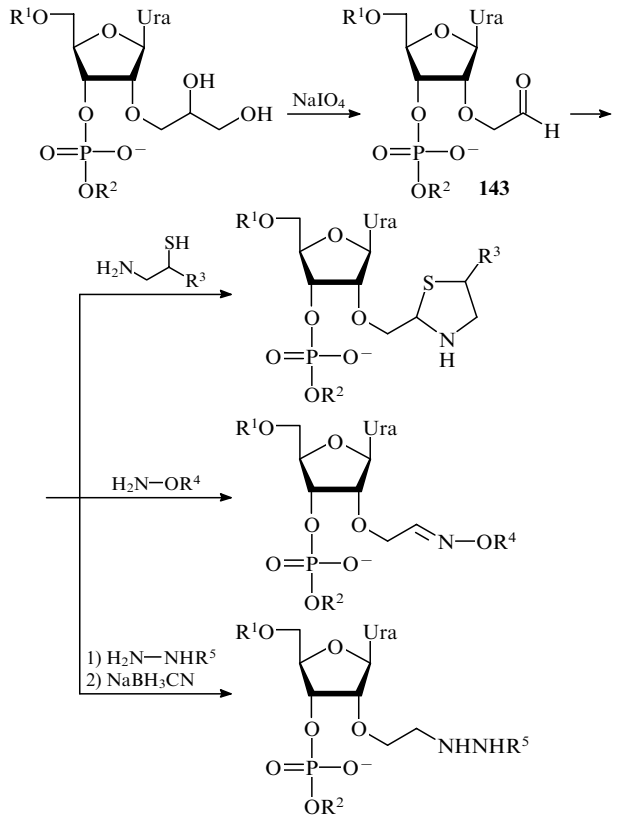
No formation of side 1′,2′-episulfides was observed, which occurs in the case of 2′-thionucleotides in an alkaline medium.[263,264] Presumably, this reaction involves silver thiolate rather than a free thio group. It is of note that 2′-thiooligonucleotides are more stable in alkaline media than non-modified oligoribonucleotides.

Cook and co-workers [265–267] have prepared a cross-linked duplex by reductive amination of an AP site in the oligonucleotide **141** with an aminoalkyl substituent at the O(2′) atom of adenosine **142** in the opposite chain.

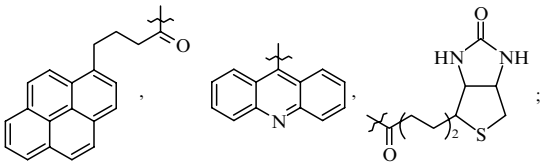


R^1, R^2, R^3 and R^4 are fragments of an oligonucleotide chain.

The addition of a series of 1,2-aminothiols, *O*-alkylhydroxylamines and hydrazides to oligonucleotides **143** containing an acetaldehyde residue at the O(2′) atom [268] yielded conjugates with peptides, pyrene, acridine and biotin. The hydrazones synthesised were unstable at neutral pH, which required their additional reduction to hydrazines with sodium cyanoborohydride. It is of note that this is the first example of simultaneous addition of several peptide residues to an oligonucleotide molecule owing to incorporation of several modified fragments into the chain.

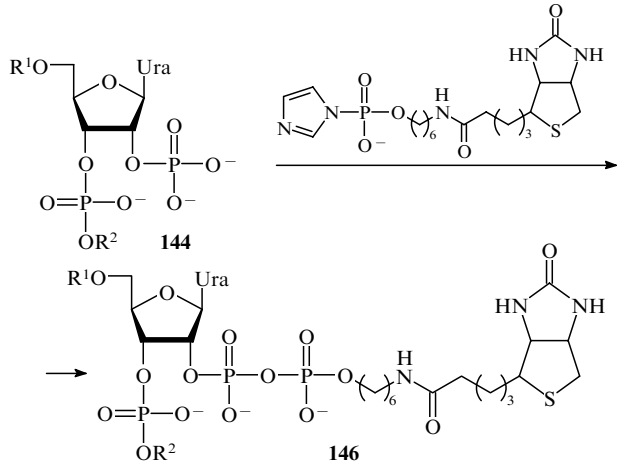


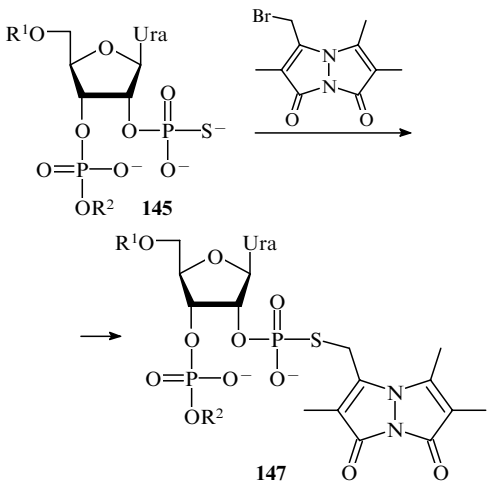
R^1 and R^2 are fragments of an oligonucleotide chain; R^3 = C(O)NHCH$_2$CO$_2$H, C(O)—CFSRAYPTPLRSKKT—OH, C(O)—GYGPKKKRKVGG—OH,



R^4 = CH$_2$C(O)–DPGYIGSR–OH;
R^5 = C(O)(CH$_2$)$_2$C(O)–DPGYIGSR–OH.

Sekine *et al.*[148] used oligonucleotides **144** and **145** containing 2′-phosphate and -thiophosphate groups for the introduction of biotin and biman to give the conjugates **146** and **147** containing the pyrophosphate and thiophosphate bonds, respectively. Later, it was shown[269] that the 2′-phosphate and -thiophosphate groups are easily and selectively removed on heating. Studies of the mechanism of this reaction have shown that the presence of a neighbouring 3′-phosphate group favours 2′-dephosphorylation.





R^1 and R^2 are fragments of an oligonucleotide chain.

IV. The use of nucleosides, nucleotides and oligonucleotides containing reactive groups in the 2′-position

1. The use of nucleosides and nucleotides

2′-Modified nucleosides and nucleotides can find application as selective inhibitors of certain enzymes. To this end, a group able to react with amino acid residues in the active site of the enzyme and thus to irreversibly inhibit it is introduced into a nucleoside. This approach is effective in a case where the structure of the enzyme active site and the mechanisms of its functioning have been studied in detail.

The use of 5′-diphosphates of pyrimidine 2′-thio- and 2′-thiocyanatonucleosides for the inhibition of ribonucleoside diphosphate reductase has been suggested.[270–272] This enzyme plays a key role in the biosynthesis of 2′-deoxyribonucleosides from ribonucleosides by catalysing the reduction of ribose as a constituent of ribonucleoside diphosphates to 2-deoxyribose. This reaction requires two hydrogen atoms which are generated by thioredoxin, a reduced protein cofactor containing two free SH groups in the cysteine residues. The reduction of ribose is accompanied by the oxidation of the cysteine residues; these conditions favour the conversion of thioredoxin into a disulfide form. It was suggested[271,273] that 2′-thio- and 2′-thiocyanate nucleoside diphosphate derivatives react competitively with the cysteine residues in the active centre of the enzyme and thus induce its inhibition. Besides, 2′-methylidene-2′-deoxyribonucleosides were used for the inhibition of ribonucleoside diphosphate reductase.[274]

2′-Hydroxyamino-2′-deoxyribonucleosides able to generate free radicals manifested high anti-fibrosacroma activity *in vitro* and *in vivo*.[28–30] It is of interest that 3′-isomers of these nucleosides inhibit RNA synthesis and suppress tumour growth in mice.

2′-Acylamino-2′-deoxyadenosine derivatives containing aromatic acid residues[195,275–277] manifested high inhibiting activity towards glyceraldehyde-3-phosphate dehydrogenase from *Trypanosoma brucei* which is the cause of sleeping sickness.[278] Effective inhibition was induced even by submicromolar concentrations of the nucleosides. X-ray diffraction analysis has shown[279] that the binding of N^6,2′-modified adenosine to glyceraldehyde-3-phosphate dehydrogenase significantly changes the enzyme structure.

2. The use of 2′-modified oligonucleotides and their conjugates

a. Antisense and anti-gene biotechnologies

The main trend over the past 15–20 years was the use of modified oligonucleotides for suppression of gene expression by their interactions with cell DNA and RNA. This is achieved using antisense and anti-gene approaches and RNAi.

The antisense mechanism of oligonucleotide action implies their intracellular complexation with mRNA to yield hybrid duplexes which prevent translation due to the inhibition of mRNA binding to ribosomes,[280,281] reverse transcription [282] or processing of mRNA.[283,284] In some cases, such hybrid duplexes act as substrates for the RNAase H,[281] which catalyses hydrolysis of a ribonucleic component, and undergo 'decapitation' of the 5′-end of the RNA molecule,[285] sequence-specific cleavage of RNA [3,286–289] or covalent binding of the oligonucleotide to RNA.[290] The most recent achievements in antisense biotechnology have been described in the review.[291]

In contrast, the anti-gene mechanism entails either direct binding of a modified oligonucleotide to genomic DNA and formation of a triplex on a complementary sequence [2,292] or unwinding of the double helix and formation of a heterogeneous duplex or D-loop.[293] This results in the inhibition of transcription of the corresponding genes and an increase in the susceptibility of the DNA site to nucleases [294] and chemical reagents.[295–298] Both antisense and anti-gene mechanisms are based on enhanced affinities of modified oligonucleotides for the complementary sequence in comparison with their native counterparts.

The phenomenon of RNA interference was discovered in 1998;[299] it consists of the degradation of mRNA induced by a double-helical RNA, which is complementary to a certain region of the former, and, as a consequence, of inhibition of gene expression. Initially, extended RNA duplexes (300–1000 bp) were used for this purpose, but later it was shown [300,301] that RNA interference was induced by shorter (21–23 bp) duplexes. A strong intracellular effect is observed upon introduction of even very few copies of RNA duplexes into the cell, which can be due to their functioning in a catalytic mode. A salient advantage of short RNA duplexes is that in mammalian cells they do not elicit non-specific immune response, which involves interferon production and cell death as in the case of extended RNA duplexes. For this reason, short RNA duplexes are considered to be efficient selective inhibitors of expression of individual genes and promising candidates for medicinal drugs.

Unfortunately, even minor modifications of RNA, *e.g.*, substitution of inosine for guanosine,[302] introduction of 2′-*O*-methylated nucleotides [303] or addition of a non-complementary base pair,[304] completely abolish RNA interference. The introduction of 2′-amino-2′-deoxyuridine or 2′-fluoro-2′-deoxyuridine into the sense chain of an RNA duplex only slightly inhibits the RNA interference, whereas modification of an antisense chain is crucial.[302] Nevertheless, it was shown that modification of two 3′-terminal nucleotides is possible.[303] Studies of RNA interference in mammalian cells have demonstrated [305] that the introduction of 2′-fluoro-2′-deoxyuridine and conformationally protected 2′-*O*-4′-*C*-methylidene nucleosides into RNA duplexes has no effect on the efficiency of RNA interference. The activities of single-helical, 22-membered RNA (the so-called miRNA [306,307]) are being investigated; their mechanism of action is similar to RNA interference.[5,6,308,309]

A recently developed SELEX procedure [4,310,311] enables the selection of NA molecules with predetermined properties from combinatorial libraries containing up to 10^{25} individual molecules.[312,313] The choice of target NA molecules is based on their ability to form stable complexes with various proteins and their low-molecular-mass analogues. As a rule, these properties are inherent in RNA molecules containing 40–100 nucleotide units, termed as 'aptamers'. The introduction of modified nucleosides into the structure of aptamers [314] increases their conformational mobilities and resistance to nucleases. The structures of modified aptamers can be established using tandem mass spectrometry combined with ESI-MS electrospray ionisation.[315,316] SELEX is also used for the analysis of ribozyme libraries.[317]

The use of oligonucleotides as therapeutic drugs requires that they possess high resistance to nucleases, can efficiently be delivered to the cell, selectively bound to the targets and are free of side effects. Low cost and availability of modified oligonucleotides are no less important. Thus, the construction of efficient antisense and anti-gene agents demands simultaneous solution of many problems.

It has been shown [318,319] that inside the cell oligonucleotides are predominantly hydrolysed under the action of exogenous nucleases. Today, the problem of stability of oligonucleotides may be considered to be solved owing to the use of 2′-*O*-methylated nucleotides, conformationally locked nucleic acids [320,321] and various 3′-terminal modifications, which significantly increase the resistance of NA against nucleases.

The problem of targeted delivery of oligonucleotides to cells is much more complicated. Its solution is difficult due to the lack of clear understanding of the mechanisms of oligonucleotide penetration across cell membranes, which involves either non-specific adsorption on the surface of the cell membrane and subsequent diffusion or receptor-mediated endocytosis. In this respect, covalent [260,322] and non-covalent [323] oligonucleotide conjugates with peptides present considerable interest. No less attention is given to the use of liposomes as vehicles for targeted delivery of oligonucleotides, *e.g.*, anionic and neutral,[324,325] cationic,[326] pH-sensitive,[327] fusogenic (*i.e.*, able to penetrate through cell membranes),[328] folate receptor-targeted liposomes [329] and immunoliposomes.[330] Of interest are oligonucleotide glycoconjugates in which receptor-mediated endocytosis is effected through lectin receptors.[331] The intracellular distribution of these conjugates between the cytosol and the nucleus is determined by their interaction with intracellular lectins. Hydrophobic nanoparticles [332] and polyamidoamine dendrimers [333] are also used as cargos for oligonucleotide delivery. The transmembrane transport of thiophosphorylated oligonucleotides [334] and of hydrophobic oligonucleotide conjugates [64] has also been discussed.

The design of antisense analogues of nucleic acids allows modification of both the sugar–phosphate backbone and heterocyclic bases. 2′-*O*-Alkyloligonucleotides containing reactive groups and their conjugates with other compounds are especially widely used along with other 2′-modified oligonucleotides in antisense biotechnology. Thus it has been found [268] that the attachment of 10–15-membered peptides to the O(2) atom of the carbohydrate fragment through a linker virtually does not affect the binding of the antisense conjugate to TAR RNA. Moreover, the solution of quite a number of practical tasks demands the introduction of more complex groups into the 2-position of the carbohydrate fragment of NA. The synthesis of 2′-*O*-{2-[2-(*N*,*N*-dimethylamino)ethoxy]ethyl}oligonucleotides is an example.[69] The introduction of such a modification into the oligomer structure increases the thermal stability of duplexes with RNA due to the *gauche*-effect,[71] while the presence of a positive charge increases its resistance against nucleases.[335]

3′-Phosphoramidite derivatives of 2′-*O*-methylnucleosides are commercially available, which determines the wide application of 2′-*O*-methyl oligonucleotides with internucleotide thiophosphate and phosphodiester bonds in antisense biotechnology. High *in vitro* [336] and *in vivo* activities of such oligomers have been demonstrated in experiments on various cell lines [337–341] and in mice.[342] One of the most popular approaches [343] entails the synthesis of a chimeric oligonucleotide which is made up of 2′-*O*-alkylribonucleosides and 2′-deoxyribonucleosides linked through internucleotide thiophosphate bonds in the middle of the chain. RNA duplexes with such oligonucleotides serve as substrates for RNAase H. It should be noted that the simultaneous presence of thiophosphate groups and 2′-*O*-methylnucleotide units results in additive inhibition of gene expression.[340] A similar approach entails the activation of RNAase P.[341] This enzyme splits the 3′-terminal fragment of RNA within the duplex,[344] which occurs more selectively than traditional RNAase H.[345]

2′-*O*-Methoxyethylated RNAs are thought to be the most promising among other 2′-modified oligonucleotides.[346] It has been shown [347] that such oligomers penetrate more easily across cell membranes, are stable in blood plasma [348] and specifically inhibit gene expression.[349]

In addition, 2′-*O*-methoxyethylated RNAs are effective inhibitors of telomerase.[350] Moreover, the inhibition of 3′-polyadenylation of pre-mRNA by such oligonucleotides is the reason for the increased stability of mRNA and, correspondingly, for the hyperexpression of proteins.[351]

2′-*O*-Alkylated oligonucleotides have also found wide application in anti-gene biotechnology. It was shown that 2′-*O*-methyloligonucleotides form kinetically and thermodynamically more stable triplexes in comparison with native oligonucleotides,[352] which is due to the pre-organisation of the oligonucleotide structure, [*i.e.*, a more favourable C(3′)-*endo*-, C(2′)-*exo*-conformation of the carbohydrate fragment] and van der Waals interactions between the 2′-*O*-methyl groups and purine bases.[353] Conformationally fixed 2′-*O*,4′-*C*-methylidene oligonucleotides confer even higher stabilities on the triplexes under conditions close to physiological,[354] the best results being observed in the case of 2′-*O*-(2-aminoethyl)oligonucleotides.[355–357] NMR spectroscopic studies have shown that in this case the increased stability of the triplex is due to electrostatic interactions of the charged amino groups of the pyrimidine oligonucleotide with the phosphate groups of the opposite purine chain of DNA.[70, 358] The so-called *gauche*-effect,[359] which determines the magnitude of the torsion angles in the system X–C–C–Y (X and Y are electronegative substituents), contributes significantly to the stabilities of the triplexes. The presence of a *gauche*$^+$-effect for the 2′-*O*-aminoethyl group determines the conformation which is optimum for the interaction with the phosphate group of the opposite strand; this favours the pre-organisation of the oligonucleotide. The presence of a charged amino group is yet another factor which determines the stabilities of the triplexes at low concentrations of Mg^{2+} close to physiological;[357] this is not typical of triplex-forming oligonucleotides.[360] It should be noted that the incorporation of a large number of modified units[356] alleviates the inhibition of gene expression *in vivo*. It was suggested[357] that this is due to the increased hydrophobicity of the oligonucleotide owing to the partial neutralisation of the negative charges of phosphate groups and, as a consequence, its adsorption on cell membranes, hydrophobic proteins, *etc*. The decrease in the intracellular concentration of a modified oligonucleotide also diminishes its anti-gene effect. Recently, it has been shown[361] that such modified oligonucleotides are promising for site-specific mutagenesis *in vivo*. The incorporation of 2′-*O*-aminoethyl-5-propargylaminopyrimidine nucleosides into oligonucleotides[362] exerted an additive effect caused by the interaction of two amino groups, which provided further stabilisation of the triplexes with DNA.

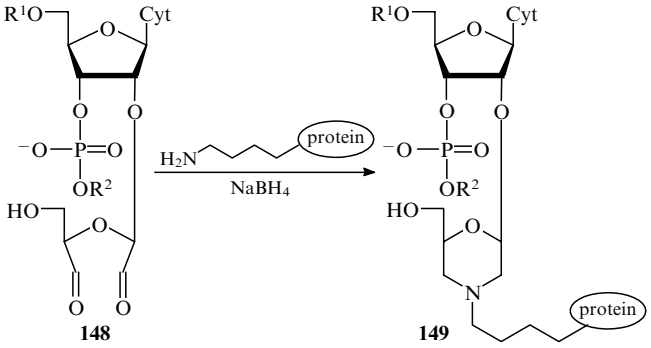
b. Studies of DNA – protein interactions

The second line of the use of modified oligonucleotides is the study of protein – nucleic acid interactions. This includes, in particular, covalent binding of nucleic acids to proteins.[142, 143, 363] The most significant information about the structures of NA – protein conjugates can be obtained by X-ray diffraction analysis,[364] however, it is not always possible to isolate sufficient amounts of specific protein complexes with DNA and/or bring about their crystallisation. Besides, the results can be wrong due to differences in the conformations of macromolecules in solution or in crystalline form. NMR analysis of the structures of NA – protein complexes is an alternative approach.[365] However, the data obtained by NMR spectroscopy are often difficult to interpret. Site-specific mutagenesis[366, 367] and chemical modification of proteins are potent methods for the study of DNA – protein interactions, however, their application demands preliminary identification of a specific site in the protein molecule responsible for the interaction with NA. The use of the 'footprinting' technique allows the identification of DNA sequences recognised by DNA-binding proteins,[368] but cannot be used for the identification of specific protein sites interacting with NA. Covalent attachment of proteins to modified nucleic acids containing reactive groups not only allows the identification of the protein site interacting with NA, but sometimes enables the determination of the amino acid responsible for the binding.[363, 369] The changes in the NA structure are minimal in this case.

Changes in the physicochemical properties of individual oligonucleotide fragments can be caused by even minor disturbances in the geometry of the molecule; the effects of modification can be determined by kinetic methods.[370]

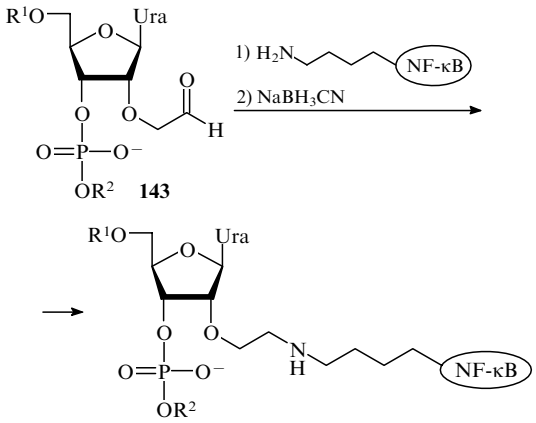
The interaction of a fragment of the Tat-protein with C(2′)-modified RNA has been studied.[258] It was shown that the conjugate **129** (see above) is formed in the reaction of the activated ester at the C(2′) atom of Urd(23) with the ε-amino group of Lys(51).

Oligonucleotides **148** containing a dialdehyde group in the 2′-position were used for the study of protein-NA interactions with restriction endonuclease *Eco*RII, DNA-methyltransferases *Eco*RII,[371] *Mva*I (see Refs 372–374) and T7 RNA polymerase.[373, 375] The use of modified oligonucleotides permits one to inhibit the enzyme activity without any effect on the ability of enzymes to bind the NA substrate. The interaction of oligonucleotides **148** with enzymes occurs in a selective manner and involves the ε-amino groups of lysine. The yields of the conjugates **149** are 3% – 5%.



R^1 and R^2 are fragments of an oligonucleotide chain.

The covalent binding of modified oligonucleotides **143** containing 2′-*O*-(2-oxoethyl)uridine to the transcription factor NF-κB has been described.[376] This modification seems to be more preferable than the dialdehyde group, since its small size favours its interaction with the ε-amino groups of lysine closest to DNA.

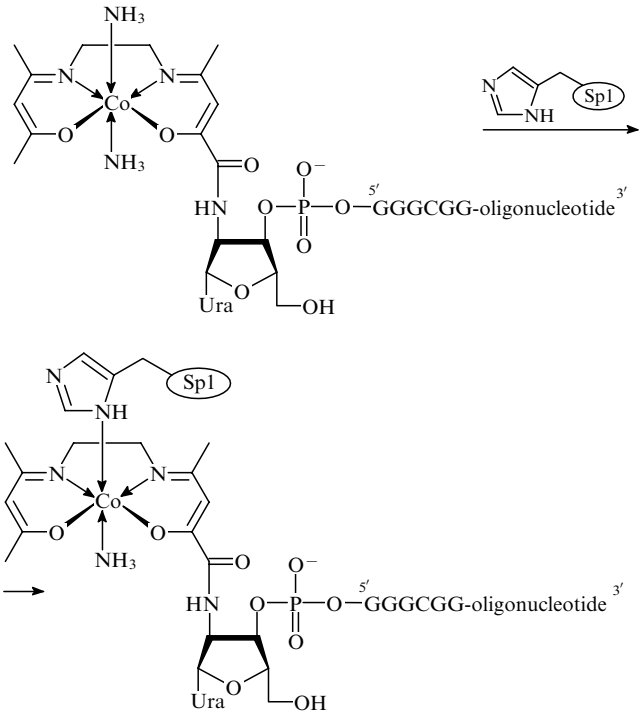


R^1 and R^2 are fragments of an oligonucleotide chain.

The covalently bound duplexes **122** and **123**[241–244] are extremely resistant against nucleases. Their interactions with the transcription factor NF-κB have been studied; the efficiency of the binding of the modified duplexes to the protein was higher than of native duplexes.[377] For a more detailed description of the synthesis and applications of covalently bound nucleic acids see Ref. 378.

Oligonucleotides **89** containing intrachain cross-links in the neighbouring nucleotide units [174, 175] have a chain kink at the modification site and structurally correspond to the U-turn of tRNA. These oligonucleotides can be used for the study of RNA – protein interactions.

It was suggested [253] that the transcription factor Sp1 could be selectively inhibited using irreversible binding of side histidine groups in the protein molecule to the cobalt atom of a metal complex covalently linked to the oligonucleotide.



Ribonucleic acids containing 2′-amino-2′-deoxyribonucleotide fragments were repeatedly used as aptamers possessing higher binding constants to various proteins and receptors than native nucleic acids. The proteolytic enzyme elastase from human neutrophils,[379] the vascular endothelium growth factor,[380] the fibroblast growth factor,[381] the protein Rev HIV-1,[382] the human γ-interferon,[383] *N*-methylmesoporphyrin (a low-molecular-mass analogue of heme-containing proteins),[384, 385] as well as insulin [386] and acetylcholine receptors [387] served as the objects of this study. After incorporation of the 2′-amino group into RNA, the ability to form hydrogen bonds remains. In addition, the presence of such modifications has only marginal effect on the local structure of RNA molecules because of the similarity of the van der Waals radii of the amino and hydroxy groups.

Oligonucleotides containing 2′-amino-2′-deoxyribonucleotide fragments were also used in the study of the role of 2′-hydroxy groups in RNA – protein interactions. The interactions of DNA with ribonuclease H1 from *E.coli*,[388] of RNA with the bacteriophage MS2 membrane protein [389, 390] and uracyl-DNA glycosylase [391, 392] have been studied. Aurup *et al.*[393] have synthesised mRNA from 2′-amino-2′-deoxyribonucleoside-5′-triphosphates and demonstrated that such an mRNA cannot be translated *in vitro* and *in vivo*.

c. Study of the structures of nucleic acids

The fluorescent properties of oligonucleotides containing a methylpyrene residue at the O(2′) atom [162] have been studied.[394 – 396] It was shown that the pyrene residue intercalates between the heterocyclic bases in a duplex with DNA as can be evidenced from the shift in its fluorescence maximum. In contrast, duplexes with RNA are characterised by strongly enhanced emission, which suggests the localisation of the pyrene residue outside the duplex. These conclusions were confirmed by the data from the thermal stabilities of the duplexes and CD spectra. In addition, the fluorescence characteristics of pyrene-containing oligonucleotides appeared to be highly sensitive to the presence of mismatches.[396] These oligonucleotides can be used in structural analysis of RNA.[397 – 399]

The emission characteristics of modified oligonucleotides where pyrene was attached to the C(2′) atom of uridine through an extended linker [170] were studied in relation to the nature of the 3′-flanking nucleotide and the presence of a complementary chain, which made it possible to determine the electron transfer energies and conformational mobilities of heterocyclic bases in various single- and double-stranded structures.

Silverman *et al.*[187, 248, 400] have used a series of modified oligonucleotides with different lengths of linkers between the pyrene residue and the C(2′) atom in order to study intron folding of the *Tetrahymena* group I P4 – P6 domain. The folding was accompanied by an increase in fluorescence intensity, which suggested changes in the environment around the modified nucleotide. It was demonstrated that the folding of RNA occurs in different ways depending on the ionic strength and pH of the solution.

The use of oligonucleotides containing 2′-*O*-(*N*-pyrenylmethylcarbamoyl)uridine has been proposed recently.[78] The spatial approximation of modified nucleosides in the complementary chains results in the formation of a pyrene excimer in the major groove of a DNA duplex.[170] The use of a linker with low conformational mobility has made it possible to prepare derivatives possessing strong fluorescence.

Nakano and co-workers [183 – 186, 235] have published a series of papers devoted to the synthesis of oligonucleotides containing various fluorescent labels at the C(2′) atom. Hybridisation of oligonucleotides containing a 4-(*N*,*N*-dimethylamino)phenylsulfamide group with a complementary DNA chain was accompanied by an increase in fluorescence intensity.[184, 185] The fluorescent properties of oligonucleotide duplexes containing fluorophore pairs (dansyl – fluorescein and coumarin — fluorescein) in the opposite chains have been studied.[186, 235] Unfortunately, in the former case the quantum yield of the energy transfer was too low, which excludes the use of such oligonucleotides for fluorescence resonance energy transfer (FRET). The quantum yield for the coumarin – fluorescein pair amounted to 25%; the quenching of the fluorescence of the energy donor was observed only in the case where the acceptor was conjugated with a complementary oligonucleotide.

Electrochemical detection of the DNA structure is a promising approach to the study of mononucleotide polymorphism.[401 – 403] A series of patents [404, 405] and papers [159, 406, 407] devoted to different applications of modified oligonucleotides containing 2′-*O*-ferrocenylalkylnucleoside fragments for the electrochemical detection of mononucleotide polymorphism in DNA fragments have been published. DNA chips and devices based on them are now commercially available (eSensor™, eSensor™ 4800 Reader, Motorola Clinical Micro Sensors, USA). For a more detailed description of the synthesis and properties of ferrocene-containing oligonucleotides see Ref. 403.

The introduction of the anthraquinone residue at the C(2′) atom [164] increases the thermal stabilities of duplexes of modified oligonucleotides with DNA and RNA.[408] ^{1}H NMR spectroscopic studies have shown [409] that the anthraquinone residue linked to the C(2′) atom intercalates between heterocyclic base pairs. This property was used in the study of electron transfer mechanisms along the DNA chain.[165] In further studies, oligonucleotides containing 2′-*O*-anthraquinonylmethyluridine were used in development of a novel type of DNA sensor.[410, 411] The efficiency of the electron transfer was shown to increase drastically upon formation of a duplex between the anthraquinone-containing oligonucleotide immobilised on an electrode and the NA target.

Whittemore *et al.*[171, 412] have used oligonucleotides containing an anthraquinone residue attached through a 2′-*O*-aminohexyl linker for electrochemical detection of complementary NA mole-

cules on the electrode surface with the help of cyclic voltammetry. The use of a dropping mercury electrode [171] did not reveal any steady dependence of the voltammetric characteristics on the concentration of the NA under study, which can be attributed to the non-specific adsorption of the oligonucleotide on the mercury surface. In further studies,[412] an oligonucleotide containing a 5′-terminal thiol group was immobilised on the surface of a gold electrode. To minimise non-specific adsorption, the electrode surface was treated with 2-mercaptoethanol after which a complementary oligonucleotide containing an anthraquinone residue was added and the detection was begun. If is of interest that the UV spectroscopic data exclude intercalation of the anthraquinone residue between heterocyclic base pairs.[412]

Oligonucleotides containing a ruthenium complex at the C(2′) atom [206] were suggested as models for the study of electron transfer along the DNA chain. However, it was found that the oxidation of the guanosine residue within the duplex occurs in very low yields.

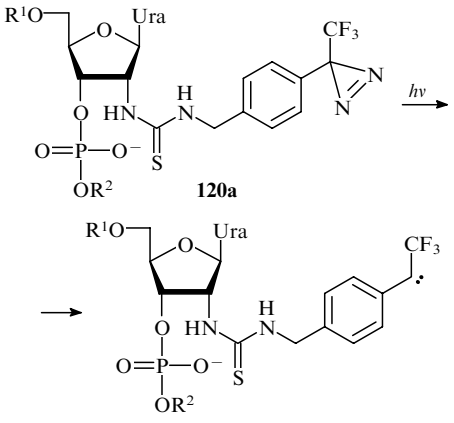
Recently published reviews are devoted to the use of thiol-containing oligoribonucleotides for the study of structures and functions of ribozymes [413] and the three-dimensional structure of RNA.[414, 415]

Sigurdsson *et al.*[238] unambiguously chose one of the two tertiary structures of a ribozyme containing covalently bound domains which have earlier been deduced from X-ray diffraction analysis data. This approach was further used to prove proximity of two domains of a hairpin ribozyme.[416]

A study of the formation of disulfide cross-links between modified oligonucleotide chains [261] has made it possible to estimate the rates of the thermal motions of structural elements of the ribozyme *Nhe*I. In further studies, the switch-over of the nuclease activity of ribozyme HHα10 to a ligating activity could be achieved through the use of similar modifications.[417, 418] A considerable increase in the ligation rate, which was not accompanied by changes in hydrolysis rates, was attributed to a sharp decrease in the thermal motions of the ribozyme domains,[417] structural changes in the catalytic site of the enzyme [418] and, as a consequence, in arrangement of the 2′-hydroxy and 3′-phosphate groups of the substrate.

Glick and co-workers [105, 106] have used disulfide bond formation between thiol-containing oligonucleotides for the study of the spatial structure of $tRNA^{Phe}$. It was found that the effects of covalent cross-links on the three-dimensional structure of tRNA are minimum. The kinetics and thermodynamics of the folding of $tRNA^{Phe}$ upon cleavage of disulfide cross-links due to thiol–disulfide exchange were studied.[419]

Modified 5S rRNA **120a**, which contains a photochemically active aryl(trifluoromethyl)diazirine group,[236] was used in the study of the spatial environment of 5S rRNA within the ribosome.



R^1 and R^2 are fragments of an oligoribonucleotide chain.

Upon UV irradiation, diazirine is converted into a highly reactive carbene which attacks even aliphatic C—H-bonds.[420] An analysis of the reaction products has made it possible to establish several contacts between 5S rRNA and 23S rRNA.

Buchmueller *et al.*[421, 422] have used oligoribonucleotides containing 2′-(4-azido-2-hydroxybenzamido)-2′-deoxyuridine for detecting non-equilibrium structures formed upon folding of RNA.

An interesting application for oligonucleotides containing pyrimidine 2′-amino-2′-deoxyribonucleosides has been proposed by Weeks and co-workers [249–251] who have demonstrated that the acylation rate of the 2′-amino group depends on the conformational mobility of the modified nucleotide fragment. This is maximum for a single-stranded NA and minimum for an ideal duplex. The kinetic and thermodynamic parameters of the acylation with the biotinylbutyric acid *N*-hydroxysuccinimide ester were established for all possible nucleotide pairs in DNA–DNA and DNA–RNA duplexes.[250, 251] The data obtained were used in further studies of the local structure of $tRNA^{Asp}$ (see Ref. 249) and detection of mononucleotide polymorphism.[251] It was shown in particular that the acylation rate of a 2′-amino-2′-deoxyribonucleoside incorporated into the anticodon loop of $tRNA^{Asp}$ (see Ref. 249) exceeds that of nucleosides involved in complementary interactions or representing elements of the tertiary structure.

It has been shown [423] that the acylation rate of the 2′-amino group is determined not only by the local conformational mobilities of oligonucleotides, but also by the chemical nature of the vicinal groups in the 3′-position. The reaction rate drops drastically in the presence of a phosphotriester group in the 3′-position of the 3′,5′-cyclophosphate group or upon substitution of threofuranose for the ribose residue. This suggests the involvement of the 3′-phosphate or the 3′-hydroxy group in the catalysis of the acylation reaction. The results obtained and the data from computer simulation prompted a conclusion on a possible catalytic role of the 2′-hydroxy group in the formation of a peptide bond in the peptidyl site of the ribosome.

Sigurdsson *et al.*[424, 425] have studied the effects of metal ions on the structure and interactions of modified TAR RNA with different fragments of the Tat-protein using RNA carrying a spin label in the 2′-position.[237] ESR studies have shown that the substitution of sodium ions for calcium ions does not influence the structure of TAR RNA, but weakens the interaction of a fragment of a mutant Tat-protein with definite nucleotide fragments. The introduction of several spin labels into the TAR RNA [426] enabled the investigation into the interactions of the latter with dyes, intercalators and antibiotics and the determination of binding sites for these molecules. In further studies, this modification was used for measuring the distances in double-helical RNA using ESR spectroscopy.[427]

d. Ribozymes

Ribozymes are short-chain RNA, which catalyse the sequence-specific cleavage of RNA, ligation and some other processes.[3] The hammerhead ribozyme is the best studied.[428–430] In this Section, we consider ribozymes that incorporate nucleosides containing reactive groups in the 2′-position.

The incorporation of 2′-amino-2′-deoxyribonucleosides,[228, 431–437] 2′-thionucleosides,[433, 435] 2′-aminooxynucleosides,[86, 433, 435] 2′-*O*-methyl- and 2′-*O*-allylnucleosides [438] into definite positions of the ribozyme significantly increases the resistance of RNA against nucleases with simultaneous preservation of, or a small decrease in, the catalytic activity. Similar results were obtained for the DNAzyme.[439]

However, it was found [440] that the catalytic activity of a ribozyme decreases significantly as a result of incorporation of certain substituents into the 2′-position. This effect does not depend on the size of the group incorporated, but rather is determined by the nature of the bond at the C(2′) atom. Some modifications, *e.g.*, 2′-acylamido and 2′-alkylcarbamoyl groups presumably prevent conformational changes in the ribozyme molecule in the catalytic act. This is confirmed by the data [441] on the lack of catalytic activity of a hammerhead ribozyme contain-

ing 2′-acetamido groups and the data of Beigelman *et al.*[193] on a substantial decrease in the catalytic activity upon acylation of 2′-amino-2′-deoxyuridine with amino acids (alanine, phenylalanine, lysine and asparagine).

According to Hamm *et al.*,[442] cleavage of an RNA substrate containing 2′-thiocytidine instead of native cytidine by the ribozyme dHH16 proceeds *via* an intermediate 1′,2′-episulfide by a mechanism similar to hydrolysis in an alkaline medium.[263, 264] Under these conditions, the cleavage rate of modified RNA decreases by two orders of magnitude in comparison with native oligoribonucleotides. Further studies of the properties of oligonucleotides containing 2′-thiocytidine units revealed[443] that this reaction requires the presence of manganese ions. Moreover, it does not occur in the absence of oxygen or in the presence of free radical scavengers in the reaction mixture.

The incorporation of several 2′-thiocytidine-5′-phosphate units into the ribozyme fully suppressed its catalytic activity.[444]

Schwans *et al.*[445] have synthesised a modified *Tetrahymena* group I intron P4–P6 domain using α-thiotriphosphates of 2′-thionucleosides. Isolation of RNAs, which differed from the native fragment in gel-electrophoretic mobilities, and subsequent cleavage of the thiophosphate groups in the modified RNAs by iodine has made it possible to determine the positions of 2′-hydroxy groups in the domain essential for its folding.

Stromberg *et al.*[446–448] have studied self-splicing of the intron IA2 of pre-mRNA formed during the expression of the gene *nrdB* of the bacteriophage T4. Attachment of guanosine to the 5′-end of the intron occurs, which was accompanied by cleavage of RNA with subsequent elimination of the guanosine residue from the intron sequence in the presence of metal ions. When 2′-amino-2′-deoxyguanosine was used as a cofactor instead of guanosine, the splicing rate decreased 20–25-fold. An analysis of the dependence of the cleavage rate of guanosine on pH, concentration and the nature of bivalent metal ions has made it possible to reveal the interactions of metal ions with 2′-hydroxy and 2′-amino groups. Similar studies of catalytic activities of *Tetrahymena* RNA have shown[449, 450] that the 2′-amino group and the bivalent metal ion compete for the same 5′-phosphate group in the active site of the ribozyme.

The modified ribozymes currently available represent complex structures which contain simultaneously 2′-*O*-methyl nucleosides, 2′-amino-2′-deoxyuridine, 2′-fluoro-2′-deoxynucleosides and thiophosphate internucleotide bonds.[451] The introduction of bulky substituents into the 2′-position significantly decreased the ribozyme activity;[229, 440] therefore, the use of such constructions seems to hold little promise.

V. Conclusion

At present, the synthesis of oligonucleotides containing reactive groups in the 2′-position and of their conjugates is a promising approach to targeted changes in the physicochemical and substrate properties of nucleic acid fragments. Among modified nucleosides, 2′-amino-2′-deoxyribonucleosides are especially popular. These can easily be incorporated into NA by chemical or enzymatic methods and then selectively acylated. This circumstance has determined the commercial availability of the pyrimidine 2′-amino-2′-deoxyribonucleoside phosphoramidite derivatives and 5′-triphosphates (TriLink BioTech, USA).

The methodology of preparation of modified oligonucleotides where the molecules or reactive groups are linked to the C(2′) or O(2′) atom has been developed fairly well. A vast number of publications are devoted to the synthesis of oligonucleotides containing nucleophilic groups, since in the majority of cases the corresponding phosphoramidite derivatives are commercially available.

Conjugates containing an amide bond are prepared by activation of the carboxy group using methods originally developed for peptide synthesis where the concentration of a compound containing a carboxy group exceeds that of the amino-containing component by an order of magnitude. It therefore seems expedient to perform the reactions of oligonucleotides bearing amino groups with an excess of carboxyl-containing compounds. Moreover, the presence of an amino group in the oligonucleotide chain fits well into the protocol of oligonucleotide synthesis, while the carboxy group needs to be deblocked prior to standard post-synthetic treatments.

Modified oligonucleotides where the thiol groups are attached to the O(2′) atom through various linkers are readily accessible and are used for the preparation of conjugates with a disulfide bond.

The reason for the rare employment of oligonucleotides containing an aldehyde or an oxo group is unclear. The synthesis and applications of aldehyde-containing oligonucleotides have been documented only in the past decade.[109] A commercially available modified polymeric carrier (Glen Research) for the synthesis of oligonucleotides with an aldehyde group at the 3′-end, has become popular. A 4-formylbenzoic activated ester designed for the incorporation of the aldehyde group into oligonucleotides containing an aliphatic amino group has recently become available (Trilink Biotech, USA).

These data altogether suggest that the aforementioned methods for the preparation of conjugates in solution and on polymeric supports are nearly equally efficient. In choosing a method for conjugation in solution, special attention should be given to the solubility of the reaction components and selectivity of the reaction, while the substances to be attached to the oligonucleotide should be easily separated from the reaction products by HPLC or gel electrophoresis. In the case of a solid-phase version, the bond formed and the molecule attached should retain stability under the conditions of post-synthetic treatments. The conjugation of nucleosides is less important but nevertheless promising in the synthesis of compounds carrying various reporter groups.

Analysis of the publications devoted to the use of 2′-modified oligonucleotides has demonstrated significant progress in many fields of molecular biology, antisense and anti-gene biotechnology and enzymology.

The authors thank Drs. A Yu Tomashevsky (University of Virginia, Charlottesville, VA, USA), O Yu Smirnova (German Cancer Research Centre, Heidelberg, Germany) and D A Stetsenko (Medical Research Council, Cambridge, UK) for their valuable assistance in the preparation of this review for publication. This review has been written within the framework of the Programme ‘Universities of Russia’ (Project No. UR.05.03.010) and with the financial support of the Wellcome Trust (Grant No. CRIG 069419) and the Russian Foundation for Basic Research (Project No. 03-04-48957).

Department of Chemistry of the Kyiv National Taras Shevchenko University

This issue of the Journal is devoted to the 170th anniversary of the Kyiv National Taras Shevchenko University (KNU) and comprises reviews written by professors and researchers of the Department of Chemistry of KNU and reflecting traditional and novel trends of research carried out at the Department.

The Kyiv University was founded in 1834. Chemistry was taught at the University from the moment of its foundation; research activities were also begun at that time. In 1904, a special building was built for the University chemists and the next year a department of chemistry was established within the University structure. Many prominent chemists, such as S M Reformatsky, A K Babko, A M Golub, A T Pilipenko, O V Palladin, I V Pyatnitsky, A I Kiprianov, K B Yatsimirsky, F S Babichev, Yu K Delimarsky and V N Yeremenko have worked there at different times. To date, the research staff of the Department of Chemistry comprises 208 people including 68 professors and 140 researchers.

The Department takes an active part in comprehensive research programmes of the KNU and the European Union. It maintains and develops constant collaboration with leading research centres in Russia, Poland, USA, Germany, Great Britain, France and Italy. An agreement for joint activities in 2001 – 2005 concluded between the departments of chemistry of the Kyiv National Taras Shevchenko University and M V Lomonosov Moscow State University is aimed at the design of new generations of functional materials, polymers, flocculants and drugs. The Division of Inorganic Chemistry collaborates with Wroclaw (Poland) and Leipzig (Germany) Universities. The studies at the Division of High-Molecular Compounds are carried out within the framework of collaboration programmes between KNU, Gdansk University and Radom Technical University (Poland), the Research Centre LG Gable (Korea) and the Charles Sadron Institute (France). The Division of Organic Chemistry collaborates with Toulouse University (France). The researchers of the Division of Physical Chemistry are carrying out joint research with their colleagues from York University (Great Britain).

The Department of Chemistry takes an active part in the organisation and holding of various national and international conferences; in particular, it was the organiser of the 21st International Chugaev Conference in June 2003 dedicated to the 130th anniversary of L A Chugaev.

The Department of Chemistry of KNU consists of five divisions, *viz*., the Divisions of Inorganic Chemistry, Analytical Chemistry, Organic Chemistry, Physical Chemistry and Chemistry of High-Molecular Compounds. Future chemists are trained there in nine specialities.

Studies devoted to the synthesis and structural analysis of coordination compounds and studies of complexation reactions of transition metals in various media occupy a significant place in the research activities of the Division of Inorganic Chemistry. Its major achievements include the development of a direct (one-step) synthesis of coordination compounds from metal powders and metal oxides, which has enabled easy preparation of a series of novel compounds which cannot be synthesised by traditional methods. The results of these studies have been generalised in the monograph by V V Skopenko, A D Garnovskii, V M Kokozey *et al*., 'Direct Synthesis of Coordination Compounds' (1997).

Considerable attention in the past decade has been given to metal complexes with amide, hydrazide, oxime and carbacylphosphoramidate ligands possessing interesting catalytic and

physical properties. These investigations are considered in the review by V V Skopenko, V M Amirkhanov, T Yu Sliva, I S Vasilchenko, E L Anpilova and A D Garnovskii 'Various types of metal complexes based on chelating β-diketones and their structural analogues'.

Yet another trend of research at the Division of Inorganic Chemistry is related to the design of novel inorganic materials possessing non-linear optical and specific electrophysical properties. In particular, studies of the regularities of phase formation of phosphates in solution-melt media of multicomponent systems and under solid-phase interaction conditions; synthesis of heterosubstituted crystalline templates of double phosphates and study of relationships between compositions, structures and properties of novel compounds are under way. Studies into the synthesis of complex phosphates under conditions of hydrothermal interaction are carried out jointly with the Institute of Magnetism of the National Academy of Sciences of the Ukraine. This trend of research is represented in the review by V V Skopenko, V V Lisnyak, N V Stus and N S Slobodyanik 'Phosphate tungsten bronzes'.

The traditional trends of research at the Division of Analytical Chemistry include studies of extraction and sorption processes which serve as the basis for the development of the most advanced methods of environmental analysis and control. The approach including the design, analysis and applications of solid-phase analytical reagents is also being developed successfully. Unique adsorbents for selective solid-phase concentration and separation of metal ions, pesticides, antibiotics and phenols in environmental objects and biological fluids and selective membranes for chemical and biological sensors have been designed. These problems are surveyed in the monographs by Yu V Kholin and V M Zaitsev 'Complexes on the surface of chemically modified silica' (1997) and by V M Zaitsev 'Complex-forming silica: synthesis and structures of graft layers and surface chemistry'. Other studies are concerned with the practical application of a novel concentration procedure, *viz*., micellar extraction or microcomponents from aqueous solutions using non-ionic surfactants. These studies gave an impetus to the development of methods for determining surfactants and toxic organic compounds in natural and waste waters.

The main lines of research at the Division of Organic Chemistry include asymmetric synthesis of organic compounds, stereochemistry, studies into mechanisms of chemical reactions, synthesis and investigation of heterocyclic and biologically active compounds, chemistry of proteins and carbohydrates and computer chemistry. The review by A A Pokholenko, Z V Voitenko and V A Kovtunenko 'Pyrido- and pyrimidoisoindoles: methods of synthesis and properties' summarises the data on the synthesis, physical and chemical properties of pyrido- and pyrimidoisoindoles with unusual electronic structures.

One of the most modern trends of research, *viz*., calculation of atomic clusters using most advanced computer programmes, is being intensively developed at KNU. In recent years, research activities of KNU investigators have been focused on the design of fluorescent probes and ionic indicators as well as peptidomimetics and peptide models. A systematic search for biologically active compounds is under way. This line of research is discussed in the review by I V Komarov, A O Grigorenko, A V Turov and V P Khilya 'Conformationally rigid cyclic α-amino acids in the design of peptidomimetics, peptide models and biologically active compounds'.

Studies into physicochemical, adsorption and catalytic properties of metal-containing systems as well as thermodynamic and structural studies of metal and oxide melts are traditional subjects of investigation at the Division of Physical Chemistry. These include studies of interactions of gas molecules with surfaces of solids including melts. An important role of heterogeneity and polymorphism in adsorption-catalytic properties of melts has been demonstrated and the microheterogeneity phenomenon in melts has been established. The oxidation mechanisms of small molecules (CO, H_2, CH_4) on surfaces of metal catalysts have been investigated and some novel classes of metal-containing catalytic systems have been discovered. The theoretical grounds for the mechanisms underlying the effects of non-ionogenic water-soluble polymers on electronic-surface properties and aggregate resistance of coarse-dispersion systems have been developed. Structure–activity relationships of ice-forming compositions of various chemical nature have been established based on an analysis of a mosaic model of a hydrophilic-hydrophobic surface. Of special noting is the synthesis of adsorption-semiconducting gas sensors, development of various devices based on them and determination of thermodynamic characteristics of various novel binary and ternary metal systems containing aluminium, germanium, silicon, *etc*.

The main trend of research at the Division of High-Molecular Compounds is the synthesis and modification of polymers, monomers and other compounds and their use in the design of polymeric compositions possessing unique properties. Novel polymeric materials for microelectronic engineering have been developed. Numerous polymeric photosemiconductors, polymeric solid electrolytes, photosensitive polymers and compositions and biologically active polymers have been prepared.

The interest in heteropolymeric systems, such as intermolecular polycomplexes (InterPC) as well as block and graft polymers has increased considerably in the past decade due to the explosive development of nanophase materials science. The review by T B Zheltonozhskaya, N E Zagdanskaya, O V Demchenko, L N Momot, N M Permyakova, V G Syromyatnikov and L R Kunitskaya 'Graft copolymers with chemically complementary components as a special class of high-molecular-weight compounds' deals with the description of modern concepts and novel approaches to the study of graft copolymers. The long-standing experience of researchers of the Division in the synthesis of photosensitive compounds and their applications in photopolymeric engineering is generalised in the review by V G Syromyatnikov, P A Kondratenko, A Yu Kolendo *et al*., 'Structures, properties and applications of photosensitive organic azides and pentazadienes' to be published in one of the next issues of 'Russian Chemical Reviews'.

The size of this issue cannot encompass the whole range of research carried out at the Department of Chemistry. Therefore, all those who are interested in more detailed information about KNU and the Department of Chemistry are invited to visit our web-sites: http://www.univ.kiev.ua and http://www.chem.univ.kiev.ua

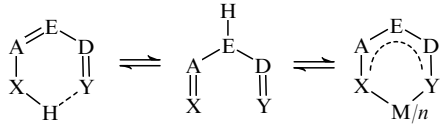
Contents

I.	Introduction	737
II.	Metal complexes of β-diketones	738
III.	Modified β-diketonates	744
IV.	Conclusion	749

Abstract. Data on the synthesis and structures of β-diketonates and their N,P-containing structural analogues are generalised and described systematically. The possibility of creating diverse metal complexes with various modes of coordination of typical chelating ligands is discussed. The bibliography includes 200 references.

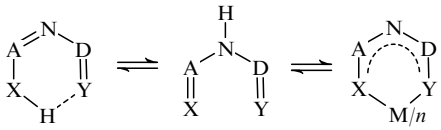
I. Introduction

Chelating systems **1**, which form, most often, six-membered metal-containing rings **2**, are among the most widely used ligands in modern coordination chemistry.[1–3]



1a **1b** **2**

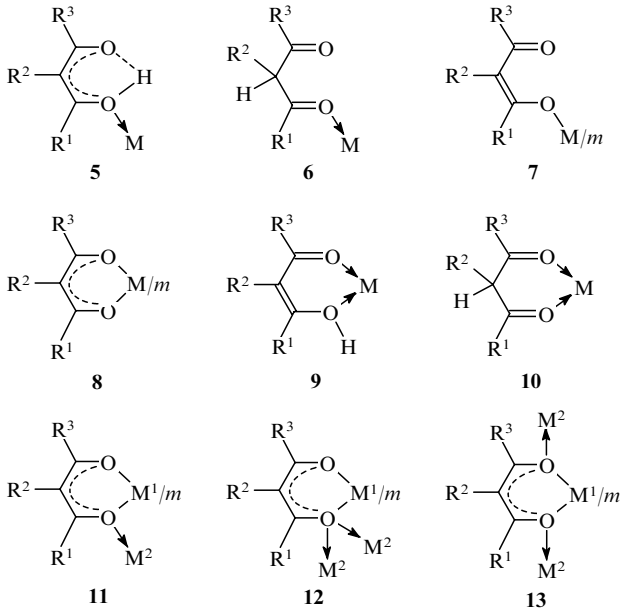
The metal complexes **2** formed by ligands **1** are mainly represented by β-diketonates (X = Y = O; A, D, E = CR, where R = H, Alk, Ar, Het),[4–9] their aza analogues (X = O, NR; Y = NR; A, D = CR, N; E = CR, where R = H, Alk, Ar)[10,11] and hetero analogues (X, Y = O, S, Se; A = CR, PR_2; D = PR_2; E = CR, where R = H, Alk, Ar).[2,3,12,13] Other examples of these ligands are compounds **3**, which are used to prepare metal chelates **4** (X, Y = O, S, Se; A = CR^1, PR^1_2; D = PR^1_2, where R^1 = H, Alk, Ar, NR^2_2, OR^2; R^2 = H, Alk, Ar, ArAlk).[14,15]



3a **3b** **4**

Although metal chelates **2** and **4** arouse the steady interest of researchers, equally important are other coordination capabilities of ligands **1** and **3**, which are not limited to the formation of chelates (intracomplex compounds†) containing the ligand as a bidentate X,Y-donor anion. This aspect of the chemistry of metal complexes of these ligands has been considered in detail only for β-diketonates **2** (X = Y = O; A = D = E = CR). The possible modes of coordination in mono-, di- and polynuclear β-diketonate complexes can be illustrated by structures **5** – **27**.[5,9,16–24]

O- and O,O-coordination



5 **6** **7**

8 **9** **10**

11 **12** **13**

† The notion 'intracomplex compound' taken from early publications (see, for example, Refs 8 and 14) is used in Russian and German literature to emphasise the fact that these compounds have been obtained from ring-forming ligands with an intramolecular H-bond, for example, from acetylacetone. More generally, the complexes with metal-containing rings are called chelates.[2]

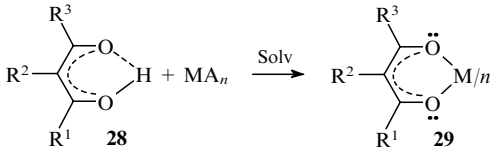
Study of the coordination modes of typical chelating ligands is important for the understanding of their ambident properties.[20–24] Therefore, this review surveys the published data (obtained mainly during the last 10 years) concerned with the ability of ligands **1** and **3** to form metal complexes in which the coordination bonds can be localised in different ways.

II. Metal complexes of β-diketones

Coordination compounds of β-diketones are prepared either by classical methods (by reactions of various compounds, most often salts, of complexing metals with β-diketonate ligands) or by specific reactions (gas-phase synthesis and electrosynthesis[2–5]). The type of the metal complex to be formed plays an important role in the transformations considered below.

1. Chelates formed by β-diketones

The chelates of β-diketones (β-diketonates) containing the monodeprotonated O,O′-anion of the ligand[25] are synthesised most often by the reactions of ligand systems **28** with metal salts in water, aqueous organic solvents, or in solvent mixtures.



28 **29**

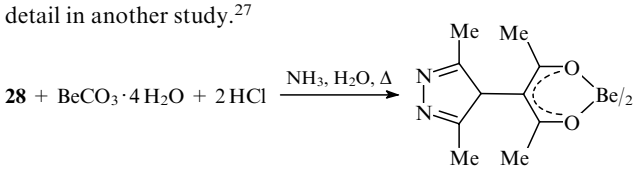
Solv is solvent.

β-Diketonates **29** for metals of virtually all Groups of the Periodic Table have been prepared in this way. Due to the enormous number of publications on this topic, only some examples of such syntheses are cited in this review.‡

Silver(I) β-diketonates **29** are formed in 20%–66% yields upon the reaction[26]

28, **29**: $R^1 = Bu^t$, $R^2 = H$, $R^3 = Bu^t$, $SiMe_3$.

The data on the syntheses of β-diketonates of Group II elements (Be, Ca, Mg, Ba, Sr) are summarised in a recent review.[9] The synthesis of beryllium β-diketonate **30** is described in more detail in another study.[27]

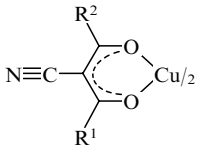


30

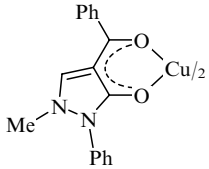
β-Diketonates of Group III metals are prepared using metal halides. In particular, aluminium and indium chelates have been obtained in this way.[28]

8, **28**: $R^1 = R^3 = Ph$, $R^2 = H$.

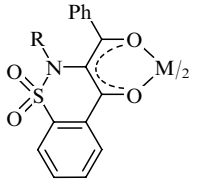
An enormous number of coordination compounds of transition metals have been synthesised on the basis of aliphatic and aromatic β-diketones.[1–8] It should be emphasised that chelates **31**–**34**, similar in structure to chelate **8**, have also been synthesised by reactions of 3d-metal salts with β-diketones containing nitrile,[29] pyrazole,[30] 1,2-benzothiazine 1,1-dioxide[31] and ferrocenyl[32] substituents, respectively.



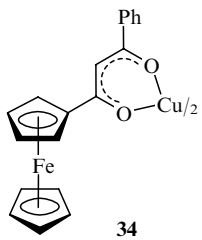
31: $R^1 = R^2 = Me, Bu^t$



32



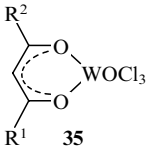
33: R = H, Me;
M = Co, Ni, Cu, Zn



34

‡ The Cambridge Structural Data Base contains structures of more than 1500 β-diketonates and related fragments as parts of monomeric and polymeric coordination compounds.

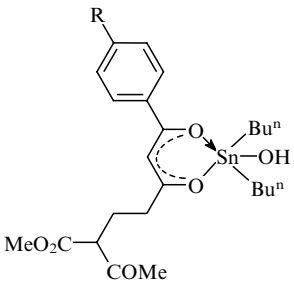
The relatively simple transformations considered above can be complicated by solvolysis, resulting in the formation of adducts and decomposition of complexes (especially, in the case of hydrolysis). Therefore, these syntheses are carried out using anhydrous organic solvents; for example, β-diketonate **35** was synthesised in anhydrous benzene.[33]



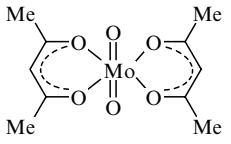
35

R^1, R^2 = Me, Ph, 4-$MeOC_6H_4$.

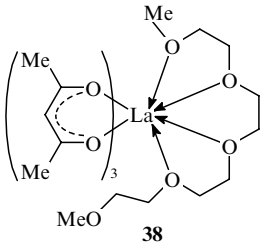
Apart from salts, metal oxides can also be used in complexation reactions.[2–4,9] These syntheses have been long known [34] and still have not lost their significance. For example, complexes **29** ($R^1 = R^3 = CF_3$; R^2 = H; M = Ag; m = 1),[35] **36**,[36] **37** [34] and **38** [37] can be prepared from silver, tin, molybdenum and lanthanum oxides, respectively.



36: R = H, Bu^t, NO_2, Cl



37



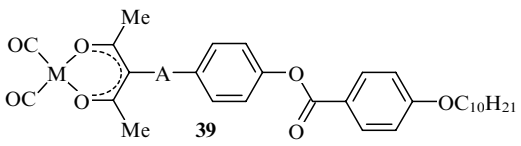
38

The reactions of ligands with metal alkoxides proved to be quite efficient for the synthesis of Group IV metal (Ti, Zr, Hf) β-diketonates.[9]

$$n\,(\beta\text{-diketone}) + M(OR)_4 \xrightarrow{Solv} M(\beta\text{-diketone})_n(OR)_{4-n} + n\,ROH$$

This reaction has been used, in particular,[38] to prepare zirconium and hafnium complexes with 2,2,6,6-tetramethylheptane-3,5-dione (LH), with the composition $M(OPr)_2L_2$, ML_4 and $M_2(OPr)_6L_2$, the synthesis being carried out in hexane.

Metal exchange reactions are often used to prepare β-diketonates **8**.[4,9] β-Diketonates of Group I metals are usually employed as the starting compounds for the exchange with d or f elements. Recently, this method has been used to synthesise mono-β-diketonates of rhodium(I) and iridium(I) **39** dicarbonyls having liquid-crystalline and nonlinear-optical properties. These complexes were prepared by replacement of potassium or sodium in acetylacetonates by platinum metals.[39]

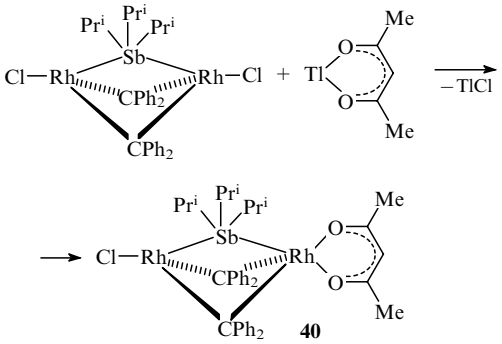


39

M = Rh^I, Ir^I; A = CH_2, CO_2, OOC.

The syntheses of mixed-ligand complexes of lanthanides (La, Sm, Er) described as $LaL_3(bipy)_2$, $[SmL_3(bipy)]bipy$, $ErL_3(phen)$ (bipy is 1,1′ -bipyridyl, phen is *o*-phenanthroline) proceed through the preliminary formation of the caesium salt of 1,1,1,5,5,5-hexafluoropentane-2,4-dione (LH).[40]

Thallium acetylacetonate has been used to prepare rhodium complex **40**.[41]



40

It is noteworthy that in some cases, reactions of β-diketone salts give products absolutely different from those formed in the syntheses from free ligands. In particular,[42] the reaction of gadolinium trichloride with the sodium salt of β-diketone (LNa) gave tetramer **41**, whereas a similar reaction of LH affords mononuclear complex **42**.

$$4\,GdCl_3 + 12\,LNa + 10\,H_2O \xrightarrow{H_2O-EtOH} Gd_4(OH)_4L_8(H_2O)_6 + 4\,LH + 12\,NaCl$$

41

$$GdCl_3 + 3\,LH \xrightarrow[-3\,HCl]{Me_2CO} GdL_3(Me_2CO)_2 \xrightarrow[-Me_2CO]{H_2O} GdL_3(Me_2CO)(H_2O)$$

42

The solid-state syntheses of β-diketonates **43** from salts of complex-forming elements and alkali metal β-diketonates deserve attention.[43–46]

$$PrCl_3 + 3\,M(acac) \longrightarrow Pr(acac)_3 + 3\,MCl$$

43

M = Li, Na; acac is acetylacetonate.

Numerous β-diketonates similar in structure to complex **8** have been prepared by ligand exchange.[4,5] In particular, metal complexes **44** were synthesised in this way.[47]

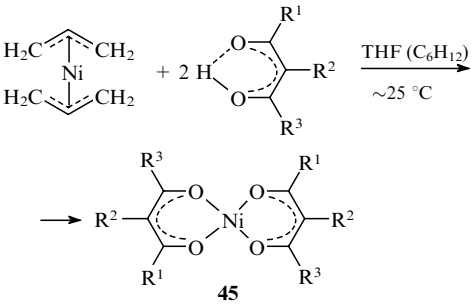
$$[M(OEt)_2(EtOH)_4]_n + 2n\,LH \longrightarrow [ML_2]_n + EtOH$$

44

M = Ca, Ba,Sr; LH = **28**: $R^1 = R^3$ = Me, Bu^t, Ph, CF_3; R^2 = H.

In addition to the above-mentioned polymeric complexes, this transformation carried out in the presence of triglyme (TG) and tetraglyme (TeG) furnished monomeric products, $BaL_2(TeG)$, $SrL_2(TG)$ and $SrL_2(TeG)$.[47]

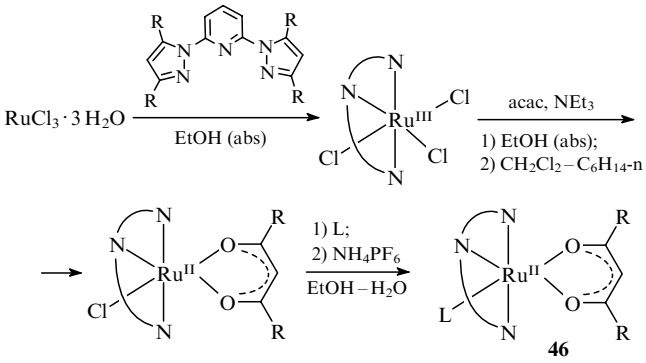
Nickel β-diketonates **45** have been synthesised by the reaction of bis(η^3-allyl)nickel with β-diketones.[48]



45

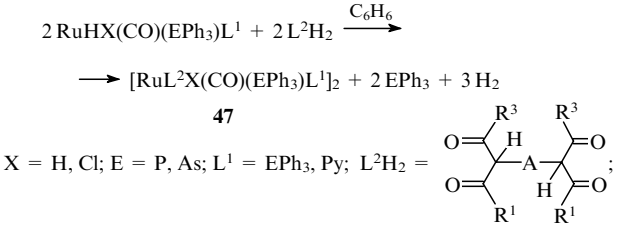
$R^1 = R^3$ = Me; R^2 = Me, Ph, Bn, $H_2C{=}CHR^4$ (R^4 = C_6H_8, C_6H_{12}, $C_{12}H_{24}$).

Mixed-ligand ruthenium(II) acetylacetonates **46** have been prepared by chlorine exchange reaction in ruthenium(III) complexes with 2,6-bis(pyrazolyl)pyridines.[49]



R = Me, Ph, CF_3; L = 4,4′-bipy, MeCN, Py, imidazole, pyrazine.

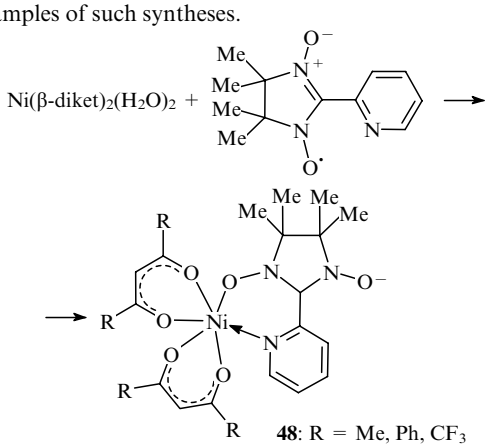
This approach has also been used for the synthesis of ruthenium(II) binuclear complexes with bridging bis-diketonate ligands.[50, 51] On refluxing for 6 h, these ligands replace H^- in the carbonyl hydride complexes of ruthenium to give coordination compounds **47**.



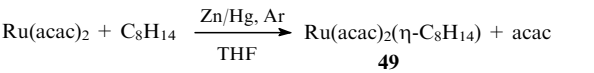
X = H, Cl; E = P, As; L^1 = EPh_3, Py; L^2H_2 = ;

A = CR^2R^4 (R^2, R^4 = H, Ph), S; R^1, R^3 = Me, Ph.

It appears of interest to use this approach to replace the ligands in β-diketonate complexes by other chelating compounds. The transformations [52, 53] giving rise to complexes **48** and **49** are examples of such syntheses.



48: R = Me, Ph, CF_3

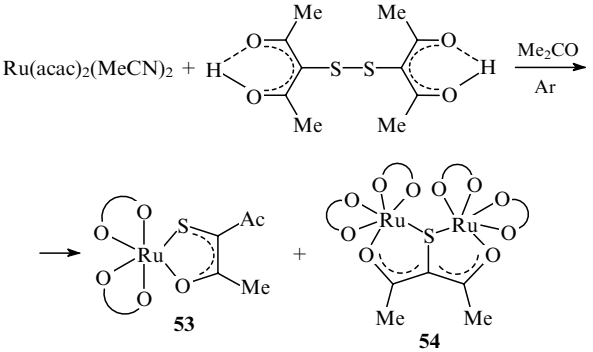


C_8H_{14} is cyclooctene.

By replacing the cyclooctene ligand by other ligands, acetylacetonate **49** has been converted [53] into a series of different-ligand complexes: $Ru(acac)_2Py_2$, $Ru(acac)_2$(bipy), $Ru(acac)_2(NCBu^t)_2$, $Ru(acac)_2(\eta^2\text{-}C_8H_{14})_2(NCMe)$, $Ru(acac)_2(NMe_3)_2$, $Ru(acac)_2(PPh_3)_2$, $Ru(acac)_2(PMePh_2)_2$, $Ru(acac)_2(PAlk_3)_2$, $Ru(acac)_2[P(OMe)_3]_2$; $Ru(acac)_2$ $[P(OPh)_3]_2$, $Ru(acac)_2[Ph_2P(CH_2)_mPPh_2]$ (m = 1–3), $Ru(acac)_2(\eta^2\text{-}C_8H_{14})_2(SbPh_3)$, $Ru(acac)_2(SbPh_3)_2$, $Ru(acac)_2$. .$(CO)(NMe_3)$, $Ru(acac)_2(CO)(PPh_3)$ and $Ru(acac)_2(CO)(AsPh_3)$.

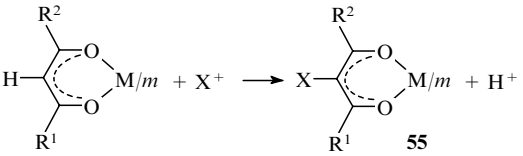
The ligand exchange reactions yielding monoacetylacetonate binuclear rhodium complexes **50**–**52** are shown in Scheme 1.[54]

Ruthenium mono- (**53**) and binuclear (**54**) tris-chelates were prepared in a similar way.[55]



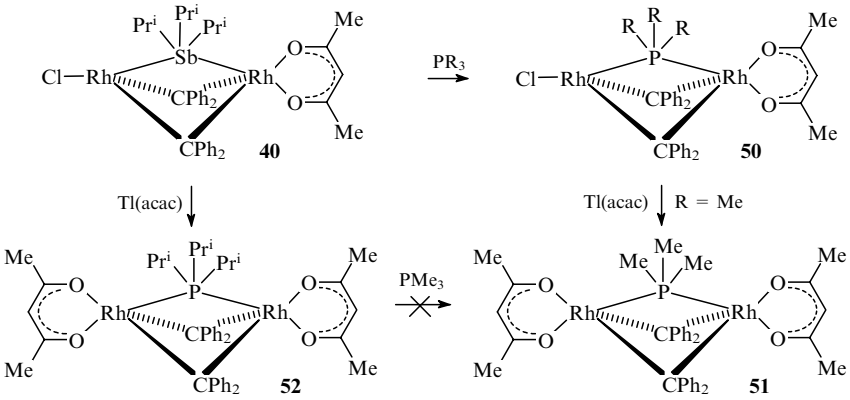
The acetylacetonate ligands can be rather easily completely replaced. This underlies the acetylacetonate method for the synthesis of metal complexes with diverse ligands,[56, 57] widely used in the coordination chemistry of gold.[57]

To our knowledge, no classical template syntheses of β-diketonates in which the β-diketonate ligand system is constructed from components on a metal template (*cf.* the studies [2, 3, 58–60]) have been reported. However, template syntheses of the second type, *i.e.*, the reactions of coordinated ligands (modification of ligand systems), [2, 3, 61–63] are represented rather extensively in the chemistry of metal complexes of β-diketones.[2–5] This is attributable to the ability of β-diketonates **8** devoid of substituents at the C(3) atom of the quasi-aromatic ligand system to undergo electrophilic substitution at this atom.[4, 5, 9]

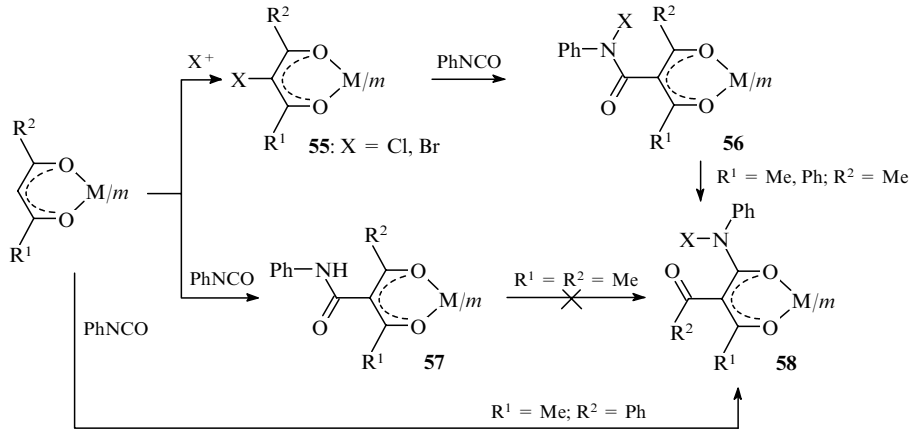


The halogenation, formylation, acylation and Mannich reactions and the introduction of thiocyanate and chlorosulfenyl

Scheme 1

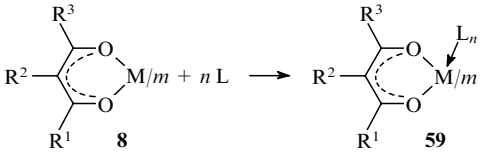


Scheme 2



groups occur according to this route.[5] Nitrile[29] and phenyl isothiocyanate[64] fragments can be introduced in the ligand system in a similar way. The presence of a substituent X in complex **55** also allows one to modify β-diketone ligand systems. Scheme 2 shows transformations of this type, resulting in complexes **56**–**58**.[64]

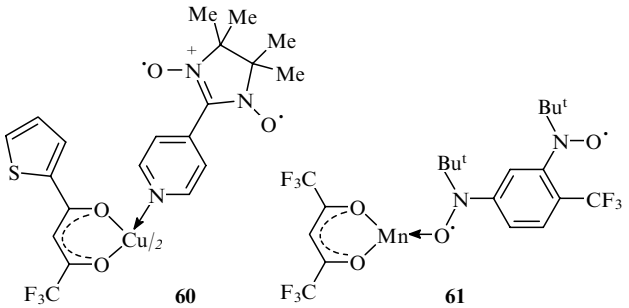
An important role in the modification of the coordination sphere belongs to the reactions of β-diketonates with N-, P-, O- and S-donors involving a coordinatively unsaturated complexing metal, giving rise to adducts **59**.



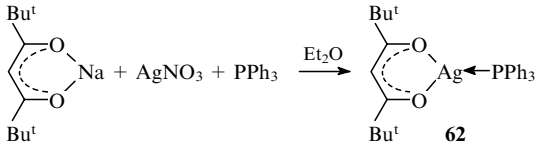
m = 1–3; *n* = 1, 2.

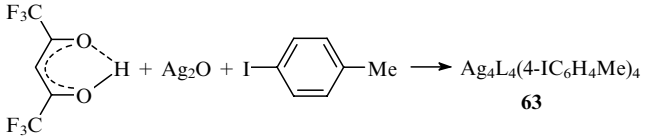
These reactions have been used to prepare adducts of silver(I) β-diketonates with tributyl- and triphenylphosphines,[26] cobalt(II) with pyrazine and 4,4′-bipyridyl,[65] rhodium(I) with cyclooctadiene[32] and iridium(II) with triallylphosphines and -stibines.[66]

In recent years, the interest in β-diketonate adducts with biradical bases such as complexes **60**[67] and **61**[68] has grown due to the development of new molecular magnets.

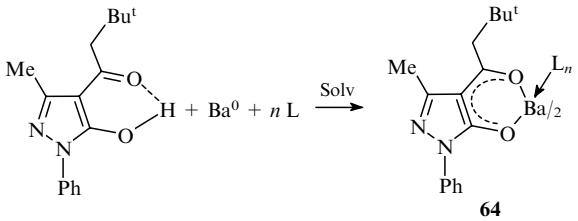


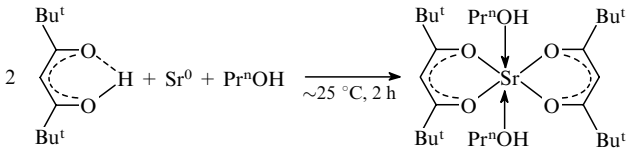
Adducts similar to compound **59** (in particular, complexes **62**[26] and **63**[69]), can also be formed in template reactions.



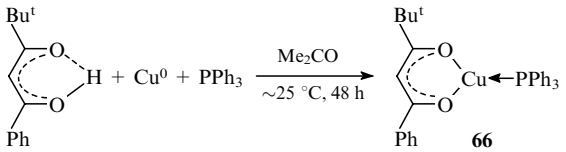


The direct method for the synthesis of β-diketones from ligands and zerovalent metals[2,3,4,9] is mainly applied for Group IA and IIA elements of the Periodic Table. This technique was used to prepare magnesium, calcium, barium and strontium β-diketonates (see the review[9] and references cited therein). Among more recent publications, noteworthy are papers devoted to the syntheses and structural studies of mononuclear chelates of barium **64**[70] and strontium **65**.[71]





Some transition metals (Co, Fe, Ni, Cu) can also directly react with β-diketones. In these syntheses, iron is activated by atmospheric oxygen, whereas cobalt, copper and nickel are activated by the addition of N- or P-bases into the reaction mixture.[72–74] This method has been used to prepare[74] the β-diketonate complex of monovalent copper **66**, which has been structurally characterised.



Direct one-step syntheses of β-diketonates from zerovalent metals in the gas phase[2,3,72,73,75–78] and under conditions of electrolysis[2,3,72,73,76,79] are especially efficient.

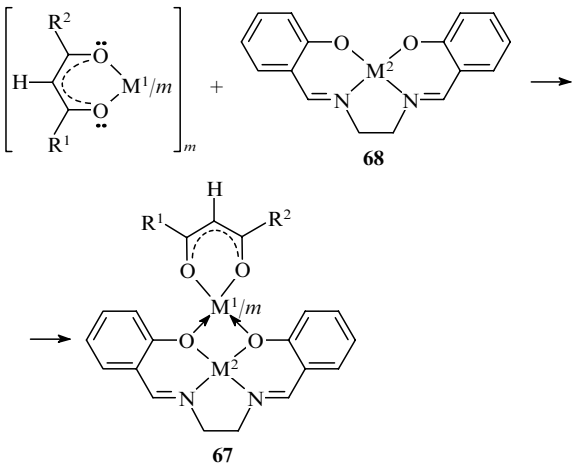
Gas-phase syntheses of β-diketonates have been developed for both non-transition and transition metals (M = Al, Sn, Pb, Ti, Zr, Hf, Co, Mn, Cr, Fe, Ni, Pd, Cu, Dy, Ho, Eu) which are evaporated *in vacuo* at 1000–2500 °C (see Refs 72, 73 and 78). A special setup for the gas-phase synthesis of β-diketonates has been designed.[73,80] Using this setup, chelates **8** of some metals (Ti, Zr, Hf, Co, Cr, Ni, Cu) can be obtained in almost quantitative yields (~90%–100%). The gas-phase syntheses of β-diketonates have been reported,[75,80] the latter publication being devoted to the synthesis of mononuclear calcium, strontium and barium trifluoro- and hexafluoroacetylacetonates (**8**: R^1 = H, CF_3;

R^2 = H; R^3 = CF_3; M = Ca, Sr, Ba; m = 2) from metals, metal oxides or fluorides.

The electrochemical method for the synthesis of β-diketonates implies anodic dissolution of the complexing metal in organic or aqueous–organic solvents containing the corresponding β-diketones (LH) and conductive additives.[2, 3, 72, 73, 75, 79–88] Graphite, platinum or some other metals, for example, nickel, are suitable as the cathode.[85–88] A systematic study of the electrochemical synthesis of β-diketonates has been reported.[75] The syntheses were carried out in 15%–20% solutions of ligands in aqueous (60%) methanol or ethanol, acetonitrile or DMF in the presence of LiCl, LiBr, NH_4Cl or Bu_4NBF_3. This gave β-diketonates ML_2 (M = Co, Mn, Ni), ML_3 (M = Al, In, Ga, Co, Fe), ML_4 (M = Zr, Hf), ML_2Solv (M = Ni, Fe), ML_3Cl (M = Ti, Zr), $TiL_3(OMe)$ and $ZrL_3(OMe)$ in yields of 60% to 90%. Several other publications [85–88] describe cobalt,[88] uranium [86] and dysprosium [85, 87] complexes obtained in an undivided electrolytic cell in ethanol. A synthesis carried out under an inert atmosphere (Ar, He) yields uranium β-diketonates UL_4, whereas in the presence of oxygen, the reaction gives UO_2L_2 (LH is acetyl- or benzoylacetone). The resulting cobalt and dysprosium β-diketonates are described as $CoL_2(EtOH)$ and Dy_3L_n (n = 1, 0.5). The use of the electrochemical method together with the chemical method (platinum cathode, methanol, Et_4NClO_4) furnishes chelates **32** (M = Co, Ni, Cu, Zn) in 17%–85% yields.[31] A promising approach is the use, in the electrochemical synthesis, of alkali metal β-diketonates in acetonitrile without any other conductive additives.[89] In this case, sodium β-diketonates can be obtained in the first stage and, subsequently, electrochemical replacement of sodium by a transition metal takes place.

β-Diketonates **8** can also be synthesised under boundary friction conditions (tribochemical mechanosynthesis);[72, 73] however, the preparative value of this method (see, for example, Ref. 90) is still obscure.

Since coordinatively unsaturated β-diketonates **8** are able to form adducts **59**–**66** with bases (see also a number of publications [91–95]), it appears of interest to convert them into heteronuclear complexes **67** .[96–99]



68

67

R^1 = Me, CF_3, Bu^t; R^2 = Me, CF_3;
M^1 = Mg, Ba, La, Y, Gd; M^2 = Cu, Ni; m = 2, 3.

In this reaction, *o*-hydroxyazomethine chelates **68** act as ligands.[10, 99, 100]

Similar procedures have been used to prepare bi- [101, 102] and trinuclear [103] complexes based on lanthanide (La, Gd) β-diketonates and transition metal *N*,*N*′-bisacetylacetone iminates.

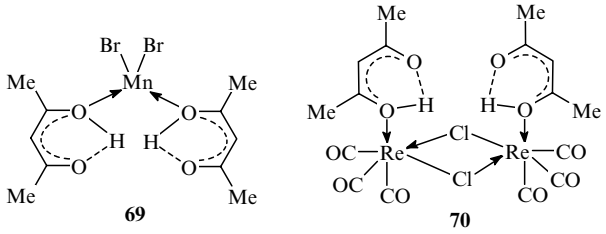
The heteronuclear complexes in question were characterised by X-ray diffraction; they present considerable interest as molecular ferromagnets [96] and as precursors for the production of films and coatings by vapour deposition of heterometallic materials.[97–99, 101–103]

Note that fragment **8** can be incorporated in more complex structures (see, for example, Ref. 9).

2. Complexes with neutral β-diketonate ligands

Complexes of this type are few; they have been studied by X-ray diffraction.[2, 3, 16–18, 21]

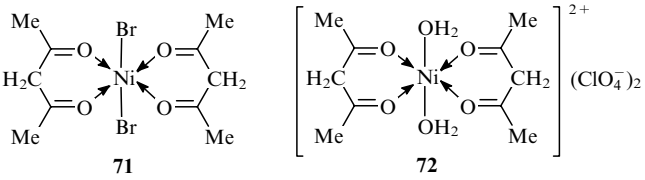
The mononuclear complex $MnBr_2(LH)_2$ (**69**) [104, 105] and the binuclear complex $[ReCl(CO)_3(L'H)]_2$ (**70**) [106, 107] correspond to structure **5**. Complexes with monodentate O-coordination corresponding to structure **7** have been discussed in the literature.[17, 18]



69 **70**

Compound **69** was synthesised without a solvent,[105] while compound **70** was prepared in benzene.[107] Apparently, the enol tautomer of the ligand is stabilised in these complexes.[104, 106]

It was found that the complexes $NiBr_2(LH)_2$ (**71**) [108] and $Ni(LH)_2(ClO_4)_2(H_2O)_2$ (**72**) have the same structure as chelate **10**.[109, 110]



71 **72**

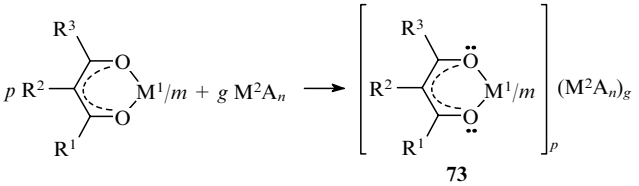
It should be emphasised that all hydrogen atoms in the structure of **72** have been located and the presence of a CH_2 group has been proven reliably. This indicates that the ligand exists in the keto form.

The data concerning other molecular complexes of β-diketones with mercury, tin, titanium, zirconium, manganese, cobalt, vanadium, rhenium, chromium, nickel, platinum, uranyl and europium halides and acetates are summarised in reviews.[17, 18] Only the results of elemental analysis (the composition was established to be MA_2L) and IR spectra were reported for these complexes, which precludes exact determination of their structures, in particular, distinguishing between the structures **9** and **10**.

3. Polynuclear complexes of O,O-coordinated β-diketones

The greatest number of structures of the type **11**–**15** is known among β-diketonates of Group IIA elements (Ca, Mg, Sr, Ba).[2, 3, 9, 21] In addition, worth mentioning are the dimer $[Ba_2L_4(NH_3)_4]$,[111] the trimer $[CaL_2]_3$,[112] the tetramer $[BaL_2]_4$,[9, 113–115] and the pentanuclear $Ba_5L_9Cl(H_2O)_7$ [116] and hexanuclear $Ba_6L_{10}(O_2)(H_2O)_6$ [117] complexes, which contain simultaneously structural elements of **8** and fragments of chelates **11**.

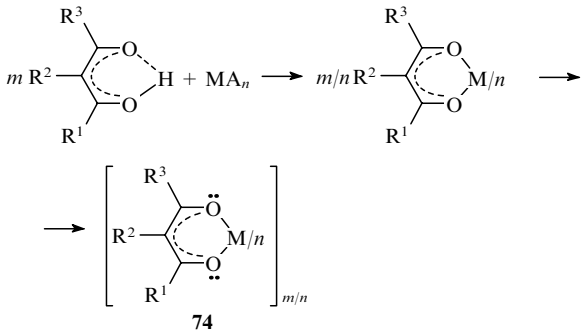
The syntheses of these polynuclear complexes are based on the ability of β-diketones to behave not only as Lewis acids but also as bases due to the oxygen electron pairs not involved in the coordination.[9, 113–120]



73

A is anion.

The formation of structures **73** can in principle be regarded as a sort of oligomerisation of metal β-diketonate monomers through M—O coordination, as in complex **74**.



74

This transformation underlies the synthesis of a series of heterometallic complexes, for example, β-diketonates and other metal chelates **75** (metal exchange in the β-diketonate fragment and the transformation of the heterocyclic ligand system)[121] or alkoxides **76**[122] as well as the template reaction giving rise to complex **77**.[123]

$$2\,CuL^1_2 + 2\,CdL^2_2(phen) \xrightarrow[\Delta,\ 1\ h]{MeCN} (Cd_2L^1_2)(\mu^3\text{-}L^3_2)[Cu_2(phen)]_2$$

75

L^1H is 1,1,1,5,5,5-hexafluoroacetylacetone, L^2H is pyridine-2-thione, L^3H is 1,3,5-tris(trifluoromethyl)-1,3,5-trioxycyclohexane trianion;

$$BaL_4 + Bi(OEt)_3 \xrightarrow[\sim 25\ ^\circ C]{C_6H_5Me} Bi_4Ba_4(\mu^4\text{-}O_2)_2(\mu^3\text{-}OEt)_8(\mu\text{-}OEt)_4(\eta^2\text{-}L)_4$$

76

LH is 2,2,6,6-tetramethylheptane-3,5-dione;

$$Cu(OMe)_3 + H_2L^1 + BaL^2_2 \xrightarrow[25\ ^\circ C,\ 4\ h]{CH_2Cl_2} Ba_2Cu_2L^1_4L^2_4$$

77

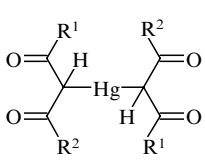
H_2L^1 is 2,2-thiodiethanol, L^2H is 1,1,1,5,5,5-hexafluoroacetylacetone.

The complex $(Pr_2CuL^1_3)HL^2_2(L^3_4)(\mu^6\text{-}O)$ was synthesised under similar conditions.

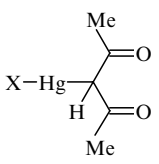
4. β-Diketonates with M—C- and M—C,O-coordination

β-Diketonate complexes of these types are represented by structures **16**, **18** and **23** studied by X-ray diffraction and reported in monographs[2–4, 16, 18, 124] and reviews.[5, 17, 20–24] Therefore, we will consider only the synthetic aspect of the design of this type of complex with unusual localisation of the coordination bonds.

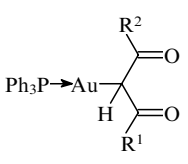
As emphasised in a monograph,[124] the M—C-coordination, which is found, for example, in compound **16**, is observed in the complexes of β-diketones with Mn^I, Rh^I, Au^I, Pt^{II}, Pt^{III}, *i.e.*, with soft metals, which is consistent with Pearson's hard–soft acid–base (HSAB) principle.[2, 3, 125, 126] Examples of such compounds are mercury(II) complexes **78**[127, 128] and **79**[129, 130] and gold(I) complex **80**.[131–135]



78: R^1, R^2 = Me, Bu^t

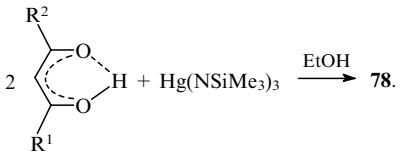


79: X = $MeCO_2$, Cl



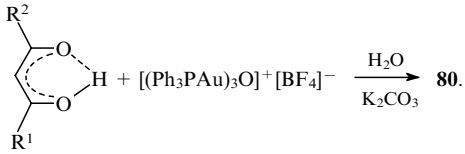
80: R^1 = Me, Bu^t, Ph; R^2 = Me, Bu^t, Ph, Fc (Fc is ferrocenyl)

Compound **78** was prepared in a quantitative yield by the following reaction:[127]



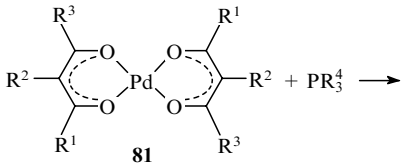
Subsequently,[128] complex **78** (R^1 = Bu^t; R^2 = n-C_3F_7) has been prepared using mercury(II) acetate. The structure of the resulting complex was studied by ^1H NMR spectroscopy and mass spectrometry, demonstrating the presence of keto–enol tautomerism (acetone, −60 to 40 °C).

Compounds **80** have been prepared in 46%–100% yields[135] upon the following transformation:

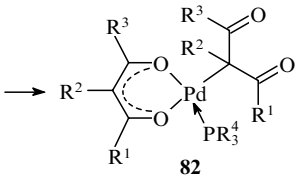


Other complexes with the structure of compound **16** have been discussed in reviews.[16–18, 136] Complexes with the structure of chelate **18** have been reported.[17, 18, 137]

The general method for the synthesis of complexes with the structure of chelate **23** is based on the reactions of β-diketonates **8** (M = Pt, Pd, Au) with organic amines and phosphines.[2, 3, 17, 18, 138, 139] This approach has received the most study in relation to the transformation of palladium diketonate **81** into complex **82**.[139–144]



81

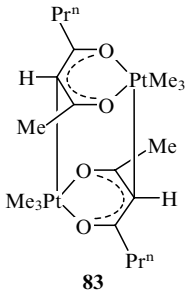


82

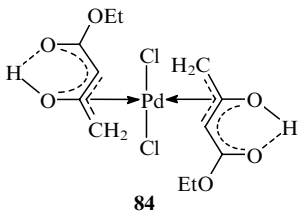
R^1–R^4 = H, Alk, Ar.

The M—C coordinated β-diketonate fragment is a part of trinuclear complexes $M[PtCl(acac)(acac\text{-}C^3)]_2$ where M = Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}, Pd^{II}, Cu^{II}, Zn^{II}, Cd^{II}, VO and UO_2.[17, 18]

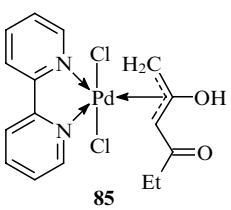
Other possible modes of coordination of β-diketone ligands have been confirmed experimentally,[16–18, 124] namely, C—O coordination as in chelate **22**; η^2(C,C′)- and μ^1(C)-coordinations in complex **83**; η-allylic coordination in complexes **84** and **85**; η^3(O,O′)-bridging coordination in complex **86**; and η^3(C,O)-bridging coordination in complex **87**.



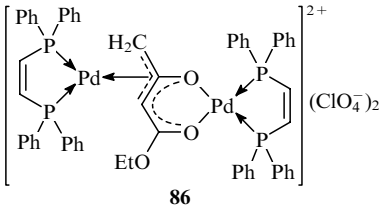
83



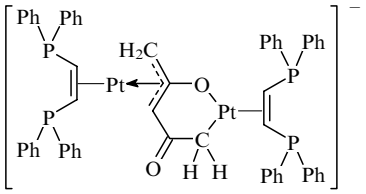
84



85

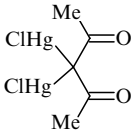


86



87

Binuclear compound **88** with the C—M-coordination, as in structure **19**, has been described and structurally characterised.[145]



88

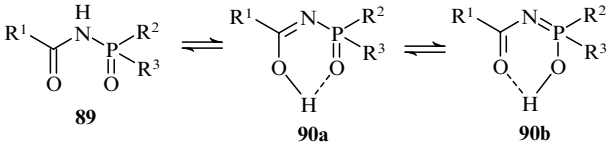
The compound **88** is the only example of a binuclear C-coordinated complex of β-diketone.

III. Modified β-diketonates

β-Diketone ligands are modified by altering the C—C—C fragment or replacing the oxygen atoms by N-, P-, S- and Se-donor centres. This gives rise to diverse ambident ligand systems. N,P-Containing analogues of β-diketones and chalcogen-substituted derivatives **3** (A = CR, D = PR^1R^2; X, Y = O, S) have been studied during the last decade.

1. N,P-Substituted β-diketonates

Among the potential polydentate ligands with N,O-donor centres, noteworthy are *N*-carbacylphosphoramidates (CAPh) **3** (A = CR, D = PR_2, X = Y = O), which have become readily available owing to the phosphazo reaction developed by Academician Kirsanov and co-workers.[146] Since CAPh are weak NH-(compound **89**) or OH-acids (compound **90**), they are able, similarly to β-diketones, to enter into the metal coordination sphere in either the deprotonated or the neutral form.[147]



89 **90a** **90b**

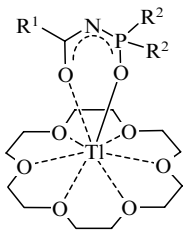
R^1, R^2, R^3 = Alk, Ar, Het.

The complexes with CAPh, like β-diketonates, exist most often as structure **4** (A = CR, D = PR^1R^2, X = Y = O). This structure was proved for thallium complex **91** prepared by the following transformation (the crown ether was used to restrict the susceptibility of Tl^+ complexes to di- and polymerisation).[148]

$$Tl_2CO_3 + 2\,HL + 2\,(18\text{-crown-}6) \longrightarrow$$

$$\longrightarrow 2\,Tl(18\text{-crown-}6)L + CO_2\uparrow + H_2O$$

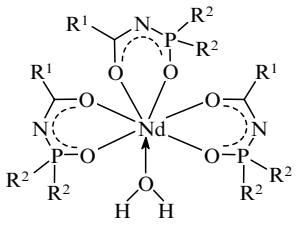
91



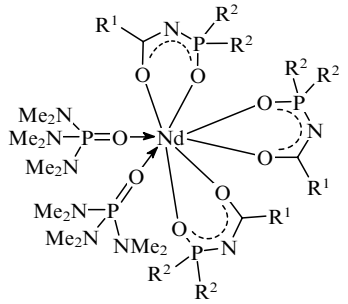
91: $R^1 = CCl_3$, $R^2 = OMe$

Structures of this type are widely represented in the series of lanthanide complexes.

In most lanthanide complexes, CAPh in the acid form is coordinated in the O,O′-bidentate mode (structures of chelates **4**, **8**). This was shown by X-ray diffraction[147] for neodymium complexes **92** and **93**.

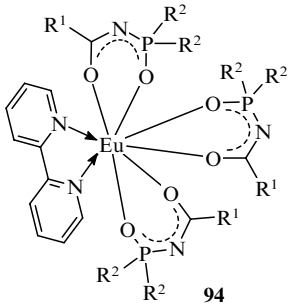


92: $R^1 = CCl_3$, $R^2 = N(C_2H_4)_2O$

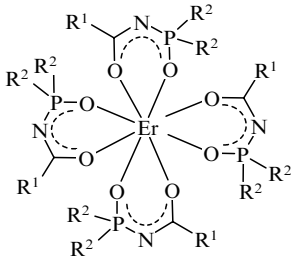


93: $R^1 = CCl_3$, $R^2 = OMe$

Complexes $LnL_3 \cdot Q$ with CAPh ligands, for example, **94** [$R^1 = CCl_3$; $R^2 = N(C_2H_4)_2O$, OPh, OMe; Q is α,α′-bipyridyl or 1,10-phenanthroline] have been prepared and structurally characterised.[149, 150]



94



95

In the anionic complex of erbium **95**, the ligands are also coordinated in the bidentate chelating mode through the oxygen atoms of the phosphoryl and carbonyl groups.[151–153]

The homoligand anionic tetrakis-complexes M[LnL_4] with the ester type CAPh ligands have been synthesised from methanolic solutions in the following way:[151]

$$LnA_3 + 4\,NaL \longrightarrow Na[LnL_4] + 3\,NaA$$

A = Cl^-, NO_3^-.

Heteroligand cationic complexes of lanthanides have been prepared by metal exchange[2,3] from the sodium salt of *N*,*N*′-tetraethyl-*N*″-trichloroacetylphosphortriamide (NaL):[154]

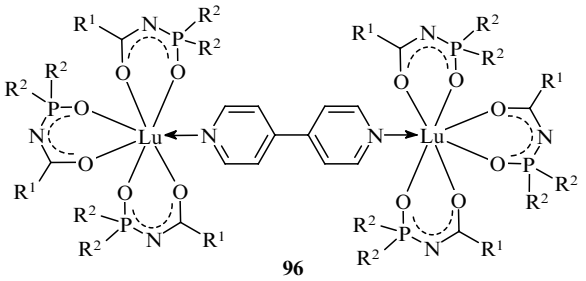
$$Ln(NO_3)_3 + (3-n)\,NaL + m\,HMPA + n\,NaBPh_4 \longrightarrow$$

$$\longrightarrow [LnL_{3-n}(HMPA)_m](BPh_4)_n + 3\,NaNO_3\downarrow$$

$m = 2, 4$; $n = 1, 2$.

The synthesis was carried out in isopropyl alcohol in the presence of a dehydrating agent, ethyl orthoformate. According to electronic spectroscopy, the coordination polyhedron is a distorted octahedron.

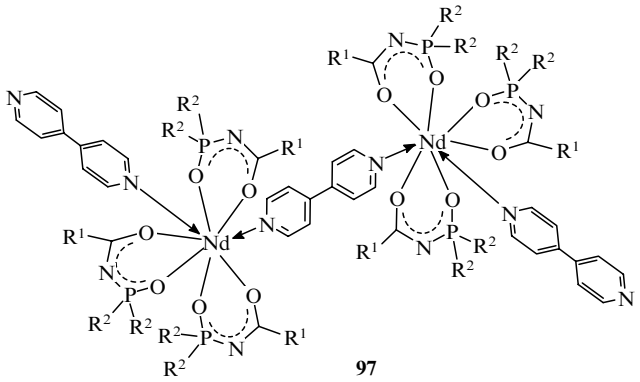
The deliberate synthesis of binuclear complexes of lanthanides proceeds successfully when coordinatively unsaturated tris-complexes are used as structural elements and potential bridging ligands. For example, in the case of γ,γ′-bipyridyl, compounds of the type $(CAPh)_3Ln(\gamma,\gamma'\text{-bipy})Ln(CAPh)_3$ (**96**) were obtained;[155] in these products, the central atom is heptacoordinated, being O,O′-chelated by the ligand (structure **4**).



96

$R^1 = CCl_3$, $R^2 = OMe$.

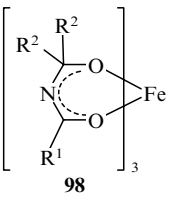
The influence of the nature of the central lanthanide atom on the composition and structure of its complexes with these ligands was demonstrated in relation to $Nd_2(CAPh)_6(\gamma,\gamma'\text{-bipy})_3$ (**97**).[147] In this case, neodymium is octacoordinated.



97

$R^1 = CCl_3$, $R^2 = NEt_2$.

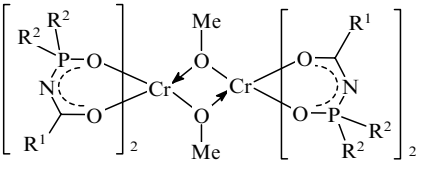
The structure of chelate **4** (or **8**) is characteristic of CAPh complexes with transition metals, for example, the complex with iron(III) (**98**).[156]



98

$R^1 = CCl_3$, $R^2 = NEt_2$, $N(C_2H_4)_2O$.

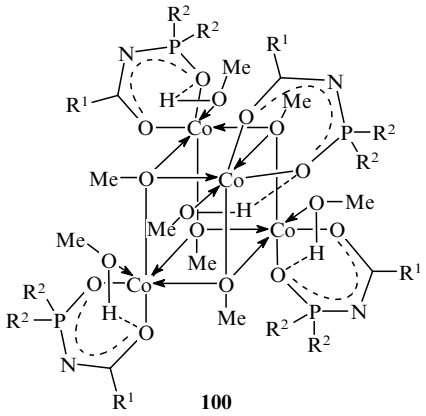
These compounds are known as not only monomeric (**98**) but also bi- and oligonuclear structures. Oligomerisation of the coordination polyhedra can take place by coordination of simple fragments such as alkoxy groups by the metal. For example, in the structure of dimeric chromium(III) complex (**99**), deprotonated CAPh ligands are coordinated in the bidentate chelating mode, the bridging functions being performed by two alkoxyl groups.[157]



99

$R^1 = CCl_3$, $R^2 = OMe$.

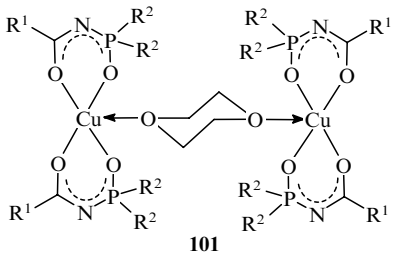
Cobalt and nickel complexes crystallise as tetramers **100** with the composition $Me_4L_4(OMe)_4(HOMe)_4$ in which the tetramer core is formed by four Co atoms and by four O atoms of the methoxy groups.[147]



100

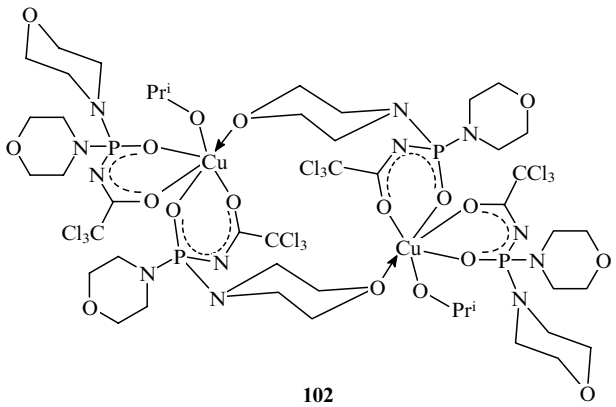
$R^1 = Ph$, $R^2 = NEt_2$.

Dioxane molecules and morpholine substituents can also function as bridges; this gives rise to dimeric copper(II) complexes **101** and **102** and polymeric complexes **103**.[158]

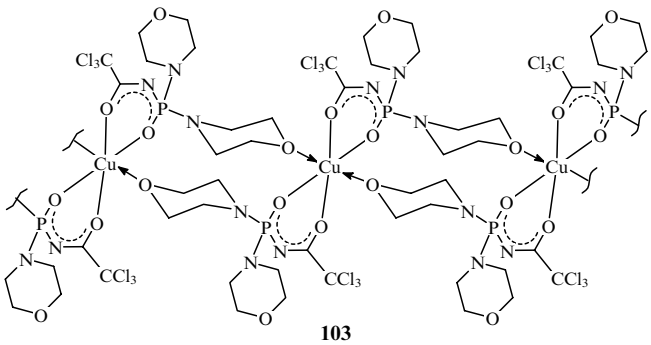


101

$R^1 = CCl_3$, $R^2 = NEt_2$.



102



103

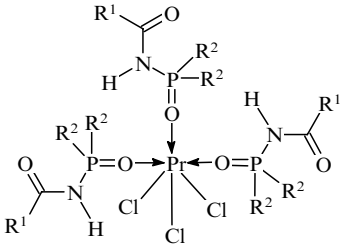
In the complexes of neutral CAPh with lanthanides, the ligand is monodentate, being coordinated through the oxygen atom of the phosphoryl group (similarly to structure **6**). These compounds

are prepared by direct reactions of the ligands (HL = CAPh) with lanthanide salts.[159]

$$LnA_3 \cdot n\,H_2O + 3\,HL \longrightarrow LnA_3(HL)_3 + n\,H_2O$$

A = Cl^-, NO_3^-.

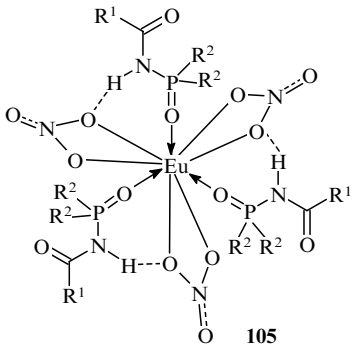
In the case of complex $PrCl_3(HL)_3$, the *fac*-isomer **104** has been isolated; its structure was proved by X-ray diffraction.[160]



104

$R^1 = CCl_3$, $R^2 = NEt_2$.

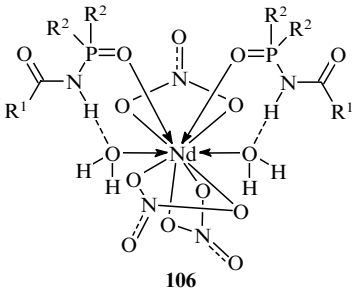
The nitrate groups in the compound $Eu(NO_3)_3(HL)_3$ (**105**), which is similar to complex **6** in structure, are arranged in three mutually perdicular planes due to the directing action of the intramolecular hydrogen bonds.[161, 162]



105

$R^1 = CCl_3$, $R^2 = NEt_2$.

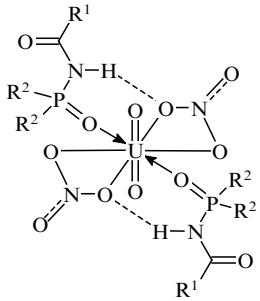
The synthesis of complex $Nd(NO_3)_3(HL)_2(H_2O)_2$ (**106**) can be considered as an example of supramolecular self-organisation,[163, 164] whose driving force is the formation of hydrogen bonds with participation of the NH proton.[165]



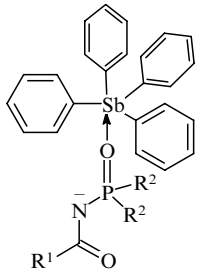
106

$R^1 = CCl_3$, $R^2 = N(C_2H_4)_2O$.

The supramolecular self-organisation typical of complexes formed by neutral CAPh (structure **6**) is manifested in the coordination compounds of uranyl $UO_2(NO_3)_2(HL)_2$ (**107**) in which the coordination polyhedron is a hexagonal bipyramid. The equatorial oxygen atoms are arranged in a virtually ideal plane.[166]



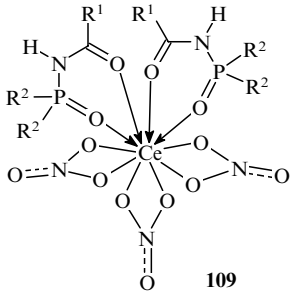
107: $R^1 = CCl_3$, $R^2 = NEt_2$



108: $R^1 = CCl_3$, $R^2 = OMe$

The monodentate coordination with participation of the phosphoryl oxygen atom has been established by X-ray diffraction also for the antimony complex **108**.[147]

The coordination compound $Ce(NO_3)_3(HL)_2$ (**109**) is the first example of bidentate chelating coordination of neutral CAPh (as in chelate **10**) realised through the phosphoryl and carbonyl oxygen atoms.[167]



109

Among the coordination compounds of CAPh, structures with tridentate ligands similar to chelate **11** are represented rather widely. These include, in particular, complexes of Group IA metals.

Compounds of complex-forming alkali metals with some CAPh can be prepared in high yields by direct reaction of the ligands with metal salts in aqueous alcohols, for example:[147]

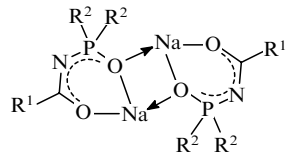
$$2\,HL + M_2CO_3 \longrightarrow 2\,ML + CO_2\uparrow + H_2O$$

M = Na, K, Rb, Cs.

Metal complexes with CAPh are also prepared by the reaction of ligands with the alkoxides of complexing metals in alcohols.[168–174]

$$HL + MOR \longrightarrow ML + HOR$$

The sodium and thallium complexes M_2L_2 crystallise as centrosymmetrical dimers **110**,[147] formed through the bridging oxygen atoms of the phosphoryl groups (the coordination mode is the same as in chelate **11**).



110

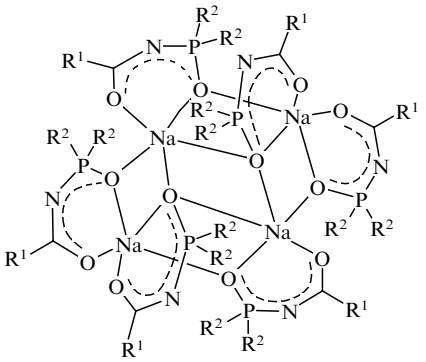
$R^1 = CCl_3$, $R^2 = OMe$.

The tendency of CAPh to form associates has been demonstrated in relation to the synthesis of the anionic $(PPh_4)_2[Na_4L_6]$ (**111**) complex [147] carried out in anhydrous acetonitrile.

$$2\,(PPh_4)Br + 6\,NaL \longrightarrow (PPh_4)_2[Na_4L_6] + 2\,NaBr\downarrow$$

111

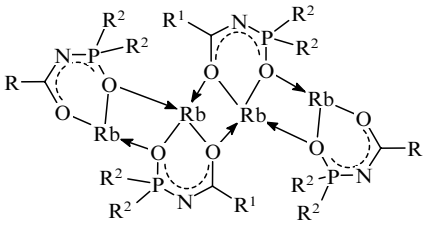
Compound **111** contains two tetraphenylphosphonium cations and the $[Na_4L_6]^{2-}$ anion. The complex anion is composed of four sodium ions connected to one another by bi- and tridentate bridging oxygen atoms of the phosphoryl groups of the ligands (the coordination mode is the same as in chelate **12**).



111

$R^1 = CCl_3$, $R^2 = OMe$.

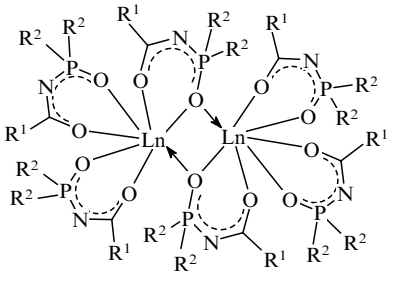
The unit cell of complex Rb_4L_4 (**112**) contains four Rb^+ ions linked by bridging oxygen atoms of the phosphoryl and carbonyl groups,[147] *i.e.*, the mode of coordination is the same as in chelate **11**.



112

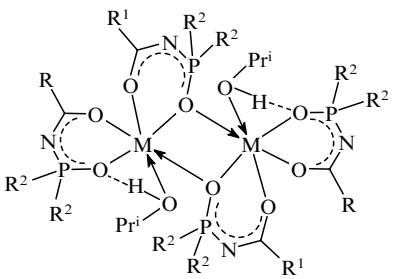
112: $R^1 = CCl_3$, $R^2 = OMe$.

The structures with mixed coordination of the ligands, similar to chelates **4** (or **8**) and **11**, are also encountered [147, 173] both in lanthanide complexes **113** and in cobalt(II) and nickel(II) complexes **114**.[175, 176]



113

$R^1 = CCl_3$, $R^2 = NEt_2$.



114

$R^1 = CCl_3$, $R^2 = OMe$; $M = Co^{2+}$, Ni^{2+}.

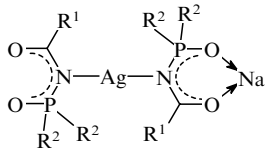
The complexes **113** were prepared in the following way:

$$2\,Ln(NO_3)_3 + 6\,NaL \longrightarrow Ln_2L_6 + 6\,NaNO_3\downarrow$$

Ln = La, Ce – Nd, Sm – Yb, Y.

Only one complex of CAPh with ligand coordination similar to that observed in compound **16** is currently known. The structure of this complex was proved by X-ray diffraction. This is the silver complex $Na[AgL_2]$ (**115**) prepared by metal exchange from acetonitrile solutions.[147]

$$2\,NaL + AgNO_3 \longrightarrow Na[AgL_2] + NaNO_3\downarrow$$



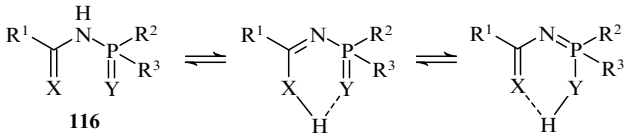
115

115: $R^1 = CCl_3$, $R^2 = OMe$.

The coordination of CAPh in this case can be compared with C-coordination of β-diketones, for example, the coordination found in compound **78**.[2, 3]

2. Metal complexes of N,P-derivatives of thio- and bisthiodiketones

The ligand systems and complexes in which structural analogues of β-diketones containing the XCNPY fragment (X = S, Y = O; X = O, Y = S; X = Y = S; X = O, Y = Se; X = Se, Y = O) are present as ligands in the coordination sphere (**116**, **117**) have been surveyed in sufficient detail.[177, 178]

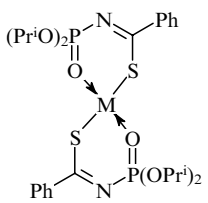


116 **117a** **117b**

X, Y = O, S, Se; R^1, R^2, R^3 = Alk, Ar, Het.

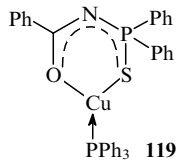
The metal complexes **116** and **117** mainly exist as structures **4** (A = CR; D = PR^1R^2; X, Y = O, S), which are classical for β-diketonates (chelates **8**). The structures of complexes **118** – **126** were confirmed by X-ray diffraction; these compounds are described below.

The synthesis and structure of copper and lead chelates ML_2 (**118**) with *N*-diisopropoxyphosphorylthiobenzamide (the MO_2S_2 coordination unit), characterised by a square planar and tetrahedral environments of the central atom, respectively, have been reported.[179, 180] The Cu^{2+} complexes were obtained from malachite (basic copper carbonate) in solutions of *N*-(thio)phosphorylated thioamides followed by reprecipitation from benzene with hexane. The Pb^{2+} compounds were synthesised by the reactions of alkali metal salts of the ligands dissolved in aqueous alcohols with lead salts or oxides.



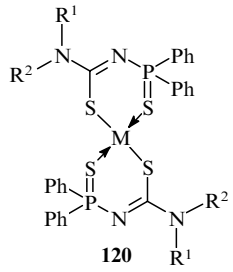
118: M = Cu, Pb

A bidentate O,S-coordination has also been found for copper(I) chelate **119**.[181]



119

A number of studies are devoted to complex compounds containing the MS_4 coordination unit (structure **4**: A = CR, D = PR_2, X = Y = S). The syntheses of cobalt, nickel and palladium chelates with S-donor ligands of the type $R^1C(S)NHP(S)R^2_2$ were first described back in 1969.[182] The conclusions about the structures of the resulting compounds **120** were drawn from data of IR spectroscopy and magnetic chemistry (the square-planar environment for Ni^{2+}, Pd^{2+} and the tetrahedral environment for Co^{2+}).

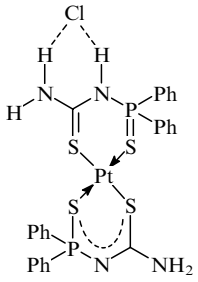


120

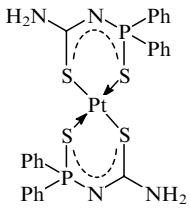
R^1 = Ph, R^2 = H; R^1 = R^2 = Et; M = Co, Ni, Pd.

Later on, data on the structure of an analogous nickel complex with *N*-(diphenylthiophosphoryl)methylthiourea (**120**, M = Ni) were documented.[183]

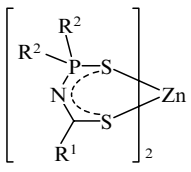
It should be emphasised that the reaction of platinum(II) chloride with diphenylthiophosphorylthiourea in CH_2Cl_2 results in complex **121**, whose coordination sphere contains bidentate chelating ligands coordinated in either deprotonated (structures **4**, **8**) or neutral (structure **10**) form. The exchange reaction of platinum(II) or zinc(II) chloride with the potassium salt of the ligand gives the usual chelates with square planar (**122**) and tetrahedral (**123**) structures, respectively.[181]



121

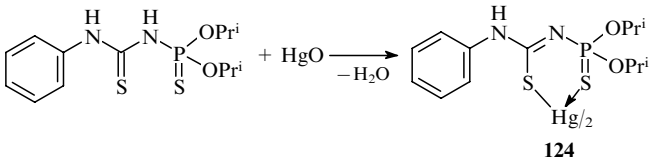


122



123

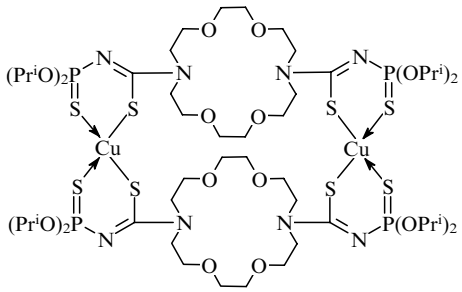
The reaction of *N*-(diisopropoxythiophosphoryl)thiobenzamide with mercury oxide in organic solvents gives mercury chelate **124**.[184]



124

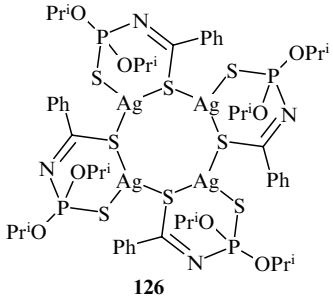
The central mercury atom in complex **124** forms a distorted tetrahedral environment.

On the basis of EPR and electronic spectroscopy studies, structures have been proposed for binuclear copper complexes (**125**); in addition, the electrochemical behaviour of these complexes has been studied.[185, 186]



125

A method for the synthesis has been described and X-ray diffraction analysis has been performed for the tetrameric Ag(I) complex **126** in which the ligands are coordinated in the same way as in structure **11**.[187]

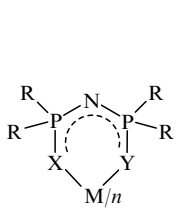


126

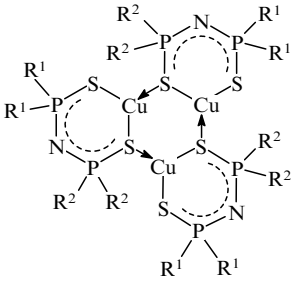
The formation of this tetramer is due to the presence of lone electron pairs at the donor sulfur atoms in mononuclear complexes, for example, in **121**–**123**. This is also quite usual for classical β-diketonates.[21, 188]

3. Coordination compounds of the N,P,P-derivatives of β-diketones and their chalcogen-containing analogues

Like the coordination compounds addressed in the preceding Sections, complexes of azobisphosphorus-containing analogues of β-diketones (their tautomers correspond to structures **89**–**91**, **116**, **117**) are represented, most often, by chelates with structure **4** (A = D = PR_2; X = O, Y = S, Se; X = S, Y = S, Se).[189–199] The structures **127** can be found in the six-membered chelates of indium,[189] palladium,[190, 195] platinum,[190] zinc[190] and cadmium.[190]



127



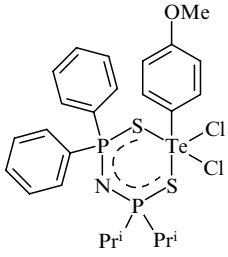
128: R^1 = Pr^i: R^2 = Pr^i, Ph, OPh

Of particular interest is the fact that the indium[189] and palladium[194] complexes were prepared directly from the corresponding zerovalent metals (synthetic strategies of this type are widely used in modern coordination chemistry[2, 3]).

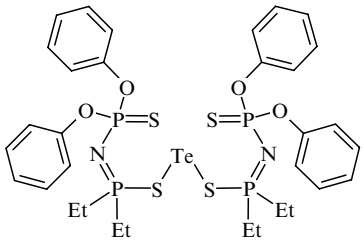
Other modes of coordination are also known for complexes of these ligands. For example, in the case of platinum complexes, in addition to the coordination as in chelate **4** (**127**: X = O, Y = S), a structure with monodentate S-coordination of the metal atom is also formed.[195] A similar structure has been found for the gold complex,[195] which could be expected in terms of Pearson's HSAB principle (in view of the softness of the metals in question).[2, 3, 125, 126]

According to X-ray diffraction data, the trimeric copper complexes synthesised from compound **3** (A = D = PR_2, X = Y = S) and $CuCl_2$ in methanol occur as structure **128**[196] with the same coordination mode of the metal as found in chelate **11** .

In relation to the problem of competitive reactivity of ligands **3**, tellurium complexes are of interest.[197, 198] Not only tellurium complexes with a ligand coordination usual[20–24] for chelates, as in **127** (M = Te; X = S; Y = Se; n = 2) and **129**, have been described, but also complexes with the monodentate ligand bound through the S-donor centre at the phosphorus atom. This type of ligand coordination is embodied in structure **4** (A = D = PEt_2; X = Y = S).



129



130

Complex **129** is of interest due to the fact that, according to X-ray diffraction data, the tellurium central atom is pentacoordinated, whereas in **130**, the same complex-forming element has a coordination number equal to two.

In conclusion, we would like to note that the material covered in this Section can be substantially extended by the data reported in the recent publication.[198]

IV. Conclusion

In writing this review, we have not set ourselves the task of embracing all the possible methods for the preparation of metal complexes of β-diketonates and their analogues. For example, we did not consider the coordination compounds of mono- and disubstituted nitrogen analogues of β-diketones, namely, β-aminovinyl ketones (**1**: A = E = D = CR^1; X = O; Y = NR^2) and β-aminovinylimines (**1**: A = E = D = CR^1; X = Y = NR^2), which have been studied rather comprehensively (see, for example, an exhaustive review [11]). All the complexes described in that review are chelates coordinated in the same manner as in chelate **2** (A = E = D = CR^1; X = O, NR^2; Y = NR^2). Meanwhile, in view of the data [10, 200] attesting to different modes of coordination of Schiff's bases in metal chelates (bidentate N,O-chelation by the anionic form of the ligand) and in molecular complexes (O-monodentate coordination of the neutral ligand), one should expect the formation of various types of complexes also for β-aminovinyl ketones and β-aminovinylimines.

This situation is typical of fairly well-known metal chelates of mono- and dithio-β-diketones (**1**: A = E = D = CR; X = O, Y = S; X = Y = S)[2, 3] and phosphorus-containing analogues of β-diketones (**1**: A = E = CR; D = PR_2; A = D = PR_2, E = CR; X, Y = O, S, Se).[12]

The material outlined in this review indicates that a number of β-diketonate ligands can be coordinated according to different modes. Therefore, metal complexes of different types can be prepared. We hope that further research will bring new data on the complexation of such ligands and will thus contribute to the development of deliberate strategies for the synthesis of complex compounds with specified coordination units on the basis of typical chelating ligands.

This review was prepared with financial support from the Russian Foundation for Basic Research (Project NSh-945.2003.3).

Abstract. Theoretical and experimental data on the synthesis, structure, properties and applications of phosphate tungsten bronzes accumulated to date are systematised. Attention is focussed on interrelations between structural features and electrophysical properties of these compounds. Prospects for practical applications of phosphate tungsten bronzes are discussed. The bibliography includes 138 references.

I. Introduction

Recently, interest in macroscopic quantum phenomena such as superconductivity and laser effect has grown rapidly. Research into and application of these phenomena introduces fundamental concepts of quantum mechanics into everyday life.[1,2] Intensive studies of oxide bronzes (low-dimensional metallic conductors) have been carried out in the last ten to fifteen years. This is, in particular, due to the fact that these compounds possess macroscopic quantum properties, *e.g.*, electronic instabilities responsible for initiation of spin density waves (SDW) and charge density waves (CDW).[3–8]

The term 'oxide bronzes' was introduced by Friedrich Wohler in 1824 to name a series of oxide compounds of tungsten. Currently, the term is used for crystalline compounds of general formula M_xEO_n, where M is usually an alkali metal and E is a transition metal. Characteristic of the oxide bronzes are intense colour and metallic luster. These compounds can possess metallic or semiconducting properties. Usually, bronzes retain the structure of the starting oxide EO_2 or EO_3 when the element E can be in an oxidation state of less than 4 or less than 6, respectively, and are characterised by certain homogeneity regions.[9] Electrons of the dopant cations inserted into the starting oxide can be delocalised over the entire structure, thus being responsible for the onset of metallic-type conductivity. The semiconducting properties are due to the interaction of polyvalent metal ions through bridging oxygen atoms.

Oxide bronzes can exhibit high anisotropy (low dimensionality) of electronic conductivity owing to peculiarities of their crystal and electronic structures. For quasi-one-dimensional compounds the conductivity along a particular crystallographic direction is several orders of magnitude higher than along two other directions while for quasi-two-dimensional compounds the conductivities along two particular crystallographic directions are several orders of magnitude higher than the conductivity along the third direction. The crystal structures of the oxide bronzes represent three-dimensional frameworks; because of this, the dimensionality of electronic conductivity can be lower than the dimensionality determined from crystallographic data.

Many transition metal oxides (among them, superconducting copper oxides are best known) possess low-dimensional properties. This also holds for both molybdenum and tungsten oxide bronzes which undergo transitions to the CDW state.[10,11] Minor variations of thermodynamic parameters (temperature, pressure, chemical potential, *etc.*) can cause significant changes in the physical properties of compounds. Because of this 'thermodynamic susceptibility' these inorganic materials can serve as model objects in studies of various instabilities.

The available models for mechanisms of the onset of CDW are inadequate. Therefore, systematic studies are carried out of CDW in compounds which exhibit low-dimensional electrophysical properties but have different compositions and structures. Among the widely used model objects are the phosphate tungsten bronzes containing perovskite-type layers built of ReO_3-type corner-sharing WO_6 octahedra separated by layers comprised of monophosphate groups or diphosphate units. Redistribution of the electron density between the phosphate groups and the layers of WO_6 octahedra in the phosphate tungsten bronzes gives rise to a partially filled conduction band composed of hybridised p- and d-AOs. These structural features are also responsible for the metallic conductivity of bronzes and for two kinds of electronic instabilities, namely, Peierls transitions leading to the CDW state [12–18] and the superconducting state instabilities.[18,19]

II. Methods of synthesis

At present, three main groups of the phosphate tungsten bronzes are known. These are the monophosphate tungsten bronzes (MPTBs) of general formula $A_x(PO_2)_4(WO_3)_{2m}$ with pentagonal (MPTBp) [20–23] or hexagonal (MPTBh) [24,25] structural channels and the diphosphate tungsten bronzes (DPTBs) of general for-

mula $A_x(P_2O_4)_2(WO_3)_{2m}$ (A is a vacancy or a monovalent or divalent cation) with hexagonal channels (DPTBh).[26, 27] Studies on phase formation in the systems $P_2O_5-WO_3-W$ and $A_2O-P_2O_5-WO_3-W$ began in the 1980s in connection with the search for new functional materials for semiconductor electronics.[28–34]

It should be noted that the phosphate tungsten bronzes are prone to form the intergrowth phases. This trend becomes more pronounced as the parameter m increases. Therefore, the MPTBp compounds with $m > 14$, MPTBh compounds with $m > 7$ and DPTBs with $m > 10$ have not been synthesised as regular single crystals.

1. Synthesis of polycrystals

Polycrystalline powders and small single crystals of a number of the phosphate tungsten bronzes were first obtained by solid-state reactions starting from tungsten trioxide, acid ammonium orthophosphates of different degree of substitution and metallic tungsten taken in the stoichiometric ratio. Here, choosing an optimum regime of synthesis of compounds of specified compositions is a challenge. Usually, the interaction of reagents involves two stages, (1) melting of tungsten trioxide with ammonium orthophosphate monohydrate in the temperature range 573–890 K for 24–48 h[20, 22, 24, 27] to form some intermediate ammonium-containing compounds and low-melting glasses[35] and (2) interaction of the product obtained with fine-grained tungsten powder at temperatures 1000–1473 K in inert atmosphere (evacuated ampoules) over a period of several weeks. In most cases the starting components are taken in a ratio that provides the desired stoichiometry of the reaction product. This technique permits the synthesis of powders and small crystals of good quality, which are often used for growth of single crystals.[36, 37]

Reduction by transition metals (in particular, tungsten) in multicomponent oxide systems is a nonequilibrium process. This leads to coexistence of the regions suitable for crystallisation of individual compounds and broad heterogeneous-heterophase regions in which co-crystallisation of several phases occurs in narrow temperature and concentration ranges.[25, 38, 39] The compositions of the compounds formed in multicomponent oxide systems strongly depend on the synthesis conditions, *i.e.*, the ratio of the starting reagents, their dispersion, temperature, presence of temperature gradients, duration of the reaction and on the presence of modifiers.

Unfortunately, no optimised general methods of preparation of polycrystalline phosphate tungsten bronzes are available as yet. It should be noticed that often crystallisation of compounds differing in composition and structure occurs under identical experimental conditions.

2. Growth of single crystals

One of the most widely used methods of growth of single crystals of the phosphate tungsten bronzes involves the use of various transport reactions (in the presence of temperature gradients) in the temperature range from 850 to 1473 K. Using this technique, it is possible to grow high-quality single crystals with typical dimensions $(1-3)\times(0.6-3)\times(0.1-0.75)$ mm over a period of one to three weeks.[40, 41] Here, the role of the transporting agents can be played by iodine, phosphorus pentaoxide and by the ammonium and some alkali metal iodides, bromides or chlorides. The method was optimised to obtain the following members of the MPTBp family: $(PO_2)_4(WO_3)_4$, $(PO_2)_4(WO_3)_8$ and $(PO_2)_4(WO_3)_{12}$.[42–44]

The possibility of control of chemical transport reactions using methods of chemical thermodynamics[45] (in particular, using the CVTRANS program package[46]) make this single-crystal growth technique attractive for both laboratory and large-scale applications.

Flux growth of crystals of phosphate tungsten bronzes using low-melting phosphate–tungsten and phosphate–tungstate–molybdate systems[38] and complex fluxes containing a glass-forming component (*e.g.*, SiO_2 and GeO_2[21, 38, 47, 48]) was found to be less promising owing to uncontrollable inclusion of impurities that deteriorate the electrophysical properties of materials.

At present, there are many methods of synthesis of polycrystals and single crystals of MPTBp compounds which crystallise in the form of plane-parallel plates with high reflectivity. Tables 1 and 2 list the synthesis conditions and characteristics of a number of MPTBp crystals.[49–55]

Table 1. Synthesis conditions and characteristics of $(PO_2)_4(WO_3)_{2m}$ crystals with $m = 2$ and 4.

m	Starting components	Synthesis conditions	Crystal colour, habit, size /mm	Ref.
Conditions for solid-phase synthesis of polycrystals				
2	$WOP_2O_7 + W$ (1 : 2)	1573 K	blue plates	49
4	$(NH_4)_2HPO_4 + WO_3 + W$ (see [a])	873 K, 1223 K (48 h), 1273 K	purple plates	50, 51
4	$(NH_4)_2HPO_4 + WO_3 + W$ (see [a])	1173 K, 1250 K	red plates	22
Conditions for synthesis of single crystals				
2	$P_2O_5 + W + WO_3$ (see [a])	heating of furnace from 873 to 1473 (1523) K for 6 h, storage for four days	dark brown plates, $2\times0.75\times0.2$	52
2	$P + WO_3$ (see [a, b])	1273–1173 K	maroon	43
2	$P_2O_5 + W + WO_3 + SiO_2$ (5 : 3 : 3 : 2)	1523 K (two or three days), 1373 K	maroon plates, $0.12\times0.09\times0.05$	21, 38
4	$(NH_4)_2HPO_4 + WO_3 + W$ (see [a])	heating from 873 to 1273 K at a rate of 200 K h^{-1}, two-zone furnace 1473/1273 K (a week), cooling down to 298 K	purple plates, $3\times3\times0.2$	50, 51
4	$(NH_4)_2HPO_4 + WO_3 + Tl_2CO_3 +$ + W (see [c])	573 (24 h), two-zone furnace, 1343 K (hot zone), $\Delta T = 130$ K (see [d])	purple plates, $1.5\times0.6\times0.3$	52

Note. Here and in Tables 2, 3 in the column 'Synthesis conditions' we present the parameters of the heat treatment regimes, *viz.*, temperatures and durations of corresponding stages (in parentheses). At the first temperature (often, the time of stay at this temperature is not reported in the original studies), the mixtures of the metal trioxide and metal phosphate (in some cases) and metal carbonate (in other cases) were initially heated. At the second temperature, metallic tungsten was added and the system was kept until complete interaction between the metal and other components. At the third temperature, particular bronzes were synthesised (cooling is accompanied by bronze crystallisation).

[a] The starting reagent ratio was calculated with respect to the stoichiometry of the reaction product. [b] Obtained with 0.5 mol.% I_2 as transporting agent. [c] Calculated with respect to the stoichiometry of the compound $TlP_4W_4O_{20}$; obtained with 5 mol.% KI as transporting agent. [d] ΔT is the temperature difference between the hot and cold zones.

Table 2. Synthesis conditions and characteristics of $(PO_2)_4(WO_3)_{2m}$ crystals with $m > 4$.

7	$(PO_2)_4(WO_3)_{12}$ (see [b])	873 K (10 h), 873 K, two-zone furnace, 1473/1273 K (a week), cooling down to 600 K	purple plates, $0.69 \times 0.15 \times 0.075$	54
10	$(PO_2)_4(WO_3)_{20}$ (see [b])	two-zone furnace, 1473/1273 K (two weeks), $\nabla T = 10$ K cm^{-1} (see [c]), cooling down to 600 K	black plates, $1.5 \times 0.5 \times 0.3$	55
12	$(PO_2)_4(WO_3)_{24}$ (see [b])	two-zone furnace, 1473/1273 K (two weeks), $\nabla T = 10$ K cm^{-1} (see [c])	blue plates, $0.125 \times 0.07 \times 0.003$	51

[a] The ratio of the starting reagents was calculated with respect to the stoichiometry of the reaction product. [b] Recrystallisation from a mixture of compounds obtained by solid-phase synthesis. [c] ∇T is the temperature gradient.

3. Peculiar features of the synthesis of compounds $A_x(PO_2)_4(WO_3)_{2m}$ and $A_x(P_2O_4)_2(WO_3)_{2m}$

One of the most widely used methods of synthesis of compounds of the families $A_x(P_2O_4)_2(WO_3)_{2m}$ and $A_x(PO_2)_4(WO_3)_{2m}$ (Tables 3 and 4) is melting of stoichiometric mixtures of ammonium orthophosphates and tungsten trioxide (if A is a vacancy) and metal carbonates (if A is a monovalent or divalent metal) followed by interaction of the glass obtained with metallic tungsten in inert atmosphere.

The use of the flux technique to obtain these compounds has some peculiar features because the glass formation region is limited and the reaction is carried out at the liquid–metal interface. It should be noted that high reactivity of melts towards the crucible materials at $1153 \leqslant T \leqslant 1270$ K causes enrichment of the system with silicates or aluminates. Therefore, the synthesis of pure phases and studies on phase formation in the systems in question become much more complicated. The phase diagrams of pseudoquaternary systems were constructed only for a few isothermal sections in narrow concentration ranges, *viz.*, $KWO_3-WO_3-PWO_5$,[25] $Li_xWO_3-WO_3-PWO_5$,[38] $Na_xWO_3-WO_3-PWO_5$,[38] $K_4P_8W_4O_{32}-P_8W_4O_{32}-Na_4P_8W_4O_{32}$ and $K_4P_4W_{12}O_{44}-P_4W_{12}O_{44}-Na_4P_4W_{12}O_{44}$.[40, 68] The phase diagrams of the two last-mentioned systems exhibit broad multiphase regions, which casts some doubt upon their correctness.

In addition to the classical method of synthesis (see above) there is a variety of methods based on the chemical or electrochemical intercalation of cations into the MPTBp or MPTB frameworks containing cations in the structural channels. A number of sodium- and lithium-containing derivatives were obtained using the redox reactions with such organometallic reducing agents as LiC_4H_9 and $NaC_{10}H_8$.[28] In this case filling of the perovskite-type cavities in the bronze structure by cations occurs in contrast to the high-temperature methods of synthesis. Using the simplest electrochemical cells, $(+)|A|AClO_4Y|[(PO_2)_4(WO_3)_{2m}/A_x(PO_2)_4(WO_3)_{2m}]|(-)$ (A = Li, Na; Y = propylene carbonate), it is possible to control the synthesis of materials with different degrees of filling of structural channels with cations and to perform ion exchange by simple charge–discharge cycles.[28] Intercalation of cations to obtain compounds of the $A_x(P_2O_4)_2(WO_3)_{2m}$ family can also be achieved *via* chemical vapour transport reactions. For instance, the $A_x(PO_2)_4(WO_3)_8$ crystals were synthesised by reactions of the Group Ia element or Tl(I) iodides with $(PO_2)_4(WO_3)_{2m}$.[69]

4. Peculiarities of phase formation in the systems containing inserted polyvalent metal cations

Recently, numerous studies aimed at obtaining phosphate tungsten bronzes modified by homovalent and heterovalent substitution have been carried out. The compositions and crystallographic parameters of a number of compounds obtained are listed in Table 5.

At present, the absence of the phosphate molybdenum bronzes similar in structure and properties to the phosphate tungsten bronzes is a paradox with no explanation, though mixed molybdenum–phosphate bronzes are known.

The use of molybdenum as the reducing agent in mixed nitrate–phosphate systems leads to formation of low-melting fluxes and to shift of the heat treatment regimes towards lower

Table 3. Synthesis conditions and characteristics of crystals $A_x(PO_2)_4(WO_3)_{2m}$ and $A_x(P_2O_4)_2(WO_3)_{2m}$ obtained by solid-phase synthesis [melting of the components $A_2CO_3 + (NH_4)_2HPO_4 + W + WO_3$ (A = Na, K, Rb, Cs) and $BaCO_3 + (NH_4)_2HPO_4 + W + WO_3$ taken in the stoichiometric ratios].

Composition	Starting components	Synthesis conditions	Crystal colour, habit, size /μm	Ref.
Conditions for solid-phase synthesis of polycrystals				
$Na_{1.4}(PO_2)_4(WO_3)_8$	$Na_2CO_3 + (NH_4)_2HPO_4 + W + WO_3$	773 K, 1173 K (three days)	light-brown with copper reflection needles, $30 \times 48 \times 456$	56
$Na_{2.2}(PO_2)_4(WO_3)_{12}$	$Na_2CO_3 + (NH_4)_2HPO_4 + W + WO_3$	773 K, 1173 K (three days)	purple needles, $48 \times 60 \times 380$	56
$Na_2(PO_2)_4(WO_3)_{2m}$ ($4 \leqslant m \leqslant 13$) and $Na_3(PO_2)_4(WO_3)_{14}$	$Na_2CO_3 + (NH_4)_2HPO_4 + W + WO_3$	873 K, 1273 K (few days)	–	57
$K_x(PO_2)_4(WO_3)_8$ ($0.75 \leqslant x \leqslant 2$)	$K_2CO_3 + (NH_4)_2HPO_4 + W + WO_3$	873 K (12 h), 1223 K (48 h), cooling down to 298 K	purple needles	58

temperatures (673 – 873 K). It should be noted that the phase crystallisation processes in the $A_2CO_3 - H(NH_4)_2PO_4 - WO_3(MoO_3)$ systems and the structure of the resulting are strongly dependent on the composition, structure and physicochemical features (namely, differences between the thermochemical properties of the starting oxides and the melts formed, the type of short-range order in melts and the size of clusters comprised of the MO_6 octahedra) of the glasses formed in these systems.[71–77] Usually, the use of complex systems leads to the formation of compounds with mixed frameworks that differ from the frameworks of the phosphate tungsten bronzes.[70–77]

For instance, a $Na_{1+x}(Mo_{0.15}W_{1.85})O_5(PO_4)$ phase was crystallised in the system $Na_2CO_3 - H(NH_4)_2PO_4 - WO_3 - Mo$ in the temperature interval 673 – 903 K.[74] The framework of this phase is comprised of infinite ribbons analogous to those observed in the monophosphate tungsten bronzes $(PO_2)_4(WO_3)_8$ (see Ref. 50) and

[a] Data of single-crystal X-ray diffraction studies.

$A_x(PO_2)_4(WO_3)_8$ (see Ref. 56) but the fashion in which the ribbons are connected by PO_4 tetrahedra and the shape of channels where the sodium atoms reside are different. One metal position in the MO_6 octahedra is occupied by tungsten atoms only while the other is occupied by the statistically disordered molybdenum and tungsten atoms.[74] The framework of the compound $K_{6.6}Mo_{2.36}W_{3.64}O_{15}(PO_4)_4$ is built of $[MO_5]_\infty$ (M = W, Mo) spiral chains with alternating *cis*- and *trans*-bonds M–O–M. The chains are connected through PO_4 tetrahedra.[72]

Most mixed molybdenum–tungsten phosphates contain isolated MO_6 octahedra or M_2O_{11} bioctahedra. These are, *e.g.*, compounds $Cs_5VW_4O_9VO_4(PO_4)_4$,[70] $Rb_2Mo_2WO_5(PO_4)_3$,[71] $Na_{0.75}(Mo_{0.42}W_{0.58})(Mo_{0.75}W_{0.25})O_3(PO_4)_2$ (Ref. 73) and $Li_{0.5}MoWO_3(PO_4)_2$.[75,76]

In contrast to molybdenum, niobium does form the niobium phosphate bronzes. This permits the synthesis of mixed bronzes $(Nb_{0.787}W_{0.213})_4O_4(PO_4)_4$ (see Ref. 78) and $K_{3.75}Nb_{8.5-x}.W_xO_{14}(PO_4)_4$.[79] At the same time, compounds of the family $A_x(NbW)_5O_9(PO_4)_3$ (A = Li, K, Rb and Cs)[80] obtained in the systems $A_2CO_3-H(NH_4)_2PO_4-WO_3-W-Nb_2O_5$ contain distorted perovskite-type layers in which some WO_6 octahedra are replaced by PO_4 tetrahedra.

III. Crystal structure

Unlike the oxide tungsten bronzes A_xWO_3 (A = Li, Na, K, Rb, Cs) (Fig. 1 *a–c*) containing three-dimensional frameworks built of WO_6 octahedra, two families of the phosphate tungsten

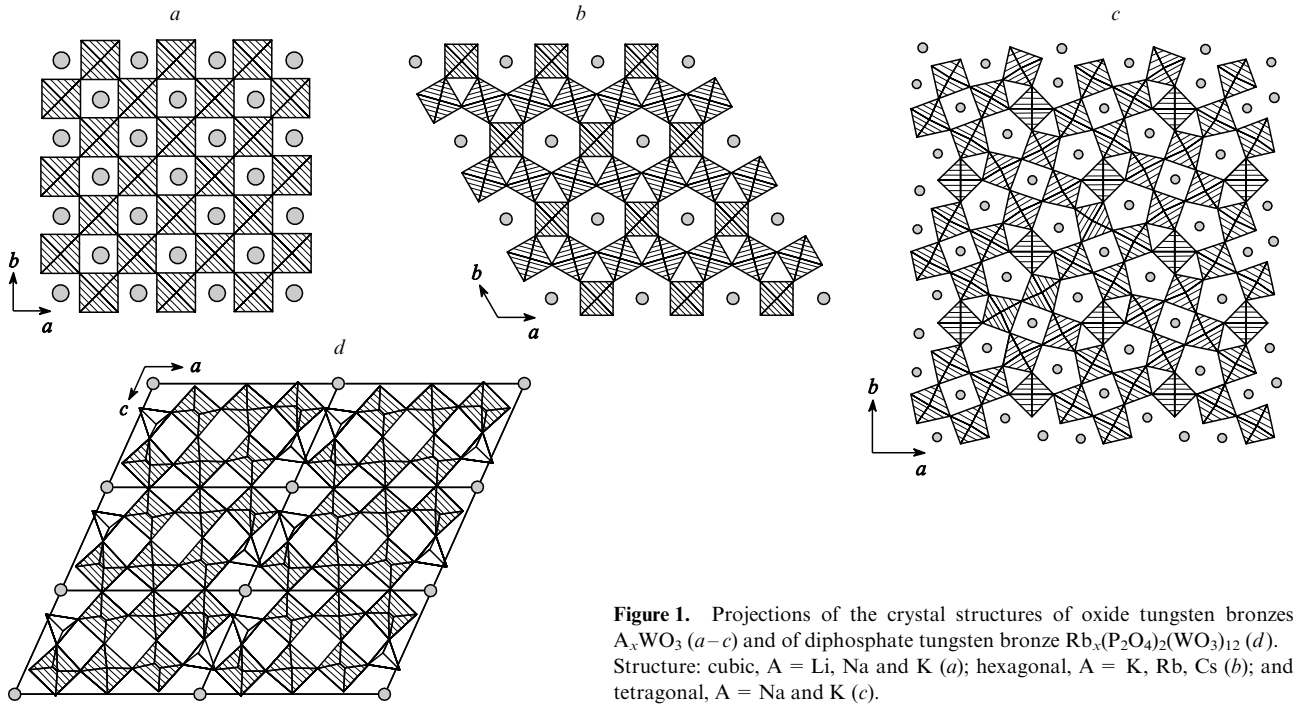

Figure 1. Projections of the crystal structures of oxide tungsten bronzes A_xWO_3 (*a*–*c*) and of diphosphate tungsten bronze $Rb_x(P_2O_4)_2(WO_3)_{12}$ (*d*). Structure: cubic, A = Li, Na and K (*a*); hexagonal, A = K, Rb, Cs (*b*); and tetragonal, A = Na and K (*c*).

bronzes, $A_x(PO_2)_4(WO_3)_{2m}$ and $A_x(P_2O_4)_2(WO_3)_{2m}$ (A is a vacancy or Na, K, Rb, Cs, Pb and Ba), contain chains or layers comprised of WO_6 octahedra connected by phosphate groups (see, *e.g.*, Fig. 1 *d*).

Because of (i) redistribution of the electron density in the mixed framework formed by the WO_6 octahedra and PO_4 tetrahedra and (ii) insertion of additional cations the oxidation state of the tungsten atoms in the phosphate tungsten bronzes usually varies between 5 and 6. Sharing of 4d electrons of the tungsten atoms and their delocalisation over the system of the W–O–W–O bonds lead to quasi-metallic electrophysical properties of the oxide and phosphate tungsten bronzes.[29,30]

The frameworks of the phosphate tungsten bronzes comprise corner-sharing WO_6 octahedra connected in the same manner as in the ReO_3-type cubic oxide tungsten bronzes (Fig. 2). In contrast to the oxide bronzes the perovskite-type blocks built of WO_6 octahedra in the frameworks of the phosphate tungsten bronzes are linked by PO_4 tetrahedra or by diphosphate units, P_2O_7. Depending on the value of the parameter *m*, these blocks can be chains (for the first members of each series with $m = 2$, see Fig. 3) or layers with the thickness increasing with *m*.

The frameworks of both the monophosphate and diphosphate tungsten bronzes containing perovskite-type layers are built based on similar principles. Namely, linear (DPTBs) or zigzag (MPTBs) slabs comprised of corner-sharing WO_6 octahedra are linked together to form infinite ribbons of composition W_mO_{4m+1} and W_mO_{4m+2}, respectively. The ribbons are connected in such a way

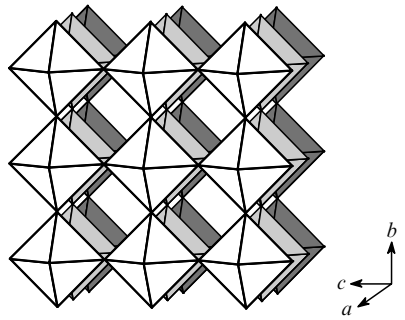

Figure 2. Structure of ReO_3.

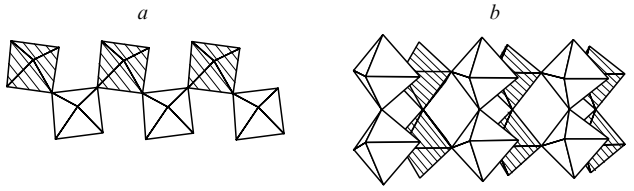

Figure 3. $(WO_5)_\infty$ chains in the structure of $(PO_2)_4(WO_3)_4$ (*a*) and $(WO_4)_\infty$ chains in the structure of $Rb_{0.5}(P_2O_4)_2(WO_3)_4$ (*b*).

that the first tungsten atom of each ribbon is bound to the third tungsten atom of the preceding ribbon through an axial oxygen atom. This results in the formation of perovskite-type layers containing corner-sharing octahedra only (the examples for $m = 4$ are shown in Fig. 4).

Usually, the layer thickness is expressed *via* the length of the linear chains of WO_6 octahedra and running along the directions of the perovskite crystallographic axes directed from the centre of an octahedron towards its vertices. The number of octahedra in two adjacent chains running along the $[001]_{per}$ axis (hereafter the subscript 'per' refers to the perovskite structure) is the same ($m/2$) for the even members of the series or differs by unity ($[(m+1)/2]$ and $[(m-1)/2]$) for the odd ones. The length of a chain of WO_6 octahedra along the $[010]_{per}$ and $[100]_{per}$ crystallographic directions equals *m* for any value of this parameter.

The orientation of the layer of octahedra can be determined with respect to the perovskite crystallographic axes; these layers are parallel to the $(112)_{per}$ plane in MPTBs and to the $(102)_{per}$ plane in DPTBs (see Fig. 4).

The phosphate or diphosphate groups are more strongly bound to one layer of WO_6 octahedra, namely, the PO_4 tetrahedra share three vertices with this layer, being connected to the adjacent layer through one vertice; while P_2O_7 units share four and two vertices, respectively. Therefore, the phosphate groups can be treated as constituents of the layer of octahedra. Different lengths of the bonds between adjacent oxygen atoms in WO_6 octahedra [$d(O-O) \approx 2.7$ Å] and in PO_4 tetrahedra [$d(O-O) \approx 2.5$ Å] lead to distortion of the octahedra linked to the phosphate groups. The structure distortion decreases on going towards the midpoint of the layer of octahedra. The inserted monovalent and divalent

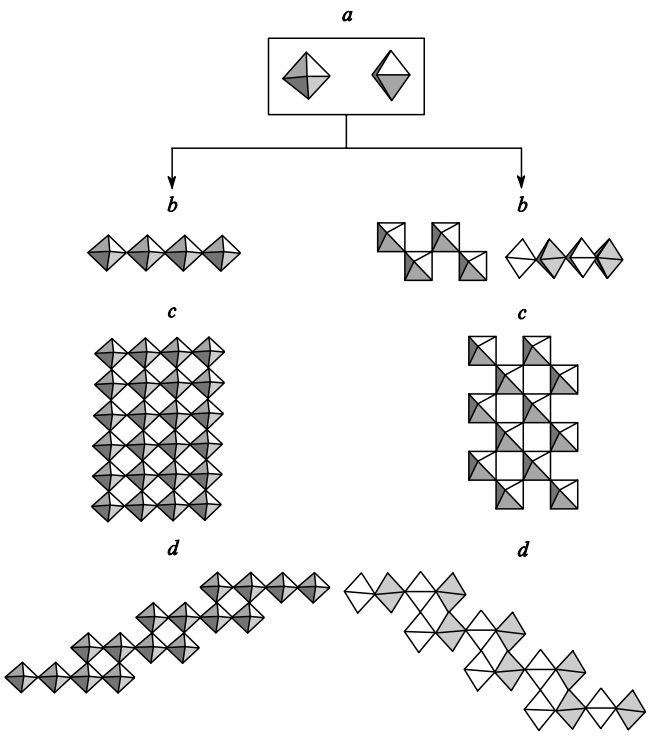

Figure 4. Structures of perovskite-type layers in the DPTB (on the left) and MPTB (on the right) compounds.
Isolated octahedra (*a*); W_4O_{21} blocks (*b*); W_4O_{17} units (on the left) and W_4O_{18} ribbons (on the right) (*c*); and the W_4O_{15} (on the left) and W_4O_{16} (on the right) layers (*d*) built of layers running normal to the plane of this Figure.

metal cations can be located within cavities of the framework which are connected by 'windows' of different shape and size.

Structural phase transitions in the phosphate tungsten bronzes can occur owing to the possibility of small tilts of octahedra in the perovskite-type layers and to ordering of the inserted cations within cavities of the framework.

1. Structural features of monophosphate tungsten bronzes

Two adjacent $W_mO_{4m}(PO_2)_2$ layers in the structure of the monophosphate tungsten bronzes $A_x(PO_2)_4(WO_3)_{2m}$ (A is a vacancy or Na, Ag, K, Pb) can be connected in two ways (see Fig. 5). In the first case, the layers are related by translation; all octahedra in the structure have the same orientation and cavities connected by hexagonal 'windows' are formed at the junction. In the second case, the layers are related by rotation about a twofold axis and cavities connected by pentagonal 'windows' are formed at the junction. Therefore, different (parallel or antiparallel) mutual orientations of layers lead to two families of the monophosphate tungsten bronzes with somewhat incorrect names, *viz*., the MPTBs with hexagonal and pentagonal channels (MPTBh and MPTBp, respectively). The frameworks of the monophosphate tungsten bronzes contain two types of cavities differing in shape and size. Cavities delimited by eighteen oxygen atoms (O_{18}) are surrounded by eight WO_6 octahedra and four PO_4 tetrahedra. The layer of octahedra contains perovskite-type cavities framed by twelve oxygen atoms (O_{12}) and connected by tetragonal 'windows'. All the structural data available at the moment indicate that monovalent or divalent cations be located only in the O_{18} cavities, whereas positions in the O_{12} cavities remain unoccupied.

Both MPTBp and MPTBh are structurally similar to the Magnéli phases containing perovskite-type layers built of MoO_6 octahedra isostructural to the W_4O_{16} layers of the monophosphate tungsten bronzes with $m = 4$. In γ-Mo_4O_{11} and η-Mo_4O_{11}, the layers built of octahedra are linked through MoO_4 tetrahedra similarly to the MPTBp and MPTBh, respectively.

Intercalation of lithium and sodium into different-type phosphate tungsten bronzes was first studied by Wang and Greenblatt [28] who reported the possibility of nearly complete filling of the perovskite cavities. However, these results require confirmation. Unfortunately, no structural studies of the bronzes obtained were performed.

The variety of symmetry types in the case of MPTB structures is due to small tilts of octahedra in the perovskite-type layer. In contrast to the WO_3 structure which permits tilting of the corner-sharing octahedra relative to three perovskite crystallographic axes, only tilting with respect to the $[001]_{per}$ direction is possible for the MPTBs. If the phosphate tungsten bronzes contain inserted cations, small tilts of octahedra in the perovskite-type

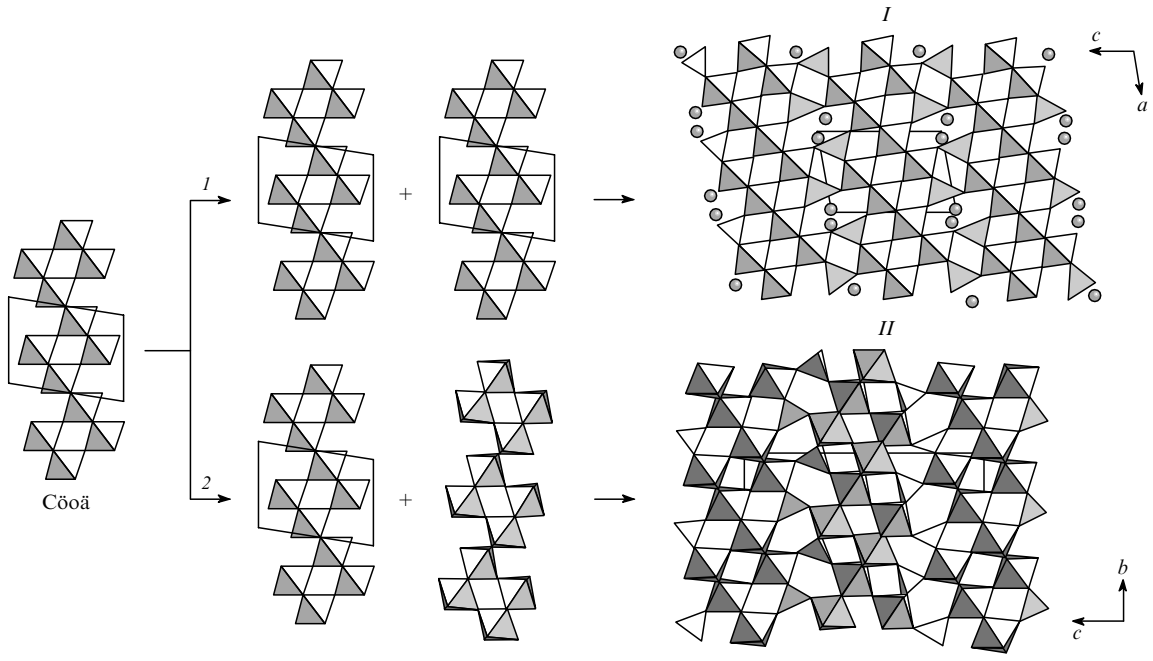

Figure 5. Parallel (*1*) and antiparallel (*2*) orientation of layers in the structures of the MPTBh (*I*) and MPTBp (*II*) compounds with $m = 4$.

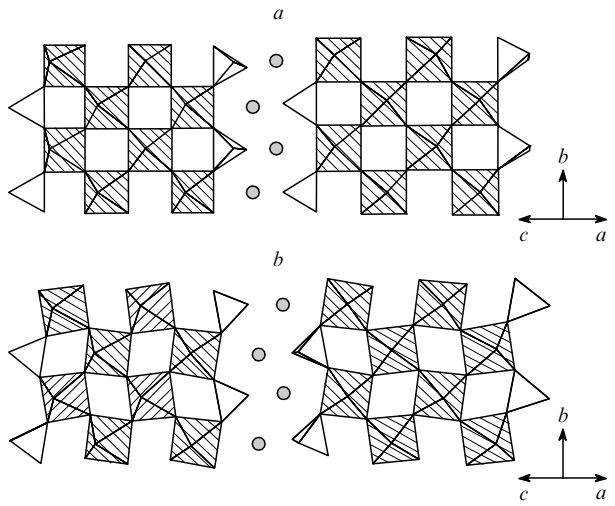

Figure 6. $(PO_2)_2(W_4O_{18})$ chains in the structures of $K_x(PO_2)_4(WO_3)_4$ (*a*) and $Na_x(PO_2)_4(WO_3)_4$ (*b*).

layer cause displacements of the cations located in the cavities and thus changes in the cavity shapes. Among the $A_x(PO_2)_4(WO_3)_{2m}$ bronzes (A = K, Na), small tilts by about 8.5° occur only in the sodium-containing compounds, whereas octahedra in the perovskite-type layer of the potassium-containing MPTBh are untilted (Fig. 6 *a*). In the $Na_x(PO_2)_4(WO_3)_{2m}$ bronze with $x < 4$ all octahedra in the linear chain running along the $[001]_{per}$ direction are rotated in one direction; correspondingly, octahedra in the four adjacent chains are rotated in the opposite direction (Fig. 6 *b*).

2. Monophosphate tungsten bronzes with pentagonal channels

Most of the MPTBp compounds have a general formula $(PO_2)_4(WO_3)_{2m}$. Structural features of this family of bronzes have been studied in most detail. The structure of the MPTBp with $m = 2$ contains the $(WO_5)_\infty$ chains instead of layers. In spite of this two tetrahedra and three octahedra also form pentagonal 'windows' similarly to other MPTBp compounds (Fig. 7). The unit cell parameters (in a standard setting) of the MPTBp compounds with the same thickness of the layer of octahedra are related to the perovskite unit cell parameters as follows:

$$a_{MPTBp} \approx a_{per}\sqrt{2},\ b_{MPTBp} \approx b_{per}\sqrt{3},$$

$$c_{MPTBp} \approx K + m a_{per}\cos 35^\circ \text{ (see Ref. 68)},$$

$$a_{MPTBp} \| [1\bar{1}0]a_{per},\ b_{MPTBp} \| [11\bar{1}]a_{per},\ c_{MPTBp} \| [112]a_{per}.$$

Here K is a constant related to the size of the PO_4 tetrahedron ($K \approx 2 \times 2.45$ Å) and 35° is the angle between the c_{MPTBp} axis and the $[001]_{per}$ axis. The unit cell thus defined has an orthorhombic symmetry with the a and b lattice constants being independent of m value. The c lattice constant linearly increases as m increases. The a_{MPTBp} and b_{MPTBp} parameters (~5.3 Å and ~6.55 Å, respectively) are close to the doubled face height and doubled edge length of the WO_6 octahedron, respectively.

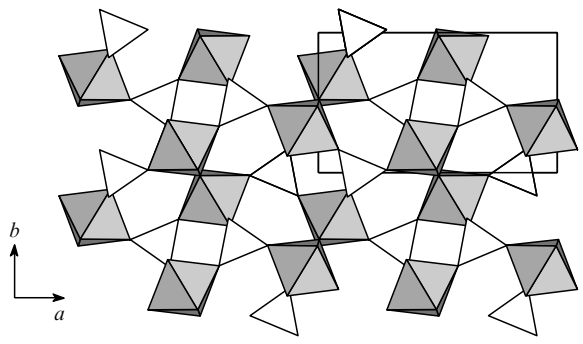

Figure 7. Projection of the crystal structure of $(PO_2)_4(WO_3)_4$.

In addition to the standard setting, a unit cell setting with the crystallographic axes running parallel to the perovskite axes is also used. If two layers of different thickness (m and m') alternate, the bronze unit cell becomes monoclinic with the following parameters [51]

$$d_{001} = K + 0.5(m + m')a_{per}\cos 35^\circ,$$

$$\tan \alpha_{MPTBp} = \frac{d_{001}}{0.5}(m - m')a_{per}\sin 35^\circ,$$

$$c_{MPTBp} = \frac{d_{001}}{\sin \alpha_{MPTBp}},$$

$$a_{MPTBp} = a_{per}\sqrt{2},$$

$$b_{MPTBp} = a_{per}\sqrt{3}.$$

Only one member of the MPTBp family (compound with $m = 5$) was obtained as two polymorphs. The structure of the first polymorph is characterised by regular alternation of the layers comprised of four and six octahedra, while the structure of the second polymorph is built of identical layers comprising five octahedra each. The structures of other MPTBp compounds contain layers of the same thickness, though irregular intergrowth of phases with different m occurs not infrequently [according to high-resolution transmission electron microscopy (HRTEM) data]. The probability of formation of the intergrowth phases increases as the m value increases.

The symmetry of many members of the MPTBp family is reduced with respect to an ideal structural type due to the possibility of small tilting of octahedra and to a different fashion of layer connection. Only one type of tilting is realised within the perovskite-type layer, the directions of tilting in two adjacent layers being the same or opposite. Taking into account different symmetry of the bronzes with the even and odd m values, the MPTBp compounds can crystallise in four structural types. The unit cell parameters of the MPTBp bronzes with the reliably (X-ray) established structures are listed in Table 6.

Most of the structures of MPTBp compounds studied by single-crystal X-ray diffraction analysis are characterised by symmetries lower than orthorhombic one. Studies of the MPTBp bronzes with large m values revealed satellite reflections indicating structure modulation at room temperature. The modulated structure of compound $(PO_2)_4(WO_3)_{20}$ with $m = 10$ was refined.[55] Structure modulation in the bronzes with small m values occurs only at low temperatures. For instance, a synchrotron radiation study of $(PO_2)_4(WO_3)_8$ (a compound with $m = 4$) at 20 K revealed structure modulation. All the MPTBp studied exhibited small tilting of octahedra, the tilt angle (8°) approaching that characteristic of WO_3.[89]

It has long been accepted that intercalation of cations into an MPTBp matrix is impossible and that crystallisation in the presence of inserted cations leads to the MPTBh compounds. The first members of the MPTBp families of composition $Na_x(PO_2)_4(WO_3)_{2m}$ with $0 \leqslant x \leqslant 1$ (isolated as individual compounds only for $m = 6$) were obtained only recently in the studies of phase relations in the systems $K_4(PO_2)_4(WO_3)_{2m}-Na_4(PO_2)_4.(WO_3)_{2m}-(PO_2)_4(WO_3)_{2m}$ with $m = 4$ and 6.[40] The $A_x(PO_2)_4.(WO_3)_{2m}$ bronzes were synthesised by intercalating monovalent cations (A = Li, Na, Ag, K) into the MPTBp structures.[90]

Changes in the structure of the MPTBp compound with $m \leqslant 14$ as a function of temperature have been reported in several studies (see, *e.g.*, Refs 2 and 15). A number of phase transitions related to periodic lattice distortions were detected at different

Table 6. Crystallographic parameters of the $(PO_2)_4(WO_3)_{2m}$ compounds with $m = 2-14$ obtained from single-crystal X-ray diffraction studies.

temperatures. These transitions correspond to anomalies of the temperature dependence of the electronic properties.

3. Monophosphate tungsten bronzes with hexagonal channels

The monophosphate tungsten bronzes with hexagonal channels have a general formula $A_x(PO_2)_4(WO_3)_{2m}$ (A = Na, Ag, K, Pb, Tl). In accord with the general framework build-up pattern, the unit cell symmetry cannot be higher than monoclinic one. Usually, the monoclinic cell is set in such a way that the twofold axis runs along the b direction. The unit cell parameters in the standard setting are as follows:[25]

$$a_{\mathrm{MPTBh}} \approx \sqrt{3}\, a_{\mathrm{per}}\,,\ b_{\mathrm{MPTBh}} \approx \sqrt{2}\, a_{\mathrm{per}}\,,$$

$$c_{\mathrm{MPTBh}} \sin\beta \approx 0.5\, K\ + 0.5\, m\, a_{\mathrm{per}} \cos 35^\circ,$$

$$a_{\mathrm{MPTBh}} || [11\bar{1}]_{\mathrm{per}}\,,\ b_{\mathrm{MPTBh}} || [1\bar{1}0] a_{\mathrm{per}}\,,\ c_{\mathrm{MPTBh}} || [112]_{\mathrm{per}}\,.$$

The parameters a_{MPTBh} and b_{MPTBh} are nearly 6.55 and 5.3 Å, respectively. Members of this series of bronzes with odd m values and most compounds containing sodium and lead are characterised by doubling of the c constant compared to the value calculated using the relation given above. The crystallographic parameters of MPTBh compounds obtained using data of X-ray studies are listed in Table 7.

The tilt angle of octahedra in the MPTBh bronzes depends on the size and content of inserted cations. For instance, all $Na_x(PO_2)_4(WO_3)_{2m}$ compounds with $x < 2$ are characterised by a tilt angle of nearly 8.5°. This angle decreases to 6.5° for the $Pb_x(PO_2)_4(WO_3)_{2m}$ bronzes with $6 \leqslant m \leqslant 10$. No tilt of octahedra was found in $Na_4(PO_2)_4(WO_3)_8$ and $K_x(PO_2)_4(WO_3)_{2m}$. These differences can be explained by the larger size of potassium ions and by the impossibility of redistribution of sodium cations in the cavities when all positions in $Na_4(PO_2)_4(WO_3)_8$ are occupied. At the same time each compound probably exists in two forms, a high-temperature form with non-tilted octahedra and a low-temperature form with tilted octahedra. At present, only the MPTBh compounds with alternation of the tilt direction from one layer to another are available. In the case of small tilts of octahedra the oxygen atom through which layers are linked virtually retains its position. This permits the formation of various intergrowth phases (layers with different m values and the MPTBh and MPTBp compounds), twins and defects.

The outermost (with respect to the centre of the perovskite-type layer in the MPTBh bronzes) WO_6 octahedra share their corners with three PO_4 tetrahedra and three WO_6 octahedra, the next octahedron shares its corners with one PO_4 tetrahedron and five WO_6 octahedra while other WO_6 octahedra are connected to one another only. The degree of distortion of the octahedra (in particular, the scatter of the W–O bond lengths) increases from the centre of the layer towards its periphery, being consistent with the increase in the formal oxidation state of the tungsten atoms calculated using data on the W–O bond lengths. In contrast to this, the average number of conduction electrons increases on going towards the centre of the layer.

All cations (sodium, potassium and lead) occupy a part of the O_{18} cavity near the phosphate groups. As the cation size increases, the average A–O distance also increases (2.68, 2.74 and 2.83 Å for Na, Pb and K, respectively), which is due to distortion of the perovskite-type layer. Positions of the sodium and lead cations differ only slightly. The decrease in the tilt angle of WO_6 octahedra in the Pb-containing structure was ascribed to the increase in the A–O bond lengths and to the steric effect of the lone electron pair whose location was established by Roussel *et al.*[51] Potassium cations are characterised by the smallest scatter of the K–O distances.

Arrangement of sodium cations in the MPTBh and MPTBp frameworks can be followed taking the structures of $Na_{1.7}(PO_2)_4(WO_3)_{12}$ (see Ref. 57) and $Na_4(PO_2)_4(WO_3)_8$ (see Ref. 91) as examples. The O_{18} cavities in the MPTBh structure are connected to four identical cavities by large hexagonal windows and by small rhombohedral windows delimited by two WO_6 octahedra and two PO_4 tetrahedra. The O_{18} cavities in the MPTBp structure are linked to four identical cavities by pentagonal windows. The surface areas of cavities are much larger than those of windows. One half of the cavity is the same for both MPTBh and MPTBp compounds while the other half can be matched by rotation about a twofold axis. On average the corresponding O–O distances in two O_{18} cavities differ by about 1.6%. In both cases the sodium ion is bound to oxygen atoms of the phosphate groups; usually, this ion is treated as an octacoordinate species (for comparison with the potassium-containing MPTB). In this case, the sodium atoms occupy significantly different positions and the scatter of the Na–O bond lengths is rather large. In the $Na_{1.7}(PO_2)_4(WO_3)_{12}$ bronze the sodium ion is displaced from the cavity centre by 1.11 Å; four Na–O bond lengths lie between 2.45 and 2.64 Å while the other four Na–O bond lengths fall within the interval 2.85 to 3.02 Å. In the $Na_4(PO_2)_4(WO_3)_8$ structure the coordination number of the sodium atom decreases to six. The edge-sharing distorted pentagonal pyramids NaO_6 form zigzag chains running along the [010] direction with a Na–Na separation of 3.211 Å (Fig. 8).[91] In the MPTBp structure the sodium ion is displaced from the centre of the O_{18} cavity by 1.5 Å, seven Na–O bond lengths are in the range from 2.37 to 2.64 Å while the eighth Na–O bond length is equal to 2.82 Å.

Table 7. Crystallographic characteristics of the compounds $A_x(PO_2)_4(WO_3)_{2m}$ with $m = 4-7$ and $A_x(P_2O_4)_2(WO_3)_{2m}$ with $m = 4-10$ obtained from single-crystal X-ray diffraction studies.

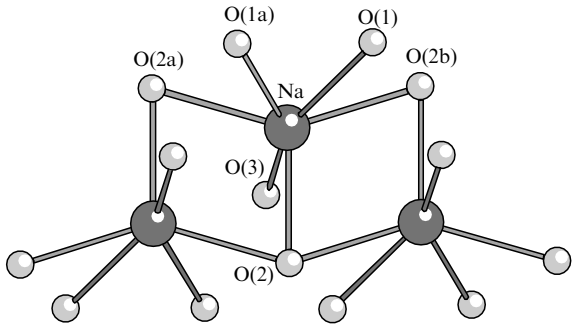

Figure 8. $(NaO_5)_\infty$ chains in the structure of $Na_4(PO_2)_4(WO_3)_8$.

4. Diphosphate tungsten bronzes

Diphosphate tungsten bronzes with hexagonal and pentagonal channels are described by a general formula $A_x(P_2O_4)_2(WO_3)_{2m}$ (A = K, Rb, Cs, Tl, Ba, *etc.*) with integer m values ($4 \leqslant m \leqslant 10$). The frameworks of the simplest members of the DPTB family, compounds $A_x(P_2O_4)_2(WO_3)_4$ (A = Rb, Tl, Ba), contain infinite chains built of ReO_3-type WO_6 octahedra running along the [001] direction of an orthorhombic unit cell. The chains are linked together by diphosphate units. As a result, octagonal channels with a large cross section running along the [001] direction are formed (Fig. 9 *a*); channels with a smaller cross section run along the [010] direction (Fig. 9 *b*). The DPTBs with $m \geqslant 4$ contain characteristic hexagonal channels extending along the [010] direction (see Fig. 1 *d*).

Ordering of cations in the cavities was studied[95] by X-ray diffuse scattering taking the bronze $Cs_{1-x}(P_2O_4)_2(WO_3)_4$ as an example. At 298 K, Cs^+ ions are locally ordered in the lattice along the direction of the channel; however, no correlation between the arrangements of these ions in adjacent channels was found. The period of one-dimensional incommensurate concentration waves depends on stoichiometry with respect to Cs^+ cations. At low temperatures, the degree of intrachannel ordering of Cs^+ cations increases and interchannel ordering appears. Kinetic effects preclude long-range three-dimensional ordering even at low temperatures. Due to the phase shift between the concentration waves of Cs^+ cations in different channels their electrostatic repulsion is minimum. Occurrence of Anderson-type transition in $Cs_{1-x}P_8W_8O_{40}$ (at small x) due to the change in the degree of disorder of ceasium was confirmed by the character of the temperature dependence of electrophysical properties.[95]

In the structure of $(WO_3)_6(P_2O_4)_2$ three nonequivalent WO_6 octahedra differ in the number of bonds with other WO_6 octa-

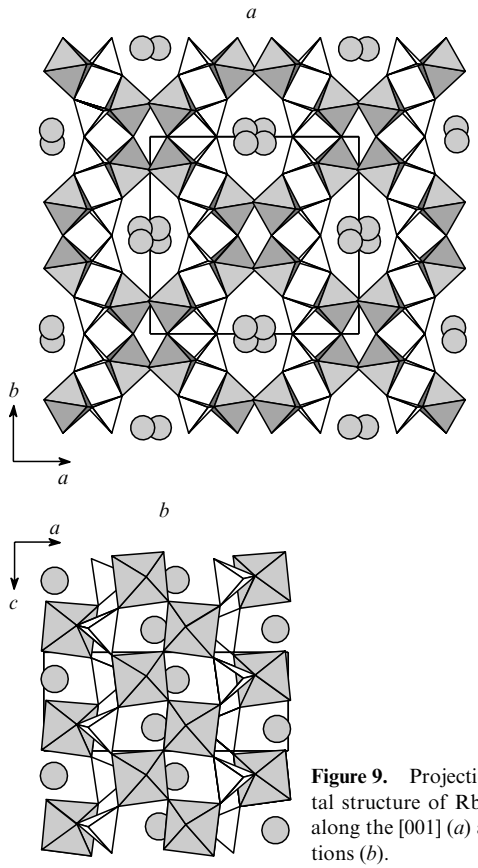

Figure 9. Projections of the crystal structure of $Rb(P_2O_4)_2(WO_3)_4$ along the [001] (*a*) and [010] directions (*b*).

hedra and PO_4 tetrahedra, which equals (5 + 1), (4 + 2) and (3 + 3), respectively. The magnitudes of displacement of the tungsten atoms from the centre of gravity of the octahedron and difference of the W—O bonds in the octahedra increase as the number of bonds with tetrahedra increases. In contrast to all other phosphate tungsten bronzes the structure of $(P_2O_4)_4(WO_3)_{12}$ comprises zigzag-shaped W_6O_{28} chains connected through not only the diphosphate units (P_2O_7) but also immediately through oxygen atoms to form a three-dimensional framework. The structure can be described as a ReO_3-type framework in which one of the four MO_6 octahedra is replaced by the diphosphate unit. Infinite perovskite-type W_3O_{14} ribbons running along the [001] direction are shown in Fig. 10. Two types of channels, *viz*., pentagonal and distorted hexagonal ones extend along the [001] direction (Fig. 11). Three types of face-sharing cavities delimited by thirteen, fourteen and fifteen oxygen atoms can be distinguished in the structure. The O_{13} cavities are formed by six WO_6 octahedra and three PO_4 tetrahedra while O_{14} cavities are formed by six octahedra and two diphosphate units. Elongated O_{15} cavities are formed

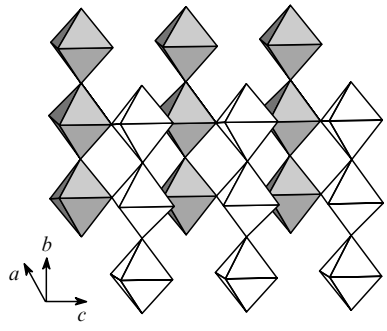

Figure 10. $(W_3O_{14})_\infty$ chains in the structure of $(P_2O_4)_2(WO_3)_6$.

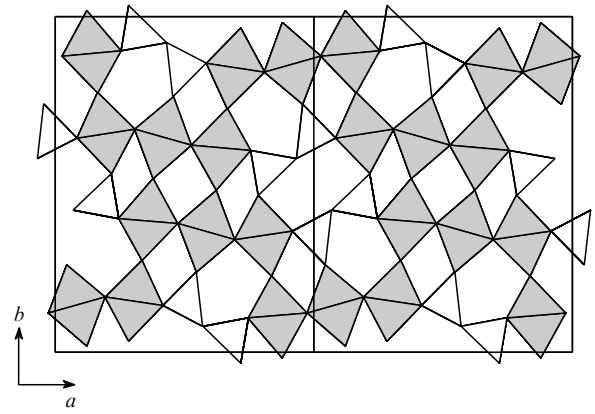

Figure 11. Projection of the crystal structure of $(P_2O_4)_2(WO_3)_6$ along the [001] direction.

by five octahedra and three diphosphate groups. Perovskite-type cavities O_{12} also exist.

The unit cell parameters of the DPTBh compounds with even *m* values ($m > 6$) in the standard setting are [64]

$$a_{\mathrm{DPTBh}} \approx K + 0.5\ a_{\mathrm{per}}\, m,$$

$$b_{\mathrm{DPTBh}} = 2\, a_{\mathrm{per}},$$

$$c_{\mathrm{DPTBh}} = \sqrt{2}\, a_{\mathrm{per}},$$

where $K \approx 2.6$ Å, $\beta \approx 116.6^\circ$.

It should be noted that only the parameter *a* depends on *m* and is related to the layer thickness. For the DPTBh compounds with odd *m* values the unit cell parameters are as follows:[68]

$$a_{\mathrm{DPTBh}} \approx K + a_{\mathrm{per}}[1 + 0.25(m-1)^2],$$

$$b_{\mathrm{DPTBh}} = 2\, a_{\mathrm{per}},$$

$$c_{\mathrm{DPTBh}} = \sqrt{2}\, a_{\mathrm{per}},$$

where $K \approx 2.6$ Å, $\beta \approx 116 - \omega$, $\omega = \arctan[2/(m+1)]$.

Stacking of layers of the same thickness along the *a* direction leads to monoclinic symmetry of the structure. The unit cell parameters of DPTBh, obtained using X-ray diffraction and phase analyses are listed in Table 7.

The diphosphate tungsten bronzes with pentagonal channels were not synthesised as individual phases; however, DPTBp microcrystals containing non-parallel domains with ReO_3-type structure of different thickness (with large *m* values) were found by HRTEM. The tungsten diphosphate WP_2O_7 (see Ref. 96) can be considered as a zeroth member of this class of DPTBs ($m = 2$). Its framework comprises isolated octahedra and zigzag channels with pentagonal windows.

5. Structural defects in phosphate tungsten bronzes

Phosphate tungsten bronzes have been the subject of intensive HRTEM studies. Using this method, it is impossible to reveal small distortions of polyhedra in a real structure with respect to the ideal structural type; however, it is possible to determine non-stoichiometric defects, intergrowth phases, domains and changes in the content of inserted cations in channels.

Structural defects in MPTBs can be divided into two groups. The first group of defects is due to the distribution of planes built of phosphate groups with respect to layers built of the WO_6 octahedra. The second group of defects is due to distribution of PO_4 groups within the phosphate planes.

Electron micrographs of the MPTBs with $m = 4 + 6$ and $m > 12$ usually exhibit certain intergrowth phases of different members of this family of compounds. Bronzes with $m > 13$ were not synthesised as regular single crystals. The compound with $m = 5$ behaves in an unusual manner compared to other phosphate bronzes.[23, 59, 64, 86] Usually, the number of octahedra in the

defect layer approaches that in the main phase. The intergrowth phases can form in both the phosphate [36, 37, 59, 64] and the oxide bronzes in which a shear deformation is possible.

The MPTBh crystals exhibit two kinds of growth defects, (i) separation of the crystal into two regions and (ii) growth of small domains of different thickness on the crystal faces.[57] Often, these domains are somewhat disoriented relative to the main part of the crystal and separated by a clearly seen boundary. In some cases, small domains are poorly crystallisable or amorphous.

A model for connection of these domains through a coherent boundary involving PO_4 tetrahedra, P_2O_7 units in the eclipsed conformation [similar to those found in the structure of $(P_2O_4)_2(WO_3)_6$, see Ref. 97] and edge-sharing WO_6 octahedra was proposed.[57] The boundary is nearly parallel to the hexagonal channel. This model cannot be considered as exclusive; however, structural units employed by the model, *viz.*, the PO_4 and P_2O_7 groups and the edge-sharing WO_6 octahedra are available at any point of the domain boundary.

Changes in the order of alternation of PO_4 tetrahedra and WO_6 octahedra cause two types of defects. Characteristic of the first type of defects is the appearance of additional hexagonal or pentagonal channels. They are observed in the perovskite-type layers containing more than thirteen octahedra [23] and appear only in a part of the layer. The contrast produced by these channels is somewhat different from that produced by the matrix (due to distortions in the framework region adjacent to the defect); however, the content of cations in these channels cannot be determined with certainty. If additional channels in crystals pass throughout the layer, two adjacent layers characterised by small m values appear in the matrix with large m value. This type of defects was found only in the sodium-containing MPTBh.

Additional pentagonal channels characteristic of the MPTBp compounds can appear at the boundary between two MPTBh domains with different orientation of WO_6 octahedra. Correspondingly, hexagonal channels typical of the MPTBh compounds can appear at the boundary between two domains in the MPTBp crystal. A quite rare case is a shear defect along the direction perpendicular to the channel axes.

The potassium- and sodium-containing MPTBh compounds with relatively high alkali metal contents ($x \approx 2$ for K and $x = 3$ for Na) exhibit local variations of the cation concentrations, which lead to distortion of the framework and manifest themselves in periodic changes in the contrast of hexagonal channels.

The nature of cations residing in hexagonal channels affects both the homogeneity region and the structure of the MPTBh compounds. Sodium-containing MPTBh compounds are more stable than their potassium-containing analogues. The sodium-containing bronzes are characterised by a greater variety of defects; a compound with $m = 5$ was stabilised.

A number of the diphosphate tungsten bronzes $Ba_x(P_2O_4)_2(WO_3)_{2m}$ were studied by X-ray diffraction analysis and electron microscopy. Electron diffraction studies showed that, in contrast to the DPTBs containing alkali metal cations, the barium-containing DPTBs exhibit the A-type of the Bravais lattice, superstructural reflections and higher stability. These differences are due to the large covalent component of the bonds between barium and oxygen atoms of the framework. Many $Ba_x(P_2O_4)_2(WO_3)_{2m}$ crystals are characterised by irregular intergrowth. At the same time, ordered intergrowth were observed for the bronzes with $m = 8$ and 9.

IV. Electronic structure

The electronic structures of phosphate tungsten bronzes were calculated by the extended Hückel method. This semiempirical approach is suitable for a more or less satisfactory description of the energy bands of crystals under study but does not allow a reliable geometry optimisation. The research strategy involves analysis of the model fragments (either finite or infinite) of a crystal structure as they become more complicated. To make the electronic structure calculations more exact, information on the band structure of the model systems is used along with the structural data obtained for real compounds.

1. Electronic structure calculations of diphosphate tungsten bronzes

The crystal structure of the first member of the DPTB series, $Cs_{0.5}(P_2O_4)_2(WO_3)_4$ ($m = 2$), is built of isolated W_4O_{18} chains. This compound is expected to possess quasi-one-dimensional electronic properties. The electron count is 1.125 d electrons per tungsten atom and 4.5 d electrons per W_4O_{18} unit. The t_{2g}-levels of $Cs_{0.5}(P_2O_4)_2(WO_3)_4$ are by and large identical to those of an ideal W_4O_{18} chain. The presence of two chains in the unit cell causes a doubling of the bands with a small splitting in each pair of bands. The main feature of the t_{2g}-bands of $Cs_{0.5}(P_2O_4)_2(WO_3)_4$ is that the Fermi level crosses a one-fourth filled one-dimensional delocalised band, whereas the fully filled localised bands and the unfilled delocalised bands are above and below the Fermi level, respectively.[7, 68]

The electronic structure of $Cs_{0.5}(P_2O_4)_2(WO_3)_4$ (see Refs 7, 66 and 67) is similar to that of the lithium bronze $Li_{0.9}Mo_6O_{17}$. In both compounds d electrons are localised within M_4O_{18} (M = W, Mo) chains that are connected in a different way, namely, through diphosphate groups in the former and through Mo_4O_{14} chains built of corner-sharing MoO_6 octahedra and MoO_4 tetrahedra in the latter case. The W_4O_{18} chains in $Cs_{0.5}(P_2O_4)_2(WO_3)_4$ are shielded more weakly than the Mo_4O_{18} chains in $Li_{0.9}Mo_6O_{17}$, so that the conduction electrons are more susceptible to the electric fields created by cations.

Thus, order–disorder transitions of the caesium cations can influence the conducting properties of bronzes. Partial interchannel ordering of cations is observed at a temperature close to the metal–semiconductor transition temperature. Probably, an increase in the resistivity at 24 K is due to the CDW created as a result of one-fourth filling of the one-dimensional bands.[7] As the electron density in the partially filled delocalised bands increases, the shielding (see above) also increases and the conduction electrons become less susceptible to the electric fields created by cations. The $Tl_yCs_x(P_2O_4)_2(WO_3)_4$ phases with $x + y > 0.5$ are isostructural to $Cs_{0.5}(P_2O_4)_2(WO_3)_4$; here, the high-temperature resistivity maximum at 160 K indicating a transition to the CDW state disappears as the sum $x + y$ increases.[7]

The three-dimensional framework of $(P_2O_4)_2(WO_3)_6$ (a DPTB with $m = 3$) contains a system of corner-sharing WO_6 octahedra. Zigzag W_6O_{28} chains are linked by $W'''O_6$ octahedra. According to Zachariasen-type group structure analysis of the W–O bond lengths, the oxidation states of the tungsten atoms W′, W″ and W‴ are 5.19, 5.10 and 5.71, respectively. The band structure of the $W_{12}O_{48}$ framework is similar to that of an isolated W_6O_{28} chain except for the delocalised π-bands in $W_{12}O_{48}$ that cross the Fermi level in all three directions. Therefore, π-orbitals of the $W'''O_6$ octahedra provide not only intrachain but also interchain π-interaction. Therefore, the bronze $(P_2O_4)_2(WO_3)_6$ must possess a three-dimensional metallic conductivity, which was confirmed experimentally. The Zachariasen-type analysis showed that the partially filled delocalised bands are to a great extent composed of the orbitals of the W′ and W″ tungsten atoms.

The $(P_2O_4)_2(WO_3)_6$ bronze significantly differs from the purple bronze $Li_{0.9}Mo_6O_{17}$ in the number of d electrons in the M_4O_{18} (M = Mo, W) chain. Namely, in $Li_{0.9}Mo_6O_{17}$ there are 5.8 electrons per formula unit of the M_4O_{18} chain and the lower lying bands are completly filled, while in the tungsten bronze there are only four electrons and both bands (π and δ) are partially filled. According to calculations, $(P_2O_4)_4(WO_3)_{12}$ must behave as a one-dimensional metal provided that the Fermi level is higher than the π-band upon filling of bands with additional electrons. According to experimental data, the $(Li,Na)_x(P_2O_4)_2(WO_3)_6$ ($x < 0.5$) bronzes containing up to five electrons per formula unit in both (π and δ) bands [7, 67] exhibit a three-dimensional metallic conductivity. Thus, group-structure analysis of the systems $Li_{0.9}Mo_6O_{17}$

and $(P_2O_4)_2(WO_3)_6$ reveals a similar pattern of the distribution of d electrons but different conductivity. This is due to the fact that two types of different-dimensionality bands correspond to the same energy. In these cases, the dimensionality of conductivity strongly depends on the degree of band filling.

For the DPTB compound with $m = 4$, layers built of corner-sharing WO_6 octahedra are similar to Mo_4O_{15} layers in the Magnéli phase Mo_8O_{23}. However, in these structures layers are connected in a different manner, *viz*., through diphosphate groups in the DPTB compound and by Mo_4O_{14} chains built of edge-sharing MoO_6 octahedra in Mo_8O_{23}. Real DPTBs have more complex structures because connection of the layers of WO_6 octahedra by P_2O_7 groups causes small distortions of the octahedra and leads to a unit cell four times larger than that of an ideal W_4O_{15} layer. The average valence corresponding to the oxidation state of tungsten in DPTBs increases with the layer thickness, being equal to $[6-(8+x)/4m]$ in the $(P_2O_4)_2(WO_3)_{2m}$ compounds. At $m = 4$, the number of d electrons per tungsten atom equals 0.625, which is close to the value of 0.5 obtained from calculations for molybdenum atoms in a Mo_4O_{15} layer of the Mo_8O_{23} structure. Therefore, these two systems are structurally similar and exhibit similar electrical properties. No alternation of short and long O–Mo–O bonds along the *b* direction occurs in DPTBs (in contrast to Mo_8O_{23}), so all three t_{2g}-orbitals of tungsten atoms can form low-lying t_{2g}-bands.

The band structures of an ideal W_4O_{17} chain and W_4O_{15} layer have also been calculated. The lowest-lying d-type energy states of the W_4O_{17} chains are four localised bonding δ-bands composed of x^2-y^2-orbitals and eight delocalised π-bands. Four of the delocalised bands are nearly degenerate. The dispersion relations for the t_{2g}-bands along the W_4O_{17} chain of the W_4O_{15} layer are similar to those calculated for a single chain except for the splitting of the four degenerate bands into two groups. The x^2-y^2 orbitals can be involved in interchain π-antibonding interaction and, hence, form a band that is delocalised along the *c* direction. In addition, there are bands originating from the antibonding interaction of the metal d-orbitals with the oxygen p-orbitals along the *b* direction.

The Fermi level calculated for 2.5 electrons in the unit cell crosses the δ- and π-bands originating from the interaction of AOs along the *c* and *b* axes, respectively.[7] Therefore, the system must behave as a two-dimensional metal, *i.e*., possess a metallic conductivity in two directions. However, the Fermi level crosses these bands in such a way that the conductivity along the *b* direction is higher than along the *c* direction. It should be noted that the two-dimensional metallic character of this system is due to the presence of two one-dimensional bands in two mutually perpendicular directions rather than essentially two-dimensional bands.

The band structures calculated for actual W–O layers in $Rb_2(P_2O_4)_2(WO_3)_8$, $Rb_{0.9}(P_2O_4)_2(WO_3)_{12}$ and $Rb_{0.87}(P_2O_4)_2 \cdot (WO_3)_8$ are qualitatively similar to the band structures of an ideal W–O layer. More complex band structure can be a consequence of the doubling of the unit cell (doubling of the parameters *b* and *c*). Hence, all these systems must be two-dimensional metals with the highest conductivity along the *b* direction, which is consistent with experimental data.

A number of bands exhibit a plateau in the vicinity of the Fermi level, which indicates a high density of states. The Fermi level population, $n(E_F)$, can be changed by increasing or decreasing its energy. The increase in $n(E_F)$ can be responsible for the observed increase in the conductivity of both electron-deficient and electron-enriched systems $K_xRb_y(P_2O_4)_2(WO_3)_{12}$ $(x + y < 1)$ and $KSn_x(P_2O_4)_2(WO_3)_{12}$ $(x > 0)$, respectively, compared to the conductivity of $K(P_2O_4)_2(WO_3)_{12}$.[66,67] However, a theoretical model[66] predicts an increase in the conductivity only for the electron-deficient systems $A_{1-x}(P_2O_4)_2(WO_3)_{14}$ $(x > 0)$.

2. Electronic structure calculations of monophosphate tungsten bronzes

The electronic properties of $P_4W_4O_{20}$ differ from those of other MPTBp compounds with $m > 2$. The crystal structure of $P_4W_4O_{20}$ contains no perovskite-type layers; it comprises only the zigzag W_2O_{10} chains built of corner-sharing octahedra. Lithium–molybdenum bronze $Li_{0.9}Mo_6O_{17}$ contains similar Mo_2O_{11} chains. The energy level diagram calculated for $P_4W_4O_{20}$ is similar to that obtained for $Li_{0.9}Mo_6O_{17}$ and exhibits both localised (in *ab* planes) and delocalised (along *c* axis) t_{2g}-bands formed as a result of the interaction of d electrons of tungsten atoms. The t_{2g}-bands are filled with two d electrons (two tungsten(V) atoms in the W_2O_{10} chain per unit cell). The last band is nearly half-filled, while the nearly degenerate localised bands are one-fourth filled. Calculations also predicted a magnetic moment created by electrons in the narrow bands, metallic properties of the compound and its electronic instability.

Perovskite-type layers in the MPTBs with $m > 2$ are characterised by nonuniform distribution of d electrons whose concentration increases from the centre of the layer towards its periphery.

The monophosphate tungsten bronzes are two-dimensional metals similar to their structural analogues, γ-Mo_4O_{11} and η-Mo_4O_{11}. The transport properties and electronic instabilities of the W–O and Mo–O layers in the Magnéli phases are different. The Mo–O layers have a larger number of d electrons due to the difference in the oxidation state of the atom in a tetrahedral environment [Mo(VI) in the Magnéli phases and P(V) in the MPTBs]. Changes in the topology of the Fermi surface as a function of the number of d electrons in the unit cell and the thickness of the perovskite-type layer have been studied.[7] The electronic band structures of the MPTBs were calculated by the extended Hückel tight binding method using the modified Wolfsberg–Helmholtz approximation.[6,7]

The electronic band structures of different MPTBs obey an identical pattern, being similar to the band structure calculated for an ideal layer built of regular WO_6 octahedra. An example of this layer is provided by, *e.g*., a W_4O_{16} layer with W–O distances of 1.916 Å. The average oxidation state of the tungsten atoms in $(PO_2)_4(WO_3)_{2m}$ is $(6m-2)/m$. Therefore, each layer of WO_6 octahedra contains two d electrons per unit cell irrespective of *m* value. In the $A_x(PO_2)_4(WO_3)_{2m}$ bronzes containing monovalent cations each layer has $(2 + x/2)$ electrons in the unit cell to fill the t_{2g}-bands (Fig. 12).[67] Two Magnéli phases, γ-Mo_4O_{11} and η-Mo_4O_{11}, are characterised by $N = 4$, the $A_2(PO_2)_4(WO_3)_{2m}$ compounds are characterised by $N = 3$ while $N = 2$ for the MPTBp compounds. At $N \leqslant 4$, only two bottom bands are partially filled, one of them being one-dimensional while the other (consisting of two subbands) is a two-dimensional one.

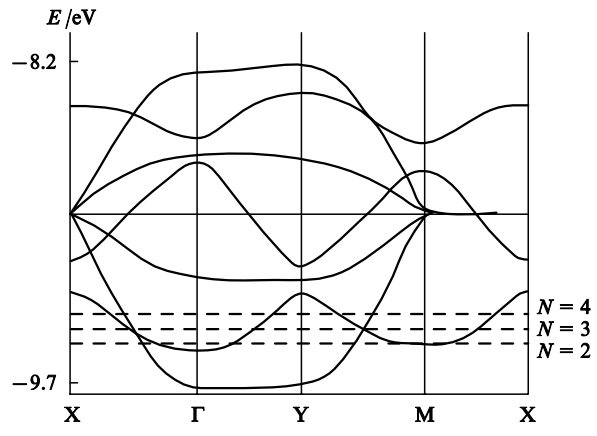

Figure 12. Dispersion relations for the t_{2g}-bands in a perfect W_4O_{16} layer. Dashed lines denote the Fermi levels at different numbers of d electrons in the unit cell (*N*).

3. The Fermi surfaces

The Fermi surface of an ideal one-dimensional metal consists of two parallel planes separated by the Fermi wave vector $2\boldsymbol{k}_F$. A Peierls transition (metal – insulator transition) causes destruction of this Fermi surface. The Fermi surfaces of quasi-two-dimensional (2D) conductors are of more complex shape.[10] In this case a Peierls transition causes a partial destruction of the Fermi surface; as a consequence, metal – metal transitions are observed. Transitions to the CDW state or between two CDW states are a consequence of the interaction between a phonon and the energy states of conduction electrons. Pre-transitional phenomena observed in the MPTBp compounds above the Peierls transition temperature (T_P) indicate that CDW-type instability is due to the quasi-one-dimensional electronic structure of these compounds. Large flat areas of the Fermi surface which include bands of different orientation can be calculated using the extended Hückel tight binding approximation.[6, 7, 10] X-Ray diffuse scattering experiments [14, 17 – 19, 47, 81, 98 – 106] allowed the Fermi vectors for each quasi-one-dimensional area of the Fermi surface to be determined (Table 8).

The Fermi surface was first imaged by high-resolution photoemission UV spectroscopy in a study of MPTBp compounds with $4 \leqslant m \leqslant 12$.[104] The Fermi surface of $(PO_2)_4(WO_3)_8$ contains quasi-one-dimensional bands,[104, 107] which is consistent with the results of earlier band structure calculations.[66, 67, 108]

V. Electrophysical properties

The electric and magnetic properties of MPTBp polymorphs with $m = 2$ [the α- and β-phases of $(PO_2)_4(WO_3)_4$] were first studied by Kinomura *et al.*[49] Both phases exhibit semiconducting properties in the temperature range 77 – 420 K. The monoclinic β-phase is characterised by higher conductivity. The results of preliminary magnetisation measurements with α-phase and β-phase polycrystals in the temperature interval 77 – 500 K revealed nonzero local magnetic moments.

The magnetic susceptibility (2 – 300 K, in a 5000 G field) and the resistivity (50 – 390 K) of oriented MPTBp single crystals were experimentally studied by Greenblatt *et al.*[52] In this temperature range, the resistivity shows a semiconducting behaviour. At 298 K, the resistivity measured along different crystallographic axes is $R_c = 5 \times 10^{-3}$, $R_b = 4 \times 10^{-2}$ and $R_a = 1 \times 10^{-1}$ Ω cm. At $T < 50$ K, the resistivity is $\geqslant 10^4$ Ω cm. Seebeck effect measurements at 300 K showed electrons as the main type of charge carriers (*n*-type conduction). Experiments revealed a semiconducting rather than the predicted metallic type of conductivity along the *c* axis (though the conductivity at 298 K approaches a value characteristic of metals).

The temperature dependence of the magnetic susceptibility (χ) in the samples exhibits the onset of antiferromagnetic ordering at 15 K. In the temperature range 50 – 300 K the dependence of $1/\chi$ on T obeys the Curie – Weiss law with $\theta = -34.6$ K. The effective magnetic moment in this temperature range is 0.88 μ_B. The large deviation of this dependence from the linear one at $T < 50$ K is likely due to the change in the type of magnetic exchange interaction upon structural phase transition.

A large anisotropy of the Neel temperature (T_N) was found along the *b* direction ($T_N \approx 16$ K), along the *c* direction ($T_N \approx 20$ K) and along the *a* direction at low temperatures the temperature dependence of χ exhibits a plateau with $\chi_{max} = 1.12 \times 10^{-2}$ cm^3 mol^{-1} at 4.6 K. Taking into account a rather low activation energy for conductivity along the *a* axis ($E_a = 0.084$ eV at 50 – 200 K), the conductivity can be described in terms of the hopping of small polarons in the narrow conduction bands originating from the overlap of 5d-orbitals of the tungsten atom and 2p-orbitals of the oxygen atom.

The crystal structure of the monophosphate tungsten bronze $(PO_2)_4(WO_3)_4$ comprises isolated chains built of WO_6 octahedra with the lowest (for this class of compounds) oxidation state of tungsten. Along $(WO_5)_\infty$ chains (*c* axis direction) the magnetisation is much lower while the conductivity is much higher than along other axes.

CDW-type electronic instabilities are also possible in bronzes. At 298 K, high semimetallic conductivity along one-dimensional chains built of WO_6 octahedra implies a transition to the metallic state, *i.e.*, a CDW-type instability at $T > 390$ K, as was predicted by Canadell and Whangbo.[109]

At present, the properties of the $(PO_2)_4(WO_3)_{2m}$ bronzes with $4 \leqslant m \leqslant 14$ have been a subject of most intensive studies.[3, 10, 88, 99] It was established that the critical temperature of Peierls transition and the resistivity at room temperature increase with the thickness of the layer of WO_6 octahedra. This is consistent with the simple models proposed for the monophosphate tungsten bronzes with $m = 4 - 12$.[16, 84, 98] At the same time, the MPTBp compounds with

$m = 4$ and 6 are treated as typical CDW-compounds while the compounds with $m = 7$ exhibit anomalous electrophysical properties.

The electrophysical properties of the bronzes $(PO_2)_4(WO_3)_{2m}$ are closely related to the character of the Fermi surface. Some studies take into account the role of electron – phonon interaction. In particular, a rather high resistivity at room temperature should be ascribed to an increase in the contribution of electron – phonon (or electron – electron) interaction, which can be due to the presence of the CDW satellites corresponding to anharmonic CDW modulation. With allowance for this fact the electrophysical properties of certain phosphate tungsten bronzes should be described using the bipolaron model rather than the traditionally used CDW model.[110]

The results of studies on the bronzes with $m = 10$ and 12 indicate that the critical temperatures of transitions to the CDW state increase as the m value increases. It should be noted that crystals were grown using glass-forming oxides. This was accompanied by doping the crystals (with *e.g.*, germanium). Due to the different electronic structures of the impurity and the host atoms it is possible to change the density of states at the Fermi level. A Ge $\leftrightarrow$ P substitution of tetrahedral positions was also proposed;[47] we believe that the Ge $\leftrightarrow$ W substitution [38] is also possible, though the impurity concentration is rather low and no significant changes in the temperature of transition to the CDW state are expected.

An increase in the resistivity at room temperature with increasing m is comparable with the decrease in the charge carrier concentration evaluated using a simple Drude model. The average number of electrons in the samples with $m = 4$ and 12 was estimated at 7×10^{27} and 3×10^{27} m^{-3}, respectively. However, this provides no explanation for the fact that the resistivity increases by two orders of magnitude in the temperature interval from 4 to 300 K and undoubtedly indicates that the band theory, as applied to the crystals in question, is of limited use. This is confirmed by the conductivity of these crystals at room temperature ($\sigma_{300\ K} = 10^2\ \Omega\ cm^{-1}$ for $m = 12$), which approaches the lowest possible value of the metallic type conductivity. It should be noticed that the electrophysical properties of the compounds $(PO_2)_4(WO_3)_{2m}$ with large m values can be described in terms of the theory of Fermi liquid.[108]

Experiments with single crystals of the bronzes with $7 < m \leqslant 12$ showed that the Peierls transition temperatures and the resistivity at room temperature increase as m increases, as is expected in accord with the known models. Diffraction intensity measurements of the CDW satellites for $m = 7$ revealed two transitions at $T_{P1} = 183 - 188$ K and $T_{P2} = 47 - 60$ K. The transition temperatures depend on the method of growth of single crystals (chemical vapour transport reactions or solid-phase synthesis) and on the purity of the starting components. The T_{P1} transition, which is accompanied by considerable changes in the resistivity, seems to be a first-order phase transition.[88]

At $T \leqslant 180$ K, the temperature dependences of the resistivity and intensity of the CDW satellites exhibit a large hysteresis. This means that the CDW state is metastable below T_{P1}. The low-temperature transition affects the transport properties of the compound only after the onset of magnetoresistance at 6 T. This transition was detected during specific heat measurements using a relaxation technique.[17] The enthalpy and entropy of this transition to the CDW state are $\Delta H_{P2} = 220$ J mol^{-1} and $\Delta S_{P2} = 5.5$ J mol^{-1} K^{-1}, respectively.

Based on the X-ray diffraction data, two families of CDW satellites at $\boldsymbol{q}_1 = a^*/2\,(T_{P1} \approx 445\ K)$ and $\boldsymbol{q}_2 = a^*/3\,(T_{P2} = 324\ K)$ were found for the compound with $m = 9$.[85] The temperature dependences show that the resistivity at 300 K and the critical temperatures of transition to the CDW state increase as m increases.

It should be noted that the resistivity ($R_{300\ K}$) increases by two orders of magnitude on going from $m = 4$ to $m = 12$. However, the compound with $m = 7$ exhibits an abnormally high resistivity ($R_{300\ K} = 30$ mΩ cm). The temperature T_P monotonically increases by about an order of magnitude for the whole series of compounds with $4 \leqslant m \leqslant 12$ including the bronze with $m = 7$.[47]

Structural studies confirmed the onset of the CDW state in the $(PO_2)_4(WO_3)_{2m}$ compounds with $m = 10$ and 12 at room temperature. For the compound with $m = 10$ the CDW wave vector [$\boldsymbol{q} = (3/7)a^*$ in the undoped sample] is shifted towards $\boldsymbol{q} = a^*/2$ in the Ge-doped samples.[85]

CDW-satellites with $\boldsymbol{q} = a^*/2$ in these bronzes characterise a phase with $m = 12$. However, the nature of the low-temperature resistivity anomaly in these compounds has not been studied as yet.

The phases with $m = 4$ and 6 are regular and undergo a CDW transition. The MPTBp compound with $m = 7$ possesses anomalous properties. The higher $R_{300\ K}$ value corresponds to strong electron – phonon or electron – electron interaction, which is indirectly confirmed by the presence of the CDW satellite harmonics, which indicate an anharmonic CDW modulation. In this context the phenomenon should be described using the bipolaron model.[107]

X-Ray diffuse scattering data obtained for the phases with $m = 4$ and 6 showed that two different CDWs coexist in the temperature intervals 40 – 60 and 75 – 85 K.[3, 88] The large magnetoresistance at low temperatures along the direction perpendicular to perovskite-type layers was ascribed to the existence of unfilled states on the Fermi surface in the CDW state.[100]

To study how the population of energy levels influences the CDW character, the conductivity, magnetoresistance, Hall effect, thermoelectric power and specific heat were studied using a number of $K_x(PO_2)_4(WO_3)_8$ samples with $0.8 < x < 1.94$ [$K_x(PO_2)_4(WO_3)_8$ is an MPTBh compound].[8] All the compounds studied exhibit anomalous dependences of the Curie temperature (T_c) on x. The $T_c(x)$ curve plotted using the conductivity data for $x = 1.3$ passes through a maximum at $T = 170$ K. Based on the results of X-ray diffraction studies of the samples,[13, 58] the observed $T_c(x)$ dependence can be explained as a manifestation of nonmonotonic behaviour of the density of electronic states upon variation of energy. In contrast to transitions in the undoped monophosphate bronze $(PO_2)_4(WO_3)_8$, transitions in $K_x(PO_2)_4(WO_3)_8$ are not determined by conventional Peierls-type charge density instability and cannot be treated only in the framework of the Bloch – Grüneisen model for collisions between charge carriers and phonons.[8, 16]

VI. Conclusion

The phosphate tungsten bronzes exhibiting unusual electrophysical properties and electronic instabilities are studied by various physical and crystallographic methods. A number of MPTBp compounds forms several CDW states. The properties of the MPTBh and DPTBh compounds strongly depend on the type and concentration of inserted cations, affecting the number of electrons in the partially filled conduction band. Peculiarities of the crystal and electronic structures of these compounds permit independent variation of the thickness of the conducting layer and the degree of filling of the conduction band. This opens up great prospects for targeted design of materials with preset electrophysical properties.

Topology features of the Fermi surface in the phosphate tungsten bronzes are studied using modern quantum-chemical calculations and experimental methods.[89, 104, 111 – 114]

The range of phosphate tungsten bronzes is continuously being extended as a result of elaboration of new methods of synthesis. Systematisation of information on the structure – property relations will be useful for development of software for computer simulation of electrophysical properties of these complex systems.

Recently, the phosphate tungsten bronzes have found some fields of practical application. Materials based on the tungsten and molybdenum oxides are now widely used in electrochromic

cells, optical devices, as secondary batteries, in gas sensors and as catalysts of various processes.[115–130] This is also possible for the phosphate tungsten bronzes that exhibit catalytic activity in some oxidation and isomerisation reactions.[131–133]

The first MOSFET-like device employing the motion of CDW in $Rb_{0.3}MoO_3$ was fabricated recently. However, it is of limited use because a single crystal is used as the working substance.[134]

Particular emphasis is placed on practical applications of the dimensionality effects, in particular, for film heterostructures (single-phase epitaxial films grown by pulse-laser deposition), which exhibit a coherent CDW transport. Nonlinear behaviour of these films in weak electromagnetic fields leads to extremely high dielectric constant (from $>10^8$ at low frequencies to 10^3 at microwave frequencies) and is of considerable interest for modern electronics.[135] At present, no devices employing the phosphate tungsten bronzes are available because of the lack of supported bronze thin films. However, first attempts at obtaining such films have been made by the authors of this review.[136–138]

One can assume that the CDW transition temperatures and the resistance of oriented thin films of the phosphate tungsten bronzes can be controlled by synthesis of layers of specified thickness. This allows fabrication of controllable heterostructures made of these new functional materials using, in particular, lithography techniques. Submicrometre-scale structures and nanostructures based on phosphate tungsten bronzes will also permit implementation of new possibilities in the studies of the influence of the dimensionality on the CDW phenomenon.

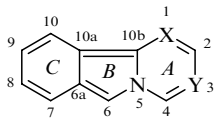
Abstract. The data on the synthesis, structures and chemical properties of pyrido- and pyrimidoisoindole derivatives with an azine ring annelated to a pyrrole ring, which have been published over the last two decades, are generalised. The structure of the π-electron system and the high reactivities of azinoisoindoles are discussed. Special attention is given to aromatic pyrido- and pyrimidoisoindoles. The bibliography includes 86 references.

I. Introduction

The heterocyclic isoindole system attracts the attention of chemists involved in both synthetic and theoretical chemistry. A combination of high reactivity with pronounced aromatic properties is the main distinguishing feature of isoindole derivatives.[1–3] Several quantum-chemical approaches to the estimation of aromaticity and description of the 10π-electron system of the isoindole ring have been proposed. It was found that the concept based on the calculation of valence activities of its fragments reflects the structures and properties of such *ortho*-quinoid heteroaromatic compounds in the most adequate way.[4,5] This concept was confirmed experimentally for isoindole derivatives using X-ray diffraction analysis[4] and mass spectrometry.[6]

The present review is devoted to the methods of synthesis and chemical properties of three types of isoindole systems fused at the pyrrole ring and containing a junction nitrogen atom, *viz*., pyrido[2,1-*a*]- (**1**),† pyrimido[2,1-*a*]- (**2**) and pyrimido[6,1-*a*]isoindole (**3**) derivatives.



1: X = Y = CH;
2: X = N, Y = CH;
3: X = CH, Y = N

The annelation, to the electron-donating isoindole ring, of an additional acceptor azine ring strongly influences the structures and reactivities of these tricyclic systems, and unusual chemical properties can be expected. To date, investigations of *a*-fused isoindole systems are scarce. Some publications are devoted to original approaches to the synthesis of such derivatives, their biological activities and other useful properties. A review[2] devoted to the synthesis and properties of simple isoindoles provides but few examples of preparation of fused isoindole systems. Thus a small chapter in the monograph[1] published in 1983 is virtually the only literature source devoted to the chemistry of azinoisoindoles, whereas a recently published review[7] deals with the description of fused triazolo- and tetrazoloisoindoles. The present review surveys the data on the methods for the synthesis and properties of pyrido- and pyrimidoisoindoles published over the last two decades and includes some earlier publications, which enables the comprehensive presentation and systematisation of the data published on the subject.

II. Methods of synthesis of pyrido- and pyrimidoisoindoles

The uniqueness of the chemistry of azinoisoindoles can well be illustrated by some specially developed synthetic methods. As a rule, the starting compounds contained a benzene ring (*C*) to which a heterocyclic system [a pyrrole (*B*) or an azine (*A*) ring or both rings simultaneously] was attached. The data on the annelation of the benzene ring to indolizine derivatives (or their aza analogues) yielding azinoisoindoles are unavailable in the literature published over the last two decades, although several syntheses of this kind were described earlier.[1]

1. Synthesis of pyrido[2,1-*a*]isoindole derivatives

a. Closure of the pyrrole ring with formation of the N(5) – C(6) bond

The closure of the pyrrole ring with the concomitant formation of the N(5) – C(6) bond is one of the general approaches to the synthesis of aromatic isoindole systems. There are only a few examples of the synthesis of pyrido[2,1-*a*]isoindoles prepared by this method. Thus the intramolecular alkylation of the pyridine nitrogen atom is based on the formation of 2-[(*o*-halogenomethylaryl)]pyridines and has only been applied to the synthesis of pyrido[2,1-*a*]isoindole[8] and its methyl derivative.[9] Treatment of pyridines **4** with HBr affords pyrido[2,1-*a*]isoindolium bromide **5** in good yields. The dehydrobromination of the salt **5** (R^1 = H) with an aqueous solution of sodium carbonate gives a base (**1**) which is unstable in air, but can be used for further conversions.

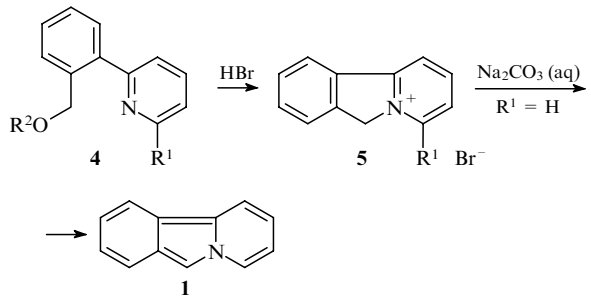
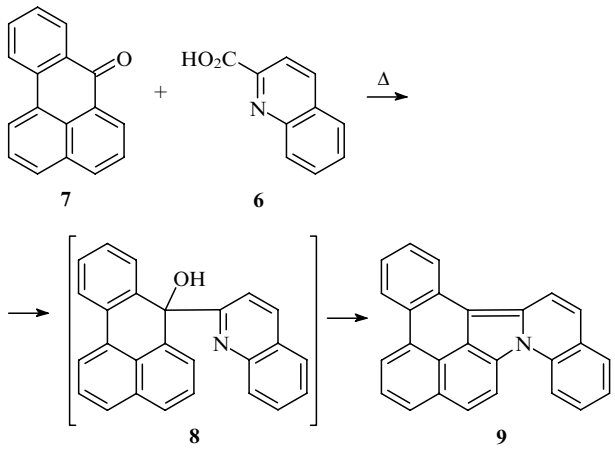
Received 1 March 2004
Uspekhi Khimii **73** (8) 833 – 848 (2004); translated by R L Birnova

† These systems can also be regarded as benzo[*a*]indolizine derivatives; however, in general, we shall consider isoindole as the base fragment.



R^1, R^2 = H, Me.

A heptacyclic heteroaromatic system with a junction nitrogen atom containing a pyrido[2,1-*a*]isoindole fragment has been synthesised.[10] Upon thermal decarboxylation of quinaldinic acid (**6**) in the presence of *meso*-benzanthrone (**7**), the intermediate 2-(7-hydroxy-7-benzanthryl)quinoline (**8**) eliminates a water molecule and cyclises into compound **9**.

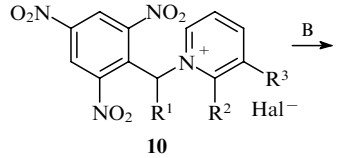


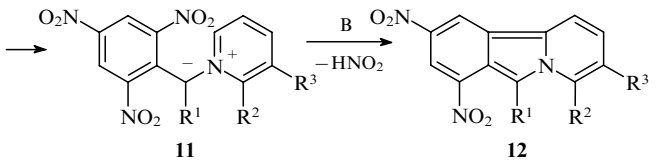
In this case, the formation of the N(5)–C(6) bond is preceded by the formation of the C(10a)–C(10b) bond, which results in the closure of the pyrrole ring and the formation of a fused pyrido[2,1-*a*]isoindole system.

b. Closure of the pyrrole ring with formation of the C(10a)–C(10b) bond

The most popular procedures for the synthesis of the pyridoisoindole system are based on the use of readily available *N*-substituted pyridine derivatives as the starting compounds. Two main types of cyclisation mechanisms are possible: one of them involves the formation of an ionic intermediate, while the second consists of the formation of a radical intermediate. Reactions *via* organometallic intermediates can be singled out into a separate group.

The Kröhnke cyclisation of pyridinium ylides. This cyclisation was discovered by Kröhnke[11] and is characteristic of ylides generated from pyridinium salts **10**. This served as the basis for the development of a general method for the formation of an isoindole fragment of nitrogenous heterocycles which was considered in detail in the monograph. [1] On treatment with a base, *e.g.*, an excess of piperidine in DMSO, pyridinium ylide **11** is converted into pyridoisoindole **12**.



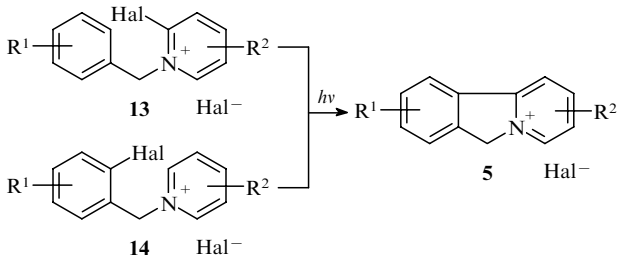


R^1 = H, ArCO; R^2, R^3 = H, Alk; B is a base.

This procedure, *viz*., short-term heating in aqueous methanol with 2 equiv. NaOH, is used for the preparation of 7,9-dinitropyrido[2,1-*a*]isoindole **12a** (R^1, R^2, R^3 = H) in 97% yield.

Cyclisation of radicals generated from aryl halides. Two approaches to the generation of free radicals, *viz*., photochemical and initiator-induced, are considered below.

Intramolecular photocyclisation enables the preparation of pyridoisoindoles containing halogens and alkyl substituents in both benzene and pyridine rings. The pyrido[2,1-*a*]isoindolium salt **5** (R^1 = R^2 = H) was synthesised for the first time by cyclisation of the isomeric pyridinium salts **13** (R^1 = R^2 = H) and **14** (R^1 = R^2 = H) upon UV irradiation of their aqueous solutions.[12]

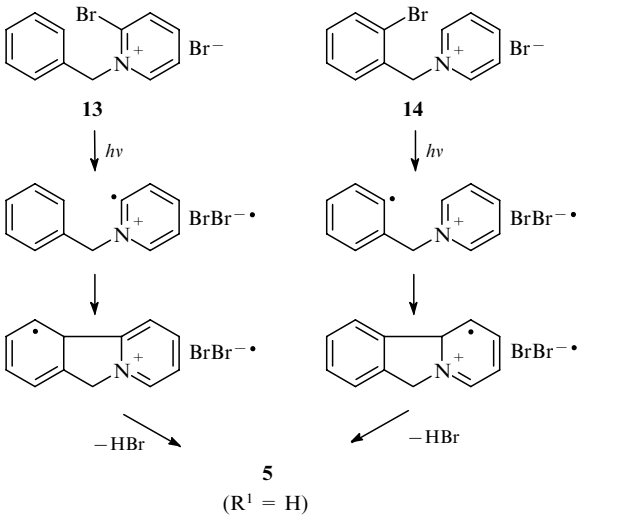


Hal = Cl, Br; R^1, R^2 = H, Me, Cl, Br.

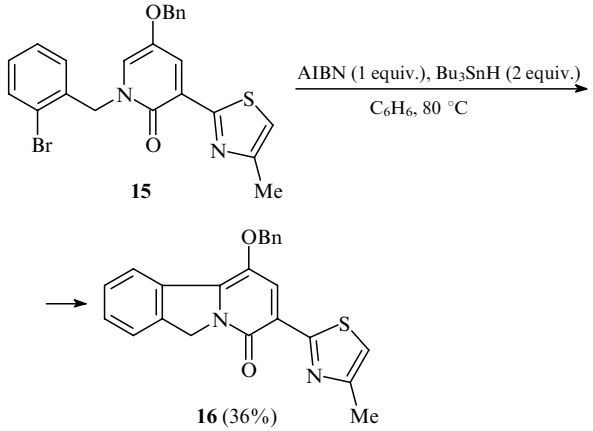
Later, this method was extended to substituted pyridinium salts.[13, 14] The best yields of reaction products were obtained upon monochromatic irradiation of the substrate at the absorption wavelengths of the starting salt (~260–280 nm).[14] It was found that *N*-benzyl-2-halogenopyridinium salts **13** are more reactive than their isomers **14**. The effects of the substituents in the benzene and pyridine rings on the reaction rates and product yields have been investigated. No photocyclisation takes place, if the benzene ring of the starting salt contains a nitro group [12] or if alcohols, *e.g.*, methanol or ethanol, are used as solvents.[14]

The intermediates and products of laser-induced flash photolysis (a laser pulse at 266 nm) of the isomers **13** and **14** have been studied [15] and the following reaction mechanism has been proposed: the initial photohomolytic cleavage of the C–Hal bond is followed by radical arylation and proton elimination (Scheme 1).

Scheme 1

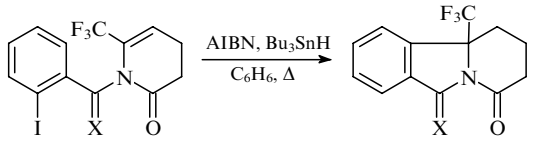


A method for the preparation of pyridoisoindoles by radical cyclisation of the corresponding *N*-(*o*-bromobenzyl)pyridone derivatives in the presence of an initiator has been developed.[16] Thus treatment of aryl bromide **15** with azobisisobutyronitrile (AIBN) and Bu_3SnH (benzene, 80 °C) results in the generation of an aryl radical which is intramolecularly attached to the pyridone ring at position 6. Retention of the double bond in compound **16** is interpreted as spontaneous oxidation of the intermediate radical addition product. This reaction occurs through a non-chain mechanism, so the initiator is used in an equimolar amount.



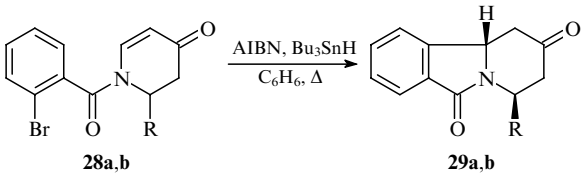
Hydrogenated pyrido[2,1-*a*]isoindoles are formed similarly from tetrahydro- and dihydropyridine derivatives containing a 5,6-double bond. Thus starting from *N*-(*o*-halobenzyl)pyridines **17** compounds **18** are formed under radical initiation conditions, whereas derivatives **19** (R = H) give rise to the isomers **20** and **21** in total yields 34% – 52%.[17] In these reactions, reductive debromination affords compounds **22** and **23** as side products (Scheme 2).

N-(*o*-Iodobenzyl and *o*-iodobenzoyl)-3,4-dihydro-2-pyridones (**24** and **25**, respectively) also undergo cyclisation under the action of the system Bu_3SnH – AIBN.[18] This reaction requires catalytic amounts of the initiator; the reaction time increases to 8 – 10 h, and the corresponding products **26** and **27** are formed in high yields.



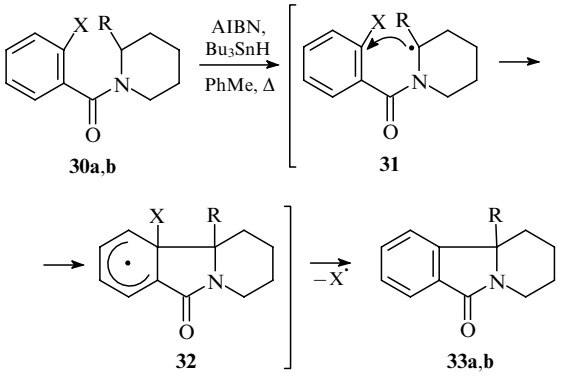
X = 2 H (**24**, **26**); O (**25**, **27**).

The radical cyclisation of 2-substituted 2,3-dihydro-4-pyridones **28** containing an *o*-bromobenzoyl group at the nitrogen atom occurs in good yields and with high diastereoselectivities. The pyridonoisoindolinones **29** formed were isolated as *trans*-isomers with a pseudo-axial position of the substituent R. The stereochemistry of the derivative **29a** was confirmed by data from X-ray diffraction analysis.[19]



R = Ph (**a**, 91%), Me (**b**, 86%).

In contrast to the previous examples, *N*-benzoylpiperidines **30** do not contain a double bond as the site for the addition of a phenyl radical. However, these substrates can eliminate the hydrogen atom from the α-position to the nitrogen atom with a subsequent attack of the benzene ring. Such products were isolated from the reaction mixture upon radical cyclisation of compounds **30** under the action of the system AIBN – Bu_3SnH.[20] A stepwise formation of two radical intermediates, **31** and **32**, eventually resulting in the pyridoisoindole derivatives **33** was suggested.

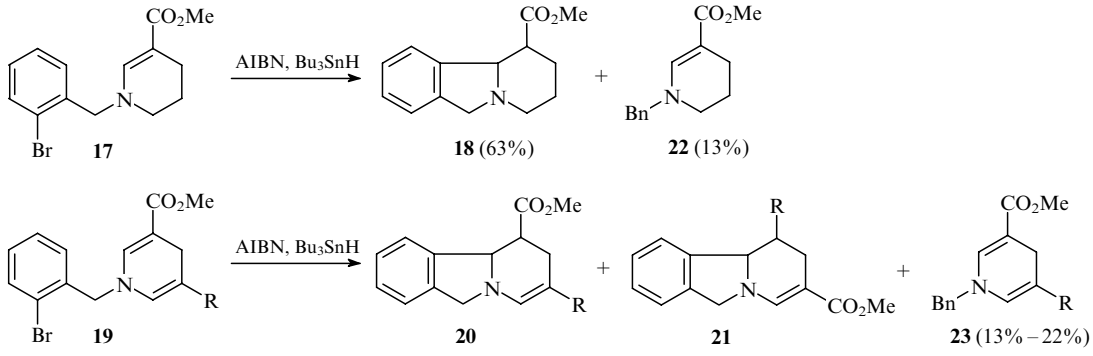


X = H, R = All (**a**, 10%); X = I, R = $CH_2C{\equiv}CSiMe_3$ (**b**, 18%).

This approach was used in the synthesis of a series of pyrido[1,2-*a*]isoindoles containing various functional groups in the pyridine ring.[21]

Intramolecular cyclisation of organometallic intermediates. The Heck intramolecular cyclisation is the most popular reaction of this type. Cyclisation of arylpalladium intermediates involving the double bonds of the tetrahydropyridine ring is the key step of this reaction. An unsuccessful attempt at cyclisation of substituted aryl bromide **15** under conditions of the Heck reaction has been described.[16] The use of the system $Pd(OAc)_2$ – PPh_3 – K_2CO_3 –

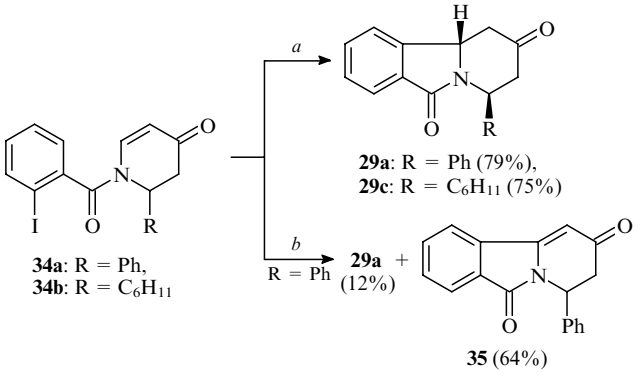
Scheme 2



R = H, CO_2Me.

Et_4NCl led only to the reduction and decomposition of the substrate.

However, the intramolecular cyclisation using arylpalladium reagents was successfully applied to *N*-acyltetrahydropyridones **34** (see Refs 22 and 23).

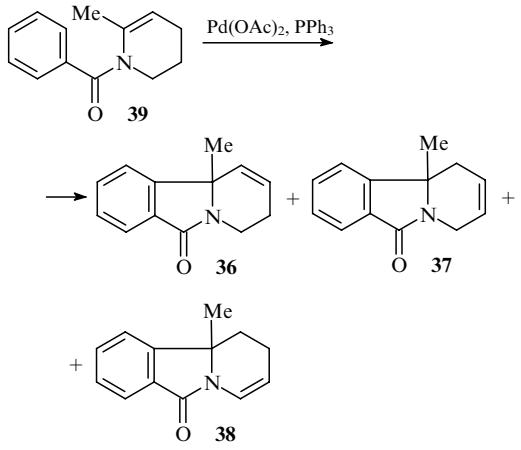


(*a*) $(Ph_3P)_2Pd(OAc)_2$, HCO_2H, Et_3N, DMF, 80 °C;

(*b*) $(Ph_3P)_2Pd(OAc)_2$, Bu_4NBr, NaOAc, molecular sieves 4 Å, DMF, 80 °C.

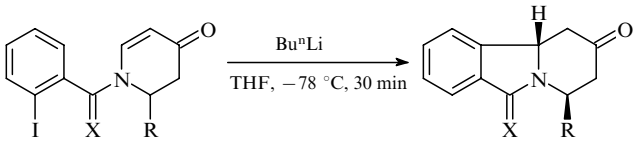
In the presence of formic acid (conditions *a*), this reaction occurs regio- and stereoselectively and yields only the *trans*-diastereomer **29** as in the case of the radical cyclisation of this substrate.[19] In the absence of a proton source (conditions *b*), the dehydrogenated derivative **35** is the main product. The carbonyl group of the amide bond is essential in this reaction; in its absence, only the dehalogenation of the substrate takes place.[22]

The competitive formation of three isomeric tetrahydropyrido[2,1-*a*]isoindolones **36**–**38** is observed in the intramolecular cyclisation of *N*-(*o*-iodobenzoyl)-2-methyltetrahydropyridine **39** *via* arylpalladium complexes. However, by varying reaction conditions one can change the ratio of the reaction products and even make this process regiospecific.[24, 25]



Conditions	*T* /°C	Time	Yield (%)	Selectivity (%)			Ref.
				36	**37**	**38**	
MeCN	–	–	–	39	34	27	24
K_2CO_3, Et_4NCl, DMF	30	2 h	72	68	32	–	25
TlOAc, MeCN	80	4 days	65	100	–	–	24

The cyclisation mechanism of 2-substituted *N*-(2-lithiobenzoyl- and 2-lithiobenzyl)-2,3-dihydro-4-pyridones formed upon treatment of substituted pyridones **34** and **40**, respectively, with butyllithium is similar to that of the Heck reaction. Rapid substitution of lithium for the halogen is followed by intramolecular nucleophilic addition.[26] This reaction is characterised by a high degree of stereoselectivity (compounds **29** and **41** were isolated as *trans*-isomers) and has found sufficiently broad synthetic application.

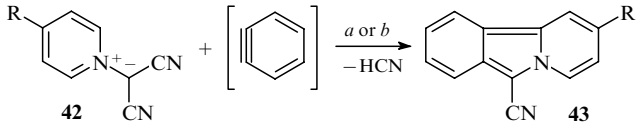


X = O (**29**, **34**); 2 H (**40**, **41**).

Compound	X	R	Yield (%)
29	O	Ph	91
	O	C_6H_{11}	86
	O	$CH_2=CH$	89
	O	$CH\equiv C$	88
	O	$C_4H_9C\equiv C$	86
41	2 H	H	50

c. Closure of the pyrrole ring with simultaneous formation of the C(5) – C(6) and C(10a) – C (10b) bonds

Heterocyclisation involving dehydrobenzene is an approach to the construction of the azinoisoindole system. 1,3-Dipolar addition of 4-substituted pyridinium dicyanomethylides **42** to dehydrobenzene results in 2-R-6-cyanopyrido[2,1-*a*]isoindoles **43** in moderate yields.[27–30] Dehydrobenzene can be generated by pyrolysis of diphenyliodonium-2-carboxylate or reaction of anthranilic acid with isoamyl nitrite. The derivatives **43** formed can themselves be used as 1,3-dipolar reagents (see Section IV.1.c). 6-Cyanopyrazino[2,1-*a*]isoindole is prepared from pyrazinium dicyanomethylide in a similar way, whereas pyrimidinium dicyanomethylide does not generate the corresponding heterocycles under these conditions.



R = H, Me, Ph, COPh, COMe, CO_2Me;

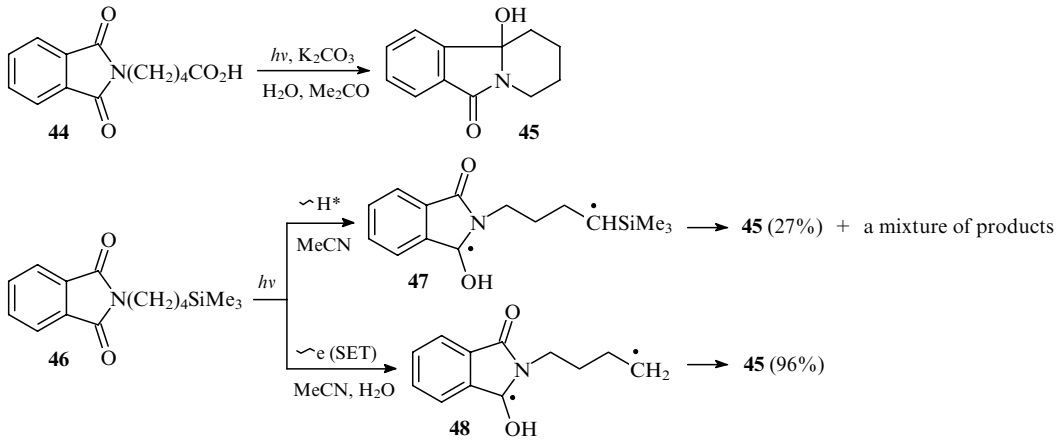
(*a*) 190–200 °C; (*b*) chloroform – acetone, Δ.

d. Closure of the pyridine ring with formation of the C(1) – C(10b) bond

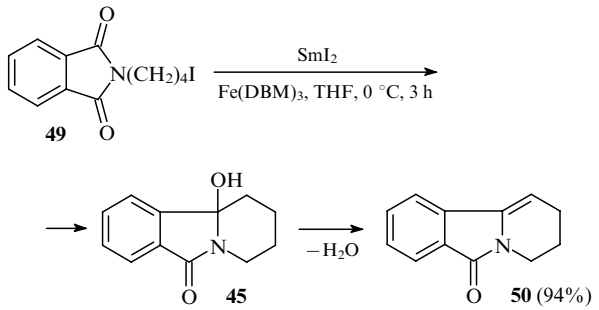
This methodology for the synthesis of a pyrido[2,1-*a*]isoindole structure is based on the use of *N*-substituted phthalimides and their analogues as the starting compounds. Two heterocyclisation principles are possible depending on the type of the intermediate formed.

Radical cyclisation. Several examples of cyclisations yielding saturated pyridoisoindoles are documented. Thus irradiation of the phthalimide derivative **44** results in photochemical triplet-sensitised decarboxylation. The intermediate biradical generated upon the electron transfer (the SET-mechanism) from the carboxylate anion to one of the carbonyl groups of the phthalimide eliminates CO_2 and undergoes cyclisation to give compound **45**.[31, 32] Irradiation of *N*-[4-(trimethylsilyl)butyl]phthalimide **46** in acetonitrile yields a mixture of products, since these conditions favour the simultaneous realisation of two mechanisms, *viz*., intramolecular abstraction of the hydrogen atom by the carbonyl group of phthalimide resulting in the formation of the biradical **47** followed by its subsequent conversions and cleavage of the trimethylsilyl group with a single-electron transfer resulting in the biradical **48**. If the reaction is carried out in an acetonitrile – water (35% of water) mixture, the second mechanism predominates and compound **45** is the only product (yield 94%) (Scheme 3).[33]

Scheme 3

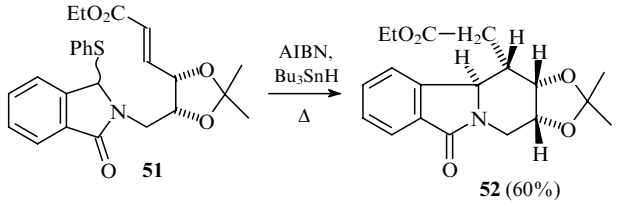


Cyclisation of the imide **49** under the action of SmI_2 (radical reduction) and subsequent spontaneous dehydration result in compound **50**.[34]

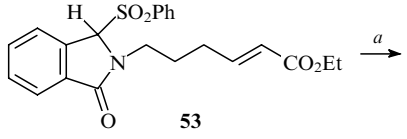


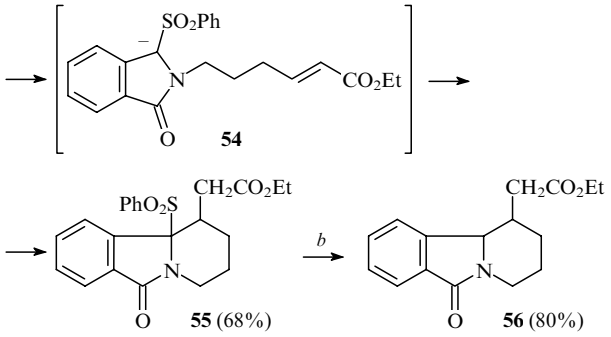
DBM is dibenzoylmethane.

Six-membered *exo*-cyclisation of the α-aminoacyl radical generated upon cleavage of the phenylthio group from phthalimidine **51** yields a functionalised saturated pyrido[2,1-*a*]isoindole derivative **52**.[35]



Cyclisation involving anionic intermediates. Among other reactions of formation of the pyridoisoindole system, this method is illustrated by the largest number of examples. Under the action of bases, substituted phthalimidine **53**, which is structurally close to the aforementioned derivative **51**, generates the α-aminoacyl-α-sulfoaryl anion **54**, which undergoes a Michael-type intramolecular addition to the double bond of the α,β-unsaturated ester substituent.[36] The tricyclic sulfone **55** is reduced to partially saturated isoindolone **56** upon treatment with Raney nickel.

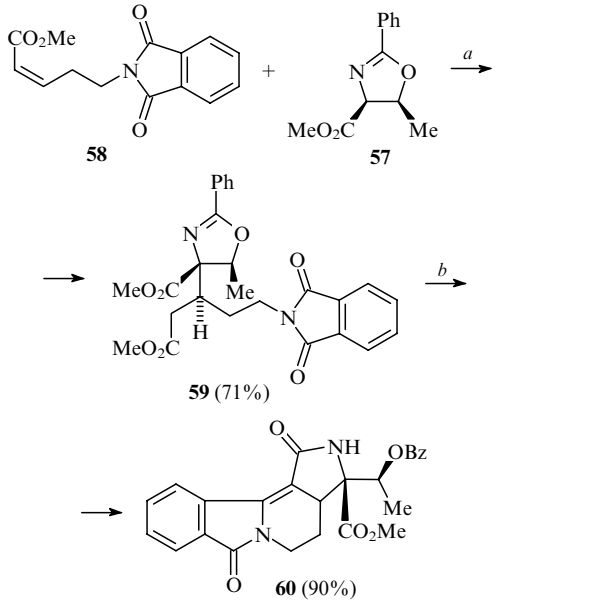




(*a*) NaH, DMSO, THF, 20 °C, 20 min;
(*b*) Ni/Re, EtOH, ultrasound, 5 min.

The formation of a nitrogen-containing tetracyclic system, which incorporates a pyridoisoindole fragment, was observed [37] in the recyclisation of the Michael addition products of a lithium derivative of the oxazoline **57** to α,β-unsaturated esters.

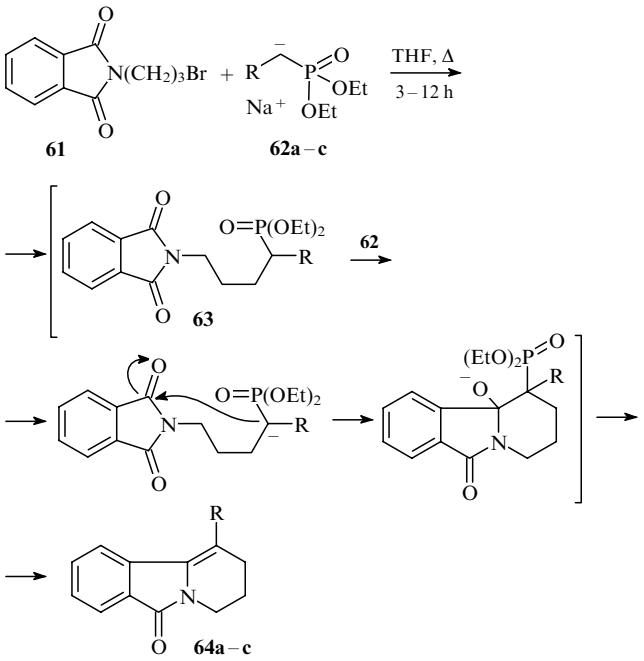
The adduct of the oxazoline anion to (*Z*)-ω-phthalimidopent-2-enoate **58**, *i.e.*, compound **59**, is converted into the tetracycle **60** in high yield under acidic conditions.[37]



(*a*) LDA, DME, −78 °C; (*b*) CF_3CO_2H, Na_2SO_4, H_2O, THF.

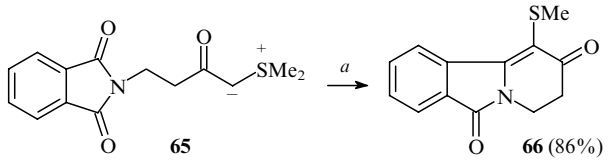
Studies of alkylation of *N*-(3-bromopropyl)phthalimide **61** under the action of an excess of the anions **62** have shown that the closure of the pyridine ring in the intermediate phosphonates **63**

formed occurs by the Horner – Wadsworth – Emmons reaction to yield the pyridoisoindole derivatives **64**.[38]



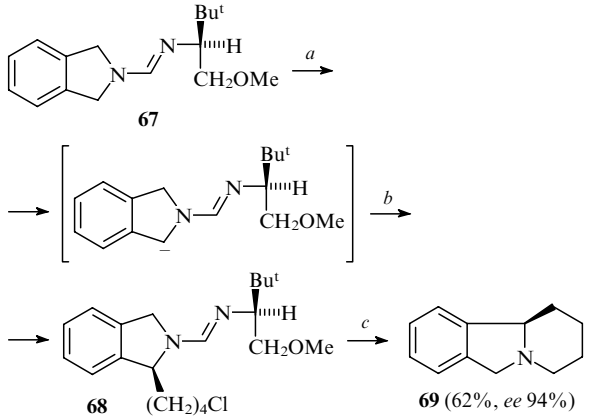
R = P(O)(OEt)$_2$ [**a** (78%)], CO_2Et [**b** (92%)], CN [**c** (95%)].

Closure of the C(1) – C(10b) bond of the pyridoisoindole system was also observed upon intramolecular cyclisation of ketone-stabilised sulfur ylides with a phthalimide substituent.[39–41] For example, cyclisation of the ylide **65** (prepared in four steps from β-alanine) in the presence of an equimolar amount of benzoic acid gave substituted pyrimidoisoindoledione **66**.[40]



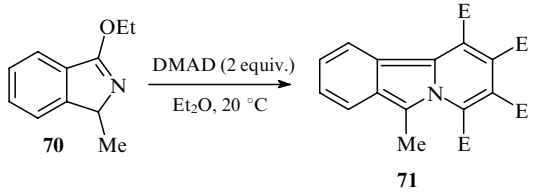
(*a*) $PhCO_2H$, PhMe, Δ.

Asymmetric mono-C-alkylation of chiral amidine **67** with 1,4-dichlorobutane gave compound **68**; the latter underwent easy intramolecular cyclisation to give an optically active hydrogenated pyridoisoindole **69** following hydrazinolysis.[42]



(*a*) Bu^{n}Li, THF, −78 °C; (*b*) $Cl(CH_2)_4Cl$, THF, −100 °C, 30 min; (*c*) N_2H_4, 20 °C, 5 – 10 min.

Pyridoisoindoles were also synthesised from substituted isoindole; in this case, the pyridine ring is 'made complete' using an addition reaction. Thus 3-ethoxy-1-methyl-1*H*-isoindole **70** reacts with dimethyl acetylenedicarboxylate (DMAD) (molar ratio 1 : 2) at room temperature to give 1,2,3,4-tetramethoxycarbonyl-6-methylpyrido[2,1-*a*]isoindole **71**.[43]

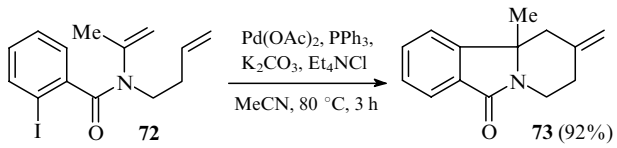


E = CO_2Me.

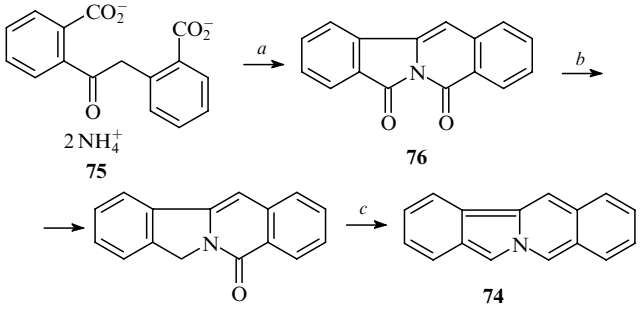
Hence, this method allows one to synthesise both saturated and aromatic pyridoisoindole derivatives.

e. Simultaneous closure of two rings

In this Section, we provide examples of several different approaches to the formation of a pyridoisoindole system. Thus aryl iodide **72** enters the so-called 'tandem' reaction with simultaneous closure of both heterocyclic rings, *viz*., pyrrole and pyridine, under conditions of the Heck reaction.[44] In terms of a hypothetical mechanism of such a double cyclisation, a palladium complex plays the role of a catalyst. Treatment of the starting iodide with palladium acetate in the presence of triphenylphosphine (2 equiv.) yields an arylpalladium intermediate where the palladium atom migrates from the aryl carbon atom to the alkyl carbon atom. This alkylpalladium complex contains no hydrogen atoms in the β-position with respect to the palladium atom which might be eliminated; therefore, it reacts with the second double bond present in the molecule. These conditions favour the transfer of the palladium atom to another alkyl carbon atom, its subsequent splitting as the initial palladium complex and formation of hydrogenated pyridoisoindolone **73**.

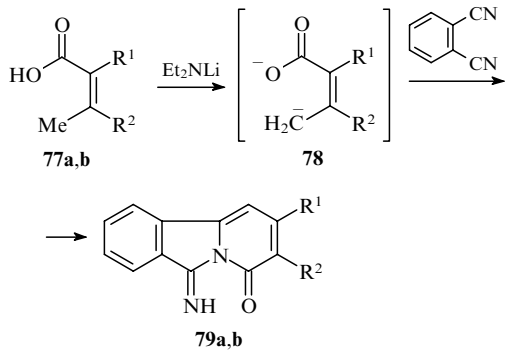


Synthesis of isoindolo[2,1-*b*]isoquinoline **74** where simultaneous formation of two heterocyclic rings also occurs has been described.[45] Heating of dry diammonium salt of 2,2′-dicarboxydeoxybenzoin **75** results in its cyclisation into 5,7-dihydroisoindolo[2,1-*b*]isoquinoline-5,7-dione **76**, which is reduced to the heteroaromatic system **74** in a two-step reaction.



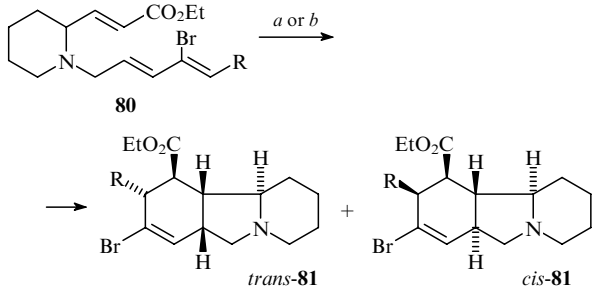
(*a*) Ph_2NH, 240 °C; (*b*) Zn, HCl, AcOH; (*c*) $LiAlH_4$, Et_2O, Δ, 3 h.

Treatment of 2- or 3-methylcrotonic acid **77** with lithium diethylamide gives the dianions **78**; their reactions with phthalodinitrile result in 6-iminopyrido[2,1-*a*]isoindolones **79**.[46] The yields of the conversion products depend on the type of the unsaturated acid used.



R^1 = Me, R^2 = H (*E*) [**a** (9%)]; R^1 = H, R^2 = Me [**b** (39%)].

The intramolecular Diels–Alder reaction in the substrates **80** also afforded partially saturated pyridoisoindoles. The starting molecule contains a piperidine ring, while the pyrrole and aliphatic rings are being constructed. The decahydropyrido-[2,1-*a*]isoindole structure is formed in a quantitative yield as a mixture of two diastereomeric pairs **81** (*cis*- and *trans*-isomers, the latter being predominant). This reaction occurs quantitatively both upon heating and under the action of a catalyst ($TiCl_4$).[47,48]



R = Me, Pr^i;

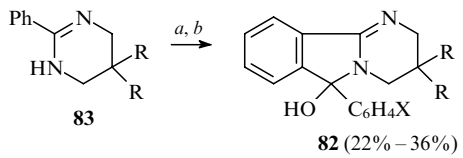
(*a*) PhMe, Ar, 100–150 °C, 16.5 h; (*b*) $TiCl_4$, CH_2Cl_2, 20 °C, 1 day.

2. Synthesis of pyrimido[2,1-*a*]isoindole derivatives

Systems containing fused isoindole and pyrimidine rings have received much less attention than pyrido[2,1-*a*]isoindoles. However, pyrimido[2,1-*a*]isoindole derivatives have recently been synthesised using both novel reactions and traditional approaches.

a. Closure of the pyrrole ring

Houlihan *et al.*[49] have performed synthesis of a series of 6-aryl-substituted 2,3,4,6-tetrahydropyrimido[2,1-*a*]isoindol-6-oles **82**. The *N*,*o*-dilithium derivatives prepared by treatment of 2-phenyl-1,4,5,6-tetrahydropyrimidines **83** with butyllithium reacted with methyl esters of halo-substituted benzoic acids. Compounds **82** represent structural analogues of the medicinal drug Mazindol (see Section V).



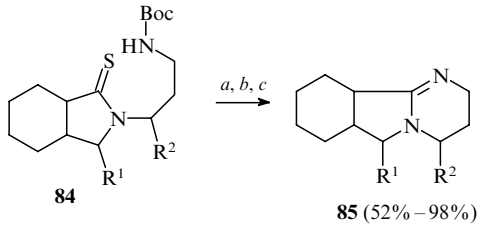
X = Cl, F; R = H, Me;

(*a*) Bu^nLi, THF, 50 °C, 3 h; (*b*) $XC_6H_4CO_2Me$, THF, 50 °C, 6 h.

Not only was this approach to the construction of the isoindole structure employed in the synthesis of annelated pyrimidine analogues, but it was also extended to imidazole and diazepine derivatives.[49]

b. Closure of the pyrimidine ring

Conventional cyclisation of thiolactams **84** into amidines[50] has recently been used for the synthesis of a series of the derivatives **85** containing a hydrogenated pyrimido[2,1-*a*]isoindole system with hydroxyalkyl substituents in positions 4 and/or 6.[51,52] This reaction includes several steps, *viz*., *S*-methylation of the starting thiolactam with methyl iodide to yield a methylthioimmonium salt, deprotection of the terminal amino group by treatment with trifluoroacetic acid and final spontaneous cyclisation into amidine **85** following deprotonation of the intermediate ammonium salt with a base.



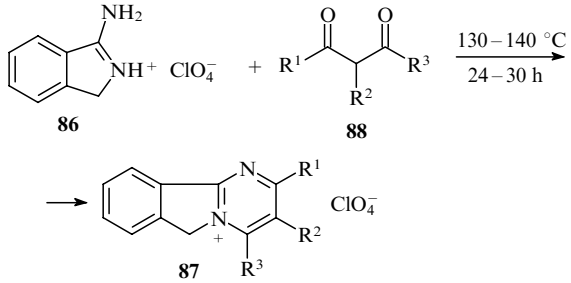
R^1 = R^2 = CH_2OH; R^2 = H: R^1 = $(CH_2)_2OH$, $CH_2CH(Ph)OH$;

(*a*) MeI, 20 °C, 17 h; (*b*) CF_3CO_2H, CH_2Cl_2, 0 °C;

(*c*) Et_3N or NaOH (solid), CH_2Cl_2, 0 °C, 2 h.

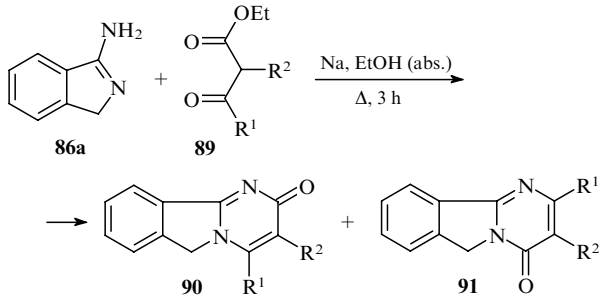
In the reactions of chiral starting thiolactams, enantiomerically pure hydroxyamidines **85** are formed, which proved to be very useful as catalysts in the asymmetric addition of nucleophiles to α,β-unsaturated ketones.

Cyclisation starting from 1-aminoisoindole. Construction of the pyrimidine ring fused to isoindole can also be performed starting from 1-aminoisoindole or its salts containing an N–C=N fragment. This methodology was initially applied to 1-aminoisoindolium perchlorate **86**. The pyrimido[2,1-*a*]isoindolium salts **87** substituted in the pyrimidine ring were prepared by its condensation with β-diketones **88**.[53,54]



R^1, R^2, R^3 = H, Me, Et.

The 1-aminoisoindole base reacts similarly with β-oxo esters **89** to give both 2-oxo (**90**) and 4-oxo isomers (**91**).[55,56] A detailed investigation into this reaction has made it possible to select the conditions for the isolation of each of the isomers. Thus it was found that the yield of 4-oxo derivatives increases with temperature.



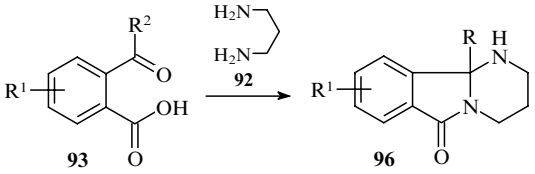
R^1–R^2 = $(CH_2)_n$; *n* = 3, 4.

c. Simultaneous closure of pyrrole and pyrimidine rings

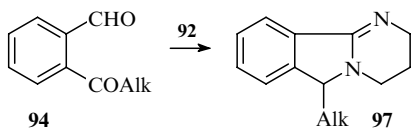
Condensation of *o*-acylbenzoic acids and related compounds with 1,3-diamino derivatives, which results in simultaneous closure of the pyrrole and pyrimidine rings, is the most efficient approach to the synthesis of the pyrimido[2,1-*a*]isoindole system and was

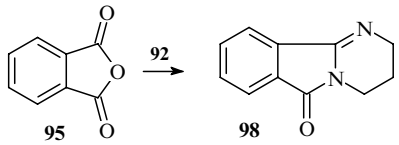
detailed in the monograph.[1] Here, the most typical examples of synthesis based on this approach are mentioned.

1,3-Diaminopropane **92** reacts with *o*-acylbenzoic acids **93**, *o*-acylbenzaldehydes **94** and phthalic anhydride **95** (but not with phthaloyl dichloride or phthalates[57]) to give hexahydropyrimido[2,1-*a*]isoindol-6-ones **96** or the tetrahydro derivatives **97** and **98**, respectively. This reaction usually occurs upon boiling of the reaction mixture in toluene or xylene with azeotropic distillation of water in the presence of catalytic amounts of toluene-*p*-sulfonic acid (for **93**, the yields exceed 60%).

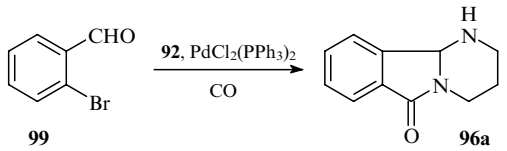


R^1 = H, Alk; R^2 = Alk, Ar.

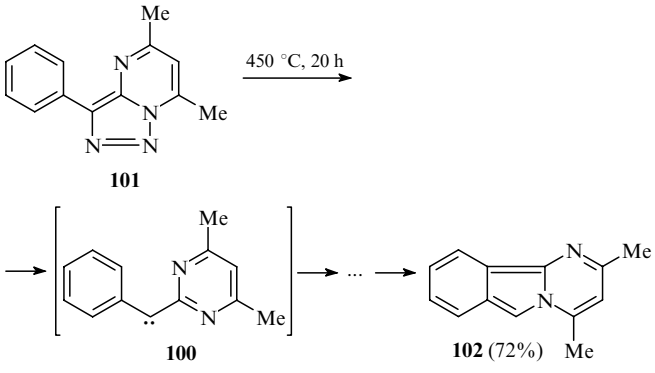




Carbonylation of 2-bromobenzaldehyde **99** with 1,3-diaminopropane **92** in the presence of a palladium catalyst also results in hexahydropyrimido[2,1-*a*]isoindol-6-ones.[58]

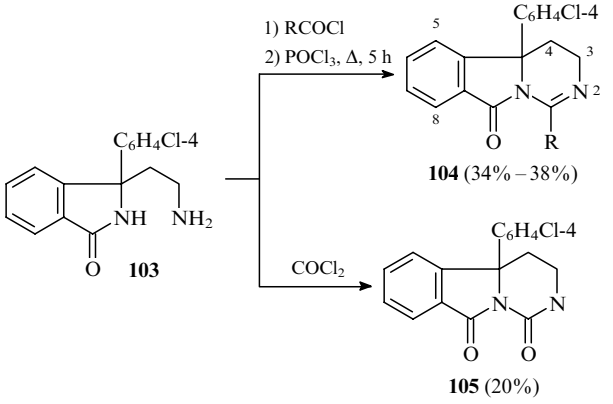


Heterocyclisation of carbene **100** formed upon gas-phase thermolysis of phenyltriazolo[1,5-*a*]pyrimidine **101** can also be related to this type. Pyrimido[2,1-*a*]isoindole **102** is the main reaction product.[59,60]



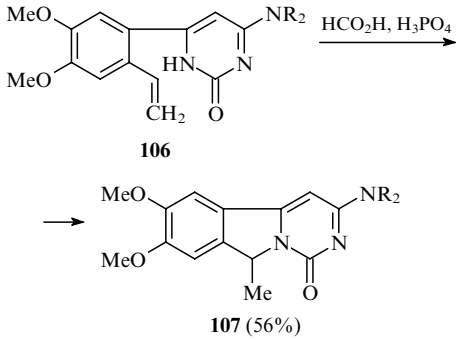
3. Synthesis of pyrimido[6,1-*a*]isoindole derivatives

The aromatic system of pyrimido[6,1-*a*]isoindole has not been synthesised so far; only a few examples of preparation of partially saturated derivatives of this heterocycle have been described. Thus cyclisation of diamides prepared by acylation of amine **103** leads to the closure of the azine ring of the pyrimido[6,1-*a*]isoindole **104**. Upon heating with phosgene, this amine forms compound **105**. The cyclic structure of the products **104** and **105** is confirmed by an upfield shift of a signal for the axial proton at the C(4) atom in the ^{1}H NMR spectra in comparison with the non-cyclic structure.[61]



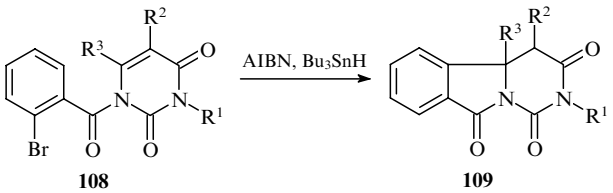
R = H, Me, 4-ClC_6H_4, CH_2Ph.

Treatment of pyrimidone **106** with formic and orthophosphoric acids results in the closure of the pyrrole ring and the formation of pyrimido[6,1-*a*]isoindole derivatives **107**.[62] Although the mechanism of this reaction has not been studied in detail, it can be assumed with a high degree of certainty that in acidic medium the arylmethyl carbocation, which is formed first, attacks either the carbon atom or the nitrogen atom of the enamine fragment. The direction of this reaction is determined by the presence, in the pyrimidine ring, of the *N*-methylpiperazine group which manifests electron-donating properties and induces strong activation of the nitrogen atom at position 1.



NR_2 is *N*-methylpiperazin-1-yl.

Treatment of the 1-(*o*-bromobenzoyl)pyrimidine derivatives **108** with Bu_3SnH or $(Me_3Si)_3SiH$ in the presence of catalytic amounts of AIBN afforded a series of tricyclic pyrimido[6,1-*a*]-isoindolinetriones **109** in good yields.[63] This synthetic approach is similar to the above-described radical heterocyclisation and allows the formation of the C(10a)–C(10b) bond and the closure of the pyrrole ring of hydrogenated pyrido[2,1-*a*]isoindolediones (see Section II.1.b).



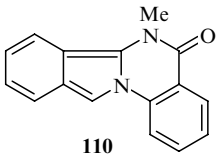
R^1	R^2	R^3	Yield (%)
Bu^s	Me	H	50
H	H	H	59
H	H	Me	80
H	H	CF_3	59

Thus, the choice of a synthetic procedure is determined by the structure of the desired azinoisoindolines.

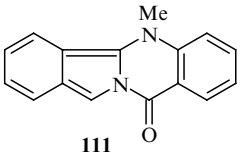
III. Electronic structures and spectral characteristics of aromatic azinoisoindoles

Quantum-chemical calculations of aromatic azinoisoindoles **1**–**3** have demonstrated that these compounds can be regarded as 14π-electron aromatic systems characterised by a high degree of internuclear conjugation and localisation of double bonds in both six-membered rings, *i.e.*, azine and benzene. The highest negative π-charge of the systems **1**–**3** is on the carbon atom 6 of the pyrrole ring and exceeds that on the nitrogen atoms.[5] These peculiarities of the electronic structure are responsible for the changes in the chemical properties of azinoisoindole compounds in comparison with isoindole itself.

It is of note that annelation of the quinazolone fragment to the side *a* of isoindole yields the corresponding isomeric 18π -electron isoindoloquinazolones **110** and **111**, which can be presented as two weakly interacting π-fragments, one of which represents the 10π-electron fragment of isoindole.



110

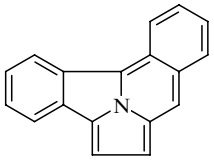


111

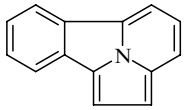
Consequently, their chemical behaviour should be similar to that of 1,2-disubstituted non-fused isoindoles.[5] The ability of isoindoloquinazolones to be involved in [4 + 2]cycloaddition reactions to give 1 : 1 adducts confirms this statement.

It is known that simple isoindoles behave as dienes in the Diels–Alder reaction involving the pyrrole ring.[1,2] Based on the results of quantum-chemical calculations, Kovtunenko *et al.*[64] attempted to predict the behaviour of various fused isoindoles in this reaction and in a competitive Michael addition in the α-position of the pyrrole ring. These calculations allowed one to suggest high activities of the compounds studied as dienes; the addition of dienophiles to all the azinoisoindoles under study (as in the case of isoindole) occurs most probably to the pyrrole diene fragment, *i.e.*, at positions 6 and 10b. The values of the static reactivity indices suggest that the activities of azinoisoindoles in both synchronous and non-synchronous cycloaddition reactions decrease in the following order: **110** = **111** > **1** > **3** > **2**.

No special studies of the spectral properties of azinoisoindoles have been carried out; however, the structures of all the derivatives synthesised were confirmed by ^{1}H NMR or, in some cases, ^{13}C NMR spectroscopy. Comparative data on the NMR spectra for six 2-R-6-cyanopyrido[2,1-*a*]isoindoles **43** are available.[29] Detailed assignment of signals in the ^{1}H and ^{13}C NMR spectra of benzo[1,2]pyrrolizino[3,4,5-*a*,*b*]isoquinolines (**112**)[65] and indolizino[3,4,5-*a*,*b*]isoindoles (**113**) was carried out based on the results of COSY, HMQC and HMBC experiments and the nuclear Overhauser effects.[66]

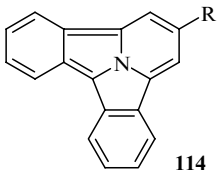


112



113

Matsumoto *et al.*[67] have measured the ESR spectra of the radical cations derived from benzo[*a*]isoindolo[1,2,3-*cd*]indolizine (1,2,3,4-dibenzocyclo[2,2,3]azine) **114** (R = H) upon its oxidation with $AgClO_4$ in dichloromethane at room temperature. It was found that despite high resonance stabilisation of the benzene rings these compounds containing a pyridoisoindole fragment as a structural element are related to the 18π-electron conjugated system.



114

R = H, D, Me, Ph, PhCO.

The redox potentials of the derivatives of compounds **114** have been studied.[68,69] It was shown that the presence of an electron-withdrawing substituent in this heteroaromatic system increases their oxidation potentials in comparison with the unsubstituted compound **114** (R = H), whereas the electron-donating and phenyl groups decrease it.

The mass-spectrometric behaviour of some fused isoindole derivatives has been described.[6] Studies of the fragmentation patterns of molecular ions of pyrido[2,1-*a*]- and pyrimido[2,1-*a*]-isoindoles suggest their aromaticity. The specific pathways of their fragmentation under electron impact have been studied.

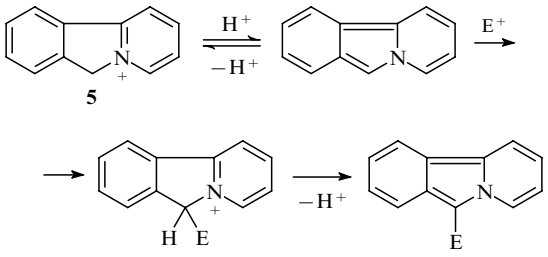
IV. Chemical properties

1. Reactions of pyrido[2,1-*a*]isoindoles

Like isoindole, aromatic pyrido[2,1-*a*]isoindoles demonstrate high reactivities. Reactions with electrophiles and addition of unsaturated compounds are the most characteristic for aromatic pyridoisoindoles.

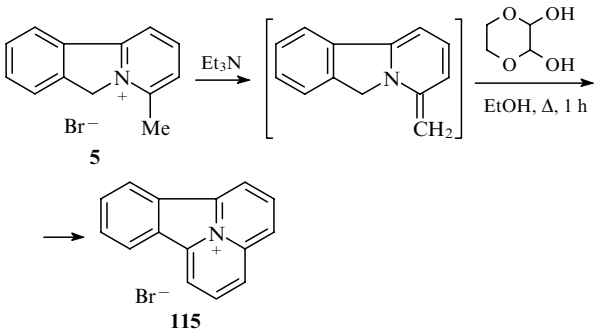
a. Reactions with electrophiles

Aromatic pyrido[2,1-*a*]isoindoles as such are unstable compounds, therefore, the stable 6*H*-protonated forms, *i.e.*, pyridoisoindolinium salts of the type **5**, are usually employed in reactions with electrophilic reagents. The electrophilic attack occurs at the most electron-excessive position 6 of the pyrrole ring. Examples of such reactions (acylation, arylation, diazotisation, *etc.*) are described in the monograph.[1]



5

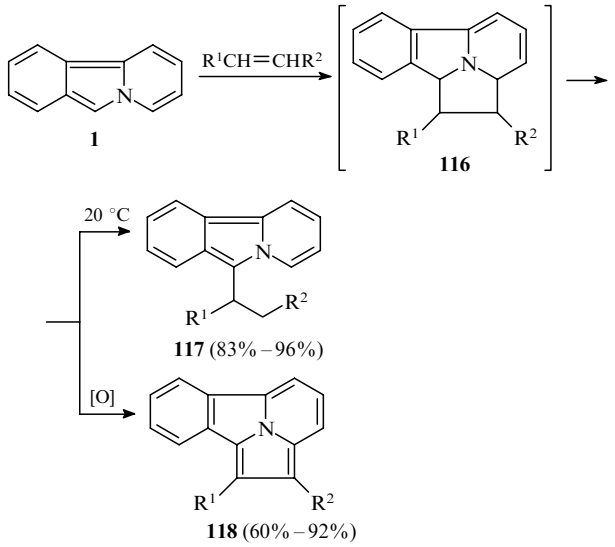
The reaction of 4-methylpyridoisoindolinium salt **5** (R^2 = 4-Me) with 2,3-dihydroxy-1,4-dioxane as the glyoxal synthon in ethanol in the presence of triethylamine (the molar ratio of the reagents is = 1 : 1 : 1), which yields compound **115** as a double condensation product at the side methyl group and at position 6 of pyridoisoindole,[9] can also be assigned to reactions of this kind. Apparently, the initial deprotonation involves the more CH-acidic methyl group.



115

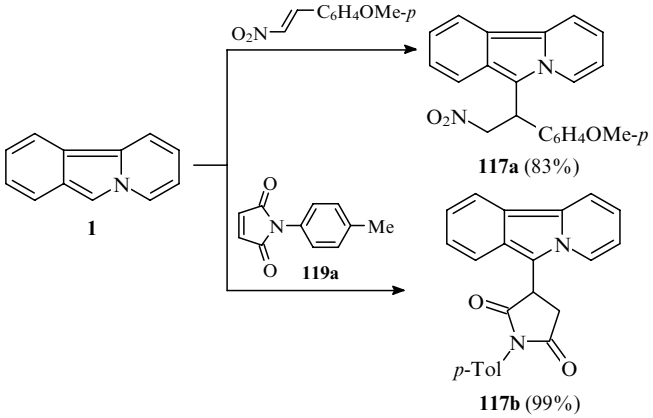
b. Addition of electron-deficient alkenes

The formation of the cyclic adducts **116** upon reactions of pyrido[2,1-*a*]isoindole **1** with compounds containing an activated double bond, *viz*., maleic, fumaric and acrylic esters and acrylonitrile, at 0 °C was established by ^{1}H NMR spectroscopy.[8] Spectral analysis revealed that the dienophile adds to the substrate at positions 4 and 6 in accordance with the [3 + 2](8π + 2π)-cycloaddition mechanism. These cycloadducts are extremely labile and at room temperature are gradually converted into the Michael adducts at position 6, *viz*., compounds **117**. Oxidation of the cycloadducts **116** with chloranil yields the indolizino[3,4,5-*ab*]-isoindole derivatives **118**.

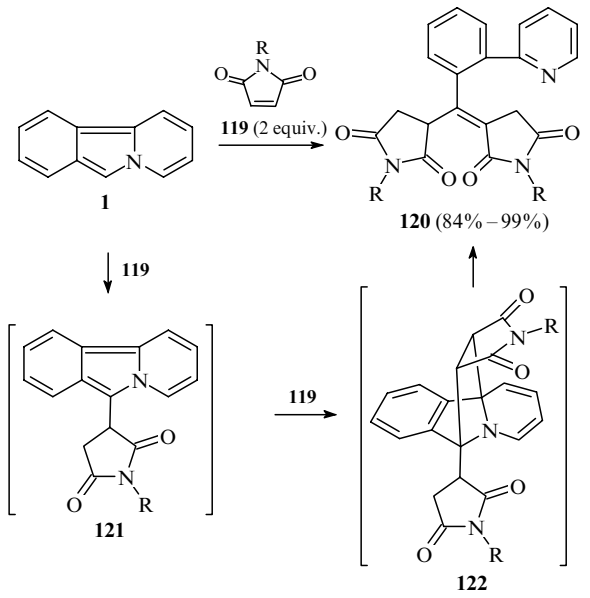


R^1 = H: R^2 = CN, CO_2Me; R^1 = R^2 = CO_2Me.

Unexpectedly, the reaction of pyrido[2,1-*a*]isoindole **1** with (*E*)-1-(4-methoxyphenyl)-2-nitroethene and *N*-(*p*-tolyl)maleimide (**119a**) at 0 °C gave directly the corresponding Michael adducts **117**. Thus, the cycloadducts represent kinetic products.[8]



Recently, it has been shown that the reaction of pyrido[2,1-*a*]-isoindole **1** with maleinimides (2 equiv.) under conditions of thermodynamic control (boiling in propan-2-ol) yields the 1 : 2 adducts **120**. Their structures were investigated by spectroscopic methods and X-ray diffraction analysis, which revealed that the reaction is quite unusual. The following mechanism has been proposed: after the formation of the Michael adduct at position 6 of one alkene molecule (**121**) (the latter is similar to compound **117b**), the second maleimide molecule is added at positions 6 and 10b (the Diels – Alder reaction). The 7-azanorbornene system in the intermediate **122** is very sterically strained due to simultaneous annelation of three rings. This leads to the rearrangement of the bonds, which is accompanied by opening of two rings, aromatisation of the pyridine fragment and formation of an exocyclic double bond.[70, 71] Such a rearrangement has been documented for neither simple isoindole systems nor for fused systems.

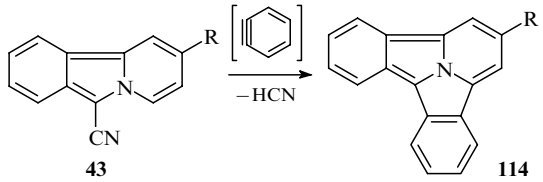


R = H, Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, 4-$NO_2C_6H_4$, Bn, naphthyl.

The conversion products **120** present interest with regard to their stereochemistry. In the solid state, they have a 'twisted' double bond (the winding angle is equal to 7 – 10°), whereas in solution they represent a mixture of atropodiastereomers due to the presence of an asymmetric carbon atom and hindered rotation around the C – C bond between the exocyclic double bond and the 2-(α-pyridyl)phenylene fragment.[70] This phenomenon was studied in detail using ^{1}H NMR spectroscopy and the possibility of atropoisomerism in this type of compounds was confirmed by quantum-chemical calculations.[72]

c. Reactions with activated alkynes

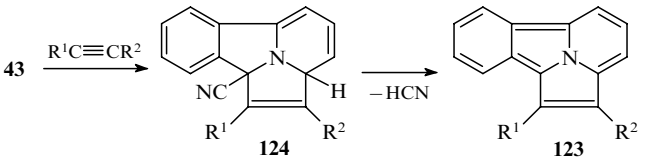
These reactions have already been mentioned in the section devoted to the synthesis of pyrido[2,1-*a*]isoindoles. Thus the preparation of 2-substituted 6-cyanopyrido[2,1-*a*]isoindoles using 1,3-dipolar addition of dehydrobenzene to 4-substituted pyridinium dicyanomethylides **42** is accompanied by the formation of benzo[*a*]isoindolo[1,2,3-*cd*]indolizines **114** as side products. Although the yields of the latter did not exceed 4% and no corresponding compounds were isolated in the case of R = CO_2Me, it is evident that 6-cyanopyrido[2,1-*a*]isoindole **43** was further coupled with dehydrobenzene with the elimination of HCN.[29, 30]



R = H, Me, Ph, PhCO, CO_2Me, MeCO.

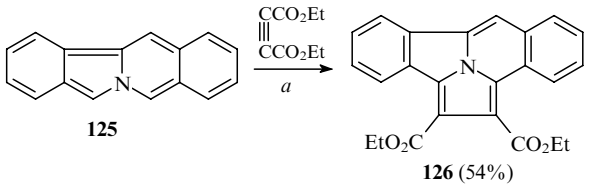
It is of interest that the change in the mode of generation of dehydrobenzene (the reaction of anthranilic acid with isoamyl nitrite was used instead of pyrolysis of diphenyliodonium-2-carboxylate) and the decrease in the reaction temperature increase the yield of the corresponding benzoyl derivative of benzo[*a*]-isoindolo[1,2,3-*cd*]indolizine **114** (R = PhCO) (up to 17%) without any significant changes in the yields of the products with other substituents.[30] If compounds **43** isolated in the individual state reacted with dehydrobenzene generated by pyrolysis of diphenyliodonium-2-carboxylate, the yields of the products **114** were 18% – 39%.

6-Cyanopyrido[2,1-*a*]isoindoles **43** as 1,3-dipolar agents also add alkynes activated by at least one electron-withdrawing group at positions 4 and 6.[27, 29, 73, 74] The yields of compounds **123** (sometimes, in a mixture with their precursors **124**) depend on the nature of the alkyne and reaction conditions; regioisomers **123** in various ratios are obtained from non-symmetrical alkynes.[74]



R^1, R^2 = H, COMe, COPh, CO_2Me, CO_2Bu^t, Ph, $SiMe_3$.

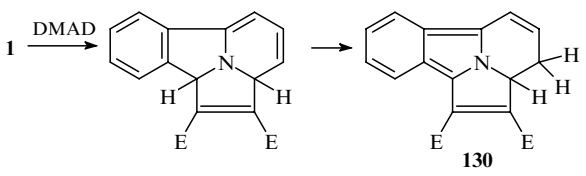
Numerous examples of reactions of fused pyridoisoindoles with dimethyl and diethyl acetylenedicarboxylates are documented. It was found[43] that isoquinolino[3,2-*a*]isoindole **125** reacts with diethyl acetylenedicarboxylate with the formation of benzoindolizino[3,4,5-*a*,*b*]isoindole **126**.



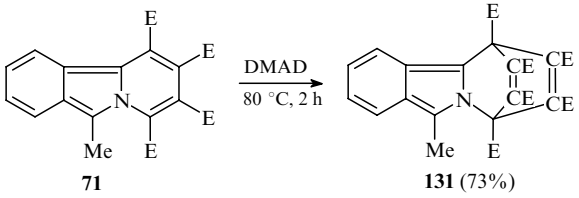
(*a*) 10% Pd/C, hydroquinone, PhMe, Δ, 14 h.

The data on the reaction of 6-cyanoisoindolo[1,2-*ab*]-isoquinoline **127** with dimethyl acetylenedicarboxylate are contradictory. Thus a product similar to the tetracycle **123** is formed in the presence of acetic acid (yield 26%),[75] whereas adducts with the composition 1 : 2 are formed in its absence (see Refs 73 and 75). The data on the structures of the latter are ambiguous. According to Matsumoto *et al.*,[73] they represent [5 + 2]-cycloaddition products which undergo further rearrangements into pyrroles **128** (3-cyanoindolizines react with DMAD in a similar way to yield pyrroles), whereas Tominaga *et al.*[75] prepared [3 + 2 + 2]-cycloadducts that underwent subsequent [1,5]-hydride shift, *i.e.*, compound **129** (an analogous reaction of 3-cyanoindolizine with DMAD has been described [73]) (Scheme 4).

Pyrido[2,1-*a*]isoindole itself reacts with DMAD involving positions 4 and 6, which is followed by a hydride shift.[8] Such structural conversion violates aromaticity of the benzene ring in favour of isoindole **130** with a quinoid structure containing a chain of conjugated double bonds.



In contrast to the above examples, 1,2,3,4-tetramethoxycarbonyl-6-methylpyrido[2,1-*a*]isoindole **71** (for the synthesis, see above) reacts with DMAD at positions 1 and 4 as a diene to give the adduct **131**.[43] This result is quite unexpected: it could not be predicted either on the basis of the general theoretical concepts of the Diels – Alder reaction (since the isoindole fragment possesses more pronounced donor properties than the pyridine one and geometrical considerations suggest that the triple bond is preferably added synchronously to the five-membered pyrrole ring) or on the basis of calculations of the reactivity indices of such derivatives.[64]

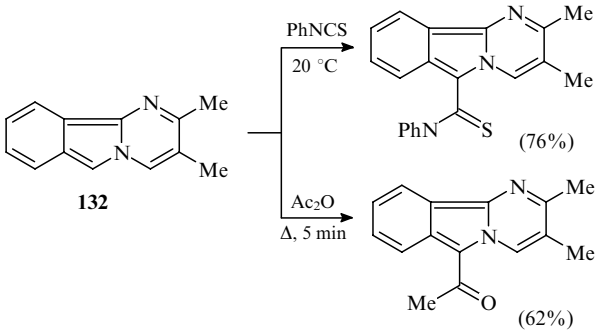


2. Chemical properties of pyrimido[2,1-*a*]isoindoles

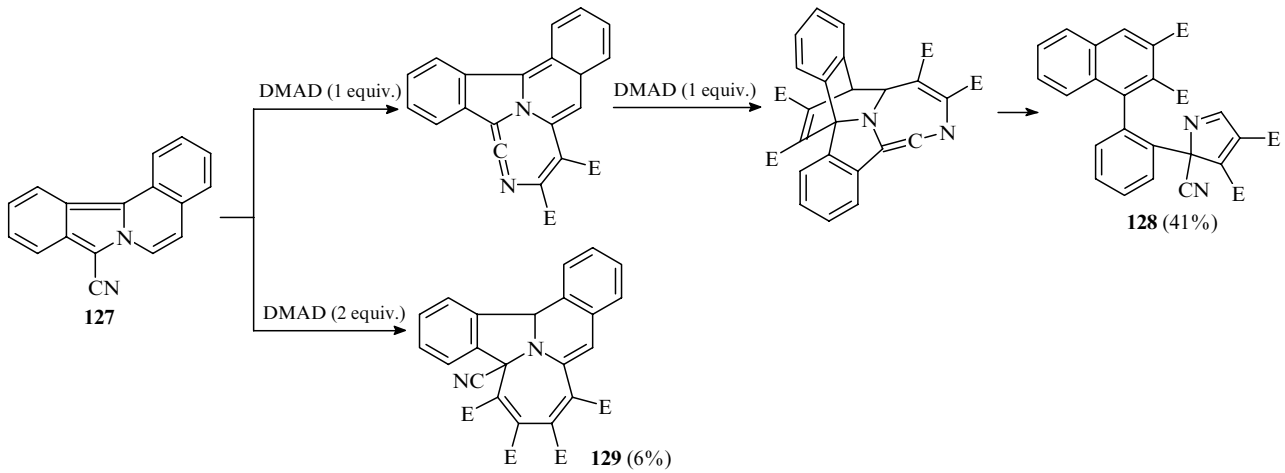
These systems are still insufficiently studied; nevertheless, reactions with pyrimidino[2,1-*a*]isoindoles or their fused derivatives as substrates can be found in the literature.

a. Reactions with electrophiles

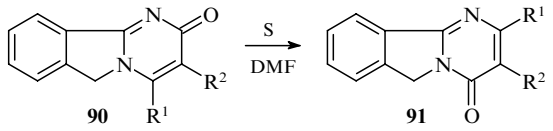
Electrophilic substitution of 2,4-dimethylpyrimido[2,1-*a*]isoindole **132** at position 6 occurs upon its treatment with phenyl isothiocyanate or acetic anhydride.[54]



Scheme 4



Rearrangement of pyrimido[2,1-*a*]isoindol-2-ones (**90**) into 4-isomers (**91**) was observed in 1985[76] and their properties including reactions with electrophilic reagents were studied. The rearrangement takes place upon heating of compounds **90** with sulfur in DMF. A similar reaction occurred upon heating with selenium; however, it was less efficient. The mechanism of this rearrangement has not been established yet.[77]



R^2 = H: R^1 = Me, Ph; R^1–R^2 = $(CH_2)_n$; n = 3, 4.

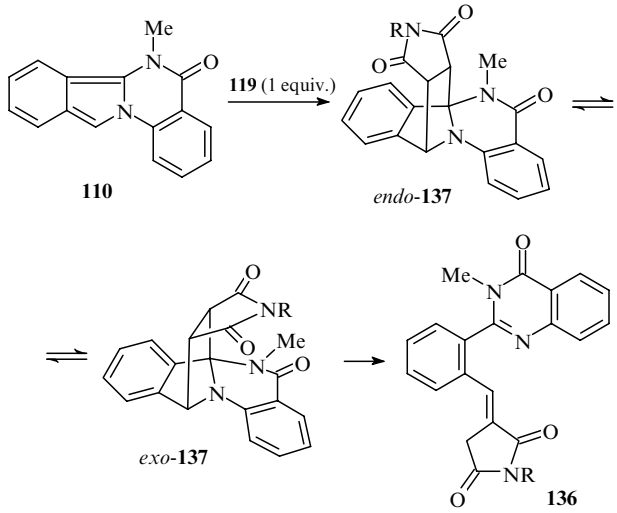
Presumably, in the initial step sulfur electrophilically attacks the position 6 of isoindole. The hemithioaminal formed undergoes recyclisation (*via* thioaldehyde) into an intermediate, which yields the isomer **91** following extrusion of sulfur.

Among other reactions with electrophiles, protonation and methylation of both isomers have been studied. According to IR spectroscopic data, compounds **90** are protonated at the oxygen atom in the formation of hydrobromides, while compounds **91** undergo protonation at the nitrogen atom at position 1. In reactions with dimethyl sulfate or methyl toluene-*p*-sulfonate, pyrimido[2,1-*a*]isoindol-4-ones **91** are methylated at the nitrogen atom at position 1. The structure of the methylation products of the 2-isomers depends on reaction temperature: at temperatures up to 100 °C, methylation occurs at the oxygen atom, whereas that at 130 °C occurs at the nitrogen atom at position 1 (see Ref. 78). Pyrimido[2,1-*a*]isoindol-2-ones **90** differ from the 4-isomers in having lower chromatographic mobilities and lower stretching vibration frequency of the C=O group in the IR spectra. Pyrimido[2,1-*a*]isoindol-4-ones **91** are characterised by a bathochromic shift in the UV spectra.[79] Other differences in physicochemical properties of these isomers have also been established.[79,80]

b. Reactions with activated unsaturated compounds

Recently, it has been found that reaction of 2,4-dimethylpyrimido[2,1-*a*]isoindole **133** with maleimides **119** yields a mixture of products (Scheme 5) from which benzo[*f*]isoindole derivatives **134** were isolated.[81,82] Their yields depended on the reaction conditions and the nature of the substituent in the imide fragment. A mechanism for the formation of these products was proposed in which extrusion of the bridging nitrogen atom from the intermediate Michael–Diels–Alder adducts **135** was the key step (see Scheme 5).

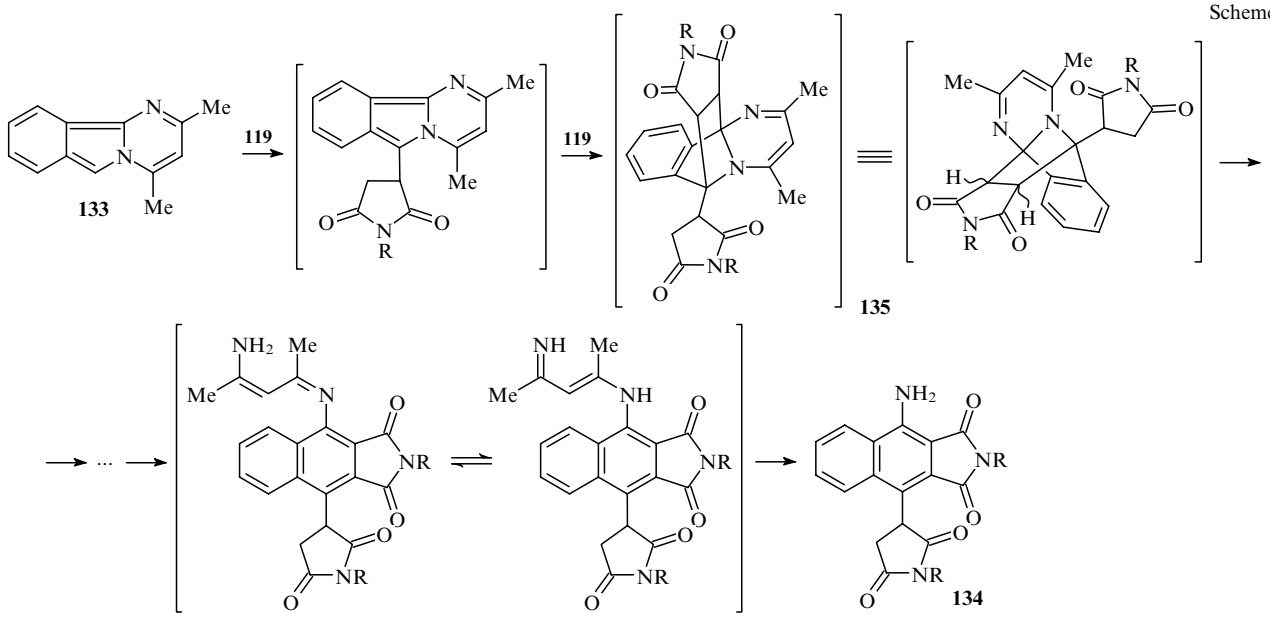
Interesting results were obtained in the study of reactions of isoindolo[2,1-*a*]quinazolin-5-ones **110** formally containing a pyrimido[2,1-*a*]isoindole fragment with maleimide derivatives. If the reagents are used at equimolar ratios, the rearranged adducts **136** are formed in high yields. This reaction occurs upon heating or brief boiling of the reactants in various solvents ($CHCl_3$, CH_2Cl_2, EtOH, Pr^iOH, PhMe). In order to establish the mechanism of this conversion under conditions of kinetic control, the intermediates **137**, which represent *endo*-Diels–Alder adducts, were isolated in the pure state. The conversion of the intermediate **137** into the final product **136** *via* the *exo*-isomer was confirmed by ^{1}H NMR spectroscopy.[83–85]



R = H, Bn, Ar.

With 2 equiv. of maleimide, the reaction under similar conditions follows another pathway: the Michael addition at the α-position of the pyrrole ring is the primary step, and the Michael adduct formed is involved in the Diels–Alder addition with the formation of stable tricyclic 7-azanorbornenes **138**. The structures of the products **136** and **138** were confirmed by X-ray diffraction analysis. No such rearrangement was observed for simple iso-

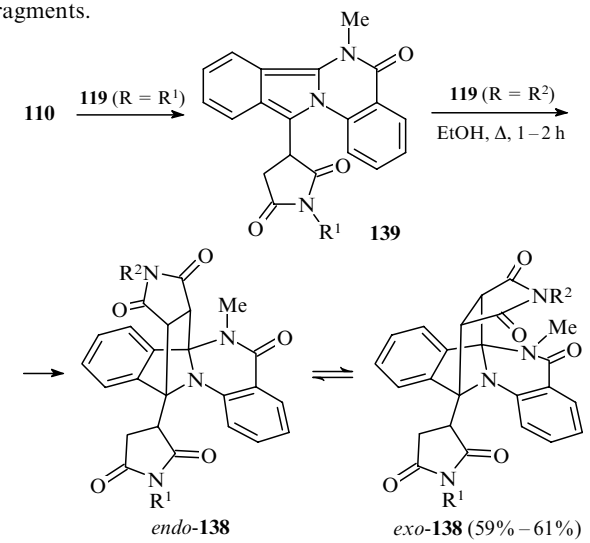
Scheme 5



R = H, 4-MeC_6H_4, 2-MeC_6H_4, 4-$MeOC_6H_4$, 1-naphthyl.

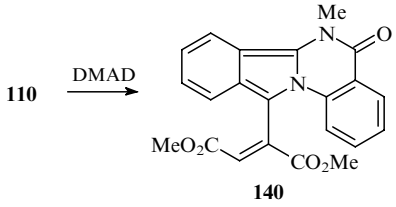
indoles (including fused ones). Compounds **138** appeared to be the first stable representatives of tricyclic 7-azanorbornene derivatives.

Compound **110b**, which represents the adduct of compound **110a** with maleimide, contains a succinimide fragment as a substituent R and can further react with maleimides. The adducts **138** or **139** formed may contain various substituents in the imide fragments.



R^1, R^2 = H, Bn, Ar.

The reaction of 6-methyl-5,6-dihydroisoindolo[2,1-*a*]quinazolin-5-one **110a** with DMAD affords the Michael adduct **140**.

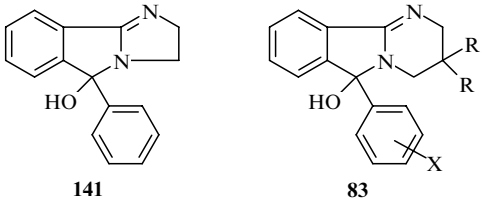


Studies of the chemical properties of various azinoisoindole compounds are under way.

V. Biological activity

Various isoindole derivatives have found application in many areas, particularly for production of polymeric materials possessing valuable properties or as biological markers and analytical reagents for chemistry and medicine. Numerous biologically active substances with a broad spectrum of activity have been found among compounds with the isoindole structure. Tricyclic isoindole derivatives (including azinoisoindoles) manifest antiviral, anti-inflammatory, analgesic and other physiological activities.[1]

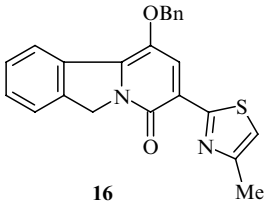
Various analogues of Mazindol **141** (a psychotropic drug recently introduced into clinical practice) have been extensively investigated in the past decade. They include a series of partially unsaturated azinoisoindoles **83**, which manifested high activity in neuronal tests.[49]



R = H: X = H, 2-F, 3-F, 4-F, 3-Cl, 4-Cl; R = Me, X = 4-Cl.

Compounds **83** inhibit the reverse capture of dopamine more efficiently than cocaine and Mazindol and by several orders of magnitude more selectively than serotonin.

Compound **16**, an analogue of known $GABA_A$ receptor agonists, was synthesised within the framework of a search for tricyclic non-sedative anxiolytic agents of the pyridine series.[21] This compound appeared to be efficient for both therapy and prophylaxis of CNS diseases.



Among other newly established biological properties of pyrimidoisoindoles, special mention can be made of the bactericidal activity of the fused derivative **140**.[86]

Other examples of practical applications of isoindole derivatives can be found in the monograph [1] and reviews.[2, 7]

* * *

It should be noted in conclusion that despite the sufficiently large number of examples of formation of the pyridoisoindole system published in the literature, the portion of direct syntheses of aromatic pyrido[2,1-*a*]isoindoles is extremely small. Deprotonation of the corresponding 6*H*-salts is still the main route to the synthesis of aromatic pyrido[2,1-*a*]isoindole derivatives. Pyrimido[2,1-*a*]isoindole and its derivatives are studied to an even lesser extent, while aromatic pyrimido[6,1-*a*]isoindole systems are presently unknown.

It thus appears that the azinoisoindoles considered above are insufficiently studied, although calculations and the recently described reactions with dienophiles demonstrate their high synthetic potential. Of particular interest is the possibility of a transition to various classes of organic compounds as a result of recently discovered rearrangements. The known reactions of azinoisoindoles with maleimides suggest their high reactivities in addition reactions occurring at position 6 of the pyrrole fragment.

Systematic synthetic, spectroscopic (including X-ray diffraction analysis) and biological studies into pyrido- and pyrimidoisoindole derivatives and the products of their diverse conversions represent a promising field of research in the chemistry of heterocyclic compounds.

Abstract. A class of conformationally rigid cyclic α-amino acids that can be used in the synthesis of peptidomimetics, peptide models and biologically active compounds is surveyed. The rigid frameworks of such amino acids enable 'fixation' of strictly defined torsion angles and hence prediction and deliberate tuning of the conformation of a polypeptide chain. Recent data on the structures and methods of the synthesis of such amino acids are presented. The bibliography includes 259 references.

I. Introduction

Synthesis of compounds with constrained conformational flexibility increasingly attracts the attention of chemists. It is commonly assumed that restriction of the conformational flexibility of molecules by structural modifications may serve as an efficient tool in the studies of, and control over, properties of various compounds. In particular, by 'fixing' a ligand molecule in the so-called biologically active conformation, one can achieve high efficiency and selectivity of its interaction with the corresponding receptor. Restriction of the conformational flexibility of chiral ligands in metal complex catalysts allows enhancement of the enantioselectivity of catalytic asymmetric reactions.[1]

The vast majority of studies which make use of this approach relate probably to the synthesis of peptidomimetics and peptide models. Synthesis of peptidomimetics is aimed at improvement of the properties of natural peptides, first of all, of their biological activities,[2] whereas that of peptide models, at studies of the properties of peptides and proteins. For instance, peptidomimetics with improved pharmacological characteristics (solubility, bioselectivity, resistance to *in vivo* degradation, *etc*.) can be prepared by modifying structures of amino acid constituents of a bilogically active natural peptide. Compounds utilised in studies of the mechanism of the enzyme catalysis may be mentioned as examples of peptide models.[3]

Both peptidomimetics and peptide models may have either peptide or non-peptide nature. A key principle of their design consists of the incorporation of conformationally constrained or rigid analogues of natural amino acids into the peptide chain.

Up to now, numerous conformationally constrained and rigid amino acids, as well as peptidomimetics and artificial peptides on their base, have been synthesised. Methods for the preparation of these compounds and their biochemical properties have been surveyed in a number of reviews.[4 – 15] Nevertheless, issues related to the structural features and conformational properties of these compounds as well as to the design of peptidomimetics and peptide models with conformationally constrained amino acids have not been adequately addressed so far. The goal of the present review is to span this gap.

Among the whole range of the known amino acids that are characterised by restricted conformational flexibility, conformationally rigid α-amino acids deserve particular mention. Hereinafter, substances the molecules of which exist in a unique conformation, are referred to as conformationally rigid α-amino acids (CRA).† These also encompass amino acids where only a specific fragment is rigid. Conformationally rigid amino acids have several advantages in the design of peptidomimetics and peptide models over amino acids that are conformationally constrained but not rigid. Rigid molecules or molecular fragments are characterised by 'fixed' bond and torsion angles, which are either known or can be calculated with sufficient accuracy by molecular mechanics. The values of these angles are virtually independent of the structure and conformation of the remaining part of the polypeptide chain. Furthermore, rigid fragments formed by CRA can impose a specific chain conformation on their immediate proximity. This simplifies the design of peptidomimetics or artificial peptides with desired characteristics.

This approach limits the number of amino acids applicable in the design, however the structural diversity of CRA is fairly broad as will be shown below. Many of the theoretically possible CRA have not been synthesised so far and one goal of the present review is to draw the attention of chemists to their synthesis.

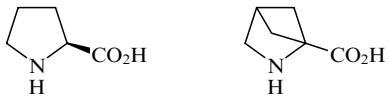
† In the present review, the generalised meaning of the term conformation is adopted, *viz*., a conformation is understood as any spatial mutual arrangement of nuclei comprising a molecule, which can be realised without disturbing integrity of the molecule.[16 – 19]

Since the term 'conformational rigidity' is central in this review, it deserves a dedicated consideration.

II. Conformationally constrained and conformationally rigid molecules

Two terms 'conformationally constrained (restricted)' and 'conformationally rigid' frequently occur in the scientific literature and are commonly considered as being intuitively obvious. L-Proline (**1**) and its bicyclic analogue 2,4-methanoproline (**2**) may be taken as examples of a conformationally constrained and a conformationally rigid molecule, respectively.



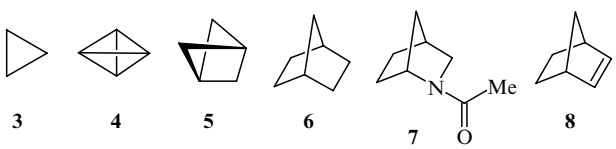
1 **2**

The presence of a five-membered ring in **1** substantially restricts the conformational flexibility of both the L-proline molecule and peptides containing its residue. Nevertheless, there exists a set of proline conformations such that transitions between them do not require significant energy expenditure.[20] The molecule of **2**, a proline analogue, is regarded as rigid, because its conformational mobility is severely restricted by the methylene bridge. Nevertheless, it does not comply with the strict definition of CRA given in the preceeding section, as it can still adopt more than one conformation.

The Chemical Encyclopaedic Dictionary [21] gives the following definition of the term 'rigid molecule': 'A characteristic feature of rigid molecules is that a transition from one of their equilibrium conformations to another requires a considerable energy (>100 kJ mol^{-1})... Only transpositions of nuclei which are realised by rigid rotations or mirror reflections of the molecule as a whole without cleavage of chemical bonds are allowed in rigid molecules'. The major drawback of this definition, in our opinion, is that it poses a specific value of the maximum energy of a configurational (conformational) transition, *i.e.*, 100 kJ mole^{-1}. Even neglecting the arbitrariness in the selection of this value, this definition can hardly be applied to a particular molecule since the exact energy profile of its conformational transitions is typically unknown.

It would be appropriate here to refer to aromatic and heteroaromatic compounds. For a long time (see, for instance, Refs 21–23), it has been believed that they represent rigid structures. However, recent theoretical and experimental studies have revealed substantial flexibility of benzene [24] and pyridine [25] rings: a change in the torsion angle by 20° in these aromatic systems results in an energy increase of not more than 13 kJ mol^{-1}. Alkenes and fragments with a triple bond cannot also be classified as conformationally rigid. According to a recent theoretical and experimental studies,[26] bond and torsion angles in unsaturated compounds can experience noticeable distortions at energy not exceeding 20 kJ mol^{-1}.

Alternatively, the conformational rigidity may be defined in a more strict and versatile way using a topological approach based on the graph theory. Within this approach, rigid molecules were described as rigid graphs with edges of fixed lengths.[27] Note that various conformationally rigid molecules can be constructed theoretically using the graph theory; these molecules, however, can prove to be unstable or non-existent in reality. The three-membered ring **3** is evidently classified as conformationally rigid. The graph **4** is also rigid but unsubstituted tetrahedrane with this skeleton is so unstable that all attempts at its synthesis undertaken so far have failed.[26]



3 **4** **5** **6** **7** **8**

At resent, there is no uniform criterion of conformational rigidity, therefore, the attribution of a particular amino acid to conformationally rigid ones is based in the following discussion primarily on literature data concerning their structures and conformational mobilities. Analysis of the published data allowed us to conclude that cyclic and polycyclic cages with fixed torsion and bond angles in their CR_4 fragments and those involving sp^2- and sp-hybridised atoms are regarded as rigid most frequently. For the former class, this is due to large force constants of both bonds and angles, while the latter class lies beyond the scope of the present review. In particular, polycyclic molecules with bridges involving 0 or 1 atom (*e.g.*, the molecule **5**) are referred to as rigid. Polycyclic molecules with two-atomic bridges are also often considered as rigid in the literature (*e.g.*, compound **6**), especially in those cases where the structure is additionally 'reinforced' by an amide group or by multiple bonds (*e.g.*, the structures **7** and **8**).

The following structural types of CRA will be considered as rigid in the following discussion:

(1) mono- and spirocyclic compounds with three- and four-membered rings;

(2) bicyclic compounds with short bridges comprising from 0 to 2 atoms;

(3) tri- and polycyclic compounds with sufficiently short bridges.

In the next sections, the major attention will be paid to conformationally rigid analogues of natural α-amino acids. This is primarily due to the fact that the design of conformationally constrained peptidomimetics or peptide models typically implies replacement of natural amino acids in the native peptide by structurally most similar analogues; the so-called 'topomers' or 'topologically equivalent' amino acids. The principles of such a 'topographic' design of peptides have been formulated quite recently.[28, 29] Evidently, in this case, the results of conformational and biological studies can be more easily interpreted since earlier experimental data on related natural amino acids can be used for comparison.

The synthesis of CRA that are not close analogues of natural α-amino acids is also of substantial practical and theoretical interest. The molecules of CRA can contain two or more fragments of natural amino acids (such amino acids are referred to as 'chimeric').

The literature data search has been accomplished using electronic databases, *viz.*, Beilstein Crossfire, SciFinder and the Cambridge Structural Database (CSD).[30]

III. Principles of the design of peptidomimetics and peptide models comprising conformationally rigid amino acids

The design of peptidomimetics and peptide models comprising CRA is based on the knowledge of the features of the secondary structure elements of peptides. The three major types of secondary structures of peptides adopted currently include helices (*I*), β-folded structures (*II*) and bends (*III*) (Fig. 1).[28, 31–33]

Conformations of polypeptide chains corresponding to each of the secondary structure elements can be described in terms of the torsion angles φ, ψ and ω whereas the conformation of side chains of amino acids can be described in terms of the torsion angles χ_1, χ_2, χ_3, and so forth (Fig. 2).

The most typical (*i.e.*, mean or standard) values of the torsion angles φ, ψ and ω for the secondary structure elements of peptides and proteins determined as a result of analysis of numerous experimental structural data and computer simulations are summarised in Table 1.[28, 32] Based on the values of the torsion angles φ, ψ and ω given in Table 1, it is possible to predict in the first approximation the effects of a replacement of a natural amino acid by its conformationally rigid analogue with fixed torsion

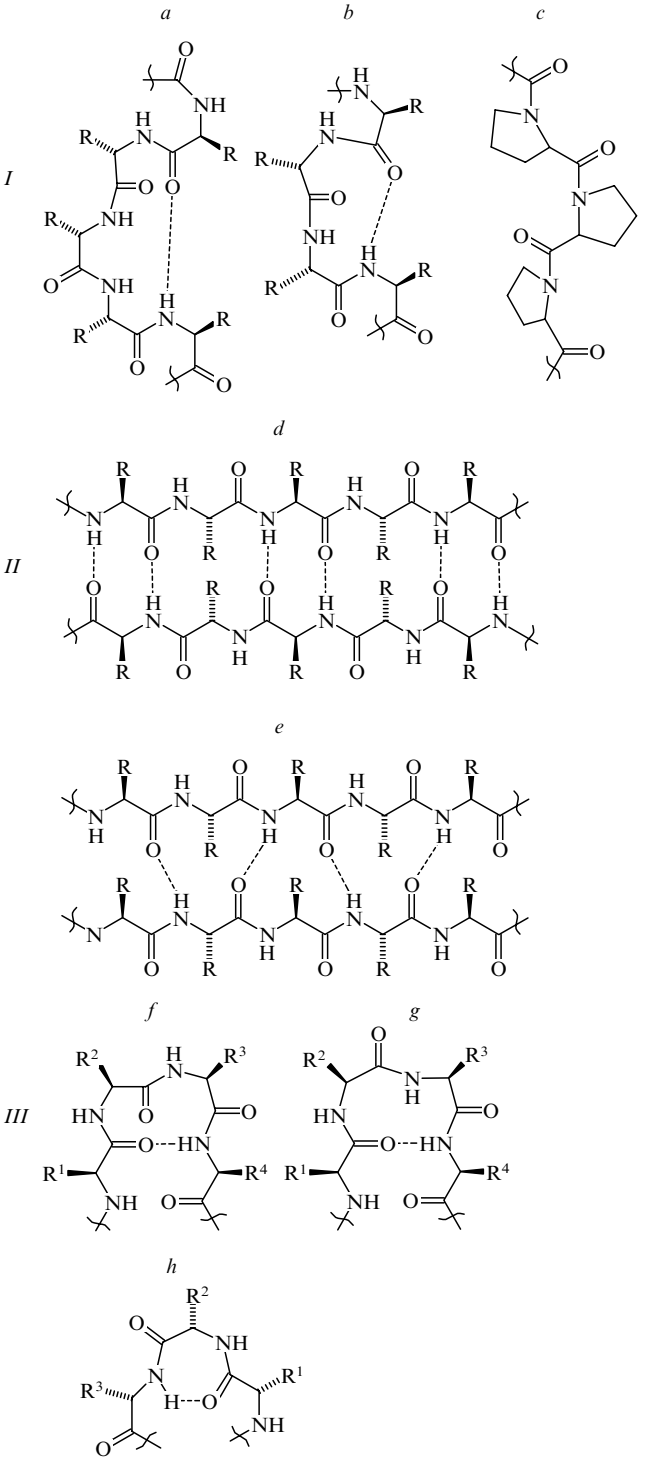


Figure 1. Elements of the secondary structure of peptides and proteins: (*I*) helices: α-helix (right-handed) (*a*), 3_{10}-helix (right-handed) (*b*), polyproline II helix (left-handed) (*c*); (*II*) β-folded structures: antiparallel (*d*), parallel (*e*); (*III*) bends: type I β-bend (*f*), type II β-bend (*g*), γ-bend (*h*).

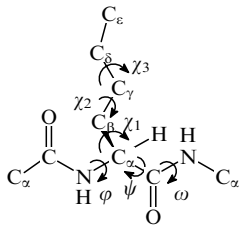
angles (most frequently, it is the torsion angle φ that is fixed) on the conformation of the peptide fragment. It is noteworthy that the torsion angles exert a decisive influence on the conformation of the whole fragment involving CRA. If torsion angles at the peptide bond formed by a CRA are close to the respective torsion angles of a secondary structure element of the native peptide, stabilisation of this structure element is expected. Otherwise, this will be destabilised and a change of its conformation can be predicted with a sufficient degree of accuracy.



Torsion angle	Notation
$C-N-C_\alpha-C$	φ
$N-C_\alpha-C-N$	ψ
$C_\alpha-C-N-C_\alpha$	ω
$N-C_\alpha-C_\beta-C_\gamma$	χ_1
$C_\alpha-C_\beta-C_\gamma-C_\delta$	χ_2
$C_\beta-C_\gamma-C_\delta-C_\varepsilon$	χ_3

Figure 2. The torsion angles φ, ψ, ω and χ in peptides.

Table 1. Mean values of the torsion angles φ, ψ and ω (deg.) typical of different elements of the secondary structure of peptides and proteins.

Secondary structure element	φ	ψ	ω
Helices			
α-helix	−57	−47	180
3_{10}-helix	−60	−30	180
polyproline I helix	−83	158	0
polyproline II helix	−76	146	180
β-Folded structures

antiparallel	−139	135	–
extended chain	180	180	–
β-Bends [a]			
type I	−60 (φ_{i+1}); −90 (φ_{i+2})	−30 (ψ_{i+1}); 0 (ψ_{i+2})	
type I′	60 (φ_{i+1}); 90 (φ_{i+2})	30 (ψ_{i+1}); 0 (ψ_{i+2})	
type II	−60 (φ_{i+1}); 80 (φ_{i+2})	120 (ψ_{i+1}); 0 (ψ_{i+2})	
type II′	60 (φ_{i+1}); −80 (φ_{i+2})	−120 (ψ_{i+1}); 0 (ψ_{i+2})	
type III	−60 (φ_{i+1}); −60 (φ_{i+2})	−30 (ψ_{i+1}); −30 (ψ_{i+2})	
type III′	60 (φ_{i+1}); 60 (φ_{i+2})	30 (ψ_{i+1}); 30 (ψ_{i+2})	
γ-Bend	−65 (φ_{i+1})	120 (ψ_i); 80 (ψ_{i+1}); −120 (ψ_{i+2})	

[a] By definition, a β-bend involves four amino acid residues. They are enumerated as *i*th to $i+3$th residue starting from the N-end. The indices of the torsion angles correspond to this enumeration.

This also holds for the torsion angles χ that characterise spatial arrangement of the peptide side chains. Knowledge of these torsion angles is exceptionally important for the understanding of the functions of the peptides. Unfortunately, studies devoted to the torsion angles χ in natural peptides are rather scarce.

In some cases, 'stereolibraries' of CRA have been compiled, which represent diastereomeric series of amino acids that are close structural analogues of the corresponding natural amino acids. In these series, strictly fixed torsion angles vary from one compound to another. Synthesis of a series of peptidomimetics or peptide models on the basis of such a library enables elucidation of the relationships between the properties of peptides and their conformations and thus increases the efficacy of the search for biologically active compounds and drugs.

However, the conformation of a peptide fragment does not depend only on the torsion angles in the CRA residue. Any structural modification (even a minor one) of a natural amino acid affects to a certain extent all the angles describing the conformation of a peptide fragment close to modification. As an

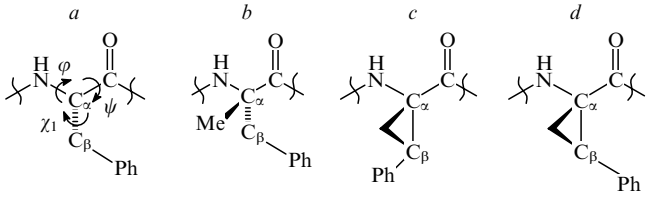

Figure 3. Structural modifications of the L-phenylalanine residue.

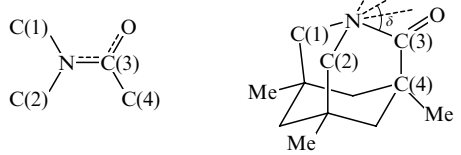
example, let us consider a diasteriomeric series of amino acid analogues of L-phenylalanine (Fig. 3).

Replacement of an L-phenylalanine residue (Fig. 3 *a*) in a peptide chain by its α-methyl derivative (Fig. 3 *b*) sterically hinders the free rotation around the bonds $C_\alpha-N$, $C_\alpha-C$ and $C_\alpha-C_\beta$. This modification influences the torsion angles φ, ψ and χ to nearly the same extent. Introduction of rigid analogues of L-phenylalanine containing a cyclopropane moiety (Figs 3 *c* and 3 *d*) results in the fixation of the angle χ_1. This also affects the angles φ and ψ: the L-phenylalanine analogue shown in Fig. 3 *c* is characterised by hindered rotation around the $C_\alpha-N$ bond while that shown in Fig. 3 *d* is characterised by hindered rotation around the $C_\alpha-C$ bond. Additionally, the well-known 'unsaturated' character of the cyclopropane ring results in a decrease in the torsion angle ψ due to the conjugation between the ring and the carbonyl group π-system. Unfortunately, no detailed conformational analysis of this kind for peptide fragments has been performed for almost all known CRA.

Let us now discuss the effects of changes in the torsion angle ω on the conformation of the peptide fragment in the proximity of modification. What is important is that the angle ω does not adequately reflect structural features of the peptide bond NH–CO in all cases. In an ideal case (the $C_\alpha-C-N-C_\alpha$ fragment is planar), this angle is 0° for the *cis*-configuration of the peptide bond and 180° for the *trans*-configuration. In the majority of amino acid residues constituting natural proteins, the peptide bonds have the *trans*-configuration although bonds with the *cis*-configuration are also encountered sometimes. Furthermore, the NH–CO fragment can be non-planar. The *cis*–*trans*-isomerisation of peptide bonds is closely related to many biologically important processes, primarily, to folding and unfolding.[34, 35] It has been shown that amides of cyclic amino acids with a nitrogen atom in the ring (these amino acids form tertiary amides in peptides) are characterised by noticeable pyramidalisation of the nitrogen and carbon atoms of the bond NH–CO and by 'twisting' around this bond. The following parameters have been suggested for quantitative description of the conformation of such a non-planar amide fragment: the twist angle τ [τ is the angle between the planes defined by the atoms C(1)NC(2) and OC(3)C(4)];[36–39] parameters ω_0(N) and ω_0(C), which reflect pyramidalisation of bonds at the nitrogen and carbon atoms, respectively; and the tilt angle (δ) between the N–C(3) bond and the plane defined by the C(1)C(2)N atoms. The substantial pyramidalisation of bonds at the nitrogen atom and 'twisting' of the amide bond can be achieved in rigid systems, such as



[$\tau = \delta = 0°$, ω_0 (N) = 360°]

9 [$\tau = 90°$, $\delta = 57°$, ω_0 (N) = 326°]

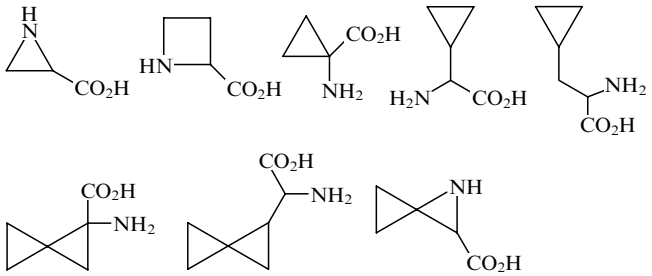
$\tau = [\angle C(4)C(3)NC(2) + \angle OC(3)NC(1)]/2$;
ω_0 (N) = ∠C(1)NC(2) + ∠C(2)NC(3) + ∠C(1)NC(3).

derivatives of 1-azaadamantan-2-one **9**. Thus, angles τ, pyramidalisation parameters ω_0(N) (hereinafter ω_0) and tilt angles δ will be discussed for peptide fragments bearing CRA (provided that the respective information is given in the original papers).

Finally, in the design of peptidomimetics and peptide models based on CRA, one should take into account changes in the chemical properties of the respective peptide fragments induced by the substitution of CRA for natural amino acids.

IV. Conformationally rigid cyclic and spirocyclic amino acids with three- and four-membered rings

The major types of known fragments of CRA, the conformational rigidity of which is due to the presence of small (three- and four-membered) rings are as follows:

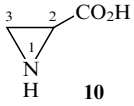


It is of note that the four-membered ring in azetidine-2-carboxylic acid is conformationally flexible but it acquires rigidity in peptides due to involvement of the nitrogen atom of the azetidine ring in the amide bond. Therefore, azetidine-2-carboxylic acid is also classified as a CRA.

A common feature of the CRA described in this section is a significant angle strain within the small rings, which strongly affects not only the structure but chemical properties of both the acids and their derivatives.

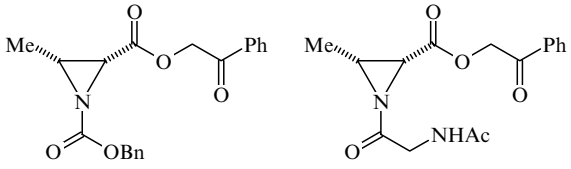
1. Aziridine-2-carboxylic acid and its derivatives

Aziridine-2-carboxylic acid (**10**)‡ may be regarded both as α- and β-amino acid with the angles φ and χ strictly fixed.



10

Unfortunately, there have been only a few structural studies of derivatives of the acid **10**, and no single-crystal X-ray diffraction data on peptides containing this residue have been published so far. Nevertheless, conformational properties of such peptides may be judged from the single-crystal X-ray diffraction studies of compounds **11** and **12**.[34]



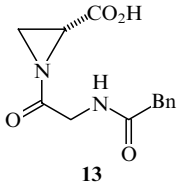
11 **12**

The experimental results suggest significant pyramidalisation of the nitrogen atom, which is evidently a consequence of the angle strain in the three-membered ring. The angle δ in **11** and **12** amounts to 37–38°, *i.e.*, the nitrogen atom is virtually tetrahedral as in the case of sp^3-hybridisation.

‡ The residue of aziridine-2-carboxylic acid in peptides is denoted as Azy.

Single-crystal X-ray diffraction studies of **11**, **12** and aziridine amides demonstrate that the steric strain within the three-membered ring results not only in pyramidalisation of bonds at the nitrogen atom but in the twisting of the amide bond as well. These compounds can serve as models in studies of the transition state of the *cis*–*trans*-isomerisation of amides, *i.e.*, the process that plays a key role in the folding of protein molecules.

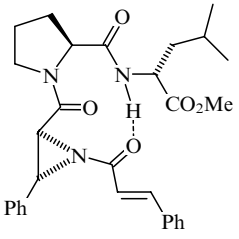
Twisting of the amide bond can lead to substantial changes in the properties of this amide fragment as has been demonstrated in a case study of a derivative of 1-azaadamantan-2-one (**9**).[39] In particular, it was found that twisting results in increased reactivity of the amide bond with respect to nucleophiles and in substantial basicity of the nitrogen atom (pK_a of **9** in water is 5.2). According to calculations,[40] aziridine amides undergo protonation at the nitrogen atom under physiological conditions in contrast to unstrained amides that are very weak bases. This fact is of great importance in the design of peptidomimetics and peptide models comprising Azy.



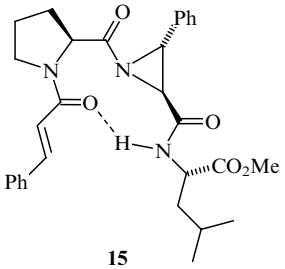
13

In a study on *N*-(phenylacetyl)glycyl-D-aziridine-2-carboxylic acid (**13**),[41] it was found that this compound with a non-planar amide group was a substrate for β-lactamases, which confirmed a hypothesis on the evolution of DD-peptidases into β-lactamases. As a result of this evolution, the enzyme active site is modified so as to provide more efficient binding of non-planar β-lactams (which are natural substrates for β-lactamases) with respect to unstrained planar amides.

The structure of several peptides containing aziridine-2-carboxylic acid residues can be inferred from spectroscopic data. For instance, NMR studies of solutions of the tripeptides **14** and **15**, which contain 3-Ph-Azy residues (a conformationally rigid analogue of phenylalanine) and L-proline, have shown that the terminal amino acid residues form a 10-membered ring involving the hydrogen bonds NH···OC typical of β-bends.[42]



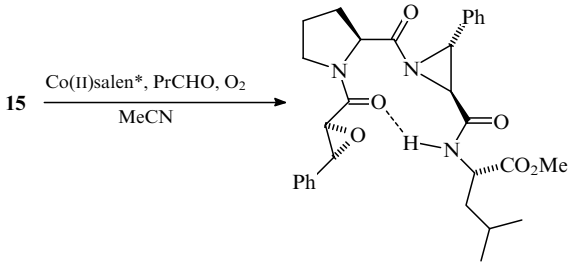
14



15

The tripeptide **15** has been utilised as a model compound to rationalise high diastereoselectivity of epoxidation of double bonds in peptides based on *N*-cinnamoyl-L-proline derivatives catalysed by cobalt(II).[43] It was suggested that the major reason for the stereoselectivity of the epoxidation is the presence of γ- and β-bends in these peptides, which directs the attack of the reagent strictly from one side of the double bond plane. High diastereoselectivity of the epoxidation reaction of the tripeptide **15**, the conformation of which in the region of β-bends is similar to that in the above peptides, has justified this hypothesis.

The model studies described above are scarce and by no means systematic. Quite another property of derivatives of aziridine-2-carboxylic acid, *viz*., the ease of opening of the strained three-membered ring under the action of nucleophiles, is exploited more frequently.§ This property makes it possible to use aziridine-2-carboxylic acid and its derivatives as irreversible inhibitors of enzymes. For instance, the acid **10** itself was used as an inhibitor of cysteine proteases. It selectively deactivates the thiol group and does not react with other nucleophilic groups present in the active sites of the proteases.[44]



Co(II)salen* is a polyaniline-supported Co(II)-salen complex.

Unfortunately, Azy-containing peptides are toxic due to its high reactivity, which prevents their use as drugs.

Later, a number of inhibitors of cysteine proteases based on aziridine-2,3-dicarboxylic acid (Azi, **16**–**18**) derivatives were discovered. A common structural feature of these inhibitors is the presence of a peptide fragment and a reactive aziridine ring. The peptide fragment binds to the active site of the enzyme and the aziridine ring irreversibly reacts with the thiol group.[45,46] Unfortunately, the influence of the rigid residue of aziridine-2,3-dicarboxylic acid on the conformation of the molecules under study has not been analysed, although it is the conformation of the inhibitor that can define the efficiency of its binding to the active site of the enzymes.

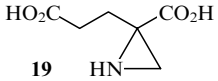
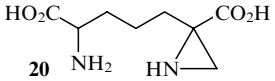
Recently, the influence of free carboxylic groups in molecules of similar inhibitors on the inhibition efficiency has been investigated.[47]

Among other inhibitors studied, 2-(2-carboxyethyl)- (**19**)[48] and 2-(4-amino-4-carboxybutyl)aziridine-2-carboxylic acids (**20**)[49] are worth noting. They act as irreversible inhibitors of glutamate racemase and diaminopimelic acid epimerase, respectively.



19



20

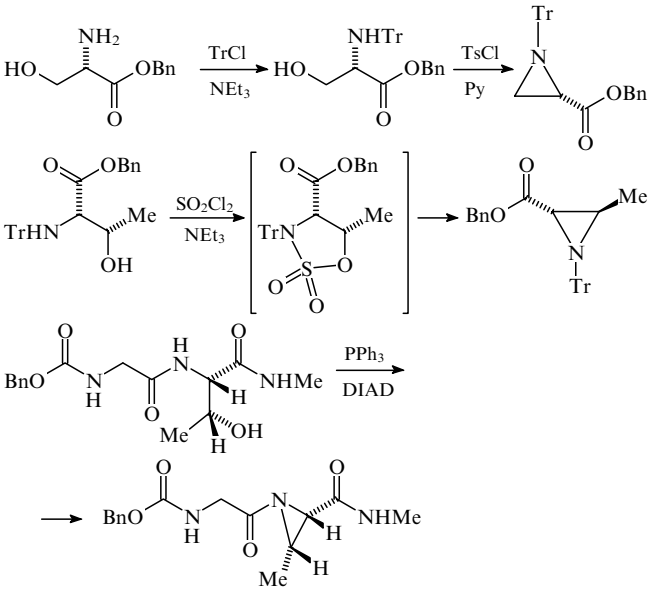
A number of methods for the preparation of aziridinecarboxylic acid and its derivatives have been developed and the major

§ It is of note that the residues of aziridine-2-carboxylic acid or its derivatives in peptides are additionally activated due to the presence of an electron-withdrawing carboxyl group linked to the nitrogen atom.

attention has been paid to the stereoselective syntheses. The development of new methods for the synthesis of these compounds was encouraged by their potential use as convenient precursors of alkaloids, β-lactam antibiotics and other biologically active compounds rather than as conformationally rigid analogues of natural amino acids in the synthesis of peptidomimetics and peptide models.[7] These methods are primarily based on the ease and selectivity of the nucleophilic opening of the aziridine ring.

The basic method for the synthesis of aziridinecarboxylic acid and its derivatives consists of cyclisation of α-amino β-hydroxy acids (Scheme 1), in particular, of serine and threonine.[50–52] (The starting chiral α-amino β-hydroxy acids can be produced from tartaric acid.[53])

Scheme 1

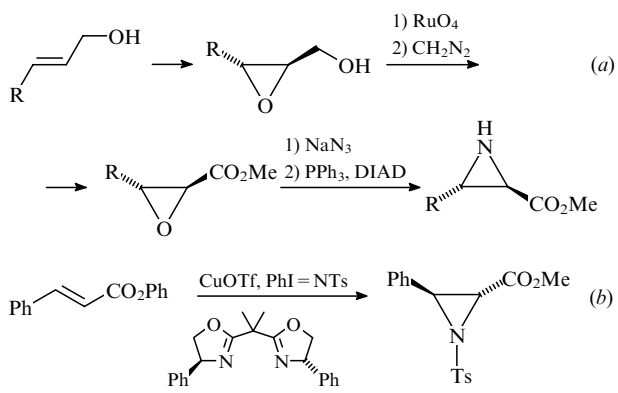


Tr = Ph_3C, Ts = $SO_2C_6H_4Me$-4,
DIAD is diisopropyl azodicarboxylate.

Cyclisation is most frequently performed under conditions of the Mitsunobu reaction (see Scheme 1). For the synthesis of substituted aziridinecarboxylic acids, reactions of sulfinylimides with lithium α-bromoenolates (the aza-Darzen reaction) are typically exploited.[54]

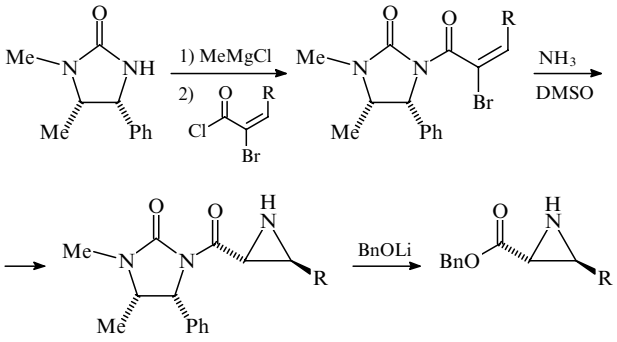
Chiral aziridinecarboxylic acids are prepared through asymmetric synthesis. The current approaches are represented in Scheme 2. The key stage in these transformations is the Sharpless catalytic asymmetric epoxidation (pathway *a*)[55,56] or asymmetric aziridination of a C=C double bond (pathway *b*).[57]

Scheme 2



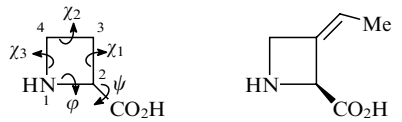
Tf = CF_3SO_2.

Syntheses using chiral auxiliary groups, *e.g.*, (4*S*,5*R*)-1,5-dimethyl-4-phenylimidazolidin-2-one, for the stereoselectivity control are worth mentioning. A scheme of the synthesis of aziridine-2-carboxylic acid derivatives by the Gabriel–Cromwell reaction used to build up the aziridine ring is shown below.[58,59]



2. Azetidine-2-carboxylic acid and its derivatives

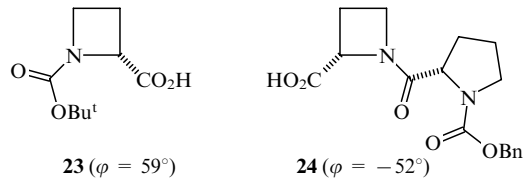
The residue of azetidine-2-carboxylic acid (**21**), when incorporated into a peptide chain, loses its mobility and becomes (φ,χ)-rigid because the nitrogen atom becomes involved in the amide bond.¶ (The Aze residue is the closest homologue of Pro.)



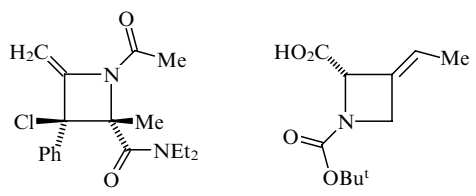
21 **22**

The amino acid **21** has been found in nature.[60] The unique amino acid **22** (polyoximic acid) was isolated from fungicide antibiotic polyoxines (peptide nucleosides).[61] It is noteworthy that the configuration of the exocyclic double bond in **22** was first erroneously assigned as *E*, but later its *Z* configuration was reliably established by structural studies and synthesis.[62]

Following structural elucidation of **21**, it was suggested that the biological activity of peptides containing the Aze residue is determined by the peculiarities of their secondary structures, and the conformational properties of azetidine-2-carboxylic acid differ from those of proline and other natural amino acids. Further structural studies have confirmed this suggestion. Compounds **23**–**26**, which are derivatives of azetidine-2-carboxylic acid[63–65] and *trans*-polyoximic acid,[66] have been used as model substances in the evaluation of conformational features of Aze in peptides.



23 (φ = 59°) **24** (φ = −52°)



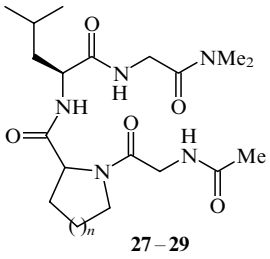
25 (φ = 56°) **26** (φ = −67°)

The azetidine rings in compounds **23**–**26** are virtually planar, which justifies the assignment of the Aze residue to conformationally rigid fragments.

¶ The residue of azetidine-2-carboxylic acid in peptides is denoted as Aze or, less frequently, Azt.

The absolute values of the torsion angle φ in **23**–**26** ($\sim 55^\circ$) are smaller by approximately 20° than in proline ($\sim 75^\circ$), which may be responsible for the differences in conformations of Aze- and Pro-containing peptides. Pyramidalisation of the nitrogen atom in Aze is substantially less pronounced than in a more strained Azy residue; the same is true for the angle δ, which is $\sim 5^\circ$ in **23**–**26** according to X-ray diffraction data. On the other hand, the Aze residue is more strained than Pro, which is reflected in a decrease in the energy barrier to the *cis*–*trans* isomerisation of the peptide bond. According to the results of dynamic NMR studies, the energy barrier to the *cis*–*trans* isomerisation in two model peptides, Ala-Aze-$NHC_6H_4NO_2$-4 and Ala-Gly-Aze-$NHC_6H_4NO_2$-4, is lower than in related peptides Ala-Pro-$NHC_6H_4NO_2$-4 and Ala-Gly-Pro-$NHC_6H_4NO_2$-4 by 10 kJ mol^{-1}.[67]

Taking into account the rigidity of the Aze unit, one should expect that substitution of Aze for Pro in peptides will inevitably affect conformation of the secondary structure elements in those fragments that previously contained proline.[68] Proline residues are often encountered in the $(i+1)$th positions of β-bends.[68] NMR studies of model tetrapeptides **27**–**29** using the NOESY technique showed that all these peptides reveal β-bends, although the distance between terminal amino acid residues in the azetidine-containing peptide ($n = 0$) is longer than in its proline-containing analogue ($n = 1$).[69]



27–**29**

$n = 0$ (**27**), 1 (**28**), 2 (**29**).

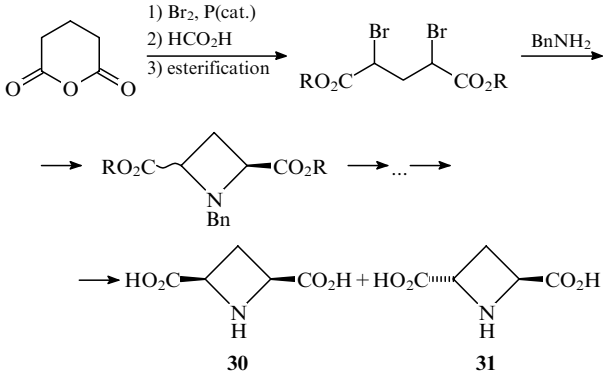
Introduction of 3- or 4-substituted Aze residues into peptides offers extended possibilities of control over the conformation of their side chains owing to the strictly fixed torsion angles χ in Aze. The values of these angles in several peptides containing the Aze residue have been reported.[64, 70]

Although a method for the preparation of racemic azetidine-2-carboxylic acid starting from γ-butyrolactone was developed rather long ago,[71–73] the synthesis of enantiomerically pure azetidine-2-carboxylic acid was accomplished only in 2003.[74] There are only a few efficient stereoselective methods for the preparation of its derivatives substituted at positions 3 or 4.

The isomers of azetidine-2-carboxylic acid **30** and **31** (which may be considered as glutamic acid analogues) were synthesised using a method similar to that applied for unsubstituted acid **21** (Scheme 3).[75]

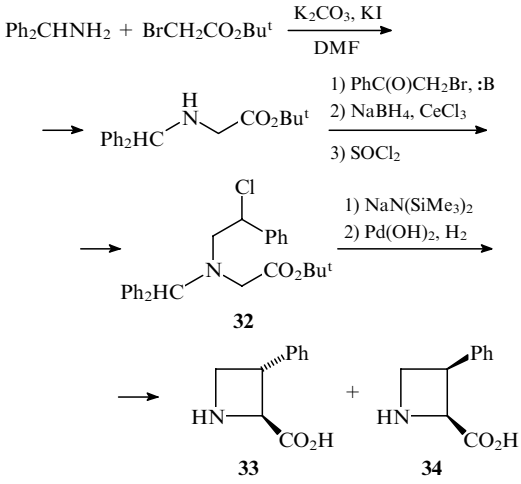
Intramolecular nucleophilic cyclisation has also been used to construct the azetidine ring.[76] In particular, intramolecular nucleophilic substitution of the Cl atom in **32** yielded two diastereomers of 3-phenylazetidine-2-carboxylic acid † **33** and **34** (Scheme 4).

Scheme 3



30 **31**

Scheme 4

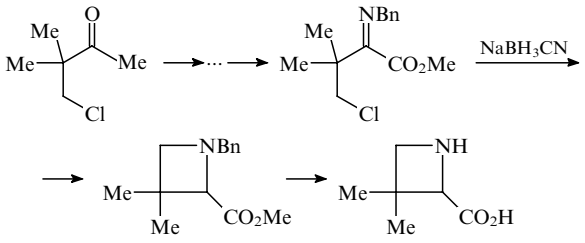


32

33 **34**

In both cases, racemic diastereomeric products were separated using liquid chromatography on silica gel.

Intramolecular nucleophilic cyclisation has also been utilised in the synthesis of 3,3-dimethylazetidine-2-carboxylic acid (an analogue of Leu).[77]



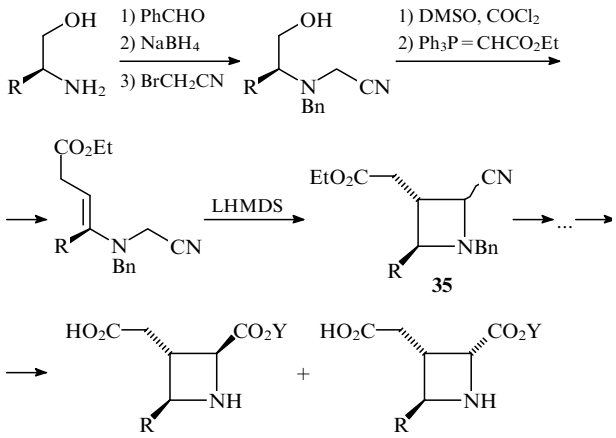
Recently, asymmetric synthesis of 2-cyanoazetidines **35**, precursors of substituted azetidine-2-carboxylic acids, has been accomplished. In this case, the cyclisation was realised through the stereoselective intramolecular Michael addition.[78] The use of optically pure β-amino alcohols as the starting compounds provided enantiomerically pure target amino acids (Scheme 5).

Taking into account that a four-membered ring is substantially less strained than a three-membered ring, one could expect that azetidine-2-carboxylic acid derivatives would appear more suitable for the design of peptidomimetics and peptide models than highly reactive aziridine-2-carboxylic acid derivatives. However, the lack of general stereoselective methods for synthesis of azetidine-2-carboxylic acid derivatives prevented their wide use. The unsubstituted amino acid **21** is the only exception which is available in multigram quantities either synthetically or from natural sources.

The acid **21** was frequently introduced into peptidomimetics in the course of systematic search for new drugs. An investigation into the structure–activity relationship for tripeptide inhibitors of thrombin (*i.e.*, the enzyme that plays an important bioregulative role in blood coagulation) [79] may be mentioned as an example. In particular, it was shown that the inhibition activity of tripeptides is strongly affected by the conformation of the central amino acid residue. Taking this into account, modification of a known thrombin inhibitor, *viz.*, Boc-D-Phe-Pro-Arg-H, by replacing the constituent amino acid residues by their conformationally constrained analogues was carried out.[79] Substitution of conformationally rigid Aze for Pro in this tripeptide resulted in a twofold increase in the inhibitory activity. Conversely, substitution of conformationally flexible residue of pipecoline-2-carboxylic acid

† 3-Phenylazetidine-2-carboxylic acid is a phenylalanine (Phe) analogue.

Scheme 5

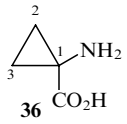


LHDMS is lithium hexamethyldisilazanide.

for Pro decreased the inhibitory activity by about two orders of magnitude.

3. 1-Aminocyclopropanecarboxylic acid and its derivatives

In contrast to aziridine-2-carboxylic acid and its derivatives described above, 1-aminocyclopropanecarboxylic acid (**36**, ACC) and its derivatives are very often used as CRA in the synthesis of peptidomimetics and peptide models.

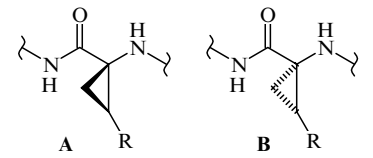


36

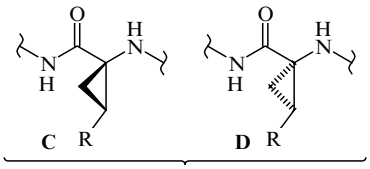
To date, cyclopropane analogues (also referred to as 2,3-methanologues or cyclopropanologues of α-amino acids) of all natural amino acids have been synthesised together with numerous artificial α-amino acids with a cyclopropane ring. Furthermore, starting from these amino acids, an array of peptides have been prepared and their structures, conformations and biological activities have been investigated. There are several reasons for such popularity of ACC and its derivatives. Primarily, it is due to the fact that the conformational rigidity of ACC derivatives (for ACC derivatives, the torsion angle χ_1 is fixed) is achieved by a minor structural modification of the respective conformationally flexible analogues, *viz*., through introduction of a methylene bridge between the α- and β-carbon atoms. This simplifies interpretation of results of conformational and biochemical studies.

Introduction of substituents into the cyclopropane ring provides the structural diversity of this type of CRA, which makes it possible to produce arrays of stereoisomeric amino acids (*i.e*., 'stereolibraries' of CRA).

For instance, 3-substituted ACC exists as four stereoisomers **A**–**D**. The residue of each of the stereoisomers introduced into a peptide is characterised by a specific torsion angle χ_1, which can easily be estimated using molecular mechanics calculations.



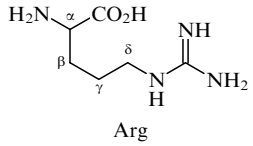
cis-Methanologues ($\chi_1 \approx 0°$)



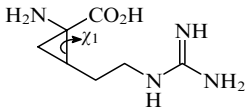
trans-Methanologues ($\chi_1 \approx -145°$ and $145°$, respectively)

For amino acids with a long side chain (*e.g*., for arginine, Arg), two types of methanologues **37** and **38** can be obtained, which differ from each other in the length of the side chain. This increases the number of available topomers of the natural amino acids.

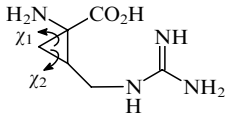
The cyclopropane fragments in the compounds **37** (2,3-methanoarginine, cyclo-Arg) and **38** (cyclo-Arg′) were introduced by insertion of a methylene bridge across the $C_\alpha - C_\beta$ bond and by formation of a $C_\alpha - C_\gamma$ bond, respectively. As a result, cyclo-Arg is characterised by a fixed angle χ_1 whereas in cyclo-Arg′, it is the angles χ_1 and χ_2 that are fixed. Therefore, the conformational mobility of the amino acid **38** is less than that of **37**.



Arg



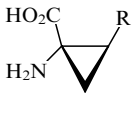
37 (cyclo-Arg)



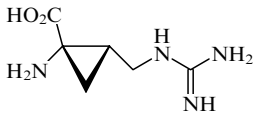
38 (cyclo-Arg′)

Yet another reason for the wide application of ACC and its derivatives in the design of peptidomimetics and peptide models is their accessibility. A number of efficient ways of their synthesis have been developed (including syntheses in gram quantities).

Finally, it is worth noting that 1-aminocyclopropanecarboxylic acid (**36**) itself and some of its derivatives occur in nature. The acid **36** is a precursor of ethylene, a plant hormone, furthermore, it is an important metabolite of methionine in plants.[80] Alkyl-substituted ACC, *i.e*., coronamic acid (**39a**, R = Et) and norcoronamic acid (**39b**, R = Me) have been isolated from hydrolysates of bacterial toxins coronatine and norcoronatine (in *Pseudomonas coronafaciens* and *Pseudomonas syringae*).[81,82] Carnosadine (**40**), which is an arginine analogue, has been isolated from the red alga *Grateloupia carmasa*.[83,84]



39a,**b**



40

Although the number of the known methanologues of natural amino acids is presently quite large, there have been only a few detailed structural and conformational studies of peptides that include these acids. The most studied peptides are those containing methanologues of methionine,[85–87] phenylalanine[88,89] and diphenyl-substituted ACC.[90–92] A number of conformational features have been revealed for the peptides based on ACC derivatives due to the presence of strained conformationally rigid three-membered rings. X-ray diffraction study of model dipeptides R^1CO-L-Pro-c_3Phe-NHR^2 (c_3Phe stands for phenyl-substituted 1-aminocyclopropanecarboxylic acids) **41a**,**b** (see Refs 88, 89) and **42** (see Ref. 92) has shown that the torsion angle χ_1 is virtually constant over this series of compounds and equal, on average, to $7\pm3°$ and $136\pm1°$ for the two diastereomers. The deviations of the angles φ and ψ from the respective mean values are due to steric repulsion of substituents in the cyclopropane rings of dipeptides **41a**,**b** and **42a**,**b** from the atoms that

form the polypeptide chain. The absolute value of φ in **41a**,**b**, **42a**,**b**, **43**–**45** is, on average, 83°; and the scatter of this value is quite small, *i.e.*, ~7° (see Refs. 89, 90, 92–95). In the majority of cases, the angle ψ is close to 0°. This suggests that the ACC residue in peptides is not only χ-rigid but φ-rigid as well. X-Ray diffraction study of **45** (which is a 2,3-methanologue of proline) has shown[95] that the angle φ (−76°) virtually does not differ from that in L-Pro. Thus, cyclo-L-Pro can be used as a conformationally rigid proline analogue in the design of peptidomimetics and peptide models.

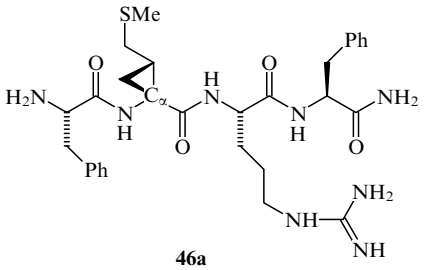
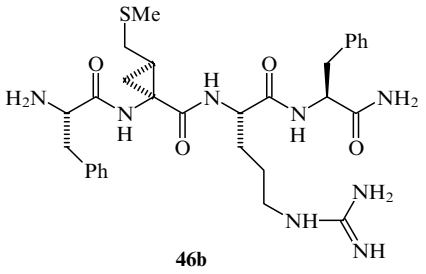
Compound	Torsion angles /deg			Ref.
	φ	ψ	χ_1	
41a	89	−4.5	135	88
41b	77	−11	−4	89
42	86	−20	7 (138)	92
43	84	−8.5	–	93
44	−84.5	0	–	94
45	−76	−7	–	95

From the aforementioned mean values of the torsion angles φ and ψ it was possible to conclude that peptides bearing ACC residues tend to form β-bends with the ACC residues in the $(i + 2)$th position.[93,94] Undoubtedly, the conformation of peptides in solutions can be different; therefore, the peptides were studied using not only X-ray diffraction, but NMR and IR spectroscopy and computer simulations as well.[88,89] It was concluded that 2,3-methanophenylalanine (a phenylalanine analogue) induces formation of β-bends in peptides, the type of the bend (β-I or β-II) being governed by the orientation of the substituent (Ph) at the C(3) atom of the cyclopropane ring, which is dictated by the strictly fixed torsion angle χ_1. For the model dipeptides **41a**,**b**, it has been shown experimentally for the first time that the orientation of the side chain can induce a specific conformation of the polypeptide chain.

The influence of methionine *cis*- and *trans*-methanologues on the conformation of peptides has been elucidated for the peptidomimetics **46a**,**b** as examples.[85–87] The conformation of **46a**,**b** in solutions has been studied using NMR and circular dichroism spectroscopy supplemented with computer simulations.[86,87] It was found that introduction of methionine methanologues into peptides gives rise to γ-bends irrespective of the isomer. Presumably, the tendency to form γ-bends relates not only to fixed values of the torsion angles φ and ψ, but to a larger value of the N−C_α−C(O) bond angle (117°) as well, which, in these compounds, substantially exceeds the corresponding values typical of residues of unstrained amino acids (~ 112° according to the CSD data).



46a

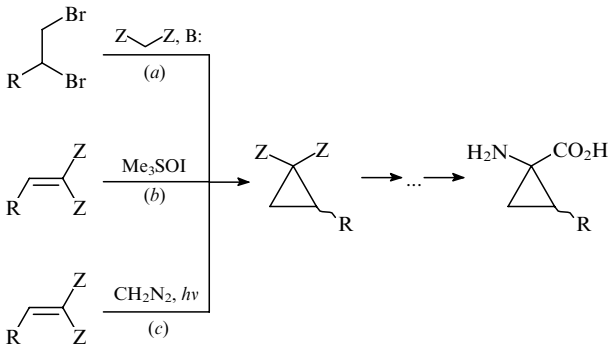


46b

The synthesis of methanologues of natural and other amino acids with a cyclopropane ring has been recently surveyed.[4,6] Therefore, in the present review we shall just outline the known methods for the preparation of ACC and discuss in more detail only methods developed in recent years.

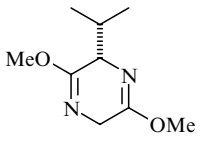
Among the most frequently applied methods of synthesis of ACC, the following are the most popular: bisalkylation (*a*), addition of oxosulfonium ylides (*b*) and 1,3-dipolar cycloaddition of diazomethane (*c*) (Scheme 6).[6]

Scheme 6

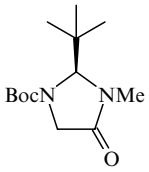


Z is an electron-withdrawing group.

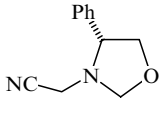
For the preparation of optically active amino acids, diastereo- and enantioselective syntheses have been developed, which make use of chiral auxiliary groups. Essentially, these syntheses exploit asymmetrical versions of the reactions *a*–*c* (Scheme 6). For instance, the bisalkylation (*a*) was conducted with a chiral glycine equivalent, *i.e.*, the Schollkopf bislactim esters (**47**),[96] the Seebach imidazolidinones (**48**)[6] or 1,3-oxazolidine chiral derivatives (**49**).[6] The diastereoselective addition of oxosulfonium ylides to derivatives of tetrahydrooxazinone **50** (*b*) has led to methanologues of amino acids. The 1,3-dipolar cycloaddition of diazomethane (*c*) was realised for a terpenoid derivative **51**.[6]



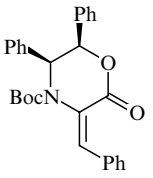
47



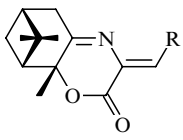
48



49

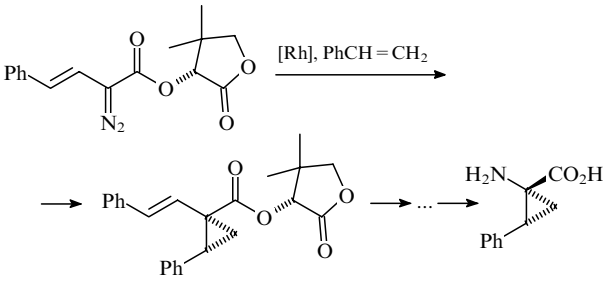


50



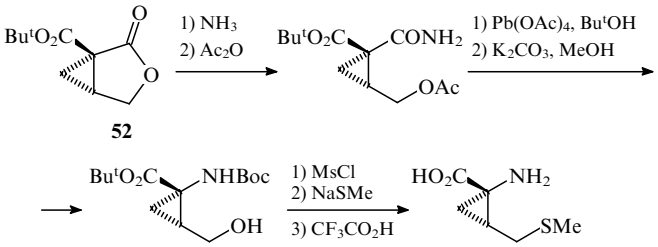
51

Elaboration of the synthetic routes that allowed preparation of ACC and its derivatives in multigram quantities is a significant achievement in this field. Among such routes, preparation of (2*R*,3*R*)-cyclo-Phe catalysed by rhodium complexes is worth a special note.[6]



Syntheses of ACC derivatives including cyclo-Met, cyclo-Arg, cyclo-Arg′, cyclo-Glu, cyclo-Gln and cyclo-Lys starting from a chiral lactone **52** proved to be extremely efficient. This lactone can be synthesised from D-mannitol, which is an accessible natural chiral compound.[6] The strategy of the synthesis of ACC derivatives starting from the lactone **52** is illustrated in Scheme 7 with (*Z*)-cyclo-Met as an example.

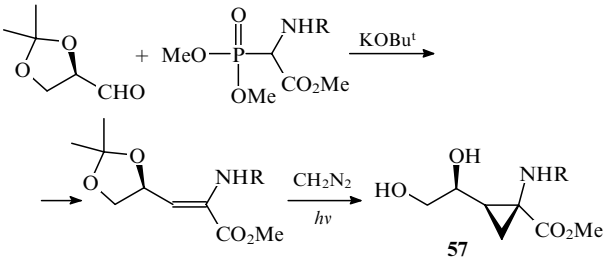
Scheme 7



52

In a series of recent studies, available chiral compounds have been used as the starting materials in the stereoselective synthesis of ACC derivatives. In particular, starting from the optically active alcohols **53** and **54**, *allo*-norcoronamic acid (**55**) and (2*S*,3*R*)-methanoproline (**56**), respectively, were synthesised (Scheme 8). The key step in these syntheses was the condensation of the corresponding cyclic sulfates with methyl benzylideneglycinate.[97, 98]

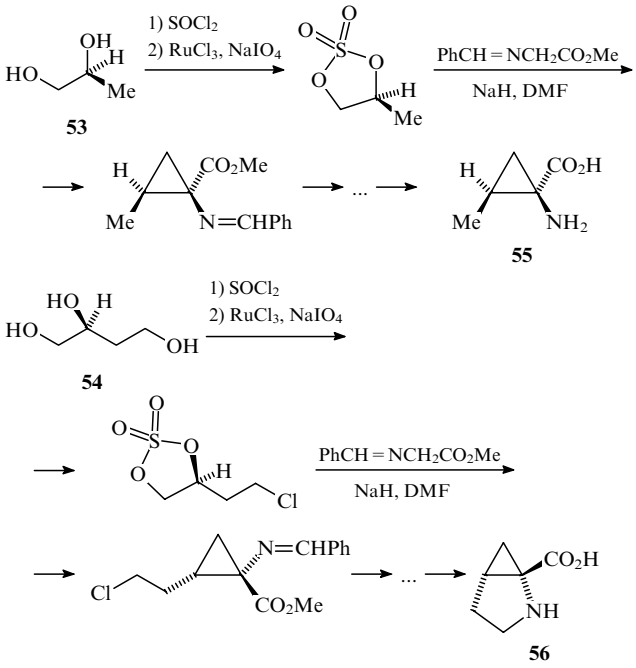
Several methanologues of natural amino acids have been prepared by functionalisation of a dihydroxy-derivative **57** synthesised starting from D-glyceraldehyde.[99]



57

Transition metal complexes are often used in the stereoselective syntheses of ACC derivatives both as catalysts and reagents. The use of palladium complexes in the synthesis of functionalised cyclopropane derivatives [100, 101] and the stereoselective cyclopropanation of alkenes by Fischer dialkylaminocarbene complexes [102] have been reported.

Scheme 8



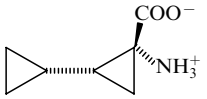
53

55

54

56

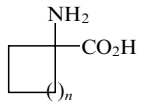
ACC, its derivatives and peptidomimetics or peptide models based on them have been the subject of numerous biochemical studies. The most prominent examples will be given here. As has been mentioned above, ACC is a precursor in the biosynthesis of ethylene. This reaction is catalysed by the iron-containing enzyme ACC oxidase. Two mechanisms of functioning of this enzyme have been suggested,[103] *viz*., nitrene- and radical-mediated ones. Recently, convincing arguments in favour of the free radical-mediated biochemical conversion of ACC into ethylene have been obtained. The formation of penta-1,4-diene upon oxidation of 2-cyclopropyl-substituted ACC (**58**) in the presence of this enzyme may be considered as an indirect proof of this suggestion.[104]



58

Russian scientists have observed [105] formation of tetrachlorophenoxy radicals upon enzymatic oxidation of ACC *in vitro* in the presence of an inhibitor, *viz*., tetrachlorohydroquinone, which also supports the radical mechanism of ACC oxidase action. ACC itself,[106] its various alkyl derivatives,[107–109] cyclo-Pro [95] and the respective hydroxamic acid [110] have been used to study the topology of the active site of ACC oxidase and the mechanism of its action.

An interesting example of studies aimed at the elucidation of factors responsible for the sweet taste of asparagine-containing dipeptides is the use of peptides containing ACC or its alkyl-substituted derivatives. Substitution of an ACC residue or its homologues, *i.e*., 1-aminocycloalkanecarboxylic acids **59**–**63**, for an L-Phe residue in Aspartame® (L-Asp-L-Phe-OMe) made it possible to reveal the dependence of the taste properties of the respective dipeptides on the steric volume of the C terminal residue. In particular, substitution of the ACC residue (**36**) and its homologues **59** and **60** for L-Phe retains the sweet taste of the dipeptide. At the same time, substitution of the residues **61** and **62** for L-Phe yields bitter dipeptides whereas the peptide containing a residue of **63** is tasteless.[111]



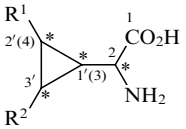
59 – 63

n = 1 (**59**), 2 (**60**), 3 (**61**), 4 (**62**), 5 (**63**).

Later, conformations of similar dipeptides containing residues of methyl-, dimethyl- and trimethyl-derivatives of ACC were analysed.[112] It was concluded that the observed changes in taste of the dipeptides are defined by their conformation, which depends upon the configuration of the cyclopropane-containing CRA in the dipeptide.

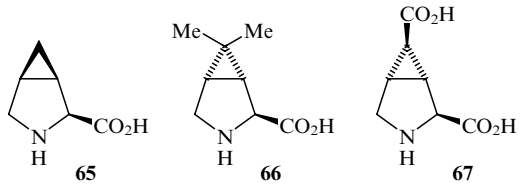
4. 3,4-Methanologues of α-amino acids

3,4-Methano-α-amino acids **64** are structural isomers of the 2,3-methano-α-amino acids discussed above.



64

Molecules of 2,3-methanoamino acids are characterised by the fixed torsion angles $\chi_{1(2)}$ whereas their 3,4-cyclopropyl analogues reveal strictly fixed torsion angles $\chi_{2(3)}$. The presence of a cyclopropane fragment in such amino acids imposes only small restrictions on the angle χ_1 and does not influence significantly the angles of the peptide chain in the corresponding peptides. An exception to this tendency is the respective proline analogue, one isomer of which, *viz*., *cis*-3,4-methylene-L-proline (**65**), has been found in nature. Its structure has been confirmed by X-ray diffraction study and synthesis.[113]

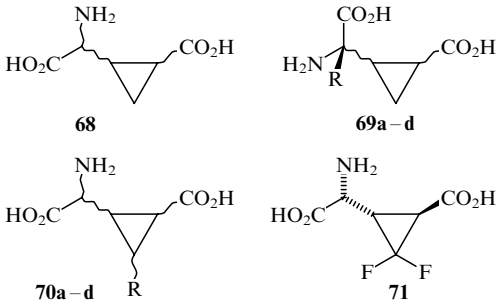


65 **66** **67**

In the 3,4-methanologue of proline, the torsion angles φ and χ are also fixed. This property was successfully employed in the design of mimetics of the polyproline II helix, which plays an important role in the processes of intracellular signal transmission.[114] The chimeric amino acids **66** and **67** have been investigated. They may be considered as analogues of both proline and leucine (the former) and proline and glutamic acid (the latter). A detailed conformational analysis of di- and tripeptides containing residues of **66** and **67** has shown that the torsion angles φ, ψ, χ_1 and χ_2 therein are $-70°$, $131°$, $-57°$ and $-158°$, respectively. These values agree with angles typical of the left-handed helix conformation of polyproline II (see Table 1).[115, 116] This conformational analysis was performed on the basis of the NMR data (for **66**) and results of computer simulations (for **66**, **67**). It is noteworthy that the calculations using molecular mechanics (MM) and *ab initio* (HF/6-31G* basis set) approaches yielded virtually identical geometric parameters of these two molecules. This illustrates an important advantage of the use of CRA in the design of peptidomimetics: the structure of their peptide fragments can be predicted on the basis of simple computational methods.

Compilation of 'stereolibraries', *i.e*., diastereomeric series of amino acids differing from each other in the configuration of chiral centres, is also possible for 3,4-methanologues. For instance, 2′-substituted derivatives have eight stereoisomers while 2′,3′-disubstituted amino acid analogues have sixteen isomers.

The large number of stereoisomers of 3,4-methanologues has been used in a study of neuroreceptors activated by L-glutamic acid. At present, several types of receptors that interact with L-glutamic acid are known. It has been suggested that L-glutamic acid interacts with different receptors adopting different conformations. This hypothesis was strongly supported by the synthesis and investigation of all diastereomers of 2-(carboxycyclopropyl)-glycine (CCG) **68**.[117, 118]

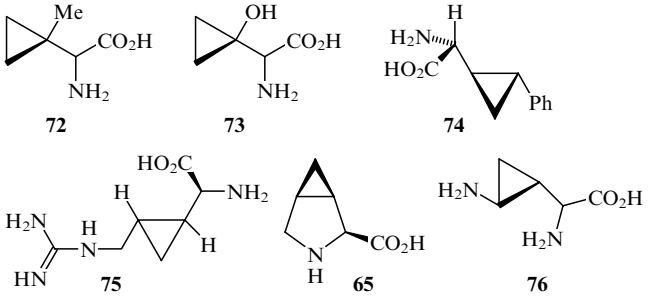


68 **69a – d** **70a – d** **71**

R = Alk (**a**), Ph (**b**), CH_2OMe (**c**), CO_2H (**d**).

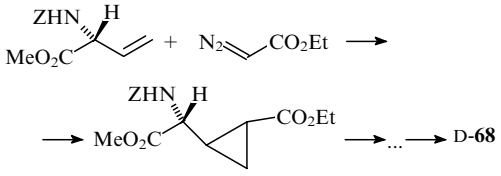
It was established that in many cases the diastereomers CCG interact with different neuroreceptors selectively. Synthesis and biological studies of α-substituted derivatives of CCG, compounds **69a – d** [119, 120] as well as the compilation of 'stereolibraries' for 2′,3′-disubstituted derivatives **70a – d** [121 – 125] and the synthesis of difluoro-substituted derivative **71** [126] provided further confirmation of this hypothesis and a significant contribution to the understanding of mechanisms of neurophysiological processes. All 16 stereoisomers of 2′-carboxy-3′-phenylcyclopropylglycine (**70b**) have been synthesised.

Analogues of other natural amino acids, such as valine, serine,[127] homophenylalanine,[128] arginine,[129] proline [130] and ornithine [131] (**72 – 75**, **65** and **76**) have also been synthesised.



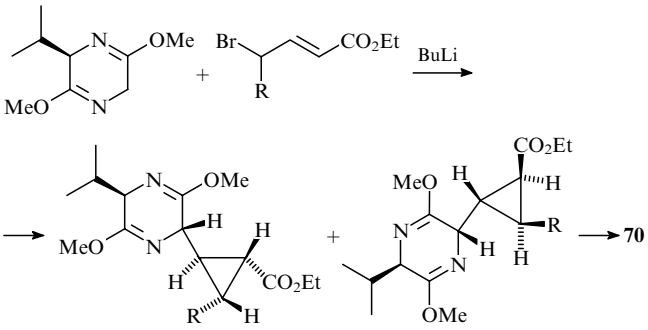
72 **73** **74** **75** **65** **76**

Methods for the synthesis of 3,4-methanologues of amino acids are analogous to those of 2,3-methanologues. Similarly, the key step of these syntheses usually consists of the build up of a cyclopropane ring. In this respect, major efforts were aimed at the optimisation of the respective tranformations to the suitable level of diastereoselectivity. The most frequently applied method is cyclopropanation of a C=C double bond, *i.e*., addition of carbenes or carbenoids. The synthesis of D-2-(carboxycyclopropyl)glycine can be mentioned as an example of this approach.[118]

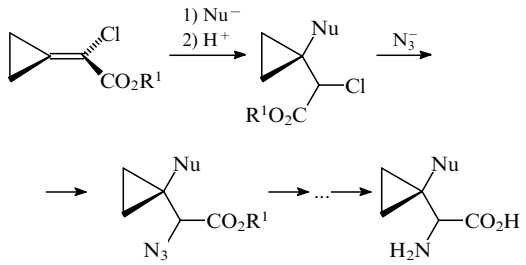


For the preparation of glycine derivatives (*e.g.*, of **70**), the Michael addition followed by elimination of hydrogen bromide was also applied to form a cyclopropane ring (Scheme 9).[121]

Scheme 9



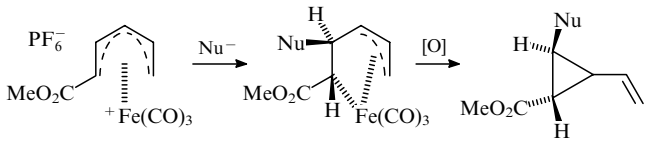
An original route to the synthesis of substances from this class of CRA has been suggested by de Meijere *et al.*[127] This involves 1,4-addition of nucleophiles to 2-chloro-2-cyclopropylideneacetates with subsequent substitution of azide for chloride, reduction and deprotection.



Nu = H, Me, NH_2, CH_2CO_2H, SMe.

The key step of the synthesis of proline 3,4-methanologues [130] is the formation of the pyrrolidone ring as a result of the intramolecular insertion of a carbene (*viz.*, cyclopropylidene) at the C–H bond.

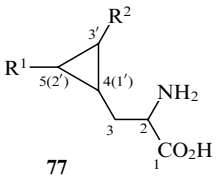
Yet another new original approach to the synthesis of carboxycyclopropylglycine derivatives consists of the addition of stabilised C-nucleophiles to tricarbonyl(1-methoxycarbonylpentadienyl)iron cation.[132]



Nu is a glycine synthon.

5. 4,5-Methanologues of α-amino acids

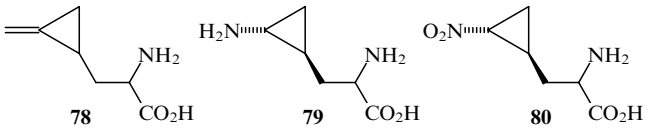
4,5-Methano-α-amino acids (**77**) are used in the synthesis of peptidomimetics and biologically active substances substantially less frequently. It is no surprise since only the torsion angle χ_3, which is situated quite far from the peptide chain, is strictly fixed in these molecules.



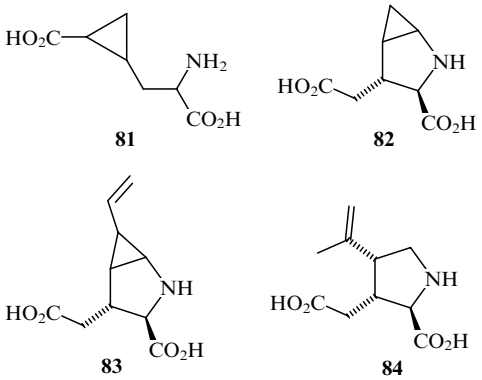
77

4,5-Methanologues of amino acids can be classified as CRA only formally. The presence of a cyclopropane moiety in 4,5-methano-α-amino acids imposes only small constrains on the torsion angle χ_2 and virtually does not affect the torsion angles φ and ψ within the polypeptide chain as well as the angle χ_1 in the respective peptides.

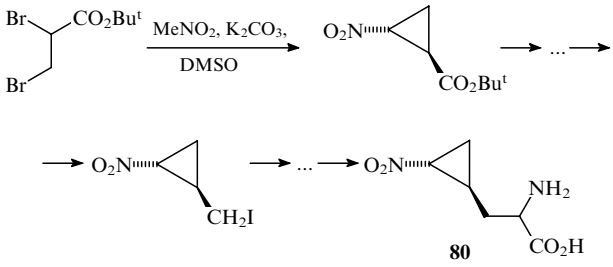
Although 4,5-methanologues of amino acids have attracted insignificant attention from researchers, they are quite abundant in nature. In particular, the compound **78**, the so-called hypoglycine A, occurs in some unripe fruits.[133] Another derivative, *trans*-(2-aminocyclopropyl)alanine (**79**), is the key component of a novel antitumour antibiotic Belastosin A.[134] Yet another derivative, *trans*-(2-nitrocyclopropyl)alanine (**80**), represents a rare example of a naturally occurring substance bearing a nitro group;[135] it is a component of a macrolide antibiotic Hormaomycine.



This class of compounds also includes the recently synthesised 2-aminoadipic acid analogue **81** [136] as well as chimeric amino acids **82** and **83**, which may be regarded as analogues of glutamic acid and proline simultaneously (the acid **83** also contains a fragment of α-cainic acid **84**, which is a naturally occurring non-proteinogenic amino acid).[137]

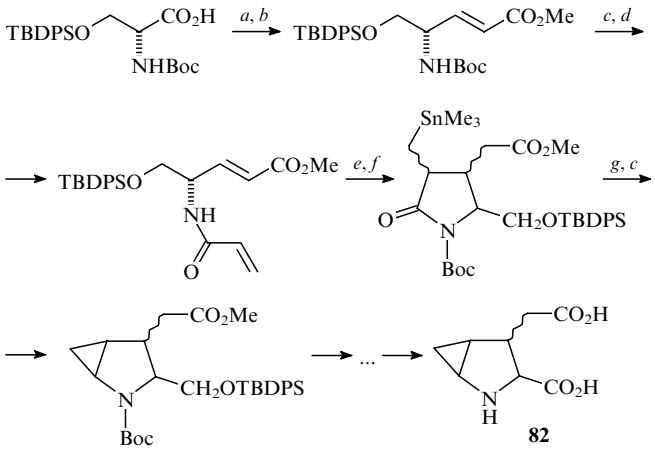


As in the case of 3,4-methanologues, the key step in the synthesis of compounds **78**–**83** is the construction of a cyclopropane ring or of a bicyclic core in the case of **82** and **83**. For the synthesis of **80**, the three-membered ring was formed using alkylation of nitromethane (the Henry reaction).



In the synthesis of compounds **82** and **83**, the five-membered and three-membered rings are built up consecutively. For instance, the acid **82** was synthesised according to Scheme 10.

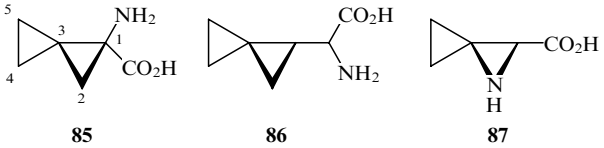
Scheme 10



TBDPS is *tert*-butyldiphenylsilyl;
(*a*) Bu^i_2AlH; (*b*) $Ph_3P=CHCO_2Me$; (*c*) CF_3CO_2H; (*d*) $CH_2=CHCOCl$; (*e*) Me_3SnCl, $NaBH_3CN$, azobisisobutyronitrile; (*f*) Boc_2O, 4-dimethylaminopyridine, Et_3N; (*g*) $LiBHEt_3$.

6. Spiro[2.2]pentane derivatives

Three types of spirocyclic CRA (compounds **85**–**87**) have been synthesised.



85 **86** **87**

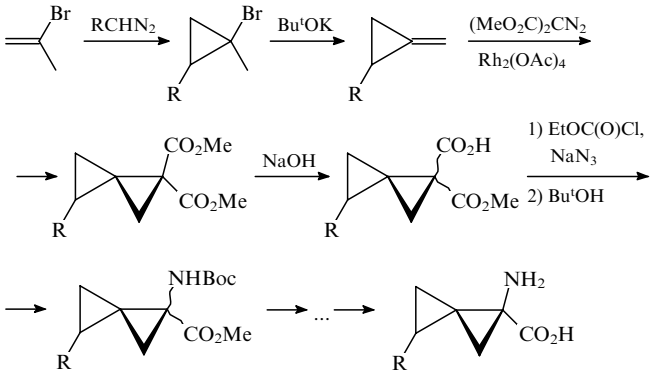
The molecule **85** with a spiro[2.2]pentane skeleton is characterised by the bond lengths and angles strongly distorted with respect to standard mean values.[26, 138] In particular, the C–C bonds involving the spiroatoms C(3) are shortened on average by 0.07 Å, while the bond angles are distorted even more strongly (the values lie in the range from 59° to 135°).

No structural data on the compound **87** with a 1-azaspiro-[2.2]pentane framework have been published. The torsion angles in the molecule **85** have been reported by Pelliciari *et al.*,[138] the corresponding values for **87** can be estimated only approximately.

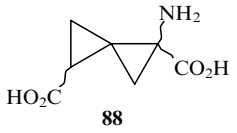
Compounds with spiro[2.2]pentane and 1-azaspiro[2.2]pentane frameworks are synthesised by different routes.

In particular, two consecutive [2 + 1]cycloaddition reactions involving carbene or carbenoid intermediates have been used for the preparation of 2-aminospiro[2.2]pentane-2-carboxylic acid (Scheme 11).[139]

Scheme 11

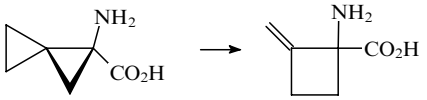


This route was also applied to the synthesis of compounds **85**, **86** and 4-carboxy-substituted derivative **88**, an analogue of glutamic acid. The latter compound was obtained in the form of four diastereomeric pairs.



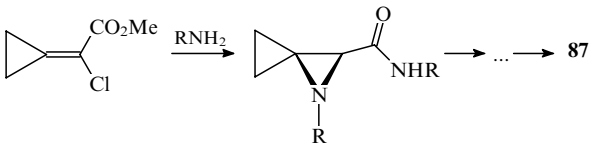
88

It is of note that compound **85** is unstable and spontaneously rearranges into a cyclobutane derivative **89** in aqueous solution in 2 weeks.[139]



85 **89**

1-Azaspiro[2.2]pentane-2-carboxylic acid (**87**) is formed by the reaction of methyl(chloro)cyclopropylideneacetate with primary amines or ammonia.



The amino acid **87** has proven to be relatively stable, it has been used to prepare a glycine-containing dipeptide.[140]

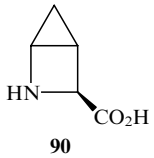
Diastereomers of compound **88** have been extensively studied as regards their binding to typical ionotropic and metabotropic glutamic acid receptors. Since the results of the biological assays were negative in all cases, one may assume that all these compounds are characterised by a spatial configuration of functional groups energetically unfavourable for glutamic acid. Weak binding was observed only with ionotropic *N*-methyl-D-aspartate (NMDA) receptor.[138]

V. Bi- and polycyclic conformationally rigid amino acids with an endocyclic nitrogen atom

Amino acids discussed in this and following sections represent bi- or polycyclic structures, which enable fixation of a larger number of torsion angles as compared to the monocyclic CRA discussed above.

This Section is devoted to amino acids possessing an amine nitrogen atom incorporated into a polycycle. Consequently, the torsion angle φ is strictly fixed in all corresponding peptides. Furthermore, the torsion angle χ_1 (and very often other angles χ as well) is fixed.

It is convenient to classify these amino acids according to the ring containing the nitrogen atom. There are only a few published examples of compounds possessing three- and four-membered C_nN rings (n = 2, 3). In addition to the spirocyclic compounds considered above, 2-azabicyclo[2.1.0]pentane-3-carboxylic acid (also referred to as 3,4-methanoazetidine-2-carboxylic acid **90**) has been reported.[141]



90

On the other hand, amino acids with larger C_nN rings ($n \geqslant 6$) are not rigid (furthermore, such amino acids are rare). Therefore, only amino acids with five- and six- membered C_nN rings ($n = 4$, 5), which are proline and pipecolic acid analogues, respectively, will be discussed below.

1. Proline analogues

Proline occupies a special place among proteinogenic amino acids due to its unique structure. In this amino acid, the amine nitrogen atom is involved in the five-membered ring, which gives rise to the following changes in the conformation of a proline-containing polypeptide chain:

— due to the absence of a hydrogen atom at the nitrogen atom, the latter cannot form hydrogen bonds;

— the *trans*-configuration of a polypeptide chain becomes only slightly more favourable than the *cis*-configuration;[142–144]

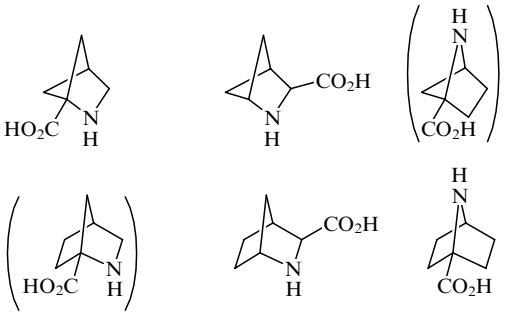
— due to steric hindrance, the values of the torsion angle φ within the five-membered ring vary in the range of $-75^\circ \pm 30^\circ$ (see Ref. 20) (the range of possible values of the torsion angle ψ is also limited due to steric requirements);

— due to significant steric strains, the nitrogen atom is substantionally pyramidalised and the amide bond is twisted;[142, 145]

— the polypeptide loses its capability to form α-helices and thus the tendency towards formation of β-bends is strengthened (especially in the case of the *cis*-configuration of the peptide bond), which explains the higher content of proline in active and peptide-binding sites of enzymes.[144]

It is of note that the above features are typical to a certain extent of all amino acids having an endocyclic nitrogen atom involved in the polypeptide chains. These are more pronounced for amino acids with strained rings.

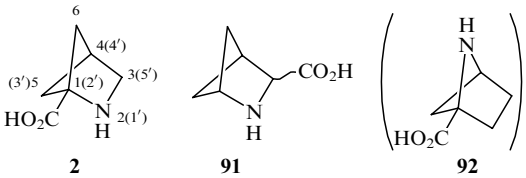
In order to confer conformational rigidity on the proline ring, it is necessary to introduce bridges with a length of 1 or 2 atoms into the molecule. When such a bridge links two adjacent positions in the ring, proline methanologues are formed, which were considered above. Other examples of theoretically possible bicyclic amino acids representing proline analogues are shown below (hereinafter, the structural types that have not been reported in the literature to date are given in parentheses):



Polycyclic proline analogues with more than two rings will be discussed separately.

a. 2-Azabicyclo[2.1.1]hexane derivatives

2-Azabicyclo[2.1.1]hexane-1-carboxylic acid (**2**) or 2,4-methanoproline (atom enumeration in parentheses corresponds to that for proline) was isolated in 1980 from the seeds of legume *Ateleia herbert smithii* among other new amino acids.[146] Recently, this acid has also been isolated from the plant *Bocoa alterna*.[147]



2 **91** **92**

2,4-Methanoproline (**2**) is one of a few naturally occurring proline analogues; the residue of this amino acid in peptides is denoted as 2,4-MePro. In addition to 2,4-methanoproline, two other proline analogues having an azabicyclo[2.1.1]hexane skeleton are possible, *viz*., 3,5-methanoproline (*exo*-**91**) and 2,5-methanoproline (**92**).

exo-3,5-Methanoproline and 2,4-methanoproline **2** have been synthesised quite recently,[148] whereas no synthesis of their 5-aza-analogue **92** has been reported so far.

The bond lengths in the molecule of 2-azabicyclo[2.1.1]hexane-1-carboxylic acid (**2**) are very similar to those in proline but the bond angles in the two molecules are somewhat different (Table 2).[145, 149] The largest difference is observed for the C(2′)–C(3′)–C(4′) and C(2′)–C(6)–C(4′) angles due to the strain in the cyclobutane moiety. The differences in the C(3′)–C(4′)–C(5′) and C(3′)–C(4′)–C(6) angles are probably caused by a specific distortion of the framework, which will be discussed below.

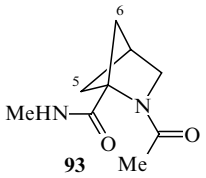
Table 2. The values of the bond angles in 2,4-methanoproline and proline (atom enumeration corresponds to that in proline).

Angle	Value (deg)	
	2,4-MePro	Pro
N–C(5′)–C(4′)	97.0	103
C(3′)–C(4′)–C(5′)	103.1	103
C(3′)–C(4′)–C(6)	100.5	103
C(2′)–C(3′)–C(4′)	82.4	103
C(2′)–C(6)–C(4′)	81.9	

Polypeptides containing a 2,4-MePro residue are characterised by fixed torsion angles φ and χ (the values of these angles may be found elsewhere [149, 150]).

No structural data on 3,5-methanoproline have been published. However, owing to the rigidity of its bicyclic framework, its structural parameters can be predicted on the basis of respective data for the 2,4-isomer.

One may conclude that the angle φ in the 2,4-MePro residue should be 0° assuming the symmetry of the 2-azabicyclo[2.1.1]-hexane framework and planarity of the amide moiety. However, the experimental value of this angle determined for *N*-acetyl-2,4-methanoproline-*N*′-methylamide (**93**)‡ is 29° (see Ref. 150).



93

The observed deviation from the ideal value of 0° is due to distortion of the 2-azabicyclo[2.1.1]hexane framework of **93**, which results in the non-equivalency of the C(5) and C(6) atoms.

The sum of the bond angles at the nitrogen atom in **93** is 356°, *i.e*., virtually no pyramidalisation of the nitrogen atom occurs. This supports the above suggestion that the distortion of the angle φ originates in the deformation of the framework. Numerous structural data on the unsubstituted acid **2** in solutions suggest that the molecules of **2** exist in the form of two interconverting enantiomers, which means, strictly speaking, that they are not rigid.

‡ This type of compounds are quite often applied to prepare peptide models in order to estimate the torsion angles in the respective polypeptide chain.

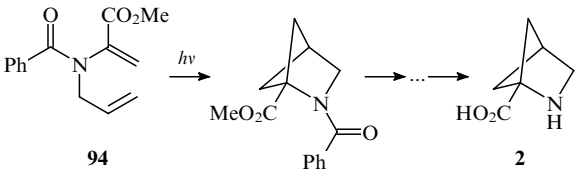
The value of the angle φ in peptides containing an *exo*-3,5-methanoproline (**91**) residue should be -60° taking into account the fact that the bicyclic framework is symmetrical and the amide bond is planar. However, the bicyclic framework is expected to be distorted in this case as well.

The tilt angle (δ) of the amide bond (at the tertiary nitrogen atom) in compound **93** is 16° and the twist angle $\tau = 10^\circ$.

The torsion angle ω in compound **93** is equal to -178° (this molecule adopts the *trans*-conformation in crystals). As has been shown, the *trans*-isomer of **93** is more stable than the *cis*-isomer both in the solid state and in solutions.[149, 150]

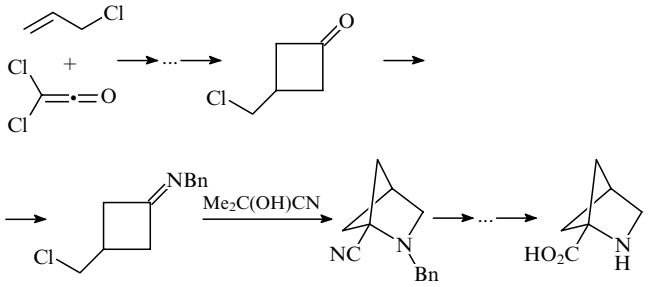
There are several approaches to the synthesis of 2,4-methanoproline. All of them are based on the [2+2]-cycloaddition reaction.

Earlier,[151–153] the photochemical cyclisation of the diene **94** was employed (the only difference between several suggested procedures consisted of the routes for the preparation of the diene **94**).



94 **2**

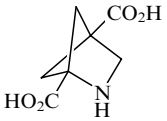
Alternatively, a recently suggested method for the synthesis of 2,4-methanoproline includes [2+2]-cycloaddition with dichloroketene followed by cyclisation.[154]



Rearrangement of 2-azabicyclo[2.2.0]hex-5-enes following addition of bromine[155] is rarely used for the preparation of 2,4-methanoproline due to difficulties associated with the introduction of a 1-carboxy group. Nevertheless, this reaction is a very promising method for the formation of the 2-azabicyclo[2.1.1]-hexane framework.

Although 2-azabicyclo[2.1.1]hexane has been known for a long time, it has rarely been used for the synthesis of amino acids. For instance, carboxylation of unsubstituted 2-azabicyclo[2.1.1]-hexane cannot be regarded as a method for the preparation of 2,4-methanoproline since it yields an equimolar mixture of 2,4- and 3,5-methanoprolines (it is of note, however, that it is exactly by this route that the 3,5-isomer **91** has been produced).[148]

Only one functionalised 2,4-methanoproline derivative, *viz*., glutamic acid analogue **95**, has been synthesised to date. It is formed in the photochemical [2+2]-cyclisation of the respective diene precursor[156] (similar to the synthesis of the acid **2** from the diene **94**).



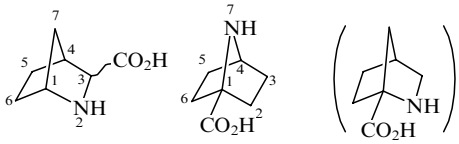
95

Like other functionalised proline analogues, the amino acid **95** is chimeric since it simultaneously mimics glutamic acid and proline.

The biological activity of 2,4-methanoproline and its derivatives is quite well explored. In particular, 2,4-methanoproline has been introduced in place of proline into oligopeptides bradykinin and angiotensin II[157] that are neurotransmitters playing a crucial role in the regulation of blood pressure and heart functioning. Unfortunately, the synthetic analogues proved less active than the original oligopeptides. Compound **95** has been tested as an inhibitor of a sodium-dependent glutamate transport protein.[156]

b. Derivatives of 2-azabicyclo[2.2.1]heptane-3-carboxylic and 7-azabicyclo[2.2.1]heptane-1-carboxylic acids

Compounds with the norbornane framework are widely employed in the synthesis of diverse conformationally rigid substances. In particular, aza-derivatives of norbornane have been used in the design of CRA analogous to proline. In principle, there are three possible variants of incorporation of proline into the norbornane framework (compounds **96**–**98**).

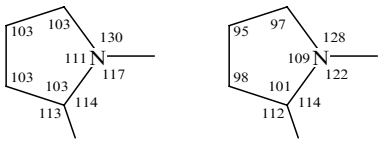


96 **97** **98**

To date, only 2-azabicyclo[2.2.1]heptane-3-carboxylic (**96**) and 7-azabicyclo[2.2.1]heptane-1-carboxylic (**97**) acids along with some of their derivatives have been synthesised.

2-Azabicyclo[2.2.1]heptane-3-carboxylic acid (**96**) (its residue in peptides is denoted as Abh) has been known for a relatively long time.[158] It was one of the first artificial conformationally rigid analogues of proline.

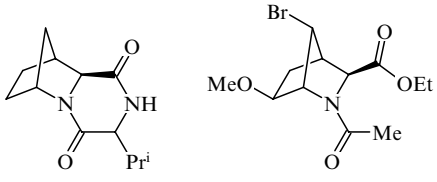
An analysis of X-ray diffraction data on proline[145] and the acid **96**[159] has revealed important differences in the bond angles within the pyrrolidine rings of the two substances despite similarity of the respective bond lengths. The values of the bond angles (in deg.) in model peptides containing Pro and Abh residues are given below.



Pro Abh

Owing to the rigid framework of 2-azabicyclo[2.2.1]heptane-3-carboxylic acid, peptides with an Abh residue are characterised by the fixed torsion angle φ. The same is valid for the torsion angles χ (the values of these torsion angles for the *exo*-isomer **96** are given elsewhere,[159, 160] similar values are expected for the *endo*-isomer).

Assuming that the bicyclic framework of **96** is symmetrical and the amide bond is planar, the torsion angle φ should be equal to -60°. Although there have been no dedicated investigations on this topic, the available data for **99** ($\varphi = -39^\circ$)[160] and **100** ($\varphi = -73^\circ$)[159] allow one to suggest that the real value of this torsion angle in **96** will deviate from the ideal value (-60°). The large deviation of the torsion angle φ from -60° observed for **99** can be partly attributed to the presence of a six-membered ring.



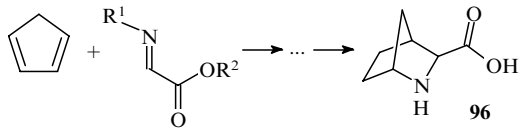
99 **100**

The nitrogen atoms in **99** and **100** are characterised by insignificant pyramidalisation ($\omega_0 \approx 358^\circ$), however, the respec-

tive peptide bonds are non-planar. The non-planarity of the amide bonds is evidenced by the values of the angles δ and τ: $\delta = 14°$, $\tau = 8°$ and $\delta = 14°$, $\tau = 6°$ for **99** and **100**, respectively.

The compound **100** in crystals adopts the *trans*-conformation ($\omega = -177°$). No data on the amide bond configuration in solutions of **100** are available.

The principal method for the synthesis of 2-azabicyclo[2.2.1]-heptane-3-carboxylic acid is the Diels–Alder reaction of cyclopentadiene (as a diene) and imine (as a dienophile) that is normally generated *in situ*.[158, 161, 162]



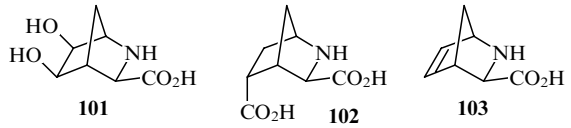
96

Using this reaction, optically active 2-azabicyclo[2.2.1]heptane-3-carboxylic acid (*exo*-**96**) can be produced in gram quantities.[161]

Substituted amino acids are usually prepared by a modification of the double bond formed at the cycloaddition stage.

Other routes to the synthesis of the amino acid **96** are based on different intramolecular cyclisations but they found only limited applications.[163]

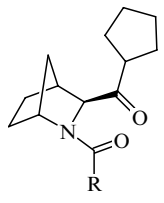
Despite the apparent simplicity of the preparation of 2-azabicyclo[2.2.1]heptane-3-carboxylic acid derivatives, there are only a few known representatives of this class. In addition to the unsubstituted compound **96**, only analogues of homoserine and glutamic acid have been reported, *i.e.*, **101** (along with its protected derivatives) [164] and **102,**[163] respectively.



101 **102** **103**

Compound **103** has also been synthesised. Since it tends to rearrange in acidic media, it was isolated only in the protected form.[165]

2-Azabicyclo[2.2.1]heptane-3-carboxylic acid (**96**) is widely employed in asymmetric synthesis.[166] It has also been used for the preparation of analogues of fragments of the tumour growth factor TGFα (see Ref. 167) and inhibitors of prolylendopeptidase § **104**–**107** (see Ref. 168).



104–**107**

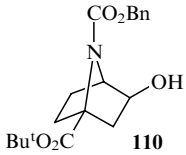
R = $Ph(CH_2)_3$ (**104**), PhCHCH$_2$CHCH$_2$ (**105**), (cyclo-C_3H_5)$_2$CH$(CH_2)_3$ (**106**), Bu^{t}O (**107**).

In contrast to 2-azabicyclo[2.2.1]heptane-3-carboxylic acid (**96**), 7-azabicyclo[2.2.1]heptane-1-carboxylic acid (**97**) has been prepared only quite recently.[169, 170]

An analysis of structural data indicates that the bond lengths and bond angles in 7-azabicyclo[2.2.1]heptane are virtually identical to those in proline (except for the angles at the nitrogen atom).[145] Certain differences in the latter (by up to 7° as compared to proline) are due to the pyramidalisation of the nitrogen atom.

An analysis of the dihedral angles shows that the angle φ as well as all angles χ in the 7-azabicyclo[2.2.1]heptane molecule are fixed (the values of these angles can be found elsewhere [171, 172]).

The theoretical value of the angle φ calculated under the assumption that the framework is symmetrical and the amide bond is planar is equal to 0°. For the sake of structural elucidation of peptides, a series of model oligopeptides with a residue of **97** (for this residue, a notation Ahc is adopted) has been synthesised. According to X-ray diffraction data, the angle φ in the protected dipeptides Piv-Ahc-L-Ser-NHMe (**108**) and Piv-L-Ser-Ahc-NHMe (**109**) strongly deviates from the theoretical value of 0°, similarly to the aforementioned case of dipeptides with a 2,4-methanoproline residue: $\varphi = -36°$ (for **108**), 40° and 44° (for two crystalline modifications of **109**). Compound **110** is characterised by an even larger deviation ($\varphi = \pm 51°$).[172]



110

The norbornane framework in **108**–**110** is undistorted and the deviation of the angle φ from the idealised value of 0° occurs due to the pyramidalisation at the nitrogen atom. Strictly speaking, the molecules again lose rigidity as regards the angle φ.

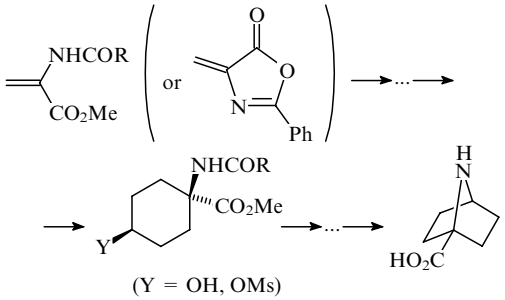
The torsion angle ω_0 is 346° in the case of Piv-Ahc-L-Ser-NHMe. Such a low value of ω_0 is observed only in a few amides (*e.g.*, in aziridine derivatives). The amide bond in **108** is characterised by the following values: $\delta = 34°$, $\tau = 5°$. For **110**, the respective parameters are 335° (ω_0), 43° (δ) and 17° (τ).

In the crystals of **110**, the angle ω is 133°, which corresponds to the *trans*-configuration. Meanwhile, the angle ω is close to ±180° in all the dipeptides studied.

Introduction of an Ahc residue into a peptide chain in place of proline stabilises the β-bend (type I).[171]

There are several approaches to the synthesis of the 7-azabicyclo[2.2.1]heptane framework. The amino acid **97** has been prepared for the first time using a radical cyclisation of 1-(*o*-bromobenzoyl)-2-(prop-2-enyl)pyrrolidines,[169, 170] which yields a series of by-products, including 8-azabicyclo[3.2.1]octane derivatives. This method is inefficient for the synthesis of the amino acid **97**; it is used solely for the preparation of 7-azabicyclo[2.2.1]heptane unsubstituted at position 1.

Another method utilises a nucleophilic substitution reaction that is accompanied by formation of a bond between the nitrogen and carbon C(4) atoms. To form the 6-membered ring, the Diels–Alder reaction is applied, in which the Danishefsky diene [CH_2=C(OSiMe_3)CH=CH-OMe] or 3-methoxy-1,3-butadiene are used as the dienes and 2-acylamidoacrylates as the dienophiles. The general scheme of the synthesis is depicted below.[173–177]



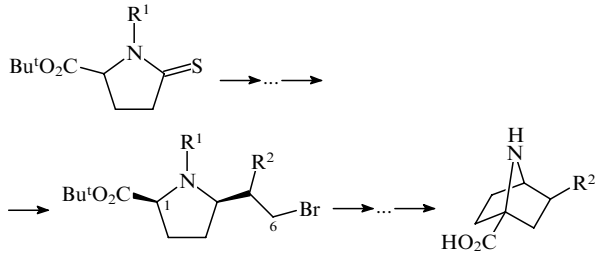
(Y = OH, OMs)

This method is especially convenient for the synthesis of 2-substituted derivatives.

Yet another approach to the synthesis of 7-azabicyclo[2.2.1]-heptane-1-carboxylic acid has been suggested,[172] which implies

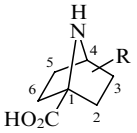
§ Prolylendopeptidase is the only enzyme capable of splitting the C-terminal peptide bond formed by the proline residue. This enzyme splits neuropeptides involved into the learning and remembering processes; thus it is one of the targets within the scope of curing of the Alzheimer decease and amnesia.

formation of a bond between the C(1) and C(6) atoms as a result of alkylation of the respective enolate anion.



This method has been used to produce a number of chimeric 3-substituted amino acids.

It should be noted that all amino acids having a 7-azabicyclo[2.2.1]heptane framework, except for the unsubstituted amino acid **97**, are chimeric since they always mimic proline in addition to the natural amino acid representing their most direct analogue. In particular, 2- and 3-substituted chimeric acids **111**–**121** have been synthesised, which are analogues of phenylalanine, 4-hydroxyproline, glutamic acid, homophenylalanine, ornithine, arginine, lysine and serine.[172–174, 177, 178]

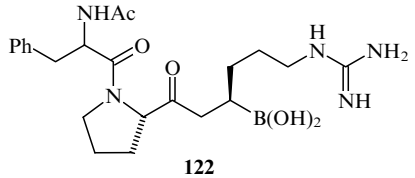


111–**121**

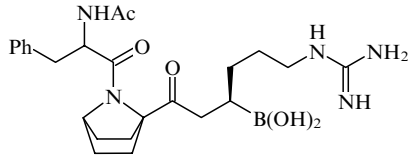
R = 2-Ph (**111**),[174] 2-CH_2CO_2H (**112**),[177] 3-OH (**113**),[177] 3-Ph (**114**),[172] 2-CO_2H (**115**),[173] 2-Pr^n (**116**),[173] 3-CO_2H (*exo*- and *endo*-**117**),[172] 2-OH (*exo*- and *endo*-**118**),[178] 3-CH_2NH_2 (*exo*- and *endo*-**119**),[172] 3-$CH_2NHC(=NH)NH_2$ (*exo*- and *endo*-**120**),[172] 3-$CH_2CH_2NH_2$ (**121**).[172]

Only protected derivatives of the amino acids **117**, **119**–**121** have been prepared.[172]

The unsubstituted amino acid **97** has been utilised in the synthesis of peptidomimetics. In particular, substitution of Ahc for Pro in the peptide Ac-D-Phe-Pro-boroArg-OH (**122**, DuP714), a thrombin inhibitor, yielded the peptidomimetic **123**. This peptidomimetic manifested the 30-fold lower thrombin affinity than the original peptide **122**, which allowed the authors to conclude[179] that the conformation of the model compound in the bound state does not correspond to that of the object being modeled.



122

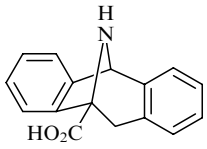


123

A benzyl derivative of the amino acid **113** has been introduced into a proline-containing inhibitor of HIV-I protease. The mimetic obtained manifested quite a high degree of binding to the enzyme.[180]

c. Other proline analogues

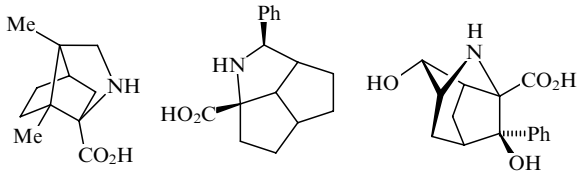
As has been mentioned above, the bridges in bicyclic CRA should include 0, 1 or 2 atoms, the presence of sp^2-hybridised atoms in the bridge enhances the conformational rigidity of the CRA molecule. For bridges containing a π-bond, lengths of up to three atoms are possible. For instance, compound **124**[181, 182] with a 2,5-bridge is classified as a CRA.



124

Compound **124** has been prepared as a potential ligand for the NMDA receptor but it can be formally regarded as a proline analogue.

The tricyclic amino acids **125**–**127** can also be considered as proline analogues.



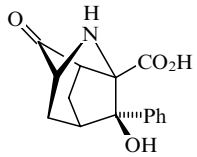
125 **126** **127**

Compound **125** has been prepared in several steps starting from camphor.[183] The molecule **125** is extremely rigid. This fact makes **125** very promising for the synthesis of peptidomimetics.

The tricyclic compound **126** is produced by intramolecular [3 + 2]-cycloaddition. This is a key intermediate in the synthesis of guanidine alkaloids.[184] It was isolated only in the protected form.

Compound **127** is of particular interest. It has the full right to be named a 'hyperchimeric' amino acid since it is an analogue of eight natural amino acids: proline, serine, homoserine, phenylalanine, threonine, isoleucine, valine and 4-hydroxyproline.[185]

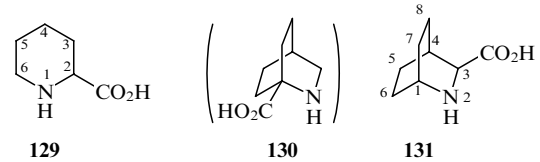
No structural data on **124**–**127** are available, although the results of an X-ray diffraction study of the amino acid **128** (which is a precursor of **127**) have been published.[185]



128

2. Pipecolic acid analogues

Pipecolic acid **129** is a non-natural cyclic α-amino acid that represents a proline homologue.

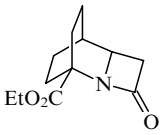


129 **130** **131**

To confer rigidity on the pipecolic acid framework, it has to be included into a bicycle with the bridge linking positions 2 and 5 (or 3 and 6). The case of a bridge containing only one atom has been discussed above since it is the 2-azanorbornane framework. In the case of a bridge containing two atoms, two structural types **130** and **131** are possible.

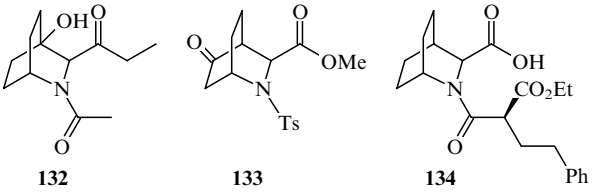
To date, only compound **131** with a carboxy group at the position 3 has been synthesised. Compound **130** has not been

reported although its β-lactam derivative has been characterised.[186]



2-Azabicyclo[2.2.2]octane-3-carboxylic acid (**131**) is quite often used as a substitute for the proline residue although it is actually an analogue of pipecolic acid (for the residue of this acid, a notation Abo is adopted). This acid can be rather easily prepared in the enantiomerically pure form.

No dedicated structural studies on the 2-azabicyclo[2.2.2]octane framework of **131** have been conducted so far, although its amide **132** (see Ref. 187), tosyl derivative **133** (see Ref. 188) and the drug Zabicipril (S 9650-3) **134** (see Ref. 189) have been studied using X-ray diffraction.



132 **133** **134**

An analysis of these structural data indicates that the C–C bonds of the piperidine rings within the 2-azabicyclo[2.2.2]octane framework are slightly (approximately by 0.03 Å) longer than in pipecolic acid;[190] no substantial difference in the bond angles is observed.

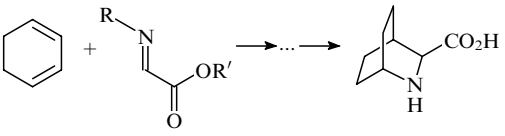
Formally, the two piperidine rings in **131**, *i.e.*, C(1)NC(3)C(4)C(5)C(6) and C(1)NC(3)-C(4)C(8)C(7), can be distinguished. According to experimental results,[190] the absolute values of the torsion angles in these rings are not identical, which indicates that the framework is somewhat distorted (as in the case of 2,4-methanoproline).

Theoretically, the value of the angle φ in derivatives of 2-azabicyclo[2.2.2]octane-3-carboxylic acid assuming the symmetrical framework and the undistorted amide bond is -60°. According to X-ray diffraction data, this value is -65° in **133** (*i.e.*, the deviation from the idealised value is small). In Zabicipril **134**, the respective torsion angle is -63°.

The pyramidalisation parameter (ω_0) of the nitrogen atom in **132** is 359.7°. Distortion of the amide bond is also insignificant ($\tau = 4^\circ$ and $\delta = 9^\circ$), *i.e.*, the amide bond in derivatives of 2-azabicyclo[2.2.2]octane is virtually planar.

According to X-ray diffraction data, the amide bond is characterised by the *trans*-configuration in **132** and **134** ($\omega = -172^\circ$ and 174° for **132** and **134**, respectively).

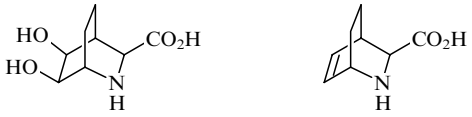
The amino acid **131** and its derivatives can be prepared using several methods. As in the case of azanorbornane, the basic method for the construction of this framework is the Diels–Alder reaction.[189, 191]



Functionalised derivatives can be produced by modification of the double bond that is formed in the cycloaddition reaction.[191]

Among other synthetic routes, the following are worth a special note: the reaction of 1,2-dihydropyridines with dienophiles,[192] the intramolecular Dieckmann and Michael reactions,[193] intramolecular S_N2 epoxide opening.[194]

Despite the apparent simplicity of these syntheses, only a few chimeric amino acids with the 2-azabicyclo[2.2.2]octane framework have been prepared, including dihydroxy-substituted acid **135**, its protected derivatives and unsaturated acid **136**.[191]

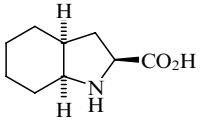


135 **136**

Derivatives of 2-azabicyclo[2.2.2]octane-3-carboxylic acid are widely applied in asymmetric synthesis.[191, 195]

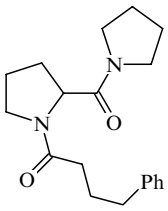
Numerous peptidomimetics have been synthesised based on Abo, in particular, the aforementioned Zabicipril **134**, which represents an efficient inhibitor of angiotensin converting enzyme (ACE), which plays a crucial role in blood pressure regulation.[196] The angiotensin II mimetic **134** is a promising antihypertensive drug.[189] This represents an example of a successful drug design: the peptidomimetic obtained retains activity of the native peptide and it is more stable against biodegradation, which gives rise to a strong prolongation effect.

The amino acid **131** along with the aforementioned acid **96** (Abh) and conformationally constrained but not rigid perhydroindole-2-carboxylic acid **137** (Phi) are often used in complex investigations of peptidomimetics as regards their biological activity.



137

For instance, these amino acids have been utilised to mimic the prolylendopeptidase inhibitor SUAM 1221 (**138**), which is a proline derivative.[168]



138

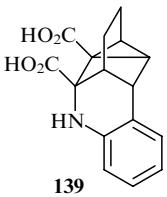
In addition to modifications involving the side chain of the acid residue,¶ different substitutes for the central proline residue were tested. The best results were achieved when the proline resudue was replaced by the Phi residue, although Abo and Abh also gave promising results.

The same amino acids have been probed as substitutes for proline in the tripeptides Val-Pro-Val and Val-Pro-Lys in the search for efficient selective inhibitors of the human leucocyte elastase (HLE).[197] The synthetic peptidomimetics manifested high potential as long-lasting inhibitors of pulmonary tissue degradation related to HLE.

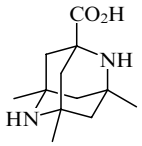
Furthermore, the amino acid **131** has been used for the preparation of antagonists for the tetrapeptide tachykinin. Introduction of an Abo residue into the peptidomimetic resulted in prolongation of the activity of the synthetic antagonist.[198]

Among other analogues of pipecolic acid, the polycyclic compounds **139** and **140** are of special interest. The polycyclic compound **139** is an analogue of pipecolic and glutamic acids. It has been produced as a protected derivative in a small yield by the reaction of substituted bicyclo[2.2.2]hexadiene with *o*-iodoaniline catalysed by palladium(II).[199]

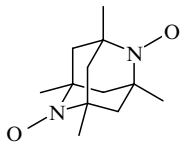
¶ These modifications were conducted within the principles of the strict conformational fixation (by introduction of cyclopropane fragments), which yielded positive results in some cases.



139



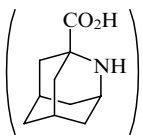
140



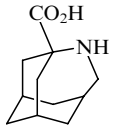
141

Compound **140** is formed as an intermediate in the synthesis of a biradical **141**, an organic ferromagnetic species.[200] It may be assumed that the presence of an additional nitrogen atom would impart particular properties to the biologically active substances produced on its base.

It is of note that the non-functionalised 2-azaadamantane derivative **142** has not been prepared so far despite the fact that adamantane is frequently used in the synthesis of CRA. Only a homologue of 2-azaadamantane **143** has been reported,[201] which is not conformationally rigid, however.



142

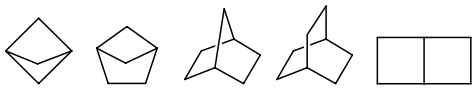


143

VI. Bi- and polycyclic conformationally rigid amino acids with an exocyclic nitrogen atom

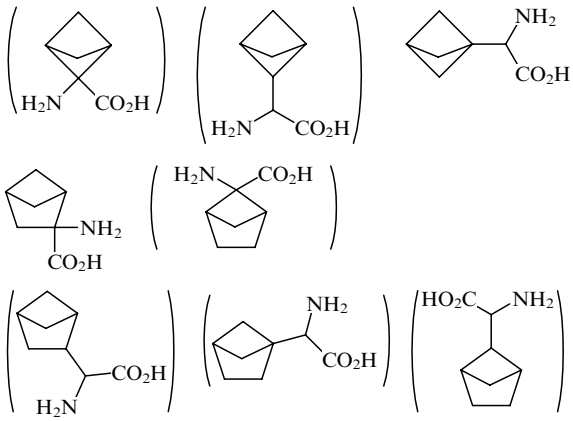
In the case of bi- and polycyclic amino acids discussed above, the conformational rigidity is achieved by inclusion of the nitrogen-containing ring into a polypeptide chain. In contrast, the torsion angles of the polypeptide chain are not fixed for cyclic amino acids with an exocyclic nitrogen atom, although the respective amino acids are χ-rigid.

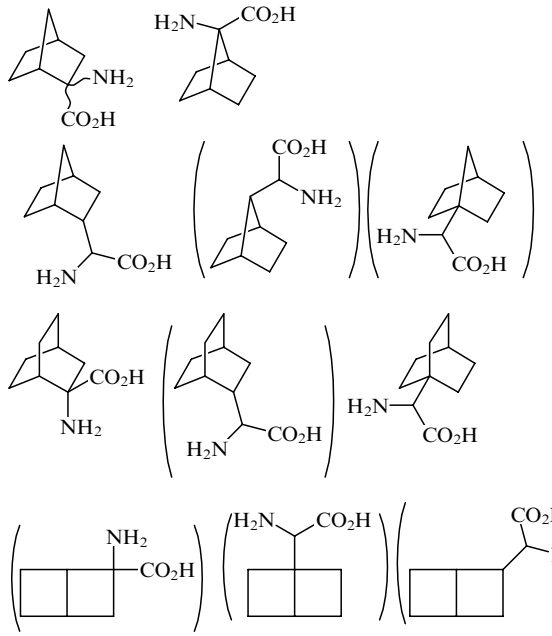
There are several rigid bicyclic cages, in particular, bicyclo[1.1.1]pentane (**A**), bicyclo[2.1.1]hexane (**B**), norbornane (**C**), bicyclo[2.2.2]octane (**D**) and bicyclo[2.2.0]hexane (**E**) with bridge lengths not more than two atoms (cyclopropane derivatives have been thoroughly discussed above and thus are not mentioned here):



A **B** **C** **D** **E**

The respective amino acids are known for all these bicyclic systems (except for bicyclo[2.2.0]hexane):



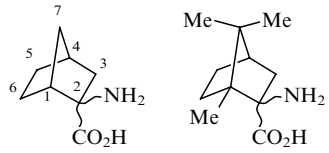


It can be noted that these bicyclic cages fix either all torsion angles χ or only some of them. Therefore, for further discussion, it is convenient to differentiate between the χ_1-rigid amino acids and other χ_n-rigid amino acids ($n \geqslant 2$).

In addition to the bicyclic amino acids, polycyclic amino acids are also known. However, examples of these are scarce (these include derivatives of adamantane, cubane and fullerene C_{60}).

1. Norbornane derivatives

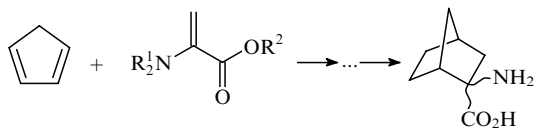
2-Aminonorbornane-2-carboxylic acid (**144**) (its residue in peptides is denoted as Bch) has been known from the mid-1950's,[202, 203] whereas synthesis of its trimethyl derivative, the camphor analogue **145**, was reported even earlier.[204] Potential biological activity of **144** was discussed following its preparation.[205]



144a,**b** **145a**,**b**

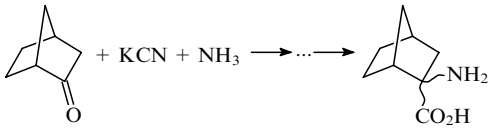
The values of the torsion angles in the bicyclo[2.2.1]hexane cage are given elsewhere.[206, 207] Introduction of functional groups into the norbornane framework gives rise to only minor changes in the torsion angles (by not more than 15°). Only the angles involving the substituents are mostly affected. No distinct effect of the norbornane fragment on the torsion angles within the polypeptide chain has been revealed.

Methods for the synthesis of norbornane-based amino acids have been recently surveyed,[11, 12] therefore, we shall just mention them. The most popular method is based on the Diels–Alder cycloaddition reaction of cyclopentadiene to derivatives of α,β-unsaturated α-amino acids.[202, 203, 208–216]

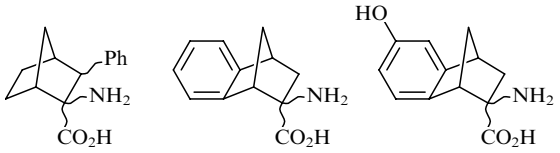


Dienophiles substituted at the β-position can also be employed in this reaction. Diastereo- and enantioselective modifications of this method have been elaborated.

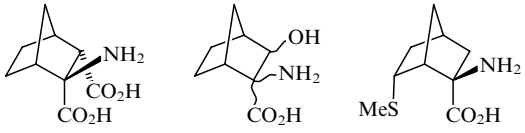
Another approach utilises the classical Strecker and Bucherer–Lieb reactions [204, 205, 217, 218] starting from 2-norbornanone, which in turn is produced by the Diels–Alder reaction.



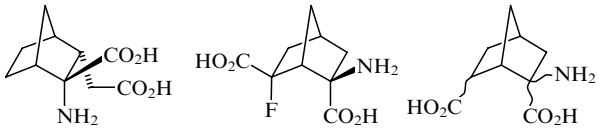
Numerous CRA with the norbornane cage have been prepared. In addition to the unsubstituted acid **144**, various functionalised derivatives **146**–**155** (which represent analogues of phenylalanine,[208, 209, 217] tyrosine,[217] aspartic acid,[211, 212] serine,[213] methionine,[219] glutamic acid [211, 219–221]), including polyhydroxy-compounds **156a**–**d** [216] have been prepared. All of these compounds are fully χ-rigid (except for **152**, which is χ_1-rigid).



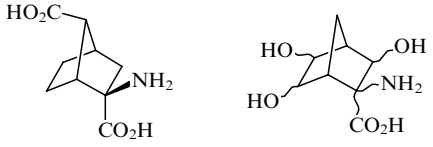
146a–d **147a,b** **148a,b**



149 **150a,b** **151**



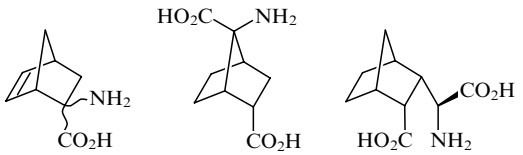
152 **153** **154a–d**



155 **156a–d**

For the synthesis of 3-substituted derivatives, the respective substituted cyclopentadienes are used, 6- and 7-substituted derivatives are produced by functionalisation of the double bond.

The unsaturated derivative **157** has been prepared only in the protected form.



157 **158** **159**

7-Aminonorbornane-2,7-dicarboxylic acid **158** has been synthesised, which is also an analogue of glutamic acid.[221]

Among norbornylglycine derivatives, only the acid **159** is known,[211] which is also a glutamic acid analogue †. This type of amino acids are not χ_1-rigid, that is why probably they attract only limited interest.

The biological activity of the unsubstituted 2-aminonorbornane-2-carboxylic acid (**144**) has been studied. For instance, it has been shown that this acid is selectively transported into nearly all cells by sodium-independent systems responsible for the transport of hydrophobic amino acids.[223] The acid is almost excluded from the metabolism and thus it can be accumulated in tissues. The Bch residue mimics most closely the properties of leucine (and, to a lesser extent, of isoleucine and valine), which makes it possible to monitor pathways of leucine transport in tissues through the use of ^{14}C-labeled Bch or to inhibit this transport. In particular, with the help of the acid **144**, the sodium-independent transport systems of phenylalanine and leucine have been shown to be identical. Furthermore, it was demonstrated that the transport system is selective to one of the diastereomers **144a** or **144b**.

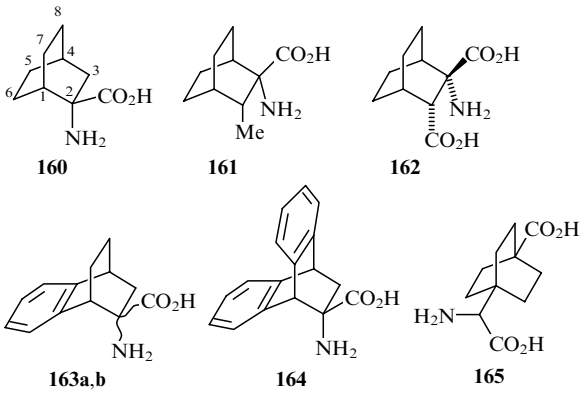
The diastereomers **144a** and **144b**, as was established in the course of the study of their transport, manifest hypoglycaemic activity (that is also typical of leucine [224]), and the effect of a decrease in the glucose concentration in blood was long-lasting. As a side effect, concentrations of at least five amino acids in blood plasma were observed to decrease. Physiological tests on rats showed that the acid **144** is non-toxic; it was almost completely excreted with urine.

Another activity was observed for the acid **144** introduced into rat mitochondria: Bch stimulates the glutamine catabolism by activating mitochondrial glutaminase (this activity was not observed for leucine).[225] The processes of insulin release and glutaminase activation under action of Bch are coupled.[226]

The biological activity of the acid **154**, which is a glutamic acid analogue, has also been studied. The activity of this acid towards metabotropic glutamic acid receptors mGluR1 and mGluR2 has been revealed.[220]

2. Bicyclo[2.2.2]octane derivatives

Amino acids with the bicyclo[2.2.2]octane framework are best studied as regards the number of derivatives synthesised. The unsubstituted acid **160** [227] as well as its derivatives **161**–**164** [203, 228–231] have been prepared and characterised.



160 **161** **162**

163a,b **164** **165**

The values of the torsion angles in the bicyclo[2.2.2]octane cage are given elsewhere.[228, 232] An analysis of the structural data indicates that amino acids with a bicyclo[2.2.2]octane framework are characterised by distorted torsion angles (especially, in the case of bulky substituents).

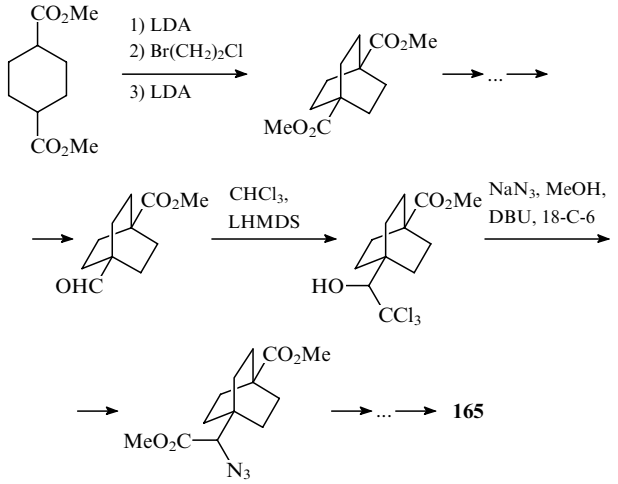
Another amino acid **165**, in which the C_α atom is exocyclic with respect to the bicyclo[2.2.2]octane framework, has been reported.[233]

Methods for the synthesis of amino acids with a bicyclo[2.2.2]octane cage are generally similar to those of norbornane derivatives, which have been discussed above. They include the Diels–Alder reaction of 1,3-cyclohexadiene with α,β-dehydroalanines, the Strecker and Bucherer reactions.[228–230] The acid **165** is formed by alkylation of enolates (Scheme 12).

The unsubstituted amino acid **160** manifests biological activity analogous to 2-aminonorbornane-2-carboxylic acid **144** .[234] Compounds **163a,b** have been investigated as analogues of phenylalanine in the inhibition of phenylalanylhydroxylase and phenylalanyldecarboxylase.

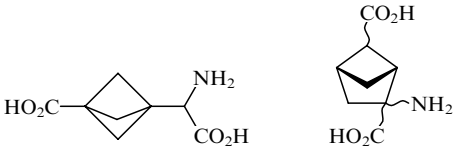
† Synthetic glutamic acid analogues attracts significant interest and thus they are especially numerous.[222]

Scheme 12



3. Derivatives of bicyclo[1.1.1]pentane and bicyclo[2.1.1]hexane

To date, only one CRA **166** with a bicyclo[1.1.1]pentane framework [235] and one acid **167** (four diastereomers) with the bicyclo[2.1.1]hexane framework [236, 237] are known. They both may be considered as analogues of glutamic acid.

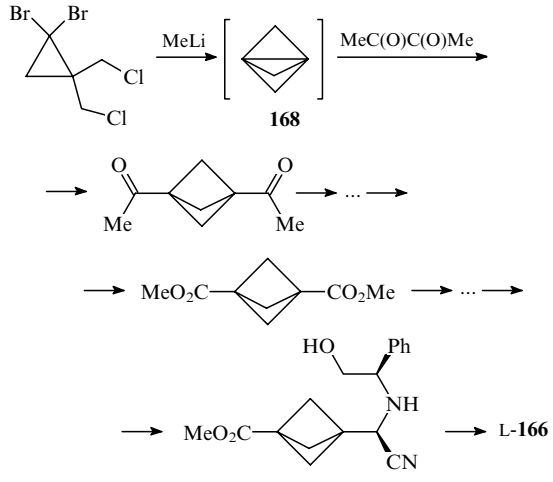


166 **167a–d**

Values of the torsion angles in bicyclo[1.1.1]pentane [238, 239] and bicyclo[2.1.1]hexane [240, 241] have been reported. These two frameworks deserve special consideration since they are extremely rigid and characterised by relatively small steric volume. Therefore, one may hope that other amino acids with these cages will be synthesised in the future, although the synthesis of such compounds is challenging. The diastereomers **167a–d** were prepared by an intramolecular photochemical [2 + 2]-cycloaddition from the appropriately substituted 1,5-diene [236] or by a contraction of the norbornane system through photochemical decomposition of α-diazoketones.[237] The amino acid **166** has been synthesised *via* [1.1.1]propellane **168** (Scheme 13).[235]

Binding of the amino acids **166** and **167** to the corresponding receptor has been elucidated. Compound **166** proved to be a fairly efficient selective antagonist of the glutamate metabotropic

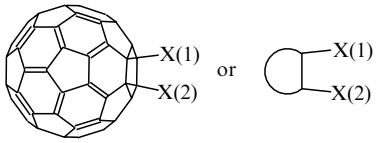
Scheme 13



receptors mGluR1 and one of the diastereomers **167a–d** was active as a common antagonist of all the mGluR receptors tested.

4. Fullerene derivatives

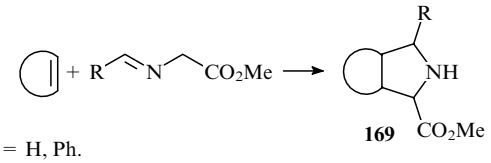
Over the last decade, numerous studies related to a greater or lesser extent to fullerene C_{60} have appeared. Taking into account the rigidity of the buckminsterfullerene cage, its introduction into side chains of amino acids is expected to lead to strict fixation of the torsion angles χ. However, due to specific restrictions related to the structure of the C_{60} molecule as well as to available methods of fullerene functionalisation, only χ_2-rigid CRA are known to date, which have been prepared by introduction of functional groups at adjacent positions of the fullerene cage.



In these compounds, the fullerene cage strictly fixes only one dihedral angle, *viz*., X(1)–C(1)–C(2)–X(2). Ideally, this angle should be close to 0° but no structural data on this class of CRA are available.

There are two ways to introduce an α-amino acid fragment into the fullerene cage.

The first one is based on the [3 + 2]-cycloaddition reaction, which gives rise to proline analogues.[242, 243] Protected proline analogues **169** with R = H (see Ref. 242) or Ph (see Ref. 243) have been produced.

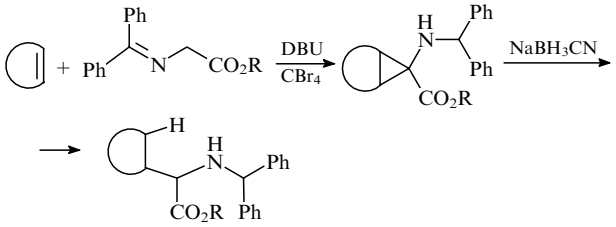


169

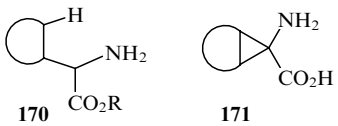
R = H, Ph.

Alternatively, proline analogues can be prepared by the direct photochemical reaction of fullerene with amino acid esters.[244] The products formed in this reaction are similar to those considered above but the mechanisms of the two reactions are distinctly different. The photochemical reaction proceeds through formation of radical intermediates. It has been applied to prepare protected proline analogue **169** with R = CO_2Me.[244]

The second way is based on a reaction that looks similar to [2 + 1]-cycloaddition but follows a different mechanism.[245]



This method has been applied to prepare 1,2-dihydro[60]fullerenylglycine (**170**) and aminomethano[60]fullerenecarboxylic acid (**171**).



170 **171**

Furthermore, this method has been successfully exploited in the synthesis of bismethano[60]fullerenylglycines, which yield monosubstituted 1,2-dihydrofullerene upon reduction.

The amino acids mentioned in this Section are characterised by a wide range of interesting biological properties, and are especially promising in such fields as photodynamic therapy,

developments of HIV protease inhibitors[246] and antibacterial drugs.[247]

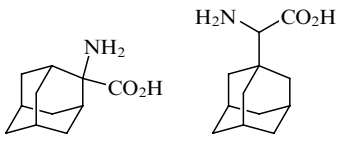
5. Miscellaneous conformationally rigid polycyclic amino acids

In the previous sections, CRA with side chains representing quite bulky carbon cages devoid of any functional groups have been considered. Biological properties of these compounds have been described in detail with 2-aminonorbornane-2-carboxylic acid as an example. It has been shown that such CRA may be regarded as analogues of hydrophobic proteinogenic amino acids, in particular, of isoleucine, and they are superior in some respects to the latter. First, they do not metabolise. Second, owing to the conformational rigidity, they are quite compact despite their relatively high molecular mass. Third, they are characterised by higher lipophilicity, which allows them to penetrate through various intra- and intercellular barriers. Thus, it is not surprising that the search for new cage amino acids continues. New structures can provide new capabilities for the design of *ad hoc* amino acids with specific conformations of their side chains.

Adamantane and cubane, which are characterised by highly symmetrical frameworks, take a special place among polycyclic hydrocarbons. While an appreciable number of studies have been devoted to the synthesis of adamantane-based CRA, cubane has been slipping the attention of researchers so far.

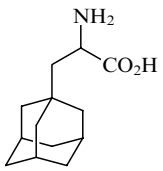
The values of the torsion angles within the adamantane cage of the corresponding amino acids and their derivatives are given elsewhere;[248,249] the respective data on the cubane cage are reported in Refs 250, 251. The experimental data indicate that the adamantane and cubane cages are essentially undistorted.

Three unsubstituted amino acids with the adamantane cage are known to date, *viz*., 2-aminoadamantane-2-carboxylic acid (**172**),[252,253] (1-adamantyl)glycine (**173**)[254] and 3-(1-adamantyl)-alanine (**174**)[255] (the latter can be classified as CRA only formally; such a remote χ_3-rigidity plays only a minor role) and 1,3-adamantylidenediglycine (**175**).[256] Derivatives of the acids **172**–**174** methylated at bridgehead carbon atoms have also been prepared.

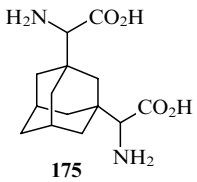


172

173



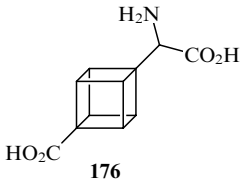
174



175

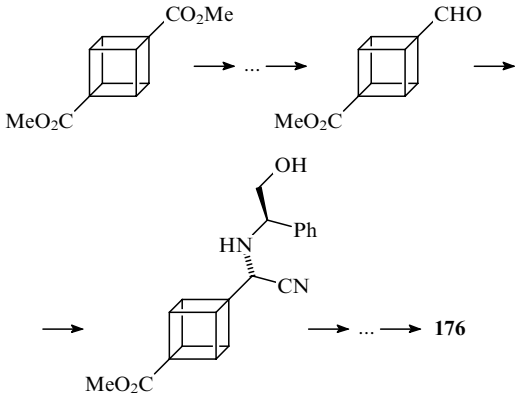
Compounds containing the adamantane cage have been used as the starting materials in the syntheses of the amino acids **172**–**174**. In particular, the amino acid **172** was synthesised from 2-adamantanone by the classical Strecker and Bucherer–Lieb reactions.[252,253] Compounds **173** and **174** have been prepared starting from adamantylacetic and adamantylpropionic acids, respectively, by α-halogenation (*e.g*., according to the Hell–Volhard–Zelinsky reaction) followed by substitution of the amino group for the halogen atom.[255] Compound **175** has been prepared similarly.[256]

In the case of cubane, only one CRA **176** is known, which is a glutamic acid analogue.[257]



176

Its synthesis has been performed starting from dimethylcubanedicarboxylate using a method similar to that used for the preparation of bicyclo[1.1.1]pentane (**166**) considered above.

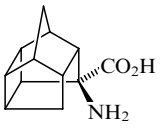


(1-Adamantyl)glycine (**173**) is an active inhibitor of leucine and methionine transport (like 2-aminonorbornane-2-carboxylic acid), however, its introduction into neoplasmatic cells did not produce the anticipated antitumour effect.[254]

Introduction of the amino acid **173** into small peptides yields model compounds which at room temperature predominantly adopt a conformation typical of the γ-bend.[258] This is very unusual since CRA typically stabilise various β-bends.

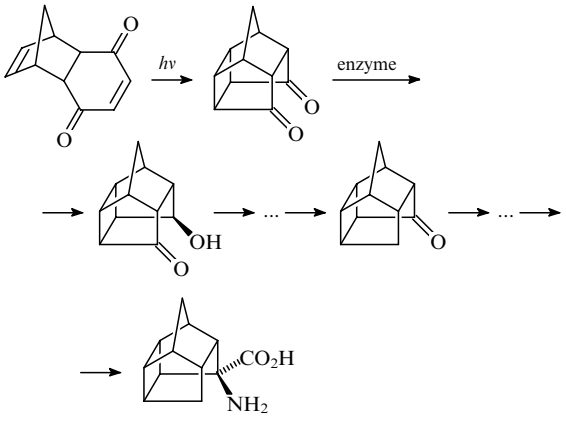
Compounds **173**–**175** manifest antiviral activity, which is, however, solely due to the presence of the adamantyl substituent.[255] A study of binding of compound **176** to metabotropic glutamate receptors has revealed that it represents a selective antagonist of mGluR1.[257]

The consideration of polycyclic amino acids with an exocyclic nitrogen atom will be incomplete, if we omit another unique substance, *viz*., pentacyclic CRA **177**, which is a pentacyclo[5.4.0.0^{2,6}.0^{3,10}.0^{5,9}]undecane derivative.[259]



177

Compound **177** has been prepared by a multistep synthesis starting from the adduct of cyclopentadiene and *p*-benzoquinone.



VII. Conclusion

Nowadays, the assortment of conformationally rigid cyclic amino acids which can be utilised in the design of peptidomimetics, peptide models and biologically active compounds, is quite wide. Some of the theoretically possible structures have not been realised so far, therefore, we expect that this list will soon be extended with new CRA suitable for the design. Furthermore, new stereoselective routes to the synthesis of the known amino acids will be elaborated since much research effort is put into this field. The primary reason for these efforts is that CRA enable preparation of peptides with high selectivity of their biological activities and degradation stability and thus are of significance as potential drugs. Introduction of CRA residues into the polypeptide chain has advantages within the context of the design of peptidomimetics and peptide models due to the particular conformational rigidity of these residues. CRA residues are able to stabilise or conversely destabilise specific elements of the secondary structure of peptides. This allows prediction of conformations of the peptides within a certain confidence level and thus gives a partial control over their biological function.

Abstract. The review surveys the synthesis, bulk structures, solution behaviour and functional capabilities of graft copolymers containing chemically complementary polymer components. The influence of a system of intramolecular bonds between the main and grafted chains and between the adjacent grafted chains on the properties of graft copolymers is analysed. Such graft copolymers are shown to belong to a special class of polymer compounds referred to as intramolecular polycomplexes. The bibliography includes 204 references.

I. Introduction

Graft copolymers are considered as promising heteropolymeric functional materials. These compounds are widely used for controlling stability of disperse systems,[1–7] as compatibilisers for improving compatibility of polymer mixtures,[8–12] as matrix binders in biotechnological processes, macromolecular therapeutic systems [13–19] and paper production,[20] as semipermeable membranes,[21–23] thickeners,[24–28] film-forming coatings,[29,30] protective coatings,[31–33] lyophilising coatings,[34–40] physical gels [41] and agents of drag reduction of turbulent flow.[42–44] Such heteropolymeric systems have attracted growing interest in recent years owing to impressive progress in developing new nanoreactor catalytic processes [45,46] and nanophase technologies for the construction of composite polymeric materials, including controlled growth of metal nanoparticles in the presence of polymer matrices [47,48] and grafting of polymer chains onto the surface of inorganic nanoparticles.[49–59] The interest in graft copolymers is associated with considerable possibilities for controlling their structures and properties through variations in the chemical nature and length of polymer components and through changes in the number (density) and distribution of grafted chains.

A combination of chemically complementary (which are able to interact cooperatively) polymeric partners in the macromolecules of graft copolymers offers considerable possibilities for varying their properties and functions. Since such copolymers have features in common with intermolecular polycomplexes, they can be considered as a special class of high-molecular-weight compounds referred to as intramolecular polycomplexes. In the present review, we discuss the characteristic features of the bulk structure, solution behaviour and functional capabilities of such intramolecular polycomplexes.

In the late 1950s, Mino and Kaizerman [60,61] were among the first to perform the directed synthesis of graft copolymers. However, comprehensive and theoretically supported knowledge of the relationship between the chemical nature of polymer components and the molecular architecture of graft copolymers and the structure – properties relationship is lacking. In early studies, this problem was difficult to solve because of difficulties associated with the preparation of graft copolymers with desired structures and the lack of efficient methods for the determination of their molecular parameters. However, fundamental studies in this field are still few in number in spite of the well-developed synthetic base and modern methods for investigation of these compounds. The reason is that most attention has been focused on practical applications of graft copolymers and, hence, exclusively properties of copolymers which are of interest from a practical standpoint, have been investigated.

Nevertheless, not only the main molecular architectures (described as stars, combs and brushes) of graft copolymers [62–64] but also the major factors influencing their structures and solution behaviour were revealed. Among such factors are the chemical nature and thermodynamic compatibility of polymer components, the number (density), length and distribution of grafted chains along the main chain and the nature of the solvent and its

selectivity (or non-selectivity) to individual polymer components.[63–69] As demonstrated below, a system of intramolecular main chain – graft and graft – graft bonds plays an important role in the structures of graft copolymers which form intramolecular polycomplexes. In addition, hydrophobic interactions between the binding regions of active groups of the polymer components, which facilitate shrinkage and association of coils, play a significant role in stabilisation of the structures of graft copolymers in an aqueous medium.

A relatively small number of publications were devoted to analysis of the properties of graft copolymers depending on the density and molecular mass of grafted chains and thermodynamic compatibility between polymer components in the last 15 years.[62–64, 70–76] The results of investigations of graft copolymers which form intramolecular polycomplexes were not analysed at all. Systematic studies of this class of polymer compounds have been carried out only for poly(vinyl alcohol)-graft-polyacrylamide (PVA-g-PAA) copolymers. Hence, in the present review emphasis is given to these graft copolymers. Published data on the synthesis, structures and properties of other graft copolymers containing chemically complementary polymer components are considered in relation to the data for PVA-g-PAA.

II. Intramolecular polycomplexes

Poly(vinyl alcohol)-graft-polyacrylamide copolymers and polysaccharide-graft-PAA copolymers were among the first graft copolymers containing chemically complementary components to be synthesised.[60, 61, 77–79] Initially, the specific rheological properties of such copolymers, in particular, significant drag reduction of turbulent flow (combined with high resistance to degradation) in dilute solutions[42, 77, 80] and high viscosity in semidilute solutions,[81] have attracted researchers' attention. Later on, yet another characteristic feature of these copolymers, *viz*., their high flocculating ability, was discovered.[5, 82, 83] It was believed that these properties are determined by a combination of the properties of polymer components involved in graft copolymers and the branched structures of copolymer macromolecules. Subsequently, graft copolymers of this type were studied over many years in parallel with copolymers containing non-interacting (incompatible) or weakly interacting polymer components without classifying them as a special group.

The possible existence of strong intramolecular interactions (hydrogen bonds), which are responsible for the properties of poly(vinyl alcohol)-graft-poly(*N*-vinylpyrrolidone) copolymers (PVA-g-PVPD) was mentioned for the first time in the study.[84] In contrast to a number of other graft copolymers, the characteristic viscosity [η] of PVA-g-PVPD in aqueous solutions decreases compared to this parameter for the starting polymer (PVA). The low value of [η] is retained over a wide temperature range. However, the addition of dimethylformamide (DMF), which facilitates destruction of H-bonds, leads to rapid swelling of the PVA-g-PVPD macromolecules.

Essentially similar effects were noted earlier.[85] The cited study was devoted to comparative investigation of the physicochemical properties of acetylcellulose-graft-PAA copolymers (AC-g-PAA) and the corresponding polymer mixtures. Actually, the solubility of the graft copolymer in aqueous solutions of acetic and formic acids, which are good solvents for both polymer components, decreases as the degree of grafting of PAA increases from 27.6% to 38.1%. Besides, the reduced viscosities of mixtures of the above-mentioned polymers are substantially lower than the calculated additive values throughout the composition range, which is unambiguously indicative of complex formation between polymers. However, the authors of the cited study have not yet interpreted these results in the context of strong interactions between AC and PAA.

Strong intramolecular interactions were revealed in the PVA-g-PVPO graft copolymers, where PVPO is poly(vinylpyridine *N*-oxide), and in mixtures of these polymers [thermodynamic studies of solvent (water) vapour sorption according to Tager's method].[86] The negative free energies of mixing and the negative values of the Flory – Huggins parameter (χ_{12}), which characterises thermodynamic affinity between polymers in a particular solvent, were observed throughout the composition range of the mixture and the graft copolymer. For the copolymers with PVPO contents of 0.39 and 0.43, the parameter χ_{12} is -1.9 and -3.8, respectively. The thermodynamic parameters of the PVA-g-PVPO copolymers also have smaller values compared to those of a mixture of the constituent polymers. From this it was concluded that compatibility between the polymer components in the graft copolymer is higher than that in their mixture.[86]

The presence of strong interactions between the main and side chains in the graft copolymers of poly(acrylic acid) (PAAc) or poly(methacrylic acid) (PMAA) onto PVA and the graft copolymers of poly(ethylene glycol) (PEG) onto PMAA was noted in the studies.[87–89] In particular, grafting of PMAA onto PVA by free-radical polymerisation in the presence of a Ce(IV) salt as an initiator was accompanied by precipitation of the copolymer[87] due to hydrogen bonding between the polymer components. In this case, the composition of the PVA-g-PMAA graft copolymer was close to equimolar. The influence of complex formation between PMAA and PEG involved in the cross-linked PMAA-g-PEG graft copolymer on hydrogel swelling and release of a drug dissolved in the hydrogel was considered.[88] It was demonstrated that hydrogen bonding hinders swelling of the hydrogel and decreases its permeability. In the presence of PEG and PMAA in an equimolar ratio, the rates of hydrogel swelling and release of the dissolved compound from the hydrogel appeared to be minimal. The complex character of association of graft copolymers based on PAAc and poly(*N*,*N*-dimethylacrylamide) (PDMAA) in solutions was noted in the study.[90] Spherical aggregates with a diameter of 150 nm, which are stabilised through both intramolecular and intermolecular H-bonds between the polymer components, were found to be formed from the PAAc-g-PDMAA molecules in an aqueous medium.

Attempts were made to analyse interactions between free and covalently bound polymer partners[91] and reveal changes in thermodynamic affinity between polymer components with increasing grafting density.[92] The thermodynamics of equilibrium complex formation between linear macromolecules and chemically complementary oligomers in dilute solutions was studied[91] for oligomers covalently end-bound to macromolecules and for mixtures of free components in solution. The polymer conformations were calculated using a general statistically mechanical approach (with a simple random walk model). The free energy of an oligomer involved in a complex was calculated using the method of generating functions. In this case, the lengths of loops, binding parts and tails were not restricted. The results of modelling of free oligomers were compared with the results obtained for oligomers covalently linked to macromolecules. Theoretical analysis provided an explanation for many experimental data, in particular, for the dependence of the part of the complex-bound oligomer links on the binding energy and the length of its chain and also for an increase in efficiency of complex formation in the presence of covalent bonds between the polymer reagents.

The influence of the grafting density on interactions between components of a binary layer of graft polymers (for amphiphilic diblock copolymers adsorbed at the liquid – liquid interface) was examined in the study.[92] The ratio of the Flory radius R_F, which characterises free isolated grafted chains in a particular solvent, to the distance D between the centres of the adjacent grafts was demonstrated to be of particular importance. The equality $D = R_F$ was considered as the overlap threshold for coils of

grafted chains. The system was shown to behave as a two-dimensional regular solution, in which the interaction parameter between components χ_{12} decreases with increasing D. Two regions in which χ_{12} decreases depending on the grafting density were revealed. In the region of D which does not reach the overlap threshold ($D > R_F$), χ_{12} decreases according to the law

$$\chi_{12} = \left(\frac{R_F}{D}\right)^2,$$

but at a high grafting density ($D < R_F$), χ_{12} changes according to the equation

$$\chi_{12} \approx \left(\frac{R_F}{D}\right)^{3/4}$$

or

$$\chi_{12} \approx \left(\frac{R_F}{D}\right)^{5/3}$$

depending on the starting theoretical premises (boundary conditions). Therefore, according to the predictions of this theory, interactions between the components of the binary layer should become weaker with increasing grafting density, the most substantial weakening occurring at $D > R_F$.[92]

It should be noted that the specific features of these copolymers were ignored in most other studies devoted to the synthesis and properties of graft copolymers containing chemically complementary polymer components, such as the above-mentioned PVA and PAA,[60, 61, 78, 93, 94] polysaccharides (dextran, starch, hydroxymethylcellulose and carboxymethylcellulose) and PAA[43, 77, 79, 81, 95–100] or poly(*N*-isopropylacrylamide) (PIPAA),[101, 102] PVA and PAAc,[89, 103] poly(ethylene oxide) (PEO) and PAA,[104] PAA,[105] the copolymer of acrylic acid (AAc) and acrylamide (AA)[106] or PIPAA,[107] chitosan and PAA [14] and, finally, PAA and PIPAA.[21, 108]

However, graft copolymers with strong intramolecular interactions serve as highly efficient flocculants,[5, 109] are used as degradation-resistant agents of drag reduction of turbulent flow [44, 110] and possess abnormally high binding ability.[88] The latter property of graft copolymers containing interacting polymer components was confirmed, in particular, by the results of the study,[111] where complex formation of individual PMAA with Cu^{2+} ions was compared with that of PMAA involved in the AC-g-PMAA graft copolymer. The constant of complex formation of the grafted chains with copper ions ($\sim 10^{6.5}$) was determined by potentiometric titration of the starting aqueous-salt solution of AC-g-PMAA ($c_{NaCl} = 0.1$ mol dm^{-3}) and of the same solution in the presence of Cu^{2+} ions (the concentration was varied from 5×10^{-5} to 5×10^{-3} mol dm^{-3}). This complex formation constant is higher than that for individual PMAA. The authors reasonably attributed the higher complex formation ability of PMAA grafted onto AC to specific conformational effects in the macromolecules of this copolymer.

Based on analysis of the data published in the literature and the results of our investigations of graft copolymers [44, 112] and intermolecular polycomplexes,[113] we hypothesised that graft copolymers containing the chemically complementary main and grafted chains belong to a special class of polymer compounds referred to as intramolecular polycomplexes.[114] This assumption was confirmed by the results of comprehensive investigation of the formation, structures, behaviour in solution and functional capabilities of the PVA-g-PAA graft copolymers depending on the grafting density and the molecular mass of the grafted chains. Further, we consider the synthesis and properties of graft copolymers which form intramolecular polycomplexes. Initially, let us determine which polymers could be assigned to the class under consideration and discuss the criteria to be used.

III. Complex formation of covalently non-bound polymeric partners as a criterion of chemical complementarity between components of graft copolymers

It is known that the spontaneous formation of intermolecular complexes through a cooperative system of bonds of a particular nature (Coulombic interactions, hydrogen bonds, donor–acceptor bonds, van der Waals contacts) is a distinguishing feature of pairs of chemically complementary polymers.[115, 116] The formation of a cooperative system of bonds causes a sharp shift of the equilibrium at the macromolecular level toward the formation of a polycomplex. The stability constant K_v of intermolecular polycomplexes increases as a power function of the number of links v (or length) in the polymer chain.[116] For cooperative interactions to occur, a particular critical chain length, which depends on the energy of a single bond, is required. In addition, the interacting macromolecules must be structurally and conformationally complementary.[115–117] The nature of the solvent is of considerable importance. The solvent molecules must neither compete with active groups of the polymers nor shield them, *i.e.*, must not hinder the formation of a network of intermolecular bonds.[116]

From the above, it can be concluded that heterogeneous block-type polymers (graft and block copolymers) containing chemically and structurally complementary polymer blocks of sufficient length can be involved in intramolecular cooperative interactions. These heterogeneous polymers belong to a class of intramolecular polycomplexes. The criterion for assigning particular graft and block copolymers to this class of compounds is spontaneous complex formation of covalently non-bound polymer components. It should be noted that the average number of units in the main chain between the adjacent grafts should be considered as the average length of the reacting blocks in graft copolymers.

Using the above criterion, it is easy to demonstrate that the assumption of chemical complementarity of a series of polymer components of graft copolymers, which was made in Section II, is justified. Actually, spontaneous complex formation between covalently non-bound polyacids (PAAc, PMAA), on the one hand, and polyalcohols (PVA), polyesters (PEO), polyamides (PAA) and polysaccharides (for example, methylcellulose, hydroxyethylcellulose or chitosan), on the other hand, was observed.[115, 118–121] Chemical complementarity between PVA and PAA was proved in our special investigations (data on complex formation between these polymers have been lacking in the literature). This was the first necessary step in studies of the PVA-g-PAA graft copolymers which form intramolecular polycomplexes.

In several studies (see, for examples, Refs 93 and 122), only selected properties of mixtures of PVA and PAA were characterised and no conclusions about the formation of intermolecular polycomplexes between these polymers were drawn. The low value of K_{AB} (0.3) for this system determined by viscosimetry is indicative of a low degree of overlapping between the molecules of the types A (PVA) and B (PAA) in dilute aqueous solutions.[93] The phase separation in the PVA–PAA–H_2O system was observed [122] at certain polymer ratios. However, this effect was not interpreted as a consequence of formation of intermolecular polycomplexes. Taking into account the above-mentioned facts, we studied the PVA–PAA system in an aqueous solution and in the bulk state by varying the molecular mass and chemical structure of the polymeric components with the use of viscosimetry, IR spectroscopy, high-speed sedimentation, gel chromatography, differential scanning calorimetry (DSC) and benzene solubilisation.[123–129] Let us briefly consider the principal results of these studies.

The formation of intermolecular polycomplexes in the PVA–PAA system at $M_{PAA} \gg M_{PVA}$ (*i.e.*, the PAA macromolecules can be considered as matrices with respect to PVA) was estab-

lished by a conventional viscosimetric method. The deviation of the ratio of the specific viscosity of mixture to the sum of specific viscosities of the individual components from unity served as the criterion for the presence of interactions between the polymers.[124] For a relatively low-molecular-weight sample of PVA ($M_v = 4 \times 10^4$), this ratio was smaller than unity, which was indicative of the formation of compact particles of intermolecular polycomplexes. For higher-molecular-weight samples of PVA ($M_v = 8 \times 10^4$ and 1.2×10^5), this ratio was larger than unity, *i.e.*, more and more friable particles of intermolecular polycomplexes appeared. Further studies of this system by high-speed sedimentation and gel chromatography demonstrated that these polycomplexes had a constant composition, which was independent of the PVA to PAA ratio in solution[124, 128] and of the molecular parameters of PVA (in the range under consideration) but decreased from $\varphi_{char} = 9$ to $\varphi_{char} = 4$ $kg_{PVA}\,(kg_{PAA})^{-1}$ (φ_{char} is the characteristic composition) as $M_{v\,PAA}$ increased from 2.72×10^6 to 4.4×10^6 (see Refs 124 and 127–129). Therefore, particles of polycomplexes contained a substantial excess of the PVA molecules. In addition, macromolecules of individual PVA and PAA were aggregated in water. These aggregates were destroyed in the process of complex formation. Taking into account this fact, a substantial excess of PVA in intermolecular polycomplexes was accounted for by interactions of the long PAA macromolecules with partially destroyed aggregates of PVA.

Interaction between the polymers through hydrogen bonding was established by IR spectroscopy.[124, 126, 127] Two of the most important regions of the IR spectra of thin films of PAA and the intermolecular polycomplex are shown in Fig. 1. The results of computer separation of overlapping bands in the Amide I and Amide II regions by the spline-function method are presented in Fig. 2. Detailed analysis of the positions and relative intensities of the bands in the spectra of the PAA film and the intermolecular polycomplexes revealed the following structures of H-bonds: a small amount of 'open' dimers of COOH groups (these groups are derived from the amide groups of PAA upon their partial hydrolysis) characterised by the band $\nu_{C=O} = 1724$ cm^{-1}; a small amount of free amide groups characterised by the Amide I band at 1707 cm^{-1}; a substantial amount of *trans*-multimers of amide groups characterised by the Amide I bands at 1692 (terminal C=O groups of *trans*-multimers) and 1679 cm^{-1} (H-bonded C=O groups of *trans* aggregates); a large amount of *cis*–*trans*-multimers of amide groups characterised by the Amide I band at 1661 cm^{-1}. In addition, the spectra of the intermolecular polycomplexes show an individual band at 1670 cm^{-1} (see Fig. 2*a*) assigned to H-bonds between PVA and PAA. With the aim of revealing changes in the structure of these polycomplexes relative to PAA, the numbers of amide groups forming one or other system of H-bonds were compared. Quantitative calculations were carried out taking into account the following facts:[127, 129] (1) similar shifts of Amide I bands of bound amide groups in the intermolecular polycomplexes and PAA relative to the band of the free amide groups; (2) the absence of substantial orientational effects in thin films of these polymers;[130] (3) the Bouguer–Lambert–Beer law

$$B_i = A_i l c_i ,$$

where B_i is the apparent integral absorption coefficient of the ith Amide I band in the IR spectrum, A_i is the true integral absorption coefficient of the absorption band, l is the film thickness and c_i is the molar concentration of amide groups, which are in the ith state, in the film.

To reduce to a minimum the effect of the difference in the film thickness along the light path and the difference in the number of acrylamide units in the films of PAA and intermolecular polycomplexes, the coefficient B_i was normalised to the apparent integral absorption coefficient B_0 of the vibration band ν_{C-H} of the methylene groups, which is proportional to the concentration of the polymer compound, and to the mole fraction of the acrylamide units in the polymer sample ($X_{n\,AA}$). The calculated $B_i/B_0X_{n\,AA}$ ratios (Table 1) are proportional to the mole fraction of the amide groups in the ith state. In addition to the above-

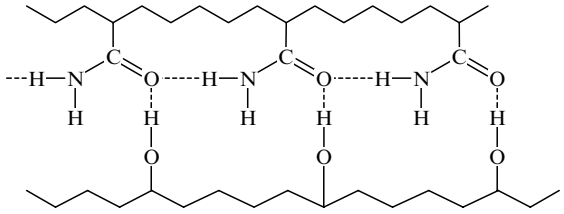
Sample — PVA–PAA (see [a])					
5.69	1.31	2.47	2.28	0.32	1.08

[a] $M_{v\,PAA} = 4.4 \times 10^6$ (hydrolysis degree is ~1%), $M_{v\,PVA} = 4 \times 10^4$.

mentioned parameters, Table 1 gives the effective lengths of the *trans*-multimers of amide groups (parameter β).

As can be seen from Table 1, complex formation between PAA and PVA is accompanied by destruction of a substantial amount of *cis*–*trans*-multimers of amide groups (band at ~1661 cm^{-1}), hydrogen bonding between the polymers (band at ~1670 cm^{-1}) and a slight decrease in the amount of *trans*-multimers of amide groups (band at ~1692 cm^{-1}) with a simultaneous increase in their length by a factor of more than 2. In our opinion, an increase in the rigidity of the polyacrylamide chain upon complex formation with PVA is attributable to appearance of the following sequence of H-bonds between segments of these polymers:[129]



The conclusion about interactions of PAA with PVA aggregates in solutions was completely confirmed by the results of comparative structure studies of PVA–PAA mixtures with $\varphi = \varphi_{char}$ and $\varphi = 1\ kg_{PVA}(kg_{PAA})^{-1}$ and the individual polymers in the bulk state.[123, 125, 127–129] Studies were carried out by DSC (Fig. 3). Actually, the PVA microcrystalline domains distributed in regions of the polymer component compatibility were found in the structures of polymer mixtures with a characteristic composition (curve *3′*) prepared from solutions. Evidently, the compatibility regions in the structures of intermolecular polycomplexes are attributable to the presence of segments of the polymer components linked to each other, whereas the microcrystalline regions occur due to the presence of PVA aggregates in the polycomplexes formed. In solid mixtures with composition $\varphi = 1$ (curve *4*), microregions formed by segments of excessive PAA, which was not involved in intermolecular polycomplexes, were revealed along with the above-mentioned two types of domains.[129] This is indicative of a constant composition of the polycomplex and the occurrence of disproportionation in this system (the presence of completely filled and free matrices).

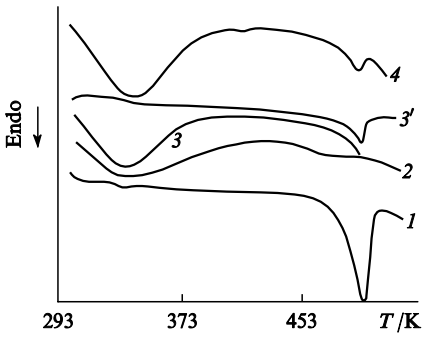


Figure 3. DSC thermograms of PVA (*1*), second scanning; PAA (*2*), first scanning; a PVA–PAA mixture at $\varphi = \varphi_{char} = 4\ kg_{PVA}(kg_{PAA})^{-1}$ (*3*), first scanning; the mixture of the same composition (*3′*), second scanning; the mixture at $\varphi = 1\ kg_{PVA}(kg_{PAA})^{-1}$ (*4*).

It was found that the stability of compact particles of intermolecular polycomplexes containing PVA with $M_v = 4 \times 10^4$ in water depends substantially on hydrophobic interactions. The volume of hydrophobic regions in the particle of the intermolecular polycomplex, which was determined by benzene solubilisation, was 408 nm^3 (see Refs 127 and 128).

The reaction of PVA with PAA in water was assigned to the known type of matrix + oligomer reactions [118, 131]

$$P_1\ (\text{matrix}) + n\,P_2 \longrightarrow$$
$$\longrightarrow \text{intermolecular polycomplex } (P_1 + n\,P_2),$$

where the PAA macromolecules act as a matrix, whereas the PVA aggregates, which are destroyed only partially, act as an oligomer (P_2). The constancy of the composition of the intermolecular complex and the existence of free matrices at $\varphi < \varphi_{char}$ are indicative of the non-uniform distribution of the oligomers between the matrices upon complex formation, *i.e.*, two levels of cooperativity take place in this reaction.[127, 128] The first level is associated with the formation of a cooperative system of H-bonds between the individual chains of the PVA aggregates and the corresponding regions of the PAA macromolecule, and the second level occurs due to interactions between the PVA aggregates onto the PAA chain (Fig. 4).

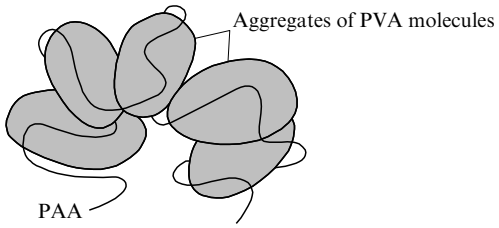

Figure 4. Schematic representation of a particle of the PVA–PAA intermolecular polycomplex.

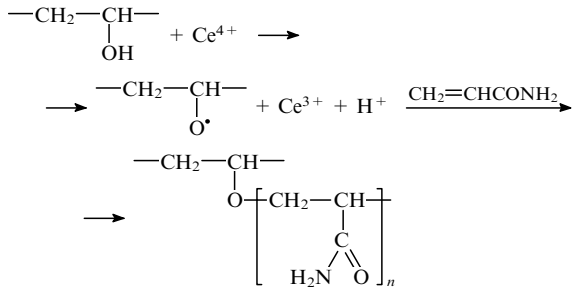
Thus, not only chemical complementarity between PVA and PAA was established but also self-assembly of small aggregates of one polymer component at the long chains of another component analogously with the known effect of self-assembly of protein globules at the chains of oppositely charged polyelectrolytes was demonstrated.[132]

IV. Matrix effects in free-radical graft copolymerisation

The synthesis of graft copolymers has been widely discussed in the literature in recent years.[72, 133–152] Let us consider the main approaches to the synthesis of graft copolymers. The first approach includes methods based on free-radical or ionic graft copolymerisation involving the transformation of the main chain into a macroinitiator as the initial step.[72, 133–145, 151] Macroinitiators can be produced with the use of redox systems involving variable-valence metals,[134–137] irradiation of chains with high-energy particles,[138–140] atom-transfer reactions [141, 142] and chemical or thermal activation of particular groups (including double

bonds) at the main chain.[141–145, 151] The second approach includes methods of polymerisation or copolymerisation involving macromonomers.[146–148] The third approach is based on the chain transfer to polymer.[149, 150] Finally, methods were developed for chemical cross-linking of the pre-formed grafts to active groups of the main chain.[152] It should be noted that many studies devoted to the kinetics and mechanisms of graft copolymerisation (see, for example, Refs 153 and 154) dealt with graft copolymers containing chemically complementary polymer components. However, the question about the possible influence of strong interactions between the main and grafted chains on the properties of these compounds has remained beyond the scope of these investigations.

At the same time, the matrix synthesis of polymers through interactions of the growing (daughter's) chain with a matrix, *viz*., a chemically complementary chain, of another chemical nature was well known.[47] Hence, it is reasonable to suggest that many processes of the synthesis of graft copolymers containing strongly interacting polymer components (in particular, graft copolymerisation) would belong to matrix processes. This aspect has received proper attention in studies of free-radical graft copolymerisation of PAA onto PVA. The PVA-g-PAA copolymers were synthesised by free-radical graft copolymerisation using a Ce(IV) salt as the initiator. The general scheme of the reaction is as follows:[129]



Until recently, the mechanism of grafting of PAA onto hydroxy-containing polymers (including PVA) was believed to be well understood.[77, 78, 81, 96, 155] This mechanism involves the formation of Ce(IV) complexes with several OH groups of the main chain as the first step [156] followed by decomposition of these complexes to form macroinitiators of free-radical graft copolymerisation.

The aim of the study [129] was to synthesise two series of graft copolymers. In each series, only one of the two major parameters responsible for the properties of graft copolymers, *viz*., the number (N) or molecular mass of the grafted chains, was varied. For this purpose, the ratio between the molar concentrations of the Ce^{4+} ions and PVA units (α) was initially varied holding the ratio (γ) between the molar concentrations of the Ce^{4+} ions and the monomer (acrylamide) constant. In a series of the PVA-g-PAA(1–3) copolymers † thus prepared, N was increased from 25 to 49 and the grafted chains in samples 1–3 had comparable molecular masses ($M_v \sim 1 \times 10^5$). In another series of the PVA-g-PAA(4–6) copolymers, N was increased from 25 to 42, and the molecular mass of the grafted chains was decreased from 3.72×10^5 to 1.63×10^5. Then the ratio γ was varied with α held constant. As a result, a series of the PVA-g-PAA(8–10) samples was prepared, in which the molecular mass of the grafted chains varied from 3.72×10^5 to 5.1×10^5 at $N = 9$.[129] In addition, the PVA-g-PAA(7) sample with $N = 4$ and $M_v = 1.12 \times 10^6$ was synthesised.[112] It should be noted that in all the copolymers synthesised, $M_{v\,PVA} = 8 \times 10^4$.

Taking into account thermodynamic affinity between PVA and PAA and the phenomenon of matrix polymerisation of monomers of the same chemical nature in the presence of complementary macromolecules of another chemical nature,[47, 155] it was hypothesised that free-radical graft copolymerisation of PAA onto PVA belongs to the category of matrix processes. This assumption was also supported by the results of the study,[157] in which the matrix effect (an increase in the growth rate of the PMAA chain by an order of magnitude) was observed in the course of grafting of PMAA onto starch granules. In order to confirm or refute this hypothesis, the kinetics of this reaction was compared with that of homopolymerisation of acrylamide performed under analogous experimental conditions.[158] The purpose was to reveal the kinetic matrix effect.[47] The kinetic parameters of the reaction, such as the time of the initial slow step (τ_0), *viz*., the initiation step, and the rates of polymerisation v_p^{20} and v_p^{60} at the conversions $K = 20\%$ and 60%, respectively, were determined by dilatometry.[158] In one series of experiments, the ratio α was increased with γ held constant (Fig. 5, Table 2). As mentioned above, this led to an increase in the grafting density in the graft copolymers [samples PVA-g-PAA(1–3)]. In another series of experiments, the ratio of α was held constant, whereas γ was decreased, the graft length being increased at constant N [samples PVA-g-PAA(8–10)]. The results of these investigations demonstrated that the rate of graft copolymerisation increases compared to the rate of homopolymerisation of acrylamide (see Table 2).[158] However, when the density of the growing daughter's chains became too high [see the data for PVA-g-PAA(3) in Table 2], the matrix effect disappeared.

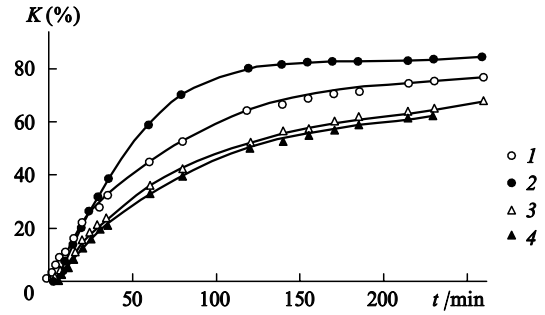


Figure 5. Plot of the monomer conversion *vs*. the reaction time of AA homopolymerisation (*1*) and graft copolymerisation of PAA onto PVA with increasing grafting density (*2–4*).
$T = 298$ K; α and γ are given in Table 2.

Table 2. Reagent ratios and the kinetic parameters for AA homopolymerisation and graft copolymerisation of PAA onto PVA.

Polymer	α (see [a])	τ_0 /min	$10^4 v_p^{20}$ (see [b])	$10^4 v_p^{60}$ (see [b])	K(%) (see [c])
PAA	1.000 [d]	8	0.95	0.48	60
PVA–PAA(1)	0.014	2	1.85	0.99	73
PVA–PAA(2)	0.027	3	1.96	1.69	82
PVA–PAA(3)	0.055	5	0.99	0.48	62

[a] For all polymers, the parameter γ was 10^{-3}. [b] In mol dm^{-3} s^{-1}. [c] The conversion after 200 min. [d] The molar ratio between Ce^{4+} and ethanol.

Therefore, not only the kinetic matrix effect was established in the synthesis of PVA-g-PAA but also its relation to the density of the growing chains was revealed. Actually, a decrease in τ_0 (compared to that for homopolymerisation of acrylamide) and a virtually twofold increase in the growth rate of the PAA chains in the graft copolymer were observed at relatively low α (< 0.055), *i.e*., in the presence of a small amount of grafted chains (small N) in the final copolymer. At $\alpha = 0.055$, the kinetic parameters of graft copolymerisation were virtually equal to those determined from the kinetic curves of homopolymerisation of acrylamide (see

† The sample numbers are given in parentheses.

Table 2). This important result can be attributable, first, to the fact that an increase in N leads to a decrease in the average length of the reacting block of the matrix (*i.e.*, the average distance between the adjacent grafted chains at the main chain), which is accessible for complex formation with the growing PAA chains, and, second, to an increase in steric hindrance to binding of grafted chains to the main chain.[158] By contrast, in the synthesis of the PVA-g-PAA(8 – 10) samples characterised by constant N and different graft lengths, the kinetic matrix effect was observed at all ratios γ and constant $\alpha = 0.014$.[158]

Investigations revealing the kinetic matrix effect and its dependence on the density of growing chains were the first step in studies of the new phenomenon, the so-called matrix graft copolymerisation. In the next step, the structural matrix effect, which is also characteristic of matrix processes, should be established.[47]

V. System of intramolecular main chain – graft and graft – graft bonds as the main factor of stabilisation of the structures of intramolecular polycomplexes

The determination of the detailed structure and the number of intermolecular bonds in intermolecular polycomplexes is of great importance for an understanding of the mechanism of complex formation of polymers at the level of single contacts between active groups. Studies devoted to these problems, most of which were carried out by IR and NMR spectroscopy, are well known (see, for example, Refs 159 – 161). The above methods allow one also to reveal the dependence of the state of these polycomplexes on different factors, in particular, on the pH of the medium [162] and temperature.[163, 164] These studies are of particular importance for polycomplexes between non-ionic polymers, in which the number of bonds is impossible to estimate by simpler methods, for example, by potentiometric titration (which can be employed in investigations of polyelectrolytes).[113, 115 – 117]

Intramolecular bonds in graft copolymers, including those containing chemically complementary components, were not studied in detail, although IR and NMR spectroscopy was used in many investigations (see Refs 14, 103, 142, 144 and 165). The aim of these investigations has been to prove the formation of graft copolymers. However, studies of systems of intramolecular bonds and changes in these systems depending on the number (density) and molecular mass (length) of grafted chains are of fundamental importance for graft copolymers, which form intramolecular polycomplexes, the more so as these systems are formed already in the course of the synthesis of these copolymers (matrix effect). Hence, considerable attention has been given to this problem in studies of the PVA-g-PAA graft copolymers. Let us briefly discuss these results.

The validity of the assignment of graft copolymers to intramolecular polycomplexes was confirmed primarily by IR spectroscopy.[114, 129, 166] The IR spectra of thin films of PVA-g-PAA(1 – 3) (which differ in N) were thoroughly analysed using computer separation of vibrational bands in the Amide I and Amide II regions by the spline-function method, and the structures of the macromolecules of the graft copolymers were demonstrated to be stabilised by an extensive hydrogen bond network, including H-bonds between the main chain and grafted chains (as in the case of the corresponding intermolecular polycomplex) and H-bonds between the units of the grafted chains (*cis* – *trans*-multimers of amide groups).[129, 166] An increase in N led to substantial changes in this hydrogen bond network (Fig. 6).[129] Actually, in the PVA-g-PAA macromolecules containing a relatively small number of grafted chains ($N \leqslant 25$), the number of main chain – graft H-bonds was large, whereas the number of graft – graft H-bonds was relatively small (see Fig. 6 *a*). As N increased from 25 to 49 in the series of the copolymers under study, steric hindrance to thermodynamic affinity between PVA and PAA became more substantial. As a result, the number of H-bonds between the main chain and the grafts decreased, whereas the number of H-bonds between the drawn together grafted chains increased (see Fig. 6 *c*). In the case of an intermediate value of N ($N = 31$), H-bonds of both types occurred (see Fig. 6 *b*), which was unambiguously established by IR spectroscopy.[129]

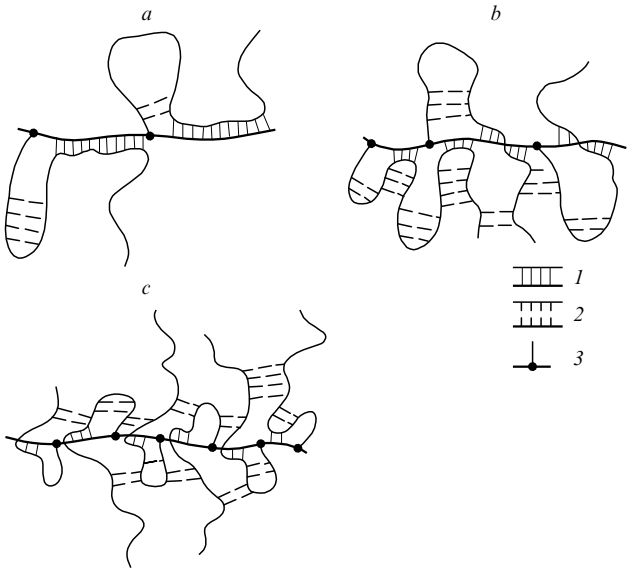

Figure 6. Redistribution of H-bonds in the PVA-g-PAA macromolecules at $N \leqslant 25$ (*a*), $N = 31$ (*b*) and $31 \leqslant N \leqslant 49$ (*c*).
(*1*) main chain – grafted chain H-bonds, (*2*) grafted chain – grafted chain H-bonds, (*3*) graft.

The influence of the molecular mass of the grafted chains on the hydrogen bond network was studied for a series of PVA-g-PAA(8 – 10) samples, in which N was held constant ($N = 9$). For this purpose, the spectra of thin films of the copolymers in the Amide I and Amide II regions were processed by the spline-function method. The spectra of these graft copolymers show all the Amide I bands which were observed in the spectra of the PVA – PAA intermolecular polycomplexes, including a band at 1670 cm^{-1} assigned to a sequence of H-bonds between PVA and PAA (see Section III).[167] Thus, it was proved that intramolecular polycomplexes are formed in macromolecules of the samples of the copolymers containing grafted chains of different lengths. It was found that the largest number of the main chain – graft H-bonds and the smallest number of the graft – graft H-bonds are characteristic of the PVA-g-PAA(9) sample containing the grafted chains with an intermediate molecular mass ($M_{v\,PAA}$ =

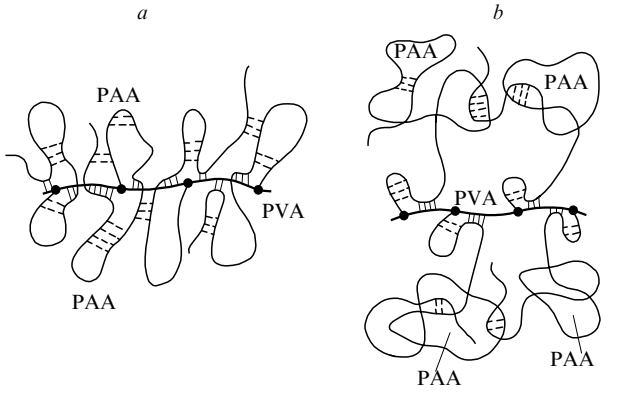

Figure 7. Scheme illustrating detachment of grafted chains from the main chain.
(*a*) $M_{v\,PAA} < M^*$, (*b*) $M_{v\,PAA} > M^*$; for notations of the elements in the scheme, see Fig. 6.

4.3×10^5). At $M_{v\,PAA} > 4.3 \times 10^5$, the hydrogen bond network in the copolymer changed as follows: the number of the main chain – graft H-bonds sharply decreased and the rigidity of the grafted chains, which was estimated from the increase in the effective length of the *trans*-multimers of amide groups, increased by a factor of more than 5. In fact, the effect of 'detachment' and stretching of the grafted chains in different directions away from the main chain was observed for polymers in which the molecular mass (length) of the grafted chains was higher than some critical value M^* (Fig. 7).[129, 167]

The above-described changes in the hydrogen bond network in PVA-g-PAA with increasing N and molecular masses of the grafted chains are reflected in all the properties of the intramolecular complexes under study.

VI. Influence of grafting density on the bulk structure and solution behaviour of intramolecular polycomplexes

The bulk structures of graft copolymers were studied in much less detail compared to their structures in solution and the structures of block copolymers. The majority of publications were devoted to graft copolymers containing thermodynamically incompatible components,[168–177] although studies of the bulk structures of graft copolymers containing chemically complementary main and grafted chains were also reported (see, for example, Ref. 25). To reveal the general and specific features of the bulk structure of PVA-g-PAA compared to the structures of other graft copolymers, let us discuss the results of the above-mentioned studies. It is known that incompatibility of components in linear block copolymers causes microphase separation to form the following regular supercrystalline structures: planar lamellas (if components are present in similar amounts), cylindrical or spherical domains, which are formed from the minor component as the percentage of the major polymer increases.[62] The state of the interface between the domains (sharp or extended) is determined by the molecular mass of the blocks. The higher the molecular mass, the higher the degree of segregation (degree of microphase separation) of the blocks and, correspondingly, the sharper the interface. The shift of the glass transition temperature of a separate microphase relative to T_g of the corresponding homopolymer is most often used as the measure of segregation of the blocks.[172, 174] A decrease in the degree of segregation of the blocks (an increase in the compatibility of the components of a block copolymer) is reflected in an increase in the shifts of T_g for the 'hard' and 'soft' microphases along the temperature scale toward each other.

In the case of star-like graft copolymers consisting of f branches, each of which is a diblock copolymer (for example, based on isoprene or butadiene as a 'soft' block and styrene or α-methylstyrene as a 'hard' block), the molecular masses of the blocks have a much lesser effect on the structure compared to the density of branches or the order of arrangement of the hard and soft blocks in the star (in the centre or at the periphery).[168–172] In particular, it was demonstrated[168–171] that the density of the branches (for f from 2 to 18) influences the structures of the star-like copolymers of isoprene (inner part of branching) and styrene (outer part of branching) with $w_{isoprene}/w_{styrene} = 0.7/0.3$ and the molecular mass of the grafted chains of $(2.3–10) \times 10^4$. Covalently non-bound branchings form a cylindrical supercrystalline structure, *viz*., long cylindrical domains of polystyrene (PS) in a polyisoprene (PIP) matrix. This structure was retained at a low density of branches ($f < 6$ and $M_n = 3.3 \times 10^4$). At higher values of f, the star structure sharply changed (both PS and PIP phases became uninterrupted). The PS blocks formed two interpenetrating tetrahedral lattices in a continuous matrix consisting of the PIP blocks. The role of the order of arrangement of the blocks in the star was considered in the study.[172] It was demonstrated that the microphases in the structures were nearly completely separated when the branched elastomeric block was located in the centre. By contrast, mixing of the components was observed when the hard block served as the branched central block.

The structures of traditional graft copolymers, in which one component serves as the main chain and another component serves as a graft, are determined not only by the density and the order of arrangement of the hard and soft blocks but also by the molecular mass of the grafted chains. This fact was supported by the results of the studies.[173–177] The authors of these studies reached the following common conclusion: the mutual mixing of the main and grafted chains increases with decreasing graft length and grafting density. Actually, irregular fractal-like microregions were observed in the structure of the PEA-g-PS graft copolymer, where PEA is poly(ethyl acrylate), at a low grafting density (on average, one grafted chain per main chain), whereas ordered lamellar microdomains were observed at a high density of rigid grafted chains (on average, three grafts per PEA chain).[173] Study of the PB-g-PS copolymer (PB is polybutadiene) by DSC revealed the effect of mutual mixing of the components (a substantial decrease in the glass transition temperature of PS in the copolymer compared to T_g of the homopolymer and a decrease in the crystallinity of PB) at a low grafting density.[174] However, this effect disappeared upon repeated heating of the sample (second scan). The glass transition temperature T_g for the PS microphase even increased (was 6–7 K higher than that of individual PS) with increasing grafting density. A substantial decrease in the difference between T_g for polydimethylsiloxane (PDMS) and PS was observed also for the PS-g-PDMS graft copolymers characterised by a low molecular mass of the grafts and low grafting density.[174] The degree of microphase separation also increased as each of these parameters increased. Analogous effects were observed for the graft copolymers of PEO onto PEA, PS, polyamide 12, copolymers of MA or MMA (MA is maleic anhydride and MMA is methyl methacrylate) and styrene and the ethylene – vinyl alcohol copolymer.[175–177] In all cases, the crystallinity of the PEO chains increased as the number of these chains grafted onto the main chain and their length increased.

X-Ray diffraction study of graft copolymers containing chemically complementary components, such as ST-g-PAA and AM-g-PAA (ST is starch and AM is amylose), revealed substantial mutual mixing of the main and grafted chains over a wide grafting-density range.[25] As a result, the main chain became uncrystallisable.

The structures of the PVA-g-PAA graft copolymers were studied by DSC[123, 129] and these results were compared with the analogous data for the individual polymers. In the case of a relatively small number of grafted chains ($N \leqslant 25$), the DSC thermograms (Fig. 8) show only one heat capacity jump, *i.e*., one glass transition (curves *1* and *2*), whose temperature $T_g = 459.5–463.5$ K (depending on the sample) was between the corresponding glass transition temperatures of PVA ($T_g = 331.5$ K) and PAA ($T_g = 464$ K). Taking into account the low PVA content in the graft copolymers (2.4 mass % –

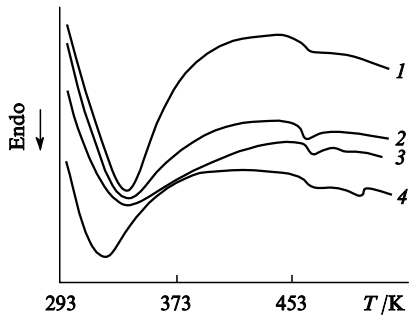

Figure 8. DSC thermograms (first scanning) for samples of PVA-g-PAA(7) (*1*), PVA-g-PAA(1) (*2*), PVA-g-PAA(2) (*3*) and PVA-g-PAA(3) (*4*).

4.0 mass %), this fact is indicative of complete compatibility of the polymer components in these samples of the copolymers and homogeneity of their structures. However, the second heat capacity jump appears in the thermograms of PVA-g-PAA at $N > 25$. This is indicative of the microphase separation in the structures of the copolymers. The height and temperature of the second heat capacity jump (second glass transition), which persisted after repeated heating–cooling cycles, increased with increasing N (see Fig. 8, curves *3* and *4*). It was established that microphase separation in the copolymers with a high grafting density is determined by the presence of compatibility regions of the polymer components along with domains formed by segments of grafted chains, which do not interact with the main chain because of steric hindrance. From the above, it can be concluded that compatibility between the main and grafted chains in graft copolymers which form intramolecular polycomplexes, is attained only for N smaller than some critical value N^* (in the series of graft copolymers under study, $N^* \approx 25$).[129]

Yet more evidence for the existence of intramolecular polycomplexes in the PVA-g-PAA(1–3) macromolecules and redistribution of hydrogen bonds with increasing N was obtained in the study of resistance of the copolymers to thermooxidative destruction by dynamic thermogravimetric analysis (DTGA). The mass-loss curves (TG curves) were processed on a computer to determine simultaneously three formally kinetic parameters of destruction steps (the total activation energy E, the reaction order n in each step and the frequency factor Z).[129, 166, 178] Three steps of thermooxidative destruction were revealed for all samples of the copolymers and for individual PVA and PAA (Fig. 9). The first step involves chemical transformations without participation of oxygen (dehydration of PVA chains, imidisation of PAA and some other conversions), as evidenced by endothermic effects in the DTA curves.

In the second step of destruction of the copolymers and PAA as well as at the end of the first step of PVA destruction, oxidation of polymer chains and accumulation of free radicals took place, which was immediately reflected in the sign of thermal effects in the DTA curves (the exothermic effect was observed instead of the endothermic effect). Bulk decomposition of the alkyl, alkoxy and peroxy radicals formed in the second step together with complete decomposition of polymer chains occurred in the final third step of destruction and was accompanied by the maximum exothermic effects.[129, 179]

The temperatures of the destruction onset (T_d) of most copolymers are intermediate between T_d for individual PVA and PAA. In the series of PVA-g-PAA(1–3) copolymers, the following changes in the parameters of destruction were observed with increasing N: a rise in the temperature of the destruction onset, an increase in the temperature ranges of the first (accompanied by the endothermic effect) and third (accompanied by the maximum endothermic effect) steps of destruction and an increase (by 92 °C) in the overall temperature range of destruction. The above-described effects are indicative of a substantial increase in resistance of graft copolymers to thermooxidative destruction with increasing number of grafted chains. Analysis of possible chemical transformations and free-radical processes in all steps of thermooxidative destruction of the polymers and the results of experimental studies of water solubility of polymer samples after thermal treatment under various conditions demonstrated that interchain cross-links, such as main chain–graft (interchain esters) and graft–graft (interchain imides) cross-links, are formed in the graft copolymers and PAA already before the onset of destruction and in its first step. Apparently, interchain cross-links formed in the PVA-g-PAA macromolecules with a low (Fig. 10 *a*) and high (Fig. 10 *b*) grafting density have different effects on further destruction. In the latter case, cross-linking between the adjacent grafted chains facilitates more substantial stabilisation of the coil as a whole. The cross-linked coil becomes poorly accessible for oxygen, and elimination of gaseous destruction products of the main and grafted chains is decelerated. This is the reason why thermal stability of the copolymers increases with increasing grafting density.[129, 179]

Interesting information was obtained in calculations of the formally kinetic parameters E, n and Z for the first step of destruction involving chemical transformations without the participation of oxygen (Table 3). In particular, for samples of the

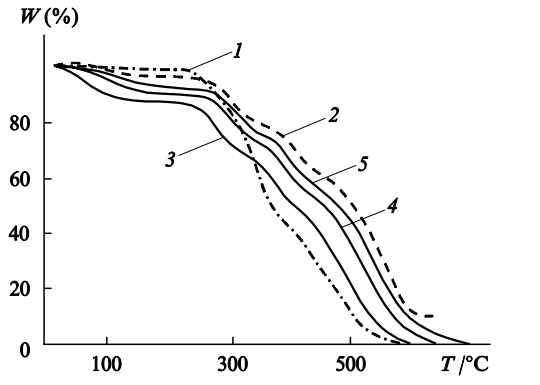

Figure 9. TG curves for PVA ($M_v = 4 \times 10^4$) (*1*), PAA ($M_v = 4.4 \times 10^6$) (*2*), PVA-g-PAA(1) (*3*), PVA-g-PAA(2) (*4*) and PVA-g-PAA(3) (*5*).

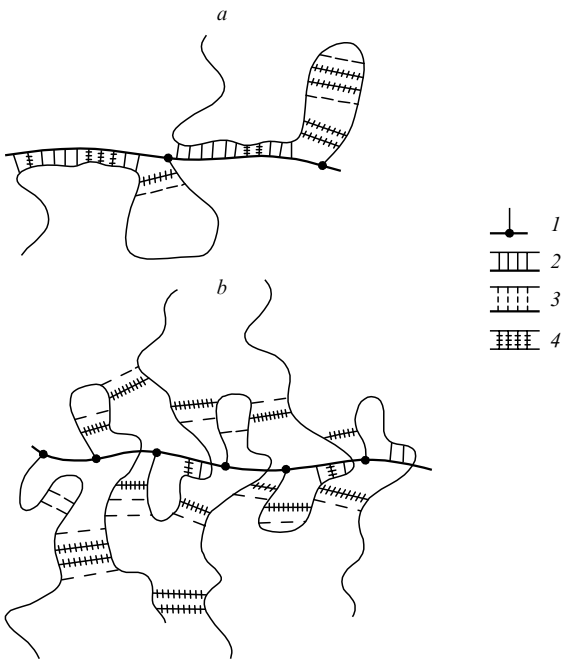

Figure 10. Schematic representation of interchain cross-links in the PVA-g-PAA macromolecules with low (*a*) and high (*b*) grafting density. (*1*) graft, (*2*) H-bonds between the main and grafted chains, (*3*) H-bonds between the units of PAA, (*4*) cross-links between the chains.

Table 3. Kinetic parameters of the first step of thermooxidative destruction of graft copolymers with different grafting densities.

Sample	E /kJ mol^{-1}	n	Z /s^{-1}	k /s^{-1} (see [a])
PVA	59.2	0.83	6.11×10^3	0.064
PAA	143.9	1.15	1.34×10^{12}	0.113
PVA-g-PAA(1)	182.2	2.36	6.9×10^{16}	0.174
PVA-g-PAA(2)	172.2	2.31	1.09×10^{15}	0.149
PVA-g-PAA(3)	139.1	1.63	6.05×10^{11}	0.140

[a] The rate constant calculated by the Arrhenius equation.

graft copolymers with $N \leqslant 25$, the parameters E, n and Z appeared to be substantially larger than the corresponding values for PAA. However, these parameters approach the corresponding parameters characteristic of PAA as N increases from 25 to 49. It is known that the parameters E and n for complex chemical processes [involving many competitive and(or) successive reactions] are integrated values. Hence, the above-mentioned substantial increase in these parameters in the first step of destruction of a PVA-g-PAA sample with a low grafting density (compared to PAA) is indicative of a specific structure in the macromolecules of these copolymers. The presence of intramolecular polycomplexes stabilised predominantly through main chain – graft H-bonds complicates chemical transformations and causes a sharp increase in the parameters E, n and Z in the first step of destruction of graft copolymers.[129, 179]

It should be noted that the results of systematic studies of thermal stability of graft copolymers and its relation to the grafting density, the molecular mass of grafted chains and thermodynamic affinity between polymer components are virtually absent from the literature. Using the results of investigations for PVA-g-PAA, we attempted to analyse the influence of not only the molecular mass of grafts and the grafting density but also of chemical complementarity between the polymer components on thermooxidative destruction of the graft copolymers. Of a few studies devoted to these problems, two investigations on thermal destruction (under an inert atmosphere) of graft copolymers containing chemically complementary components, such as ST (or AM) and PAA,[25] PVA and the AA – MMA copolymer,[103] are noteworthy. Thermal treatment of the ST-g-PAA and AM-g-PAA graft copolymers, in which only the molecular mass of the grafted chains was varied, was accompanied by several characteristic effects, such as a rise in the temperatures of the onset and completion of destruction with increasing molecular mass of PAA and an increase in thermal stability (extension of the temperature range of destruction) of graft copolymers compared to that of individual ST and AM.[25] An increase in thermal stability of the PVA-g-P(AA-co-MMA) graft copolymers compared to that of PVA was evidenced by the DTGA data obtained in the study.[103] Unfortunately, the authors of the cited studies did not report analogous results for individual PAA, which did not allow us to compare thermal stabilities of the graft copolymers and PAA. Resistance of the α-cellulose-g-PMMA graft copolymers, where PMMA is poly(methyl methacrylate), to destruction was examined by DTGA.[180] According to the results of an X-ray diffraction study, the components of these copolymers weakly interact with each other. In contrast to the above-described data, it was found that thermal stability of the α-cellulose-g-PMMA graft copolymers decreases with increasing amount of grafted PMMA. However, this fact remains to be explained.

Let us consider the change in ability of PVA-g-PAA to swell and dissolve in water depending on the number N of grafted chains. In the course of swelling and dissolution, all characteristic features of the chemical structures of the polymers, their molecular, supermolecular and macroscopic structures, the phase state and thermodynamic affinity for a particular solvent reveal themselves. The results of investigations of these properties are widely used for characterisation of the structures of graft copolymers.[21, 34, 63, 88, 104, 144] These studies are of particular importance for copolymers containing chemically complementary polymer components, because the formation of a cooperative system of bonds between these components sharply decreases accessibility of the active groups of the components for a solvent. Swelling and dissolution of films of PVA-g-PAA(1 – 3) and (for comparison) PAA in water (the thickness of the film of the copolymer was ~ 23 μm) were studied using a specially developed procedure.[181, 182] It should be noted that samples of the graft copolymers and PAA were characterised by the virtually equal amounts of hydrophilic groups (0.0141 – 0.0143 mol g^{-1}). However, the behaviour of the graft copolymers in the course of swelling and dissolution in water differs substantially from that of PAA. The PVA-g-PAA(1) sample with a low grafting density ($N = 25$) appeared to be the least hydrophilic of all the polymers under study. Among the above-mentioned three copolymers, this sample has the largest number of main chain – graft H-bonds. As N increased, the rates of swelling and dissolution of the films increased, the thickness of the polymer layer that remained undissolved (after 24 h) decreased and the degree of its swelling diminished due to a decrease in the number of H-bonds between the main and grafted chains. Therefore, thermodynamic affinity of the copolymers for water increased with increasing N.

The state of PVA-g-PAA in aqueous solutions was studied [129, 166, 183] by static light scattering. The molecular and thermodynamic parameters of the light-scattering coils were determined from the Zimm plots by the double extrapolation method. Only samples of PVA-g-PAA(2, 3) with $N \geqslant 31$, which spontaneously dissolved in water at room temperature, were examined. It was found that the PVA-g-PAA(2) and PVA-g-PAA(3) macromolecules occur as aggregates even in dilute solutions, which is attributable to low values of the second virial coefficient A_2. The latter, though it increases with increasing N (Table 4), remains close to zero, which is typical of θ solvents. This result is reasonable taking into account that PVA-g-PAA is an intramolecular polycomplex. Solubility of the copolymers in water noticeably increases with increasing N, as evidenced by an increase in A_2 and a decrease in both Z and $\langle R^2 \rangle_z^{1/2}$. Such behaviour of the graft copolymers in solutions is consistent with the above-described effect of a successive decrease in the number of main chain – graft H-bonds with increasing grafting density.

It was demonstrated [129, 183] that the grafting density influences substantially the hydrodynamic and optical characteristics of PVA-g-PAA(1 – 3) in water. Studies by viscosimetry and light scattering (by determining the depolarisation coefficients of scattered light) showed that the characteristic viscosity of solutions and the Huggins constant decrease, whereas the crossover concentration and optical anisotropy of the coils in water increase with increasing number of grafts.

[a] The mass-average molecular mass of scattering particles. [b] Number of macromolecules in the aggregate. [c] The z-average radius of gyration of the coil.

In aqueous solutions of intermolecular polycomplexes, segregation of the bound parts of active groups of polymers through hydrophobic interactions gives rise to compact particles of the polycomplexes with developed hydrophobic regions [115, 131] or leads to phase separation of the system analogously to that observed for stoichiometric polyelectrolyte complexes.[116] Hence, it was of interest to examine this stabilisation factor in the intramolecular polycomplexes under consideration. The contribution of hydrophobic interactions to stabilisation of the structures of intramolecular polycomplexes in water was estimated by benzene solubilisation.[129, 183] The results of these studies not only confirmed that such stabilisation occurs but also demonstrated that the role of this factor substantially decreases with increasing N. Actually, the volume of hydrophobic regions in the PVA-g-PAA(1 – 3) series decreased from 794 to 98 nm^3 (per macromolecule) as N increased from 25 to 49, which correlates with

improvement of thermodynamic quality of water serving as the solvent for this series of polymers.

Therefore, a decrease in the grafting density in the PVA-g-PAA copolymers in an aqueous medium is accompanied by strong aggregation (self-assembly) of the coils of the graft copolymers to form increasingly dense and hydrophobic particles of intramolecular polycomplexes. A substantial increase in the density of aggregates with decreasing N is supported by the fact that the changes in the parameters Z and $\langle R^2 \rangle_z^{1/2}$ (see Table 4) in going from PVA-g-PAA(2) to PVA-g-PAA(3) occur at substantially different rates. Analysis of the published data demonstrated that a decrease in viscosity of aqueous solutions of the graft copolymers with increasing grafting density is typical also of other copolymers involving chemically complementary components, for example, of the dextran-g-PAA copolymer.[81, 96] However, taking into account all the above, this fact is attributable to the influence of the grafting density on complex formation between the main and grafted chains rather than to the known fact that an increase in branching leads to deterioration of thermodynamic quality of a solvent for branched macromolecules.[184, 185]

The results obtained for PVA-g-PAA provide a new insight into the fundamental principles of the state-of-the-art statistical theories of graft copolymers, which have been developed in the context of general theoretical analysis of a series of similar systems commonly referred to as polymer brushes.[62] Evidently, these theories are valid for graft copolymers containing incompatible or weakly interacting polymer components.

According to these theories, the role of the main chain (matrix) is reduced to merely a spatial factor (a 'sphere' and a 'cylinder' for star-like and comb-like graft copolymers, respectively), while the possible contributions of interactions between the main and grafted chains to the free energy are ignored. Hence, it was concluded that the state of grafted chains at a low grafting density, *i.e.*, in the absence of their overlapping, should be close to the state of an isolated chain in the same solvent.[62] As demonstrated above, an opposite situation is observed for the PVA-g-PAA graft copolymers. As the grafting density decreases, the grafted chains nestle against the main chain, which is accompanied by sharp deterioration of the quality of the solvent, segregation of hydrophobic binding regions of active groups and aggregation of macrocoils. In fact, the macrocoil as a whole undergoes collapse. However, only collapse of grafted chains is considered in the above-mentioned statistical theories.[62] This is yet another drawback restricting application of such theories to graft copolymers which form intramolecular polycomplexes. It should be noted that the effect of shrinkage of particles of intermolecular polycomplexes through strong interactions between polymeric partners (collective collapse) is well known.[47, 115–117]

Therefore, the collapse of a macrocoil as a whole, which occurs due to complex formation of the main and grafted chains, and the collapse of the main or grafted chains, which occurs due to incompatibility of the polymer components (for example, in a selective solvent), should be distinguished for graft copolymers which form intramolecular polycomplexes. Our results agree with the predictions made in the study.[92] Actually, a decrease in the grafting density leads to strengthening of thermodynamic affinity between PVA and PAA.

Investigation of the changes in the state of the PVA-g-PAA macromolecules in solution induced by factors able to destroy an H-bond network (*i.e.*, intramolecular polycomplex) is of special interest. Among these factors, the temperature[186–188] and the hydrodynamic shear field[189, 190] were examined. The complex extreme dependence $[\eta] = f(T)$ was found and the Huggins constant was demonstrated to decrease in parallel with increasing temperature. A sharp decrease in $[\eta]$ to a minimum (Fig. 11 *a*) and the corresponding sharp increase in the Huggins constant (Fig. 11 *b*) in a narrow temperature range of 303–308 K, which is virtually independent of N, are indicative of the possible conformational transition in the copolymer macromolecules. Analogous extreme temperature dependences of $[\eta]$ were observed

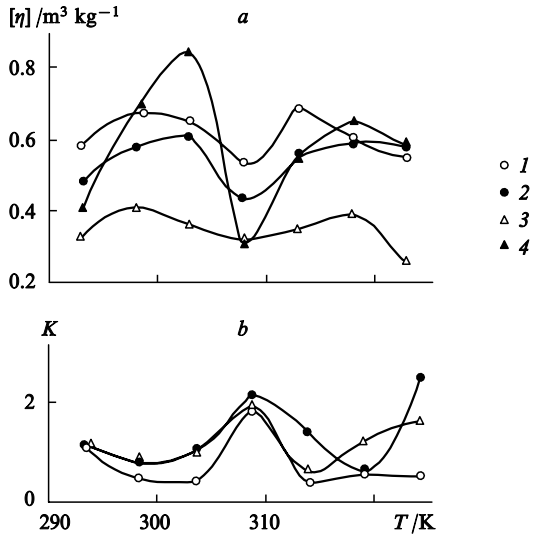

Figure 11. Temperature dependences of the characteristic viscosity (*a*) and the Huggins constant (*b*) for PVA-g-PAA(7) (*1*), PVA-g-PAA(4) (*2*), PVA-g-PAA(5) (*3*) and PVA-g-PAA(6) (*4*) (c = 0.4 kg m^{-3}).

also for a series of other graft copolymers containing chemically complementary polymer components, for example, for AC-g-PAA in acetic and formic acids,[85] DAC-g-PAA (DAC is diacetylcellulose) in formic acid [70] and PVA-g-PEO in water.[105]

The occurrence of the conformational transition in the macromolecules of PVA-g-PAA(7) (for this sample, the largest decrease in $[\eta]$ was observed) was confirmed by the results of investigations of solutions of this copolymer by quasielastic laser light scattering.[186–188] The correlation function of scattered light in a dilute solution of the graft copolymer was measured at different temperatures. The diffusion-coefficient distribution was calculated from these data using the corresponding regularisation procedure. The bimodal distribution on the diffusion coefficients was revealed (Fig. 12). Taking into account the rigid structure of coils of the copolymer, the characteristic narrow molecular-mass distribution and the criterion $\boldsymbol{q}R_g > 1$ ($\boldsymbol{q}$ is the scattering vector and R_g is the radius of gyration of macroparticles), which was maintained in the experiment, the bimodality of the distribution curves was interpreted as a sum of two exponential contributions to the normalised correlation function. The contributions are attributable to translational motion and translational-rotational motion of scattering particles,[129, 188]

Table 5. Diffusion parameters of PVA-g-PAA(7) at different temperatures.

T /K	$10^{10} D_t$ /m^2 s^{-1}	$10^{-3} D_r$ /s^{-1}
298	1.8	3.5
303	1.7	2.6
308	1.7	8.2
313	2.1	7.4

$$g_1(t) = A_0(\boldsymbol{q})\exp(-\Gamma_0 t) + A_1(\boldsymbol{q})\exp(-\Gamma_1 t).$$

Here $\Gamma_0 = D_t\boldsymbol{q}^2$ and $\Gamma_1 = D_t\boldsymbol{q}^2 + 6\,D_r$ are the time constants of the exponential components of the correlation function, D_t and D_r are the effective coefficients of translational and rotational diffusion. Changes in the temperature caused the following changes in the state of the PVA-g-PAA(7) macromolecules. An increase in the temperature to $\sim$303 K led to swelling of the macrocoils due to partial cleavage of the main chain – graft H-bonds, which was accompanied by a decrease in asymmetry of the coils (increase in D_r, see Table 5) and, correspondingly, to a decrease in the contribution of the translational-rotational mode to the total scattering intensity. In the range $\sim 303 < T < 308$ K, the rupture of a large number of H-bonds led to a sharp contraction (collapse) of the coils and an increase in their asymmetry (an increase in D_r, see Table 4) because of poor solubility of PVA in water compared to PAA. This transformation was referred to as an intramolecular polycomplex $\rightleftarrows$ segregated state transition (Fig. 13).[186] A further increase in the temperature was accompanied by swelling of asymmetrical coils. The depth of conformational changes, which can be estimated as a decrease in the characteristic viscosity, was found to depend on N. The smallest changes were observed for PVA-g-PAA(6), which is characterised by the largest grafting density ($N = 42$) compared to all the other samples prepared in this experiment. This result can be attributable to substantial stretching of the main chain with a high grafting density.[62] Consequently, the ability of the main chain to be contracted on collapse is limited due to volume effects. It should be noted that no changes in [η] were observed [34] for the PVA-g-PVPD copolymer containing strongly interacting polymer components, and low viscosity persisted over a wide temperature range. Evidently, the reason is stability of intramolecular hydrogen bonding at high temperatures (in the temperature range under study).

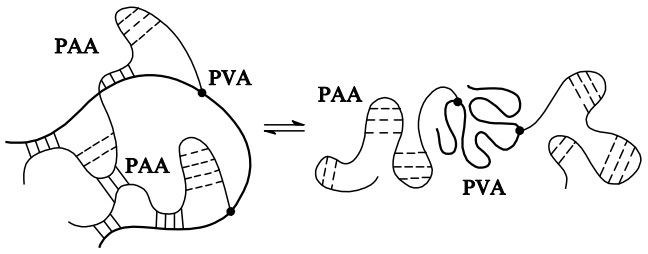

Figure 13. Scheme of the conformational transition in the PVA-g-PAA macromolecules on heating.
For notations of the elements in the scheme, see Fig. 6.

The influence of hydrodynamic shear field on the structure of PVA-g-PAA in solutions was studied on a rheo-viscometer equipped with coaxial cylinders. A non-traditional behaviour of solutions of the copolymers was observed in hydrodynamic fields.[189, 190] This is illustrated by Figs 14 and 15, which show the dependences of the effective viscosity of solutions of PVA-g-PAA(2) on the shear rate gradient and the concentration dependences of the reduced viscosity of these solutions. At relatively high

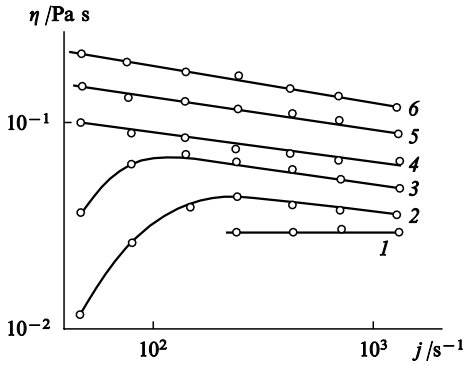

Figure 14. Plot of the effective viscosity of solutions of PVA-g-PAA(2) *vs.* the shear rate gradient.

concentrations ($c \approx 3-5$ kg m^{-3}), typical non-Newtonian flow was observed for all copolymers. At lower concentrations ($c \approx 1-3$ kg m^{-3}), the flow curves have a maximum, whose position is determined by N and c. In a dilute solution ($c \approx 0.5$ kg m^{-3}), the viscosities at small shear rate gradients j were initially low to an extent that they were beyond the sensitivity limits of the instrument. However, the viscosity of the solution sharply increased (ten – hundred times) at a critical value of j^*.[189, 190] The largest value of j^* (243 s^{-1}) is characteristic of the PVA-g-PAA(2) copolymer. According to the IR spectroscopic data, this copolymer had the largest number of main chain – graft and graft – graft bonds (see Fig. 6 *b*). It should be emphasised that all flow curves were completely reversible. A substantial reversible increase in viscosity of solutions with increasing j (negative thixotropy) indicates that the PVA-g-PAA macromolecules exhibit viscoelastic properties due to destruction of an H-bond network (destruction of the intramolecular complex) induced by the hydrodynamic field.

The critical concentration c^*, below which the intramolecular polycomplex was destroyed, was determined from the concentration dependences of the reduced viscosity of solutions of the copolymers at different j, which were calculated with the use of flow curves.[189, 190] The critical concentrations c^* in the PVA-g-PAA(1 – 3) series changed in parallel with the crossover concentration and increased from 2 to 4 kg m^{-3} with increasing grafting density. Hence, two levels of reversible destruction of PVA-g-PAA in solutions induced by the hydrodynamic shear field were revealed. At the first level, a network of pinnings is destroyed. In the second deeper level, the intramolecular polycomplexes along with primary aggregates are destroyed (Fig. 16).

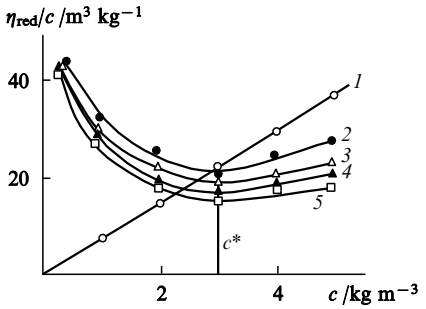

Figure 15. Concentration dependences of the reduced viscosity of solutions of PVA-g-PAA(2) at j of 49 (*1*), 146 (*2*), 437 (*3*), 729 (*4*) and 1312 (*5*) s^{-1};
η_{red} is the reduced viscosity, c and c^* are the concentration and the critical concentration of the solutions, respectively.

The critical values are marked with an asterisk.

Interestingly, rheological studies revealed exclusively non-Newtonian (pseudoplastic) flow for a series of other graft copolymers containing chemically complementary polymer components. These results were obtained, in particular, for the dextran-g-PAA,[81,96] ST-g-PAA, AM-g-PAA,[25] PVA-g-PMAA,[87] P(AA-co-AA)-g-PEO[106] and PAA-g-PEO copolymers.[105] However, taking into account high molecular masses of the samples under study ($\sim 2-6\times10^6$), high concentrations of the solutions used in measurements ($\sim 2-30$ kg m^{-3}) and the fact that PVA-g-PAA exhibits viscoelastic properties only in dilute solutions, the above-described result for these graft copolymers seems to be reasonable.

VII. Characteristic features of the structures and properties of intramolecular polycomplexes depending on the graft length

The molecular mass (length) of grafted chains is an important parameter, which allows one to control the structure and properties of graft copolymers. However, the role of this parameter is poorly understood. First attempts to reveal the influence of this factor on the thermodynamic properties and behaviour of graft copolymers in solutions have been made in the studies.[68,70] The 'pure' influence of the molecular mass of grafted chains is difficult to reveal because of the necessity to prepare and study samples, which should be characterised by the same grafting density and a narrow molecular-mass distribution of the grafts. This problem has attracted increasing interest in recent years because graft copolymers can be synthesised starting from macromonomers with controlled chain length. The results of the studies[148,176] devoted to the influence of the molecular mass and the grafting density of PEO on the bulk structures of PMA-g-PEO [PMA is poly(methyl acrylate)], PMMA-g-PEO and PS-g-PEO were discussed above. Among investigations of graft copolymers in solutions, several interesting systematic studies have been undertaken to reveal the role of the molecular mass and the density and distribution of hydrophobic hydrocarbon grafted chains (in comb-like copolymers with PEO[26] or with the AA – MA copolymer[27,28]) in their aggregation in an aqueous medium. Studies by static light scattering, fluorescence spectroscopy and rheology demonstrated that an increase in the concentration of solutions was accompanied by a characteristic transition from intramolecular aggregation of hydrophobic branchings to intermolecular aggregation for all the above-mentioned copolymers. This transition was shifted to lower concentrations and was attended by a sharper and sharper increase in viscosity of the solution as the length and number of neighbouring hydrophobic tails increased. In many other studies (see, for example, Ref. 31), the molecular mass and the number of grafted chains (PMMA) in graft copolymers were varied with the aim of solving single-purpose problems (in particular, for the purpose of enhancing the strength of two-component polyurethane coatings). Analogous systematic studies of the role of the molecular mass of grafted chains in graft copolymers containing chemically complementary components are few.

When studying the structure and state of the PVA-g-PAA(8 – 10) samples which are characterised by the constant number but different molecular masses of the PAA chains, in solutions, our main interest was to elucidate how the effect of 'detachment' of the grafted chains from the main chain at $M_{v\,PAA} > M^*$ (which was revealed by IR spectroscopy) is reflected in the properties of the copolymers.

The above-mentioned phenomenon was confirmed primarily by the structure studies of these copolymers by DSC.[191] The DSC thermograms of the PVA-g-PAA(8, 9) samples with $M_{v\,PAA} \leqslant 4\times10^5$ show only one heat capacity jump (Fig. 17, curves *1* and *2*), *i.e.*, these copolymers are characterised by complete compatibility of the polymer components. The DSC thermogram of the PVA-g-PAA(10) sample with $M_{v\,PAA} = 5.1\times10^5$ has already two heat capacity jumps (curve *3*), which is indicative of the microphase separation in the structure of this copolymer. One microphase ($\sim 85\%$) corresponds to regions of compatibility of the polymer components, whereas another microphase ($\sim 15\%$) corresponds to domains formed by segments of PAA, which are 'detached' from the main chain.[129,191]

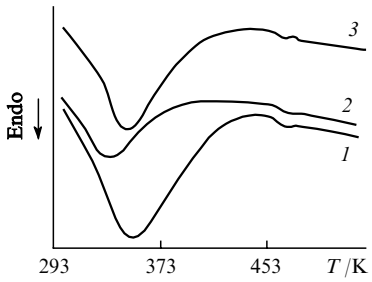

Figure 17. DSC thermograms for PVA-g-PAA(8) (*1*), PVA-g-PAA(9) (*2*) and PVA-g-PAA(10) (*3*).

Three main steps of thermooxidative destruction were revealed for these copolymers by TGA.[191] The temperatures of the onset of destruction of the copolymers were close to the analogous temperature for PAA but lower than that for PVA. The parameters of destruction changed with increasing $M_{v\,PAA}$ as follows: (1) the temperature of the onset of destruction rose; (2) the temperature of completion of destruction increased; (3) the temperature range of the first step of destruction (accompanied by the endothermic effect) became narrower; (4) the temperature range of the third step of destruction (accompanied by the maximum exothermic effect) decreased; (5) the overall temperature range of destruction decreased.

Hence, an increase in the molecular mass of the grafted chains led, on the one hand, to a slight growth of thermal stability of the copolymers (an increase in the temperature of the onset of destruction) but, on the other hand, to an increase in the rate of their complete decomposition. The latter fact is indicative of loosening of the PVA-g-PAA structure with increasing $M_{v\,PAA}$, due to which different elements of the structure become more accessible for oxygen, removal of gaseous decomposition products becomes easier and, that is why, thermooxidative destruction is accelerated. These data actually confirm the effect of 'detachment' of the grafts from the main chain. The parameters E, n and Z of the first two steps of destruction were calculated using

computer processing of the TG curves. In the first step, in which chemical processes occur without the involvement of oxygen, the parameters E, n and Z pass through a maximum for PVA-g-PAA(9) with $M_{v\,PAA} = 4.3 \times 10^5$ with increasing $M_{v\,PAA}$. This fact is in complete agreement with the maximum number of the main chain – graft H-bonds in this graft copolymer compared to those in all other samples of PVA-g-PAA under study and indicates that complicated chemical transformations occur in the first step of destruction of this copolymer.

The properties of copolymers containing grafted chains with different molecular masses were studied also by light scattering.[167] All samples of the series under consideration are water-soluble at room temperature. According to the results obtained with the use of the Zimm plots (Table 6), the thermodynamic quality of water with respect to the copolymers was improved (the parameter A_2 increased) with increasing $M_{v\,PAA}$. At the same time, the number of macromolecules in aggregates and their radius of gyration reached minimum values for PVA-g-PAA(9), which was characterised by an intermediate value of $M_{v\,PAA}$ (4.3×10^5) and existed in water in the molecular-disperse state. Two other copolymers occurred as aggregates, which differed from each other in the packing density of segments. It was demonstrated [129, 167] that loose swollen aggregates of the copolymer containing grafted chains with the highest molecular mass ($M_{v\,PAA} = 5.1 \times 10^5$) were formed due to 'detachment' of the grafted chains from the main chain and improvement of the quality of the solvent, in contrast to compact aggregates of PVA-g-PAA(8) with $M_{v\,PAA} = 3.72 \times 10^5$.

Table 6. Results obtained by light scattering for graft copolymers containing grafted chains with different molecular masses ($N = 9$).

Sample	$10^{-6} M_w$	$10^{-4} M_{w\,PVA\text{-}g\text{-}PAA}$	Z	$10^9 A_2$ (see [a])	$\langle R^2 \rangle_z^{1/2}$ /nm
PVA-g-PAA(8)	6.92	3.46	2	1.18	299
PVA-g-PAA(9)	3.81	3.81	1	1.55	253
PVA-g-PAA(10)	18.83	4.71	4	1.66	777

[a] In m^3 kmol kg^{-2}.

The depolarisation coefficients of scattered light were determined at $\theta = 0$ and $c = 0$ (θ is the scattering angle and c is the concentration of the solution), and aggregates (or macromolecules) of all samples of the copolymers in the series under consideration were demonstrated to be optically isotropic in water (the optical anisotropy is equal to zero).[129, 167] According to the results of viscometric measurements at 298 K, an increase in $M_{v\,PAA}$ in the series of PVA-g-PAA(8 – 10) leads to a successive increase in the Huggins constant, and the parameter $[\eta]$ passes through a small minimum. These results correlate qualitatively with the data obtained by static light scattering.

The results of measurements of benzene solubilisation in solutions of the copolymers were somewhat unexpected.[192] Actually, an increase in $M_{v\,PAA}$ to 4.3×10^5 did not lead to a substantial change in the amount of benzene in the bound state. However, a further increase in the molecular mass of the grafted chains to 5.1×10^5 led to a sharp increase in solubilisation. To account for this effect, the contributions to solubilisation determined, first, by dispersion interactions of benzene with hydrophobic regions (the contribution of S_d) and, second, by binding of benzene to proton-donor groups of the polymer through H-bonding (the contribution of S_H) were considered.[129, 192] Then the UV spectra of benzene in water and solutions in ethanol, PAA and the PVA-g-PAA(10) sample containing the grafted chains of maximum length were measured. These studies revealed an increase in the intensity of the characteristic absorption band of benzene at $\lambda = 260$ nm in solutions of the graft copolymer. Taking into account this fact, it was concluded that the above effect is associated with a sharp increase in the amount of H-bound benzene in swollen coils of this sample of PVA-g-PAA.

Investigation of the temperature dependence of $[\eta]$ in solutions of the above-mentioned samples of the graft copolymers demonstrated [192] that the PVA-g-PAA(10) sample, in which the grafted chains are 'detached' from the PVA chain, has the lowest temperature of the onset of conformational transition. The deepest conformational changes (a sharp decrease in $[\eta]$ in the transition region) took place in the macromolecules of the copolymer characterised by the intermediate value of $M_{v\,PAA}$ (4.3×10^5). As mentioned above, these macromolecules possessed the largest number of main chain – graft H-bonds.

VIII. Functional capabilities of intramolecular polycomplexes

It is known that intermolecular polycomplexes can adsorb various organic compounds, ions, colloidal particles and biopolymers from solutions.[115 – 117, 131, 193] Such versatility is due to the fact that these polycomplexes contain hydrophobic binding regions of the polymer components and hydrophilic cavities formed by loops of non-bound polymer units and, in addition, to the possibility of self-adjustment of the system, *i.e.*, changes in the hydrophilic – hydrophobic balance in the polycomplex particle in the course of sorption, due to which the best results can be obtained.[115, 116, 193] However, intermolecular polycomplexes have drawbacks as binding agents because of the existence of a complex formation equilibrium at the macromolecular level. Hence, these complexes can be destroyed to individual components in highly dilute solutions,[115] under the action of strong competitive agents [116] or under changes in external conditions (for example, temperature or pH of the solution).[115 – 117] In this respect, intramolecular polycomplexes, in which the interacting polymer components are additionally linked by covalent bonds, hold more promise. Due to the absence of an equilibrium at the macromolecular level, intramolecular polycomplexes are not destroyed to individual polymers even under conditions of competitive binding of the sorbed compound to just one of the components. Presently, high binding ability of intramolecular polycomplexes is used for the construction of macromolecular therapeutic systems providing prolonged action of drugs.[14, 16, 21, 88, 103]

Films of the PVA-g-PAA intramolecular polycomplex can efficiently (and selectively) adsorb phenol from water (Fig. 18). Detailed investigation of this phenomenon [194, 195] made it possible to construct highly efficient sensors for measuring phenol in natural water.

Graft copolymers containing chemically complementary polymer components are promising as flocculants. Actually, a higher flocculating ability of the graft copolymers of PAA onto oxyethylcellulose and amylopectin compared to PAA with the same molecular mass was observed in the study.[196] Later on, graft

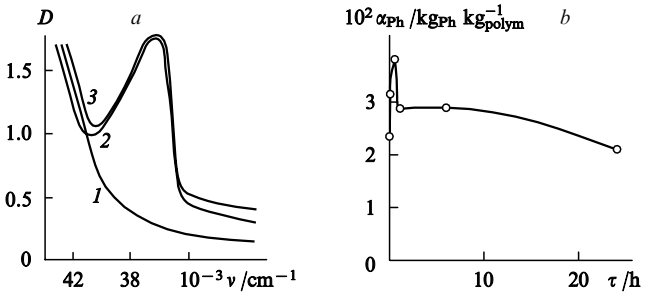

Figure 18. UV spectra (*a*) of the starting thermally treated film of PVA-g-PAA(2) (*1*) and a film kept in an aqueous solution of phenol ($c = 10$ kg m^{-3}) for 4 (*2*) and 5 (*3*) min and the change in the amount of phenol in the bound state (α_{Ph}) at $T = 293$ K calculated from the above data (*b*).

copolymers of acrylamide and acrylic acid onto water-soluble cellulose derivatives were tested and covered by patents as flocculants for clearing of water and conditioning of precipitates of waste-water treatment facilities.[5]

Numerous examples of the use of graft copolymers as flocculants were offered in the literature. In particular, graft copolymers of PAA onto polysaccharides, such as sodium alginate, starch and its components (amylose and amylopectin), were studied.[6, 7, 109, 110, 197, 198] Their flocculating ability was tested using kaolin suspensions, waste waters from the pulp-and-paper industry and waste waters obtained upon iron ore processing and in the course of concentration of 10% iron ore slurry. It was found that the copolymer of PAA grafted onto branched amylopectin is the most efficient of all the flocculants studied.[109, 110, 197] A series of samples of this copolymer containing different amounts of grafted chains with different molecular masses was studied. Unfortunately, detailed characteristics of these copolymers are lacking in the literature. However, it was noted that both a decrease in the grafting density and an increase in the graft length lead to enhancement of the flocculating effect.

Highly efficient non-ionic Unicomfloc^{intra} flocculants were developed based on the PVA-g-PAA intramolecular polycomplex for clarification of highly turbid clay suspensions [199] and preparation of drinking water at water treatment plants.[200] The effect of one sample of these flocculants in coagulative–flocculative clearing of river water is compared with that of the known Magnafloc LT-27 flocculant (Allied Colloids, UK) in Table 7. The efficiency of the individual coagulant (aluminium sulfate) and coagulant–flocculant pairs was estimated taking into account the main characteristics of the quality of water, such as turbidity, chromaticity, permanganate oxidisability and the content of residual aluminium. The advantages of the Unicomfloc^{intra} flocculants are their ability to perform complex purification of water from suspended substances of both natural and anthropogenic origin, such as phenol [201, 202] and ^{137}Cs radionuclides.[203]

Semidilute aqueous solutions of the PVA-g-PAA intramolecular polycomplex exhibit a substantial negative thixotropic effect. Thus, these solutions become thickened on slight stirring and occur in this state for several hours. As mentioned above, the reason is that a hydrodynamic field induces reversible destruction of the polycomplex. Substantial reversible thickening of solutions of the copolymers induced by a hydrodynamic shear field can serve as a basis for the development of a special type of thickening agents providing high viscosity of a solution only for a desired period of time.

Graft copolymers containing chemically complementary main and grafted chains are highly efficient agents for drag reduction of turbulent flow.[42, 44, 82, 112] For example, PVA-g-PAA samples containing a small polymer additive at $Re = 5 \times 10^3 - 5 \times 10^4$ show a drag reduction of turbulent flow $W \approx 60\%$ (Fig. 19 *a*). A somewhat higher efficiency in drag reduction of turbulent flow ($W \approx 65\% - 68\%$ at $Re = 1.4 \times 10^4$) was achieved with the use of particular samples of CMC-g-PAA (CMC is carboxymethylcellulose) and ST-g-PAA.[82] The activity of the above copolymers decreases substantially with increasing density and decreasing molecular mass of the grafted chains. It is important that solutions of these graft copolymers not only exhibit high hydrodynamic activity but are also resistant to degradation induced by turbulent flow (see Fig. 19 *b*, curve *1*), as distinguished from solutions of high-molecular-weight PEO (curve *2*) and PAA.[204] It should be noted that the time interval between two adjacent points in the curves in Fig. 19 *b* corresponds to the time during which a polymer solution was passed once through a capillary of a rheometer, and the total number of points corresponds to the number of repeated cycles of exposure of the solution to turbulent flow. Hence, resistance of solutions of PVA-g-PAA (as well as of CMC-g-PAA, ST-g-PAA and other graft copolymers, which form intramolecular polycomplexes) to degradation is determined by the fact that the macromolecules of the copolymers can rapidly and virtually completely restore their original molecular and supermolecular structures under conditions when the action of a strong hydrodynamic field is periodically interrupted. Reversibility of destruction of PVA-g-PAA in solution, which is also observed in usual rheological experiments, distinguishes these graft copolymers from PEO and PAA and is indicative of the existence of a special force, which restores the system to its original state after termination of the action of a hydrodynamic field. Undoubtedly, this is thermodynamic affinity between the main and grafted chains.

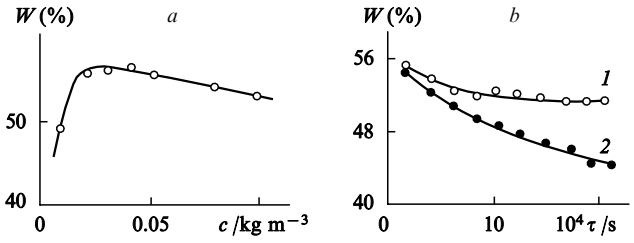

Figure 19. Drag reduction of turbulent flow *vs.* the concentration of PVA-g-PAA(7) (*a*) and the time of hydrodynamic field action of solutions of PVA-g-PAA(7) (*1*) and PEO (*2*) ($M_v = 6 \times 10^6$ at $T = 293$ K) (*b*).

Table 7. Efficiency of the clearing effect of the coagulant (aluminium sulfate) and different coagulant–flocculant pairs {a water sample from the Desna river: $T = 15$ °C, the turbidity was 4.3 mg dm^{-3}, the chromaticity was 37 deg (Cr–Co scale), the alkalinity was 3.65 mg-equiv. dm^{-3}, pH 8.2, $[NH_3] = 0.26$ mg dm^{-3}, the permanganate oxidisability was 9.1 mg dm^{-3}}.

Sample of a flocculant	Amount /mg dm^{-3} (see [a])		Turbidity /mg dm^{-3}	Chromaticity /deg (Cr–Co scale)	Oxidisability /mg dm^{-3}	c_{Al} /mg dm^{-3} (see[b])

[a] The concentration of chlorine water was 4.8 mg dm^{-3}. [b] The concentration of residual aluminium. [c] The parameters of the starting water after clarification for 3 h.

IX. Conclusion

To summarise, graft copolymers containing chemically complementary main and grafted chains, such as PVA-g-PAA, belong to a special class of polymer compounds, which may be classified as intramolecular polycomplexes. Their structures and properties in the bulk state and solutions are determined by intramolecular H-bonds of the main chain – graft and graft – graft types. The formation of intramolecular polycomplexes occurs, evidently, already in the course of free-radical graft copolymerisation of PAA onto PVA. Hence, the synthesis of PVA-g-PAA belongs to the category of matrix processes. At a too-high density of the growing grafted chains (about three grafts per 100 units of the main chain), the matrix effect (which is reflected in an increase in the rate of graft copolymerisation compared to that of AA homopolymerisation) decreases.

An increase in the density and(or) molecular mass of the grafted chains is accompanied by redistribution of H-bonds in the PVA-g-PAA macromolecules toward a decrease in the number of main chain – graft bonds and an increase in the number of bonds between the grafted chains. As a result, the structure of graft copolymers in the bulk state retains homogeneity only up to some critical mutually dependent values of N^* and M^*. At higher N and(or) molecular masses of the grafted chains, the structures of the copolymers contain ordered microregions (domains) formed by segments of PAA along with compatibility regions of the polymer components. Due to steric hindrance (at $N > N^*$) and(or) overlapping and interactions between long grafted chains (at $M_{PAA} > M^*$) at large distances from the main chain, these PAA segments cannot realise their thermodynamic affinity for PVA, and, hence, the PAA segments form an individual microphase in the PVA-g-PAA structure. Evidently, this type of microphase separation cannot be considered as a criterion for thermodynamic incompatibility between polymer components involved in graft copolymers.

Thermodynamic affinity between the main and grafted chains is responsible for reversibility of cleavage of an H-bond network and, correspondingly, destruction of the molecular and supermolecular structure of the PVA-g-PAA macromolecules in solution induced by temperature and hydrodynamic shear field. This fact is responsible for high resistance of solutions of PVA-g-PAA and other analogous graft copolymers to degradation in turbulent flow.

Graft copolymers which form intramolecular polycomplexes composed of chemically complementary polymer components additionally linked by covalent bonds, possess high binding ability. This provides, in particular, high flocculating ability of PVA-g-PAA as well as of the known graft copolymers of PAA onto polysaccharides in clearing of various suspensions and natural water.

Abstract. The lines of research in the field of inorganic chemistry that are closely related to the design of novel functional materials are analysed. Special attention is given to areas of inorganic materials chemistry that have been developed most intensely at the Division of Inorganic Chemistry of the Department of Chemistry and at the Department of Materials Science of the Moscow State University over the past decade. The bibliography includes 135 references.

I. Introduction

Much of the actual knowledge which constitutes the basis of modern inorganic chemistry was obtained rather long ago; however, in the second half of the 20th century inorganic chemistry faded into the background of extraordinary achievements in organic chemistry and the chemistry of living systems. The progress in electronic engineering,[1] photonics,[2] sensorics[3] and spintronics,[4] which is impossible without the development of new generations of functional materials, has resulted in a kind of renaissance in inorganic chemistry in the past 10 – 15 years.

An active search for ways of utilisation of virtually all chemical elements systematised as the Periodic Table aimed at the development of novel materials and technologies is under way. The increasing applications of the most recently discovered chemical elements, *e.g.*, rhenium, technetium and francium, to say nothing of plutonium, americium and other actinides, provide illustrative examples.

The transition from chemical elements to materials is extremely complicated, and even the development of methods of combinatorial chemistry[5,6] does not allow one to master a multitude of combinations of the elements. Just for elements having stable isotopes, the number of such combinations exceeds 7×10^{23}. This increases by many orders of magnitude considering that the majority of the existing functional materials are developed on the basis of metastable (rather than thermodynamically stable) states of substances which are indefinably numerous for each particular compound with a fixed composition.

Obviously, the method of random enumeration of compositions is inefficient in the design of novel materials, and a significantly more pronounced effect is produced owing to the use of various approaches based, in particular, on the progress in inorganic chemistry. Despite the well-established traditions in the development of inorganic chemistry in Russia, the range of research in the field of inorganic synthesis in our country has recently narrowed considerably due to the limited experimental facilities of many research groups wich have no access to modern high-precision equipment, such as electron microscopes, synchrotron radiation sources, squid magnetometers, high-resolution NMR spectrometers, *etc*. This is all the more distressing taking into account the outstanding contribution of Russian scientists to the development of modern inorganic chemistry. Suffice it to mention the investigations by D I Mendeleev, N S Kurnakov, L A Chugaev and I I Chernyaev and more recent studies by A V Novoselova, I V Tananaev, V I Spitsyn and many others.

At present, the inorganic chemistry of materials is being developed especially intensively at such research centres as the N S Kurnakov Institute of General and Inorganic Chemistry of the RAS (Moscow), the A V Nikolaev Institute of Inorganic Chemistry of the Siberian Branch of the RAS (Novosibirsk), the Institute of Solid State Chemistry of the Urals Branch of the RAS (Ekaterinburg), the I V Grebenshchikov Institute of Silicate Chemistry of the RAS (Saint-Petersburg) as well as by divisions of inorganic chemistry of the largest classical and technical Russian universities including the M V Lomonosov Moscow State University (MSU).

In writing the present review and other reviews published in this issue of the Journal, the authors did not set themselves the task encompassing all the trends in contemporary inorganic chemistry, which is impossible in principle. They have consciously confined the range of scientific problems to those directly related to the design of novel functional materials and appropriate to their own research experience gained at the Division of Inorganic Chemistry of the Department of Chemistry and the Department of Materials Science of MSU over the past 10 – 15 years.

It may be hoped that despite the inevitable subjectivity, the reviews presented in this issue will provide an insight into modern

Uspekhi Khimii **73** (9) 899 – 916 (2004); translated by R L Birnova

inorganic chemistry as a fundamental for the design of new generations of functional materials. The main research trends touched upon in the present review are as follows:

— chemistry of ionic and molecular precursors;
— crystal chemical design of novel inorganic compounds and design of materials based on them;
— inorganic nano- and supramolecular chemistry;
— chemistry of non-stoichiometric compounds;
— chemistry of elements in unusual oxidation states;
— inorganic chemistry of biomaterials and implants;
— inorganic synthesis of functional materials using ultrasonic, hydrothermal and microwave methods.

II. Chemistry of ionic and molecular precursors

The design of materials with a definite range of structure-dependent properties on the basis of chemical compounds (rather than merely the synthesis of chemical compounds) is the ultimate goal for a wide range of inorganic chemists engaged in the development and perfection of functional materials. Such properties depend on the real structure of a material beginning with the structure of the unit cell and ending with the peculiarities of polycrystalline (ceramic) structures with their characteristic defects (dislocations, crystallite boundaries, pores and cracks). Different structural levels are mutually related. The possibility of control over such relationships is considered in reviews [7,8] within the framework of approaches of non-linear dynamics. The latter can be used for the description of the evolution of physicochemical systems under non-equilibrium conditions determined by specific interactions of these systems with the environment. It has been shown [9] that some factors, among which the unambiguity and reproducibility of the original states of chemical precursors are critical, should be taken into consideration in the optimisation of the reaction zone for the synthesis of materials. The more complex are the systems the more difficult this is to attain. Here, we define the complexity of a system as both its chemical and phase compositions and activities of its precursors determined by their chemical and thermal prehistories, *i.e.*, the effect of 'topochemical memory'.[10]

If a material, which is the target product of chemical and phase conversions, is multicomponent, additional requirements for homogeneity and ability to preserve it upon transition to the target product are imposed on its precursors. It is for this reason that solid-phase synthesis, which seems to be technologically the simplest and has been widely employed previously for the manufacture of magnetic dielectrics and piezoceramics, is fairly ineffective in the preparation of many functional materials. Thus the synthesis of manganese–zinc ferrites with high magnetic permeability was carried out by the reaction:

$$1/3\,MnCO_3 + 2/3\,ZnO + Fe_2O_3 = Mn_{0.33}Zn_{0.67}Fe_2O_4 + 1/3\,CO_2.$$

It was found, however, that in many cases the combination of traditional processes, such as mechanical blending, compaction of precursor mixtures and high-temperature annealing ($\sim$1200 °C), does not allow preparation of a single-phase product. An increase in temperature results in inevitable losses of volatile zinc oxide and dissociation of iron(III) oxide to form magnetite. These processes significantly deteriorate the composition and properties of the product due to considerable magnetic and dielectric losses, especially at ultrahigh frequencies. Repeated grinding and heating at constant temperatures lead to further contamination of the product with the mill materials, which markedly decreases the magnetic permeability of the target ferrites.

The problem of reproducibility and enhancement of functional properties of solid-phase synthetic products can be overcome by combining the solid-phase synthesis and thermolysis. In this case, mechanical mixtures or co-precipitated salts of various oxoacids [11] including sulfates, carbonates, nitrates, oxalates, acetates, citrates, formates and stearates are used as chemical precursors. The use of salt solid solutions obtained under equilibrium or non-equilibrium conditions was next step forward. It has been found [12,13] that schoenite-type salts of the general formula $M^{2+}A^{+}(RO_4)_2\cdot 6\,H_2O$ (M = Mg, Mn, Ni, Co, Fe, Cu, Zn; A is an alkali metal or NH_4; R = S, Se, Te, Cr) or alum-type salts $A^{+}M^{3+}(SO_4)_2\cdot H_2O$ (where A is an alkali element or NH_4; M = Fe, Cr, Co) are the most convenient for equilibrium crystallisation.

The ability to form continuous solid solutions at any ratios of the reaction components and good solubility in water, which decreases drastically upon cooling, were used as a basis for the development of original methods for the preparation of highly homogenous isomorphic salt mixtures. These methods are based on isoconcentration evaporation of the solvent or isoconcentration elimination of micro-oversaturation of the solution.

The practical implementation of these processes has become possible due to extensive studies [12] of equilibrium diagrams of ternary (salt 1 – salt 2 – water) and more complex systems and determination of thermodynamic distribution coefficients of salt components between co-existing liquid and solid phases aimed at selecting the conditions for equilibrium crystallisation of salt solid solutions the cationic compositions of which are identical to those of the ferrites to be synthesised. The transition from the salt precursor to the target product occurs upon thermolysis using a reaction of the type:

$$(Ni_{1/3}Fe_{2/3})SO_4\cdot(NH_4)_2SO_4\cdot 6\,H_2O =$$
$$= 1/3\,NiFe_2O_4 + 2\,SO_2 + 2\,NH_3 + 3/2\,O_2 + 7\,H_2O.$$

The conditions of this reaction predetermine, to a large extent, the feasibility of preparation of a polycrystalline material with a preset ceramic structure and structure-dependent properties.

The cryochemical method may be regarded as a versatile procedure for the preparation of salt-like multicomponent precursors. The cryochemical technology [13–15] is based on a balanced combination of heating and cooling processes, the latter being used to prevent the uncontrollable changes in intermediate and target products (Fig. 1). Rapid freezing (*e.g.*, in liquid nitrogen) of solutions containing metal salts as constituents of materials to be synthesised and dispersed in the form of mono- or polydispersed drops is a crucial step in the cryochemical technology. Frozen

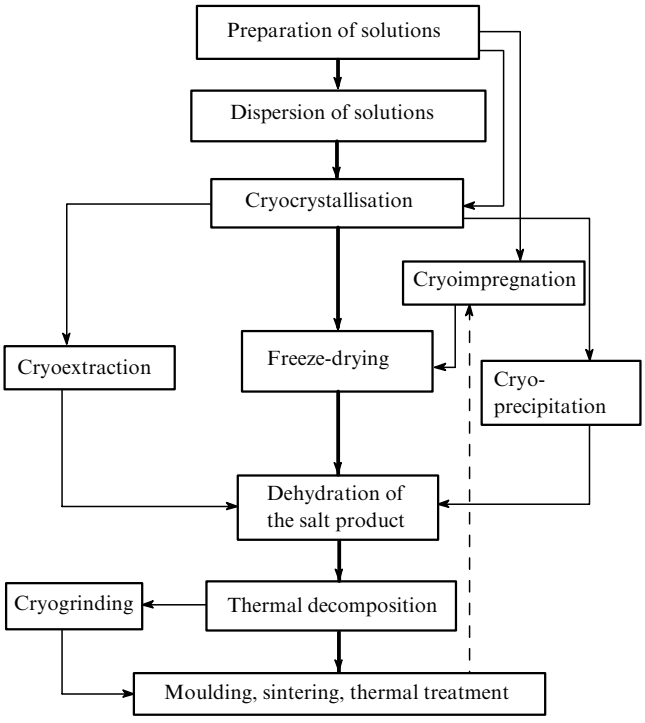

Figure 1. Processes of cryochemical technology.

solutions of salts in the form of cryogranules are usually subject to freeze-drying; its optimum conditions provide the preparation of highly homogenous salt precursors. The rate of cryocrystallisation exceeds that of solid phase formation by several orders of magnitude when other known non-equilibrium methods (*e.g.*, solvent replacement by desalting from aqueous solutions with non-aqueous solvents, such as acetone, ethanol or methanol) are used for the preparation of salt precursors.

The wide application of cryochemical technology was preceded by fundamental investigations of cryocrystallisation, freeze-drying, cryoprecipitation, cryoextraction, cryodispersion and some original cryocalorimetric procedures.[13–16] The cryochemical synthesis of salt precursors underlies the preparation of various functional materials (Fig. 2). Dispersed powders prepared by thermal decomposition of salt precursors are distinguished by microplasticity, high reactivity and sintering ability in addition to their chemical homogeneities.

The so-called topochemical memory, *i.e.*, the ability of solid-phase chemical conversion products to store ('to remember') information about their origin and to transfer it upon subsequent topochemical reactions, is a characteristic feature of salt-like ionic precursors. A real structure, which is usually formed under non-equilibrium conditions and affects significantly the properties of functional materials obtained as polycrystalline ceramics, seems to be the most probable candidate for 'storing' and 'delivering' information in solids.[10]

Studies related to the chemistry of molecular precursors are extremely important for the design of thin-film materials by molecular deposition. In order to solve the global problem of the increase in the density of information recording in silicon chips, it is necessary to replace the 'natural' oxide (SiO_2) by oxides with higher dielectric constants. The most probable candidates are HfO_2, ZrO_2 and Ln_2O_3. Preparation of films of such oxides on the surface of silicon by MOCVD (Metal-Organic Chemical Vapour Deposition) requires development of molecular precursors possessing high volatilities and relative thermal stabilities as well as abilities to undergo hydrolysis, pyrohydrolysis or other decomposition reactions leading to the formation of amorphous oxides on the surface of silica. The main idea realised at the Laboratory of Coordination Chemistry of MSU [17] consists of the use of novel molecular precursors based on metal complexes with complete saturation of the coordination sphere with ligands that form relatively weak donor–acceptor bonds. Saturation (and, as a consequence, volatility) was provided by the introduction of an additional neutral ligand (*e.g.*, phenanthroline); charged ligands were chosen on the basis of quantum-chemical calculations of the energies of the metal–ligand bonds.

Complexes with organic ligands were also successfully used for the solution of yet another vital task, *viz.*, preparation of thermoprotective (barrier) coatings for gas-turbine unit blades. It was shown [18] that deposition of coatings from vapours of β-diketonates of appropriate metals using ZrO_2 (Y_2O_3) is the most

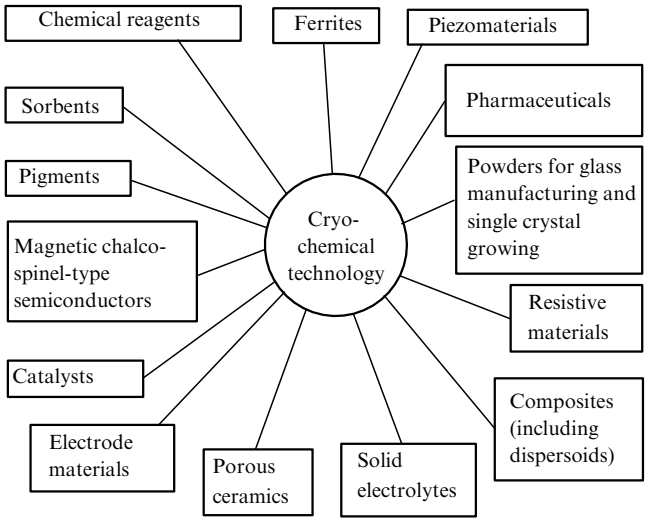

Figure 2. The main products prepared by cryochemical technology.

efficient approach which allows radical reduction of the production cost owing to the use of inexpensive acetylacetonates. As for the problem of insufficient volatility of polymeric $Y(acac)_3$, it is solved by co-evaporation with volatile $Zr(acac)_4$, its small portions being fed gradually into the evaporator. The well-known synergistic effect is observed, *i.e.*, joint evaporation is more complete than separate.

A series of novel REE mixed-ligand complexes including Tb(III) complexes with some aromatic acid derivatives to be used as luminescent materials for an organic light emitting diode (OLED) have been synthesised. An OLED represents a multilayer unit constructed using planar technology. The material of the working layer should not only possess bright electroluminescence, but also be temperature-resistant (since OLED is spontaneously heated during operation) and form smooth films upon deposition on the surface of the substrate, *i.e.*, be readily soluble in organic solvents, to moisten the surface of the anodic layer and be resistant to cracking. Such luminescent materials are prepared by mixed-ligand complex formation using neutral ligands.

Spectral characteristics of the terbium salicylate complex $Tb(sal)_3 \cdot H_2O$ with triphenylphosphine (TPPO) obtained by the reaction

$$Tb(sal)_3 \cdot H_2O + TPPO \xrightarrow{EtOH-C_6H_6} Tb(sal)_3 \cdot (TPPO)_2$$

are shown in Fig. 3 as an example.

Terbium salicylate is stable at temperatures up to 120 °C, whereas the complex $Tb(sal)_3 \cdot (TPPO)_2$ retains stability up to

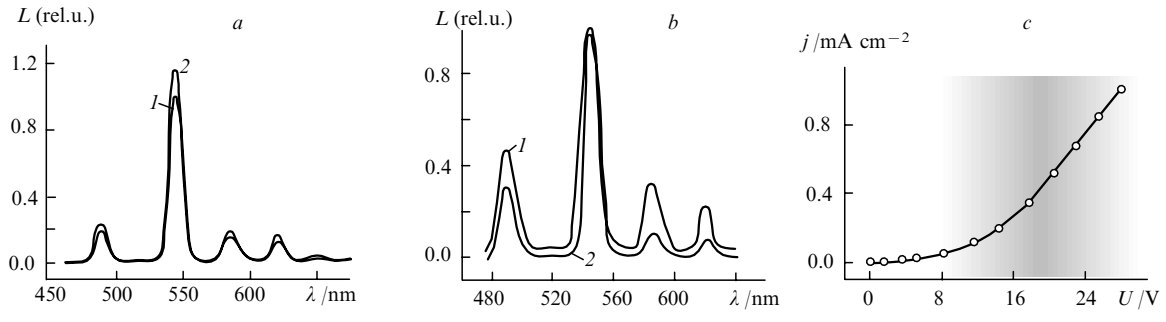

Figure 3. Spectral characteristics of $Tb(sal)_3 \cdot H_2O$, $Tb(sal)_3 \cdot (TPPO)_2$ (*a*) and OLED based on $Tb(sal)_3 \cdot (TPPO)_2$ (*b, c*).
(*a*) Luminescence spectra of $Tb(sal)_3 \cdot H_2O$ (*1*) and $Tb(sal)_3 \cdot (TPPO)_2$ (*2*); (*b*) photo- (*1*) and electroluminescence (*2*) spectra of OLED; (*c*) voltammetric characteristics of OLED (the luminescence zone is shown in grey).

200 °C, the surface roughness of the former being 66 nm, that of the latter being 9 nm.

One of the latest successful investigations related to molecular precursors was carried out by Romanov *et al.*[19] These authors have synthesised a mixed-ligand complex niobium isopropoxide–dipivaloylmethanate and used it, along with dipivaloylmethanate potassium *tert*-butoxide, for the preparation, by the MOCVD method, of epitaxial films of potassium niobate $KNbO_3$ characterised by extremely high values of non-linear optical and piezoelectric constants.

III. Crystal chemical design of novel inorganic compounds and preparation of materials based on them

Antipov and co-workers[20] have developed a concept of intergrowth structures and used it in a search for novel oxide materials. This was achieved through the use of structural design which had proved to be efficient in the preparation of novel high-temperature superconductors based on complex copper oxides. The latter contain structures derived from perovskite (ABO_3) or a perovskite-like fragment as one of the structural components of intergrowth structures. The prediction and synthesis of novel superconductors were carried out by selecting various intergrowth structures. Such a synthesis is, to a certain extent, similar to that of organic compounds; however, its realisation demands an analysis of infinite two-dimensional layers forming structural units rather than of isolated groups of atoms as in the case of organic molecules.

The geometric commensurability of structurally different fragments in the plane *ab* is a prerequisite for the formation of intergrowth structures. By varying the cationic compositions of the units and the formal degree of oxidation of copper ions, one can vary the geometrical sizes of the units and obtain the desired compounds using an appropriate synthetic procedure. In predicting the compositions of intergrowth structures, attention should be given to crystal chemical characteristics of the cations, their chemical similarities and electron neutrality of the elementary cell as a whole. The choice of a synthetic procedure is determined by the chemical peculiarities of the starting compounds and the degree of oxidation of the cations in the target structure.

This approach was used for the preparation of more than 100 novel complex copper oxides among which about 30 oxides possess superconducting properties.[21]

The search for novel superconductors was carried out among compounds comprising an anion-deficient perovskite-like structure, *viz.*, $A_n(Cu,M)_nO_{3n-\delta}$, and a series of novel oxides was obtained. The 'structural substitution' approach was also used in the synthesis of novel compounds where prototypes with a layer sequence corresponding to the formula $(CuO_2)(M\square)(CuO_2)$ served as the basis of the structure. In the structures of novel compounds, this fragment was rearranged into the sequence $(CuO_2)(A_2O_2)(CuO_2)$ the (A_2O_2) block in which has the structure of fluorite.

Crystal chemical simulation has made it possible to predict the existence and to synthesise a new family of superconductors, *viz.*, $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ with record values of T_c. The transition temperatures for superconduction of the phases $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ depend on the content of oxygen (δ) and the number of CuO_2 layers (n). A progressive increase in T_c on going from the first member of the homologous family (97 K) to the second (127 K) and third (135 K) members is followed by its decrease for the fourth (127 K), fifth (110 K) and sixth (107 K) members. The T_c value for $HgBa_2Ca_2Cu_3O_{8+\delta}$ at 23.5 GPa was found to be equal to 157 K. The possibility, in principle, of a transition into the superconducting state at $T_c = 150-160$ K at atmospheric pressure has been demonstrated for compounds with the Cu–O distances corresponding to those in the $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ complexes under external pressure. The fact that the anionic sublattice may contain fluorine atoms along with oxygen atoms significantly expands the area of a search for Cu-containing oxofluoride superconductors. Xenon difluoride, which was employed for the first time as a mild fluorinating agent by Abakumov,[22] has a number of advantages over traditional fluorine sources. First, XeF_2 is solid at room temperature, which permits its precise quantification to attain a required level of fluorination and desired copper oxidation state; second, XeF_2 is less aggressive than gaseous fluorine, which excludes the use of sophisticated equipment and, third, no reaction products that could contaminate the target material are formed from XeF_2. Altogether, more than twenty novel cuprates including superconductors, such as $YBa_2Cu_3O_6F_2$ ($T_c = 94$ K) and $Y_2Ba_4Cu_7O_{14}F_2$ ($T_c = 62$ K), have been synthesised. Special mention should be made of the synthesis of $HgBa_2Ca_2Cu_3O_8F_{0.32}$; here, the introduction of fluorine caused anisotropic chemical compression and a record-high elevation of T_c (138 K).

The method of structural design was successfully used for the simulation of structures of novel complex manganites that sometimes possess colossal magnetoresistance.[23]

Epitaxial stabilisation of unstable oxide phases in the form of thin films developed by Kaul *et al.*[24] is a new in principle approach to the design of novel materials. Based on the results of thermodynamic simulation, direct syntheses of the novel phases RBO_3 (R = REE; B = Ni, Co, Mn, Fe, In) have been carried out. Some of them are ferroelectrics ($RFeO_3$ and $RMnO_3$); in others ($RNiO_3$, $RCoO_3$), a transition 'metal–insulator' is possible; ($R_3Fe_5O_{12}$) is a magnetic material. It was found that epitaxial stabilisation can successfully be used in the technology of preparation of thin-film materials for microelectronics. This technology was used as a basis for realisation of the local epitaxy principle during photolithographic formation of planar heterostructures.

A detailed study of epitaxial ratios of various structural types has made it possible to significantly expand the potential of heteroepitaxy. This method was used,[24] in particular, for the design of nanodomain epitaxial structures based on REE manganites characterised by high tunnel magnetoresistance values. It was shown that nanodomain epitaxial structures are formed as a result of self-organisation of a system that is crystallised at the nanolevel. Provided the energetically identical heteroepitaxial approaches exist, these structures can be used as a basis for the manufacture of inexpensive, highly sensitive magnetic field sensors.

The fundamental physicochemical problems related to the design of HTSC materials based on nonstoichiometric phases $R_{1+x}Ba_{2-x}Cu_3O_z$ with predetermined compositions, homogeneities and structures conferring desired structure-dependent properties, are considered in recent reviews.[25,26] TTT diagrams (Time–Temperature–Transformation) have been developed for the first time and the efficiency of their use in the design of HTSC materials has been demonstrated based on the results of systematic studies of temperature- and time-dependent changes in these phases.

The properties of manganites manifesting colossal magnetoresistance, which make them promising components of various magnetic sensors and novel magnetic information-recording devices, depend critically on structural parameters. Compositions with extremely high sensitivities to the magnetic field, light and other factors including changes in the isotopic composition have been obtained for the first time.[27,28] Optimisation of chemical compositions of manganites was carried out with due regard to the results of physical simulation of electron transfer processes. The phases $(La_{1-x}Pr_x)_{0.7}CaO_3MnO_3$ in the form of ceramics and thin epitaxial films have been studied in detail. It was found that unusually high sensitivities of electric resistances of critical compositions to the light and electric and magnetic fields are related to the competition between the metallic and charge-ordered states. The material synthesised by Babushkina *et al.*[28] ($x = 0.75$) manifests an anomalously high isotope effect upon the substitution of ^{18}O for ^{16}O and a transition from the metal-type con-

ductivity to a dielectric state. The magnetoresistances of film materials depend on elastic stresses generated upon their epitaxial fusion with the substrate. Critical compositions of the system $R_{1-x}Sr_xMnO_3$ are characterised by extremely high magnetostriction concomitant with a strong magnetocalorific effect. Such phases present considerable interest for the design of magnetic and mechanical sensors and Freon-free refrigerating plants having high coefficients of efficiency.

Needless to say, the ideology of the construction of functional materials is not confined to a crystal chemical design of novel inorganic compounds. Suffice it to remember the system of physicochemical principles formulated by the author of the present review rather long ago [29] and successfully used for the optimisation of properties of many functional materials, such as ferrites, magnetic semiconductors based on chalcospinels, electronic-ionic conductors of the oxide bronze type, complex silver chalcogenides and lanthanoidates, ceramic electrolytes with unipolar conductivities with respect to anions, cations and hydrogen as well as piezoceramic materials and flexible piezocomposites based on them.[30] This system comprises the following principles:

periodicity (properties of compounds of elements arranged according to the increase in their atomic numbers change periodically);

physicochemical analysis (principles of continuity, conformity and compatibility of components of an equilibrium system);

limitation of the number of independent parameters of states (among the multitude of parameters of state that characterise an equilibrium system comprising material-forming solid phases, only very few are independent according to the Gibbs' phase rule);

disordering and variability of composition (diverse defects are formed in crystalline lattices of solids at any temperature different from the absolute zero, while any solid-phase compounds with non-molecular types of bonds have variable compositions);

complication of composition (properties of a system change as a result of its chemical, structural and phase complication);

homogeneity (properties of solid-phase materials are sensitive to the degree of their homogeneities at both micro- and macrolevels);

equivalence of disorder sources (under equilibrium conditions, materials acquire specific defects which ensure a maximum increase in the entropy at minimum energy expenditures);

similarity of responses to physicochemical effects (necessary changes in the properties of materials can be achieved under the influence of various physicochemical factors);

nonequivalence of volume and surface;

metastable diversity (the number of non-equilibrium states of materials is indefinitely large; these states can be kinetically stable in solid phases).

The aforementioned principles constitute the system which defines possible approaches to the solution of material-science problems from the point of view of a chemist. Initially, no preference to these principles can be given, they represent a specific set of alternatives. However, when a specific problem is concerned, a decisive (key) principle is isolated from the system for a particular step by analysis of physicochemical conditions and used for the solution of problems aimed at the practical realisation of this principle. The next step towards the solution of the entire problem entails return to the system of principles, isolation and realisation of the next alternative, and so on.

IV. Inorganic nano- and supramolecular chemistry

In 2000, a national programme for investigations and developments in the field of nanotechnologies which has the name 'The National Nanotechnology Initiative' was set up in the USA. In the 2001 budget, the financing for its realisation constituted \$500 M, *i.e.*, significantly larger than, for example, the sum allocated for investigations in the field of high-temperature superconductivity immediately after its discovery in 1986. This is not surprising, however, since it is with nanotechnology that the next industrial revolution is associated. Amazingly, many research groups in Russia manage to carry on successful research in the field of nanomaterials and nanotechnologies with financial support which is three orders of magnitude smaller than that in the USA.

The interest in nanomaterials is associated with their unusual physical properties which are not characteristic of bulk materials. For example, a decrease in the size of semiconductor particles below a certain critical level can lead to the change in the width of a band gap, the generation of a second harmonic and dimensional quantisation of energy levels. At the same time, it is known that the predisposition of free nanoparticles to aggregation restricts their practical application. In this context, the development of methods for preparation of nanocomposites, *i.e.*, nanoparticles incorporated into an inert matrix, which protects the particles from environmental factors and thus prevents their aggregation, appears to be of crucial importance.

A promising method of matrix isolation of nanoparticles is based on chemical modification of lamellar double hydroxides (LDH) [31] with the general formula $M^{2+}_{1-x}M^{3}_{x}(OH)_2[(X^{n-})_{x/n}\cdot m\,H_2O]$. These compounds are made up of positively charged hydroxide layers $M^{2+}_{1-x}M^{3}_{x}(OH)^{x+}_{2}$ and interstitial anions X^{n-}. The method for the synthesis of nanocomposites is related to the chemical modification of these anions. The reaction zone is surrounded by hydroxide layers, so the conditions for the synthesis of the nanophase are similar to those observed in a two-dimensional nanoreactor.

The unique characteristics of lamellar double hydroxides open up broad opportunities for the design of nanocomposite materials based on them. Magnetic (based on metallic iron, cobalt and nickel) and semiconducting (based on MS, M = Pb, Zn, Cd) nanomaterials prepared from anion- and cation-substituted hydrotalcite, $Mg_{1-x}Al_x(OH)_2[(CO_3)_{x/2}\cdot m\,H_2O]$, using the above-mentioned method were the subjects of investigation.[32–35] Some of the factors influencing the structures and properties of nanocomposites synthesised have been established. Thus the dependences of the composition, size distribution, morphology and anisotropy of the nanostructures on the structure and composition of LDH used as a lamellar matrix were revealed. Conditions for chemical modification of substituted LDH also have a pronounced effect on the composition and structure of the nanophase formed inside the matrix.

In addition to LDH, a family of silica-based mesoporous molecular sieves has been recommended as a template for the synthesis of nanocomposite materials with a nanophase endowed with predetermined properties.[36] The structure of silica is characterised by the presence of a highly ordered system of pores with the diameters ranging from 20 to 100 Å. It is of note that such specific features of the aforementioned mesoporous materials as uniform size distribution of pores, extremely high specific surface ($\sim$1000 $m^2\ g^{-1}$) and broad variability of a pore size, make them especially attractive for investigators. By virtue of its ordered structure, mesoporous SiO_2 can be used as a template in the synthesis of metal and semiconductor nanoparticles as well as polyaniline and carbon fibres.

Currently, the main attention of specialists in inorganic supramolecular chemistry is focused on the design of supramolecular ensembles manifesting specific properties. Of considerable interest are ideally ordered ensembles, their structure being determined by the structure of the backbone of the 'host' (receptor), while the functional properties are determined by the nature of the 'guest' (substrate). The diversity of physical properties is due to structural peculiarities of the 'guest' structures including magnetic ordering of d^1-, d^3- and d^9-centres, spin transitions in d^6-centres, electron transitions with valence fluctuations and dynamic effects.

The properties related to dynamic effects are employed in the design of novel thermoelectrical materials. Semiconducting clathrates provide an example of compounds that are studied to this end.[37] The crystalline structure of a clathrate includes the backbone of the 'host' with 'guest' atoms with the coordination numbers of 20 and 24 in its cavities. The 'guest' atoms are not

bound to the 'host' backbone by covalent bonds and oscillate inside the cage with frequencies ensuring effective scattering of heat-conducting phonons. This results in a very low heat conductivity (as in the case of glasses). At the same time, the covalently bound backbone ensures high concentrations and mobilities of charge carriers, which accounts for high electroconductivity. A combination of these two features makes clathrates promising compounds for the design of effective thermoelectric materials. It has been found [38] that abnormal magnetisation and thermal capacities of tin-containing clathrates observed at $\sim$250 K are not associated with ordinary phase transitions. These data point to the possibility, in principle, of independent optimisation of electro- and heat-conducting properties determined by the structure of the backbone and the dynamics of guest molecules, respectively.

A new trend in inorganic supramolecular chemistry is related to controlled self-assembly of ordered supramolecular ensembles under conditions of high-temperature reactions where reaction systems are complex and heterophasic and are not subject to analysis. Such processes are based on the mutual adjustment of the 'host' and the 'guest' where the 'guest' is a template for the formation of a definite topology and geometry of the 'host' backbone and it itself changes its parameters in accordance with the 'host' requirements. It has been found [39] that weak 'guest–host' interactions are decisive in such self-assembly. Being limited by van der Waals forces, these interactions control the reciprocal arrangement of the 'guests' and the particles forming the 'host' backbone in the first step. If the 'guest' and the 'host' match each other, the formation of ideally ordered supramolecular ensembles takes place where hosts are recognised by 'guests' of various compositions and occupy their predetermined specific sites. As an illustration, Fig. 4 shows the structure $[Hg_6P_4](TiCl_6)Cl$ formed as a result of self-assembly of $TiCl_6^{3-}$ and Cl^- in the cavities of the backbone of $[Hg_6P_4]^{4+}$.

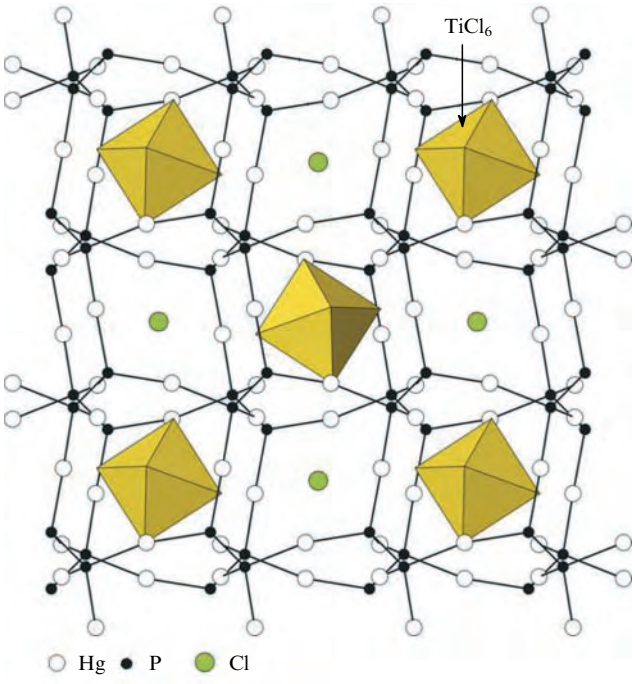

Figure 4. The structure of $[Hg_6P_4](TiCl_6)C1$ prepared by high-temperature synthesis.
The structure was formed by self-assembly of TiC_6^{3-} and Cl^- in the cavity of a three-dimensional cage of $[Hg_6P_4]^{4+}$.

V. Chemistry of compounds with variable compositions

The formation of chemical compounds with variable compositions, which have the name 'berthollides', was discovered over 100 years ago by N S Kurnakov who studied silicate and metallic systems. Later, it was found that compositional variability is an intrinsic property of inorganic solid-phase compounds with ionic bonds predominating. Depending on the nature of the elements constituting inorganic compounds, the area of their existence is either very broad (*e.g.*, titanium and iron monoxides) or, *vice versa*, extremely narrow (*e.g.*, alkali metal halides, zinc, lead and cadmium chalcogenides). In any case, a deviation from stoichiometry is a critical factor in the formation of binary and more complex crystals.

Using statistical thermodynamics methods, Schottky and Wagner [40] have established a correlation between the defects of crystal lattices of inorganic compounds and their non-stoichiometries and proved the inevitable existence of the latter in any ionic crystal. Minor deviations from stoichiometry are usually described within the framework of disordering models with formation of non-interacting vacancy-type point defects, incorporated atoms or antistructural defects. Defect formation is accompanied by pronounced changes in electrical, magnetic, optical, thermal and mechanical properties of solid-phase compounds; therefore, an analysis of their non-stoichiometries is one of the most important directions in inorganic chemistry of solids.[41]

The development of methods for coulometric titration in reversible electrochemical circuits with solid electrolytes possessing ionic (anionic or cationic) conductivity [42] has led to considerable progress in the study of non-stoichiometry, in particular of compounds manifesting a narrow range of homogeneity. Quasichemical models of defect formation in inorganic compounds were successfully employed for the description of functional properties of semiconductors and ferrites. For example, the results of studies of non-stoichiometry as a function of oxygen pressure and temperature using a quasichemical approximation have provided a clue to the solution of problems related to directed doping of ferrites.[43]

Defect formation in ferrospinels MFe_2O_4 can be described by the following system of equations:

$$O \rightleftharpoons e' + h^{\bullet}, \qquad K_1 = np,$$

$$Fe_{Fe}^{x} \rightleftharpoons Fe_i^{\bullet\bullet\bullet} + V_{Fe}^{\prime\prime\prime}, \qquad K_2 = [Fe_i^{\bullet\bullet\bullet}][V_{Fe}^{\prime\prime\prime}],$$

$$M_M^{x} \rightleftharpoons M_i^{\bullet\bullet} + V_M^{\prime\prime}, \qquad K_3 = [M_i^{\bullet\bullet}][V_M^{\prime\prime}],$$

$$M_M^{x} + Fe_{Fe}^{x} \rightleftharpoons M_{Fe}^{\prime} + Fe_M^{\bullet}, \qquad K_4 = [M_{Fe}^{\prime}][Fe_M^{\bullet}],$$

$$O \rightleftharpoons V_M^{\prime\prime} + 2V_{Fe}^{\prime\prime\prime} + 4V_O^{\bullet\bullet}, \qquad K_5 = [V_M^{\prime\prime}][V_{Fe}^{\prime\prime\prime}]^2[V_O^{\bullet\bullet}]^4,$$

$$O_O^{x} \rightleftharpoons 1/2\,O_2 + V_O^{\bullet\bullet} + 2e', \qquad K_6 = [V_O^{\bullet\bullet}]n^2p_{O_2}^{1/2},$$

$$Fe_2O_3 \rightleftharpoons 2Fe_{Fe}^{x} + 3O_O^{x} + V_O^{\bullet\bullet} + V_M^{\prime\prime}, \qquad K_7 = [V_O^{\bullet\bullet}][V_M^{\prime\prime}]a_{Fe_2O_3}^{-1},$$

$$3[Fe_i^{\bullet\bullet\bullet}] + 2[M_i^{\bullet\bullet}] + [Fe_M^{\bullet}] + 2[V_O^{\bullet\bullet}] + p = [M_{Fe}^{\prime}] + 3[V_{Fe}^{\prime\prime\prime}] + 2[V_{Fe}^{\prime\prime\prime}] + n.$$

In addition to activity ($a_{Fe_2O_3}$), temperature (T) and partial oxygen pressure (p_{O_2}), the role of variables is played by the concentrations of all possible types of point defects, *viz.*, $[M_i^{\bullet\bullet}]$, $[Fe_i^{\bullet\bullet\bullet}]$, $[M_{Fe}^{\prime}]$, $[Fe_M^{\bullet}]$, $[V_O^{\bullet\bullet}]$, $[V_M^{\prime\prime}]$, $[V_{Fe}^{\prime\prime\prime}]$, n, p, which can be calculated as functions of the parameters of state. Whilst the quasichemical approach is not strictly accurate, its practical utility leaves no doubt.

Figure 5 shows a defect formation diagram plotted in the coordinates $\log[i]-f(\log p_{O_2})$ at constant values of T and $a_{Fe_2O_3}$, where $[i]$ is the concentration of the defects of the ith type. From the diagram it follows that changes in thermal treatment and sintering regimes of ferrites can underlie the transitions from electron to hole conductivity and the predominance of ionic conductivity for compositions close to stoichiometric.

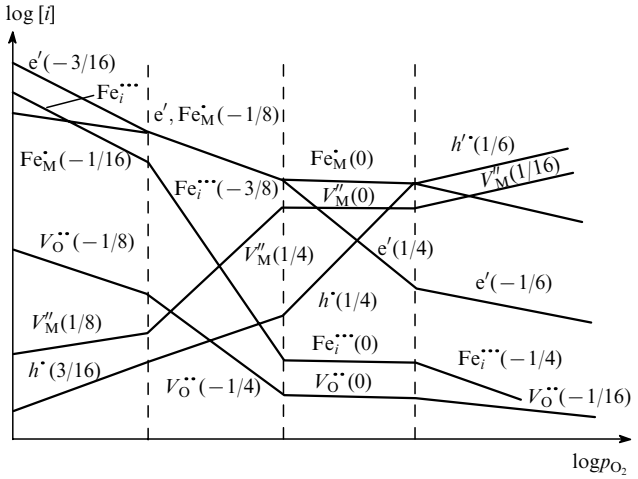

Figure 5. A diagram of defect formation in a crystal lattice of a ferrospinel at constant temperature and constant activity of Fe_2O_3. The individual segments of the dependences show the predominant defects; the numbers in parentheses indicate the slopes.

Passage to inorganic compounds with more pronounced non-stoichiometries casts doubts on the existence of a strict correlation between the non-stoichiometry index and the concentration of predominant point defects as is implied by the quasichemical approximation.

Changes in the structures of binary or more complex crystals as a result of increasing non-stoichiometries have a different origin. Sometimes, they are related to the formation of associates, the simplest being bivacancies, to a spatial ordering of superstructure-type defects and finally to annihilation of point defects accompanied by changes in the types of bonds of coordination polyhedra and formation of the so-called crystallographic-shift structures of the type of homologous series: M_nO_{3n-1} where n = 8, 9, 10, 11, 12 and 14. However, the concept of discrete compositional changes resulting necessarily from rearrangements of coordination polyhedra upon crystallographic shift (CS) is questionable.

According to Anderson,[44] there exist many systems possessing infinitely adaptable structures, *i.e.*, the phases that maintain a high level of structural organisation despite continuous composition changes by virtue of changes in the repetition frequencies of CS planes or orientation of the latter with the preservation of fragments of the matrix structure rather than involvement of point defects. The former process is discrete and gives rise to the formation of various homologues of the same series, while the latter is continuous. Their combination ensures the continuity of compositional changes within the same order. An infinitely adaptable structure was found, for example, in phases with variable compositions of $Y(OF)_{2.13-2.22}$, solid solutions ($TiO_2-Cr_2O_3$) and cerium–cadmium alloys.

The imperfections of structural patterns, *e.g.*, coherent intergrowth of sites with different orientations of CS planes, are predominant defects in the case of non-stoichiometric phases with a high level of structural organisation. These defects, which are commonly referred to as Wadsley defects, strongly affect the properties of solid phases and their behaviour under the action of various chemical and physical agents.

It is clear that the compositions and structures of non-stoichiometric compounds do not always correspond to the equilibrium conditions of their formation. On the contrary, very often the conditions of synthesis, thermal treatment and existence of such compounds are far from equilibrium and the net result is determined by the rates of processes involved. For example, nickel monoxide prepared by thermolysis of nickel nitrate at moderate heating temperatures may contain excess oxygen up to the composition $NiO_{1.5}$, whereas nickel monoxide synthesised in air under equilibrium conditions has the composition NiO_{1-x}, where $x = f(T, p_{O_2})$. At 1373 K and $p_{O_2} = 2 \times 10^{-9}$ atm, the value of x is equal to 1.8×10^{-8}.

Undoubtedly, the fundamental principles of chemistry of non-stoichiometric compounds considered above are valid for any newly produced functional materials, be they superconducting cuprates, manganites with superhigh magnetic resistance or cerates manifesting high proton conductivity. At the same time, any of these materials have specific features of their own and demand analysis of their non-stoichiometries as in the case of semiconducting or ferrite systems.

The design of superconducting materials able to maintain high levels of critical currents in strong magnetic fields has become possible owing to the passage from yttrium–barium cuprate $YBa_2Cu_3O_z$ with strict cationic stoichiometry to neodymium–barium cuprate $Nd_{1-x}Ba_{2-x}Cu_3O_z$ with a broad range of homogeneity for both oxygen and cations. It was found also that a change in the cationic composition within the homogeneity zone is accompanied by evolution of the structure from 123 *via* 336 to the superstructure 213.[45] The use of a TTT diagram, which characterises the behaviour of a metastable, slowly evolvable system, is necessary because of an extremely low rate of cationic ordering in neodymium–barium cuprates.

VI. Chemistry of elements in unusual oxidation states

The design of novel functional materials based on chemical elements in unusual oxidation states is a nontrivial process, at least because the unusual oxidation state is equivalent to the instability of a particular state of an element. Hence, the phenomenon of the appearance of one or another unusual oxidation state of a chemical element is insufficient from the practical point of view, one should also be sure that the lifetime of a chemical element in an unusual oxidation state is commensurate with the period of functioning of the material containing this element. A significant contribution to the chemistry of elements in unusual oxidation states has been made by researchers of the Institute of Chemical Physics of the RAS and the Department of Chemistry of the MSU. The former have succeeded in obtaining Np(VII), Pu(VII), Am(VII), Cm(VI), Cm(V) (see Ref. 46) and a series of actinides and lanthanides in lower oxidation states,[47] the latter have demonstrated the possibility of existence of Tm(IV) and found that the tetrad effect characteristic of lanthanides and actinides is more significant for 'distant' lanthanides than for 'near' lanthanides in solid compounds.[48]

At first, the values of extremely high oxidation states for transition metals of Groups 3–11 of the Periodic System correlate with the group number, but then this correlation is absent, which is determined by the electronic structure or, more precisely, by disturbances in the fine balance between binding and loosening forces in atomic orbitals and increasing instabilities of the corresponding compounds in their extremal oxidation states.

'Matrix' systems formed upon crystallisation from homogeneous media (solutions, melts), co-precipitation or solid-phase synthesis present the greatest interest for specialists in materials sciences. Matrix systems containing Fe(IV), Fe(V), Fe(VI) and Co(VI) were prepared by reactions of binary oxides with dopant oxides.[49]

An alternative approach consists of the so-called constitutional substitution where the doping ion occupies the host metal positions of the matrix; the properties of which predetermine the oxidation state of the doping ion. Thus Fe(V) is stabilised in vanadium pentaoxide; this oxidation state unusual for iron is formed upon dissolution of trivalent iron oxide in a melt of vanadium pentaoxide. However, the formation of Fe(V) could be observed only after quenching of the samples into metallic mercury.

The formation of matrix systems under conditions of oxidative synthesis (sintering of Group 3–11 metal oxides with alkali

metal peroxides) revealed certain peculiarities of the final products which are determined by the properties of the matrix metal and the mechanisms of reactions. Thus it was found that the final products prepared with the use of molybdate and tungstate matrices contained extrinsic magnetics, *i.e.*, Mo(V)- and W(V)-containing exchangeable clusters of the ferro- and antiferromagnetic type. The initial steps of the reactions may involve the formation of bronze-type derivatives, trace amounts of which are partly stabilised in final products and elicit the corresponding magnetic responses.[50]

Yet another line of research related to the synthesis of bismuth derivatives in lower oxidation states has been described.[51] The authors have succeeded in preparation of homonuclear polycations of the types Bi_5^{3+}, Bi_8^{5+} and Bi_9^{5+}. A fragment of the crystal structure and the main structural elements of compound $Bi_{10}Nb_3Cl_{18}$ synthesised upon heating of a $Bi-BiCl_3-NbCl_5$ mixture to 550 °C are shown in Fig. 6. In the structure of this compound, the polycations Bi_9^{5+} are surrounded by octahedral counteranions $NbCl_6^{2-}$ containing Nb(IV). Usually, it is $NbCl_6^-$ ions containing Nb(V) that are more stable.

The crystal structure of compound Ni_8Bi_8SI synthesised by Baranov *et al.*[52,53] contains unusual bimetallic infinitely one-dimensional cationic columns of $[Ni_8Bi_8SI]_\infty^+$ which are made up of square nickel antiprisms surrounded by a sheath of bismuth atoms (Fig. 7). In this compound, nickel and bismuth atoms exist in unusually low oxidation states, which are responsible for the formation of such an unusual system of metallic bonds between the metal atoms. This structure can be regarded as consisting of a set of 'molecular' metal wires (a thread of nickel antiprisms) enclosed in an insulating matrix (a sheath of bismuth atoms). According to its physical properties, this compound represents a one-dimensional metallic conductor and a Pauli paramagnet.

VII. Chemistry of inorganic biomaterials

Natural ageing of biomaterials, the building elements of any living organism, shortens their lifetime. What is most surprising is that ageing problems are inherent in such strong, at first glance,

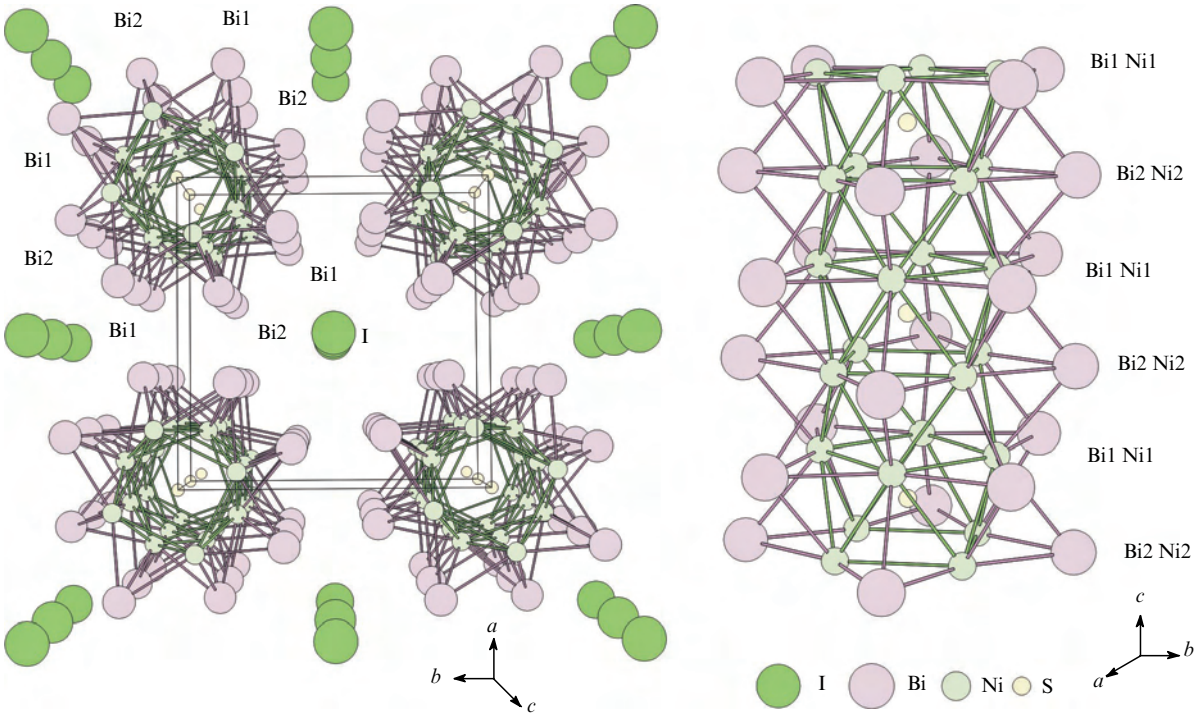

Figure 7. The crystal structure of Ni_8Bi_8SI.

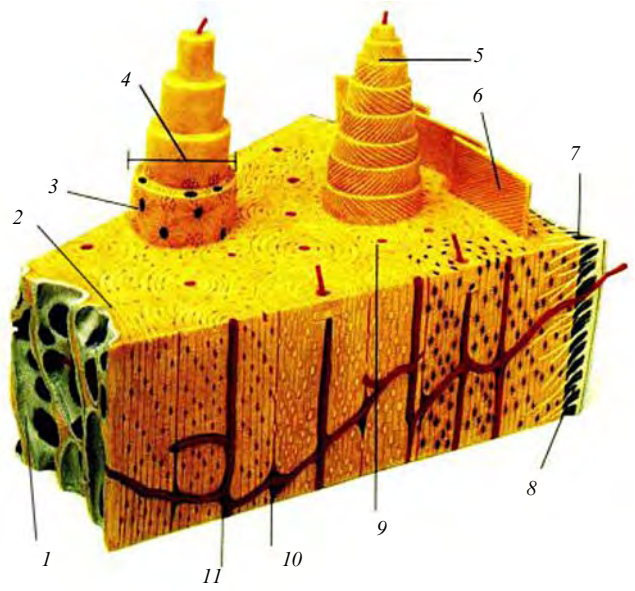

Figure 8. The levels of structural organisation of the bone tissue. (*1*) Internal bone tissue membrane, (*2*) intermediate plate, (*3*) osteocyte (bone cell), (*4*) osteon (Haversian system), (*5*) Haversian plate, (*6*) outer plate, (*7*) the Sharpie fibre, (*8*) peroosteum, (*9*) Haversian canal, (*10*) lacuna, (*11*) the Volkmann vessel.

natural materials as bone and dental tissues. From the standpoint of materials science, the bone tissue is a composite material which comprises both inorganic and organic components,[54–57] *viz*., hydroxyapatite $Ca_{10}(PO_4)_6(OH)_2$ (63 mass %) and the protein collagen (20 mass %), respectively (Fig. 8). In addition to Ca^{2+} and PO_4^{3-}, bone tissue contains appreciable amounts of Na^+, Mg^{2+}, K^+, Cl^-, F^- and CO_3^{2-} ions. The physicochemical character of the interactions between bone components, which ensures, in particular, its high strength properties, has not been finally established yet. Even the use of modern biotechnological approaches does not permit one to construct a full analogue of the natural bone tissue. Therefore, the use of artificial materials (implants) is still the only way to restore functioning of large regions of damaged bones.

Metal alloys based on low-toxic titanium are used in those cases where it is required to restore the bones of parts of the body exposed to heavy cyclic loads (*e.g*., hip joints). In other cases, preference is given to ceramic or composite materials based on calcium phosphates; their chemical compositions are similar to that of bone.[54–58] Among other modern trends in the field of implant design, special mention should be made of 'regeneration', *viz*., synthesis and application of materials able to stimulate regenerative processes in damaged tissues owing to their active interaction with the organism.[54] Such implants cannot be prepared without a thorough knowledge of mechanisms of reactions occurring in bone tissues in all steps of their evolution.

It is believed that not only the chemical composition, but also the morphology of synthetic hydroxyapatite (HAP) crystals are important characteristics that determine the response of the organism to the exogenous material of an implant. In this context, an ideal material should possess the chemical composition and granulometric properties similar to those of a bone biomineral, *e.g*., non-stoichiometric hydroxyapatite, $Ca_{10-x}(HPO_4)_x.(PO_4)_{6-x}(OH)_{2-x}$ ($0 < x < 1$). Its crystals have the shapes of plates ($40 \times 20 \times 5$ nm) with an axis c lying in the crystal plane (sp.gr. $P6_3/m$ of the hexagonal system; $a = b = 9.432$ Å, $c = 6.881$ Å) (Fig. 9).[55]

Calcium phosphate-based ceramic materials prepared by high-temperature treatment are routinely used in clinical practice.[59–62] Strong hydroxyapatite ceramic materials are chemically

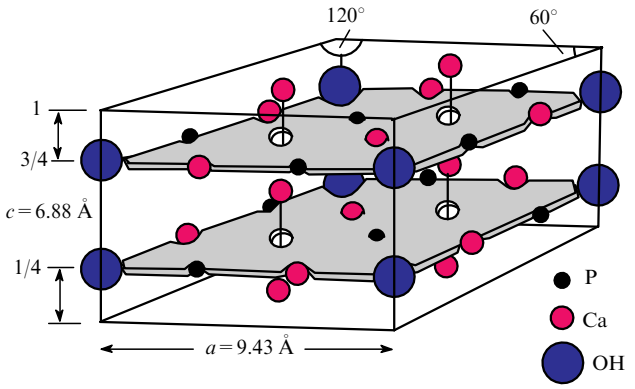

Figure 9. A simplified representation of a unit cell of hydroxyapatite.

inert, which significantly decelerates the resorption of the material and inhibits the growth of the contact bone tissue. Large specific surfaces of calcium phosphates prepared by solution methods (up to 100 $m^2\ g^{-1}$) make them more reactive in comparison with their high-temperature counterparts ($\sim 1\ m^2\ g^{-1}$). The results of the use of calcium phosphate-containing cements and biphasic composite materials suggest that in some cases the use of materials that could serve as bioapatite 'sources' *in vivo* is a simpler and more efficient approach (Fig. 10).[54, 59, 61]

Large-scale production of materials strictly corresponding to calcium phosphates of biological origin as regards their chemical and structural characteristics is very problematic. Nevertheless, there is every reason to believe that chemical and morphological match of a biomaterial and a bone mineral is one of the basic principles in the design of novel materials for biomedical purposes. Deviations of the compositions and sizes of artificial crystals from those of their natural counterparts can be employed for the directional synthesis of biomaterials with predetermined bioactivities. The practical implementation of such a programme requires the elucidation of a quantitative relationship, first, between chemical composition and micromorphology of calcium phosphate crystals and parameters of their solution synthesis and, second, between micromorphological parameters and bioactivity of the material.

The existing methods for the synthesis of HAP enable the preparation of highly dispersed powders with particle shapes varying unpredictably in a rather broad range, *viz*., from equiaxial to needle-shaped, depending on conditions.[55, 56, 63] Nevertheless, no explicit and quantitative information about the effects of parameters of HAP synthesis on the morphology of the target

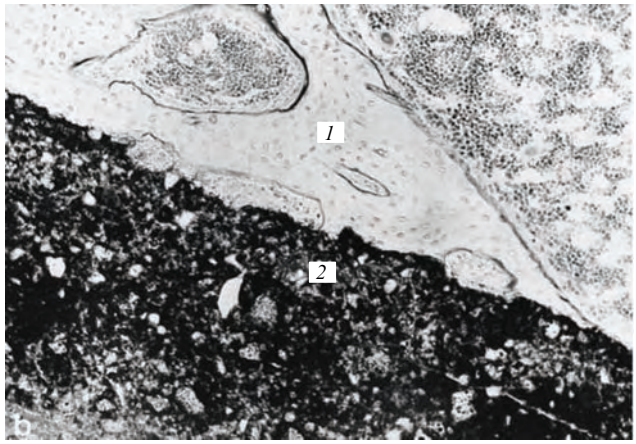

Figure 10. Formation of new bone tissue at the boundary of a cement implant with the composition 75% $Ca_3(PO_4)_2$ + 20% $Ca_4P_2O_9$ + 5% $CaHPO_4$.[62] (*1*) New tissue, (*2*) implant.

product is available. It is noted that samples of calcium phosphate powders prepared according to one synthetic procedure elicit different responses of an organism up to a complete rejection of the material. This brings forth a vast variety of chemical and materials science-related problems connected with the synthesis of calcium phosphates with predetermined compositions and micromorphological characteristics as well as with prediction of their bioactivities *in vitro* and development of methods for the bioactivity correction by chemical modification of the synthetic product.

In practice, synthesis of HAP is mainly carried out in aqueous solutions and the existing methods can be classified into three main groups: (1) precipitation in solutions with constant or variable composition; (2) hydrothermal synthesis and (3) hydrolysis of calcium phosphates.[55, 56, 58, 63, 64] Precipitation of HAP from aqueous alkaline solutions yields fine-crystalline calcium hydroxyapatite.

$$10\,CaX_2 + 6\,M_2HPO_4 + 8\,MOH = Ca_{10}(PO_4)_6(OH)_2 + 20\,MX + 6\,H_2O,$$

where M = Na, K, NH_4, H; X = Cl, NO_3, CH_3COO, OH.

The formation of HAP is usually preceded by precipitation of amorphous calcium phosphate.[57, 65] The degree of crystallinity of the precipitated HAP increases with temperature and duration of ageing, while its non-stoichiometry, *i.e.*, the deviation of the Ca/P ratio from 1.67, increases with a decrease in pH, temperature and duration of synthesis.[55] The hydroxyapatite powders prepared by solution methods have a large specific surface ($\sim$100 m^2 g^{-1}) and a small size of crystallites ($\sim$100–200 nm). The size and the habitus of crystals depend on a number of factors, such as duration of crystallisation, temperature, composition of solution, degree of supersaturation, ionic strength, pH, the order of addition and mixing rates of reactants.[55, 56, 58, 64] The diversity of morphology of HAP crystals can be attributed to the fact that the synthesis is performed under strictly non-equilibrium conditions; the shape of the crystals strongly depends on the presence of admixtures.[65–68] In the presence of carbonate ions in the solution, carbonate apatite crystals of type A [$Ca_{10}(PO_4)_6(OH)_{2-x}\cdot(CO_3)_{x/2}$] or type B [$Ca_{10-x}Na_x(PO_4)_{6-x}(CO_3)_x(OH)_2$] differing in shape (plates or needles) depending on the carbonate content are formed.

As was mentioned above, the micromorphology of HAP powders is an important property which largely determines the areas of application of calcium phosphate-based biomaterials. It is of note that the choice of experimental conditions for the synthesis of HAP crystals of predetermined morphology implies knowledge of the contribution of each parameter (factor) of synthesis to, and of the result of their mutual action (interaction of factors) on, the two characteristic sizes of anisotropic HAP crystals, *viz.*, along and perpendicular to the axis [001]. This information, which has not been explicitly and quantitatively documented in the literature concerning the methods of apatite synthesis, is considered in a review.[64] A systematic study of effects of various parameters of HAP synthesis by precipitation from salt solutions (initial concentration of reagents, pH and temperature) on the sizes and shapes of the crystals formed has been carried out. The morphological characteristics of HAP crystals were established through mutual application of a comprehensive X-ray diffraction analysis and transmission electron microscopy (Fig. 11).

Mathematical models based on the results of statistical analysis of morphological characteristics of crystals allowed quantitation of various factors on HAP synthesis by precipitation. These factors (separately and in combination) determine ionic equilibria in solutions, since changes in temperature, pH and initial concentrations of solutes induce changes in the concentrations of ionic forms as can be judged from the calculations on activities of ions and ion pairs. One can state that there is a tendency towards an increase in the size of HAP crystals as the activities of the ion associates of $CaPO_4^-$ and $CaOH^+$ in solutions increase. The formation of HAP occurs in two steps. Amorphous calcium phosphate is formed from ion associates with the composition $Ca_9(PO_4)_6$ (the 'Pozner clusters') by a sol–gel transition mechanism in the first, relatively fast step. This has a mesoporous structure and hydroxyapatite nanocrystals formed in the second step by an AFC dissolution–HAP precipitation mechanism inherit porosity.[64, 65]

The use of hydrolytic reactions of calcium orthophosphates of the type

$$3\,Ca_3(PO_4)_2 + H_2O = Ca_9HPO_4(PO_4)_5OH$$

is yet another convenient approach to the synthesis of HAP crystals with different micromorphological features (needles, plates) [55, 63, 69, 70] (Fig. 12).

The sizes of HAP crystals obtained upon heating of solutions exceed significantly those synthesised by precipitation ($\sim$0.5–5 μm and $\sim$20–100 nm, respectively). It was noted above that materials with particles of submicrometric sizes are preferable for practical use. If HAP are prepared by hydrolysis of poorly soluble calcium orthophosphates [$CaHPO_4$, $CaHPO_4\cdot 2\,H_2O$, α- and β-$Ca_3(PO_4)_2$, $Ca_8(HPO_4)_2(PO_4)_4\cdot 5\,H_2O$, $Ca_4(PO_4)_2O$], the composition of the solution can be considered as being quasi-equilibrium, this depending on the solubility product of the solid phase. Like the majority of heterogenous processes, hydrolysis of calcium orthophosphates is characterised by a low rate, since the layer of the product formed blocks the surface of the starting material. The reaction can be accelerated by increasing the temperature and/or activating the

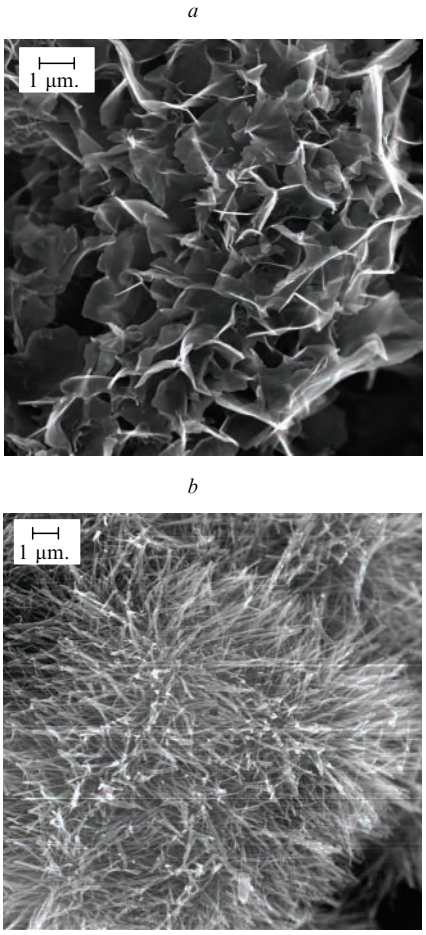

Figure 12. Micrographs of samples prepared by hydrolysis of α-$Ca_3(PO_4)_2$ at 40 (*a*) and at 100 °C (*b*).

reagent surface by sonication. It was shown that the conversion rate of a $CaHPO_4 - Ca(OH)_2$ mixture into HAP upon sonication of the suspension is 20% – 30% per 1 h, which is comparable with the rate of HAP synthesis from the same mixture at 60 °C. This is accompanied by the formation of aggregates consisting of spherical hydroxyapatite particles with a diameter of ~100 – 300 nm.[64]

The biological activities of calcium phosphates can be increased by increasing the specific surfaces of the powders and decreasing the sizes of the crystallites as well as by changing the physicochemical characteristics of the surface. An alternative approach consists of chemical modification of calcium phosphates aimed at preparing materials able to undergo active resorption upon interaction with body fluids. In this context, special attention is given to the development of methods for the synthesis of carbonate-containing hydroxyapatite $Ca_{10-0.5x}(PO_4)_{6-x}(CO_3)_x(OH)_2$ as well as silicon-containing hydroxyapatite, $Ca_{10}(PO_4)_{6-x}(SiO_4)_x(OH)_{2-x}$.[64,68] The latter can be synthesised by precipitation of HAP from solution using a reaction of amorphous calcium phosphate with tetraethoxysilane in an alkaline medium. It was found that silicon-containing HAP is more soluble in weakly acidic solutions than non-substituted hydroxyapatite.[64]

The very fact of design of materials stimulating osteogenesis suggests that the nearly half a century-old history of intense application of biomaterials has led to the comprehension that regeneration and replacement of bone tissue is an extremely complex and ambiguous problem. The use of one or another material depends on both the biomedical characteristics of a bone defect and, perhaps, the clinical case. Therefore, the solution of this problem is possible only if a broad range of biomaterials is available, while the choice of a maximum suitable material, which meets all the specific requirements, is the key to success.

VIII. Inorganic synthesis of functional materials using sonication, hydrothermal treatment and microwave irradiation

Inorganic synthesis of functional materials always requires the activation of the starting reactants whatever the mechanisms of chemical transformations involved. The simplest method is heating; its efficiency is estimated from the activation energy in the Arrhenius equation. However, this parameter, which is determined experimentally as a temperature coefficient of the reaction rate, has a physical meaning only if it is associated with a particular elementary process which limits the reaction rate in a given temperature range.

In real systems used in the synthesis of functional materials, chemical interactions involve at least two fundamental processes, *viz*., the chemical reaction itself and transfer of a substance to the reaction zone. Since the latter occurs owing to diffusion and the diffusional mobility of components of the solid is determined by the imperfection of its structure, it can be expected that the defects influence substantially the conditions of the solid-phase synthesis. This in turn suggests that the rate and direction of chemical transformations can be controlled through physical actions, which occur either simultaneously with the thermal activation or separately. It is often recommended that high-temperature factors are excluded, since both the reactants and the reaction products may be subject to undesirable changes which include:

— dissociation of the solid-phase product of inorganic synthesis, *e.g*., thermal dissociation of ferrites having a spinel structure according to the reaction:

$$6\,MFe_2O_4 \longrightarrow 4\,Fe_3O_4 + 6\,MO + O_2\,.$$

The magnetic and dielectric properties of the material are usually deteriorated by the reaction products;

— changes in the composition of reaction products due to the loss of volatile components, especially in gaseous media containing water vapour and CO_2. These changes are substantial, *e.g*., in the synthesis of solid electrolytes based on alkali metal polyaluminates and lithium-containing ferrites.

The efficacy of sonication in reactions occurring in various reaction systems in the synthesis of materials [71,72] depends on the phase state of a system. In liquid-phase systems (solutions, melts), cavitation, *i.e*., the formation, oscillation and collapse of microvesicles, is the main result of sonication which leads to the formation of short-living hot zones with characteristic temperatures up to ~5000 K and pressures up to 1000 atm. In some cases, 'collapse' of cavitation vesicles is accompanied by formation of intense microcurrents of fluids and potent shock waves, which enhance the mass transfer. As a consequence, in physicochemical systems (both homogenous and heterogenous) decomposition of volatile compounds, like metal carbonyls, acceleration of redox reactions, formation of stable emulsions and suspensions and disaggregation of particles in colloid solutions take place. Sonication of liquid-phase systems has proved to be efficient in classical reactions of organic and inorganic synthesis [73,74] as well as in the synthesis of amorphous and crystalline metal, oxide and carbide nanopowders.[75,76]

In solid-phase systems, sonication is efficient only if a certain power threshold of acoustic vibrations is exceeded concomitantly with a significant (by one or two orders of magnitude) increase in the number of dislocations and in the values of effective diffusion coefficients and the formation of new interphase contacts.[77,78] As a consequence, sonication of reaction mixtures may change the reaction mechanism, decrease considerably the apparent activation energy and the temperature of vigorous interactions of the reactants.[79–81] Acoustic activation of solid-phase processes enables synthesis of various oxide materials [80,81] and active forms of

precursors [82] and, in some special cases, directed modulation of the structure-dependent properties of solid-phase products.[83]

It has been found [83] that the concentration of structural defects in sonicated compounds depends non-linearly on the amplitude of input acoustic vibrations and the temperature. The defectiveness of samples increases significantly (by more than one order of magnitude), in a definite temperature interval and at a definite ultrasound volume, *i.e.*, the acoustic and thermal effects are synergistic.

At fixed temperatures, a significant (2–3-fold) increase in effective diffusion coefficients of carbon in steels is observed only at definite acoustic input vibration amplitudes.[84] Similarly, at fixed ultrasound volume the defectiveness of simple metal oxides increases anomalously, however, only in a narrow temperature range.[85] It is of note that the temperature range corresponding to the maximum activation is determined by the chemical nature of the oxides that undergo sonication. Thus it has been shown that in high-temperature sonication of iron(III) oxide ultrasonic generation and annihilation of defects and their thermal annealing compete.[85] The rates of each of these processes depend differently on temperature; therefore, the defectiveness of α-Fe_2O_3 and the corresponding reactivity change non-linearly reaching a maximum at $\sim$800 °C.

Combination of different factors allows one to change both the kinetics and the mechanisms of solid-phase reactions. Studies of interactions in the system $Fe_2O_3 + Li_2CO_3$ have shown [79] that superposition of an acoustic field at definite temperatures induces changes in the reaction mechanism, *viz.*, the chemical interaction at the interphase becomes a limiting step, whereas under normal conditions this reaction is limited by the formation of nuclei and their progressive diffusion-dependent growth. In turn, the reaction rate increases significantly with a change in the reaction mechanism and an increase in the mass transfer rate. It is noteworthy that in this case the temperature, which corresponds to the maximum effect of the ultrasound, is lower than the temperature of the onset of the reaction in the system under ordinary conditions, *i.e.*, sonication allows one to reduce significantly (by 100–150 °C) the temperature of synthesis. Studies of solid-phase reactions of ferrite formation

$$LiFeO_2 + 2\,Fe_2O_3 \xrightarrow{530-650\ ^\circ C} LiFe_5O_8\,,$$

$$ZnO + Fe_2O_3 \xrightarrow{600-800\ ^\circ C} ZnFe_2O_4\,,$$

$$NiO + Fe_2O_3 \xrightarrow{600-800\ ^\circ C} NiFe_2O_4$$

have shown [86, 87] that temperatures of the onset of the reaction decrease by 50–200 °C in the case of sonication, while the time of synthesis of monophasic ferrites diminishes 1.5–2-fold. A change in the reaction mechanism is due to a direct formation of the reaction zone in the acoustic field; its most characteristic feature is the presence of a well-defined initial step of a sonochemical reaction mediated by a special mechanism of formation of intercrystallite contacts in the ultrasonic field.

Of special interest are studies of effects of sonication on hydrothermal synthesis of simple and complex oxides and chalcogenides.[88] First of all, it has been established [89] that sonication causes cavitation both in hydrothermal solutions and ordinary liquid media the intensity of which at 250 °C is 70%–80% of that observed at 25 °C. Cobalt, titanium and zirconium oxides as well as ferrites $Ni_{1-x}Zn_xFe_2O_4$ were used as subjects in these studies. Hydrothermal treatment and sonication of a suspension of an amorphous gel of $Co(OH)_2$ in water at 250 °C yielded the phase Co_3O_4; no such phase was formed without sonication. Most probably, sonolysis of water in hydrothermal solutions gives rise to hydrogen peroxide which induces the oxidation of Co(II) into Co(III). The particle sizes of the oxide products of hydrothermal synthesis in an ultrasonic field are significantly smaller than those of an analogous product synthesised without sonication (Fig. 13).

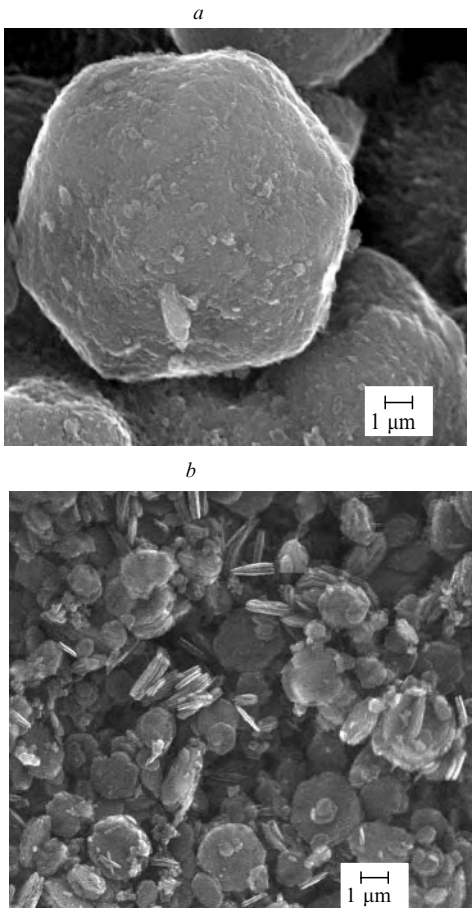

Figure 13. Micrographs of products of hydrothermal syntheses in the absence (*a*) and in the presence of an ultrasonic field (*b*).

Hydrothermal treatment of amorphous gels $ZrO_2 \cdot n\,H_2O$ and $TiO_2 \cdot n\,H_2O$ and simultaneous sonication result in a significant increase in the rates of their crystallisation, whereas sonication of products of hydrothermal synthesis favours the formation of thermodynamically more stable phases (Fig. 14).[90]

Although the idea of large-scale application of microwave heating for domestic and technological purposes was realised rather long ago [91] and numerous studies were undertaken in the past decade on the microwave-induced synthesis and sintering of functional materials,[92, 93] the physicochemical nature of the processes occurring in microwave synthesis still remains obscure. Oxides, hydroxides, salts or their mixtures were used as precursors for various functional materials including ferrites, manganites, cobaltites, nickelates and cuprates subject to microwave radiation.[94–96]

According to theoretical concepts on the interaction of microwave radiation with matter,[97] effective absorption of energy requires the presence in the matter of either dipoles capable of changing their orientation and rotating under the action of microwave radiation, or free charge carriers able to move in an applied microwave field. Many inorganic salts possess low electronic, hole or ionic conductivities. At the same time, water molecules, which are present in the crystal lattices of crystal hydrates, and some anions have high dipole moments. Thus, in the majority of salt systems the most probable mechanism of absorption of microwave radiation is related to dipoles.

It has been found experimentally [94] that compounds devoid of chemically bound water (carbonates, nitrates and oxalates of alkali and alkaline-earth elements) virtually do not adsorb microwave radiation. In contrast, crystal hydrates of inorganic salts interact with a microwave field, the mode of this interaction being

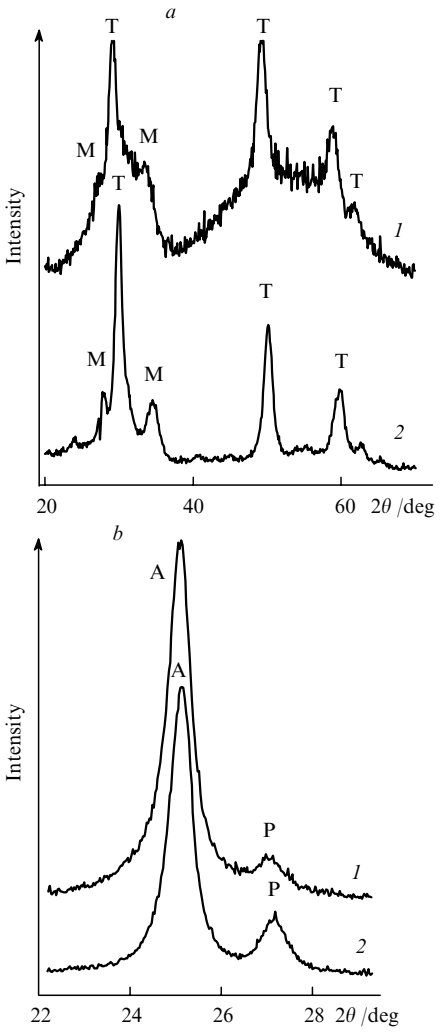

Figure 14. X-ray diffraction spectra of products of hydrothermal treatment of $ZrO_2 \cdot n\,H_2O$ (*a*) and $TiO_2 \cdot n\,H_2O$ (*b*) performed at 250 °C for 3 hours without (*1*) and with (*2*) sonication.

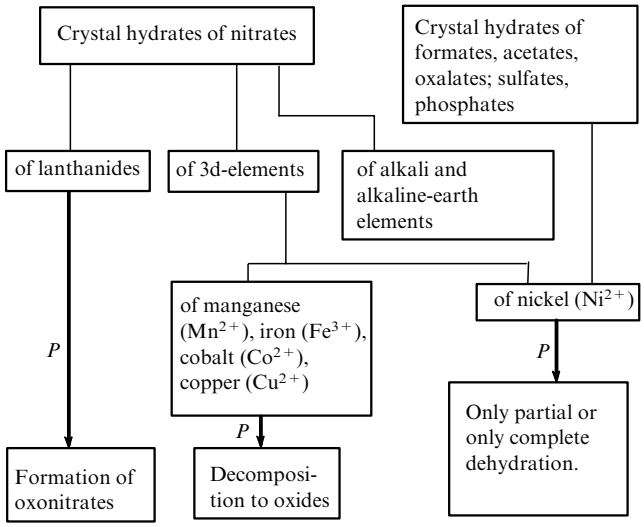

Figure 15. Interaction of crystal hydrates with microwave radiation. *P*, energy of a microwave field.

dependent on the chemical nature of the cations (Fig. 15). Later, it was shown that the decomposition of crystal hydrates in the microwave field to oxides takes place only if the oxide formation occurs prior to the removal of all the water present in the system. Of all the salt crystal hydrates tested in this study,[94] only 3d-metal nitrate crystal hydrates meet this requirement and can be used as active (with respect to microwave radiation) components in the synthesis of complex oxide phases. A generalised scheme of interaction of metal salt crystal hydrates with microwave radiation is shown in Fig. 16. Studies of salt precursors have demonstrated the expediency of *in situ* application of microwave treatment of salt mixtures in solid-phase reactions, since highly dispersed oxide particles formed upon decomposition of salt mixtures and distributed uniformly throughout the reaction bulk react actively with one another.

Specific 'non-thermal' effects of microwave radiation caused by generation of ionic currents on intercrystallite and interaggregate boundaries make a significant contribution to diffusional processes occurring in the solid-phase reactions; the intensity of ionic currents increases in highly dispersed systems. Consequently, microwave irradiation of a reaction mixture can be accompanied by an increase in the rate and a decrease in the temperature of solid-phase interactions. It is this effect that is observed in synthesis of functional materials.[98–105]

However, it would be erroneous to think that microwave-induced synthesis always makes use of salt precursors able to convert microwave energy into thermal energy starting from room temperature. It is known that the energy (*P*) absorbed by an object placed into a uniform microwave field is expressed by the equation:

$$P = 2\pi f \varepsilon_0\, K \tan\delta\, |E|^2,$$

where f is the microwave frequency, ε_0 is the vacuum permittivity, K is the dielectric constant of the sample, $\tan\delta$ is the dielectric loss tangent and E is the microwave field intensity in the sample under assay. The K and δ values depend on temperature and on the nature of the phases used as precursors. For example, the mixture $SrCO_3 - Co(NO_3)_2 \cdot 6\,H_2O - Fe_2O_3$ used in the synthesis of $SrFeCo_{0.5}O_y$, a promising electron-ionic conductor, can absorb low-wavelength energy only in those cases where microwave irradiation is preceded by ordinary heating as a result of which the oxidative thermolysis of cobalt nitrate yields Co_3O_4. The latter effectively absorbs microwave energy and favours rapid heating of the entire reaction mixture to temperatures above 1000 °C, although other components of the reaction mixture ($SrCO_3$, Fe_2O_3) are inert in the microwave field and are thermally activated only upon interaction with Co_2O_3.[106]

Non-stoichiometric oxides of the type TiO_{2-x} or Ta_2O_{5-x},[107] hydroxides or basic salts[95] as well as amorphous carbon used as soot[108] or a highly dispersed metal[109] can be used as active components for microwave irradiation. In the manufacture of compact piezoelectric ceramic materials of the type $(Ba,Sr)TiO_3$ (see Ref. 110) or ion-conducting ceramic materials of the type Na-β-alumina,[111] the powdered precursor with the identical composition is synthesised by ordinary heating, whereas sintering is performed in a microwave field.

And, finally, the use of the so-called monomodal microwave heating[112,113] based on the propagation of an electromagnetic beam from a magnetron along a waveguide where a standing wave is established opens up radically new opportunities for inorganic synthesis, for it allows one to focus the microwave energy in a small volume of the reaction mixture and to initiate very rapidly chemical and structural transformations that are impossible in the case of ordinary thermal or multimodal microwave heating.

IX. Conclusion

In the past two decades, inorganic chemistry has experienced impressive changes owing to its integration with physical chemistry, physics of solids, organic chemistry and biochemistry and the use of advanced instrumental methods. The range of subjects of inorganic chemistry has been extended considerably. Now, these encompass not only chemical compounds, but also materials, sometimes even those which contain, along with an inorganic component, organic, polymeric or biopolymeric fragments. At present, studies of the majority of subjects are carried out at several levels. In addition to crystal or molecular structures, they involve electronic and magnetic structures of various compounds, specific defects of their crystal structures, distribution of microadmixtures, structures of interfaces in multicrystalline compounds, nanostructures, micro- and mesopore structures and surface structures as well as the effects of the aforementioned organisational levels of a substance on its properties. Special mention should be made of the unusual extension of the range of the impact of different kinds of energy on substances aimed at determining their limit characteristics and the development of methods for the construction of novel materials.

The spectrum of problems considered in this review does not encompass all the trends in inorganic chemistry related to the design of novel functional materials. For example, the problem of organisation of the reaction zone in the synthesis of materials considered in the review [7] was mentioned only briefly. Neither was the problem of the development of microcomposite materials based on superconducting cuprates [114] discussed in proper detail. In addition to the functional inorganic materials considered in the present review, the subjects under study at the Division of Inorganic Chemistry of the Department of Chemistry and the Department of Materials Science of MSU include:

— inorganic structures as materials for gas sensors;†

— barrier materials based on $BaMO_3$ (M = Zr, Hf, Th, Ce, Ti);[116, 117]

— luminescent nanocomposites based on $A^{IV}B^{VI}$;[118, 119]

— low-dimensional structures and superlattices;[120, 121]

— new generations of semiconductors and semiconductor heterostructures;[122 – 124]

— oxygen-conducting membranes and solid electrolytes;[125, 126]

— materials for lithium current sources;[127 – 129]

— magnetic nanocomposites based on glassy matrices;[130]

— photonic crystals;[131]

— ceramic pigments based on hydroxyapatites containing copper ions in an unusual linear coordination.[132]

It should be mentioned in conclusion that other promising trends of research related primarily to the development of molecular electronics,[133] spintronics [134] and biocrystal systems [135] require active participation of inorganic chemists. Taking into account the extreme dynamism shown by the scientific community towards the design of novel functional materials, it has become necessary to follow closely the new trends in this field which are especially successfully documented in journals such as 'MRS Bulletin', 'Advanced Materials', 'Materials Today' and 'Materials Chemistry'. Unfortunately, no domestic analogues are available so far.

The author thanks his colleagues at the Division of Inorganic Chemistry of the Department of Chemistry and the Department of Materials Science of MSU for valuable assistance in the preparation of this review for publication. The contributions of

† A review devoted to this subject [115] will be published in the next issue of 'Russian Chemical Reviews'.

Drs A V Lukashin, A G Veresov, A R Kaul and E A Goodilin are especially highly appreciated.

Abstract. Structural features and methods for the synthesis of complex manganese oxides with the brownmillerite structure $A_2MnB'O_{5+\delta}$ (A = Ca, Sr; B′ = Ga, Al) and of their derivatives are surveyed. Modern approaches to the description of crystal structures containing various types of chains of tetrahedra are considered and possible ordering patterns of these chains are discussed. The effects of the electronic structure and crystal chemical properties of the B′ cations on the possibility of formation of a layered ordered structure is noted. The emphasis is placed on the anion non-stoichiometry of the brownmillerite phases and the influence of the excess oxygen (fluorine) on the structure of the compounds. A comparative analysis of properties of oxygen- and fluorine-doped brownmillerites is given. The data on the magnetic structures, transport and magnetoresistive properties of Mn-containing brownmillerites are generalised. The bibliography includes 74 references.

I. Introduction

Among complex manganese oxides, oxides with a general stoichiometry $Ln_{1-x}A_xMnO_3$ (where Ln is a rare-earth cation and A = Ca, Sr, Ba) are most thoroughly studied primarily due to the fact that many representatives of this class manifest colossal magnetoresistance† (see Refs 1 – 6). These compounds possess perovskite-like structures (Fig. 1 *a*) and are characterised by complex correlations between their compositions, crystal structures and physical properties. The magnetic and electronic properties of manganites are usually interpreted within the double exchange theory, which considers the electron transfer between adjacent Mn^{3+} (in the high-spin state $t_{2g}^3e_g^1$) and Mn^{4+} ($t_{2g}^3e_g^0$) ions through the Mn – O – Mn bond chain.[7,8] A specific type of structural distortion of the perovskite lattice is realised owing to cooperative tilts and rotations of the MnO_6 octahedra, which is defined by the ratio of the radii of the cations in the sublattices A and B. Additionally, a deformation of the MnO_6 octahedra due to the Jahn – Teller effect (which is typical of Mn^{3+} cations in the high-spin electronic configuration) is superimposed on the cooperative distortion of the 3-dimensional framework. The situation can be further complicated if the deformation is static, *i.e.*, the

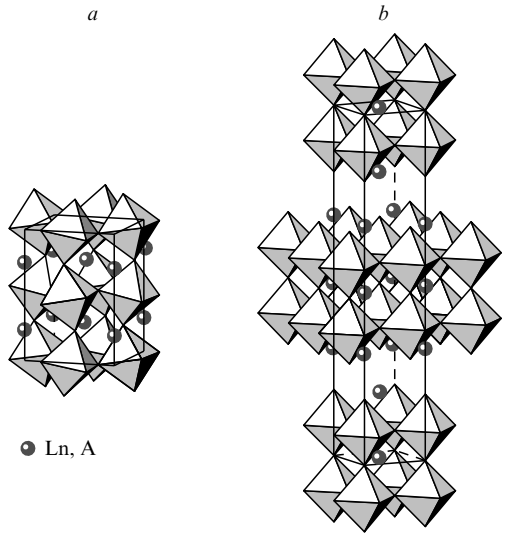

Figure 1. The crystal structures of $Ln_{1-x}A_xMnO_3$ (space group *Pnma*, $GdFeO_3$ structural type) (*a*) and $Ln_{2-x}A_{1+x}Mn_2O_7$ {$[(Ln,A)MnO_3]_n$.$[(Ln,A)O]$} (*b*).
Manganese atoms are in the centres of octahedra.

† Magnetoresistance is a change in the electrical resistance of a sample in an external magnetic field. Quantitatively, it is described by the magnetoresistive effect, which is given by the formula MR (%) = $100[(R_0 - R_H)/R_H]$, where R_0 and R_H are resistivities of the sample in the absence and in the presence of the external magnetic field with a strength H at a certain temperature, respectively. The term colossal magnetoresistance is applied to situations when the electrical resistivity changes in a magnetic field by a few orders of magnitude.

effect of orbital ordering takes place, and/or charge ordering occurs, being mainly observed at a doping level corresponding to the Mn^{3+} to Mn^{4+} ratio equal to unity (see Refs 9, 10). Nevertheless, a common feature of compounds $Ln_{1-x}A_xMnO_3$ is the retention of the spatial perovskite framework formed by vertex-sharing MnO_6 octahedra.

The discovery of colossal magnetoresistance in complex oxides $Ln_{2-x}A_{1+x}Mn_2O_7$ (Ln = La, Pr, Nd; A = Ca, Sr) stimulated studies of this phenomenon in other manganites with anisotropic layered structures.[11–15] The oxides $Ln_{2-x}A_{1+x}Mn_2O_7$ belong to the homologous series of the Ruddlesden–Popper phases with a general stoichiometry $A_{n+1}B_nO_{3n+1}$; their crystal structures may be described as intergrowth structures formed by regularly alternating perovskite and rock salt motifs, *i.e.*, $[(Ln,A)MnO_3]_n[(Ln,A)O]$ (Fig. 1 *b*). In terms of their electrical properties, the Ruddlesden–Popper phases are quasi-two-dimensional since conducting perovskite units (formed by vertex-sharing MnO_6 octahedra) are separted from each other by insulating blocks with the rock salt structure. These phases are convenient model objects for elucidation of the magnetic and electronic properties of complex manganites as a function of the dimensionality of the framework of the Mn–O–Mn bonds. Furthermore, the two-dimensional layered manganites represent a natural structural matrix suitable for the realisation of the colossal magnetoresistance by the mechanism of tunnelling of the conductivity electrons through the insulating blocks which separate the conducting perovskite fragments.

Complex manganites are similar to a certain extent to high-temperature superconducting (HTSC) cuprates as regards the possible formation of layered structures owing to the similarity in the crystal chemical properties of the cations Cu^{2+} and Mn^{3+}. Indeed, both cations are of the Jahn–Teller type due to partial filling of their e_g orbitals and thus it is a distorted octahedral environment (most often an axially elongated one) formed by oxygen atoms that is typical of them. The radii of octahedrally coordinated cations Cu^{2+} and Mn^{3+} (the latter being in the high-spin state) are also similar: $r(Mn^{3+}) = 0.79$ Å while $r(Cu^{2+}) = 0.87$ Å. Some of the axial oxygen atoms can be relatively easily removed from both the octahedrally coordinated Cu^{2+} and Mn^{3+} cations thus converting the coordination polyhedra into tetragonal pyramids. However, the square planar environment, which is often encountered in the structures of complex copper oxides, is not typical of manganese. Taking into account this close similarity, it is of no surprise that some layered perovskite-like complex manganese oxides have close analogues among HTSC cuprates. Perovskite and rock salt fragments are the major building blocks of layered cuprates as well. The known high-temperature superconducting cuprates $La_{2-x}A_xCuO_4$ (A = Sr, Ba) belong to the homologous series of the Ruddlesden–Popper phases $A_{n+1}B_nO_{3n+1}$ ($n = 1$) and have a structural analogue among manganites ($LaSrMnO_4$).[16, 17] A series of manganites including $Bi_{2-x}Pb_xSr_2MnO_{6+\delta}$ ($x = 0$, 1; the so-called 2201 phases)[18, 19] and $Bi_{2-x}Pb_xSr_{1.5}Ca_{1.5}Mn_2O_{9-\delta}$ (the 2212 phase) have been synthesised by analogy with the HTSC cuprates.[20] Another series of compounds with the composition $Bi_2Sr_2MnO_{6+\delta}$ (where δ is varied over a wide range), which correspond to an oxidation state of manganese in the range of $+2.7 < V_{Mn} < +3.3$ (see Ref. 21), have been prepared under high pressure.

The analogy between complex oxides of copper and manganese can be extended even further. According to one of the crystal chemical prerequisites to the formation of a layered perovskite-like structure with two different cations in the sublattice B, ordering of the cations is favoured by the difference in their coordination of oxygen atoms. The structure of brownmillerite $A_2BB'O_5$ represents a possible version of such a perovskite-derived layered structure. Formally, this anion-deficient structure is formed as a result of ordering of the anion vacancies giving rise to a regular alternation of the BO_2 and $B'O$ layers, which are characterised by the octahedral and tetrahedral coordination of the B and B′ cations, respectively (Fig. 2).

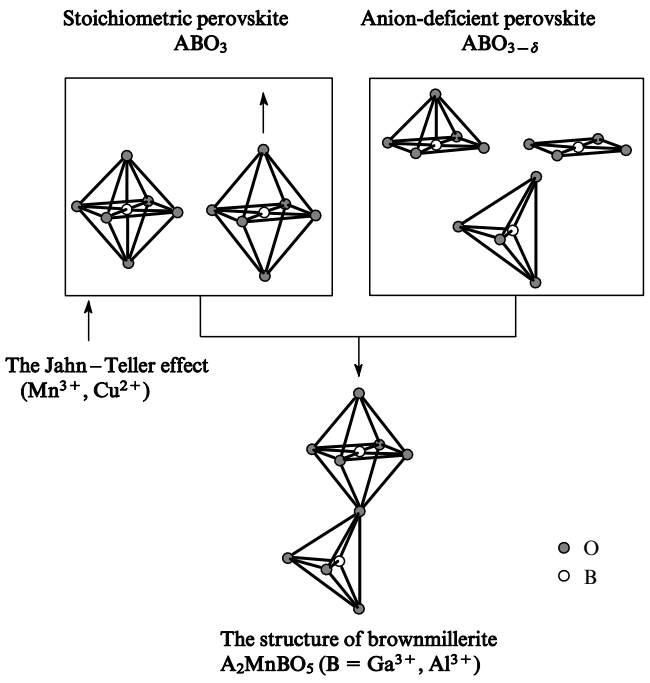

Figure 2. A scheme of formation and bonding of the coordination polyhedra BO_6 (an axially elongated octahedron) and $B'O_4$ (a tetrahedron) in the brownmillerite structure.

Since complex copper oxides with this structure are known, *viz.*, $LnACuGaO_5$ (Ln = La, Pr, Nd; A = Ca, Sr),[22–25] we have suggested that the synthesis of analogous manganese compounds is also possible. Taking into account different formal oxidation states of copper and manganese, the stoichiometry of manganites with the brownmillerite structure should be A_2MnGaO_5 ($V_{Mn} = +3$). An Al-containing analogue, *viz.*, Ca_2MnAlO_5, has been reported but it was considered only as a cement component rather than a potential magnetoresistant material.[26] An attractive feature of the brownmillerite structures as model objects in studies of magnetic and transport properties of layered manganites as a function of their composition and manganese oxidation state is its broad capability of 'tuning' changes in the anion stoichiometry and manganese valence. The preferable octahedral coordination of manganese atoms in oxidation states from +3 to +4 ensures retention of the perovskite-like MnO_2 layer whereas anion vacancies within the tetrahedral $B'O$ layers allow variations in the anion stoichiometry. The present review surveys different aspects of the synthesis of brownmillerites $A_2MnB'O_{5+\delta}$ (A = Ca, Sr; B′ = Ga, Al) and related compounds, their crystal structures and magnetic properties.

II. General information on the crystal structure of brownmillerites $A_2BB'O_5$

Brownmillerite $A_2BB'O_5$ is an anion-deficient analogue of perovskite ABO_3, which crystallises in the orthorhombic system and has unit cell parameters related to the unit cell parameter a_{per} of cubic perovskite as $a \approx \sqrt{2}a_{per}$, $b \approx 4a_{per}$, $c \approx \sqrt{2}a_{per}$. The structure of brownmillerite may be described as a result of regular alternation of the layers AO, BO_2 and $B'O$ along the unit cell axis *b* giving rise to the following layer sequence: BO_2–AO–$B'O$–AO–BO_2 (which constitutes half a repeat period along the *b* axis). The anion vacancies are ordered and localised in the $B'O$ layer, which can be formally produced from a perovskite $B'O_2$ layer (Fig. 3 *a*) by removal of half the oxygen atoms so as to form chains of anion vacancies going along the *a*

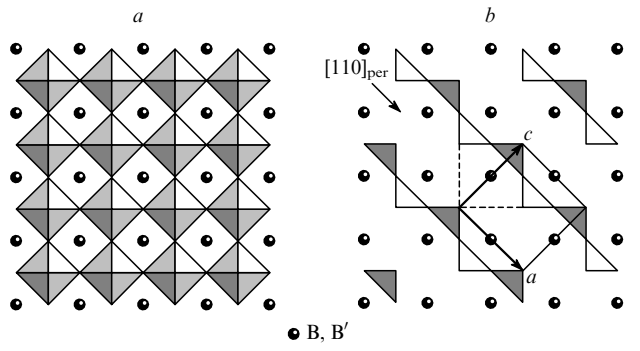

Figure 3. The structures of the BO_2 layers in the perovskite structure (*a*) and B′O layers in the structure of brownmillerite $A_2BB'O_5$ (*b*).
A cations are situated above and below the layer, the unit cell of perovskite is marked with dashes.

axis or, alternatively, along the [110] crystallographic direction of the parent perovskite (Fig. 3 *b*). The chains of vacant anion sites alternate with chains of sites occupied by oxygen atoms along the direction $c = [\bar{1}10]_{per}$. Owing to this ordered arrangement of anion vacancies, the coordination environment of the B′ cations is converted from octahedral to tetrahedral.

Thus, alternating layers of BO_6 octahedra and $B'O_4$ tetrahedra can be distinguished in the crystal structure of brownmillerite. The $B'O_4$ tetrahedra in the B′O layers are linked to each other through shared vertices to form chains along the *a* axis. The oxygen atoms in the B′O layers are shifted from their positions in the ideal cubic perovskite structure due to cooperative rotations of the tetrahedra in the chains around the *b* axis that is equivalent to the [001] direction of the parent perovskite (Fig. 4). As a result of the formation of the anion vacancies and cooperative shifts of oxygen atoms, the coordination number of the cations A (that are located between these layers) decreases from 12 to 8 + 2 (this notation means that two out of ten A−O bond lengths are substantially larger than the others).

The $B'O_4$ tetrahedra with opposite directions of rotation, *i.e.*, clockwise (CW) and counterclockwise (CCW), alternate along the chains of tetrahedra (see Fig. 4). These chains can adopt two configurations, *viz.*, left (L) and right (R), which are mirror reflections of each other.[27,28] If the vector $[\bar{1}10]_{per}$ translates a CW-tetrahedron of one chain into a CW-tetrahedron of another chain, both chains possess the same configuration (either L or R). On the contrary, if the vector $[\bar{1}10]_{per}$ translates a CW-tetrahedron of one chain into a CCW-tetrahedron of another chain or *vice versa*, these two chains possess different configurations. Mutual

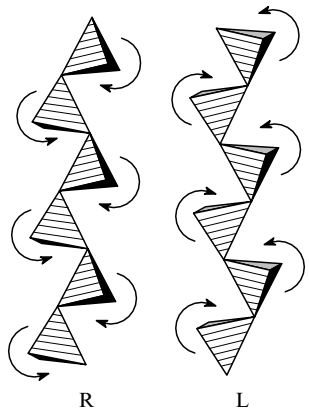

Figure 4. Chains of tetrahedra in the brownmillerite structure.
The arrows show directions of rotation of the respective tetrahedra.

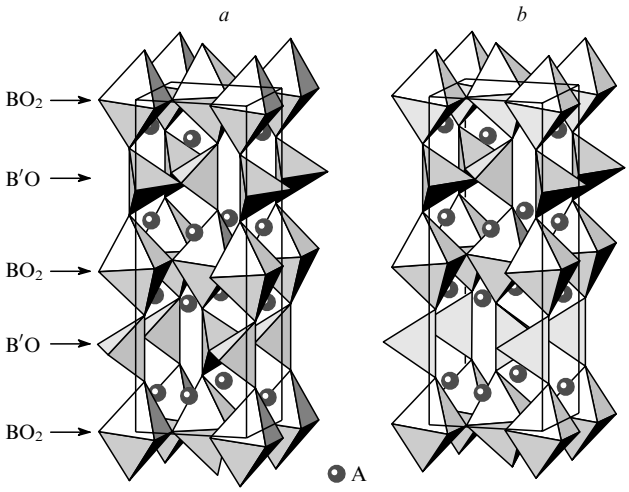

Figure 5. Crystal structures of two brownmillerite modifications with the space groups *I2mb* (*a*) and *Pnma* (*b*).

conversions of the L- and R-chains change neither the coordination polyhedra of the cations A, B and B′ nor respective interatomic distances since the space group of the parent perovskite includes the symmetry operations realising such conversions.[27,28] Hence, the L- and R-chains should be energetically equivalent and with similar probabilities of their formation.

For the majority of brownmillerites, three variants of space symmetry, which correspond to different ways of ordering the chains of tetrahedra belonging to the two configurations, are considered. In the case of completely random arrangement of the L- and R-chains, the structure belongs to the space symmetry group *Imma*. If only one type of chain is present, the structure belongs to the noncentrosymmetrical group *I2mb* (Fig. 5 *a*). Regular alternation of the B′O layers formed exclusively by either L- or R-chains gives rise to the space group *Pnma* (Fig. 5 *b*). However, the pattern of ordering of the chains of tetrahedra can be more complicated than the above three variants. Ordering of the L- and R-chains of tetrahedra can occur within one B′O layer thus increasing the repeat period along the *c* axis. Superstructural reflections corresponding to the regular alternation of the chains of tetrahedra along this axis have indeed been observed for brownmillerites such as Sr_2CuGaO_5,[29] $Ba_2In_2O_5$ [30] as well as for related phases $LnSr_2GaCu_2O_7$ (where Ln is a rare-earth element, the so-called Ga1212 phases), which contain GaO layers with brownmillerite-like chains of tetrahedra.[27,28]

A unified model encompassing all types of such superstructural ordering has been proposed by Lambert *et al.*[31] According to this model, the brownmillerite structure may be regarded as a lattice commensurately modulated with respect to the starting orthorhombic unit cell (with the unit cell parameters $a \approx \sqrt{2}a_{per}$, $b \approx 4a_{per}$ and $c \approx \sqrt{2}a_{per}$) by a modulation vector $\boldsymbol{q} = \gamma c^*$ giving rise to the (3 + 1)-dimensional space group $Imma(00\gamma)s00$.‡ In this case, the pattern of alternation of the chain of tetrahedra in the structure can be unambiguously described by a step function of the occupancy modulation. This function is defined in (3 + 1)-dimensional space by an interval on the a_4 axis with a width $\Delta(x_4)$ centred at x_4^0. An atom is assigned an occupancy of 1 if its x_4 coordinate lies inside the interval Δ, while an occupancy of 0 is assigned if the coordinate lies beyond it. In order to determine the widths and centres of the intervals defining the step functions of the occupancy modulation, it is necessary to apply the symmetry operations of the (3 + 1)-dimensional space group $Imma(00\gamma)s00$

‡ Fundamentals of space groups with the dimensionality > 3 as applied to description of modulated structures (supplied with a detailed reference list) are given in the International Tables for Crystallography.[32]

to all oxygen atoms in the B′O layer taking into account that the change in the configuration of a chain of tetrahedra should not change the composition of the layer or result in defects in the sequential arrangement of tetrahedra along the chain. For a cross-section of the brownmillerite structure on the $(x, 1/4, z)$ plane, which corresponds to the plane of the B′O layer, the sequence of atoms O*a*–Ga1–O*c*–Ga1 corresponds to the R-chain of tetrahedra, while the sequence Ga2–O*b*–Ga2–O*d* corresponds to the L-chain (Fig. 6). Since only one chain can be present in a specific point of the crystal lattice, the interval width Δ of the step function is equal to 1/2 for all atoms in this layer. The atoms O*a* and O*c* belong to the same chain of tetrahedra and thus they should be present in the structure simultaneously. Phases of the step function for these atoms should be equal, *i.e.*, $t(\mathrm{O}a) = t(\mathrm{O}c)$. This gives rise to the following relation between the coordinate t of the centre of the step function domain and the γ component of the modulation vector (see Fig. 6 for the case of $\gamma = 1/2$).

$$t = \frac{1-\gamma}{4}.$$

Taking into account that $t = x_4 - \boldsymbol{q}\,\boldsymbol{r}_{\mathrm{av}}$ (where $\boldsymbol{r}_{\mathrm{av}}$ is a vector defining the position of an atom in the average structure), the coordinate x_4^0 of the domain centre for the chain O*a*–Ga1–O*c*–Ga1 is given by

$$x_4^0(\mathrm{R}) = \frac{1-\gamma}{4} + \gamma z\,.$$

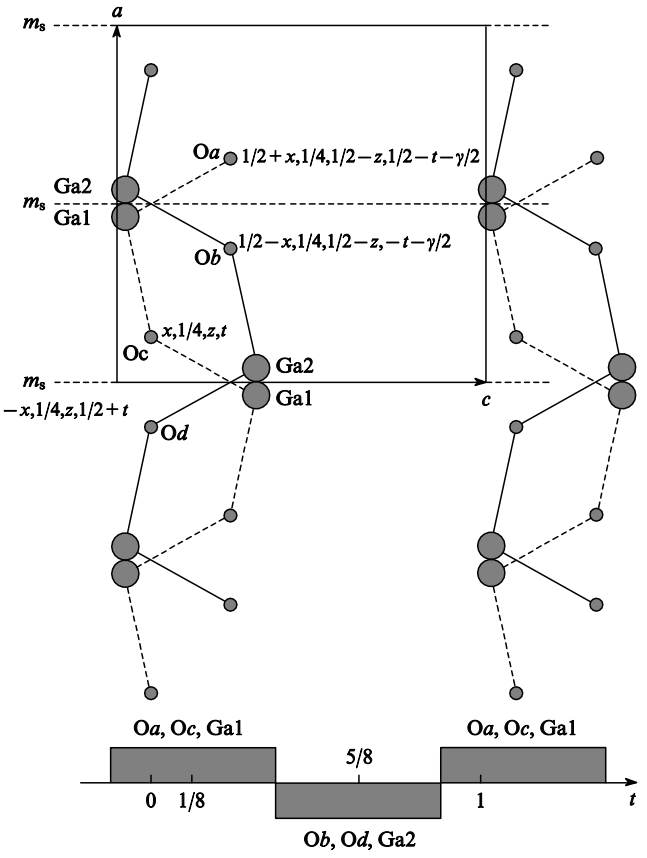

Figure 6. Arrangements of atoms in the B′O layer $(x, 1/4, z)$ for R- and L-chains of tetrahedra.
The sequence O*a*–Ga1–O*c*–Ga1 (dashed line) corresponds to the R-chain; the sequence Ga2–O*b*–Ga2–O*d* (solid line) corresponds to the L-chain; for the oxygen atoms, four-dimensional coordinates (x, y, z, t) are given; the positions of domains of the step function of the occupancy modulation are given for $\gamma = 1/2$.

The chain Ga2–O*b*–Ga2–O*d* is symmetrically related to the chain O*a*–Ga1–O*c*–Ga1 through a mirror plane m_s, which shifts the modulation phase by 1/2

$$x_4^0(\mathrm{L}) = \frac{1-\gamma}{4} + \gamma z + 1/2\,,$$

i.e., since $\Delta(x_4) = 1/2$, the two chains cannot be present at the same point of the crystal structure simultaneously. A translation by one repeat period of the parent structure along the *c* axis (*i.e.*, between two neighbouring chains in the layer) shifts the modulation phase by γ. Therefore, the sequence of alternation of the L- and R-chains can be unambiguously defined by the γ component of the modulation vector. This model is applicable for any values of the γ component. The three-dimensional symmetry group of a specific structure can be derived from the symmetry operations of the (3+1)-dimensional space group *Imma*(00γ)*s*00 for any rational γ and initial phase t of the modulation (Table 1).[31] As is clearly seen from Table 1, the brownmillerite structures with the space groups *I*2*mb* and *Pnma* correspond to two limiting cases, *viz.*, $\gamma = 0$ and $\gamma = 1$.

The crystal structure of brownmillerite is a suitable matrix to accomodate the Jahn–Teller cations in its octahedral sites. A common feature of brownmillerites contaning transition metals is the elongation of two axial B—O distances in the BO_6 octahedra as compared to four equatorial distances. This distortion is due to alternation of the vertex-sharing BO_6 octahedra and $B'O_4$ tetrahedra along the *b* axis rather than to the electronic structure of the B cation. Since the B′—O distances are shorter than the B—O distances owing to the smaller coordination number, a decrease in the $B'-O_{ax}$ bond length has to be compensated by the respective elongation of the $B-O_{ax}$ bond. In fact, axial distortions of the BO_6 octahedra are observed not only for cations manifesting the Jahn–Teller effect, such as Cu^{2+}, but also for cations devoid of this property (Table. 2). Brownmillerites contaning Fe^{3+} (electronic configuration d^5) may serve as an example. Filling an octahedral cavity with a Jahn–Teller cation favours the formation of the brownmillerite structure owing to stabilisa-

tion of a distorted octahedral environment. Therefore, possible retention of the oxidation state +3 for the manganese cations should be taken into account when selecting a method for the synthesis of Mn-containing brownmillerites.

III. Synthesis of Mn-containing brownmillerites

The ceramic method is typically applied for the synthesis of Mn-containing brownmillerites $A_2MnB'O_5$ (A = Ca, Sr; B′ = Ga, Al). The temperature and partial pressure of oxygen at which the solid-state reaction is performed strongly influence the phase composition of the reaction products and degree of ordering of the manganese and B′ cations over octahedral and tetrahedral sites. Monophasic $Ca_2MnB'O_5$ with fully ordered manganese and B′ cations (according to the neutron diffraction data) is obtained in a ceramic synthesis starting from $CaCO_3$, manganese oxides (Mn_2O_3, MnO_2) or manganese oxalate and B'_2O_3 oxides conducted at 1200–1250 °C in a flow of an inert gas (N_2).[40,41] Synthesis of the same products in air requires higher temperatures (1300–1350 °C) in order to stabilise the phase at elevated partial oxygen pressure. An analysis of IR spectra of Ca_2MnAlO_5 suggested that an increase in the temperature of the synthesis favours partial disordering of the manganese and aluminium cations.[26] When the synthesis of Ca_2MnGaO_5 is performed in air at 1300 °C, a perovskite phase (presumably with disordered positions of manganese and gallium cations) is formed as an admixture.[40] Disordering of these cations (up to 5% of the Mn cations occupy Ga positions) is also observed in the synthesis of Sr_2MnGaO_5 at 1350 °C in a flow of nitrogen.[41,42] Meanwhile, $SrCaMnGaO_5$ with the fully ordered structure can be prepared at 1200 °C in a flow of argon.[43]

Taking all the above data into account, one may conclude that the formation of the ordered layered brownmillerite structure is favoured by a decrease in the temperature of the solid-state reaction and in the partial oxygen pressure. The latter is necessary to preserve the formal +3 oxidation state of the manganese cations and the overall anion stoichiometry, which should be identical or close to the nominal stoichiometry of brownmillerite, *i.e.*, $A_2MnB'O_5$ [this makes it possible to utilise differences in the coordination environment of the manganese (octahedral) and B′ (tetrahedral) cations to stabilise the ordered layered phase]. For instance, an increase in the coordination number of the B′ cations to 6 gives rise to disordered perovskite phases with a three-dimensional framework of octahedra despite the retention of the manganese oxidation state $V_{Mn} = +3$. In particular, the compounds Ln_2MnGaO_6 (Ln = La, Nd) are characterised by an orthorhombic structure (which belongs to the structural type of $GdFeO_3$) with manganese and gallium cations statistically occupying octahedral sites.[44,45] A similar situation was revealed for solid solutions with a common stoichiometry $La_{2-x}Sr_xMnGaO_6$ ($x = 0.7$), which crystallise in the monoclinic system (sp. gr. $I2/c$) and are characterised by an oxidation state of manganese other than +3.[46,47] A change in the Mn/Ga stoichiometric ratio also prevents formation of the layered brownmillerite structure. Solid solutions $SrMn_{1-x}Ga_xO_{3-\delta}$ ($0 \leqslant x \leqslant 0.33$) have a disordered cubic perovskite structure whereas for $0.33 < x < 0.5$, a two-phase region was found.[48]

We have suggested that the optimum conditions for the formation of brownmillerites Ca_2MnGaO_5 and Sr_2MnGaO_5 could be achieved provided that the synthesis is performed in evacuated sealed quartz tubes starting from CaO (SrO) preformed by decomposition of the respective carbonates in a dynamic vacuum (10^{-2} mbar, 900 °C), Mn_2O_3 and Ga_2O_3. The use of highly reactive oxides of alkaline-earth metals at a low partial oxygen pressure in the tube allows the preparation of monophasic ordered brownmillerites at 1000 °C.[40,49,50] The samples containing alkali-metal oxides have to be handled in a glove box free of water vapour and CO_2.

Brownmillerites containing manganese in an oxidation state slightly above +3 can be prepared by the heterovalent substitution of a bivalent cation for a trivalent one in the B′ sublattice. A series of solid solutions $Ca_2MnGa_{1-x}Zn_xO_{5+\delta}$, where $x = 0.1$ ($\delta = 0.075$, $V_{Mn} = +3.25$) or $x = 0.2$ ($\delta = 0.08$, $V_{Mn} = +3.36$) have been synthesised; phases with an increased manganese oxidation state are formed when the synthesis is performed at 1200 °C in air.[40] The manganese atoms in the original brownmillerite $Ca_2MnGaO_{5+\delta}$ with $\delta = 0$ can be further oxidised by annealing at low temperature and high partial oxygen pressure. Insertion of oxygen into this compound proceeds under drastic conditions ($T = 415$ °C, $p_{O_2} = 80$ atm); no complete oxidation of manganese to $V_{Mn} = +4$ occurs, the maximum reachable value of δ is 0.39.[40] Annealing $Sr_2MnGaO_{5+\delta}$ under milder conditions ($T = 415$ °C, $p_{O_2} = 1-20$ atm) gives rise to almost complete oxidation to $\delta = 0.47-0.505$. $Sr_2MnGaO_{5+\delta}$ with an intermediate value of the oxygen overstoichiometry index $0 < \delta < 0.5$ can be prepared by reduction of fully oxidised $Sr_2MnGaO_{5.5}$ in a closed circuit with a preset partial oxygen pressure.[51] In this method, the annealing is performed in a circulating flow of an argon–oxygen mixture; the required partial oxygen pressure is kept constant using a Cu/Cu_2O getter and controlled by an electrochemical cell with a solid oxygen-ionic electrolyte. A series of phases with $\delta = 0.13$ ($\log p_{O_2} = -5.19$), $\delta = 0.41$ ($\log p_{O_2} = -4.04$) and $\delta = 0.46$ ($\log p_{O_2} = -1.12$) have been synthesised at 415 °C using this method. A biphasic region corresponding to a mixture of a reduced and an oxidised phase with $\delta = 0.13$ and 0.41, respectively, was observed in the range of $0.13 < \delta < 0.41$.

IV. The crystal structure of $A_2MnB'O_{5+\delta}$ (A = Ca, Sr; B′ = Ga, Al; $\delta \approx 0$)

Unit cell parameters and space groups of Mn-contaning brownmillerites corresponding to different oxygen overstoichiometry indices are listed in Table 3. Based on X-ray powder diffraction data,[26] a primitive orthorhombic unit cell was suggested for Ca_2MnAlO_5. A subsequent low-temperature neutron diffraction study of this phase has given the space group $I2mb$.[41] For the Ga-containing analogue, *i.e.*, $Ca_2MnGaO_{5.045}$, formation of the *Pnma* modification of brownmillerite was unambiguously established by electron diffraction and X-ray powder diffraction.[40] Refinement of the crystal structure of $Ca_2MnGaO_{5.045}$ within the *Pnma* model using the Rietveld method resulted in a good correspondence between the experimental and calculated X-ray powder diffraction patterns.

Nevertheless, the real structure of $Ca_2MnGaO_{5.045}$ proved to be much more complicated than the idealised *Pnma* model, as evidenced by neutron diffraction and high-resolution electron microscopy (HREM). While the *Pnma* model provides a reasonable description of the experimental X-ray diffraction pattern, the neutron diffraction pattern can be fitted within this model only with large reliability factors. Systematic underestimation of the calculated intensities of reflections with $h + k + l = 2n$ and a nonmonotonic dependence of the FWHMs of reflections on the interplanar distance indicate the co-existence of two brownmillerite polymorph modifications with the space groups *Pnma* and *I2mb* in the sample. If the *I2mb* phase is taken into account in the fitting procedure, the fit quality is significantly improved. However, the Fourier difference maps for the *Pnma* phase still reveal extra maxima corresponding to incomplete ordering of the chains of tetrahedra (89% of one type of chain and 11% of another type within one layer instead of 100% of a certain type of chain, which has to be observed in the case of the ideal *Pnma* model). These results of structure refinement using neutron diffraction data can be interpreted as indicating the simultaneous presence of the *Pnma* and *I2mb* domains in the crystal structure of $Ca_2MnGaO_{5.045}$. The HREM data fully support this model.[40] Figure 7 shows two HREM micrographs of $Ca_2MnGaO_{5.045}$ along the crystallographic direction [101] and their Fourier images corresponding to the *Pnma* and *I2mb* phases. Reflections of the hkl, $k \neq 2n$ type are clearly resolvable in Fig. 7 *a* but absent in Fig. 7 *c*, so that the

[a] TGA stands for thermogravimetric analysis, ND stands for neutron diffraction, CA stands for chemical analysis. [b] Primitive orthorhombic lattice.

apparent repetition period along the b axis for the *I2mb* phase appears half as long as that for the *Pnma* phase (b = 15.3 Å).

In addition to crystallites strictly corresponding to one of the two variants (either *Pnma* or *I2mb*), the HREM data revealed crystallites with narrow extended domains of the *I2mb* phase embedded into the *Pnma* matrix. Thus, the real structure of $Ca_2MnGaO_{5.045}$ represents a mixture of the polymorph modifications *Pnma* and *I2mb*, both at the level of separate crystallites (which manifests itself in the structure refinement using neutron diffraction data as a contribution from the *I2mb* phase) and narrow domains within one crystallite (which manifests itself in the neutron diffraction data as the presence of differently oriented chains within the *Pnma* phase).

Substitution of strontium atoms for calcium in $Ca_2MnGaO_{5+\delta}$ suppresses formation of the *Pnma* modification. The crystal structure of $SrCaMnGaO_{5.035}$ was successfully refined using neutron diffraction data within the fully ordered *I2mb* model.[43] A similar model was applied to refine the structure of $Sr_2MnGaO_{5+\delta}$ ($\delta < 0$) from X-ray[49] and neutron powder diffraction data.[52, 53] However, it was found that it is the *Imma* structural model with a disordered arrangement of the L- and R-chains of tetrahedra that better reproduces the neutron diffraction pattern for Sr_2MnGaO_5. The difference between the fit qualities obtained for this compound within the *I2mb* and *Imma* models is not as significant as in the case of Ca_2MnAlO_5.[41, 52] This can be seen from a comparison of the corresponding integral discrepancy factors χ^2 (see Ref. 41):

Oxide	Sr_2MnGaO_5	Sr_2MnGaO_5	Ca_2MnAlO_5	Ca_2MnAlO_5
Sp. gr.	*Imma*	*I2mb*	*Imma*	*I2mb*
χ^2	3.30	5.28	27.5	2.99

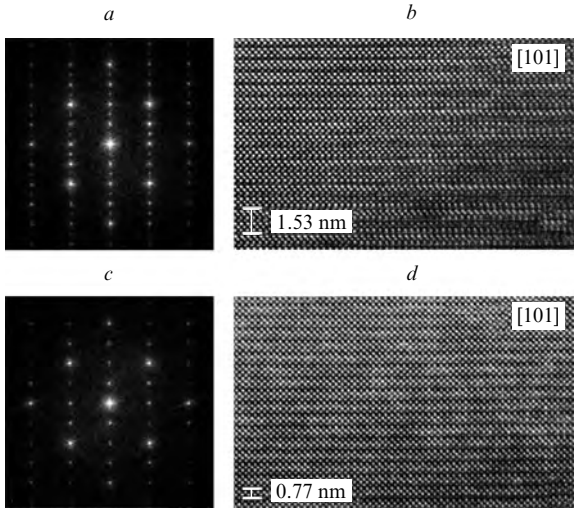

Figure 7. HREM micrographs (a, c) and respective Fourier images for $Ca_2MnGaO_{5.045}$ along the crystallographic direction [101] (b, d) showing domains of the *Pnma* (a, b) and *I2mb* (c, d) phases.

Actually, the ordering of the chains of tetrahedra in Sr_2MnGaO_5 has a more complicated character as compared with the idealised *I2mb* and *Imma* models. An electron diffraction study of Sr_2MnGaO_5 has revealed superstructural reflections corresponding to ordering of the L- and R-chains in the GaO layers along the axis c.[54] These reflections can be indexed assuming a modulation vector of $\boldsymbol{q} = (1/2)c^*$, which corresponds to a sequence of alternating chains of tetrahedra L–R–L–R–L along the c axis according to the Labmert model (see section II). Alternatively, this structure can be described in the orthorhombic space group *Pcmb* with a doubled c parameter (Fig. 8). This model was confirmed using HREM.[54] In addition to the regularly ordered fragments of the *Pcmb* phase, domains with another type of shift of the ordered layers of tetrahedra, which corresponded to a monoclinic unit cell (a = 17.100 Å, b = 5.406 Å, c = 11.118 Å, β = 108.97°, sp. gr. $P2/c$) (Fig. 9), were revealed together with numerous defects due to disturbed alternation sequences of the L- and R-chains of tetrahedra.

These two examples, *viz*., $Ca_2MnGaO_{5+\delta}$ and $Sr_2MnGaO_{5+\delta}$ demonstrate that structural analysis of brownmillerite phases can become very complicated due to the multitude of ordering patterns of the chains of tetrahedra. Even neutron powder diffraction, which is quite sensitive to the positions of oxygen atoms, is often insufficient to determine the real structure of brownmillerites and thus it should be applied in a combination

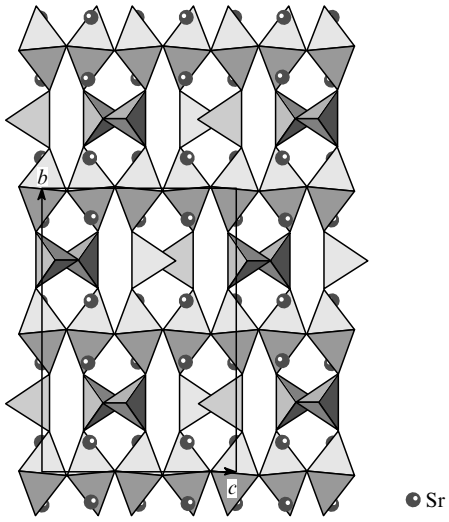

Figure 8. A model of the crystal structure of Sr_2MnGaO_5 with the chains of tetrahedra ordered according to the L – R – L – R pattern.
The two different projections of the GaO_4 tetrahedra correspond to the two chain types.

with local diffraction methods, *e.g.*, electron diffraction as implemented in transmission electron microscopes and HREM. High-temperature electron diffraction makes it possible to determine the influence exerted by the synthesis and annealing conditions on the character of ordering of the chains of tetrahedra. The electron diffraction patterns for the [010]* zone of Sr_2MnGaO_5 in the temperature range from room temperature to ~900 °C are shown in Fig. 10.[54] It is clearly seen that at 620 °C, the intensity of satellite reflections corresponding to the superstructure $\boldsymbol{q} = (1/2)c^*$ decreases and stripes of diffuse scattering oriented along the c^* axis appear. At 665 °C, the satellites completely disappear while the stripes of diffuse scattering remain, which suggests the loss of long-range ordering in the arrangement of the chains of tetrahedra at this temperature. Ordering is completely destroyed at ~900 °C (Fig. 10 *d*). This temperature is lower than the minimum temperature required for the synthesis of Mn-containing brownmillerites (1000 °C). This means that specific ordering of the chains of tetrahedra is realised not at the temperature of the synthesis of the sample but rather during its subsequent cooling. Hence, the exact character of the ordering should depend on the cooling rate.

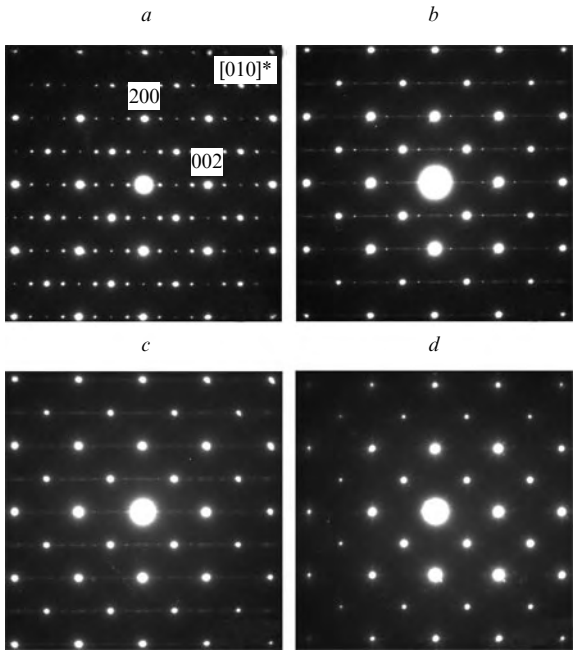

Figure 10. Electron diffraction patterns for the [010]* zone of Sr_2MnGaO_5 at room temperature (*a*), 620 °C (*b*), 665 °C (*c*) and 905 °C (*d*).

All brownmillerites $A_2MnB'O_{5+\delta}$ (A = Ca, Sr; B′ = Ga, Al; $\delta \approx 0$) are characterised by strong distortions of the MnO_6 octahedra. The lengths of the equatorial and axial Mn – O bonds for various members of this family, as determined by neutron diffraction, are listed in Table 4. A direct comparison of the bond lengths would not be informative since the respective values were determined for compounds with different oxygen content at different temperatures. However, a tendency that two axial Mn – O bonds are substantially longer than four equatorial ones is apparent for all the structures. Such a deformation of the coordination polyhedron is typical of the Jahn – Teller high-spin Mn^{3+} cation with the electronic configuration $t_{2g}^3e_g^1$. It is of note that the length of an axial Mn – O bond depends on the mean radius of cations in the sublattice A: it increases from 2.239 Å for A = Ca to 2.308 Å for A = Sr, Ca and further to 2.368 Å for A = Sr. As will be shown below, the bond length is also dependent on the oxidation state of manganese.

Table 4. The Mn – O bond lengths in the structures of brownmillerites $A_2MnB'O_{5+\delta}$ (A = Ca, Sr; B′ = Ga, Al) with $\delta \approx 0$.

V. Specific pattern of the oxidation of brownmillerites $A_2MnGaO_{5+\delta}$ (A = Ca, Sr)

An increase in the formal oxidation state of manganese in $A_2MnGaO_{5+\delta}$ as a result of a heterovalent substitution in the cation sublattice or insertion of oxygen atoms converts the electronic configuration of Mn from $t_{2g}^3e_g^1$ to $t_{2g}^3e_g^0$ and is accompanied by a suppression of the Jahn–Teller effect and decrease in the axial Mn–O bond lengths in the MnO_6 octahedra. In the case of $Ca_2MnGaO_{5+\delta}$ and solid solutions based on it, these bond lengths decrease monotonically with an increase in the oxidation state of manganese (V_{Mn}).[40, 55]

Oxide	$Ca_2MnGaO_{5.045}$	$Ca_2MnGa_{0.8}Zn_{0.2}O_{5.08}$	$Ca_2MnGaO_{5.39}$
V_{Mn}	+3.09	+3.36	+3.78
d(Mn–O) /Å	2.239(3)	2.221(9)	1.873(9)

In the latter compound, the MnO_6 octahedra are axially compressed (*i.e.*, the axial Mn–O bonds are shorter than the equatorial ones). Since the axial Mn–O bonds are oriented nearly parallel to the *b* axis, their contraction results in a decrease in the *b* parameter of the unit cell. In the case of $Ca_2MnGaO_{5+\delta}$ and $Ca_2MnGa_{1-x}Zn_xO_{5+\delta}$, the *b vs.* V_{Mn} function is nearly linear (Fig. 11). Therefore, the *b* parameter is sensitive to changes in the oxidation state of manganese. The range of oxygen nonstoichiometry possible for Ca_2MnAlO_5 has not been studied, however, one may assume that this compound can be characterised by variable oxygen content, since the *b* parameter for a sample prepared in air [26] is significantly smaller than the respective value for a sample prepared in an inert atmosphere,[41] which assumes that the oxidation state is higher for the products synthesised in air.

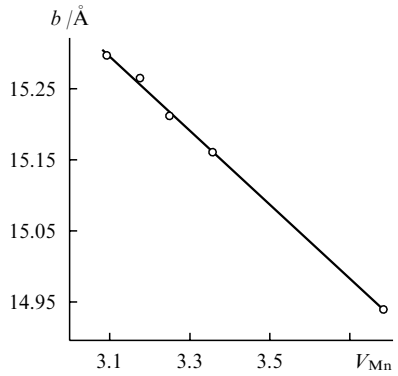

Figure 11. Changes in the *b* parameter as a function of V_{Mn} for $Ca_2MnGaO_{5+\delta}$ and $Ca_2MnGa_{1-x}Zn_xO_{5+\delta}$.

A heterovalent substitution of Zn for Ga leads to a substantial change in the *b* parameter alone while the *a*, *c* parameters and the degree of the orthorhombic distortion of the unit cell change insignificantly, mainly due to variation of the mean radii of cations occupying B and B′ positions. On the contrary, insertion of excess oxygen (*i.e.*, an increase in the index δ) gives rise to a significant decrease in the degree of the orthorhombic distortion, which is reflected in an increase in the *a* parameter coupled with a decrease in the *c* parameter (see Table 3). This occurs because the geometry of a part of the anion-deficient $GaO_{1+\delta}$ layers changes when extra oxygen atoms appear. An electron diffraction and HREM study has shown that insertion of oxygen into the $Ca_2MnGaO_{5+\delta}$ structure proceeds inhomogeneously.[40] Oxidation affects only half of the anion-deficient GaO layers giving rise to an ordered arrangement of GaO_2 and GaO□ (□ is the anion vacancy) (Fig. 12). The idealised structure of the oxidised material can be represented by the following layer sequence:

$GaO_2–CaO–MnO_2–CaO–GaO□–CaO–MnO_2–CaO–GaO_2$,

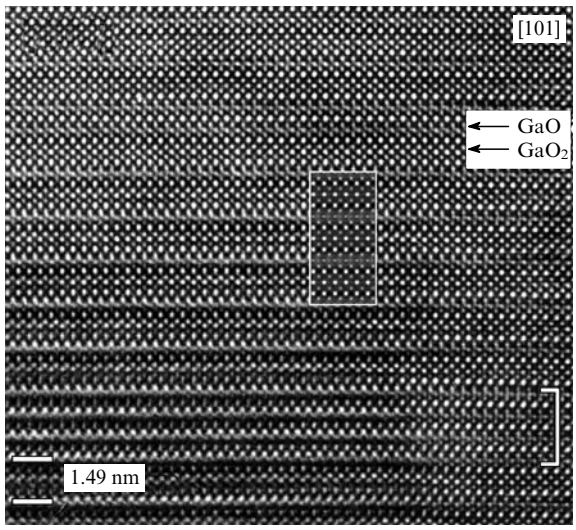

Figure 12. HREM micrographs of $Ca_2MnGaO_{5.39}$ along the crystallographic direction [101].
The square bracket shows a domain of the starting reduced phase with the *I2mb* structure, the inset in the centre shows an image calculated theoretically for the $Pmc2_1$ model.

two adjacent Ga layers are not symmetrically related to each other. Such a structure can be described in the noncentrosymmetrical space group $Pmc2_1$, which is actually a noncentrosymmetrical subgroup of the group *Pnma*. The resultant unit cell parameters relate to the unit cell parameters of the original cubic perovskite as $a \approx 4a_{per}$, $b \approx c \approx \sqrt{2}a_{per}$. The ordered disposition of the GaO□ and GaO_2 layers is violated by the slabs of the starting reduced phase with the *I2mb* structure. The structure of a completely oxidised compound is described by an idealised formula $Ca_2MnGaO_{5.5}$ [$Ca_4(Mn_2Ga)GaO_{11}$], which corresponds to the third member of the homologous series of the brownmillerite structures $A_{n+1}B_nB'O_{3n+2}$ (n = 3, Fig. 13). In this structure, triple layers of BO_6 octahedra (B = Mn, Ga) are separated by a layer of $B'O_4$ tetrahedra (B′ = Ga). According to the above stoichiometry, the oxidation state of manganese in these fragments should be +4, however the mean oxidation state of manganese was +3.78 in a sample oxidised at p_{O_2} = 80 atm due to the presence of areas with the original *I2mb* structure corresponding to $V_{Mn} \approx +3$. Probably, the phase with the ideal

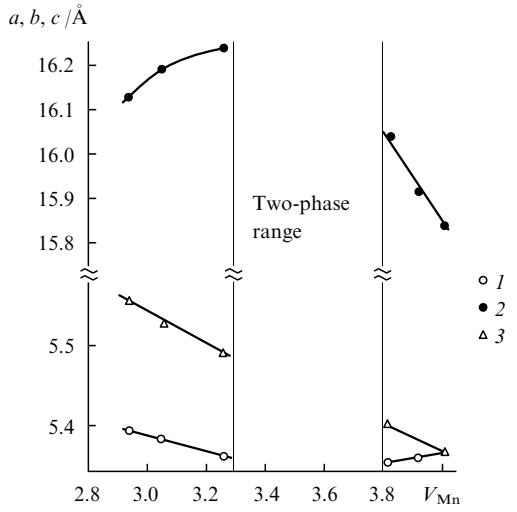

Figure 14. Changes in the unit cell parameters *a* (*1*), *b* (*2*) and *c* (*3*) as a function of the manganese oxidation state in $Sr_2MnGaO_{5+\delta}$.

stoichiometry $Ca_2MnGaO_{5.5}$ can be prepared at a higher partial oxygen pressure and longer duration of annealing.

The oxide $Sr_2MnGaO_{5+\delta}$ is characterised by a more complex dependence of the unit cell parameters on the oxidation state of manganese V_{Mn} and oxygen content.[51,56] The unit cell volume, degree of its orthorhombic distortion and *c* parameter decrease regularly with an increase in δ (Fig. 14, see Table. 3). The *a* and *b* parameters behave differently in two ranges of the manganese oxidation state, *viz*., $+2.94 \leqslant V_{Mn} \leqslant +3.26$ (the weakly oxidised range) and $+3.82 \leqslant V_{Mn} \leqslant +4.01$ (the strongly oxidised range). In the weakly oxidised range, the *a* parameter decreases whereas the *b* parameter increases. Conversely, in the strongly oxidised range, the *a* parameter increases whereas the *b* parameter decreases. The unit cell vectors and the space group also undergo changes. In the weakly oxidised range, the brownmillerite structure is retained. In the strongly oxidised range, the intensity of the *hkl* reflections with $k \neq 2n$ becomes zero, which corresponds to a transition to a new unit cell with the following parameters: $a \approx c \approx \sqrt{2}a_{per}$, $b \approx 2a_{per}$ and space group *Bmmm*. A progressive decrease in the degree of the orthorhombic distortion for $Sr_2MnGaO_{5.505}$ ultimately gives rise to a tetragonal unit cell with $a \approx a_{per}$, $c \approx 2a_{per}$ and space group *P*4/*mmm* (Fig. 15). For the oxidised phase $Sr_2MnGaO_{5.5}$, an orthorhombic structure was established[48] based on the neutron diffraction data (see Table 3). It is likely that discrepancies in the crystallographic symmetry suggested for this compound by different authors (see Refs 48, 51, 52, 56) arise due to different procedures used for the preparation of different samples or variable oxygen content in these samples, which lies within the accuracy limits of the available determination methods.

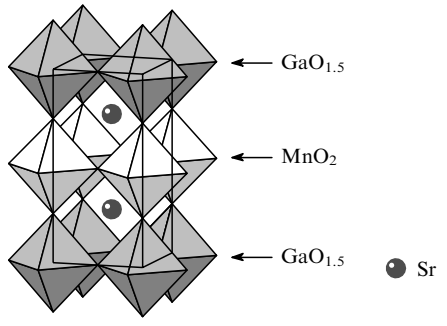

Figure 15. The crystal structure of $Sr_2MnGaO_{5.5}$.

The character of structural changes that occur upon oxidation of $Ca_2MnGaO_{5+\delta}$ and $Sr_2MnGaO_{5+\delta}$ is similar to that induced by insertion of fluorine atoms into the structure of brownmillerite $LaACuGaO_5$ (A = Ca, Sr).[57] In the case of A = Sr, fluorination of $LaACuGaO_5$ yields a tetragonal phase with $a \approx a_{per}$, $c \approx 2a_{per}$, whereas in the case of A = Ca, the orthorhombic symmetry is retained although the degree of the orthorhombic distortion substantially decreases. Similarly, oxidation of Mn-containing brownmillerites gives rise to a tetragonal structure only for A = Sr. According to X-ray diffraction, the structure of the tetragonal phase $Sr_2MnGaO_{5.5}$ is similar to that of oxofluoride $LaSrCuGa(O,F)_{6-\delta}$ (see Refs 53, 57). Probably, the differences in the oxidation of the Ca- and Sr-containing phases are due to steric hindrance associated with insertion of overstoichiometric oxygen atoms. The coordination number of the A cation in the tetragonal structure *P*4/*mmm* should be equal to 12 provided all anion sites are fully occupied or 11 if 1/4 of the oxygen atoms in the Ga layer are absent as in the case of $Sr_2MnGaO_{5.5}$. Realisation of large coordination numbers is difficult in the case of a Ca system (the ionic radius of Ca^{2+} is 1.35 Å) but possible for the larger Sr^{2+} ion (the ionic radius is 1.44 Å). Meanwhile, fluorination of $LaACuGaO_5$ can be represented as anion exchange $O^{2-} \rightarrow 2F^-$, which does not affect the oxidation state of copper. As a result, strong Jahn–Teller distortions of the CuO_6 octahedra are retained in the structure of oxofluorides $LaACuGa(O,F)_{6-\delta}$ and the perovskite subcell undergoes elongation in the direction perpendicular to the CuO_2 layers owing to orbital ordering. Insertion of oxygen into manganites with the brownmillerite structure proceeds oxidatively and results in suppression of the Jahn–Teller deformation.

In the case of $Sr_2MnGaO_{5+\delta}$, oxygen is inserted into every GaO layer, in contrast to the case of $Ca_2MnGaO_{5+\delta}$. According to a refinement of the crystal structure of $Sr_2MnGaO_{5.46}$, the coordination number of gallium atoms increases from 4 to 5 and their coordination polyhedron is a distorted trigonal bipyramid, although oxygen atoms are not completely ordered in the $GaO_{1+\delta}$ layer. Ordering of oxygen atoms and anion vacancies at certain values of δ can be observed by electron diffraction. For $Sr_2MnGaO_{5.41}$, such ordering lowers the symmetry to the monoclinic space group *P*2/*m* ($a = 10.813$ Å, $b = 8.019$ Å, $c = 8.486$ Å, $\beta = 108.57°$). A structural model of this oxide has been developed based on the analogy between the $GaO_{1+\delta}$ layers and anion-deficient $MnO_{1.5}$ layers in the compounds $A_2B_2O_5$ (A = Ca, Sr, La; B = Mn, Cu),[58–61] $Ca_2MnO_{3.5}$[62] and $Sr_2MnO_{3.5}$ (see Ref. 63). The $Mn(Cu)O_{1.5}$ layers consist of vertex-sharing $Mn(Cu)O_5$ tetragonal pyramids (Fig. 16 *a*,*b*). A probable arrangement of the GaO_5 polyhedra, which agrees with the unit cell parameters and space group symmetry of $Sr_2MnGaO_{5.41}$, is shown in Fig. 16 *c*. In order to convert tetragonal pyramids into GaO_5 trigonal bipyramids, both gallium and oxygen atoms have to be slightly shifted (Fig. 16 *d*).

The observed changes in the unit cell parameters of $Sr_2MnGaO_{5+\delta}$ as a function of the oxygen overstoichiometry δ can be rationalised taking into account the following trends:

— the mean radius of manganese cations decreases with an increase in the oxidation state from +3 to +4 [$r(Mn^{3+}) = 0.79$ Å, $r(Mn^{4+}) = 0.68$ Å];

— the Jahn–Teller distortions of the MnO_6 octahedra are suppressed;

— the degree of distortion of the MnO_2 layers is decreased owing to a smaller tilt angle of the MnO_6 octahedra with respect to the *a* axis;

— the mean Ga–O bond length increases with an increase in the coordination number of gallium atoms due to the appearance of additional oxygen atoms in the Ga layer.

A decrease in the degree of the orthorhombic distortion with an increase in δ occurs as a result of interactions between gallium and inserted oxygen atoms. When the latter occupy vacant anion sites within the $GaO_{1+\delta}$ layer, the distance between two nearest gallium atoms and the additional oxygen atom from neighbouring

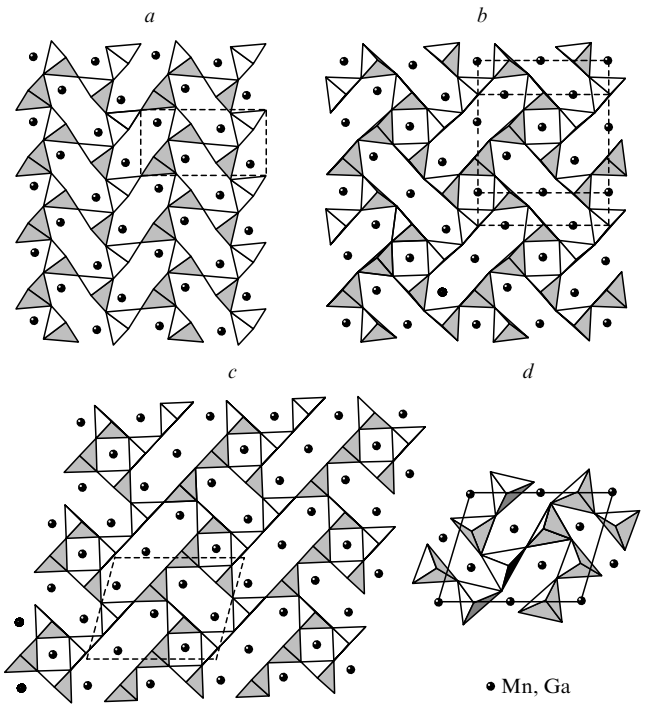

Figure 16. Arrangement of layers composed of the MnO_5 tetragonal pyramids in the structures of $Ca_2Mn_2O_5$, $Ca_2MnO_{3.5}$ (*a*) and $Sr_2MnO_{3.5}$ (*b*) and of the GaO_5 tetragonal pyramids in the structures of $Sr_2MnGaO_{5.41}$ (*c*) (*d* shows the conversion of a GaO_5 tetragonal pyramid into a trigonal bipyramid).

chains of tetrahedra becomes too large. In order to decrease this distance, the gallium atoms from the neighbouring chains shift towards the positions of the B cations in the original perovskite structure thus giving rise to a decrease in the distance between the chains of tetrahedra and the unit cell parameter *c*, the latter being almost linearly dependent on V_{Mn} and, consequently, on δ. The two opposite trends contribute to the change in the parameter *a*. With an increase in the manganese oxidation state in $Sr_2MnGaO_{5+\delta}$, the equatorial Mn – O bond length decreases.

δ	−0.003	0.025	0.13	0.46	0.47
$d(Mn-O)_{eq}$ /Å	1.945(20)	1.9243(5)	1.9222(4)	1.9010(1)	1.8998(1)

In the weakly oxidised range, this leads to a decrease in the *a* parameter and is accompanied by an increase in the degree of distortion of the chains of tetrahedra owing to cooperative rotation of the GaO_4 tetrahedra around the *b* axis by a larger angle, which is reflected in the change in the Ga – O – Ga bond angle from 134.4(5)° in $Sr_2MnGaO_{4.97}$ to 131.4(5)° in $Sr_2MnGaO_{5.025}$. However, further decrease in the degree of the orthorhombic distortion and formation of the tetragonal structure in the strongly oxidised range requires an increase in the Ga – O – Ga angle [*e.g.*, this angle is 165.8(4)° in $Sr_2MnGaO_{5.46}$], which finally leads to an increase in the *a* parameter in this range.

With an increase in the manganese oxidation state, axial distortions of the MnO_6 octahedra progressively decrease affecting the axial Mn – O bond lengths

δ	−0.03	0.025	0.13	0.46	0.5
$d(Mn-O)_{ax}$ /Å	2.411(4)	2.372(5)	2.225(8)	1.983(6)	1.956(3)

Since the axial Mn – O bonds are oriented along the *b* axis, a decrease in the respective unit cell parameter might be expected. Notwithstanding, the *b* parameter increases in the weakly oxidised range. The reason for this is a decrease in the degree of distortions of the MnO_2 layers due to a smaller tilt angle of the MnO_6 octahedra around the *a* axis. The Mn – O – Mn bond angle in the MnO_2 plane increases from 169.5(10)° (δ = −0.03) to 173.7(3)° (δ = 0.025), 176.8(5)° (δ = 0.13) and becomes equal to 180° for δ = 0.46, 0.47, 0.505. Simultaneously, the axial Ga – O bond elongates: 1.816(5) Å (δ = −0.03), 1.847(5) Å (δ = 0.025), 1.977(9) Å (δ = 0.13). As a result of this elongation and subsequent orientation of the axial Mn – O bond lengths parallel to the *b* axis, the *b* parameter in the weakly oxidised range increases despite shortening of the axial Mn – O bond.

VI. Complex oxofluorides $Sr_2MnGaO_{5-x}F_{1+x}$

In addition to oxygen atoms, fluorine atoms can also be used to modify the composition of the anion sublattice and the manganese oxidation state in brownmillerite Sr_2MnGaO_5. Oxygen and fluorine atoms are similar in terms of their crystal chemical properties. Their anions have similar ionic radii (r_{F^-} = 1.29 Å, $r_{O^{2-}}$ = 1.35 Å for the coordination number of 2). Several examples of successful insertion of fluorine into the structures of complex manganese oxides resulting in respective oxofluorides have been reported, including $Sr_2Mn_2O_{5-x}F_{1+x}$,[64] $LaSrMnO_4F$ (Ref. 65) and $La_{1.2}Sr_{1.8}Mn_2O_7F_2$.[66] As has been shown recently,[57] fluorine-derivatives of copper-contaning brownmillerites $LaACuGaO_5$ (A = Ca, Sr) can be synthesised using XeF_2 as a fluorinating agent. A similar method was applied to the synthesis of oxofluorides $Sr_2MnGaO_{5-x}F_{1+x}$. A detailed discussion of the utilisation of xenon difluoride for the fluorination of complex oxides and analysis of the processes accompanying fluorination may be found in a recent review.[67] Oxofluorides $Sr_2MnGaO_{5-x}F_{1+x}$ were synthesised starting from completely oxidised $Sr_2MnGaO_{5.5}$ at 500 – 600 °C using an anion exchange reaction, which gives rise to a decrease in the formal oxidation state of manganese.[56, 68]

$$Sr_2MnGaO_{5.5} + \frac{1+x}{2}XeF_2 \longrightarrow$$

$$\longrightarrow Sr_2MnGaO_{5-x}F_{1+x} + \left(\frac{1}{2}+x\right)[O] + \frac{1+x}{2}Xe.$$

Chemical reduction in the reaction with xenon difluoride is achieved owing to involvement of the walls of the copper tube that is used as the reactor. Oxygen evolved upon anion exchange is adsorbed by the walls giving rise to the Cu/Cu_2O getter, which regulates the partial oxygen pressure in the course of the reaction. Oxofluorides $Sr_2MnGaO_{5-x}F_{1+x}$ crystallise in the tetragonal system (sp. gr. *P*4/*mmm*) with the following unit cell parameters: $a \approx a_{per}$, $c \approx 2a_{per}$ (Table 5). According to a calculation of the bond valence sum and crystal lattice energy, partial substitution of fluorine for oxygen and insertion of excess fluorine atoms takes place in the Ga layers. Consequently, all vacancies in these layers become filled giving rise to the stoichiometry $GaO_{1-x}F_{1+x}$. It is of interest to analyse changes in the behaviour of the compound Sr_2MnGaO_5 doped with either fluorine or oxygen as a function of the manganese oxidation state. The changes in the Mn – O bond lengths for the fluorinated and oxidised phases are plotted in Fig. 17 *a*. In both cases, the equatorial Mn – O bonds in the MnO_6 octahedra elongate with a decrease in V_{Mn} (which is equivalent to a decrease in δ or an increase in the fluorine content) from 1.8998 Å (V_{Mn} = +4) to 1.9222 Å (V_{Mn} = +3.26, δ = 0.13)[51]

Table 5. The crystallographic data for oxofluorides $Sr_2MnGaO_{5-x}F_{1+x}$.

Fluorination conditions	Unit cell parameters /Å		V_{Mn}
	a	*c*	
Starting oxide (without XeF_2)	3.8003(7)	7.948(3)	+4.00
1 : 1 XeF_2, 500 °C, 10 h	3.8557(3)	7.7843(8)	+3.78
1 : 1 XeF_2, 600 °C, 20 h	3.865(1)	7.779(3)	+3.54
1 : 3 XeF_2, 600 °C, 20 h	3.8794(3)	7.7328(6)	+3.39

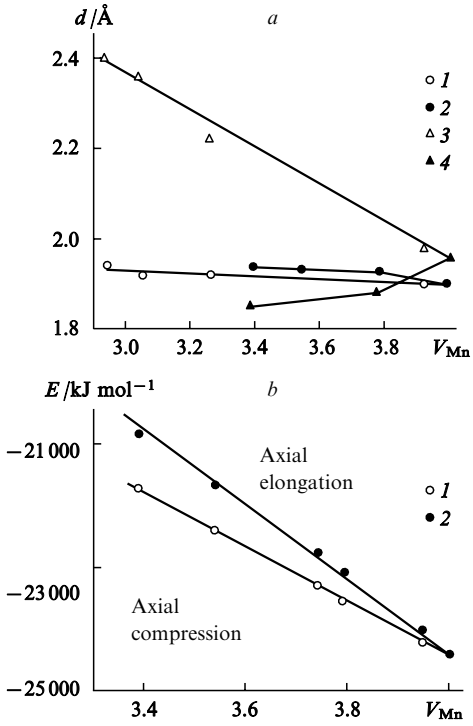

Figure 17. Changes in the $(Mn-O)_{eq}$ (*1*, *2*) and $(Mn-O)_{ax}$ (*3*, *4*) bond lengths in $Sr_2MnGaO_{5+\delta}$ (*1*, *3*) and $Sr_2MnGaO_{5-x}F_{1+x}$ (*2*, *4*) (*a*) and in the crystal lattice energy for $Sr_2MnGaO_{5-x}F_{1+x}$ in the case of axially compressed (*1*) and axially elongated (*2*) MnO_6 octahedra (*b*) as a function of the manganese oxidation state.

and further to 1.9411 Å ($V_{Mn} = +3.39$, $x_F = 0.61$) owing to an increase in the ionic radius of manganese upon reduction.

In the case of $Sr_2MnGaO_{5+\delta}$ ($\delta \approx 0.5$), reduction is also accompanied by an elongation of the axial Mn–O bonds due to the Jahn–Teller effect. Conversely, a progressive compression of the MnO_6 octahedra with a decrease in the manganese oxidation state is observed for solid solutions $Sr_2MnGaO_{5-x}F_{1+x}$. The axial Mn–O bonds in $Sr_2MnGaO_{4.78}F_{1.22}$ [*viz.*, 1.876(8) Å] are significantly shorter than in $Sr_2MnGaO_{5.5}$ [1.956(3) Å]. Thus, the reductive fluorination leads to a change in the type of Jahn–Teller effect from axially elongated to axially compressed. Presumably, this is due to competitive changes in the lattice energy and stabilisation energy associated with the Jahn–Teller distortion of the octahedral environment of manganese atoms.

In manganites $Sr_2MnGaO_{5+\delta}$ doped with oxygen, the axial elongation of the MnO_6 octahedra is partly compensated by shortening of the axial Ga–O bonds due to a decrease in the coordination number of gallium to 4. For solid solutions $Sr_2MnGaO_{5-x}F_{1+x}$, the axial Ga–O bond lengths remain constant upon variation of the composition of the solid solution since all anion sites in the Ga layer are already occupied and thus the coordination number of gallium atoms does not change. Therefore, in this case, the elongation of the axial Ga–O bond coupled with the lack of a compensating contraction should result in too long Sr–O bonds and thus in inevitable losses in the crystal lattice energy (Fig. 17 *b*).

The change in the type of Jahn–Teller distortion on going from $Sr_2MnGaO_{5.5}$ to $Sr_2MnGaO_{5-x}F_{1+x}$ should give rise to a change in the type of orbital ordering, as it was established for solid solutions $Nd_{1-x}Sr_xMnO_3$.[69] A change in the strontium/neodymium stoichiometric ratio and, consequently, in the manganese oxidation state results, at $x = 0.6$, in a change in the type of Jahn–Teller distortion from axially compressed [$0.55 < x < 0.6$, $d(Mn-O)_{eq} = 1.948$ Å, $d(Mn-O)_{ax} = 1.906$ Å] to axially elongated [$x > 0.6$, $d(Mn-O)_{eq} = 1.894$ Å, $d(Mn-O)_{ax} = 1.955$ Å]. The reason for the change in the type of Jahn–Teller distortion is the change of the type of orbital ordering from $d(x^2-y^2)$ to $d(z^2)$, which, in turn, is accompanied by a change in the magnetic structure from type A (antiferromagnetically ordered ferromagnetic planes) to type C (ferromagnetically ordered antiferromagnetic planes) and a metal–dielectric transition at $x = 0.6$.

VII. Magnetic and transport properties of brownmillerites $A_2MnB'O_{5+\delta}$ (A = Ca, Sr; B′ = Ga, Al) and their derivatives

Despite differences in the crystal structures of brownmillerites $A_2MnB'O_{5+\delta}$ (A = Ca, Sr; B′ = Ga, Al) with $\delta \approx 0$ due to different ordering patterns of the chains of tetrahedra, their magnetic structures are essentially similar. These phases convert into an antiferromagnetic state at $T_N = 150-180$ K. The respective saturated magnetic moments (μ) and the Néel temperatures (T_N), as determined by neutron diffraction for several compositions, are listed in Table 6. The magnitudes of the magnetic moments are in good agreement with the theoretical values for Mn^{3+} (which is characterised by the electronic configuration $3d^4$, $t_{2g}^3e_g^1$). The magnetic moments of manganese atoms are oriented perpendicular to the MnO_2 layers. All reduced brownmillerites reveal the G-type antiferromagnetic structure, which implies that the magnetic unit cell conforms to the crystallographic one and the magnetic moments of adjacent manganese atoms are antiparallel not only in the MnO_2 layers but between the layers as well (Fig. 18 *a*).

The magnetic interaction in the brownmillerite structure has a three-dimensional character despite the fact that the distances between adjacent Mn atoms along the *b* axis are approximately twice as large as in the *ac* plane. The three-dimensional character of the magnetic ordering assumes significant superexchange interactions between consecutive MnO_2 layers along the *b* direc-

Table 6. The magnetic characteristics of brownmillerites $A_2MnB'O_{5+\delta}$ (A = Ca, Sr; B′ = Ga, Al).

Oxide	μ /μ_B	T_N /K	Ref.

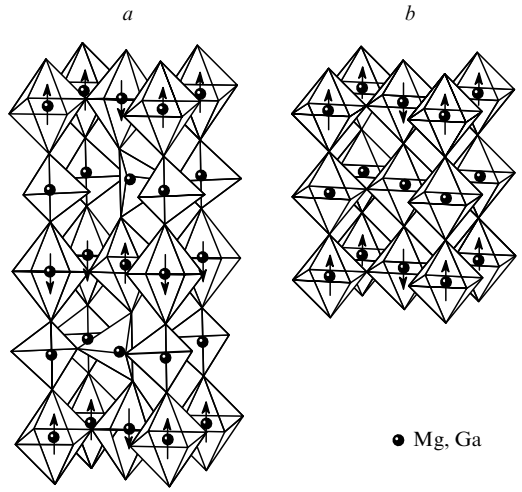

Figure 18. The magnetic structure of Sr_2MnGaO_5 (G-type) (*a*) and $Sr_2MnGaO_{5.5}$ (C-type) (*b*).

tion of the orthorhombic unit cell. The involvement of the superexchange interactions is directly supported by the NQR data.[55] The frequency of the local magnetic field on a gallium atom exceeds the calculated frequency of a dipole field by two orders of magnitude. This suggests that the experimentally observed local field has a dominant contact character and is induced by the superexchange interactions between manganese ions through a 'nonmagnetic' GaO_4 tetrahedron. The magnetic structure of $Sr_2MnGaO_{5.5}$, although also antiferromagnetic, is different from that of the reduced compound. In this structure, the MnO_2 layers (in which manganese atoms are ordered antiferromagnetically) are coupled ferromagnetically, which corresponds to type C of the perovskite magnetic structures (Fig. 18 *b*). The magnetic unit cell remains tetragonal although its volume is twice as large as that of the crystallographic cell. The parameters of the magnetic and crystallographic unit cells relate to each other by the following equations: $a_m = \sqrt{2}a_c$, $c_m = c_c$. The changes in the magnetic structure type on going from Sr_2MnGaO_5 to $Sr_2MnGaO_{5.5}$ occur due to the appearance of extra oxygen atoms in the Ga layers, which additionally stabilise the type C magnetic structure due to more distant 'diagonal' superexchange interactions through the GaO_6 octahedra.[52] Interactions through the $Ga(O,F)_6$ octahedra in $Sr_2MnGaO_{5-x}F_{1+x}$ [$T_N = 70$ K, $\mu = 1.5(1)\ \mu_B$] also give rise to ferromagnetic ordering of antiferromagnetic planes.[70] Nevertheless, in contrast to Sr_2MnGaO_5 and $Sr_2MnGaO_{5.5}$, the orientation of the magnetic moments in oxofluorides is parallel to the MnO_2 layers rather than perpendicular to them, which can be explained assuming the change in the orbital ordering type. This was suggested based on the analysis of interatomic distances in the structures of oxofluorides.[68]

According to neutron diffraction and muon resonance spectroscopy, $Sr_2MnGaO_{5.5}$ is characterised by an inhomogeneous magnetic structure below 180 K. This manifests itself in the appearance of small domains ($\sim$40 Å) with the type G magnetic structure embedded into a matrix with the type C structure.[52] When the oxygen overstoichiometry index δ is decreased to 0.41, the local magnetic order of the type G is replaced by co-existence of two regular magnetic structures: an antiferromagnetic type G structure is formed at $T = 140$ K while an admixture of a type C phase appears at $T = 110$ K.[71] The co-existence of these two long-range magnetic structures was observed for $Sr_2MnGaO_{5.5}$ as well (see Ref. 48). It is the local ordering of oxygen atoms in the $GaO_{1+\delta}$ layer giving rise to differences in the character of interactions between adjacent MnO_2 layers that should be considered as the most probable reason for this phenomenon. Indeed, such an ordering, which results in the symmetry lowering to monoclinic system, was experimentally established for $Sr_2MnGaO_{5.41}$ (see Refs 51, 56).

Complex oxides $Ca_2MnGaO_{5.045}$, $Ca_2MnGa_{1-x}Zn_xO_5$ ($x = 0.1-0.2$)[55] and $SrCaMnGaO_5$ (see Ref. 43) are insulators. Their electrical resistance as a function of temperature follows the normal activation law with sufficient accuracy. $SrCaMnGaO_5$ manifests magnetoresistance that amounts to 85% in a field of 6 T and up to 90% in a field of 13 T at 159 K.[43]

VIII. The oxide $Ca_{2.5}Sr_{0.5}GaMn_2O_8$ as the second member of the homologous series of brownmillerite-like structures

The homologous series of brownmillerite structures $A_{n+1}B_nB'O_{3n+2}$ is formally constructed by adding a certain number of octahedral layers to the brownmillerite structure. The *n*th member of the series contains blocks composed of *n* layers of BO_6 octahedra separated from each other by a layer of $B'O_4$ tetrahedra. The second member of the manganese-containing homologous series, which corresponds to stoichiometry $Ca_{2.5}Sr_{0.5}GaMn_2O_8$, was synthesised at 1100 °C in air.[72] Since the formal oxidation state of manganese in this compound is +3.5, the synthesis does not require an inert atmosphere. This

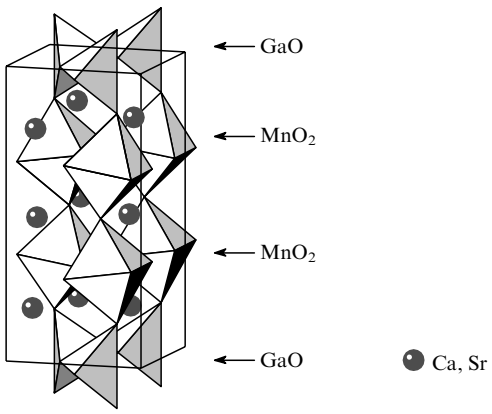

Figure 19. The crystal structure of $Ca_{2.5}Sr_{0.5}GaMn_2O_8$.

oxide crystallises in the orthorhombic system [sp. gr. $Pcm2_1$, $a = 5.4294(1)$ Å, $b = 11.3722(3)$ Å, $c = 5.2983(1)$ Å] (Fig. 19). In this structure, the MnO_6 octahedra are distorted but the character of the distortion differs from that in brownmillerite. An MnO_6 octahedron is characterised by five shorter [1.857(10) – 1.950(4) Å] and one longer [2.163(5) Å] Mn – O bonds. The elongated axial Mn – O bond is directed towards the layer of tetrahedra whereas the short axial bond is responsible for the Mn – O – Mn bonding between the layers of octahedra. Apparently, such an atomic arrangement provides the optimum coordination of the A cations located between the octahedral layers. This oxide converts between 150 K and 125 K into an antiferromagnetically ordered state with the magnetic moments oriented perpendicular to the MnO_2 layers [$\mu = 3.09(1)\ \mu_B$]. Within the MnO_2 layer, the neighbouring manganese atoms interact antiferromagnetically whereas adjacent octahedral layers and their pairs separated from each other by a GaO layer interact ferromagnetically. The transition into the magnetically ordered state is accompanied by an abrupt decrease in the electrical resistance (which, notwithstanding, remains too high to refer this transition to a dielectric – metal transition) with the magnetoresistance effect being about 50% in a field of 80 kŒ.[72]

Reduction of manganese in $Ca_{2.5}Sr_{0.5}GaMn_2O_8$ by means of partial substitution of trivalent cations for bivalent cations of alkaline-earth metals gives rise to a structural transformation resulting in a new type of anion ordering, which has been observed for the first time in the crystal structure of $Sr_{0.7}Y_{0.3}CoO_{2.62}$ (see Ref. 73). The oxide $Y_{0.8}Sr_{2.2}GaMn_2O_{7.9}$ is characterised by a tetragonal unit cell with the following parameters: $a = 7.6373(3)$ Å and $c = 15.6636(10)$ Å, sp. gr. $I4/mmm$.[74] This structure is composed of alternating octahedral and tetrahedral layers; the B sites are statistically occupied by manganese and gallium atoms with manganese atoms preferably occupying the octahedral sites. The structure of $Y_{0.8}Sr_{2.2}GaMn_2O_{7.9}$ contains isolated squares of vertex-sharing tetradera instead of chains of tetrahedra typical of the brownmillerite structure. The coordination environment of the B cations within this layer is supplemented by additional oxygen atoms situated between the squares of tetrahedra giving rise to a total coordination number of 5.[74] Presumably, the driving force for the formation of this structure is ordering of crystallographically non-equivalent Sr^{2+} and Y^{3+} cations.

IX. Conclusion

It is the differences in the ionic radii, electronic structures and typical coordination polyhedra of various cations differing in their crystal chemical properties that can be deliberately exploited in the design and synthesis of layered perovskite-like compounds. This idea is demonstrated in the present review by the example of complex oxides $A_2MnB'O_{5+\delta}$ (A = Ca, Sr; B′ = Ga, Al) having

the brownmillerite structure. A method for the synthesis of such complex oxides has to provide the optimum conditions (including a proper choice of composition, temperature and partial oxygen pressure) for ordering of cations. The presence of anion vacancies in the brownmillerite structure enables chemical modifications of the structure and adjustments of properties by variations of the anion stoichiometry under mild conditions not affecting the initially achieved ordered arrangement of cations. The brownmillerite structure is capable of adapting to changes in the anion composition (owing to the anion-deficient B′O layers); it is characterised by stable octahedral environment of manganese atoms in the oxidation states +3 and +4; it allows preparation of various members of the homologous series $A_{n+1}B_nB'O_{3n+2}$ manifesting magnetoresistance (for $n = 1, 2$). Thanks to all these features, browmillerite-like complex oxides of manganese should be considered as highly promising objects for the synthesis of novel magnetoresistive materials.

The current review has been written with partial financial support from the 'Petroleum Research Fund' (Project No. 38459-AC5), the INTAS (Grant for young scientists YSF 03-55-1035) and the 'Federal Programme in Support of the Leading Scientific Schools of the Russian Federation' (Project NSch-2033.2003.03). The role of heteroepitaxy in the development of new thin-film oxide-based functional materials

A R Kaul, O Yu Gorbenko, A A Kamenev

Contents

I.	Introduction	861
II.	Epitaxial stabilisation	861
III.	Variant structures	874
IV.	Conclusion	878

Abstract. The methods of synthesis of new oxide compounds and thin-film materials based on the use of heteroepitaxy are considered. The thermodynamic model and the theory of the epitaxial stabilisation phenomenon are outlined, the role of thermodynamic and structure-geometric factors determining the possibility of epitaxial stabilisation of unstable phases is interpreted. The use of epitaxial stabilisation for the design of heterostructures with specific electric properties is demonstrated. The characteristic features of the structural relations between the film and substrate materials, resulting in the formation of thin films with different numbers of variants, are discussed. The bibliography includes 128 references.

I. Introduction

Epitaxy, *i.e.*, oriented growth of a crystal on another crystal, has long been used to synthesise thin-film materials. This is the simplest and the most economical way of preparing structurally perfect film materials, which successfully replace single crystals with large diameters. Numerous examples of using epitaxial processes in elementary semiconductors are known, in particular, heteroepitaxy of silicon films on the surface of a sapphire single crystal, preparation of films of the Si_xGe_{1-x} solid solution on the surface of single crystal silicon plates, silicon autoepitaxy on silicon plates and so on. By means of epitaxy, one can produce materials with different widths of the forbidden gap. The most impressive results in the design of semiconductor materials of the $A^{III}B^{V}$ family for optoelectronics were attained using this method. Epitaxy was used to obtain layers with a low concentration of defects and periodic structures with alternation of numerous layers with diverse compositions several nanometers thick. For the synthesis of such structures, a MOC-hydride process has been developed and special highly automated equipment has been designed (in particular, AIXTRON equipment has found extensive application).

Unlike the epitaxy of semiconductors, the epitaxy of oxides is far from being well-developed in both theoretical and engineering aspects, although the demand for oxide materials in semiconductor engineering was realised long ago. This lag is due to a number of reasons, most of all, to the great diversity of structures and chemical properties of oxides. It often remains unknown whether it is possible to perform epitaxial intergrowth of oxides corresponding to different structural types and having different lattice parameters. The necessity of using high temperature and, most often, a high partial pressure of oxygen promotes side chemical reactions of oxides, in particular, those with the products of surface oxidation of semiconductors. These circumstances appreciably complicate the preparation of epitaxial oxide materials. In addition, the structural and chemical diversity of oxides accounts for more diverse manifestations of the epitaxy (compared to those for semiconductors) and opens up new prospects for the application of this phenomenon.

This review deals with two original methods for the preparation of new thin-film oxide materials, namely, epitaxial stabilisation of unstable phases and the design of variant structures. The review mainly presents the studies carried out by researchers engaged in the chemistry and physics of thin oxide films at the Chair of Inorganic Chemistry of the Department of Chemistry of the M V Lomonosov Moscow State University.

II. Epitaxial stabilisation

1. The principles of epitaxial stabilisation

The last 15 years have seen intensive research into the preparation of epitaxial films of multicomponent complex oxides. The attention of researchers was focused on perovskite-type or related compounds, which possess unique properties. These include high temperature semiconductors of the $RBa_2Cu_3O_{7-\delta}$ (R is lanthanide) and Bi – Ca – Sr – Cu – O families, the $Pb(Ti,Zr)O_3$ and $(Ba,Sr)TiO_3$ ferroelectrics, materials with colossal magnetoresistance $La_{1-x}(Ca,Sr)_xMnO_3$, and electron – ion conductors $La_{1-x}(Sr,Ca)_xCoO_3$.

Much effort was devoted to methods for the preparation of multicomponent oxide films, such as metal organic chemical vapour deposition (MOCVD), pulse laser deposition (PLD), magnetron sputtering, *etc*. Despite the difference, these methods have one feature in common — the mass transfer processes that underlie them are incongruent, *i.e.*, during the substance transfer from the target or the gas phase onto the substrate, the ratio of the cationic components changes to some extent. This often violates the stoichiometry of the cationic composition of the films and usually gives rise to second phases (inclusions). In order to obtain single-phase epitaxial films, the composition of the target or the

flow of volatile components should be consistently corrected based on the results of elemental analysis of films.

Examination of phase analysis data for off-stoichiometric epitaxial films has shown that impurity phases often differ from those expected relying on the known phase diagrams of the systems under consideration. In addition, it was found that the growth of single-phase epitaxial films often takes place under thermodynamic conditions (P_{O_2} and T) where this compound as a bulk material (polycrystalline powder, ceramics or a single crystal) is thermodynamically unstable. These phenomena are of a common nature and can be explained by phase stabilisation due to the epitaxy on the substrate or due to the epitaxy at the interface between two phases formed simultaneously (the matrix and the inclusion).

The relationship between the formation of metastable phases and the epitaxy was first noted by Dankov [1,2] when growing oxide layers on metals. Later, van der Merwe [3,4] performed a comprehensive theoretical analysis of the growth of epitaxial layers. The data they obtained were summarised to formulate the structural and size compliance principle (the Dankov–van der Merwe principle). As applied to epitaxial stabilisation, this principle can be outlined as follows: the competitive formation of new phases on a substrate surface would predominantly yield phases congruent to the substrate. In Russian publications, this is called more often the Dankov–Konobeevskii principle.

The appearance of metastable phases on the single crystal surface may be of both thermodynamic and kinetic nature. The Dankov–van der Merwe principle is apparently applicable both to systems in which the particle diffusion in the growing layer is sufficient for ensuring a phase equilibrium and to systems in which diffusion is retarded.

In the systems we are interested in, epitaxial films of complex oxides grow, most often, at high temperatures ($\sim 600-900\,^{\circ}C$), *i.e.*, the thermodynamic factor predominates. Depending on the structural correspondence between the film and the substrate, either epitaxial or polycrystalline films are formed. Experiments show that the phase composition of the polycrystalline films does not differ from that predicted by equilibrium phase diagrams for the given elemental composition and the number of phases obeys the Gibbs phase rule. In addition, the phase composition is reproduced in successive experiments on film preparation and does not change during long-term annealing at the film deposition temperature. These findings prove that the polycrystalline oxide layers formed on the substrates in the above-indicated temperature range are quite close to true thermodynamic equilibrium,† although film growth from the gas phase is undoubtedly a non-equilibrium process.

As regards epitaxial films produced under the same conditions, their phase composition is also reproducible and also does change after long-term annealing at the temperature of film growth. However, the phase composition of the epitaxial films, unlike that of polycrystalline films, often does not correspond to that predicted relying on the equilibrium phase diagram. However, epitaxial films are much closer to an ideal single crystal and have a lower free energy than polycrystalline films of the identical composition, as they do not have an extensive internal surface typical of polycrystals. Thus, one can state that the observed deviations of the phase composition of the oxide epitaxial films from that predicted on the basis of equilibrium phase diagrams constructed for bulk states are due to thermodynamic factors. These deviations are related to the formation of new equilibrium phase relations in the film material. This is caused by the decrease in the system free energy following a decrease in the contribution of the free energy of the film/substrate interface in the case where they are structurally coherent.

The epitaxial stabilisation (ES) can be defined, from the thermodynamic standpoint, as extension of the $P-T-x$ space of the thermodynamically stable existence of the epitaxial phase with respect to the bulk state of this phase free from a substrate.

Table 1 presents examples of epitaxial stabilisation which shows itself as metamorphism of simple and complex oxides, the formation of new oxide phase and as the stabilisation of compounds containing metals in unstable oxidation states.

This Table is not meant to be exhaustive, giving only the epitaxial phases formed upon epitaxial stabilisation of the thermodynamic origin. It is noteworthy that most of the researchers cited were prone to treat the results they obtained as a curiosity observed for unknown reasons in a particular system rather than a predictable phenomenon of the thermodynamic nature.

In the next Sections, we consider the theoretical foundations of the epitaxial stabilisation and demonstrate, using our studies as examples, that this phenomenon can be utilised for the synthesis of new solid-state compounds and new materials.

The greater part of the data included in Table 1 refer to the polymorphism of simple oxides. This is due to several reasons: first, the preparation of the phases of simple oxides is not complicated by the necessity of controlling the cationic composition; second, selection of the $P_{O_2}-T$ conditions for their synthesis is more obvious than in other cases; third, highly symmetric single-crystal substrates can be used in their synthesis.

Examples of preparing new compounds with complex compositions due to the ES are scarce since the necessary conditions unknown in advance, namely, the stochiometric ratio of the cations, the $P_{O_2}-T$ film growth conditions, and the similarity of growing film and substrate parameters, are unlikely to be simultaneously fulfilled by chance. The choice of these conditions should be deliberate.

2. The thermodynamic model of epitaxial stabilisation

Let us consider the formation of a new phase nucleus on the surface of a single crystal during deposition from the gas phase. The Gibbs energy (ΔG_f) of the formation of this nucleus‡ is described by the equation:

$$\Delta G_f = \Delta g_V V + \sigma S + \Delta G^{El}, \quad (1)$$

where Δg_V is the specific volume Gibbs energy, J m^{-3}; σ is the surface tension, N m^{-1}; V and S are the volume and the surface area of the nucleus, respectively; ΔG^{El} is the contribution of elastic tension arising in the nucleus due to the compressive or tension effect of the substrate. Note the difference between the units of measurement of the free Gibbs energy (ΔG_f) and the specific volume Gibbs energy (Δg_V), the former being related to one nucleus of the phase and expressed in J and the latter being related to the unit volume of the phase and measured in J m^{-3}. The Δg_V value can be determined directly from the standard thermodynamic parameters, while ΔG_f is calculated from Eqn (1) and takes into account the energetic contributions of the volume and the surface of the nucleus and stress in the nucleus. For a thermodynamically stable phase, $\Delta g_V < 0$, while the energy contribution of the nucleus surface to the Gibbs energy is always positive ($\sigma S > 0$), which hampers the growth of the nucleus.

Now we consider in more detail the contributions of all components to ΔG_f using the Little and Zangwill formalism.[49]

To simplify the manipulation, we will make a number of model assumptions which do not influence the results. We consider the influence of epitaxy on the growth of an oxide film in which a polymorphic transition of the $A' \rightarrow A''$ type, where A' is a phase coherent to the substrate and A'' is a non-coherent phase, may take place. For conservation of the amount of substance, as a first approximation, one can neglect the difference between the densities ρ of the two competing polymorphic forms A' and A''.

† This statement implies impossibility of further solid-state transformations in the layer.

‡ The calculation of the free energy of formation of a nucleus is a routine procedure in consideration of nucleation thermodynamics.[48]

Table 1. Epitaxial stabilisation of oxide phases in thin films.

Epitaxially stabilised phases (structural type)	Substrate [a] [misfit of the unit cell parameters of the film and the substrate $(a_f - a_s)/a_s$]	Equilibrium phases formed in bulk materials under the same conditions (structural type)	Film thickness /nm	Film deposition method	Remarks	Ref.
Metamorphism						
Simple oxides						
TiO_2 (anatase)	(001)$SrTiO_3$ (−3.1%)	TiO_2 (rutile)	1000	MOCVD, molecular beam epitaxy (MBE)	deposition on the leucosapphire (Al_2O_3) with different orientation on the surface under the same conditions gives rutile	5–9
	(001)$LaAlO_3$ (−0.2%)	TiO_2 (rutile)	$n \times 10$	MBE		10
	$La_{0.5}Sr_{0.5}CoO_3$ (−0.5%)	TiO_2 (rutile)	–	PLD		11
	(001)MgO (−10.1%)	TiO_2 (rutile)	1000	MOCVD		6
	(110)MgO (−10.1%, 12.9%)	TiO_2 (rutile)	1000	MOCVD		6
ZnO (sphalerite)	ZnS/(001)GaAs	ZnO (wurtzite)	560	MBE from organometallic compounds		12
Mn_3O_4 (cubic spinel)	(001)MgO	Mn_3O_4 (hausmannite, tetragonal spinel)	–	MOCVD		13
WO_3 (tetragonal phase)	*R*-Al_2O_3 (10.3%, 2.5%)	WO_3 (orthorhombic phase)	30	electron beam evaporation		14
γ-Fe_2O_3	(001)MgO (−0.9%)	α-Fe_2O_3	100	MBE	deposition on the leucosapphire (*a*-, *c*- and *R*-Al_2O_3) under the same conditions gives α-Fe_2O_3	15
Complex oxides						
$BaRuO_3$ (perovskite)	(001)$SrTiO_3$	$BaRuO_3$ (hexagonal, 9R)	100	radio frequency sputtering		16, 17
$Sr(Ru_{0.5}Sn_{0.5})O_3$ (perovskite)	(001)$KTaO_3$ (0.25%)	$Sr(Ru_{0.5}Sn_{0.5})O_3$ (hexagonal, 4H or 9R)	600	PLD		18
$BaTi_{1-x}Nb_xO_3$ (x = 0.01–0.15) (hexagonal)	*R*-Al_2O_3 (17%)	$BaTi_{1-x}Nb_xO_3$ (x = 0.01–0.15) (perovskite)	60	PLD	deposition on (001)$SrTiO_3$ gives perovskite	19
β-BaB_2O_4	*c*-Al_2O_3, *R*-Al_2O_3	α-BaB_2O_4	–	PLD	deposition on (001)Si gives α-BaB_2O_4	20
$PbZr_{1-x}Ti_xO_3$ (pyrochlore)	(001)CeO_2/*R*-Al_2O_3 (3.8%)	$PbZr_{1-x}Ti_xO_3$ (perovskite)	–	PLD	deposition on (001)$SrTiO_3$ and (001)LiF gives perovskite	21
Epitaxial stabilisation of new oxide phases						
Complex oxides						
$Bi_3Fe_5O_{12}$ (garnet)	(001)$Gd_3(Sc,Ga)_5O_{12}$, (111)$Gd_3(Sc,Ga)_5O_{12}$ (<0.5%)	$BiFeO_3$ + $Bi_2Fe_4O_9$	<1000	reaction deposition from ion beams		22, 23
				plasma sputtering, radio frequency sputtering		24, 25
				PLD		22, 26, 27
Ba_2RuO_4 (K_2NiF_4 type)	(001)$SrTiO_3$ (2.1%)	no data	150	PLD	no Ba_2RuO_4 phase is formed on the substrates: (001)MgO, (001)$MgAl_2O_4$, (001)$LaSrGaO_4$, (001)$LaAlO_3$, (001)$LaAlO_3$–Sr_2AlTaO_6	28
Epitaxial stabilisation of oxide phases with metal atoms in unusual oxidation states						
Simple oxides						
CrO_2 (rutile)	TiO_2 (rutile) in different orientations (2%–4%), *c*-Al_2O_3 (−7.1%, 6.0 %)	Cr_2O_3 (corundum)	1000	MOCVD	$T \leqslant 550$ °C, P_{O_2} = 1 bar, CrO_2 is not formed on SiO_2 (quartz)	29–35

[a] The orientations of the perovskite substrates are given in the cubic system.

This assumption does not introduce a significant error but eliminates the necessity of knowing the density or the molar volume (V'_M) of the coherent phase in the absence of stresses (in particular, the latter value is difficult to estimate for a material obtained only as a stressed film).

Assume that new-phase nuclei having a square base with side d and height h are formed on the surface of a single-crystalline substrate representing a two-dimensional lattice with a square unit cell. The relative misfit of the crystal lattice parameters of the substrate and the film at the interface will be defined as

$$\varepsilon = (a_f - a_s)/a_s = \Delta a/a_s ,$$

where a_f and a_s are the unit cell parameters of the growing film and the surface, respectively. Let us consider the case where the film occurs in a uniformly strained state. The expressions for calculating the Gibbs energies for the formation of unit nuclei of the coherent ($\Delta G'_f$) and non-coherent phases ($\Delta G''_f$) can be written as

$$\Delta G'_f = \Delta g'_V d^2 h + (\sigma^s_c)' d^2 + (\sigma^V)'(d^2 + 4dh) + h\frac{\mu}{1-\nu}\varepsilon^2 d^2, \quad (2)$$

$$\Delta G''_f = \Delta g''_V d 2h + (\sigma^s_{ic})'' d^2 + (\sigma^V)''(d^2 + 4dh). \quad (3)$$

The subscripts c and ic refer to the coherent and non-coherent states of the interface, respectively, and the superscripts s and V refer to the nucleus / substrate and nucleus / surrounding gas phase interfaces, respectively. The last term in Eqn (2) is the contribution of the epitaxial stress energy of the nucleus of the coherent phase. This includes the shear modulus μ and Poisson's ratio ν.

The nucleus of the non-coherent phase A″ occurs in a relaxed (*i.e.*, unstressed) state, because it is not bound epitaxially to the substrate. Therefore, Eqn (3) does not have a term corresponding to the stress energy in the nucleus. It is worth mentioning that the surface tension at the non-coherent nucleus/substrate interface is much higher than at the coherent nucleus/substrate interface, $(\sigma^s)' \ll (\sigma^s)''$. The surface tensions at the interfaces between A′ and A″ and the surrounding vapour phase can be taken to be equal: $(\sigma^V)' = (\sigma^V)''$.

We will assume that the non-coherent phase A″, which is free from the substrate, is thermodynamically more stable than the coherent phase A′ under the $P_{O_2} - T$ conditions of film preparation, *i.e.*,

$$\Delta g''_V < \Delta g'_V .$$

[On the substrate, the relative stability of the phases may change due to the pronounced differences between $(\sigma^s)'$ and $(\sigma^s)''$.] By subtracting Eqn (2) from Eqn (3), we get the expression for the Gibbs energy that characterises the stability of one polymorphic form with respect to the other one. Dividing both equations into d^2 (for simplification) gives the equation for determining the Gibbs energy of unit surface of the nucleus ($\Delta E_f = \Delta G_f/d^2$). Hence,

$$\Delta E = \Delta E''_f - \Delta E'_f = \quad (4)$$
$$= h\left[(\Delta g''_V - \Delta g'_V) - \frac{\mu}{1-\nu}\varepsilon^2\right] + \left[(\sigma^s_{ic})'' - (\sigma^s_c)'\right].$$

To take into account the difference between the densities of phases A′ and A″, the difference $(\Delta g''_V - \Delta g'_V)$ should be replaced by

$$\frac{\Delta g''_V V''_M - \Delta g'_V V'_M}{V'_M} = \frac{\Delta G_t}{V'_M},$$

where ΔG_t is the free energy of the solid-state transition per mole.

Equation (4) reflects the opposite effects of two contributions to the Gibbs energy, the surface and the volume ones. Indeed, the first term (the total contribution of the volume energy) is always negative, whereas the second term (the total contribution of the surface energy and the epitaxial stress) is always positive. If the ratio of these contributions is such that $\Delta E > 0$, the condition of epitaxial stabilisation of the coherent phase A′ is fulfilled, although in the free state, this phase is less stable than the non-coherent phase A″. Thus, the ΔE value is the energy of epitaxial stabilisation.

As can be seen from Eqn (4), the misfit between the unit cell parameters of the phase being stabilised and the substrate is a highly significant parameter. The dependence of ΔE on the misfit parameter ε follows a quadratic law, whereas the dependences on the difference between the specific Gibbs energies and the difference between the interface energies with the substrate are linear. The variation of the ES *vs.* film thickness is also linear. The equilibrium condition for the two polymorphic forms A′ and A″ ($\Delta E = 0$) is met at a critical film thickness (h_c):

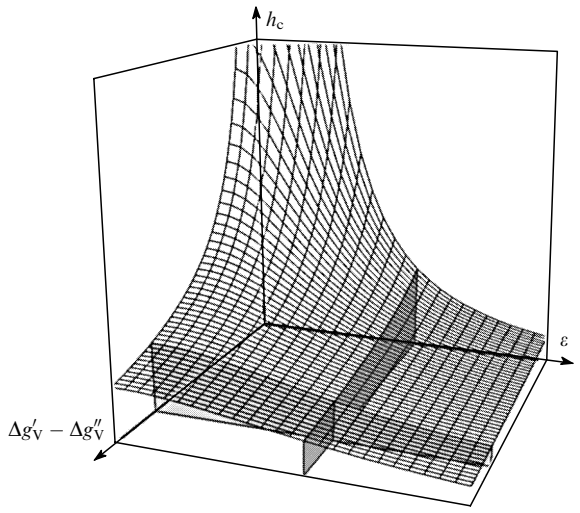

Figure 1. Critical film thickness (h_c) *vs.* the misfit of the unit cell parameters at the substrate/epitaxial film interface (ε) and *vs.* the difference between the specific volume energies of the unstable and stable phases.

$$h_c = \frac{(\sigma^s_{ic})'' - (\sigma^s_c)'}{(\Delta g'_V - \Delta g''_V) + [\mu/(1-\nu)]\varepsilon^2}. \quad (5)$$

Figure 1 shows a draft view of the dependence of the critical film thickness on the misfit of the cell parameters at the film/substrate interface and on the difference between the specific volume energies of the stable and unstable phases.

When the difference between specific volume energies of the competing polymorphic forms and the misfit between the cell parameters of the substrate and the stabilised form are small, the critical film thickness may be fairly large. Estimation of the h_c value from Eqn (5) shows that for a difference between the free energies of the phases of ~ 10 kJ mol^{-1} (this value is usual for polymorphic forms at a moderate deviation of the thermodynamic conditions from the polymorphic transition point), $\varepsilon \approx 0.01$ and for interfacial energies taken from published sources (presented below, see Ref. 50), the critical thickness of the stabilised layer amounts to tens of nanometres.

Interface (i)	Coherent (c)	Semicoherent (sc)	Non-coherent (ic)
σ^s_i /mJ m^{-2}	5–200	200–800	800–2500

When the film thickness is about several tens of nanometres, the model of uniformly strained film is no longer realistic. Stress relaxation in a non-uniformly strained film occurs through the formation of misfit dislocations. In this case, Eqn (4) should be supplemented by a term taking into account the non-uniformity of stresses. For simplicity, we assume that the Burgers vector of the misfit dislocation is equal to the unit cell parameter of the film a_f. Then the expression for ΔE has the form

$$\Delta E = h\left[(\Delta g''_V - \Delta g'_V) - \frac{\mu}{1-\nu}\left(\varepsilon - \frac{a_f}{l}\right)^2\right] + \quad (6)$$
$$+\left[(\sigma^s_{ic})'' - (\sigma^s_c)'\right] - \frac{1}{l}\left[E_{core} + \frac{\mu}{1-\nu}Ka_f^2 \exp\left(-\frac{4\pi h}{l}\right)\right],$$

where l is the distance between the neighbouring misfit dislocations, E_{core} is the energy of the dislocation nucleus and K is the pre-exponential factor. In the limit, $l = a_f/\varepsilon$, which corresponds to full relaxation of the epitaxial stress and disappearance of the term taking into account the contribution of uniform stresses from Eqn (6). When $h > a_f/\varepsilon$, the exponential term in the expression for non-uniform stress also disappears and the remaining addend, which does not depend on the film thickness, can be introduced as a correction for the interfacial energy [this correction transforms the energy of a coherent interface (σ_c) into the energy of a semicoherent interface (σ_{sc})]:

$$\Delta E = h(\Delta g''_V - \Delta g'_V) + [(\sigma^s_{ic})'' - (\sigma^s_{sc})']. \quad (7)$$

The term $[(\sigma^s_{ic})'' - (\sigma^s_{sc})']$ in Eqn (7) is positive, while the term depending on the film thickness is negative. The contribution of the surface energy $[(\sigma^s_{ic})'' - (\sigma^s_{sc})']$ to the Gibbs energy is lower in the case of a non-uniformly strained film than for a uniformly strained film with a coherent interface due to the higher energy of the semicoherent interface. However, the first (positive, 'destabilising') term also decreases in this case due to disappearance of the stress contribution. Thus, the epitaxial stabilisation can also take place in the growth of relaxed films on semicoherent substrates. In other words, epitaxial stresses in the film are not obligatory for the epitaxial stabilisation. Taking the difference between the Gibbs energies of the polymorphic forms to be, as in the previous case, 10 kJ mol^{-1} and substituting the interfacial energies into Eqn (7), one can estimate the critical thickness of the stabilised phase. The result is of the order of tens of nanometres.

The experience in preparation of thin films indicates that the phase non-coherent to the substrate always grows as a polycrystal. The internal interfaces in a polycrystalline materials make a substantial contribution to the Gibbs energy. This contribution (so-called excessive Gibbs energy), which has not yet been included in the energy balance of two polymorphic phases, undoubtedly affects the epitaxial stabilisation. Assuming that the average grain size in the non-coherent phase equals r and the average energy of the boundaries of chaotically oriented grains equals σ''_{gb} and taking into account the fact that the number of grains on unit surface equals d^2/r^2 ($d \gg r$), we obtain a relation for the total energy of the grain boundaries of the non-coherent phase concentrated on unit surface area of the substrate

$$E_{gb} = \frac{2h\,\sigma''_{gb}}{r}. \quad (8)$$

By substituting the E_{gb} value as an additional term for the non-coherent phase energy, into Eqn (7), we get an expression for the epitaxial stabilisation energy

$$\Delta E = h\left[(\Delta g''_V - \Delta g'_V) + \frac{2\,\sigma''_{gb}}{r}\right] + [(\sigma^s_{ic})'' - (\sigma^s_{sc})']. \quad (9)$$

It should be noted that the surface tension σ''_{gb} in a polycrystalline film is of the same order of magnitude as σ_{ic}, and, hence, the influence of polycrystallinity, which increases ΔE, may become prevailing. The role of this factor appreciably increases with a decrease in the grain size. As the polycrystalline film of the stable phase grows, the grain size does not remain constant but increases; however, under steady-state conditions of growth, this increase follows the law $r \propto \sqrt[n]{h}$ ($n \geqslant 2$). Therefore, the increase in the grain size does not much decrease the excessive free energy of the intergrain boundaries and, finally, does not interfere with the preparation of the epitaxially stabilised phase as films with a large critical thickness.

In order to verify the applicability of Eqns (7) and (9) for the calculation of ΔE, we will consider the results of calculations of the polymorphic transition TiO_2(anatase) → TiO_2(rutile) (Fig. 2). It follows from the data of Table 1 that the TiO_2(anatase) film grows on the (001)$LaAlO_3$ surface epitaxially to form a semicoherent interface. According to the above data, the energy of the semicoherent interface between the thin film and the substrate can be taken to be $(\sigma^s_{sc})' = 800$ mJ m^{-2}. A hypothetical film of the stable rutile phase could grow in the polycrystalline form under these conditions. The energy of the non-coherent interface between such a film and a substrate $(\sigma^s_{ic})''$ can amount to 2500 mJ m^{-2}; the non-coherent intergrain boundaries σ''_{gb} have the same energy. The difference between the specific volume energies $(\Delta g''_V - \Delta g'_V)$ calculated using the published value of the Gibbs energy for the TiO_2(anatase) → TiO_2(rutile) transition (-5 kJ mol^{-1}) [51, 52] and

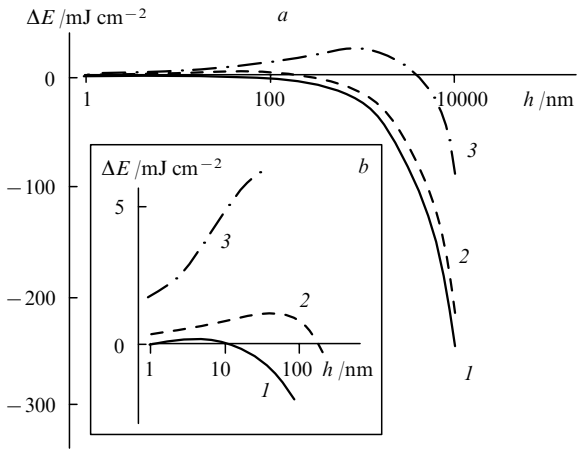

Figure 2. Results of model calculations for the TiO_2(anatase) → TiO_2(rutile) polymorphic transition using Eqns (7) (curve *1*) and (9) (curves *2* and *3*) (*a*). The inset (*b*) shows the enlarged view of the initial course of curves *1*–*3*;
r/μm: ∞ (*1*), 25 (*2*), 1 (*3*).

the theoretical density values for rutile and anatase (4.25 and 3.89 g cm^{-3}, respectively), is equal to 243.7 J cm^{-3}.

It can be seen from Fig. 2 that the anatase epitaxial film is thermodynamically more stable than the rutile polycrystalline film when the film thickness is smaller than the critical value h_c, corresponding to the condition $\Delta E = 0$. With the reasonable assumption that the rutile film can be formed by crystallites with the size $\sqrt{h}$, we finally get that the critical thickness of an epitaxially stabilised film of anatase can reach 4 μm! Although the exact value of h_c depends on the numerical values $(\sigma^s_{ic})''$, $(\sigma^s_{sc})''$ and σ''_{gb} used for calculations, this calculation still proves the theoretical possibility of preparing stabilised phases as epitaxial films with a sufficient thickness for many practical applications. In other words, the epitaxial stabilisation can be an efficient tool for the preparation of new functional materials.

Undoubtedly, crystallisation under real conditions is much more complicated than is described in terms of the above model. First of all, this model does not take into account any kinetic effects, resulting in accumulation of non-equilibrium point and extended defects in the epitaxial films (stacking faults, antiphase boundaries, development of mosaic block low-angle boundaries) and ultimately in the inevitable disappearance of the epitaxy following an increase in the film thickness. Apparently, these kinetic effects rather than the value we calculated from thermodynamic considerations are responsible for restriction of the stabilised phase thickness. Thus, the growth of films under conditions favourable for acceleration of diffusion processes and crystallisation, in particular, the growth at a temperature exceeding the Tamman temperature,§ or implementation of the liquid-phase growth mechanism (for example, vapour–liquid–crystal or the liquid-phase epitaxy) would promote the formation of stabilised phases as epitaxial films with the critical thickness predicted by the thermodynamic model outlined above.

This model can be applied not only to a polymorphic transformation of two phases but also to more complicated phase ensembles; however, considering such ensembles requires much more complicated equations but does not reveal any new significant aspects of epitaxial stabilisation.

§ The Tamman temperature is the temperature above which intensive self-diffusion occurs in a solid. As a rule, the Tamman temperature is taken to be 0.6 T_m (the Tamman rule).

3. Preparation of epitaxial oxide films by MOCVD

Metal organic chemical vapour deposition (MOCVD) is a promising and efficient method for the preparation of films of simple and complex oxides.

The MOCVD method has a number of obvious advantages over the high-vacuum physical (physical vapour deposition, PVD) methods, in particular,

— relatively low cost,
— relatively low requirements to the vacuum equipment,
— the possibility of high deposition rate,
— remarkable versatility as regards the variation of the elemental composition of films.

These advantages make the MOCVD method very attractive for the modern technology of films and coatings. A substantial progress in the development of this method as applied to the production of films of simple and complex oxides has been attained during the last 15 years. This was largely due to the advent of methods for the preparation of epitaxial films of high-temperature superconductors (HTSC), especially those of the $RBa_2Cu_3O_{7-\delta}$ family.[53] The superconducting properties of films are highly sensitive to minor changes in the composition and structure; therefore, the problem of preparing HTSC with reproducible properties is much more challenging than the problem of preparing other thin-film materials. The advances attained in MOCVD syntheses of HTSC films stimulated the extension of this method to many other functional oxide materials often having rather complex elemental composition.

The heterogeneous MOCVD process consists of several consecutive stages: evaporation or sublimation of the starting compounds (volatile organometallic compounds), their transfer through the gas phase (often complicated by gas-phase reactions) and, finally, oxidative thermolysis on the substrate with simultaneous crystallisation of the product. Each stage is complicated. In the case of multicomponent films, the difference between the chemical and thermal properties of compounds used to transport each of the starting components results in a substantial incongruence of the process, *i.e.*, in different stoichiometric ratios of the metallic components in the vapour of the starting compounds and in the film. This is the major syntetic challenge in the preparation of multicomponent films.[54, 55]

Nevertheless, the synthesis of new volatile compounds with improved properties (more stable and more volatile) for a large number of metals, perfection of batching and vaporisation techniques and the design of more advanced reactors with optimised thermal fields and gas dynamics turned MOCVD into an advanced process technology.

Most often, metal dipivaloylmethanates $M(dpm)_n$ or their adducts with *o*-phenanthroline were used as the starting compounds for the synthesis of the thin films of manganites $R_{1-x}M_xMnO_3$ (R = La–Lu; M = Ca, Sr, Pb, Na), nickelates $RNiO_3$ (R = La, Pr, Nd, Sm, Gd), cobaltates $RCoO_3$ (R = Tm, Lu), ferrites $RFeO_3$ (R = Eu–Lu), garnets $R_3Fe_5O_{12}$ (R = Nd, $Nd_{1-x}La_x$), indates $RInO_3$ (R = La–Lu), ruthenates $(Ca,Sr)RuO_3$ and superconductive cuprates $RBa_2Cu_3O_{7-\delta}$ (R = Lu, Ho, Y, Gd) considered in this review. These compounds were evaporated as microbatches fed successively to the evaporating chamber; thus, the flash vaporisation principle, which minimises the thermal degradation of the precursors, was implemented. Various special devices (feeders) were used for the supply of precursors: aerosol, vibratory, belt, frictional and screw feeders. The precursor vapours were transported by an argon–oxygen stream to tubular reactors heated by the external resistance furnace or induction method.

The temperature of the substrates (usually single crystals cut along a definite plane and polished) was varied, depending on the system, in the 650–900 °C range and the oxygen pressure was 1–7 mbar. The total pressure in the reactors (maintained constant in each experiment) was in the range 3–20 mbar. The

MOCVD conditions are described in more detail in our original publications.[53, 56–60]

4. Epitaxial stabilisation of unstable compounds RMO_3 (R is lanthanide, M = Mn, Ni, Co, Fe, In)

Manganites $RMnO_3$. In the series of $RMnO_3$, phases with the perovskite structure are formed under ambient pressure only for lanthanides with great ionic radii (R = La–Dy), whereas elements with smaller ionic radii (Y, Ho–Lu) form hexagonal structures with the same stoichiometry.[61] The corresponding perovskites $RMnO_3$ (Y, Ho–Lu) were prepared only under high pressure.[62] However, the situation can change upon the change in the contribution of the surface free energy. Thus the $YMnO_3$ nanoparticles synthesised under normal pressure are no longer hexagonal but have a perovskite structure.[63]

We attained epitaxial stabilisation of the perovskite phase $RMnO_3$ (R = Y, Ho, Tm, Lu) by MOCVD deposition of the $RMnO_3$ films onto the (001)$LaAlO_3$ and (001)$SrTiO_3$ substrates.[64] The orthorhombically distorted perovskite $YMnO_3$ was also prepared by PLD on a substrate.[65]

The most efficient stabilisation takes place on the $LaAlO_3$ substrate because this is characterised by a minimum misfit (~0.5%) between the unit cell parameters and the growing perovskite film. Using this substrate, 100–200-nm thick perovskite films were prepared (T = 750 °C). Under the same conditions, no perovskite phase is formed on the $(1\bar{1}02)Al_2O_3$ and (111)$ZrO_2(Y_2O_3)$ substrates. The resulting perovskite films were structurally identical to those formed in the polycrystalline state at high pressure: their perovskite structure experienced substantial orthorhombic distortion (orthorhombicity parameter ~5%, space group *Pnma*). The distortion of the perovskite structure gave rise to twinning in the films. According to powder X-ray diffraction and high-resolution transmission electron microscopy (HREM) of film cross-sections, the unit cell parameters are always doubled along the substrate plane (Figs 3, 4) and the direction of doubling of the cell parameter in each successive domain is changed by 90°. This type of twinning reduces the stress arising in the film due to the misfit in the cell parameters of the film and the substrate because this markedly decreases the energy of the film/substrate interface, in conformity with the theory developed by Little and Zangwill.[49]

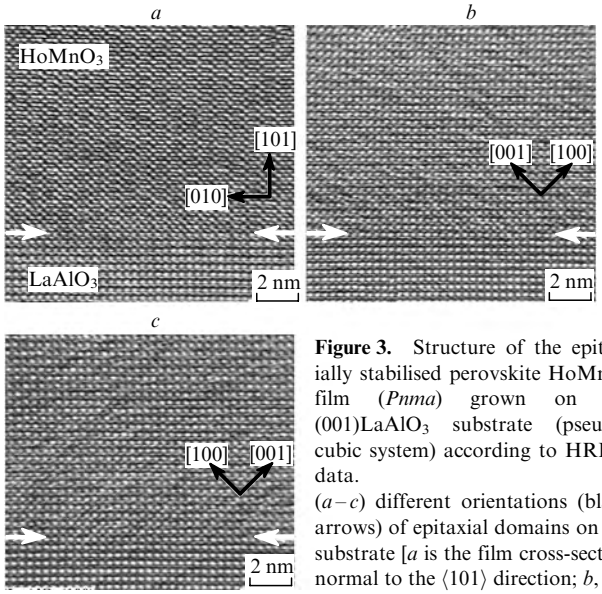

Figure 3. Structure of the epitaxially stabilised perovskite $HoMnO_3$ film (*Pnma*) grown on the (001)$LaAlO_3$ substrate (pseudocubic system) according to HREM data.
(*a*–*c*) different orientations (black arrows) of epitaxial domains on the substrate [*a* is the film cross-section normal to the ⟨101⟩ direction; *b*, *c* is the same normal to the ⟨010⟩ direction.] Here and below, light arrows designate the film/substrate boundary.

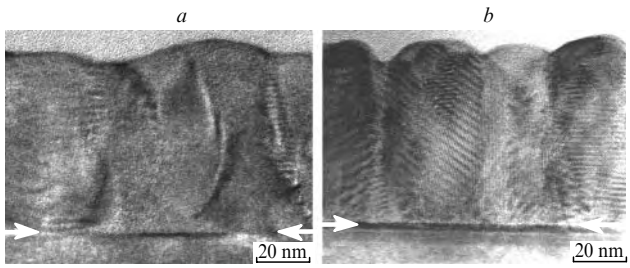

Figure 4. Photomicrograph of the cross-section of $HoMnO_3$ (*a*) and $LuMnO_3$ (*b*) perovskite films on the (001)$LaAlO_3$ substrate (TEM data).

The size of domains correlates with the misfit of the crystal lattice parameters between the film and the substrate at the interface; an increase in the misfit results in a decrease in the size of domains. For example, much more extended domains are formed in the perovskite $HoMnO_3$ films (Fig. 4*a*) than in $LuMnO_3$ films (Fig. 4*b*).

The results of investigations of the real structure of $RMnO_3$ perovskite films confirm the conclusion drawn above, namely, that a stress in the lattice is not a necessary factor of epitaxial stabilisation, as some researchers believe [see, for example, A Zunger, D Wood *J. Cryst. Growth* **98** 1 (1989)].

Compounds $RMnO_3$ with a hexagonal structure of the $LuMnO_3$ type (space group $P6_3cm$) stable under ambient pressure are formed only for lanthanide cations with small ionic radii (R = Ho–Lu, Y). Their structure can be represented as a close packing of oxygen ions (ABCACB) in which the Mn^{3+} ions occupy positions with C.N. 5 (a five-vertex trigonal bipyramid), while the R^{3+} ions occur in positions with C.N. 7 (a seven-fold one-cap octahedron).[57] The interest in these compounds is due to the fact that they crystallise in space group $P6_3cm$. It is known that compounds that belong to this structural type can exhibit ferroelectric properties. In particular, $YMnO_3$ is a promising ferroelectric, which could find application in electronics.[66]

The complex oxide $DyMnO_3$ ($r_{Dy} > r_{Ho}$), prepared under usual solid-state synthesis conditions, has a stable perovskite structure. For this compound to crystallise in the hexagonal phase, heat treatment at a temperature of ⩾1600 °C with subsequent quenching is required.[63] The greater the lanthanide ionic radius, the higher the temperature of the perovskite-to-hexagonal phase transition. Indeed, for $GdMnO_3$, the temperature of this polymorphic transition should be as high as about 2800 °C (determined by extrapolation), which knowingly exceeds the melting point of this compound and other manganites. In other words, $RMnO_3$ with R = Gd and larger lanthanide ions cannot exist as stable bulk samples in a hexagonal modification; however, these can be obtained as thin films using epitaxial stabilisation.[67]

On the basis of the available structural data for stable hexagonal phases, (111)$ZrO_2(Y_2O_3)$ was concluded to be the substrate of choice for the synthesis of hexagonal epitaxial films. In this case, the crystallographic positions of oxygen atoms at the substrate/hexagonal $RMnO_3$ interface perfectly coincide and the misfit parameter ε is a minimum [the films deposited on the (001)$LaAlO_3$, (001)MgO and (001)$ZrO_2(Y_2O_3)$ substrates had purely perovskite structures]. The X-ray diffraction patterns of the $DyMnO_3$, $GdMnO_3$ and $EuMnO_3$ films on the (111)$ZrO_2(Y_2O_3)$ substrate (Fig. 5) contained both symmetric (00*l*) and asymmetric (111), (112) reflections typical of a hexagonal structure of the $LuMnO_3$ type (asymmetric reflections are not shown in Fig. 5). It should be noted that the intensity of the (00*l*) reflections from the hexagonal phase decreases on passing from Dy to Eu and becomes zero for Sm; conversely, the intensity of the perovskite reflections increases in the same sequence. This means that the $DyMnO_3$ film grows as a purely hexagonal phase, the $EuMnO_3$ and $GdMnO_3$ films contain the hexagonal phase coexisting with the perovskite one (this was confirmed by recording the

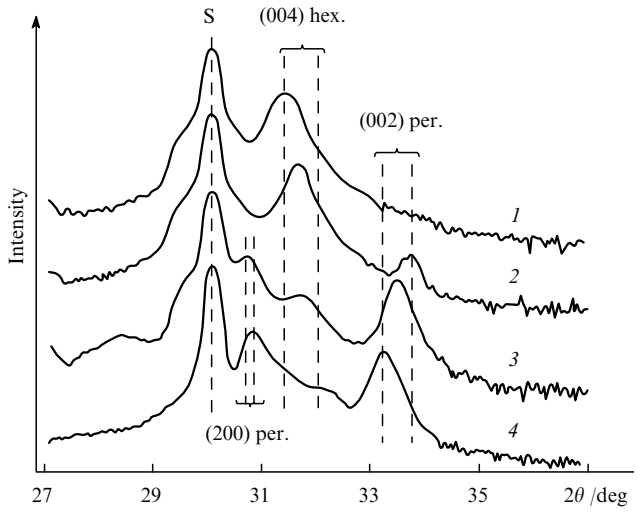

Figure 5. X-Ray diffraction patterns ($Cu_{K\alpha}$) of the $RMnO_3$ films grown on (111)$ZrO_2(Y_2O_3)$. R = Dy (*1*), Gd (*2*), Eu (*3*), Sm (*4*). Here and below, the reflections marked by S correspond to the substrate.

pole figures), and the $SmMnO_3$ film contains only the perovskite phase.

The hexagonal phase is *c*-oriented [as follows from X-ray φ-scanning spectra (Fig. 6) and pole figure images] and has the following epitaxial relations:

$$(001)_{hex}\,\langle 1\bar{1}0\rangle_{hex}\,RMnO_3 \parallel (111)\langle 1\bar{1}0\rangle\,ZrO_2(Y_2O_3),$$

i.e., the hexagonal (001) plane is parallel to the (111) plane of the substrate; the direction $\langle 1\bar{1}0\rangle_{hex}$ of $RMnO_3$ and $\langle 1\bar{1}0\rangle$ of the cubic substrate are also parallel.

Figure 7 shows the model of the epitaxial growth (polyhedral image) of the hexagonal $RMnO_3$ phase on (111)$ZrO_2(Y_2O_3)$.

It should be noted that an increase in the film thickness to 300 nm entailed an increase in the intensity only of perovskite reflections and not of reflections from the hexagonal phase. This indicates that the hexagonal phase grows only in the region adjacent to the substrate, while away from the substrate (in the upper part of the film), the usual perovskite phase is formed, stable in the bulk materials with this composition.

By extrapolating the available thermodynamic data on lanthanide manganites[68] to the region of epitaxially stabilised phases, one can estimate the thermodynamic effect of the ES for manganites with the perovskite and hexagonal structures (Fig. 8).

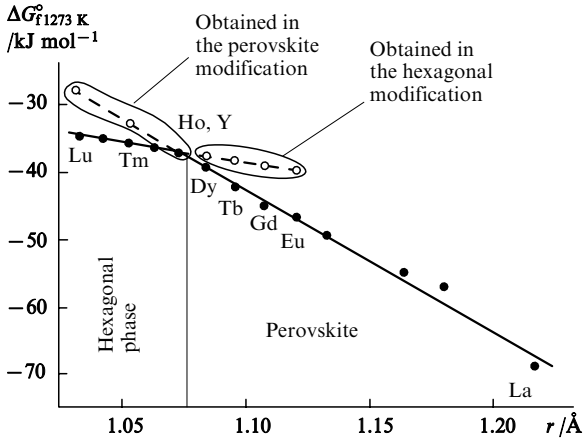

Figure 8. Gibbs energy of the formation of $RMnO_3$ (R is lanthanide) by the reactions $1/2\,R_2O_3 + 1/3\,Mn_3O_4 + 1/12\,O_2 = RMnO_3$ *vs.* ionic radius of the lanthanide (from Ref. 68).
The dashed lines represent the extrapolation to the epitaxial stabilisation region.

It can be stated that the ES of a thermodynamically less stable phase is possible if the difference between the Gibbs energies of the formation of the polymorphic forms does not exceed 10–15 kJ mol^{-1}, because in this case, the difference between the Gibbs energies can be counterbalanced by the decrease in the free energy of the system due to the low energy of the coherent interface between the epitaxial film and the substrate. The critical thickness of the stabilised phase decreases with an increase in the energy difference between the stable and unstable phases: even in thin films of the $GdMnO_3$ hexagonal phase, the upper layer has a perovskite structure. In the $EuMnO_3$ films, the layer of the stabilised hexagonal phase is even thinner.

We have also prepared previously unknown orthoferrites with the hexagonal structure, $RFeO_3$ (R = Eu, Er, Tm, Yb, Lu),[69] by stabilising them on the (111)$ZrO_2(Y_2O_3)$ substrate and confirmed, as in the case of manganites, the key conclusions of the thermodynamic model of ES. It was shown that these compounds may, in principle, exhibit ferroelecteric properties.[69]

The nickelates $RNiO_3$. A general structure–thermodynamics relationship for series of perovskite compounds has now been established, in particular, deformation of the perovskite structure with a decrease in the tolerance factor is accompanied by a decrease in the thermodynamic stability of compounds.[70] In the series of lanthanide perovskites (nickelates and cobaltites), this is manifested as an increase in the equilibrium pressure of oxygen

(for T = const) following a decrease in the lanthanide ionic radius. The solid-state synthesis of $RNiO_3$ powder or ceramics, except for $LaNiO_3$, requires high pressure P_{O_2}, which reaches 100 bar for the last members of the lanthanide row.

Using the ES, we succeeded in preparing thin epitaxial films of $RNiO_3$ (R = Pr, Nd, Sm, Gd) at a reduced oxygen pressure, which did not exceed 20 mbar.[71] The formation of perovskite phases was observed only for substrates having a perovskite structure ($LaAlO_3$, $SrTiO_3$), whereas the films grown on MgO and $ZrO_2(Y_2O_3)$ consisted of a mixture of the R_2O_3 and NiO oxides. Single-phase $RNiO_3$ films were prepared only on the $LaAlO_3$ substrate, which is most consistent with nickelates as regards the crystal lattice parameter ($\varepsilon = 0.2\% - 0.7\%$), whereas on the $SrTiO_3$ substrate with greater ε ($\varepsilon \approx 3\%$), phases of simple nickel and lanthanide oxides are formed in addition to $RNiO_3$ perovskite (Fig. 9). The content of the epitaxial perovskite $RNiO_3$ phase in the films prepared by MOCVD under identical conditions decreased with a decrease in the ionic radius of R^{3+}, due to the decrease in the perovskite stability in the same series.[72, 73] The least stable nickelate we studied, $GdNiO_3$, could be obtained only on $LaAlO_3$. These experiments revealed a clear-cut correlation between the thermodynamic properties of nickelates (the measure of their instability) and the critical film thickness for stabilised phases, which is consistent with the ES theory considered above.[67] After the critical thickness had been attained, a layer of the R_2O_3 and NiO oxide mixture started to grow on the surface of the perovskite phase.

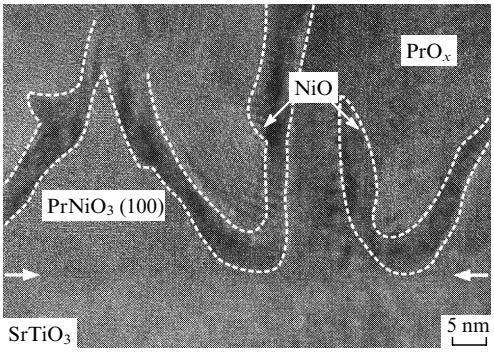

Figure 9. Cross-section of the $PrNiO_3/(100)SrTiO_3$ film in the (100) plane obtained by HREM (see the comments in the text).

Important information was gained from a HREM study of cross-sections of nickelate films. It was found that the atomically smooth interface between the epitaxial $RNiO_3$ film and the $LaAlO_3$ substrate is not distorted by misfit dislocations, which indicates unambiguously the presence of epitaxial compression stresses in the films, resulting in the tetragonal deformation of the film crystal lattice. Previously, this type of deformation has been found by X-ray diffraction.[74] It was demonstrated that nickelates crystallise in an orthorombic group of symmetry *Pnma*. It was shown that epitaxial films of nickelates (like manganite films) consist of orthorhombic domains; the axis directed along the doubled cell parameter can be oriented along the three orthogonal axes (Fig. 10) ¶ and the ε parameters for all the possible domain orientations are virtually equal. In this case, the formation of orthorhombic domains (twins) in nickelate films does not eliminate the epitaxial stresses (the situation opposite to that described above for $RMnO_3$ perovskite films). As a result, the anisotropic epitaxial stresses represent one more factor (in addition to the misfit of the lattice parameters at the film/substrate interface) to restrict the critical thickness of the stabilised phase.

¶ Note that orthorhombic distortions in lanthanide nickelates are much less pronounced than in manganites.

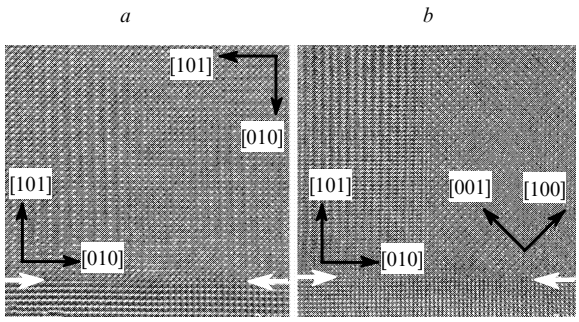

Figure 10. Domain structure of the $SmNiO_3/(001)LaAlO_3$ film (according to HREM data).
(*a*, *b*) Different domain orientations are shown.

An HREM study of the cross-sections of the films has also shown that the perovskite phase coexists, in some range of thicknesses, with simple oxide phases (see Fig. 9) and the volume fraction of perovskite gradually decreases with an increase in the film thickness. This result attests to the limitation of the model in which the phase composition sharply changes as the film reaches the critical thickness h_c and, conversely, validates the idea put forward by Little and Zangwill,[49] which predicts gradual transition from the epitaxially stabilised phase to phases stable as bulk materials.

The cobaltates $RCoO_3$. In the series of $RCoO_3$ perovskites, the border of high-temperature stability of phases at $P_{O_2} = 1$ bar is situated between Yb and Tm; hence, the last members of the row, $YbCoO_3$ and $LuCoO_3$, can be obtained by solid-state synthesis only under an elevated pressure of oxygen.[75] An estimate of the Gibbs energy for the reactions

$$Co_3O_4 + R_2O_3 + O_2 \longrightarrow RCoO_3$$

R = Tm – Lu

by extrapolation of the linear dependence of $\Delta G^\circ_{1100\,K}$ on the tolerance factor[76] obtained for more stable cobaltates gives positive values. In particular, the $\Delta G^\circ_{1100\,K}$ value for the least stable $LuCoO_3$ is equal to 8 kJ mol^{-1}, which confirms that this compound is unstable under solid-state synthesis conditions.

We attempted to prepare $LuCoO_3$ films by epitaxial stabilisation without using a high pressure of oxygen. The films were synthesised by MOCVD at 700 – 850 °C and P_{O_2} = 6.5 mbar on single-crystalline substrates, $(001)CaGdAlO_4$, $(001)LaAlO_3$, $(001)SrTiO_3$ and (001)MgO,[77] whose parameters ε were 0.3%, 3%, 6% and 14%, respectively. The X-ray diffraction patterns of $LuCoO_3$ films (Fig. 11), obtained on different substrates at the same temperature, imply a dependence of the formation of $LuCoO_3$ on the ε value. Indeed, a film of the Lu_2O_3 and Co_3O_4 oxide mixture grew on the non-coherent MgO substrate, while the films grown on more coherent $SrTiO_3$, $LaAlO_3$ and $CaGdAlO_4$ substrates were epitaxial $LuCoO_3$ films with the perovskite structure in the (001) orientation with an admixture of simple oxides, the content of the admixture decreasing on passing from $SrTiO_3$ to $CaGdAlO_4$ (one should note a low intensity of reflections from polycrystalline phases in the films). Similar results were obtained in the synthesis of $TmCoO_3$ films. However, the films of more stable $GdCoO_3$ with $\Delta G^\circ_{1100\,K} < 0$ [76] were also grown on MgO, moreover, in the polycrystalline form, *i.e.*, without the directing effect of the substrate.

An increase in the temperature of film deposition resulted in disappearance of the perovskite phase due to an increase in the equilibrium oxygen pressure above cobaltates. However, in this case, too, the behaviours of the films grown on different substrates were markedly dissimilar: the film stabilisation energy was correlated with ε. On the $CaGdAlO_4$ substrate, the perovskite phase was observed even at 820 °C, whereas on $SrTiO_3$, this phase did

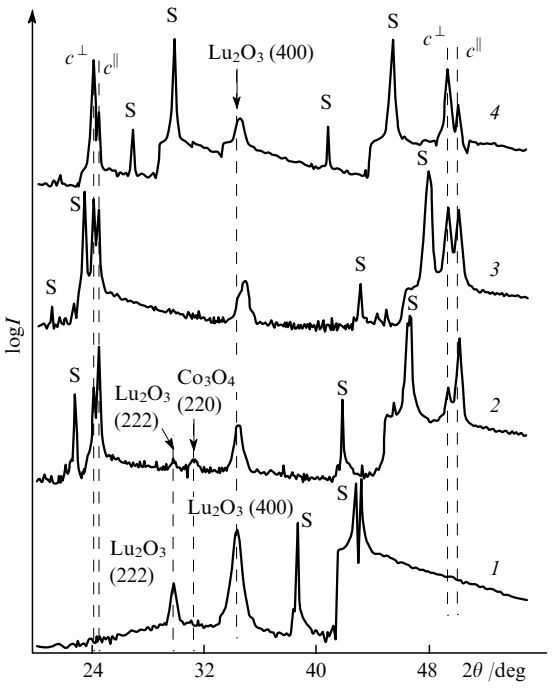

Figure 11. X-Ray diffraction patterns of the $LuCoO_3$ films grown on various substrates (S is the substrate reflections, $c^{\parallel}$, $c^{\perp}$ are perovskite reflections).
Substrate [ε (%)]: (*1*) (001)MgO (14), (*2*) (001)$SrTiO_3$ (6), (*3*) (001)$LaAlO_3$ (pseudo-cubic notation) (3), (*4*) $CaGdAlO_4$ (0.3).

not exist above 800 °C. The process of disappearance of the stabilised $LuCoO_3$ film on raising the deposition temperature differed from the process of disappearance of the bulk dissociating oxide: the latter disappeared immediately after some threshold $P_{O_2}-T$ conditions (equilibrium dissociation conditions). In the case of films, the intensity of X-ray reflections from $LuCoO_3$ gradually decreases with temperature rise; this is in line with the decrease in the critical thickness of the stabilised phase following a decrease in the thermodynamic stability of this phase [*i.e.*, with an increase in $\Delta g''_V - \Delta g'_V$, see Eqn (9)].

Evidently, even at the optimal temperature of film deposition (750 °C) on the most coherent substrate, an admixture-free $LuCoO_3$ perovskite phase can be obtained only in a limited range of thicknesses. When the film thickness is ~100 nm, the films contain only the perovskite phase, whereas ~400-nm thick films contain pronounced amounts of Lu_2O_3 and Co_3O_4 impurities. These are equilibrium phases (under film deposition conditions) of the bulk polycrystalline Lu–Co–O system formed in the upper layers of the $LuCoO_3$ films as they exceed the critical thickness.

The essential orthorhombicity inherent in the $RCoO_3$ phases is responsible for the doubling of the diffraction peak for the cubic perovskite. The orientation of the orthorhombic domains in epitaxially stabilised films depends on the nature of the substrate. According to X-ray diffraction data, two types of domains are formed in the $LuCoO_3$ films: in the first-type domains ($c^{\parallel}$), the doubled parameter (*i.e.*, the *c* axis within the *Pbnm* group) is directed along the substrate surface, while in second-type domains ($c^{\perp}$), it is perpendicular to the substrate. It was found that the fraction of $c^{\parallel}$-type domains increases in the series $CaGdAlO_4$–$LaAlO_3$–$SrTiO_3$, whereas the fraction of $c^{\perp}$-type domains decreases in this series (see Fig. 11). This regularity was interpreted by mininisation of the misfit between the film and substrate parameters through giving preference to either type of domains. This raised the question of whether both types of domains originate simultaneously during film deposition, or twinning occurs during cooling of the films. The X-ray diffraction analysis of the films quenched after deposition at 800 °C has shown that single-domain films of the $c^{\parallel}$ type originate and grow on $SrTiO_3$, and $c^{\perp}$ type films grow on $LaAlO_3$ (Fig. 12). The structure of twin domains is formed during cooling, apparently according to the martensite mechanism. Twinning is a way of decreasing thermomechanical stresses arising at the film/substrate interface on slow cooling.[77]

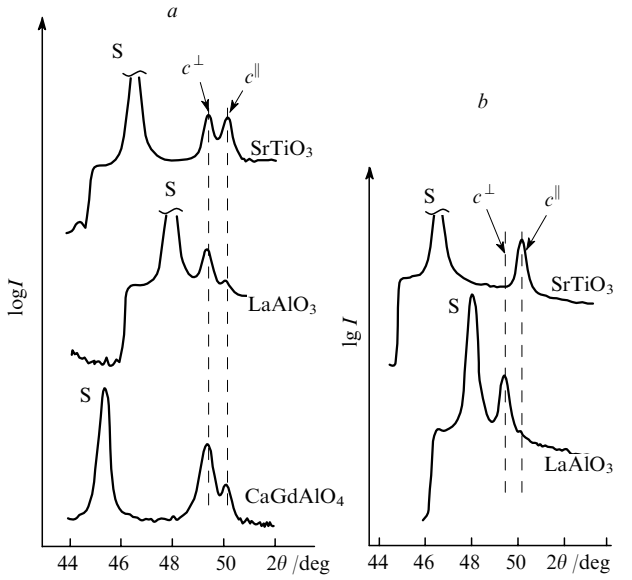

Figure 12. Sections of the X-ray diffraction patterns of the $LuCoO_3$ films on various substrates.
(*a*) X-ray diffraction patterns of the films slowly cooled after deposition; (*b*) X-ray diffraction patterns of the films hardened after deposition on the substrate at 800 °C in air. The reflection (220) refers to type $c^{\perp}$ domain and (004), to type $c^{\parallel}$ domain.

The indates $RInO_3$. The lanthanide indates of the composition $RInO_3$, existing in the bulk state, can be divided into three groups in terms of the structure, namely, perovskites, hexagonal phases and fluorite type phases. The compounds $RInO_3$ with R = La–Sm can be prepared as perovskites by the conventional solid-state synthesis, whereas the homologues with R = Eu–Dy form hexagonal phases under the same conditions. Under the action of high pressure (65 kbar), these phases can turn into perovskites.[78] The compounds $RInO_3$ with R = Y and Ho are solid solutions of the fluorite type, which also acquire a perovskite structure under the action of high pressure.[79] No data on the phase formation in the R–In–O systems (R = Er–Lu) have been reported.

We attempted to synthesise indates $RInO_3$ (R = Eu–Lu) with the perovskite structure without using high pressure but by means of the ES.

As the substrate for growing $RInO_3$ films, we chose $SrTiO_3$, which best fits the known perovskites $RInO_3$ as regards the cell parameter. We have grown $RInO_3$ films (R = Eu–Lu) on this substrate. Figure 13 shows X-ray diffraction spectra of the resulting films, which confirm their perovskite structure [reflections (001) and (002)], and the photomicrograph of the $NdInO_3/SrTiO_3$ film, which proves that the h_c value is greater than 80 nm. The decrease in the intensity of perovskite reflections (002) upon a decrease in the ionic radius of R^{3+} indicates that the stability of perovskites decreases with an increase in the tolerance factor and that the critical thickness of the stabilised perovskite phases decreases as they become less stable in the form of bulk materials. It was found that the conductivity of the resulting thin films of lanthanide indates can be appreciably changed by heterovalent doping. The doped films can be used in gas sensors.

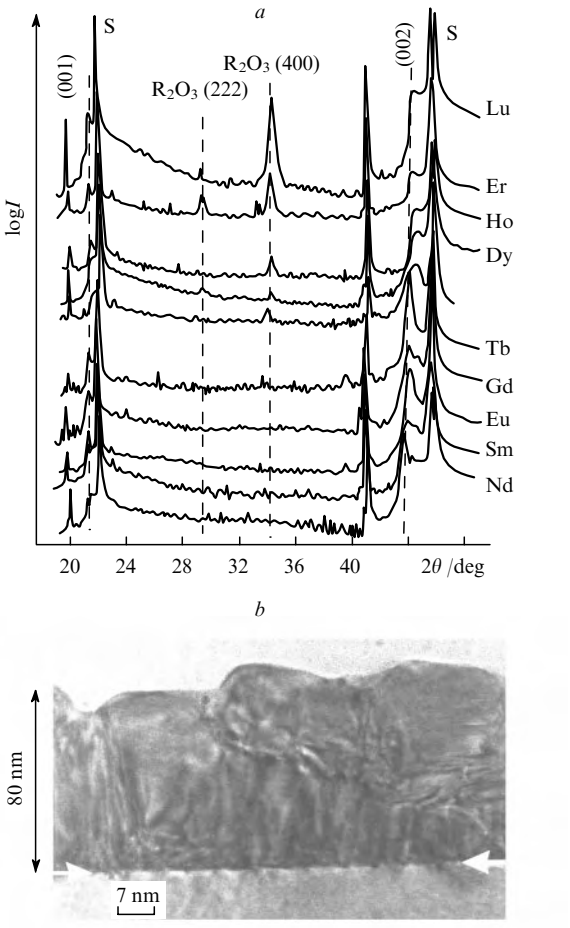

Figure 13. X-Ray diffraction patterns of the $RInO_3$ films (R = Nd – Lu) grown on $SrTiO_3$ (*a*) and photomicrograph of the $NdInO_3/SrTiO_3$ film (*b*) obtained by HREM.

The garnets $R_3Fe_5O_{12}$. A necessary condition for the formation of a garnet structure is fulfillment of the criterion $r_{M^{3+}} : r_{Fe^{3+}} \leqslant 1.7$, which means that ferrogarnets are formed only in those cases where the ionic radius of the lanthanide is not larger than 1.14 Å, *i.e.*, only for R = Sm – Lu, Y. The elements of the beginning of the row (La, Ce, Pr, Nd) do not form garnets in the conventional solid-state synthesis, although $Nd_3Fe_5O_{12}$ can be synthesised at high pressure.[80]

We managed to prepare (by means of the ES) thin films of garnet-type solid solutions $(La_xNd_{1-x})_3Fe_5O_{12}$ on the $(111)Gd_3Ga_5O_{12}$, $(210)Gd_3Ga_5O_{12}$, $(111)Nd_3Ga_5O_{12}$ and $(111)(Y_{0.8}Ca_{0.9}Tm_{0.7}Sm_{0.6})(Ge_{0.2}Fe_{0.8})_5O_{12}$ substrates with a garnet structure; the orientation of the garnet films corresponded to the substrate orientation (no garnet phase was formed in films with the same composition on substrates with the perovskite or MgO structure).

The photomicrographs of the $(La_xNd_{1-x})_3Fe_5O_{12}$ films (Fig. 14) give an idea of the critical film thickness of stabilised garnets. In the case of $Nd_3Fe_5O_{12}$, the film thickness was unexpectedly great (more than 3.6 μm, Fig. 14 *b*). It was found that the film thickness decreases with an increase in the La concentration in the solid solution (Fig. 14 *c*). When the critical thickness is exceeded, $RFeO_3$ and Fe_2O_3 equilibrium phases start to grow on the surface of the stabilised phase of the garnet.

The concentration ranges of stability of the garnets $(La_xNd_{1-x})_3Fe_5O_{12}$ grown on substrates with the garnet structure were determined using powder X-ray diffraction and HREM (Fig. 14). It was found that films with the garnet structure are formed only in the range of $0 < x < 0.66$. Differences in the

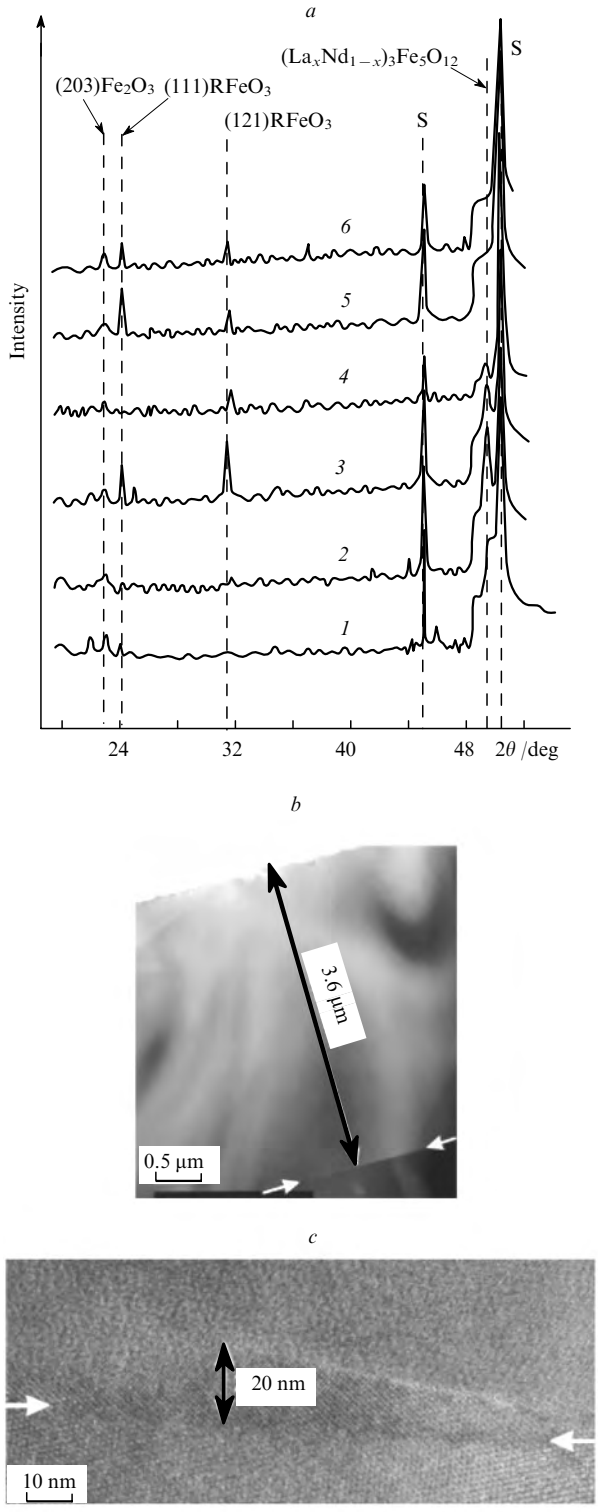

Figure 14. Formation of garnet phases $(La_xNd_{1-x})_3Fe_5O_{12}$.

substrate material do not much influence the stability limits of the $(La_xNd_{1-x})_3Fe_5O_{12}$ phases.

Epitaxially stabilised lanthanide-derived ferrogarnets, which are soft ferromagnetic materials, can find application in devices for amplification of an external magnetic field and in thin-film magnetooptical devices.

5. Application of epitaxial stabilisation for the development of functional heterostructures (selective epitaxy)

Epitaxial stabilisation can be used successfully for the design of multilayer heterostructures in selective epitaxy processes. The selective epitaxy is performed on specially prepared areas of the substrate which are characterised by structural coherence with the stabilised phase. On those substrate sections where the coherence condition is not fulfilled, products would crystallise that correspond to the equilibrium bulk state of the system. An example of such application of the ES is reported in our study [81] aimed at designing a heterostructure composed of numerous alternating lanthanide manganite and nickelate ribbons. This heterostructure shows an unusual temperature dependence of the resistivity (Fig. 15, curve *1*), because it combines the manganite phase (curve *2*), characterised by a sharp decrease in the resistivity on the dielectric–metal transition, and the nickelate phase (curve *3*), whose resistivity, conversely, sharply increases below the temperature of the metal–dielectric transition. As a result, the temperature behaviour of the resistivity of this heterostructure exhibits a sharp minimum.

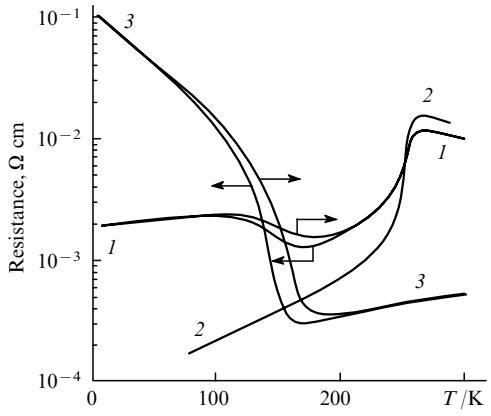

Figure 15. Temperature dependence of the resistance of the $NdNiO_3$–$La_{0.7}Ca_{0.3}MnO_3$ heterostructure (*1*) and its components $La_{0.7}Ca_{0.3}MnO_3$ (*2*) and $NdNiO_3$ (*3*).

The heterostructure was formed using MOCVD and photolithography (Fig. 16). First, the epitaxial $(La,Pr)_{0.7}Ca_{0.3}MnO_3$ layer was formed on the $LaAlO_3$ substrate (Fig. 16 *a*). Then this layer was etched with H_2O_2 and H_2SO_4 solutions through a photolitographic mask (Fig. 16 *b*), a polycrystalline layer of CuO was applied on it (Fig. 16 *c*), and the spots meant for $NdNiO_3$ were etched with an HCl solution (Fig. 16 *d*). The etching resulted in exposure of areas on the surfaces of the perovskite substrate and the manganite layer; hence, during the subsequent deposition of $NdNiO_3$, perovskite phase grew epitaxially exactly on these areas (Fig. 16 *e*), while an equilibrium mixture of the Nd_2CuO_4 and NiO phases with high resistivity was situated on the surface bearing the remaining CuO (structurally non-coherent to perovskite). The current that was passed along the substrate surface ran succesively through the alternating manganite and nickelate regions.

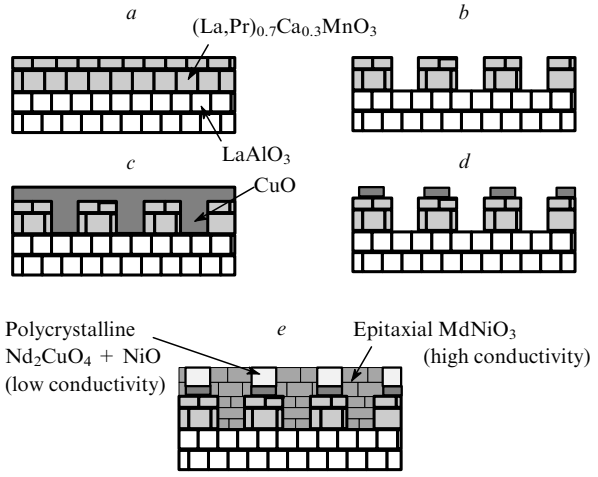

Figure 16. Formation of the manganite/nickelate heterostructure [for the description of stages (*a*–*e*), see the text].

It should be noted that in the epitaxial stabilisation of these heterostructures, one should take into account the stressed state of the substrate ($LaAlO_3$) surface and the buffer layer [$(La,Pr)_{0.7}Ca_{0.3}MnO_3$]: with the same deposition conditions and the same composition of the deposited components, different types of these stresses may completely change the phase composition of the deposited layer. Thus the epitaxial $NdNiO_3$ films obtained on a buffer manganite layer, $(La,Pr)_{0.7}Ca_{0.3}MnO_3$, which was, in turn, deposited on the perovskite $LaAlO_3$ and $SrTiO_3$ substrates were substantially dissimilar. Quite perfect epitaxial layers of $NdNiO_3$ up to a thickness of 200 nm were obtained on the $(La,Pr)_{0.7}Ca_{0.3}MnO_3/LaAlO_3$ substrates, whereas in the case of $(La,Pr)_{0.7}Ca_{0.3}MnO_3/SrTiO_3$, the perovskite phase contained simple oxides even at early stages of the growth (films with a similar phase composition were grown on the $SrTiO_3$ substrate without a buffer layer [82]). The epitaxial quality of the $(La,Pr)_{0.7}Ca_{0.3}MnO_3$ buffer layer grown on both substrates was equally high; however, the epitaxial stresses in the layers had opposite signs on different substrates, namely the buffer layer on $LaAlO_3$ experienced compression and that on $SrTiO_3$ underwent stretching in the substrate plane. This is indicated unambiguously by comparison of the lattice parameters of the non-deformed $(La,Pr)_{0.7}Ca_{0.3}MnO_3$ layer ($a = 0.385$ nm) with those of the $(La,Pr)_{0.7}Ca_{0.3}MnO_3/LaAlO_3$ ($a = 0.383$ nm) and $(La,Pr)_{0.7}Ca_{0.3}MnO_3/SrTiO_3$ ($a = 0.387$ nm) layers. The lattice parameter of the compressed $(La,Pr)_{0.7}Ca_{0.3}MnO_3/LaAlO_3$ layer is much closer to that of $NdNiO_3$ ($a = 0.381$ nm) than the parameter of the stretched layer, which accounts for the better properties of the former in stabilisation of the nickelate perovskite phase.

6. Effect of the epitaxy on the mutual solubility of oxides

The change in the phase equilibria in oxide systems under the influence of epitaxy is encountered rather often. However, we have not yet mentioned the possibility of extending the homogeneity regions for the cations of the epitaxially stabilised phases.† Below we consider several typical examples.

$R_{1-x}MnO_{3+\delta}$ (R = La, Nd). The perovskite $R_{1-x}MnO_{3+\delta}$ phases formed by lanthanides with a great ionic radius can be markedly non-stoichiometric as regards the cations,[83] the excess negative charge being counterbalanced by the transition $Mn^{3+} \rightarrow Mn^{4+}$. The maximum allowable lanthanide deficiency in the $R_{1-x}MnO_{3+\delta}$ ceramic samples corresponds to the subscript $x = 0.1-0.15$ (the x value depends on the conditions of high-temperature treatment; the highest non-stoichiometry can be attained under oxidative conditions). The epitaxial $R_{1-x}MnO_{3+\delta}$ films prepared by MOCVD on the $LaAlO_3$ and $SrTiO_3$ substrates allow a much higher deficiency of lanthanide ions. For example, single-phase perovskite $R_{1-x}MnO_{3+\delta}$ films (R = La, Nd) with $x \leqslant 0.3$ have been synthesised.[84]

$Zn_{1-x}M_xO$ (M = Mg, Mn). In wurtzite (ZnO), zinc can be partially replaced by other cations with similar ion radii such as Mg^{2+}, Cd^{2+} or Mn^{2+}. In ceramic $Zn_{1-x}Mg_xO$ samples, the x value does not exceed 0.02–0.04,[85] while in single-phase (0001)$Zn_{1-x}Mg_xO$ epitaxial films obtained by MBE at

† In this case, the term 'stabilised phases' is used to mean not only phases that cannot be obtained in the bulk state under the given thermodynamic conditions but also stable phases whose thermodynamic properties have changed in the epitaxially bound state.

550 °C,[86–88] the x values reach 0.22 and for the films obtained by PLD at 700–750 °C,[88] $x \leqslant 0.36$. The difference in the mutual solubility of the ZnO and MgO oxides in ceramics and epitaxial films is emphasised by the fact that two-phase ceramic pellets were used as targets (the sources of ZnO and MgO vapours). The epitaxial films were grown on the $(0001)Al_2O_3$ substrate. The film thickness reached 150 nm[86–88] and $\leqslant$500 nm.[89] The epitaxial relations for the ZnO–MgO solid solution reported in the literature[89]

$$(0001)[\bar{1}2\bar{1}0]Zn_{1-x}Mg_xO \parallel (0001)[01\bar{1}0]Al_2O_3$$

coincide with those for the films of pure ZnO grown on sapphire.[90] This mutual orientation of the film and the substrate corresponds to a misfit of the parameters $\varepsilon = 15\%$ which induces a substantial dislocation density at the interface.[89] In addition, it was shown that the $Zn_{0.85}Mg_{0.15}O$ film is stable during annealing (1000 °C, $P_{O_2} = 1$ bar, 1 h), whereas the film with the composition $Zn_{0.78}Mg_{0.22}O$ decomposes under the same conditions to give an equilibrium mixture of the wurtzite solid solution $Zn_{0.85}Mg_{0.15}O$ and the solid solution $Mg_{0.46}Zn_{0.54}O$ with the NaCl structure.[88] Thus, the extension of the wurtzite solid solution in the ZnO–MgO system markedly increases as a result of the ES.

The synthesis of epitaxial films of wurtzite doped with manganese oxide, $(0001)Zn_{1-x}Mn_xO/(0001)Al_2O_3$, has been reported.[91] Films several hundred nanometres thick were obtained at 600 °C. It was found that the unit cell parameters of wurtzite (a and c) increased monotonically with an increase in the Mn content up to $x = 0.35$; this markedly exceeds the solubility level of manganese oxide in zinc oxide in equilibrium bulk systems, which corresponds to $x_{lim} = 0.13$.[92]

$Ni_xFe_{3-x}O_4$. Nickel oxide NiO, like iron oxide Fe_3O_4 (spinel type), can grow epitaxially on the MgO substrate; however, the parameters of Fe_3O_4 are in better agreement with the substrate parameters; therefore, the spinel type solid solution $Ni_xFe_{3-x}O_4$ is stabilised on the substrate. The limiting nickel content in the solution is higher than in equilibrium polycrystalline solid solutions under the same conditions. The distribution of the Ni and Fe atoms over tetrahedral and octahedral positions of the spinel structure differs appreciably from that in the bulk materials.[93] This indicates that the ES can substantially influence the degree of inversion of spinels and, correspondingly, their magnetic properties.

$BaRuO_3$–$SrRuO_3$. From consideration of the equilibrium phase diagram of the $BaRuO_3$–$SrRuO_3$ binary system, one can predict the formation of two immiscible solid solutions, namely, the perovskite solution based on $SrRuO_3$ and stable up to Ba : Sr = 1 : 1 and a hexagonal (polytype 9R) solution based on $BaRuO_3$ and stable up to Ba : Sr = 9 : 1.[94] The preparation of a continuous series of solid solutions of the perovskite type, from $SrRuO_3$ to $BaRuO_3$, by radio frequency sputtering on the $SrTiO_3$ substrate has been reported.[17] However, an attempt to prepare $BaRuO_3$ as a perovskite on the $(001)KTaO_3$ perovskite substrate ($a = 0.3989$ nm) failed. This may be due to the fact that $BaRuO_3$ in the perovskite form experiences pronounced tetragonal distortions; as a result, its lattice becomes more consistent with the $SrTiO_3$ lattice than with the $KTaO_3$ lattice.

These examples provide the conclusion that solid solutions in epitaxial films are more extended than the same solid solutions in powders, ceramics, single crystals or polycrystalline films. The degree to which the ES extends the homogeneity regions depends on the coherence of the structures of the resulting film and the substrate and on the enthalpy of formation of the solid solution. If the consideration is restricted to the formation of regular solid solutions for which $\Delta H = x_A x_B Q$ (where x_A and x_B are the mole fractions of the components, Q is the energy parameter of interaction independent of the composition), it can be stated that the smaller the Q value (which is always positive), the more pronounced the effect of epitaxial extension of the solubility limits. In some cases, continuous solid solutions can be prepared.

7. The effect of epitaxy on the reactivity of thin films

The set of experimental data considered in this review attests that the $P–T–x$ space of thermodynamically stable existence is greater for the epitaxial phase than for its substrate-free bulk state. This implies that the chemical potential of the epitaxially bound phase (μ_{el}) is lower than the standard chemical potential (μ^0) of the same phase. In view of the fact that

$$\mu_{el} = \mu^0 + RT\ln a_{el},$$

the thermodynamic activity of the phase in the epitaxial state is given by $a_{el} < 1$. Thus, the epitaxial binding of some phase by a coherent substrate has the same consequence (namely, a decrease in the thermodynamic activity of the phase) as the formation of a solid solution or a chemical compound by this phase. A decrease in the thermodynamic activity of the phase in the epitaxial state ($a_{el} < 1$) implies a decrease in its reactivity compared to that of the substrate-free phase. It should be emphasised that this conclusion is valid not only for the 'unusual phases' which can arise under these conditions only owing to the ES but also for any epitaxial phases, no matter whether they are stable in the free (bulk) state.

The chemical consequences of the reduced thermodynamic activity may vary. In particular, the dissociation equilibrium

$$ABO_x \rightleftharpoons AO + BO_{x-1} + O_2$$

would be shifted more appreciably to the left in the case of epitaxial films than for the same phases in the bulk state at the same $P_{O_2}–T$ conditions (in other words, at the same temperature, the equilibrium pressure of oxygen P_{O_2} above an epitaxial film is lower than that above a powder or ceramic with the same composition).

In those cases where the growing phase is not stoichiometric for oxygen and dissociation does not result in the phase decomposition

$$ABO_x \rightleftharpoons ABO_{x-\delta} + \delta/2\,O_2,$$

one can expect that the epitaxial and bulk phases brought to equilibrium under the same $P_{O_2}–T$ conditions would differ in the oxygen content.‡

This conclusion may appear defamatory for the common practice of investigation of the dependence of the functional properties of films on the oxygen non-stoichiometry. Since the direct determination of the oxygen content in thin films is an exceptionally complicated analytical problem yet unsolved, the amount of oxygen is usually determined in the corresponding powders or ceramics, which can be easily analysed by both chemical and physical methods (the oxygen content in epitaxial films is considered to be the same as in powders and in ceramics after identical heat treatment). The observed differences between the functional properties (first of all, electric and magnetic ones) of epitaxial films and ceramics with the composition as close as possible to that of the films are interpreted most often as being due to different microstructures and/or stressed states of the films; however, the role of differences in the oxygen non-stoichiometry also cannot be neglected.

The problem becomes even more complicated if one takes into account the dependence of the thermodynamic properties of the epitaxial layer on its thickness; obviously, the difference $\mu^0 - \mu_{el}$ in each section parallel to the substrate plane should decrease on moving away from the film/substrate interface toward the upper surface of the film. For a non-stoichiometric oxide, this means, in particular, that the content of oxygen in an epitaxial film would vary along the thickness coordinate. Unfortunately, due to the lack of experimental data, this aspect can be discussed only as a problem definition.

‡ The quantitative difference between the oxygen contents is difficult to predict, because the uncertainties in the estimation of the energy benefit from the epitaxial growth in particular systems are rather high.

Below we elucidate how the decrease in the phase reactivity in the epitaxial state would influence the solid-state reactions involving them. We demonstrated that in the epitaxial heterostructures $YBa_2Cu_3O_{7-\delta}/CeO_2/R\text{-}Al_2O_3$, no chemical interaction takes place between the $YBa_2Cu_3O_{7-\delta}$ superconductor and the $(001)CeO_2$ buffer layer grown epitaxially on the *R*-sapphire, not even during the long-term high-temperature annealing (Fig. 17 *a*).[95,96] In addition, it is well known [97] that polycrystalline CeO_2 reacts with $YBa_2Cu_3O_{7-\delta}$ according to the reaction

$$3\,CeO_2 + 2\,YBa_2Cu_3O_{7-\delta} \longrightarrow 3\,BaCeO_3 + Y_2BaCuO_5 + 5\,CuO.$$

The Gibbs energy of this reaction calculated for conditions similar to the conditions of MOCVD [98] under which the epitaxial heterostructures were obtained ($T = 820$ °C and $P_{O_2} = 2$ mbar) equals -5 kJ mol^{-1}. This reaction will not take place if ΔG becomes positive. This will happen when $a_{CeO_2} \approx 0.83$. Apparently, such decrease in the activity of CeO_2 occurs during its epitaxial growth on *R*-sapphire.

If polycrystalline CeO_2 is replaced by ZrO_2, the following reaction will proceed at the $YBa_2Cu_3O_{7-\delta}/ZrO_2$ interface

$$3\,ZrO_2 + 2\,YBa_2Cu_3O_{7-\delta} \longrightarrow 3\,BaZrO_3 + Y_2BaCuO_5 + 5\,CuO.$$

The replacement of polycrystalline ZrO_2 by the epitaxial one does not terminate the reaction. The reason can be understood from thermodynamic considerations: the Gibbs energy ΔG for this reaction calculated for the MOCVD conditions [98] is equal to -30 kJ mol^{-1}. This energy remains negative even if $a_{ZrO_2} = 0.83$, *i.e.*, the reaction does not stop. It is of interest that the product of reaction of ZrO_2 with $YBa_2Cu_3O_{7-\delta}$, namely, compound $BaZrO_3$, which separates the superconductor layer from the ZrO_2 substrate, belongs to the perovskite type and, therefore, it forms epitaxial interfaces with both the $YBa_2Cu_3O_{7-\delta}$ film and the substrate (Fig. 17 *b*).

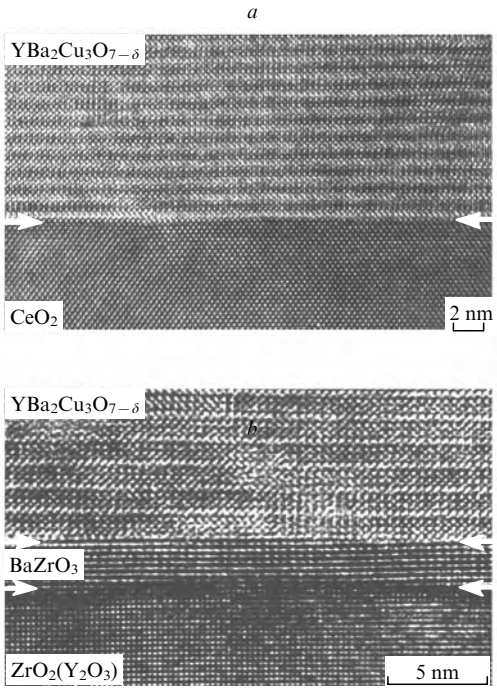

Figure 17. Images of the cross-sections of the $YBa_2Cu_3O_{7-\delta}$ films on CeO_2 (*a*) and on $ZrO_2(Y_2O_3)$ (*b*) (the images were obtained by HREM). (*a*) no chemical reaction takes place at the interface between the $YBa_2Cu_3O_{7-\delta}$ superconductor and the CeO_2 buffer layer, (*b*) a $BaZrO_3$ layer is formed at the interface.

III. Variant structures

During the last 15–20 years, vast experimental material has been accumulated on the heteroepitaxy of simple and complex oxides of various structures. The diversity of the crystal structures formed in the heteroepitaxy of oxides gives rise to a series of interesting phenomena not involved in classical metallic and semiconductor systems. For example, a definite type of orientational relations between an epitaxial film and a single-crystalline substrate can often be realised in different ways.

The orientational relations in heteroepitaxial systems are usually analysed in terms of the concept of coincident site lattices (CSL). Within the framework of this concept, the two-dimensional crystal lattices (site networks) of the film and the substrate are compared in the region of their contact.[99–101] Usually, an idealised view of the surface structure is invoked, *i.e.*, the structure of the surface of each crystal is regarded as being identical to the structure of a similar crystallographic plane inside the crystal, the rearrangement effects that took place on the exposed surface being ignored.[102] This simplification proved to be quite satisfactory, because the energy of the epitaxial surface is much lower than the energy of the free surface of the crystal. Therefore, the surface rearrangement is hampered due to overlaying of the epitaxial film.

Despite the diversity of the CSL sizes and shapes, they can always be reduced to one of five types of two-dimensional lattices (Fig. 18) corresponding to four types of symmetry (in the same way as three-dimensional lattices can be reduced to one of the 14 Bravais lattices, which form six systems). In the simplest case, the type of two-dimensional CSL coincides with the type of the two-dimensional lattice of the film and substrate site networks in the contact region. For example, for the epitaxial growth of the $(001)CeO_2$ film (fluorite structure) on the $(001)SrTiO_3$ substrate (perovskite structure), the site network and the CSL are square lattices. For $(001)CeO_2$, [100] and [010] are the CSL vectors, while for $(001)SrTiO_3$, these are [110] and [1$\bar{1}$0], respectively, *i.e.*, the *a* parameter of the CSL is $\sqrt{2}$ times greater than the lattice parameter of $SrTiO_3$.[103] In the example considered, this epitaxial relation is the only one possible; no other epitaxial relations arise in this case.

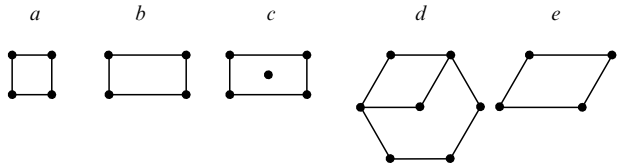

Figure 18. Types of two-dimensional lattices: primitive square (*a*), primitive orthogonal (*b*), centred orthogonal (*c*), primitive hexagonal (*d*), primitive oblique (*e*).

If the three-dimensional crystal lattices of the film and the substrate belong to different systems but the two-dimensional lattices correspond to the same system, in this case, too, only one epitaxial relation is realised. As an example, consider the $(001)TiO_2$ epitaxial films with a tetragonal anatase structure grown on perovskite substrates of the $(001)SrTiO_3$ type. This gives rise to the only possible square CSL with a spacing corresponding to that of the square site networks in the contact plane of the film and the substrate.[5,11,104]

Thus, a single variant of the CSL arises in those cases where the site networks of the film and the substrate in the contact plane correspond to the same system. If they are different, several variants of CSL fully equivalent from geometric and energetic standpoints may appear. The greatest possible number of variants is dictated by the order of the principal normal axis of the site

network that has a higher symmetry. It can be easily demonstrated that several equivalent CSL containing 2, 3, 4 and 6 epitaxial orientations can exist. The number of variants decreases if any additional symmetry elements in the film and substrate site networks coincide in the contact region (*e.g.*, symmetry planes parallel to the principal normal axis). The standard methods for determination of the number of variants of the epitaxial growth and orientation include X-ray diffraction (pole figures, φ-scanning), electron diffraction and transmission electron microscopy.

The formation of the variant structures is related genetically to the xenotaxy phenomenon (literally, this means a foreign growth on the surface), which represents the formation of a CSL, at the film/substrate interface, whose two-dimensional symmetry is lower than that allowed by the symmetry conditions. This situation is possible in the case where the low-symmetry configuration is clearly preferred from the energy standpoint. A low-symmetry CSL on a substrate site network with a higher symmetry also gives rise to variant structures. Depending on the relationship between the interface energies for the same film/substrate pair, different types of xenotaxy can arise, resulting in different variant structures.

Let us consider a simple example. During the deposition of films of the $RBa_2Cu_3O_{7-\delta}$ high-temperature superconductors (R is a lanthanide) on single-crystalline perovskite substrates in a pseudo-cubic (001) orientation (so-called *c*-orientation), the epitaxial growth of a film in the (100) orientation (*a*-orientation) is often observed. The smaller the misfit between the substrate and film lattice parameters (*i.e.*, the better the CSL coincidence), the easier the switching from the thermodynamically preferred growth along the (001) direction to the growth along the (100) direction (Fig. 19).[105–107] The site network of the perovskite substrate in the (001) plane is square. The $RBa_2Cu_3O_{7-\delta}$ site network in the (100) plane and the CSL are orthogonal and the ratio of their unit cell edges is close to 1 : 3. The maximum number of variants of the epitaxial growth for this case is 4, but the condition of collinearity of the perovskite and $RBa_2Cu_3O_{7-\delta}$ site networks reduces the possible number of variants to two:

$$(001)[100]SrTiO_3 \parallel (100)[001]RBa_2Cu_3O_{7-\delta}$$

and

$$(001)[010]SrTiO_3 \parallel (100)[001]RBa_2Cu_3O_{7-\delta}.$$

The existence of structural variants in the *a*-oriented $RBa_2Cu_3O_{7-\delta}$ films is responsible for the substantial difference between their electric properties and those of the *c*-oriented films with the same chemical composition. The critical current density in two-variant *a*-oriented $RBa_2Cu_3O_{7-\delta}$ films does not exceed 10^5 A cm^{-2} at 77 K, whereas in the monovariant *c*-oriented samples, this value reaches $\geqslant 10^6$ A cm^{-2} (see the studies [108, 109]). This difference is not at all due to the poor crystallinity of the two-variant structure compared to the monovariant one; conversely, the X-ray diffraction and HREM data indicate unambiguously that the *a*-oriented films are structurally more perfect (in particular, the integral width of the X-ray rocking curves is several times smaller for these films than for the *c*-oriented $RBa_2Cu_3O_{7-\delta}$ films). The decrease in the critical current density is due to the fact that in the HTSC structure, the superconducting carriers move efficiently only in the CuO_2 planes normal to the *c* axis. Thus, in the *c*-oriented films, the superconductive planes are stretched along the substrate plane. In the two-variant structure with the *a*-orientation, more intricate routes for the supercurrent are formed, *i.e.*, 'superconducting tapes', perpendicular to the substrate plane; this decreases the supercurrent critical density.

More complex variant structures are formed on the deposition of films of the perovskite series (for example, manganites $R_{1-x}A_xMnO_3$ (R is lanthanide, A is the alkaline earth element), cobaltites $R_{1-x}Sr_xCoO_3$ and ruthenates $CaRuO_3$ and $SrRuO_3$) [58] on substrates with the fluorite structure. The fluorite site network in the (001) plane is square. On the given surface these perovskites form an orthogonal site network in the (110) plane. The vectors of the orthogonal CSL are as follows: for the (001)$ZrO_2(Y_2O_3)$ fluorite, $[1\bar{1}0]$ and $4\times[\bar{1}\bar{1}0]$; for the (110) perovskites, $[1\bar{1}1]$ and $3\times[1\bar{1}\bar{2}]$ (Fig. 20). The similarity of the lengths of the body diagonal in the perovskite cube $[1\bar{1}\bar{2}]$ and the face diagonal in the fluorite cube $[1\bar{1}1]$ is the crucial factor for this type of epitaxial growth. However, a better dimensional fit may be observed in the perpendicular direction to the interface. For example, in the growth of (110)$La_{0.7}Ca_{0.3}MnO_3$ films on the surface of (001)$ZrO_2(Y_2O_3)$, the misfit in the CSL is 8% for the $[1\bar{1}0]$ and $[1\bar{1}1]$ pair and 2% for the $[\bar{1}\bar{1}0]$ and $[1\bar{1}\bar{2}]$ pair. The number of epitaxial variants for this case is 4 (Fig. 20). These variants are fully equivalent from the geometric and energetic standpoints. The HREM data (Fig. 21) indicate that these growth variants occur in the film as nanodomains (f1 and f2) with a characteristic size of 20–50 nm (Fig. 21 *c*). Interestingly, their lateral size almost does not change with thickness and the mutual coherence of the domains along the substrate surface normal is retained throughout the whole film thickness (Fig. 21 *d*).[110]

The formation of four-variant structures in the epitaxy of perovskites on the (001)fluorite has also been reported in a

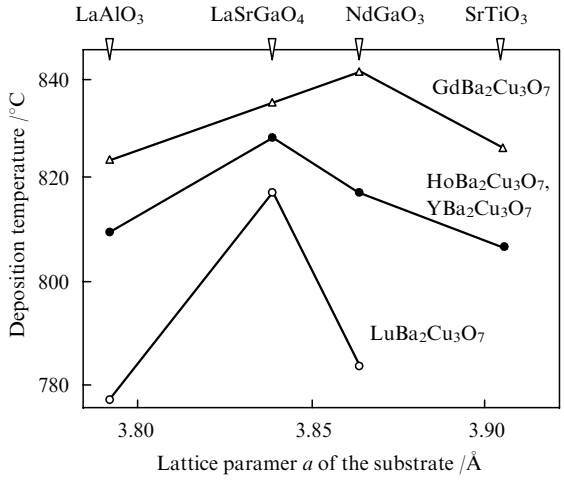

Figure 19. Temperature regions corresponding to the *c*-oriented epitaxial growth (above the line) and the growth with mixed *c* + *a*-orientation (below the line) of the $RBa_2Cu_3O_{7-\delta}$ films on substrates with a small (< 2%) misfit of parameters at the interface.

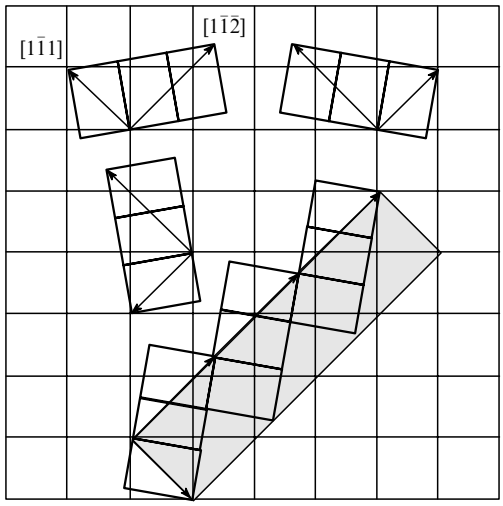

Figure 20. Four variants of perovskite growth on the (100)fluorite. The hatched region shows the CSL unit cell.

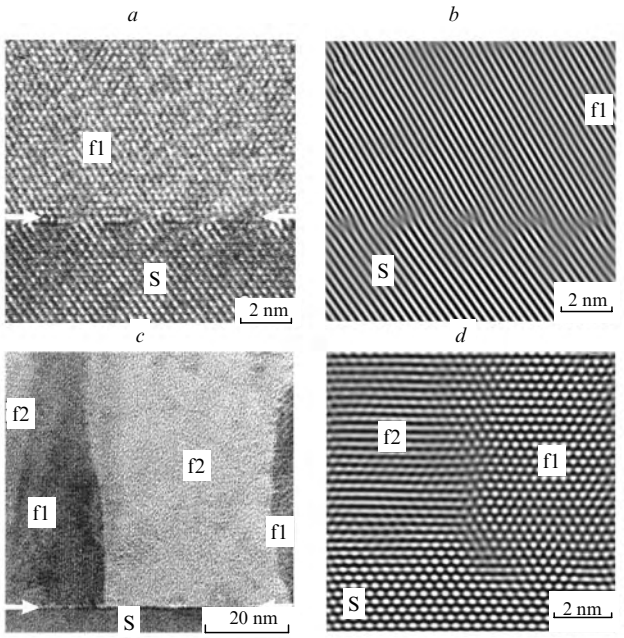

Figure 21. HREM study of the variant $(La_{0.5}Pr_{0.5})_{0.7}Ca_{0.3}MnO_3$ film on $(001)ZrO_2(Y_2O_3)$. In all cases, the $[110]ZrO_2(Y_2O_3)$ area is shown: (*a*) epitaxial stresses completely relax at the film/substrate interface, (*b*) Fourier image of the same region of the interface, (*c*) orientational growth modes (domains f1 and f2) in a low resolution, (*d*) coherence of the oriented variants along the film growth direction.

number of studies [111–114] dealing with the preparation of epitaxial films of the $Ba_{0.5}Sr_{0.5}TiO_3$, $Bi_{3.25}La_{0.75}Ti_3O_{12}$ and $SrBi_2TaO_9$ ferroelectrics with a ferroelectric polarisation axis oriented normal to the surface of the (001)silicon substrate. For solving this highly topical problem, epitaxial film heterostructures of the $(100)Bi_{3.25}La_{0.75}Ti_3O_{12}/(110)SrRuO_3/(001)ZrO_2(Y_2O_3)/(001)Si$ type were prepared. The conductive layer of the $SrRuO_3$ perovskite had a four-variant structure; as a result, $Bi_{3.25}La_{0.75}Ti_3O_{12}$ a layered phase derived from perovskite grown on $SrRuO_3$, had 8 options of arrangement in the plane parallel to the substrate.

A large number of boundaries between numerous structural variants may have an adverse effect on the ferroelectric properties; therefore, the possibility of affecting the pattern of the variant structure by changing the CSL on the surface of the $ZrO_2(Y_2O_3)$ single crystal through its slight $(1-5^\circ)$ deviation from the (001) plane has been studied.[114] This expedient proved to be most efficient when the deviation was performed along the [110] direction; the number of epitaxial variants in the $(110)SrRuO_3$ film decreased to two. Obviously, this approach could also find application in the studies of other heteroepitaxial systems.

A multivariant growth motif is also observed in the deposition of $La_{0.7}Ca_{0.3}MnO_3$ on $(111)ZrO_2(Y_2O_3)$. In this case, the body diagonal of the perovskite cube also corresponds to the face diagonal of the fluorite cube at the interface. In this case, the vectors of the orthogonal CSL determined from X-ray diffraction and HREM data are $[\bar{1}01]$, $3\times[1\bar{2}1]$ for $(111)ZrO_2(Y_2O_3)$ and $[1\bar{1}1]$, $4\times[1\bar{1}\bar{2}]$ for the (110)perovskite. The misfit of the CSL equals 8% for the $[\bar{1}01]$ and $[1\bar{1}1]$ pair and 0% for the $[1\bar{2}1]$ and $[1\bar{1}\bar{2}]$ pair. The theoretical number of equivalent epitaxial variants for this case is six, and all these are actually encountered in the film (Fig. 22).

A direct consequence of the formation of epitaxial variant structures is the presence in the film of a high density of special high-angle boundaries. The set of angle orientations of such boundaries is strictly fixed and their concentration does not change over the film thickness. This represents the basic difference between the variant structures and polycrystalline materials in which the angle orientations of the boundaries make a broad

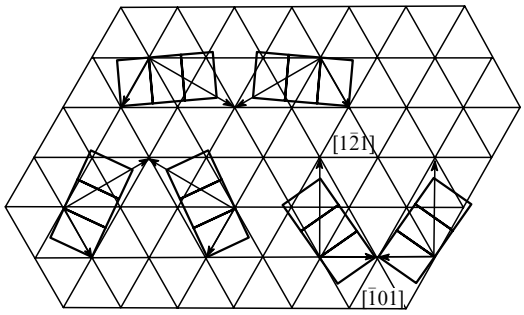

Figure 22. Six variants of the growth of perovskite on the (111)fluorite.

spectrum even in highly textured materials and the concentration of the boundaries themselves is not very high.

The epitaxial multivariant structure of the manganites is responsible for their interesting electrophysical properties which are not inherent in monovariant epitaxial films. First of all, this refers to the appearance of a substantial magnetoresistance (the change in the electric resistance of the material in a magnetic field) in weak magnetic fields over a broad temperature range below the Curie point.[115] This is due to the spin-dependent tunnelling of charge carriers through special high-angle boundaries. This is characteristic of the epitaxial films of manganites grown on bicrystalline perovskite substrates.[116]

The appearance of a substantial magnetoresistance in weak magnetic fields is of considerable interest as regards the manufacture of high-sensitivity magnetic field sensors. In the design of such sensors, one can use both the appearance of sharp maxima of positive magnetoresistance (*MR*) in the region of technical magnetisation (*i.e.*, magnetisation related to the re-orientation of magnetic domains) in fields weaker than 100 Œ and the appearance of great negative magnetoresistance ($\sim 30\%$) related to the tunnelling effect in fields of 100–5000 Œ (Fig. 23).

Both effects are also manifested in the traditional polycrystalline materials; however, the former requires much stronger fields (about 500–1000 Œ) and has a lower field gradient,[117] while the latter is much smaller in magnitude.[118] This is due to the fact that the structural coherence of high-angle boundaries implies a compression of the tunnelling barrier following an increase in the field strength,[119] which is impossible for non-coherent boundaries. We found that the magnitude of the tunnelling effect increases with an increase of the off-orientation angle of the neighbouring nanodomains in films with a variant structure.[109]

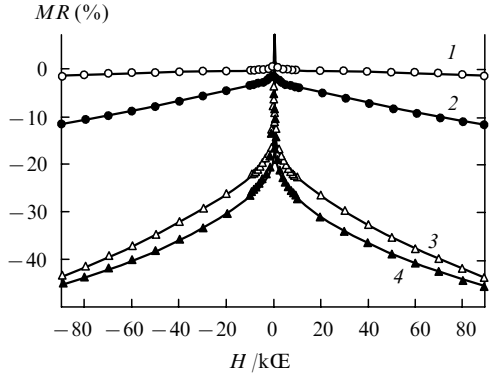

Figure 23. Magnetoresistance (*MR*) in the $(110)La_{0.7}Ca_{0.3}MnO_3$ epitaxial films grown on different substrates (temperature, 10 K). Substrate: (*1*) $(110)SrTiO_3$, (*2*) $(110)ZrO_2(Y_2O_3)$, (*3*) $(001)ZrO_2(Y_2O_3)$, (*4*) $(111)ZrO_2(Y_2O_3)$. Real structure of the obtained film: (*1*) monodomain, (*2–4*) multidomain with small-angle (*2*) and high-angle (*3*, *4*) boundaries (in the order of increasing off-orientation angle).

In particular, in the (110)perovskite films with a variant structure, the tunnelling magnetoresistance increases on passing from (001)$ZrO_2(Y_2O_3)$ to (111)$ZrO_2(Y_2O_3)$.

Tunnelling structures are often designed using epitaxial films of manganites on bicrystalline perovskite substrates. The films are grown on a special boundary produced, for example, by diffusion welding of two halves of a single-crystalline substrate. The structure of this boundary is inherited by the epitaxial film. Obviously, for practical application, multivariant structures on single-crystalline substrates have essential advantages over monovariant epitaxial structures on bicrystalline substrates. First, they are much less expensive and second, the whole surface of a variant film rather than only the bicrystalline boundary region can be used for the preparation of magnetic sensors.

Our further research has demonstrated that the field sensitivity of the variant structures based on manganite films can be increased through deposition of a layer of a soft ferromagnet (based on $MnFe_2O_4$) on a layer of the variant structure formed on the (111)$ZrO_2(Y_2O_3)$ substrate (Fig. 24, *cf.* curves *3*, *4* and *5*, *6*).

The variant structures also appear in films with other types of epitaxial interface. For example, a study of an In_2O_3 film (bixbyite cubic structure, $a = 1.0117$ nm) on (001)MgO (NaCl type, $a = 0.4213$ nm)[120] has shown that domains with the (111)In_2O_3 ‖ (001)MgO orientation, which split into four variant structures in the substrate plane, predominate in these films. In all of these structures, the diagonals of the cube faces of In_2O_3 and MgO are parallel: $[1\bar{1}0]In_2O_3$ ‖ [110]MgO, $[\bar{1}10]In_2O_3$ ‖ [110]MgO, $[110]In_2O_3$ ‖ $[1\bar{1}0]$MgO and $[110]In_2O_3$ ‖ $[\bar{1}10]$MgO. The same type of variant structure is typical of isostructural Y_2O_3 films on (001)MgO (Fig. 25 *a*).[121, 122] In both films (In_2O_3 and Y_2O_3), some of the crystallites are oriented with the (001) axis normal to the substrate; these crystallites are monovariant (Fig. 25 *b*). The ratio of the (111)- and (001)-oriented domains depends on the film deposition temperature and on the oxygen pressure in the evaporation chamber,[123] although the role of the latter is not quite clear. Probably, oxygen influences the rate of film deposition, which often switches the (111)-growth to the (001)-growth for cubic crystals. The formation of the variant structures has an essential influence on the conductivity of In_2O_3 films, because high-angle boundaries of the domains create additional resistance to the carrier transport. This circumstance should be taken into account when using In_2O_3 as a conductive layer on single-crystalline substrates.

Now we consider the growth of films with a rutile structure (TiO_2, CrO_2, RuO_2, SnO_2) on substrates of the fluorite and perovskite type. The length of the diagonal of the tetragonal face in the RuO_2 structure is close to the length of the edge of the fluorite cube [in $ZrO_2(Y_2O_3)$ and CeO_2] and to the length of the face diagonal of the perovskite cube [in $LaAlO_3$].[123] The orientation of the (100)RuO_2 ‖ (001)substrate film gives rise to four epitaxial modes of the growth (Fig. 26). In the RuO_2 film on *a*-sapphire, the (100)RuO_2 ‖ (0001)substrate orientation gives rise to three growth patterns with a common motif at the interface, $[010]RuO_2 \parallel [11\bar{2}0]Al_2O_3$, $[010]RuO_2 \parallel [\bar{2}110]Al_2O_3$ and $[010]RuO_2 \parallel [1\bar{2}10]Al_2O_3$.[124] It is noteworthy that the same film orientation takes place in the growth of rutiles on *R*-sapphire; however, the *R* plane has only one vector of the $[1\bar{2}10]Al_2O_3$ type; therefore, the epitaxy is monovariant: $(101)[010]MO_2 \parallel (\bar{1}012)[1\bar{2}10]Al_2O_3$.

The variant structures in the CrO_2 films with the rutile structure, as those in the manganites described above, show the tunnelling magnetoresistance effects, although they are weaker in magnitude.[125]

It follows from the foregoing that the variant structures (with high-angle domain boundaries) are actually heteroepitaxial nanostructures resulting from self-assembly on the substrate surface occurring in particular orientational relations with the growing film. They are to be distinguished from the mosaic single crystals in which the low-angle domain structures predominate and no rigid restrictions on the mutual orientation angle are involved.

Meanwhile, the variant structures have common features with single-crystalline twins. Whereas the prediction of a twin structure requires only crystal parameters, a variant epitaxial structure can be determined only with known crystallographic data for the film and the substrate and their epitaxial relations. Only in rare cases, does a variant structure correspond to twins known for this

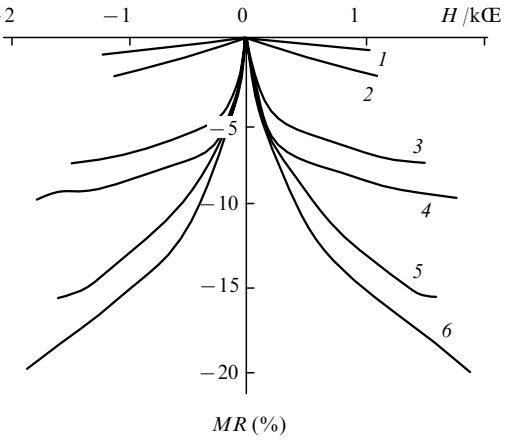

Figure 24. Magnetoresistance $MR = \{[R(H) - R(0)]/R(0)\} \cdot 100\%$ of films and heterostructures on different substrates.
(*1*) $(La_{0.7}Sr_{0.3})MnO_3$/MgO, (*2*) $(La_{0.7}Sr_{0.3})MnO_3$/(001)$SrTiO_3$, (*3*) $(La_{0.7}Sr_{0.3})MnO_3$/(110)$ZrO_2(Y_2O_3)$, (*4*) $MnFe_2O_4$/$(La_{0.7}Sr_{0.3})MnO_3$/(110)$ZrO_2(Y_2O_3)$, (*5*) $(La_{0.7}Sr_{0.3})MnO_3$/(111)$ZrO_2(Y_2O_3)$, (*6*) $MnFe_2O_4$/$(La_{0.7}Sr_{0.3})MnO_3$/(111)$ZrO_2(Y_2O_3)$.

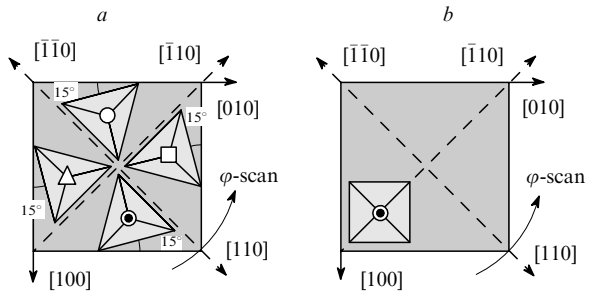

Figure 25. Modes of the epitaxial growth of Y_2O_3 on (001)MgO.[121, 122]

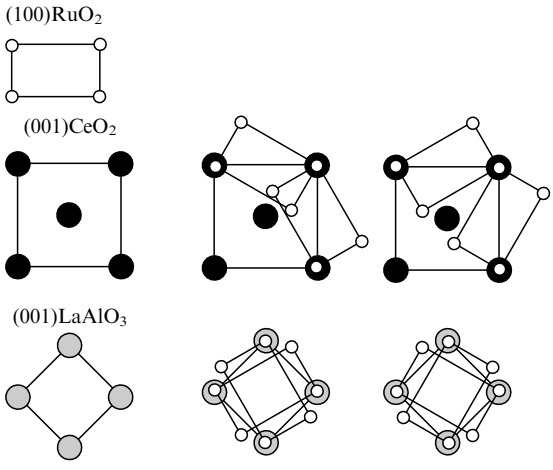

Figure 26. Four modes of the RuO_2 growth on the (001)CeO_2 fluorite and (001)$LaAlO_3$ perovskite.

crystal. This is usually the case for systems where the number of variants is reduced due to coincidence of some additional symmetry elements, as in *a*-oriented structures of $RBa_2Cu_3O_{7-\delta}$ related to each other by the (013) twinning plane.

It has been noted above that many perovskites tend to grow in the (110) orientation on fluorite substrates, for example, on $(001)ZrO_2(Y_2O_3)$. However, there are some exceptions. The $BaTiO_3$ epitaxial films have the (111) orientation on this substrate, which implies four epitaxial growth modes with a common motif: the length of the face diagonal of the perovskite cube is close to the length of the edge of the fluorite cube. These conditions are violated upon the change in the ratio of the lattice parameters of the film and the substrate. For example, deposition of $BaTiO_3$ on a buffer layer of the cubic praseodymium oxide (with the lattice parameter $a = 0.546$ nm) results in switching of the orientation of the $BaTiO_3$ film to (001), which provides the least misfit between the CSL parameters and the (001) layer of praseodymium oxide.[126]

Of considerable interest is further research into the kinetics of formation of variant structures and the possibility of controlling the nanodomain size, shape and arrangement on the substrate surface. The experimental data available to date attest to a dependence of the nanodomain size on the diffusive mobility of the film components. This in the MOCVD deposition of the $RBa_2Cu_3O_{7-\delta}$ films under conditions where the figurative point of the crystallising system occurs near the solidus surface, the domains of variant structures can grow to submicron dimensions. Some published data may be indicative of the possibility of controlling the shape anisotropy of the variant nanodomains. For the three-variant $(100)RuO_2$ structure on $(0001)Al_2O_3$, the following correlation was established: nanodomains with an average size of 30 nm are most extended along the direction of the least misfit of the CSL and least extended along the greatest misfit of the CSL. If this dependence is general, this would allow effective control of the shape of nanodomains through a change in the substrate material (and, hence, the parameter *a* of the substrate) by doping or deposition of buffer layers. The question concerning the possibility of fixing the arrangement of epitaxial variant structures on the substrate surface remains open. Apparently, interesting results could be provided by using vicinal or single-crystalline substrates with an artificial relief (graphoepitaxy).

Generally, variant structures represent a new group of thin-film materials whose physical properties (including electrical and magnetic ones) are determined at the nano-size level and differ appreciably from the properties of both monovariant epitaxial films and polycrystalline materials. Further research into these structures will promote extension of the scope of their application in the modern micro- and nanoelectronics.

IV. Conclusion

We would like to emphasise once again that the epitaxial stabilisation of oxide films discussed in this review is an equilibrium phenomenon, *i.e.*, the growing oxide phase exists in an external equilibrium with the substrate and the gas-phase oxygen and also in an internal (in the case of phase assembly) solid-state equilibrium. If the decrease in the Gibbs energy of the film/substrate system caused by epitaxy is greater in magnitude than the ΔG value of any solid-state process involving the phase growing on a substrate surface (a polymorphic transition, redox reaction, *etc.*), one can expect that phase equilibria in an epitaxial film would differ from the phase equilibrium in the same system without epitaxy. In particular, with epitaxial stabilisation, the 'unusual' simple or complex oxide phases that require high pressure, high temperature or high oxygen pressures to be formed can be prepared without resorting to these extrem conditions. In multiple phase films, the epitaxial relations of separate phases with the matrix phase in whose bulk they grow and/or with the substrate can give rise to stable phase assemblies differing from those dictated by the equilibrium phase diagram. All these phenomena can be regarded as being due to the change in the thermodynamics of the system under the action of epitaxy rather than to manifestation of slow kinetics of the surface reaction, which precludes attainment of the Gibbs energy minimum during the film growth. The effect of epitaxy on the thermodynamics of the growing phase is enhanced with an increase in the coherence of the film structure and the substrate. In the case of a perfect fit of the structures, the critical thickness of the stabilised phase reaches a maximum value.

This review considers examples of ES, taken mainly from our studies on gas-phase epitaxy; however, the ES phenomena are equally typical of the liquid-phase epitaxy (from aqueous solutions and melts), electrocrystallisation,§ and, perhaps, solid-state epitaxy. Moreover, the ES can be detected not only in the preparation of thin films or in the solid-state chemistry, but also in mineralogy (examples of pseudomorphism in minerals are frequently encountered [128]).

The understanding of the nature of the ES attained to date allows one to use this phenomenon for deliberate synthesis of unstable compounds as thin epitaxial films, which can soundly be expected to be a success. The films of epitaxially stabilised phases are of considerable interest not only as objects for the study of the fundamental properties of materials but also as real materials with potentially useful properties. The selective epitaxy based on the ES can find application in the preparation of complex heterostructures. It is beyond doubt that involving new types of single crystalline substrates in the practice of epitaxial stabilisation would give rise to new oxide compounds and materials.

The variant epitaxial structures have not yet received adequate attention. Meanwhile, they represent a new class of nanostructures in which self-assembly of nanodomains is due to the energetic degeneracy of various geometric modes of epitaxy. By conscious selection of substrates, one can change the number and the mutual orientation of epitaxial variant structures in the film. The considered examples of enhancement of the magnetoresistance in the doped lanthanum manganite films represent the first achievements made owing to the targeted design of high-angle boundaries of the epitaxial variant structures. Even now, one can state that this approach would diversify and, in some cases, markedly enhance the properties of materials (magnetic, electric, including ferroelectric, and optical properties) depending on the structure of internal interfaces.

In conclusion, the authors are happy to thank the colleagues who actively participated in various stages of the research covered in this review: Drs. I E Graboi, S V Samoilewnkov, M A Novozhilov and A A Bosak and students S Antonov, A Mikhailov and O Boitsova for their inestimable contribution to the experiments.

This work was carried out with partial financing by the Russian Foundation for Basic Research (Project Nos 02-03-33258 and 04-03-32505), the Volkswagen Stiftung (Grant I/77821) and the NWO Program of the Russia – Holland cooperation.

Abstract. The review considers characteristic features of the crystal structure, phase relations, microstructure and physical properties of the most important classes of modern cuprate and manganite materials including high-temperature superconductors, CMR magnetic semiconductors and superionic conductors. The bibliography includes 189 references.

I. Role of the d-elements in design of new materials

In design of modern functional materials possessing nonlinear magnetic and electric properties an important role is played by the transition elements capable of being in different oxidation states and spin states.[1,2] Among oxide materials, there are two most promising classes which have become the subjects of intensive research recently. These are high-temperature superconductors (HTSC)[3–8] and 'colossal magnetoresistive' (CMR) materials.[9–11] Open framework structures have also attracted close attention of researchers.[12,13] Often, these classes of compounds comprise complex oxides of copper and/or manganese. Peculiarities of the properties of these elements and their oxides are of crucial importance for practical applications because they allow one to trace how the chemical properties of the d-elements influence the functional properties of materials.

In a rather short time, large-scale research on high-temperature superconductivity has contributed largely to modern inorganic chemistry, physical chemistry, solid state chemistry and materials science.[3] High-temperature superconducting cuprates represent one of the most promising classes of ceramic materials possessing structure-sensitive properties. They are still complex and very interesting objects that are far from being studied comprehensively. Methodological approaches and experimental basis of inorganic chemistry and solid state chemistry are of particular importance for carrying out basic research on these compounds.

The ability of manganese to form complex framework structures built of joined MnO_6 octahedra and filled with different types of cations located in the framework cavities predetermines the variety of manganese-containing oxide materials.[14] For instance, hollandite, $BaMn_8O_{16}$, is one of the most prominent and well-known examples of compounds with a specific tunnel structure, which provides the possibility of using this phase as a catalyst, solid electrolyte, matrix for nuclear waste disposal and an electrode material.[13,15]

The magnetic, magnetotransport and other practically important physical properties of manganites are to a great extent governed by the ability of manganese to be present in the structure simultaneously in different oxidation states, by electron exchange between Mn^{3+} and Mn^{4+} and, sometimes, by the spin and charge ordering.[9–11] The discovery of the CMR effect in the manganites with perovskite structure, $R_{1-x}A_xMnO_{3-\delta}$ [R is a rare-earth element (REE) and A is an alkali or alkaline-earth metal[9–11]] was followed by a new flare of interest in studies of manganite systems in connection with the possibility of using them in magnetometers, reading heads for high-density magnetic recording, data storage devices, metal detectors, sensors, *etc.*[11] Perovskite-type manganites of compositions $CaCu_xMn_{7-x}O_{12}$ exhibit some features such as specific magnetoresistance mechanism different from that observed in conventional perovskites, the possibility for a rather high magnetoresistance to be achieved at relatively low magnetic fields and smooth temperature dependences of these parameters (in contrast to manganites $AMnO_3$). This offers great prospects for practical applications of these phases.[16–19] The temperature and the magnetic field dependences of the magnetoresistance indicate a large contribution of intergrain tunnelling to the total magnetoresistance of $CaCu_xMn_{7-x}O_{12}$ compounds. Generally, the tunnelling magnetoresistance depends on the microstructure, in particular, on the grain size, mutual orientation of grains and on the surface area of grain boundaries. Optimisation of these characteristics requires elaboration of novel methods of synthesis of these materials.[20] Thus, similarly to superconducting cuprates, complex oxides of alkaline-earth metals and manganese are of particular interest for inorganic chemistry and materials science.

This review concerns the main methods of preparation of modern functional materials and the 'composition – treatment –

structure – property' correlations. We also summarise here the results of theoretical and experimental studies on fabrication of ceramic materials and coatings based on superconducting cuprates, cupromanganite-based CMR magnetic semiconductors and superionic conductors based on the manganites with framework structures.†

II. Crystal structures of cuprates and manganites

The main structureal types of superconducting cuprates are as follows:

oxygen-deficient perovskites characterised by the presence of 'infinite CuO_2 layers' separated by (La,Ca) – vacancy layers [*e.g.*, (Sr,Ca)CuO_2, see Fig. 1 *a*], substitution solid solutions $Nd_{1+x}Ba_{2-x}Cu_3O_z$ based on the triple perovskite-type unit cell CuO_{1-z} – BaO – CuO_2 – Nd – CuO_2 – BaO – CuO_{1-z} with different types of ordering of the heavy cations and the oxygen sublattice (Fig. 1 *b*,*c*);

intergrowth structures characterised by intergrowth of the perovskite units containing superconducting CuO_2 planes, NaCl [*e.g.*, La_2CuO_4 (Fig.1 *d*), $Bi_2Sr_2CaCu_2O_8$ (Fig. 1 *e*), $Pb_2SrYCu_3O_8$], fluorite bloks, *etc.*;

homologues, *i.e.*, phases with different numbers of CuO_2 layers [*e.g.*, $HgBa_2CaCu_2O_{6+z}$ and $HgBa_2Ca_2Cu_3O_{8+z}$ phases (Fig. 1 *f*)] or CuO layers (*e.g.*, $RBa_2Cu_3O_7$, $R_2Ba_4Cu_7O_{14}$, $RBa_2Cu_4O_8$);

low-dimensional structures formed by differently joined planar CuO_2 units [*e.g.*, $Sr_{14}Cu_{24}O_{48}$ (Fig. 1 *g*), $Sr_2Cu_3O_5$ (Fig. 1 *h*), $LaCuO_{2.5}$ (Fig. 1 *i*)].

Almost all HTSC are complex layered copper-containing oxides containing oxygen-deficient perovskite-type structural fragments.[5,7,8,106–108] The structure and properties of the HTSC are strongly influenced by the Jahn – Teller effect and ordering of ions.[3,7,8] The former effect is responsible for the formation of low-coordinated copper polyhedra in the structure while the latter causes local distortions and charge transfer between structural blocks.

In a planar CuO_2 layer the copper atoms form a square network while the oxygen atoms are located on the lines connecting the sites of the copper atoms. The $3d_{x^2-y^2}$ electrons of the copper atoms and the $2p_{x,y}$ electrons of the oxygen atoms form the in-plane bonds in the layer. These electrons are delocalised and do not belong to a particular atom. Below the critical temperature, superconductivity arises on 'doping' the CuO_2 layers with an optimum amount of charge carriers[6] in the absence of strong structural distortions. The phases with nearly ideal planar CuO_2 layers are, *e.g.*, mercury-containing[106] HTSC and 'infinite-layer' structures.[8] The onset of superconductivity requires that the formal oxidation state of copper in the layers containing shared electrons be in the ranges from +2.05 to +2.25 (hole-doped superconductors) or from +1.8 to +1.9 (electronic superconductors). The length of the in-plane Cu – O bond must be 0.19 to 0.197 nm provided that the distance between adjacent copper atoms is 0.380 to 0.394 nm. For any member of a homologous series the dependence of T_c on the charge carrier concentration passes through an extremum, while the highest transition temperature is usually observed for the homologue with an optimum number of the superconducting planes.[21,107]

It is believed that transition to the superconducting state occurs as a result of formation of a Cooper pair (a boson) provided that the motion of two charge carriers is correlated.[108] In the early stage of research into the HTSC mechanism it was assumed that the Cooper pair is a pair of holes that polarise the lattice. The electron – phonon interaction and symmetry of the ordering parameters in terms of the Ginzburg – Landau superconductivity theory (d-, s- or mixed type) are still the subject of wide speculation.[109] At present, the most probable mechanism of superconductivity considers a two-hole charge carrier and magnetically ordered spin moments of the copper atoms in the localisation region of the Cooper pair (sometimes, this is called a magnetic polaron or a 'spin bag'). In this case the coherence length of the charge-carrier wave function is rather small and different along the main crystallographic directions.[108] The Bose 'liquid' flows through a HTSC crystallite without dissipation provided that the critical current density (the critical magnetic field) is not exceeded; otherwise, the Cooper pairs are destroyed and the HTSC passes to the normal (resistive) state.

The structures of famous superconductors are built of alternating CuO_2 planes and 'dielectric' BaO, SrO, TlO, BiO, PbO, HgO, $Ca^{\square}$, *etc.*, layers.[5,7,8,107] In the intergrowth structures the non-superconducting units often act as specific charge reservoirs that ensure the formation and transfer of charge to the superconducting planes by insertion (or removal) of extra oxygen and by heterovalent doping. This is responsible for crucial importance of another structural parameter, *viz.*, the length of the bond between the copper atoms and oxygen atoms in the neighbouring layers. These bonds are usually much longer (more than 0.22 nm) than the in-plane bonds. In other words, the structures of superconducting cuprates contain unequal chemical bonds Cu – O, namely, strong bonds in the plane of the CuO_2 layer and much weaker bonds perpendicular to these layers.

The 'infinite-layer' superconducting structures obtained under high pressure[8] (see Fig. 1 *a*) and 'ladder'-type cuprates (see Fig. 1 *g* – *i*)[110,111] are of interest from the standpoint of both fundamental superconductivity theory and crystal chemistry. Both families of cuprates are low-dimensional, strongly correlated systems built of differently connected planar $(CuO_2)_n$ units with variable dimension (1D – 2D) and width (in the case of ribbon-like structures). As a consequence. they exhibit unique features of the spin and magnetic interactions.

The structure types characteristic of manganites are as follows: perovskite [$CaMnO_3$ (Fig. 2 *a*)], spinel [Li_2MnO_4 (Fig. 2 *b*)]; homologues, Ruddlesden – Popper phases $(R_{1-x}A_x)_{n+1}Mn_nO_{3n+1}$ [R is a rare-earth element and A is an alkali-earth element; $n = 1$ (Fig. 2 *c*) and 2 (Fig. 2 *d*)] characterised by intergrowth of different numbers of perovskite-type blocks $(R_{1-x}A_x)MnO_3$ and $NaCl(R_{1-x}A_x)O$ units; layered and chain manganites [birnessite $K_{0.5}Mn_2O_{4.3}(H_2O)_{0.5}$ (Fig. 2 *e*) and $Ba_6Mn_5O_{16}$ (Fig. 2 *f*)]; and tunnel structures related to pyrochlore [$Tl_2Mn_2O_7$ (Fig. 2 *g*)], pyrolusite [β-MnO_2 (Fig. 2 *h*)], hollandite [$A_{2-x}Mn_8O_{16}$, where A = Ba, Sr, Ca, *etc.* (Fig. 2 *i*)], todorokite [$MMn_6O_{12}\cdot 3H_2O$, where M = K, Ca, Mn, *etc.* (Fig. 2 *j*)], ramsdelite R-MnO_2 (Fig. 2 *k*) and psylomelane [$Ba_{0.66}Mn_5O_{10}(H_2O)_{1.35}$ (Fig. 2 *l*)].

Most simple manganese oxides have framework or layered structures (see Fig. 2).[2,12] The oxide Mn_3O_4 has a distorted spinel structure at room temperature which undergoes a transition in the cubic polymorph (γ-Mn_3O_4) at temperatures above 1170 °C. In the structure of hausmannite (β-Mn_3O_4) the distance from the cation to each of the two anions along the [001] direction is 16% longer than the distance from the cation to any anion in the (001) plane (at room temperature). Compounds γ-Mn_2O_3 and Mn_3O_4

† These investigations are carried out by the research staff of the Department of Chemistry, M V Lomonosov Moscow State University, in collaboration with domestic and foreign research centres. The research avenues are as follows: crystal chemistry of HTSC[21–23] and modification (fluorination)[24–30] of the superconducting phases and CMR manganites; synthesis of homologues of mercury-containing HTSC[31–38] and determination of their crystal chemical features[39–42] and physical properties;[43–45] single-crystal structure refinements;[46–48] studies on thermodynamics of HTSC systems[49,50] including mercury-containing HTSC;[51,52] studies on non-stoichiometry (with respect to oxygen) in and phase stability of manganites;[53] preparation of microcomposites based on bismuth-containing HTSC phases,[54–57] CMR manganite ceramics;[58–61] fabrication of thin films and heterostructures[62–71] based on HTSC or CMR manganites with preset microstructure and defect content;[72–82] studies on giant isotope effect[83–86] and magnetooptical properties of manganites;[87–90] stabilisation effect in film structures;[91] and determination of the local structure of complex oxide phases.[92–95] Detailed reports on the research avenues mentioned above can be found in Refs 5, 11, 96 – 107.

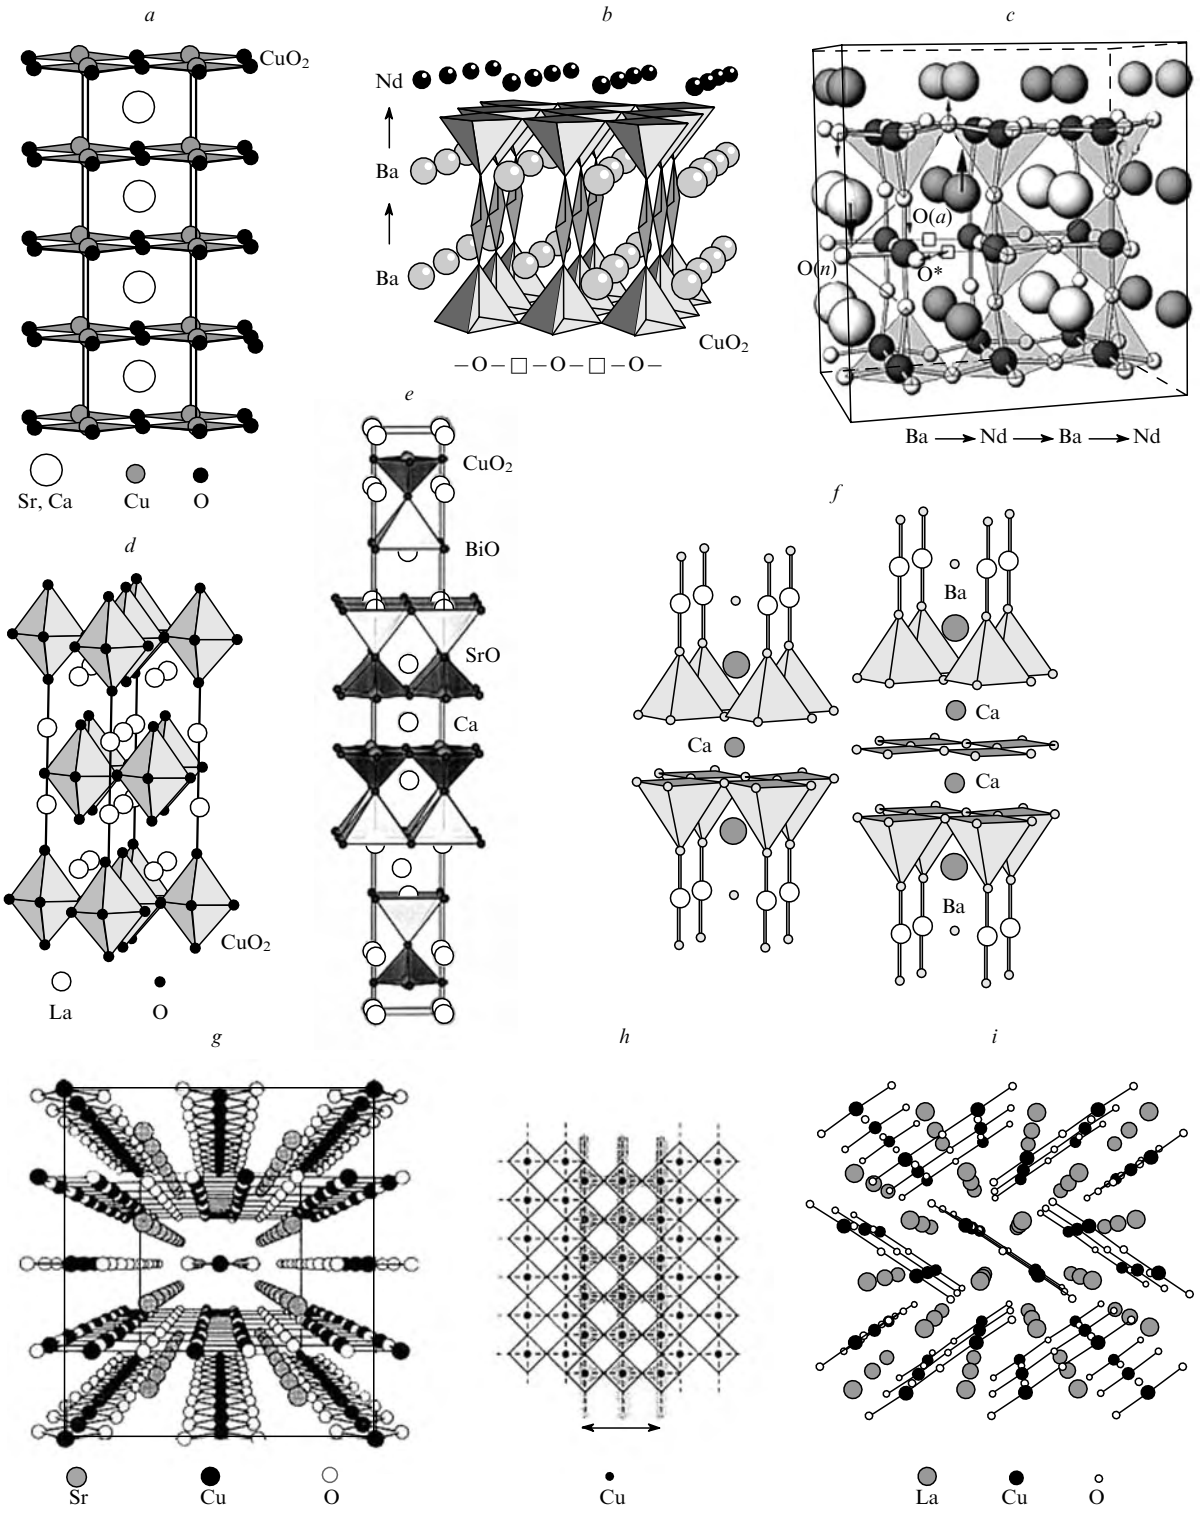

Figure 1. Main structures of superconducting cuprates.[7,8] (Sr, Ca)CuO_2 (*a*), $NdBa_2Cu_3O_z$ (*b*), $Nd_2BaCu_3O_z$ (*c*), La_2CuO_4 (*d*), $Bi_2Sr_2CaCu_2O_8$ (*e*), $HgBa_2CaCu_2O_{6+z}$ (on the left) and $HgBa_2CaCu_3O_{8+z}$ (on the right) (*f*), $Sr_{14}Cu_{24}O_{48}$ (*g*), $Sr_2Cu_3O_5$ (*h*), and $LaCuO_{2.5}$ (*i*).

are characterised by the same type of tetragonal distortion; MnO is isostructural to NaCl. The oxide Mn_5O_8 is described by the formula $Mn_2^{2+}Mn_3^{4+}O_8$. The structure of Mn_5O_8 can be represented by CdI_2-type layers in which 25% of the metal sites are vacant and the Mn^{2+} ions located above and below the vacant positions connect the layers to form a three-dimensional framework.

Depending on the fashion in which the MnO_6 octahedra are joined, tunnels of different shape and size are formed. The presence of tunnels usually leads to high anisotropy of the structure and in some cases to ionic conductivity. For instance, hollandite, cryptomelane, coronadite and α-MnO_2 belong to minerals described by a general formula $A_x(Mn^{4+}, Mn^{3+})_8(O^{2-},OH^-)_{16}$, where A is a large cation, usually, Ba^{2+} (hollandite) or K^+ (cryptomelane). The structure of hollandite comprises double chains of edge-sharing MnO_6 octahedra, which results in the formation of 2×2 tunnels. The structure of psylomelane, $(Ba,H_2O)_2Mn_5O_{10}$, is built of doubled and tripled chains of octahedra and large 2×3 tunnels filled with Ba^{2+} ions and water molecules. Dehydration of this compound by heating to

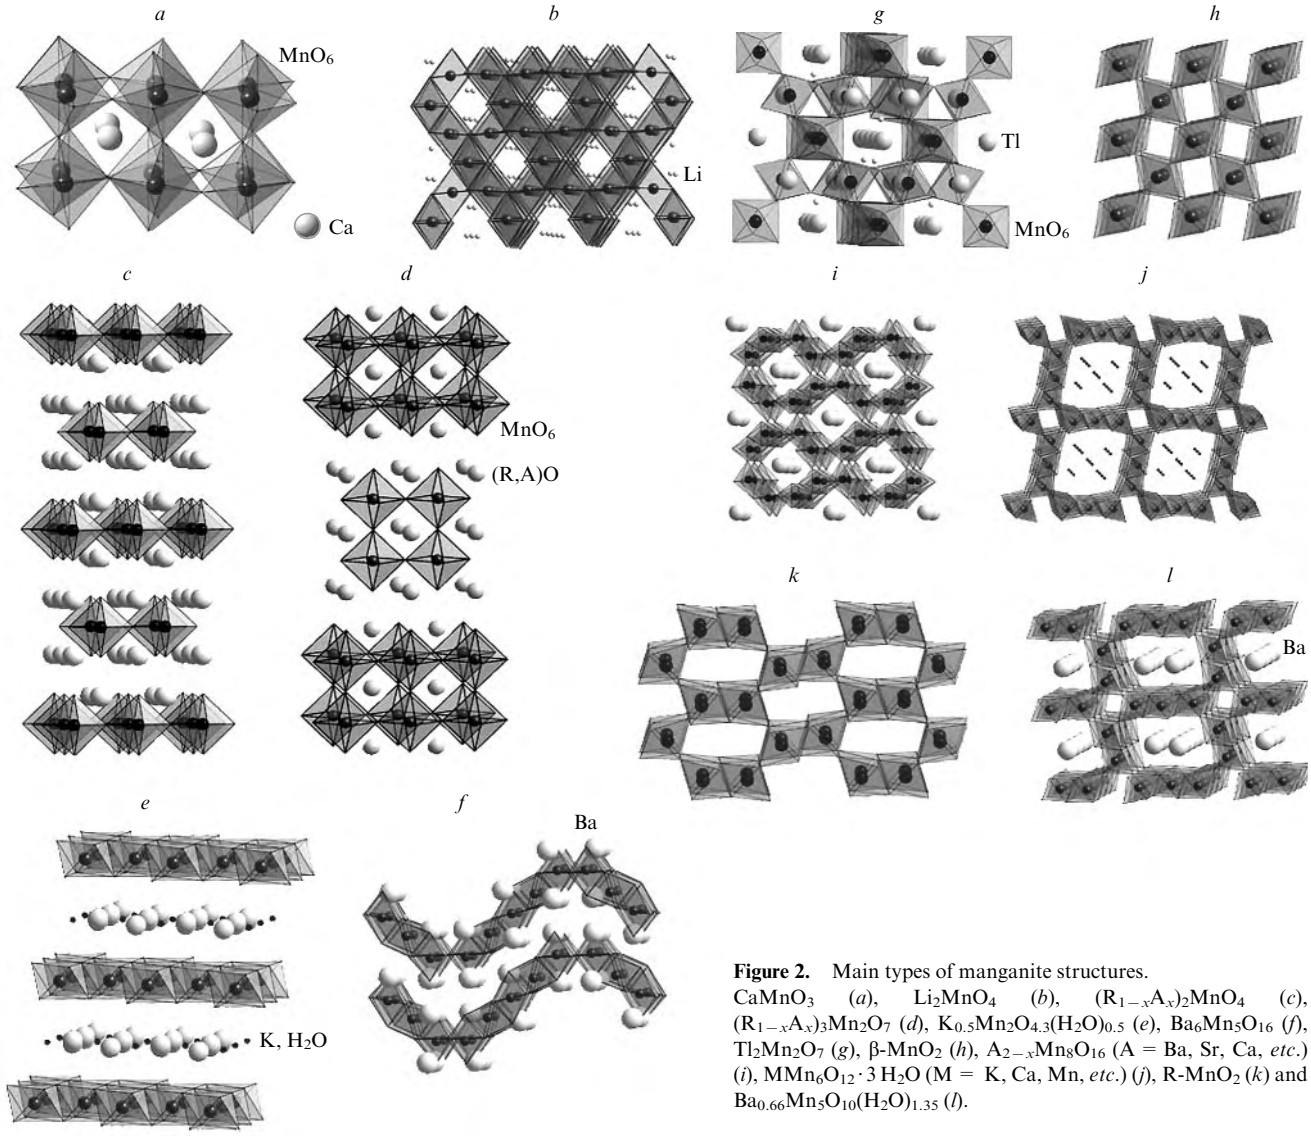

Figure 2. Main types of manganite structures. $CaMnO_3$ (*a*), Li_2MnO_4 (*b*), $(R_{1-x}A_x)_2MnO_4$ (*c*), $(R_{1-x}A_x)_3Mn_2O_7$ (*d*), $K_{0.5}Mn_2O_{4.3}(H_2O)_{0.5}$ (*e*), $Ba_6Mn_5O_{16}$ (*f*), $Tl_2Mn_2O_7$ (*g*), β-MnO_2 (*h*), $A_{2-x}Mn_8O_{16}$ (A = Ba, Sr, Ca, *etc.*) (*i*), $MMn_6O_{12}\cdot 3\,H_2O$ (M = K, Ca, Mn, *etc.*) (*j*), R-MnO_2 (*k*) and $Ba_{0.66}Mn_5O_{10}(H_2O)_{1.35}$ (*l*).

~550 °C is followed by its transformation in hollandite [12] with a disordered structure, which is due to the fact that the large tunnels enclosed on four sides by chains or ribbons of the manganese–oxygen octahedra are partially filled with cations. Tunnels in the todorokite structure are built of tripled 3 × 3 chains of edge-sharing octahedra and contain different numbers of Na, Ca and K atoms; tunnels of more complex shape can also form.[12]

The structure of birnessite, δ-MnO_2, is built of layers comprised of edge-sharing MnO_6 octahedra separated by layers containing water molecules and OH groups (see Fig. 2 *e*). The main structural feature of the manganites $BaMn_3O_5(OH)$ and $BaMn_2O_3(OH)_2$ are ribbons composed of four parallel chains of MnO_6 octahedra.[112] Layered manganites $Ba_4Mn_3O_{10}$ and $Ba_6Mn_5O_{16}$ containing no water molecules are also known.[113] Barium ions stabilise Mn(IV) in the structure. All compounds mentioned above can be obtained *via* 'molecular templates' in the synthesis of manganese oxides and their derivatives by 'soft chemistry' methods (see note ‡).[12]

‡ Here, the term 'soft chemistry methods' covers thermal decomposition of salt and hydroxide components, sol–gel technique, cryochemical or hydrothermal synthesis, which permit fabrication of materials with preset granulometric composition, stoichiometry, *etc.*, at rather low temperatures.

Compounds with a perovskite structure form a broad class of practically valuable materials. Distortion of an ideal perovskite structure in manganites appears due to three factors, namely, cooperative rotation of octahedra about a certain axis, Jahn–Teller distortion of MnO_6 octahedra and displacement of cations from their positions.[2] Thus, the initially cubic perovskite structure can experience a tetragonal, orthorhombic, rhombohedral or monoclinic distortion.

Phases of compositions $A_2Mn_2O_7$ (A = Dy–Lu, Sc, In, Tl) with pyrochlore-type structures [114] have cubic face-centred unit cells. Their structures represent frameworks built of vertex-sharing MnO_6 octahedra with the Mn–O–Mn angle of about 135°. In the structures of $A_2Mn_2O_7$ compounds the atoms A occupy centres of the hexagonal rings formed by the oxygen atoms (O) of MnO_6 octahedra and the oxygen atoms (O′) located above and below the ring plane (see Fig. 2 *g*). Thus, the environment of the atom A can be represented by a distorted cube. The MnO_6 octahedra are distorted, being in fact a kind of trigonal antiprisms; however, this is not a Jahn–Teller distortion characteristic of $R_{1-x}A_xMnO_3$ compounds.

Compounds $(R_{1-x}A_x)_{n+1}Mn_nO_{3n+1}$ belong to the Ruddlesden–Popper phases,[115] *i.e.*, layered manganites with a coherent intergrowth structure of perovskite-type units (the number of layers in the perovskite unit is *n*) and NaCl-type blocks (see

Fig. 2 *e*, *f*). The limiting case $n = \infty$ corresponds to the perovskite structure; the case $n = 1$ corresponds to the K_2NiF_4 structure.

III. Local structure and defects

The possibility of fabrication of cuprate- and manganite-based materials with preset functional properties and solution to the problem of 'anomalous' states of the phases with irreproducible fluctuations of functional properties [116–122] are to a great extent related to control of the cation ordering in the crystal lattices of solid solutions (Fig. 3).

Detailed studies showed that the physical properties of HTSC phases are often governed by the prehistory of samples.[116, 120, 121, 123–125] For instance, $Nd_{1+x}Ba_{2-x}Cu_3O_y$ solid solutions synthesised at low temperatures are characterised by cation disordering; therefore, the degree of local structural distortions in mixed REE–barium cuprates can be controlled by varying the temperature and duration of isothermal annealing (see Fig. 3 *a*). To establish an optimum regime of fabrication of superconducting materials, one should construct TTT-diagrams for different states of solid solutions, *viz*., ceramics, single crystals and films. This approach can also be used for efficient control of solid-phase decomposition of HTSC-cuprates, which can lead to the formation of microinclusions (efficient pinning centres).

Difficulties in studies of cation disordering using diffraction techniques (in particular, X-ray powder diffraction) are associated with integral character of information obtained in the experiments; in this case, investigations of local structural distortions by other methods can be more informative. To perform quantitative analysis of the local structure of high-temperature superconductors and manganites, it is appropriate to employ not only transmission electron microscopy but also efficient methods based on anomalous absorption of radiation, in particular, Mössbauer spectroscopy [119–122] and X-ray spectroscopic analysis [Extended X-ray Absorption Fine Structure (EXAFS)[116, 117]]. The EXAFS technique permits reliable determination of the average distances, coordination numbers and degree of disordering of the coordination environment in different clusters in solid solutions. Valuable additional information suitable for estimation of parameters of the nearest oxygen environment and the valent state of the probe atoms (^{57}Fe, *etc*.) can be extracted from the Mössbauer spectra. Raman spectroscopy provides important information on the local symmetry and force constants of the metal–oxygen bonds.[116, 117] Using Raman spectroscopy and Mössbauer spectroscopy, it is possible to study disordering of light atoms (*e.g*., oxygen atoms), thus complementing information obtained by powder X-ray diffraction methods in structure refinements.

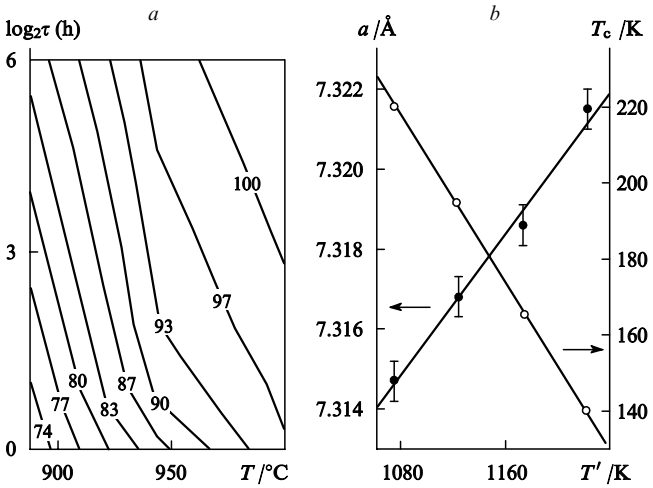

Figure 3. TTT-diagram § for the HTSC phase of $NdBa_2Ca_3O_7$ (*a*) and the lattice parameters and the temperature of magnetic ordering (T_c) of cupromanganite $CaCuMn_6O_{12}$ samples plotted *vs*. synthesis temperature (T') (*b*). Shown in the isolines are the superconducting transition temperatures (in per cent with respect to $T_c = 94$ K).

§ The Time–Temperature–Transformation diagram.

Mössbauer spectroscopy belongs to the most efficient and widely used methods of investigation of the local structure of HTSC phases.[126] The technique precludes on-site studies of defectivenes of the cation sublattice because parameters of hyperfine interactions depend mainly on the state of the first coordination sphere (oxygen environment) of the iron probe atoms occupying positions of copper atoms. At the same time the character of distortions of the oxygen polyhedra surrounding copper atoms is to a great extent governed by the extent of occupation of barium positions by other cations (*e.g*., neodymium ions in the $Nd_{1+x}Ba_{2-x}Cu_3O_z$ solid solution [5]). Schemes presented in Fig. 4 are convenient for establishment of correspondence between parameters of Mössbauer spectra and particular types of coordination polyhedra of the iron atoms occupying positions of copper atoms.[119, 120]

With heterovalent substitution of neodymium for barium the isomer shifts of the corresponding components increase (see Fig. 4) owing to stabilisation of the Fe^{3+} ions occupying the Cu1 positions in the substitutional solid solutions characterised by charge transfer between the dielectric block and the superconducting planes. An increase in the quadrupole splitting of spectral doublets is due to displacement of the apical oxygen O3, which is also characteristic of substitutional solid solutions. A spectral component associated with the $Fe_{Cu1}(III)O_{3+1}$ polyhedron, an unusual distorted configuration of the oxygen environment of the Fe atom occupying the Cu1 position [2 O(*a*) + O(*n*) + O*, see Fig. 1] should be pointed out. This component is characteristic [119, 127] only of annealed samples of the Nd213 : Fe solid solution with superstructural ordering of neodymium and barium atoms.

The main feature of the Mössbauer spectra of the pseudocubic phase $Nd_{1+x}Ba_{2-x}Cu_3O_z$ and substitutional solid solution Nd336 is the presence of components associated to the $Fe(IV)_{Cu1}O_6$ polyhedron.[116–120] These components originate from replacement of neodymium atoms by barium atoms.[118, 119] The $Fe(IV)_{Cu1}O_6$ octahedra are distorted owing to asymmetry of the second coordination sphere comprised of Ba atoms occupying their proper positions and Nd atoms occupying positions of Ba atoms. An increase in the formal oxidation state of iron atoms (decrease in isomer shift) can be explained by the formation of an associate of defects, $Fe(IV)_{Cu1}O_6-Nd_{Ba}$ (Fig. 5). In this case heterovalent substitution of Nd^{3+} for Ba^{2+} leads to displacement of apical oxygen atoms and occupation of vacant oxygen (O4) positions; as a consequence, the coordination sphere of the iron atoms occupying the Cu1 positions takes the shape of a distorted octahedron. No transfer of the excess local positive charge to the $Cu2O_2$ plane occurs, which increases the effective charge on the ^{57}Fe probe atoms. These data confirm the hypothesis that partial exchange of neodymium and barium in their proper crystallographic positions is possible in the pseudocubic phase $NdBa_2Cu_3O_7$ (see Fig. 5 *a*).

At high temperatures, the experimental temperature dependences of the magnetic susceptibility of the CMR manganites $CaCu_xMn_{7-x}O_{12}$ with $x > 0$ obey the Curie–Weiss law. However, the plots show clearly seen downward curvature typical of ferrimagnetics over a broad temperature interval.[16–20] The parameter of the cubic unit cell and the magnetic ordering temperature of the single-phase samples with identical cation and anion compositions depend on the synthesis temperature (see Fig. 3).

These correlations are due to specific structural features of solid solutions. For instance, the $CaCu_xMn_{7-x}O_{12}$ solid solution

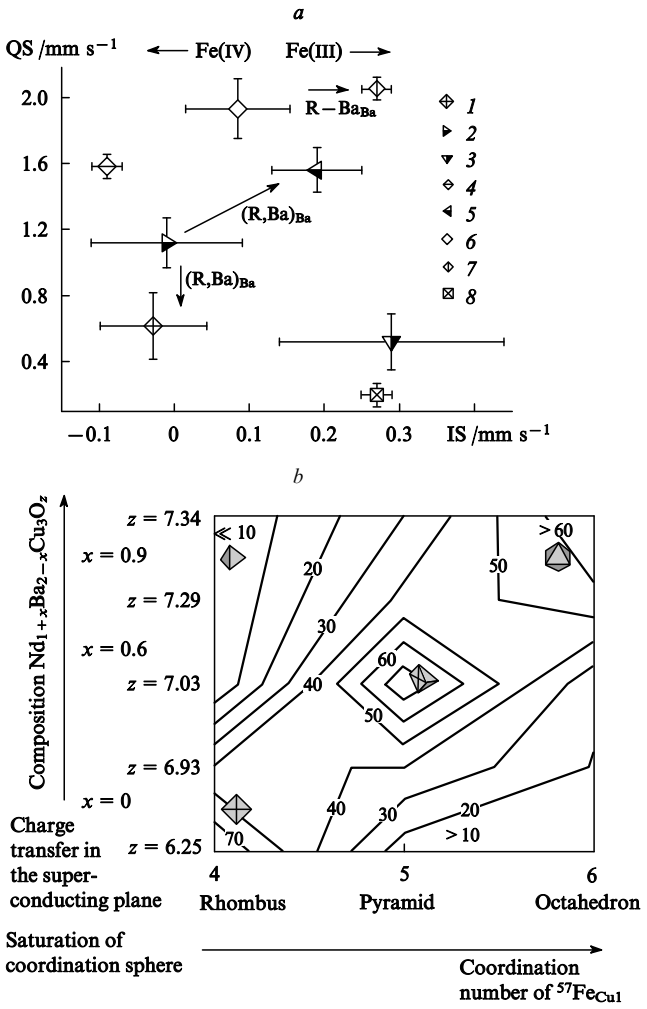

Figure 4. Schematic illustration of the results of Mössbauer spectroscopy studies of mixed REE–barium cuprates (*a*) and a generalised scheme of changes in the iron–oxygen polyhedra (a square, distorted rhombus, pyramid or octahedron) in the Cu1 position in the solid solution phase $Nd_{1+x}Ba_{2-x}Cu_3O_z$ with increasing x and z upon oxidation of samples (*b*). (*a*) Distorted octahedron (Cu1) (*1*), pyramid (Cu1) (*2*), pyramid (Cu2) (*3*), tetrahedron, twins (Cu1) (*4*), distorted pyramid (Cu1) (*5*), rhombus (Cu1) (*6*), distorted rhombus (Cu1) (*7*), and octahedron (Cu1) (*8*); QS is the quadrupole splitting and IS is the isomer shift; shown in the isolines are the contributions of the corresponding coordination numbers of the probe iron atoms (in per cent) (*b*).

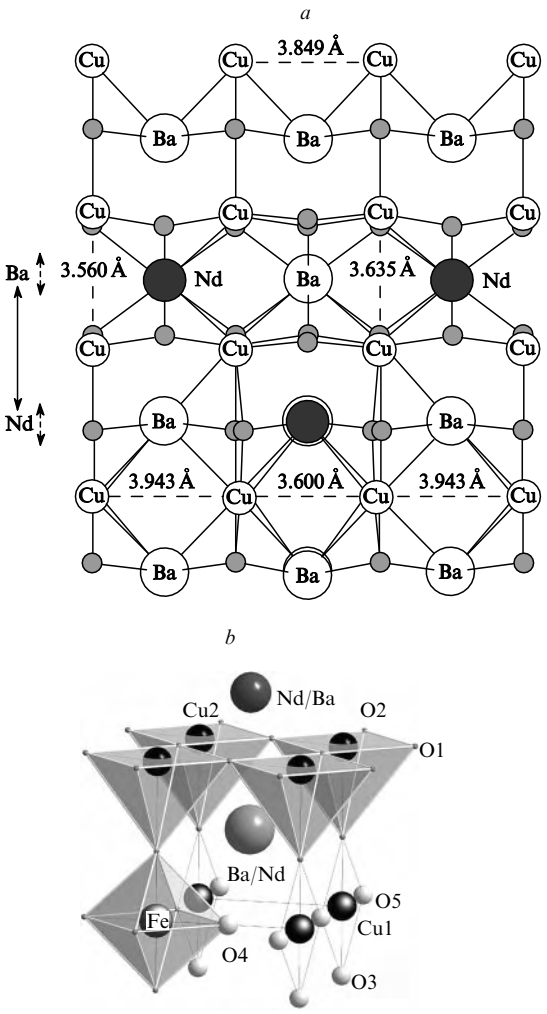

Figure 5. General model of defect (*a*) and a model of associated defects (*b*) $Fe(IV)_{Cu1}O_6-Nd^{3+}_{Ba^{2+}}$, which forms upon doping the substitutional solid solution $Nd_{1+x}Ba_{2-x}Cu_3O_z$ with iron in the case of antistructural disordering of neodymium and barium.

(Fig. 6 *a*) belongs to perovskite-type compounds [16–18] of general formula $AC_3B_4O_{12}$ (A is an alkali metal, alkaline-earth metal or REE cation; B = Mn^{4+}, Mn^{3+}, Ti^{4+}, Ru^{4+} or Ge^{4+}; C = Cu^{2+} or Mn^{3+}). In their framework structures, tunnels are filled with Ca^{2+}, Mn^{3+} and Cu^{2+} cations. The Mn^{3+} ions are also constituents of distorted MnO_6 octahedra occupying the unit cell vertices while the Mn^{4+} cations occupy ideal octahedral positions.

The solid solution (except for the composition with $x = 0$) crystallises in the cubic system (space group $Im\bar{3}$). This is accompanied by doubling of the parameter of ideal perovskite unit cell. The oxidation state of manganese in the B-position depends on the Cu^{2+}/Mn^{3+} ratio (x value) in the solid solution. Magnetic ordering arises as a result of interaction between the Cu^{2+} and Mn^{3+} magnetic sublattices, which depends on the occupation of crystallographic positions by cations and is governed by the procedure employed for sample preparation.

Yet another phase whose properties depend on the sample prehistory is $Ba_6Mn_{24}O_{48}$ with a composite structure (see Fig. 6 *b*) related to the known rutile and hollandite structures.[128] The crystal structure of $Ba_6Mn_{24}O_{48}$ can be represented as a combination of two sublattices, *viz*., a $[Mn_{24}O_{48}]$ framework containing randomly distributed Mn(IV) and Mn(III) and a sublattice of Ba^{2+} chains located within tunnels of the manganese–oxygen framework. Both sublattices have a tetragonal symmetry and the following parameters: $a \approx 18.2$ and $c \approx 2.8$ Å for Mn and $a \approx 18.2$ and $c \approx 4.6$ Å for Ba. The manganese sublattice comprises double columns of edge-sharing $Mn3O_6$ and $Mn1O_6$

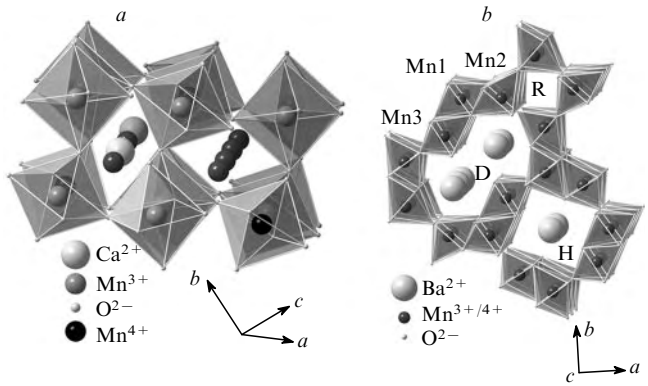

Figure 6. Fragments of the crystal structures of manganites $CaMn_7O_{12}$ (*a*) and $Ba_6Mn_{24}O_{48}$ (*b*).

octahedra and single columns of $Mn2O_6$ octahedra that join the double columns. This results in the formation of double (D), hollandite-type (H) or rutile-type (R) tunnels. Barium cations in the Ba sublattice are partially disordered and can be displaced along the z axis. In addition, barium cations located in the D-type tunnels form domains with a characteristic size of a few nanometres.

The Mössbauer spectra of $CaMn_{6.86}Fe_{0.14}O_{12}$ recorded at 300 K are superpositions of two doublets with similar chemical shifts;[122] small quadrupole splittings of both components confirm that all Fe probe atoms occupy octahedral positions. The Mössbauer spectrum of $Ba_6Mn_{23.76}Fe_{0.24}O_{48}$ is more complicated and can be described as a superposition of four doublets with different quadrupole splittings and equal contributions.

Because the Fe probe atoms have the same oxidation state (+3), both types of the Mössbauer spectra of manganites can be described using a model of continuous distribution of the electric field gradient, P (Fig. 7).[122] A symmetric narrow distribution obtained for $CaMn_7O_{12}$ indicates that the Fe^{3+} cations occupy positions with similar quadrupole splittings and have nearly identical nearest environments. In contrast to the flexible, readily deformable $CaMn_7O_{12}$ framework comprised of vertex-sharing octahedra, the octahedra in the $Mn1O_6-Mn3O_6$ unit of $Ba_6Mn_{24}O_{48}$, which confine the D- and H-type tunnels, are joined rigidly; as a result, distortions typical of these units are imposed on the probe atoms.

The composite structure of $Ba_6Mn_{24}O_{48}$ and the charge redistribution due to specific features of the distribution of barium cations lead to additional local distortions (see Fig.7 *b*).[122] Because of this, the Mössbauer spectrum of $Ba_6Mn_{24}O_{48}$ is best described using the model of continuous distribution of the electric field gradient; the distribution curve exhibits two broadened peaks whose positions correspond to the quadrupole splittings of the ^{57}Fe probe atoms that replace the manganese atoms in the double and single columns. Thus, parameters of spectral components of the Mössbauer spectra are strongly dependent on distortions of polyhedra in the starting structure and are governed by the fashion in which the polyhedra are connected and by the cation distributions within the framework cavities.

Unique information, which can be obtained by analysing the Mössbauer spectra, also concerns some features of the magnetic ordering in these systems. Most of Mössbauer spectroscopy studies of manganites were carried out using $R_{1-x}A_xMnO_3$ phases. The main goal was to investigate their magnetotransport properties as a function of the Mn^{3+}/Mn^{4+} ratio which varied by changing the type and amount of the divalent cation inserted into the perovskite structure.[129–133] Because manganese and iron have similar ionic radii, replacement of Mn^{3+}/Mn^{4+} by Fe^{3+} in the CMR manganites leaves the unit cell parameters almost unchanged but affects the Mn–O–Mn angle, which in turn influences the exchange interaction. Nevertheless, by doping with iron one can obtain information on the localised spin moment in the magnetic ordering region. Establishment of the role of structural distortions in the temperature-induced variations of the magnetotransport properties is also of great importance;[129, 130] therefore, Mössbauer spectroscopy studies allow one to obtain valuable information on specific features of the physical properties of manganites.

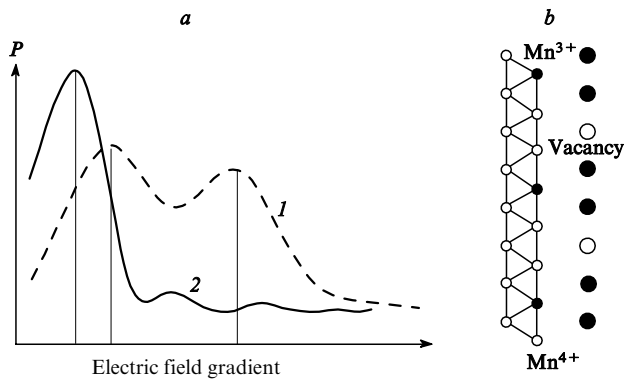

Figure 7. Mössbauer spectra of $Ba_6Mn_{23.76}{}^{57}Fe_{0.24}O_{48}$ (*1*) and $CaMn_{6.86}{}^{57}Fe_{0.14}O_7$ (*2*) samples processed using a model of continuous distribution of electric field gradient (*a*) and a scheme of local changes in the oxidation state of manganese in the case of incomplete filling of tunnels by barium ions (*b*).

IV. Chemical properties and phase diagrams

Difficulties in fabrication of manganite and especially HTSC materials are associated with complex chemical compositions and structures of these compounds (in some cases this is responsible for their thermal and chemical instability). Phase relations in the cuprate and manganite systems depend, in particular, on the size of the cations present in the framework formed by the manganese–oxygen or copper–oxygen polyhedra and on the existence of solid solutions with heterovalent substitution (Figs 8–10).

The $CaMn_2O_4-MnO_x$ polythermal section of the system Ca–Mn–O is characterised by the presence of a large number of phases with different $CaO:MnO_x$ ratios (1:2, 1:3, 1:7 and 1:8; adapted using the data taken from Ref. 134). It was shown [135] that the phase relations in the $BaO-MnO_x$ system are strongly different from those found in the $CaO-MnO_x$ system and the existence regions of compound $Ba_6Mn_{24}O_{48}$ and hollandite $Ba_{2-x}Mn_8O_{16}$ were also determined (see Fig. 8). Thus, changes in the ionic radii of alkaline-earth metal cations (Ca^{2+} or Ba^{2+}) lead to significant changes in the phase relations.

A scheme of phase relations for the polythermal section $CaMn_7O_{12}-CaCu_3Mn_4O_{12}$ of the system Ca–Mn–Cu–O is shown in Fig. 9.[20] The solid solution $CaCu_xMn_{7-x}O_{12}$ with a different degree of substitution ($0 \leqslant x \leqslant 1.5$) is formed in the temperature interval $750 \leqslant T \leqslant 1060$ °C. The highest degree of substitution ($x = 1.5$) is achieved at ~850 °C, whereas the $CaCuMn_6O_{12}$ phase ($x = 1$) exists in a broad temperature range from 750 to 1000 °C. At ~1060 °C, the complex oxide $CaMn_7O_{12}$ decomposes into marokite $CaMn_2O_4$ and hausmannite Mn_3O_4. At 750–1050 °C, the $CaCu_xMn_{7-x}O_{12}$ solid solution with the maximum degree of substitution is in equilibrium with $CuMn_2O_4$ and CuO.

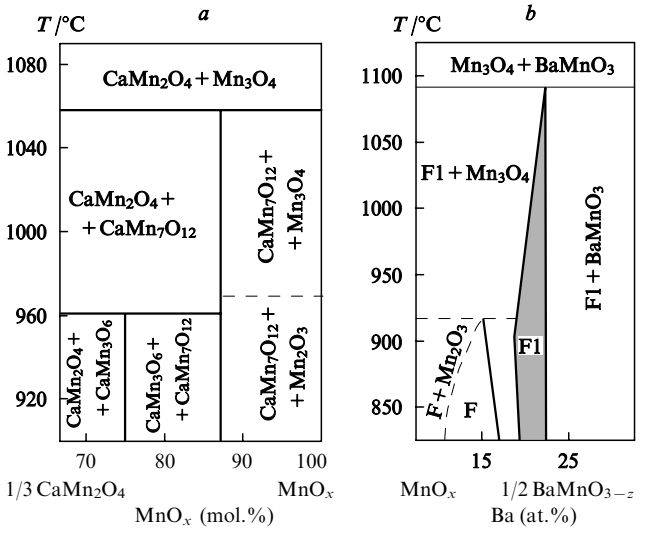

Figure 8. Polythermal section $CaMn_2O_4-MnO_x$ (*a*) and a scheme of phase relations in the system Ba–Mn–O (*b*).
$p_{O_2} = 1$ (*a*) and 0.21 atm (*b*).

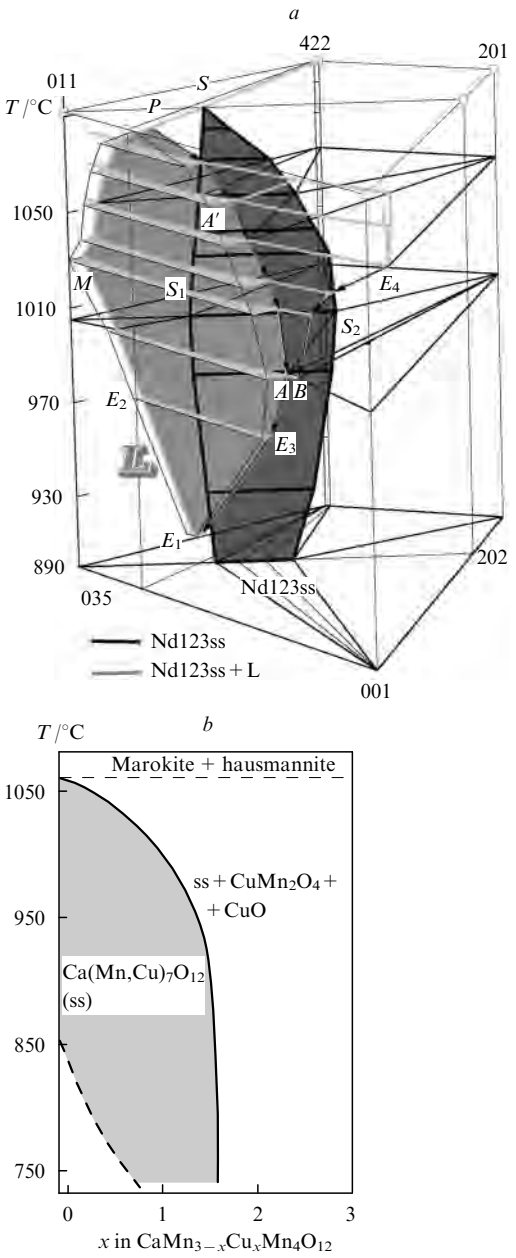

Figure 9. Three-dimensional model for phase relations in the $NdO_{1.5}$–BaO–CuO_x system at $p_{O_2} = 0.21$ atm (*a*) and a scheme of $CaMn_7O_{12}$–$CaCu_3Mn_4O_{12}$ polythermal section at $p_{O_2} = 1$ atm (*b*). The region of the $Nd_{1+x}Ba_{2-x}Cu_3O_z$ solid solution (S_1SS_2 is the high-temperature bound of the stability region) is shown by dark grey and the fraction of the liquid surface, which is in equilibrium with the solid solution phase ($E_1E_2MPA'AE_3$), is shown in light grey. Connodes for the two-phase region (solid solution – melt) are not shown. A and B are the points of peritectic decomposition of the limiting solid solution (Nd123ss + Nd_2CuO_4 + L) and the Nd_2CuO_4–CuO–(BaO) eutectic, the point A′ corresponds to passage from the equilibrium Nd123ss + 201 + L to the equilibrium Nd123ss + 422 + L; E_1, E_4 are eutectics in the binary systems $BaCuO_2$–CuO and Nd_2CuO_4–CuO, respectively.

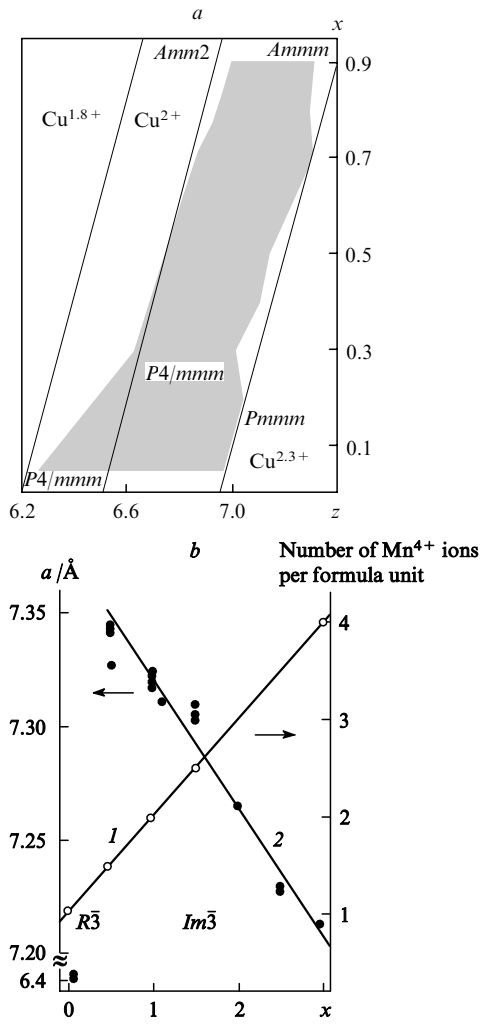

Figure 10. Average oxidation states of copper as functions of the cation and anion compositions of the $Nd_{1+x}Ba_{2-x}Cu_3O_z$ solid solution (*a*); dependences of the average oxidation state of manganese in the $CaCu_xMn_{7-x}O_{12}$ solid solution upon replacement of Mn^{3+} by Cu^{2+} (*1*) and of the lattice parameter (*2*) on *x* (*b*). The region of existence of the solid solution within its cationic and anionic composition ranges is shown in grey. Shown are the space groups of symmetry of the phases.

Phase relations in the supersolidus regions of the systems containing transition elements can be illustrated [4, 5, 136] taking the family of HTSC cuprates $RBa_2Cu_3O_z$ as an example (see Fig. 9). When considering the systems R_2O_3–BaO–CuO_n–O_2, the following deserves particular attention: the partial pressure of oxygen (especially in the coexistence regions of the solid and liquid phases) [137, 138] and the possibility of formation of substitutional solid solutions in which barium atoms are replaced by REE atoms due to rather large ionic radii of the early REE (La, Pr, Nd, Sm, Eu, Gd). For instance, the existence region of the solid solution $Nd_{1+x}Ba_{2-x}Cu_3O_z$ has a 'classical shape' and the limiting phases of compositions 123 and 213, $-0.1 < x < 1.0$ (see Fig. 9 *a*), are characterised by peritectic melting and a maximum decomposition temperature [5, 136] achieved at $x \approx 0.1$. Equilibria with the liquid phase in the solid solution – melt region and reasons for changes in the types of secondary phases ($Nd_4Ba_2Cu_2O_{10}$ and Nd_2CuO_4) formed in the course of peritectic decomposition have been studied in detail. [4, 136–140]

A good example of thoroughly studied materials with a broad region of cation and anion homogeneity is provided by HTSC cuprates (see Fig. 10 *a*). The existence region of solid solutions can be divided into three regions. [4, 136, 137, 141] Compounds with $0 < x < 0.3$ have tetragonal unit cells after quenching and orthorhombic unit cells after oxygenation, the unit cell constants *a* and $c/3$ ($a < c/3$) monotonically decrease as Ba^{2+} ions are replaced by ions with smaller radius (Nd^{3+}). At $0.3 < x < 0.6$, the unit cell is always tetragonal irrespective of the oxygen content ($a \approx c/3$). At $0.6 < x < 0.9$, the phase has an orthorhombic unit cell due to superstructural ordering of neodymium and barium ions. Interrelation between the cation and anion ordering was confirmed by the T–x–z-diagrams. [137] The range of the average oxidation

states of copper in the solid solution varies in accord with the concentration phase transitions; the lower the degree of substitution, the broader the range (see Fig. 10 *a*).

In the $Ca(Mn,Cu)_7O_{12}$ solid solution an increase in the degree of substitution of copper(II) for manganese(III) causes a reduction of the upper bound of the stability region of the solid solution from 1060 to ~950 °C (see Fig. 9 *b*) due to an increase[20] in the Mn^{4+} content (see Fig. 10 *b*). The lattice constant of the cubic solid solution (space group $Im\bar{3}$) decreases obeying the Vegard law (see Fig. 10 *b*). This is consistent with the heterovalent substitution of Mn^{3+} ions for Cu^{2+} ions, which causes an increase in the Mn^{4+} content in the phase and, hence, a decrease in size and in degree of distortion of the manganese–oxygen framework. Thus, the oxidation states of copper and manganese play the key role in stabilities of cuprate and manganite phases.

V. Single crystals

Construction of phase diagrams is an important stage in experimental studies of the growth of single crystals. Cuprate and manganite single crystals with preset chemical homogeneity, size, shape, concentrations of defects and impurities (Figs 11 and 12) are necessary for both basic and applied research and, in particular, for studies on crystallisation mechanisms of multicomponent melts. The advantage of these single crystals is the possibility of investigating the anisotropy of properties on different crystal faces. This is widely used in structural analysis, spectroscopy, oxygen diffusion studies, atomic force microscopy, in the determination of fundamental physical constants,[4] *etc*.

Single crystals of HTSC materials were obtained using almost all known melt growth techniques modified to allow for specific features of HTSC:[4, 138, 142–147] spontaneous crystallisation from solution in melt, Bridgman method, zone melting and the Kyropulos and Czochralski methods (see Fig. 11). Distinctive features of most of them are multicomponent composition of crystallising systems and a variety of interfacial interactions.[4] The mechanisms of crystallisation and growth of faces of HTSC crystals in different crystallographic directions seem not to be specific to the systems in question, being also different for each method mentioned above. The most commonly encountered growth mechanisms are the Frank–Kabrer mechanism and layer-by-layer growth.[4]

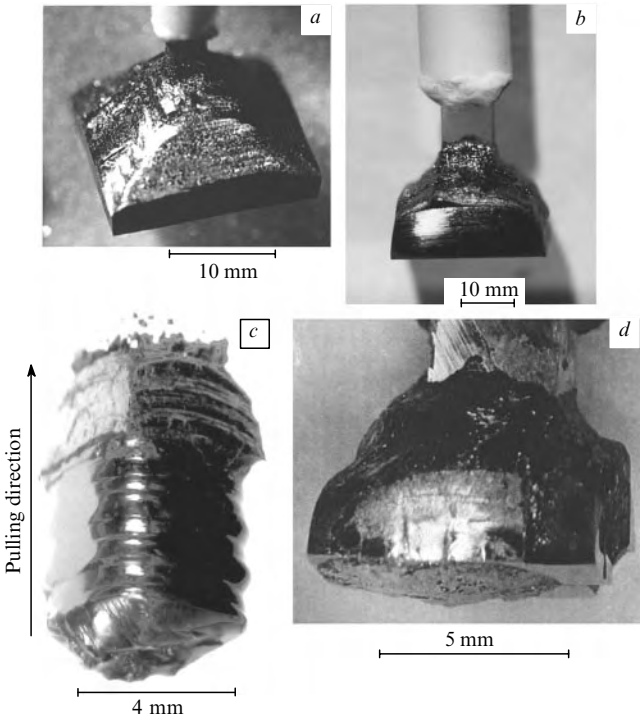

Figure 11. Photographs of the crystals of mixed REE–barium cuprates of different compositions grown using the modified Czochralski method (courtesy of Prof. Y Shiohara, SRL ISTEC, Japan).[142–145] One of the largest superconducting $NdBa_2Cu_3O_7$ crystals (*a*); large superconducting $YBa_2Cu_3O_7$ crystal grown using the modified Czochralski method (*b*); a cylindrical crystal of the superconducting phase $YBa_2Cu_3O_7$ grown in an automated growth setup (*c*); and a $Nd_{1.85}Ba_{1.15}Cu_3O_7$ crystal possessing a semiconductor-type temperature dependence of resistance (*d*).

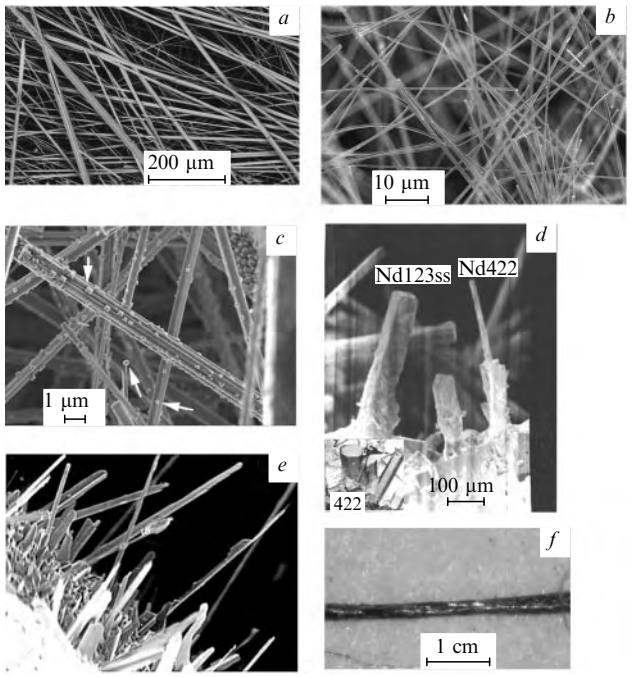

Figure 12. Micrographs of cuprate and manganite whiskers.
Hollow hollandite whiskers ($Ba_{2-x}Mn_8O_{16}$) obtained by isothermal evaporation of chloride fluxes (*a*); $Ba_6Mn_{24}O_{48}$ whiskers with a tunnel structure oriented along the growth direction, obtained by isothermal evaporation of KCl (*b*); the same crystals after storage in molten $LiNO_3$ at 300 °C (ion exchange causes replacement of barium in the channels by lithium; the arrows show octahedral spinel Li_2MnO_4 crystals oriented along the etching pits of the whiskers) (*c*); high-temperature superconducting $Nd_{1+x}Ba_{2-x}Cu_3O_z$ and $Nd_4Ba_2Cu_2O_{10}$ whiskers formed in the polythermal regime; superconducting $Bi_2Sr_2CaCu_2O_8$ whiskers (*e*) and a wire prepared by pulling of the glue mass containing $Ba_6Mn_{24}O_{48}$ filaments (*f*).

Anisotropy of the rate of growth of mixed REE–barium superconducting cuprates along the main crystallographic directions depends on the REE type and on crystallisation conditions in a very complicated manner.[4] This can be due to the crystallographic anisotropy, different energies of crystal faces and different growth mechanisms; the anisotropy of growth also causes changes in the face morphology and crystal habit (see Fig. 11). For instance, crystals grown by spontaneous crystallisation usually have a shape of thin plates with the smallest thickness along the ⟨001⟩ direction, because at high cooling rates ('kinetic control') the growth rate of the {100} faces is nearly five times higher than the growth rate of the {001} faces. A decrease in the melt cooling rate down to 0.5–1.0 deg h^{-1} causes the formation of thick prisms-parallelepipeds and even isometric crystals. Under these conditions not only the {100}, {010} and {001} faces but also the {101}, {011} and {111} faces grow, *i.e*., the crystal grows under thermodynamic control.

The method of top-seeded crystal pulling from a supercooled melt is characterised by rather low supersaturations; here, an important role is played by the hydrodynamic conditions and the temperature and concentration distributions near the growing crystal.[142, 143] By controlling the pulling rates and growth aniso-

tropy it is possible to grow various 'bulk' single crystals including pyramidal crystals with extending base, large isometric crystals with small edge angularity, pyramidal crystals with 'concave' low face and cylindrical crystals (see Fig. 11). Other crystallisation techniques allow growth of single crystals in the form of needles, plates and parallelepipeds.[4,5]

Considerable advances have been made in the field of single-crystal growth due to the development of a method of continuous growth of mixed REE–barium cuprate crystals,[142] in which the growing single crystal is fed under steady-state conditions owing to separation of the crystal growth zone ($T < T_p$) and the Y_2BaCuO_5 dissolution zone ($T > T_p$, T_p is the peritectic temperature) by a melt layer. In the presence of a temperature gradient (~ 3 deg cm^{-1}), diffusion and convective transport of yttrium-saturated melt occurs across this layer. To prevent the crystal contamination with the crucible material, crucibles made of yttria (generally, an REE oxide) are often used. Growth of Nd123 single crystals by the modified Czochralski method is performed in the presence of small temperature gradient.[143,144] Because of much higher solubility of neodymium oxide in the melt here we deal with isothermal crystal growth from supercooled melt in a crucible made of neodymium oxide. The modified Czochralski method is versatile and allows one to grow single crystals of almost all R123 (R = Y, Nd, Sm, Pr) phases and $(R^1R^2)Ba_2Cu_3O_z$ (R^1 = Y, R^2 = Sm, Nd), $Nd_{1+x}Ba_{2-x}Cu_3O_z$, $Pr_{1+x}Ba_{2-x}Cu_3O_z$, $Nd_{1+x}Ba_{2-x}Cu_{3-y}Ga_yO_z$, $YBa_2Cu_{3-y}Zn_yO_z$, *etc.*, solid solutions.[4,143] Using the floating zone technique, superconducting Pr123 crystals were obtained at reduced partial pressure of oxygen.[148] Recently, considerable attention has been paid to the development of methods of preparation of single-crystalline HTSC 'whiskers' (see Fig. 12).[149–152] These crystals can possess unique electrophysical and mechanical properties.

Experimental difficulties in growing manganite single crystals are caused by high melting temperatures of these compounds (~ 2000 °C) and low solubility in conventional high-temperature solvents. In most cases this problem is solved using an IR heated floating zone technique[153] because it excludes the interaction between the crystal and the container material. To grow manganite crystals, it is necessary that the feed rod have the same density along the whole length and homogeneous composition. The feed rods are produced by hot pressing and sintering appropriate components at ~ 1100 °C. This allows one to avoid melt penetration into pores of the sample (due to the capillary effect) and to stabilise the melt composition in the growth zone. The seeds used are both dense polycrystalline samples and pre-oriented single crystals. For instance, $La_{1-x}A_xMnO_3$ (A = Sr, Ca; $x = 0-0.3$), $Nd_{0.7}Sr_{0.3}MnO_3$, $La_{0.5}Ca_{0.5}MnO_3$ and $Nd_{1-x}(Sr,Pb)_xMnO_3$ rods (crystals) nearly 5 mm in diameter are usually grown at a growth zone rate of 5 to 7 mm h^{-1}. The floating zone method is also efficient for growth of single crystals of the Ruddlesden–Popper phases[154] possessing highly anisotropic properties due to their structural features. At the same time this technique is unsuitable for the synthesis of manganites $R_{1-x}A_xMnO_3$ (A is an alkali metal) owing to high volatility of A_2O oxides and of thermally unstable phases related to pyrolusite MnO_2 and hollandite.

Using traditional spontaneous crystallisation technique, it is possible to grow alkaline-earth manganite crystals. For instance, isotropic $Ln_{1-x-y}Sr_xPb_yMnO_3$ (Ln = La, Pr, Nd) crystals with a volume of up to 3 cm^3 are obtained using Bi_2O_3, PbF_2 and PbO as fluxes. $Sr_4Mn_3O_{10}$ crystals were flux grown with $SrCl_2 + SrF_2$.[155] An alternative to spontaneous crystallisation is electrolysis of manganite solutions in a molten mixture of Cs_2MoO_4 and MoO_3 using platinum electrodes in crucibles made of stabilised zirconia.[156] This technique was employed to obtain plate-like, strontium-doped lanthanum manganite crystals with a surface area of 0.25 to 4 mm^2. The temperature of the process was reduced to 1000 °C (alkali metal doped manganite crystals grow at 980–1000 °C).

Often, crystals of metastable or thermally unstable phases, *e.g.*, $BaMnO_3$, $BaMn_2O_3(OH)_2$ and $BaMn_3O_3OH$ are grown using the hydrothermal method.[112,157] This permits preparation of manganites with tunnel structures (pyrolusite, ramsdelite, hollandite and todorokite, see Fig. 2) starting from a layered manganite with the structure of sodium-containing birnessite treated with LiCl, KCl, $MgCl_2$ or $BaCl_2$ solutions; the size and shape of tunnels in the structure depend on the type of the cation inserted.[12]

MnO_2 and Mn_3O_4 nanowires were grown using hydrothermal method or microemulsions.[158,159] A simple method called isothermal evaporation of chloride fluxes was developed[135] to obtain filaments of potentially one-dimensional superionic conductors $BaMn_8O_{16}$ and $Ba_6Mn_{24}O_{48}$ with tunnel structures (see Fig. 12). The method not only provides a means of transportation of the components required for crystal growth by the 'vapour–liquid–crystal' mechanism but also allows an important problem of selection of the crystals obtained from solvent (flux) to be solved. The optimum temperature for growth of $Ba_6Mn_{24}O_{48}$ crystals from KCl is 950 °C. At $T < 900$ °C, an impurity of hollandite whiskers was always observed, while at $T > 950$ °C, hausmannite was formed, which is consistent with the phase diagram (see Fig. 8 *b*). Within the limits of experimental error for local X-ray spectroscopic analysis the crystals obtained were chemically homogeneous along the length and contained less than 1 at.%–2 at.% of flux components (K, Cl). These phases with anisotropic unit cells were also observed in the form of (i) 'pseudo-single-crystalline' whiskers with small-angle boundaries, (ii) hollow needles, (iii) dendrites and (iv) 'bundles' (see Figs 12 *a–c*). The $Ba_6Mn_{24}O_{48}$ whiskers were 1 to 5 μm thick, the hollandite whiskers were somewhat thicker ($\sim 20-50$ μm).

VI. Microstructure and new methods of preparation of ceramic composites

Methods of fabrication of polycrystalline materials with improved functional properties are based on the concept of a real structure characterised by a number of hierarchic levels of organisation.[5] As shown above, the fundamental properties of compounds are determined by the crystal structure and its local distortions. Individual crystallites comprised of certain units separated by extended defects form the mesoscopic level of structural organisation. The macroscopic level is formed by ensembles of crystallites and pores.

Superconducting phases with controllable superconducting transition temperature can be synthesised in a different manner.[5] At the same time improvement of such important characteristics of superconducting materials as the critical current density, J_c, and its stability in high magnetic fields faces reasonable difficulties. The superconducting transition temperatures of HTSC ceramics much exceed those of metallic superconductors while the coherence length of ceramics (0.2 nm) is an order of magnitude smaller than that of intermetallides. The thickness of grain boundaries in polycrystalline HTSC ceramics is greater than the coherence length; therefore, the magnitude of current flowing along the ceramic samples is strongly dependent on the intergrain contacts. In addition, layered crystal structures of almost all high-temperature superconductors cause their physical properties to be highly anisotropic; this requires texturing of polycrystalline materials. High-temperature superconductors are type II superconductors; therefore, under some conditions the external magnetic field can penetrate into the bulk of a sample in the form of Abrikosov vortices trapped in non-superconducting inclusions (pinning centres).[5,160] To achieve high critical current densities (greater than 10^5 A cm^{-2}) and stabilise them in the magnetic fields of 1 to 10 T, one should create efficient pinning centres, which is a practically important problem in the materials science of HTSC.

The magnetoresistance, as the phenomenon of relative change of electrical resistance in an external magnetic field, has long been known.[9–11] Intrinsic magnetoresistive effects are due to the properties of a particular compound; the tunnelling magnetoresistive effects are related to the specific features of interfaces and

various natural or artificial inhomogeneities. A commonly accepted model for the mechanism of intrinsic magnetoresistance involves the concept of double exchange first proposed by Ziner,[161] which has been successfully used to explain the magnetoresistance effect in $R_{1-x}A_xMnO_3$ solid solutions. The experimentally observed magnetoresistance is also explained by the influence of additional factors, in particular, the electron–phonon interaction and dynamic Jahn–Teller effect for Mn^{3+} (see Ref. 162). A model by Millis, Littlewood and Shraiman [163] includes local rearrangement of the crystal lattice, because hopping of charge carriers between the lattice sites occupied by the manganese ions produces a charge fluctuation and the charge carrier in the crystal becomes a charged magnetoelastic polaron.

The model of double exchange is inapplicable to pyrochlore-type manganites and cupromanganites [16–19, 114] because of the absence of the Mn^{3+} ions or large deviation of the Mn–O–Mn angle from 180°. In this connection alternative models for description of the CMR phenomemon have been developed. These are, *e.g.*, the magnetic impurity theory [164] and a model based on the concept of one-electron σ-bonding between the manganese and oxygen ions due to high covalency of the manganese–oxygen bond, which leads to the formation of a strongly correlated electronic state.[165]

The intrinsic magnetoresistance of polycrystalline materials is only a part of the total magnetoresistance. Indeed, in most of these materials the magnetoresistance effect manifests itself in wide temperature and magnetic field ranges rather than near the Curie point in high magnetic fields. In this connection the existence of the tunnelling magnetoresistance was hypothesised.

Peculiarities of the microstructural organisation of polycrystalline materials (see above) make traditional methods of solid-phase synthesis of cuprates and manganites inefficient for fabrication of materials with good operating characteristics. Hence, it was reasonable to elaborate new methods of synthesis of cuprates and manganites, *e.g.*, techniques involving mechanically activated reactants [166] and melt technologies [5, 160] permitting an integrated treatment of the real structure of a material.

A method of fabrication of $RBa_2Cu_3O_z$-based superconducting materials (Fig. 13) at record low temperatures (500–600 °C) during unique short reaction times (10–30 min) was proposed.[166, 167] The starting reactants were [166] copper(I) oxide obtained using 'soft' chemistry methods and a mixed oxide '$YBa_2O_{3.5}$' (containing BaO_2). Both compounds were mechanically activated in a ball mill and then 'warm' pressed at 250 °C. A feature of the technique is the use of oxides as reactants which react without liberation of gaseous products that could break the intergrain contacts in the reaction mixture. In addition, the mixed REE–barium oxide is a source of the yttrium and barium ions with low diffusion mobilities, whereas the copper(I) oxide is a source of the copper ions characterised by higher diffusion coefficients. Different reactants contain different cations; this provides high chemical potential gradients of the components, unambiguous direction of the diffusion processes in the system and, by and large, a high driving force of the formation of a superconductor. Pilot experiments were carried out on fabrication of superconducting aluminum-sheathed tapes with an oxide wire which becomes a superconductor ($T_c \approx 45–85$ K) after low-temperature synthesis at 600 °C using a procedure of mechanical activation of 'two-powder' precursors proposed in Ref. 166.

To prevent reduction of manganese to an oxidation state lower than +3 in the synthesis of a family of manganites, high oxygen pressure is required. For instance, phases in the system Ca–Mn–Cu–O are usually synthesised under oxygen pressures of 0.18–50 000 atm in sealed quartz ampoules or autoclaves.[16–18] The use of mechanically activated reactants, which is similar to that described above for the HTSC phases,[20] appeared to be efficient for the synthesis of cupromanganites. Clearly, pressing of mechanically activated powders at elevated temperatures (250–400 °C) to a great extent promotes a subsequent solid-phase reaction and permits the obtaining of complex manganese oxides

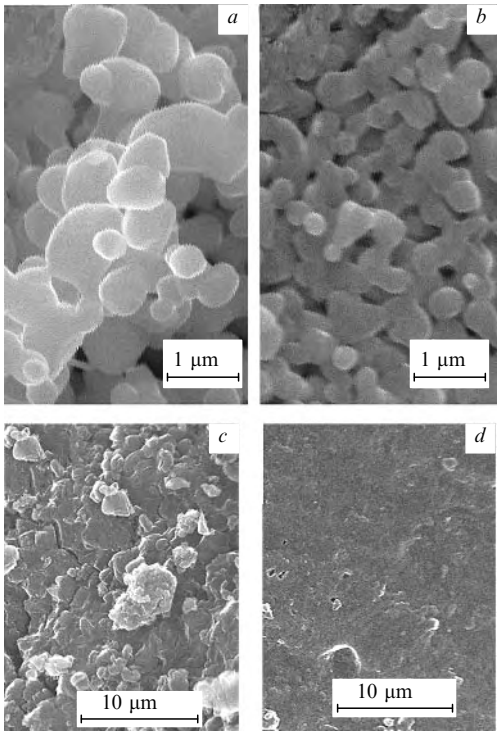

Figure 13. Changes in the morphologies of the ceramic samples of CMR manganites $CaCuMn_6O_{12}$ (*a*, *b*) and HTSC cuprates $YBa_2Cu_3O_z$ (*c*, *d*) obtained using mechanically activated reagents pressed at 250 °C. Duration of mechanical activation of the phases, min: 15 (*a*, *c*) (pressing under different loads), 120 (*b*) and 240 (*d*).

in the form of ceramics (see Figs 13 *a*,*b*) with improved magnetotransport properties at so low temperatures that Mn(IV) appears to be stable at a standard partial pressure of oxygen $p_{O_2} = 0.21–1$ atm.

Microstructural features have a strong effect on the transport properties of HTSC ceramics;[4, 5] this is also characteristic of manganites and cupromanganites. In spite of the fact that the CMR is intrinsic in mixed-valence manganites, a decrease in the grain size can make the role of the grain boundaries more important and favour charge transport due to the spin-polarised intergrain tunnelling. This can provide an explanation for 200% to 300% variation of the magnetoresistance of samples of the same composition $CaCuMn_6O_{12}$, which were synthesised under the same conditions but had different microstructures (Fig. 14).

Melt techniques have provided the best route to HTSC-materials.[4, 5] A feature of the melt-produced, coarse-grained HTSC ceramics is the presence of ensembles of pseudo-single-crystal domains of size 0.5 to 5 cm. Each domain is an aggregate of $RBa_2Cu_3O_z$ lamellae (5–50 nm), which are aligned and separated by small-angle boundaries through which electric current can flow. The microstructure of the melt textured HTSC ceramics is characterised by the presence of different types of extended defects such as twin boundaries, highly disperse inclusions of the non-superconducting phase, dislocations, microcracks and macrocracks.

Thus, melt-produced HTSC ceramics can be considered as a system possessing pronounced 'co-operative' superconducting properties due to specific crystallisation mechanisms. Pseudo-single-crystal domains form macroscopic aggregates capable of carrying heavy currents, because at the microstructural level they represent a system with pure superconducting boundaries and biaxially textured crystallites. High concentration of defects favours the formation of efficient pinning centres.

In addition to coarse-grained ceramics (Fig. 15 *a*) modern methods permit fabrication of HTSC-materials of complex

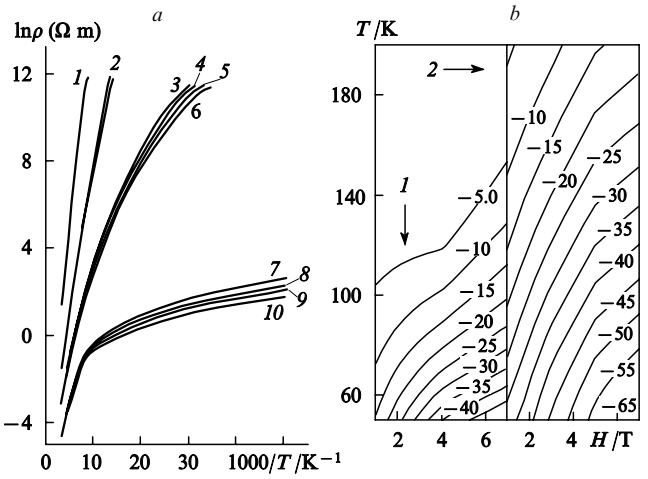

Figure 14. Magnetoresistive properties of the ceramic samples of $CaCu_xMn_{7-x}O_{12}$ solid solutions prepared using mechanically activated reactants (*a*) and the magnetoresistive effect in $CaCuMn_6O_{12}$ samples with different microstructures (*b*).
$x = 0$ (*1*), 0.5 (*2*), 1.0 (*3*–6), 1.5 (*7*–*10*); $T_c = 194$ (*1*–*6*) and 245 K (*7*–*10*); $H = 0$ (*3*, *7*), 1 (*4*, *8*), 3 (*5*, *9*) 5 T (*6*, *10*) (*a*); the microstructures of the samples *1* and *2* are shown in Figs 13 *a* and 13 *b*, respectively; figures in the isolines illustrate the magnetoresistive effect in % (*b*).

shape and(or) in the form of thick-film coatings (Figs 15 *b*–*e*).[168–174] These methods include saturation of a fabric obtained from yttria filaments or a ceramic 'foam' prepared using Y_2BaCuO_5 powder, organic binder and a polymer matrix with high-temperature cuprate melt.[168–173] On cooling of the Y_2BaCuO_5–melt system the non-superconducting REE oxides are transformed in the superconducting mixed REE–barium cuprate due to the reaction with the melt. Introduction of oriented seeds initiates directed crystallisation of the superconducting phase in the form of ceramics, fabric, foam, *etc.* (Figs 15 *b*,*c*). Studies on 'glueing' of individual geometrically matched blocks of dense coarse-grained ceramics into complex structures using mixed REE–barium cuprates, silver-containing and fluorine-containing fluxes with low melting temperatures (Fig. 15 *d*)[174] deserve particular attention. A unique method of directed crystallisation of mixed REE–barium cuprates on metallic substrates in artificially induced concentration gradient of the rare-earth elements was developed [175] (Fig. 15 *e*).

The use of the concentration gradients [175] is an efficient method of control of the crystallite orientations in thick films because of large local supersaturations (supercooling) produced in the system. The entire starting film can be in the form of a layer of a vapour deposited Y_2BaCuO_5 phase, which is then saturated with a melt. A seed strip of a polycrystalline $NdBa_2Cu_3O_z$ powder is arranged along the main layer. On the opposite side, an Yb_2BaCuO_5 strip is arranged to increase the concentration gradient and to preclude the formation of the HTSC phase in the adjacent region.

Cooling of the system after saturation with the melt is accompanied by nucleation of crystallites of the HTSC phase near the seed strip. Similarly to seeds, the HTSC crystallites have arbitrary initial orientations and growth directions. The direction in which crystals grow at the highest rate 'survives', *i.e.*, geometrical selection of crystallites occurs. As a result, the spatial evolution of the whole ensemble of crystallites beyond the transient zone of certain length occurs concertedly along the same direction. Experimental confirmation (see Fig. 15 *e*) of the efficiency of thick film texturing using a concentration gradient opens up great prospects for the development of new technologies of fabrication of highly oriented layers of functional materials with anisotropic properties.

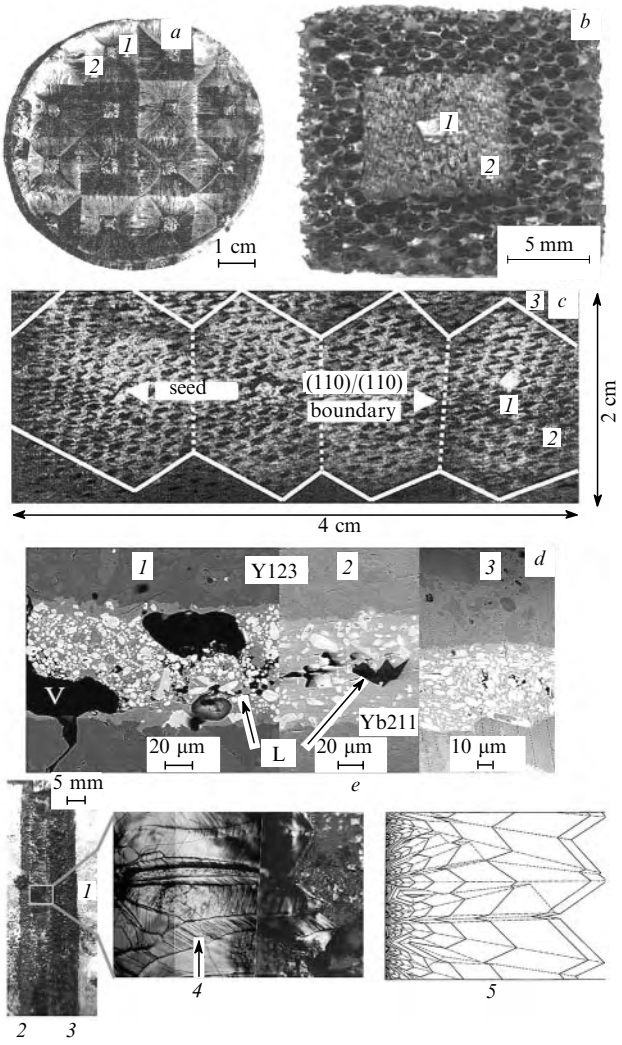

Figure 15. Coarse-grained superconducting samples of melt-solidified mixed REE–barium cuprates (courtesy of Prof. G Schmitz, ACCESS e.V., Germany).
(*a*) $YBa_2Cu_3O_z$ ceramics: mutually oriented $NdBa_2Cu_3O_z$ seed crystals (*1*) and pseudo-single-crystal blocks (*2*); (*b*) superconducting ceramic $YBa_2Cu_3O_z$ 'foam': $NdBa_2Cu_3O_z$ seed crystal (*1*) and pseudo-single-crystal domain (*2*); (*c*) HTSC-samples with a fabric structure obtained by infiltration technique using seeds (*1*), oriented domains (*2*) and a polycrystalline domain (*3*); (*d*) joining of pseudo-single-crystal superconducting mixed REE–barium cuprates using low-melting ytterbium–barium cuprates: polished surfaces of $YBa_2Cu_3O_z$ blocks (*1*); the same with an external pressure of 20 kPa applied (*2*); the same with PtO_2 added to reduce the size of crystallites of the secondary phases (V are structural voids and L is the liquid phase) (*3*); (*e*) spontaneous directed crystallisation in the presence of concentration gradient: substrate (silver–palladium alloy) (*1*); a seed strip of polycrystalline $NdBa_2Cu_3O_z$ with high temperature of peritectic melting, obtained by screen printing (*2*) and an $YbBa_2Cu_3O_z$ or Yb_2BaCuO_5 strip to induce the concentration gradient of the rare-earth element. The rectangle indicates a region of the Y_2BaCuO_5 layer impregnated with the cuprate melt in which crystallites of the superconducting $(Y,Nd,Yb)Ba_2Cu_3O_z$ solution grow on cooling (*3*), general view of superconducting crystallites at higher magnification (*4*) and graphic reconstruction of the grain selection process (*5*).

VII. Geometrical control of mutual orientation of crystallites (graphotexturing)

Modern functional materials (superconductors, piezoelectrics, giant-magnetoresistance materials, *etc.*) are usually characterised by high crystallographic anisotropy of physical properties. Therefore, the desired operating characteristics of a layer can be in some

cases improved by several orders of magnitude due to biaxial texturing. A good example of the texturing effect is provided by mixed REE – barium cuprates, for which an in-plane misorientation of only 5 – 10° can cause a decrease in the density of the intergrain transport current by 10 to 100 times. Texturing of modern functional materials is related to various aspects of crystal growth in complex oxide systems. New methods of preparation of textured HTSC-coatings [176 – 178] include, in particular, the use of artificial relief of the surface of a substrate (graphotexturing, Figs 16 – 19).

At present, of particular interest is fabrication of highly textured coatings on long-length substrates or surfaces of complex shape. This problem has been inufficiently studied because of numerous technical difficulties. Most well-studied methods of deposition of textured thin films involve epitaxy.[5] High absolute values of functional parameters can also be achieved using bulk ceramic materials, which are textured using the temperature, magnetic field or electric field gradients.[4, 5] However, in these cases the specific characteristics of materials are much worse than those of the films due to imperfect texture and the presence of various macroscopic defects. A drawback of epitaxy or gradient crystallisation is that they do not allow fabrication of samples of complex shape due to a complicated procedure for preparation of substrates, which must meet severe requirements (in the case of thin films), and to brittleness of ceramics and difficulties in mechanical treatment of this material (bulk samples).

In this situation a reasonable compromise is to use thick films. To attain high specific and absolute values of the functional parameters of thick films, one should follow a hybrid approach, *i.e.*, the orientation effect of substrate (*cf.* thin films) and melt growth of large grains (*cf.* bulk materials). Unfortunately, the 'molecular' nature of epitaxy makes it efficient only for films less than 1 μm thick while conventional methods of preparation of thick films cannot be used for complete biaxial texturing.[179] In the case of thick films the orientation effect of the substrate must be based on other principles (Fig. 19). Melt crystallisation should also be modified to retain the continuity and shape of the initial layer, which undergoes melting and crystallisation, and to minimise the chemical interaction between the film and substrates.

The appearance of a film texture is a result of two main processes, *viz.*, superficial nucleation characterised by certain arrangement and orientation of seeds owing to short-range molecular fields (saturation of 'uncompensated surface bonds') and/or the motion and mutual adjustment of the 'building blocks' from the nutrient medium due to, *e.g.*, external fields and forces (see Fig. 19). As a consequence, there are two film texturing methods.

The first approach is practically implemented in the form of gas-phase or liquid-phase heteroepitaxy on single-crystalline or biaxially textured substrates. This technique is most widely used for preparation of thin films of new functional materials and heterostructures.[4, 5] However, it has significant drawbacks such as a complicated film deposition procedure, poor scaling, low performance, high cost of the deposition procedure and substrates, low deposition rate and impossibility of film deposition on two-sided items of complex shape. These drawbacks are typical of even the most recently developed methods, such as the Ion Beam Assisted Deposition (IBAD), Rolling Assisted Biaxially Textured Substrate (RABiTS) and Inclined Substrate Deposition (ISD) techniques.[180]

The second approach is independent of the substrate nature and, similarly to texturing of ceramics, does not use external factors such as thermal or magnetic field gradients and single seeds or multiseeds (see Fig. 19). Because of this, it imposes virtually no limitation on the film thickness. Usually, practical implementation of this approach requires a condensed medium, *e.g.*, a melt or a solution, to provide high thick film growth rates. The scaling problem can be solved using the principles of self-organisation or self-assembly of polycrystalline layers of multicomponent functional materials, which permit simultaneous mutual correlated

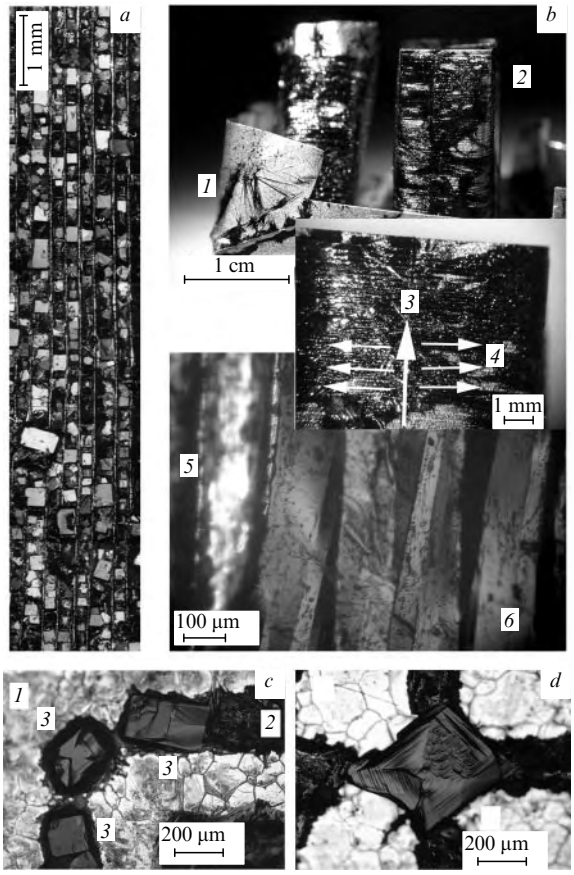

Figure 16. Micrographs of graphotextured HTSC phases.
(*a*) Biaxial texturing of polycrystalline yttrium – barium cuprate layer owing to the use of symmetrical surface relief: nearly 75% of 220 crystallites are oriented with respect to periodic striped relief (and to one another) due to nucleation near the relief elements;
(*b*) biaxially textured HTSC $Bi_2Sr_2CaCu_2O_8$ samples fabricated using silver tapes with artificial surface relief: a silver bath containing a peritectic melt of the HTSC phase (*1*), a cylinder coated with a textured HTSC layer (*2*), vertical grooves that help the melt to move upwards across the surface of the sample due to the action of capillary forces (*3*), horizontal grooves to provide (i) spillover of the melt across the surface and (ii) mutual orientation of the HTSC grains during crystallisation (*4*), a groove (*5*), ensemble of oriented crystallites (*6*);
(*c*) screen printing on silver substrate (*1*) with necessary surface structure (*2*) using an Y_2BaCuO_5 suspension followed by melt infiltration. Yttrium – barium cuprate crystallites formed on cooling (*3*) reproduce the pattern of the elements of the initial surface relief;
(*d*) surface relief (rectangular grid), which favours spontaneous formation of ⟨110⟩-oriented crystallites of mixed REE – barium cuprates (*4*).

growth on all portions of the ribbon surface. At present, these ideas are also used in nanotechnology, namely, self-assembling of monolayers causing a spontaneous formation of complex structures from the necessary building blocks; the phenomenon involves different-level energy interactions and imposition of limitations upon certain degrees of freedom of the system.[179] Research in the field of semiconductor engineering is aimed at using 'orientation filters' of the growing grains to control their growth in the desired direction.[181]

Artificial epitaxy (graphoepitaxy) was proposed nearly four decades ago for organic crystals and a number of semiconductors.[182] The method is based on the orientation effect of a microrelief created on the surface of a substrate. The relief is characterised by a certain symmetry and a period that can be several orders of magnitude greater than the lattice constant of the material. Therefore, crystals can be 'forced' to adopt a necessary

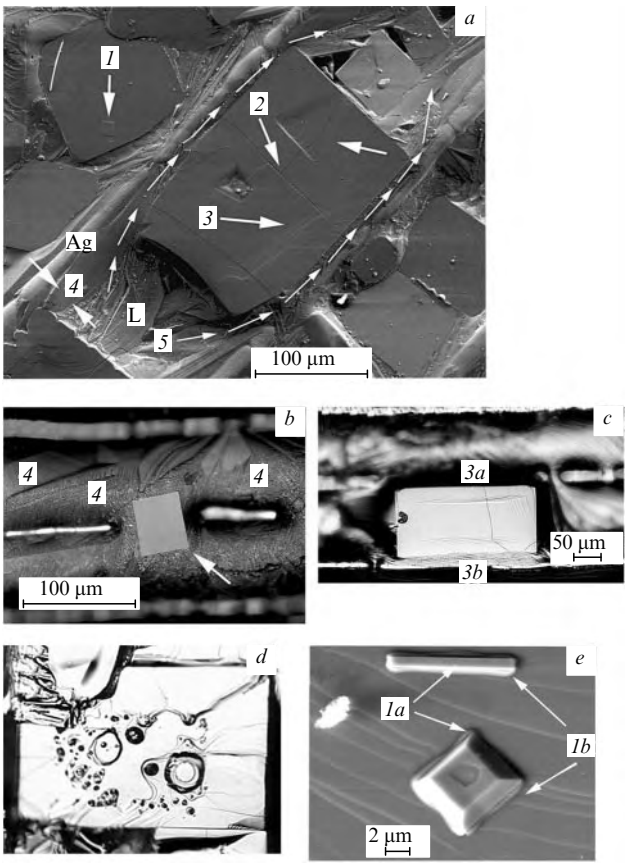

Figure 17. Micrographs of graphotextured mixed REE–barium cuprates.
Orientation of crystallites by the relief walls (*a*), a mobile crystallite solidified from melt in the early stage of growth (*b*), immobilisation of crystallite near the wall (*c*), face growth morphologies (*d*,*e*).
Notations: (*1*) barium cuprate on a crystallite face of mixed REE–barium cuprate, which interacts with growth steps (*1a*,*b*); (*2*) cracks; (*3*) (*3a*,*b*) growth steps moving from the periphery towards the centre in the case of capillary flow of the melt near the meniscus (*4*) between the relief walls and the crystallite [the direction of motion of the liquid phase, L, is shown by arrows (*5*)].

orientation by imposing necessary geometrical constraints on their growth. A few communications have been reported concerning the use of specific substrates, 'atomic' graphoepitaxy or application of photolithography for creation of the surface microrelief and influence of defects in the substrate on the morphology of HTSC films on polycrystalline silver.[183–185] Graphoepitaxy is efficient only for thin layers ($\sim$1 μm) and, correspondingly, only for small crystallites of size nearly 1 to 10 μm, whose orientation can be effectively controlled using methods of conventional thin-film epitaxy.

Optimisation of the deposition techniques and heat treatment regimes suitable for biaxial texturing of thick HTSC films has been the subject of recent studies.[176–178] It was established that the artificial relief must meet the following requirements: it must contain only those most efficient elements, which induce oriented growth of crystallites, and provide specified geometric constraints on the growth of crystallites in the case where the symmetry (habit) of crystallites matches the symmetry of artificial relief elements. Of great importance is also to provide conditions for nucleation near the elements of the artificial relief (otherwise, a reduced efficiency will be attained).

The artificial relief is a controllable parameter, which provides the possibility for crystallisation to occur in the desired direction. The microstructures of the samples (see Fig. 17) can be explained taking into account the effect of the artificial relief of the surface

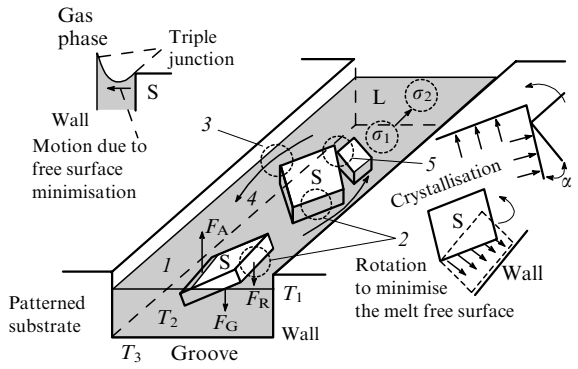

Figure 18. A model for orientation of growing crystallites.
T_1 is the temperature of the substrate surface contacting the gas phase and re-emitting heat, T_2 is the melt temperature inside the artificial relief elements (*1*), T_3 is the temperature in the bulk of the substrate, F_A is the Archimedian force, F_G is the gravity force, F_R is the surface tension force in the melt film (*2*) near crystallites (the resultant force stabilises small crystallites on the melt surface and drives them horizontally), meniscus (*3*), interacting crystallites (crystallisation pressure or a change in the meniscus shape) (*4*, *5*); σ is the surface tension depending on the component concentrations (Marangoni effect).

on the elementary processes occurring in the system on crystallisation, *viz*., nucleation, face growth of individual crystallites and interactions in the ensemble of the growing crystallites.

Elements of an artificial relief, which provides imposition of 'favourable' constraints on the growth of crystallites, are in fact a kind of geometrical template. A static effect of the template disturbs isotropy of the crystallising system and, finally, leads to desired orientation of crystallites in the ensemble. Unfortunately, such a template is a necessary but not sufficient condition for the formation of biaxially textured layers.

Stochastic nucleation and chaotic growth of a large number of crystallites can be among undesired factors, which preclude the growth and(or) motion of those crystallites, which could be oriented due to the effect of the artificial relief. Correspondingly, the number of crystallites per element of the artificial relief depends on both the probability density of nucleation and the characteristic size of the artificial relief elements.

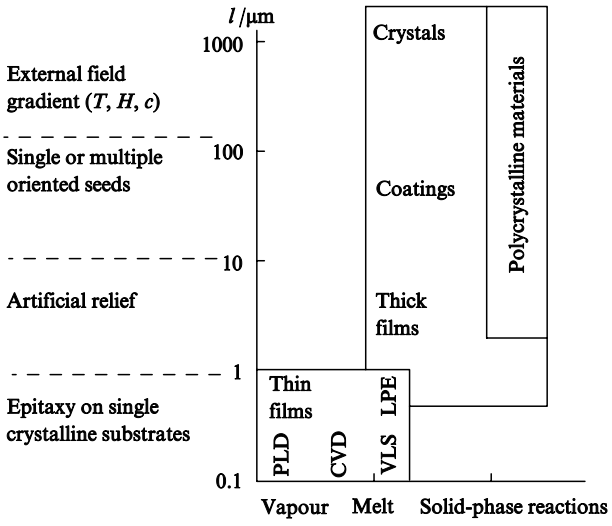

Figure 19. Main texturing techniques of polycrystalline HTSC-materials as functions of the thickness of the superconducting layer and deposition technique. Notations: PLD is Physical Layer Deposition, CVD is Chemical Vapour Deposition, VLS is Vapour Liquid Solid (mechanism) and LPE is Liquid Phase Epitaxy.

The most efficient orientation of HTSC-crystallites is attained using a simple striped relief (see Fig. 16).[176, 178] It provides (i) efficient geometric constraints on the crystal growth in the form of parallel walls of narrow grooves, (ii) a desired symmetry corresponding to the habits of the growing mixed REE–barium cuprate crystals and (iii) the density of the ensemble of crystallites, which is nearly independent of the cooling rate (because the crystallite size is limited to the groove width). At present, about 75% to 90% of the crystallites of sub-millimetre size can be readily and reproducibly aligned with a misorientation angle of less than 10° on substrates with artificial relief.

Artificial epitaxy does not use epitaxial relations for orientation of crystallites, because the technique is based on specific aspects of wetting, surface tension and meniscus, heterogeneous nucleation, redistribution of melt components, capillary effects, effects of crystallisation pressure and the topographic effect of the walls of relief elements, local temperature gradients,[176, 182] *etc*. (see Fig. 18). Clearly, high mobilities of the medium and particles in melt must provide a nearly instantaneous adjustment of orientations of the growing embryo-crystals floating on the melt surface, controlled by the relief elements, whereas the kinetics of the process depends on the adhesion, wetting of the crystallites and substrate and capillary forces and surface tension forces. The process under consideration can be practically implemented using various mechanical, electric and thermal effects that appear due to the creation of the artificial relief. The technique is convenient when using various materials and arbitrary substrates and can lead to nearly complete texturing of a polycrystalline layer in accord with the symmetry of the superficial pattern. Probably, the results reported in Refs 176–178 are among the first successful attempts to apply the method based on graphoepitaxy principles in texturing thick polycrystalline layers of complex, multicomponent systems.

VIII. Fields of practical applications of cuprates and manganites

The most promising field of practical application of the HTSC cuprates considered is design of materials for heavy-current engineering, in particular, fault current limiters (FCL). The material characteristics for an optimum FCL must be as follows:[172, 186] negligible resistance in the normal operating mode, sufficiently high resistance to limit the fault current, and high switching rate between the superconducting and resistive states. Additionally, as the fault currents are exceeded, a large amount of Joule heat releases after transition of the system to the resistive state. Therefore, the ability of the material to absorb the dissipated energy without damage should be considered as an extra necessary condition. This is possible in the case of, *e.g*., a good contact between the superconducting elements and the liquid cooling agent (this depends on the specific features of the cooling system and on the shape of the superconducting element). Respectively, high-temperature superconductors with a fabric structure having a well-developed system of regular pores (see Figs 15 *b*,*c*) to improve the contact with liquid nitrogen can be of considerable practical interest.¶

By creating a periodic and symmetrical artificial surface relief using ribbons made of commercial polycrystalline untextured silver as substrate it is possible to attain a nearly 90% mutual orientation of melt-grown HTSC crystallites in the *ab* plane.[176–178] These samples can be used as 'seed ribbons' and 'smart' seeds and for fabrication of items of complex shape. In the last-mentioned case (see Fig. 16 *b*) using a prototype device (artificially patterned HTSC coils) it was shown that the method including capillary 'suction' of melt, spillover of the melt across the surface and biaxial graphotexturing of the superconducting cuprate grains formed on cooling can be efficient in large-scale production of thick HTSC films on cheap metallic substrates in a uniform thermal field. It is possible to produce a batch of samples during one heat treatment cycle.

Growth of large superconducting crystals is mainly of academic interest to elaborate the crystal growth technique, to determine the growth mechanism and crystal parameters, *etc*. The fundamental physical characteristics can be successfully measured using small crystals. Owing to high cost and lower critical currents, the superconducting crystals can compete with neither coarse-grained ceramics used in heavy current devices nor thin films used as active elements in microelectronics.

At the same time neodymium–barium cuprate crystals with the limiting content of neodymium replacing the barium ions seem to be promising as substrate materials for fabrication of thin superconducting films. These crystals possess good dielectric properties and a small mismatch between their lattice parameters and those of the superconducting phases of other mixed REE–barium cuprates.[187] In this case, growth of large $Nd_{1.85}Ba_{1.15}Cu_3O_z$ crystals by the Czochralski method is worthwhile because the necessary surface area of polished substrates can reach a few square centimetres per device and large-scale production of this type of substrate can lead to considerable reduction of the high cost of devices for superconducting microelectronics.

This type of substrate offers some additional advantages such as chemical homogeneity (achieved using the modified Czochralski method), sufficiently high chemical stability (even in moist atmosphere), low degree of non-stoichiometry with respect to oxygen and orthorhombic unit cell. Morphology disturbance of the deposited HTSC-films at temperatures of *tetragonal–orthorhombic* transition can be prevented by oxygenation of the samples, because the anisotropy of the $R_2BaCu_3O_z$ lattice constants in the *ab* plane can act as an anisotropic strain field, which suppresses formation of twin defects in the superconducting film being deposited.

The $CaCu_xMn_{7-x}O_{12}$ solid solution can be considered as a candidate for the material to be used in magnetoresistive devices and spintronics.[188] The conductivity of $CaCu_xMn_{7-x}O_{12}$ (see Fig. 14) varies over a wide range depending on the x value and the magnetoresistance effect exhibits no pronounced thermal features. Ceramic samples synthesised from mechanically activated reactants showed the record (for this system) magnetoresistance effect of 65% at 35 K and 5 T.[20] Correspondingly, composites based on the CMR and HTSC-phases offer good prospects for practical application.[189]

Inorganic fibres provide a convenient means for fabrication of new types of materials in the form of, *e.g*., ion-conducting or catalytically active 'felts', multifilament wires or fabric (see Fig. 12 *e*). Tunnels in the structure of barium–manganese whiskers $Ba_6Mn_{24}O_{48}$ and the direction of their growth coincide. This permits practical implementation of structurally determined anisotropy of one-dimensional superionic conductivity. Usually, whiskers contain no dislocations and possess improved mechanical properties owing to the low defectiveness. In addition, studies on the behaviour of $Ba_6Mn_{24}O_{48}$ whiskers in lithium nitrate melt (see Fig. 12 *c*) showed that lithium penetrates into the structure of $Ba_6Mn_{24}O_{48}$ as a result of exchange reaction, thus inducing contraction of the unit cell along the normal to the growth direction of the whiskers. Because of this whiskers can be more stable than ceramic samples with respect to charge–discharge cycles when used as electrode materials.

Thus, the fundamental physical properties of cuprates, manganites and cupromanganites reflect the complex chemistry of copper and manganese, which predetermines structural and chemical features of these compounds. Methods of synthesis of materials with desired structures, microstructures and functional properties must be chosen allowing for this fact.

IV.	Synthesis of nanoparticles in ordered matrices	901

Abstract. Approaches to the synthesis of functional nanocomposites based on zero-, one- and two-dimensional solid-state nanoreactors formed by zeolite cages, pores of mesoporous matrices, or interlayer cavities in layered compounds are considered. It is demonstrated that the use of solid-state nanoreactors opens up extensive opportunities for designing nanocomposites with specified physicochemical properties and makes it possible to avoid the aggregation of nanoparticles and to protect them from exposure to external factors, thus essentially facilitating the practical utility of these materials. The bibliography includes 304 references.

I. Introduction

The upsurge of interest in nanomaterials and nanotechnologies observed in the past decade manifests itself as a yearly growth (in geometrical progression) in the number of publications on this topic.[1] The unique properties of compounds in the nanocrystalline state [2] made it possible not only to create totally new generations of materials and devices but also to change the fundamental views about the world around us.[3, 4]

The reduction of particles to nanometre sizes changes considerably the properties of materials obtained on this basis, such as the melting point, heat capacity, electric conductance, *etc.*[5, 6] Furthermore, such materials acquire new optical, magnetic and electronic properties.[7, 8] In general, these changes are more prominent the smaller the particle sizes.[9]

The term 'nanoparticle' or 'nanosized particle' has appeared in scientific literature over ten years ago; however, there is no common opinion as to the size below which particles should be considered as nanosized. Quite different definitions of nanosizes can be found in the literature, namely, from a few nanometres to several hundred nanometres.[10] Sometimes, the definition of nanoparticles is related to the emergence of new properties other than the properties of the bulk phase rather than to the particle size.[11] It is believed that the size of nanoparticles is comparable to the correlation radius of some physical phenomenon (*e.g.*, the free-path length of electrons or phonons, the coherence length in a superconductor or the size of a magnetic domain or a solid-phase nucleus).[12] In such case, particles are characterised by quantum-size effects that depend both on the nature of the substance and on its properties. The majority of scientists believe that the maximum size of nanoparticles is 100 nm; however, they do admit that this is a purely arbitrary value, which is only necessary to provide a formal classification.[2, 13]

Two types of nanoparticles are usually distinguished: i, clusters or nanocrystals; and ii, nanoparticles as such. The first type comprises particles with well-defined structures and with sizes of 1 – 5 nm containing up to 1000 atoms, while the second type comprises nanoparticles with sizes of 5 – 100 nm consisting of $10^3 - 10^6$ atoms.[14] However, the latter definition is valid only for isotropic (spherical) nanoparticles, whereas nanowires and layered particles containing many more atoms and having one or two linear dimensions do not satisfy this definition, though they are typical nanoparticles as regards their properties. Owing to such differences in the linear sizes of nanoparticles, it is expedient to subdivide them into one-, two-, and three-dimensional nanoparticles (1D, 2D and 3D, respectively).[11] Lately, a distinction of geometrical and physical dimensionality of nanoparticles appeared.[15] It should be noted that if a nanoparticle has complex shape and structure, it is the size of its structural element rather than the linear size (which can often be much larger than 100 nm) that serves as the characteristic size. Such particles are called nanostructures. They are also subdivided into one-, two- and three-dimensional (zero-dimensional) particles (Fig. 1), depending on the anisotropy of the geometrical elements.

Owing to their unique physicochemical properties, nanoparticles are widely used in the creation of functional nanomaterials; among these, a special role belongs to magnetic and semiconducting nanomaterials due to the exceptional role of the latter in the progress of information technology. For example, superparamagnetic materials based on nanocrystalline transition metals (*e.g.*, Fe, Co and Ni) are used in memory devices with ultra-high data storage density;[16] nanomaterials based on semiconductors (*e.g.*, $A^{II}B^{VI}$ and $A^{IV}B^{VI}$) have unique optical properties and show promise as active elements in lasers with adjustable wavelength, elements of nonlinear optics, and nanoelectronic devices.[17]

II. Methods for the synthesis of nanomaterials

Numerous methods have been developed by now for the synthesis of nanomaterials, both in the form of powders and as inclusions in porous or solid matrices. In this case, ferro- and ferrimagnetics, metals, semiconductors, dielectrics *etc.* can serve as nanophases.

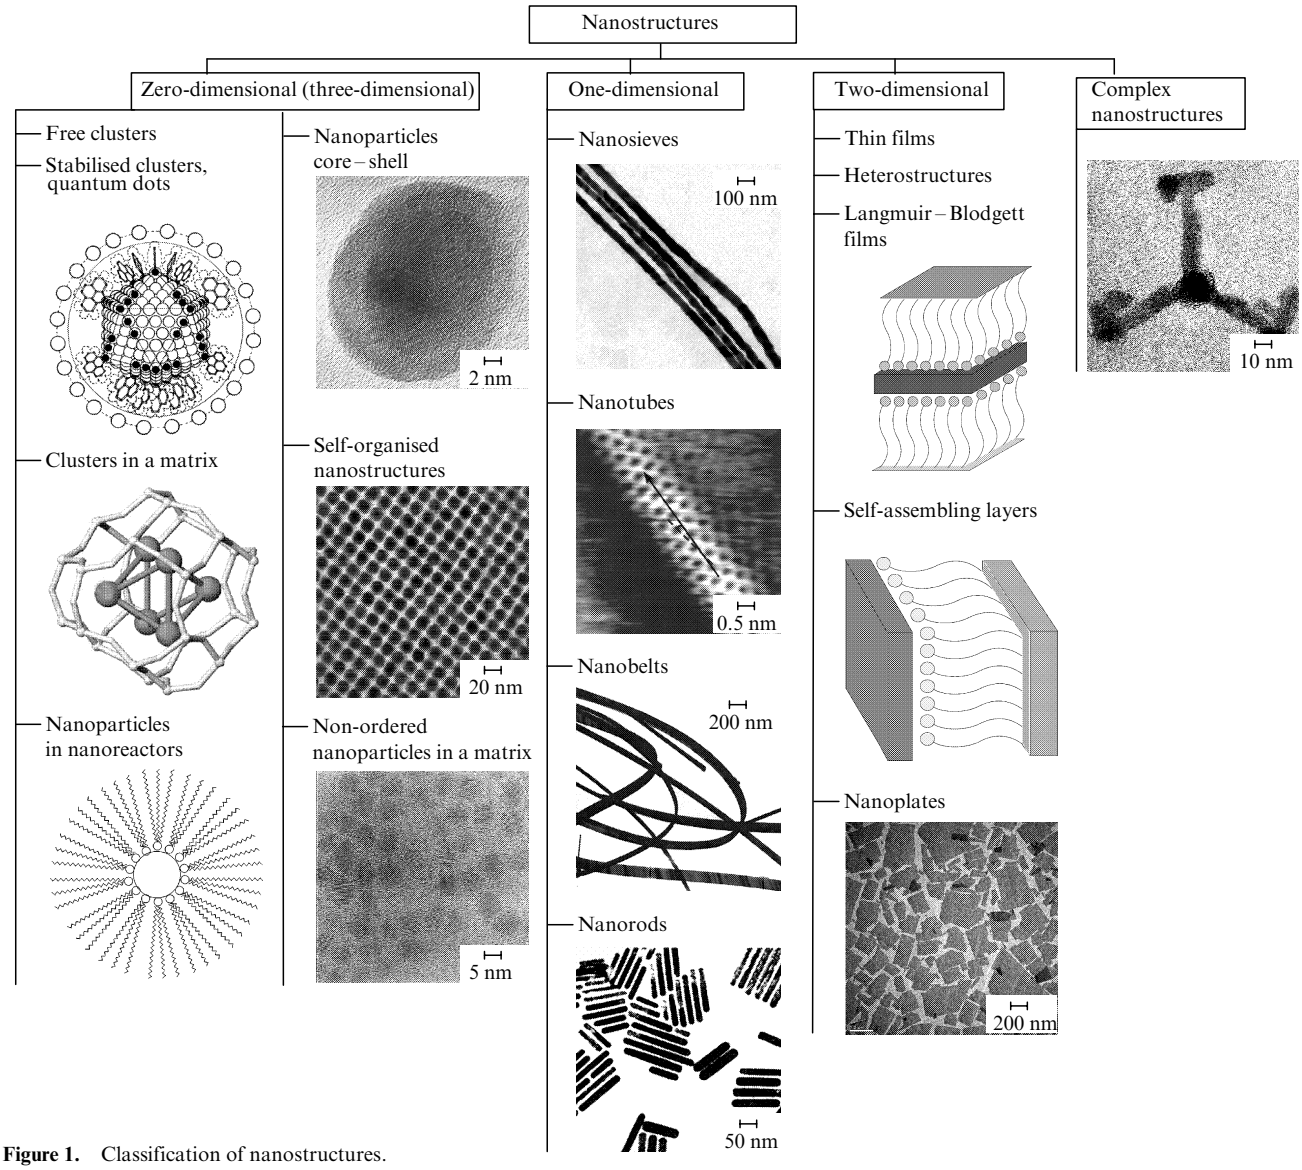

Figure 1. Classification of nanostructures.

According to Fendler,[18] the following conditions are of primary importance in the synthesis of nanomaterials:

1. The systems should be non-equilibrium. Virtually all nanosystems are thermodynamically unstable; they are obtained under conditions that are far from equilibrium, which allows one to achieve spontaneous nucleation and avoid the growth and aggregation of the nanoparticles formed.

2. Uniformity of nanoparticles. The high chemical uniformity of a nanomaterial is ensured if separation of components does not occur during the synthesis, either within a single nanoparticle or between the nanoparticles.

3. Monodispersity of nanoparticles. The properties of nanoparticles depend very strongly on their sizes; therefore, the synthesis of materials with good functional characteristics requires that particles with a sufficiently narrow size distribution be used.

It will be shown below that these conditions are not always mandatory. For example, solutions of surface-active compounds (micellar structures, Langmuir – Blodgett films, liquid – crystal phases) are thermodynamically stable but still give rise to various nanostructures.

All methods for the synthesis of nanomaterials can be tentatively separated into several large groups. The first group includes the so-called high-energy methods based on the rapid condensation of vapours under conditions precluding the aggregation and growth of the particles formed. The methods of this group mostly differ in the techniques of evaporation and stabilisation of the nanoparticles formed. Evaporation can be carried out by means of plasma excitation (plasma-arc), laser radiation (laser ablation), electric arc (carbon arc), or thermal exposure.[19, 20] Condensation was carried out either in the presence of a surfactant that slows down the growth of particles upon adsorption on their surfaces (vapour trapping); or on a cold matrix where the growth of particles is limited by the diffusion rate;[21] or in the presence of an inert component, which allows directed syntheses of nanocomposite materials with various microstructures.[22] If the components are mutually insoluble, the nanoparticle size can be controlled by thermal treatment.[19]

The second group includes mechanochemical methods (ball-milling), which make it possible to obtain nanocomposites by milling together mutually insoluble components in planetary mills or by decomposition of solid solutions to give new phases under exposure to mechanical stress.[23]

The third group of methods is based on the formation of spatially confined systems, that is, nanoreactors (micelles, droplets, films, *etc.*).[24–26] They also include synthesis in reverse micelles,[27] in Langmuir – Blodgett films[28] and in adsorbed layers.[29] Obviously, the size of the particles formed in this case cannot exceed the size of the corresponding nanoreactor,[30] hence these methods make it possible to obtain monodisperse systems. The biomimetic[31] and biological methods for nanoparticle syn-

thesis, where biomolecules (proteins, DNA, *etc.*) serve as nanoreactors, can also be attributed to this group.

The fourth group includes the methods based on the formation of ultramicrodisperse colloidal particles in solutions by polycondensation in the presence of surfactants that prevent aggregation.[32]

The fifth group comprises chemical methods for the synthesis of highly-porous and finely-dispersed structures (Rieke metals, Raney nickel) based on the removal of one component from a microheterogeneous system as a result of a chemical reaction or anodic dissolution. The traditional synthesis of nanocomposites by quenching a glass or salt matrix with a dissolved compound, which results in crystallisation of this compound in the matrix (glasses modified by semiconducting or metallic nanoparticles)[33] can also be classified as such a method. In this case, a compound can be introduced in a matrix in two ways: by adding it to a melt (solution) followed by quenching or by direct introduction into a solid matrix using ion implantation.[34]

Sol–gel synthesis is among the most widespread chemical methods for the synthesis of nanomaterials. It is used to obtain homogeneous oxide systems; chemical modifications of the latter (reduction, sulfidising, *etc.*) gives nanoparticles of the corresponding material in a matrix.[35–39] It should be noted that the sol–gel method makes it possible to obtain nanomaterials with improved functional properties by monitoring the composition and structure of the intermediate products.[40–42] It is also attractive because it can be implemented under laboratory conditions.[24] However, this method suffers considerable drawbacks. First, it does not ensure the formation of monodisperse particles. Second, it does not allow one to obtain anisotropic systems that can be synthesised in nanoreactors, such as two- and one-dimensional nanostructures as well as spatially ordered structures consisting of nanoparticles arranged at equal distances from each other or of parallel nanoplates interlaid with an inert matrix. Finally, in certain cases the required nanocomposite cannot be obtained due to the chemical reaction of particles with a gel-forming agent.

It should be noted that the use of free nanoparticles and nanostructures as materials is quite difficult due to the metastability of compounds in the nanocrystalline state. As noted above, this is caused by an increase in the specific surface of particles with a decrease in their linear dimensions to nanometres resulting in an increase in the chemical reactivity of a compound and in the enhancement of aggregation processes. In order to prevent the aggregation of nanoparticles and to protect them from external factors (*e.g.*, oxidation by atmospheric oxygen), nanoparticles are enclosed in a chemically inert matrix.[43]

Analysis of literature data shows that dozens of methods for matrix isolation of nanostructures have already been developed; these can be arbitrarily separated into two groups: i, synthesis of free nanoparticles followed by incorporation into an inert matrix and ii, direct formation of nanostructures in the bulk of a matrix in the course of its chemical modification.[12,44]

The first group of methods is easy to implement but the choice of the matrices is limited considerably. As a rule, polymeric organic compounds that do not have very high thermal stability and do not always have the required physical properties (*e.g.*, high optical transparency) are used as the matrices.[45] Furthermore, aggregation of nanoparticles during the incorporation cannot be prevented.[46]

The second group of methods makes it possible not only to avoid these drawbacks but also to directly monitor the parameters of nanoparticles in a matrix during the stage of their formation and even to change these parameters during the exploitation of a material. Matrices used for these purposes should contain structural cavities that can be occupied by compounds, subsequent modification of which would result in the formation of nanoparticles in these cavities.[47] In other words, these cavities should confine the zone of a reaction involving the compounds incorporated in them, *i.e.*, serve as specific nanoreactors. Obviously, it is possible to synthesise nanostructures with different morphology and anisotropy by choosing compounds with different shapes of their structural cavities.

The syntheses of nanomaterials with the use of porous oxide matrices (usually SiO_2 or Al_2O_3)[48,49] can serve as examples. However, due to the disordering of the porous structure of such matrices and the rather wide pore size distribution, it is almost impossible to obtain satisfactorily formed nanosystems by this method. Nanocomposites obtained in porous oxide matrices are usually employed in catalysis where the requirements for the monodispersity of particles are not too high.[50] Moreover, the rigid porous structures of such matrices do not allow the size and morphology of particles to be changed during the synthesis; as a rule, the latter parameters depend very strictly on the pore size and morphology,[51] that is, a very limited range of nanostructures can be obtained in a single type of matrix.

Sometimes, fast directed formation of nanoparticles in a matrix is achieved using additional physical effects, such as ultrasonic treatment as well as microwave and laser irradiation.[52–54]

III. Synthesis of nanoparticles in amorphous matrices

The first practical experience in obtaining nanoparticles in amorphous matrices, *viz.*, the preparation of coloured glass, dates back to the age of ancient Egypt.[4] However, the mechanism of colouring in such amorphous matrices was established only 100 years ago.[55] At present, crystallisation of glass is the main method for the synthesis of nanoparticles in amorphous matrices. It is known that the nucleation and growth of crystals in an amorphous matrix depend both on the heat treatment conditions of a glass and on its composition. The crystal size can be controlled by creating a certain concentration of nuclei, which is achieved by heat treatment of a glass at a relatively low temperature. The subsequent growth of crystals occurs at the higher temperature of annealing. It should be noted that the matrix composition changes during the crystallisation and hence the diffusion mobility of ions that constitute the crystalline phase also changes (decrease in the diffusion coefficient slows down the growth of particles and favours the formation of smaller particles of the disperse phase, whereas an increase in the diffusion coefficient favours the formation of larger particles).

Glass crystallisation has been used to obtain diverse nanoparticles of semiconducting, magnetic and catalytically active materials.[56–59] In particular, glasses doped with nanoparticles of semiconductors are widely used as optical filters. In the first place, they are attractive owing to their nonlinear optical properties, such as a considerable resonance effect, a dependence of the position of the absorption edge on the particle size, the doubling of the incident radiation frequency (generation of the second harmonic), *etc.*[60] The possibility of utilising glasses containing nanoparticles of high-coercivity magnetic phases (barium and strontium hexaferrites) as a medium for data recording and storage was considered.[61–68]

However, the glass crystallisation method does not provide nanoparticles with a sufficiently narrow size distribution, which is necessary for the manifestation of the quantum confinement effects or for the utilisation of such nanoparticles in technology.[66] This problem is solved by using porous materials with ordered pore structures, such as mesoporous silica and zeolites having one-dimensional channels or two-dimensional cavities.[67–69] It these cases, nanoparticles of filiform, layered or spherical shapes (depending on the type of the porous structure) with narrow size distributions were obtained.[67,70,71]

IV. Synthesis of nanoparticles in ordered matrices

Ordered matrices (or nanoreactors) are usually classified in accordance with the dimensionality of the pores they contain. Let us successively consider the synthesis of nanoparticles in zero-, one- and two-dimensional nanoreactors.

1. Synthesis of nanoparticles in zero-dimensional nanoreactors

Zero-dimensional nanoreactors are materials characterised by open porosity with an ordered arrangement of spherical pores. Such materials primarily include zeolites, *i.e.*, natural and synthetic aluminosilicates with the composition $M^{i}_{x}M^{ii}_{y}(Al_{x+2y}Si_{z}O_{2x+4y+2z})\cdot n\,H_2O$.[72] More than 150 types of zeolites, including about 30 natural ones, are known to date. Zeolite structures are built of $[SiO_4]^{4-}$ and $[AlO_4]^{5-}$ tetrahedra connected by common vertices into a three-dimensional framework penetrated by cavities and channels where water molecules and cations of alkaline (M^{i}) and alkaline-earth metals (M^{ii}) are located.

Unlike the framework atoms bound by covalent bonds, the cations located in the channels are bound with a matrix only electrostatically and can easily be exchanged for other cations in aqueous solutions.

Isomorphous replacement of aluminium atoms belonging to the framework by atoms of other elements, such as B, Ga, Fe, Co, Ti, or V, and exchange of cations incorporated in the pores allow one to modify the properties of zeolites in a desired direction. There are several factors that determine the possibility of isostructural replacement:[73]

— the similarity of the radii of the replaced and replacing atoms (the larger the difference in the radii the less energetically favourable the replacement);

— the replacement of a smaller atom by a larger one is possible provided that the coordination of the latter is smaller, and *vice versa*;

— the similarity of the electronegativities and ionisation potentials of the replaced and replacing atoms;

— the achievement of the minimum free energy during isomorphous replacement with retention of the coordination number.

The structures of zeolites are more open than those of other tectosilicates. The TO_4 tetrahedra (primary assembly units) form rings of various sizes and the rings are connected to give more complex structures (secondary assembly units). Each type of zeolites is characterised by a definite set of secondary assembly units. [It should be noted that the Si—O—Si angle can vary in rather a wide range (135–165°); as a result, the existence of silicon–oxygen rings with different numbers of atoms becomes possible.] Rings with five oxygen atoms, in which the Si—O—Si angle is about 145°, are more typical of zeolites with a high silicon content. Zeolites with a high aluminium content, which incorporate many Si—O—Al bonds, are mostly built of rings containing three or six oxygen atoms. The structures of natural zeolites most often contain rings with four or six oxygen atoms.

The classification of zeolites is rather a complex task. Each individual structure is described by the structural code comprising three Latin letters, *viz.*, the so-called IZA-code accepted by the International Zeolite Association Structure Commission (http://www.iza-structure.org/databases/). This code is applicable both to aluminosilicates and to some other compounds with similar structures containing atoms of elements (Si, Al, P, Ga, Ge, B, Be, *etc.*) in a tetrahedral environment.

The most general approach to the synthesis of zeolites is based on the joint hydrolysis of silicon compounds and compounds of a three-charged metal (most commonly aluminium) in the presence of an alkali and a quaternary amine (template). Organosilicon compounds that readily undergo hydrolysis, sodium silicate and silica gel with large surface area ($>200\ m^2\ g^{-1}$) are the most common sources of silicon atoms, whereas metal salts (sulfates, nitrates or chlorides) or alkoxides (isopropoxides, butoxides) are most commonly used as the sources of M^{3+} ions.

The schemes for the synthesis of zeolites with different compositions and structures are almost the same. The gels containing silicon and aluminium compounds are aged for prolonged periods of time below the crystallisation temperature (often under hydrothermal conditions) in the presence of templates. This time is necessary for a zeolite with a required structure to be formed in a high yield. The aging conditions and the nature of the templates play a decisive role in the structures of the zeolites formed.[74] The presence of template molecules increases the crystallinity of the aluminosilicate framework and affects its structure. Zeolites of some structural types can also be formed without a template. The structural type of the resulting zeolite also depends on the nature and concentration of the source of the three-charged metal.

The negative charge of the matrix in a zeolite is compensated by ions of alkaline metals, ammonium and/or alkylammonium (depending on the reagents used in the synthesis). Metal cations are generally removed by washing or by ion exchange for NH_4^+, since the presence of metal cations decreases the thermal stability of the matrices obtained. In order to remove the template, the ready zeolites are burnt off in a stream of oxygen at 500–550 °C, which converts them into the so-called H-form. The Si : Al ratio in zeolites is determined by standard methods of quantitative analysis.

Zeolites and similar porous materials are used as ion exchangers, selective adsorbents, catalysts and catalyst supports. The preparation of nanocomposite materials for catalytic purposes (isomerisation of aromatic hydrocarbons, treatment of NO and NO_2 gases) based on zeolites is a promising field of application of zeolites, hence it is not surprising that the majority of works in this field deal with the synthesis of nanoparticles of metals belonging to the 8–11th groups of the Periodic system. Zeolites of the FAU, LTA, SOD and MFI types are most commonly used as the matrices due to their accessibility and the facility of synthesis.[75–82] It should be noted that these matrices have a number of unique properties that are important for the directed synthesis of nanomaterials. Their structures are stable over a broad temperature range. The number of cations in the pores determined by the Al : Si ratio can be easily controlled during the synthesis, which allows one to vary the concentration of the reaction centres in the matrix.

Due to the open porosity of zeolites and the high diffusion rate of gases in the pores, chemical reactions involving intercalated cations can be carried out at elevated temperatures (*e.g.*, reduction with hydrogen required for the preparation of magnetic nanocomposites) almost without destruction of the matrix that confines the reaction zone. These properties open up rich possibilities for the chemical design of nanocomposite materials based on zeolites.

Nanomaterials based on zeolite Y (FAU type) are the most popular.[76, 77, 79–85] The structure of a Y-zeolite consists of the following secondary assembly units: 6-6 (hexagonal prism), 6-2 (hexagon and square with a common edge), 6 (hexagon) and 4 (square) (Fig. 2). The main structural motif of FAU zeolites consists of an octahedron truncated by a cube, *i.e.*, a sodalite cell or a small β-cage with an internal diameter of 0.66 nm comprising four-membered (the free diameter is less than 0.1 nm) and six-membered rings (the diameter is ~0.22 nm) from T-atoms. The vertices of the polyhedron contain 24 T-atoms, whereas the oxygen atoms are located between them. Connection of such polyhedrons through hexagonal prisms (cage diameter 0.36 nm) consisting of T- atoms gives the structures of zeolites (X and Y). They are charactised by a cubic symmetry (*Fm*3*m*) with lattice parameters of $a = 24.345$ Å (Fig. 3). The structure contains different types of cages: the α-cage (supercage) is the largest (its diameter is 1.2 nm) and is surrounded by eight truncated octahedrons; the β-cage (sodalite cage) is limited by a truncated octahedron; and the γ-cage is a hexagonal prism (see Fig. 2).

The main method for the preparation of nanocomposite materials based on zeolites involves the exchange of Na^+, H^+ and NH_4^+ cations contained in zeolites for cations of other metals in aqueous solutions followed by the reduction of the metal with hydrogen. For example, the preparation of a copper-containing zeolite by ion exchange of copper nitrate with a NaY-zeolite or by annealing a mixture of a NaY-zeolite with copper chloride at 420 °C was reported.[86] In the case of solid-phase annealing, the starting zeolite NaY was first stabilised by adding NaBr in order

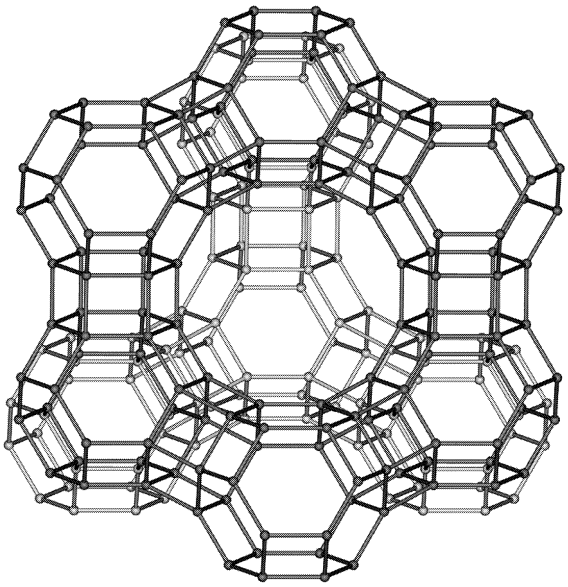

Figure 2. Structure of zeolite Y.

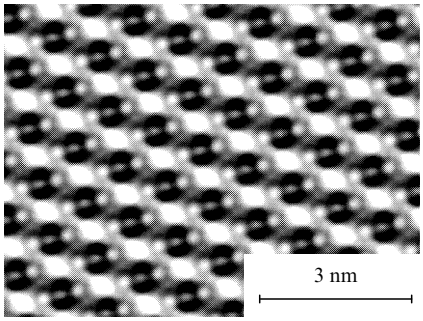

Figure 3. A photomicrograph of a NaY crystal along the [110] direction obtained by transmission electron microscopy (TEM).[76]

to fill the β-cages. This made it possible to introduce copper into α-cages and to increase the thermal stability of matrices. The reduction was carried out in a hydrogen atmosphere at temperatures of 300 – 600 °C. In both cases, the resulting copper particles (3 – 7 nm) were larger than the α-cages and the porous structure of the zeolite was damaged.

Au/NaY and Au-Fe/NaY nanocomposites were obtained in a similar way.[79, 82] Again, the nanoparticles resulting from the reduction of the metals were much larger than the size of the zeolite's α-cage.

Lanthanide-containing zeolites of the FAU structural type are formed upon ionic exchange of cations within zeolites with chlorides or nitrates of rare-earth metals.[83] Annealing at 500 °C of zeolites modified by this method gives oxides of rare-earth metals and results in a partial replacement of aluminium atoms in the zeolite structure by rare-earth atoms, which improves the thermal stability of the zeolite. At sufficiently high concentrations of lanthanides, their oxides are also formed outside the zeolite.

Aside from metal salts, complex cations can also be used. For example, the $Pd(NH_3)_4Cl_2$ complex was used[87] to obtain a palladium-containing zeolite. A Y-zeolite was soaked with a solution of the complex, annealed at 500 °C in a stream of oxygen and reduced with hydrogen at 400 °C. Samples with an overall palladium content from 1% to 10% were obtained using this method; at high palladium concentrations, the size of the nanoparticles that formed exceeded the size of the Y-zeolite cavity, which resulted in the destruction of the porous structure. In contrast, the sample containing 1% of palladium retained the structure of the original zeolite and its pores contained palladium particles with sizes about 1 nm.

Guillemot *et al.*[80] described the synthesis of gold nanoparticles with diameters of ~2 nm in a Y-zeolite matrix by soaking the zeolite with the $Au(en)_2Cl_3$ complex (en is ethylenediamine) followed by decomposing the complex at 250 °C in a stream of helium. According to X-ray photoelectron spectroscopy (XPS), the particles of gold occupied the α-cages of the zeolite.

Publications on the synthesis of nanoparticles of intermetallides† using zeolites have recently appeared. This method was used to obtain (Pt, Pd)-substituted zeolites.[88] Ammonia complexes of palladium and platinum were incorporated in a Y-zeolite by ion exchange. Thermolysis of metal complexes in a stream of oxygen at 300 °C followed by reduction in a stream of hydrogen at 300 °C produced nanoparticles of an alloy containing ~40% of platinum; however, data about the arrangement of the nanoparticles in the zeolite matrix are not available.

An Au – Pd intermetallide was obtained in a Y-zeolite using the $[Au(en)_2]^{3+}$ complex as the source of gold and $Pd(NH_3)_4^{2+}$ as the source of palladium.[89] Ion exchange was carried out in two stages. In the first stage, the palladium complex was introduced in the zeolite matrix; thermolysis of this complex in oxygen was accompanied by the formation of Pd atoms and their transfer to β-cages that are more favourable in terms of coordination. After that, ion exchange with the gold complex and reduction of the composite were carried out. The alloy was formed in the α-cage of the zeolite. Depending on the Au : Pd ratio and the composition of the starting zeolite, particles with sizes from 1 to 3 nm were obtained. Prolonged annealing resulted in the melting of the nanoparticles and their simultaneous growth (to 3.5 – 4 nm) as well as in a partial destruction of the porous structure of the zeolite.

Lázaro *et al.*[78] suggested a very interesting approach to the synthesis of clusters in zeolite cages based on the incorporation of hydrophobic compounds. Iron pentacarbonyl was used as the starting hydrophobic compound due to its ability to form iron clusters upon decomposition *in vacuo*; a dehydrated FAU-zeolite was used as the zeolite. Homogeneous incorporation of the carbonyl into the structure of the dehydrated zeolite could be expected, since the absence of internal OH groups on the cage walls makes their surfaces close to hydrophobic. In order to synthesise nanoparticles, a dehydrated NaY-zeolite was first soaked with iron pentacarbonyl at 77 °C and the pentacarbonyl was then thermally decomposed in a high vacuum. This resulted in superparamagnetic iron clusters with particle sizes from 1.5 to 2.0 nm (according to data from Mössbauer spectroscopy, more than 90% of the iron in the zeolite existed in the metallic state). Clusters were formed in pores, and the zeolite structure was not destroyed.

Carlsson *et al.*[76] studied the arrangement of iron oxide clusters in a Y-zeolite. The clusters were obtained by oxidation of iron pentacarbonyl in the matrix at low temperatures.[90] According to chemical analysis and electron diffraction data, the composition of iron oxide clusters is Fe_6O_n. The clusters are arranged in the β-cavities of the zeolite (Fig. 4); they are octahedra of iron atoms with a distance of 3.6 ± 0.15 Å between the latter. There are 76 $FeO_{1.5}$ units per unit cell of the zeolite.

It should be noted that the synthesis of nanocomposites in zeolites is not limited to matrices of the FAU structural type. There are a fair number of works dealing with the synthesis of nanocomposites in zeolites of the MFI structural type (as well as of the ZSM, MAS and other types) that correspond to one-dimensional nanoreactors.

An unconventional physical approach to the intercalation of chemical compounds into a zeolite matrix is described in a series of

† Nanoparticles of intermetallides are usually obtained by the substitution of ions in solutions containing either both cations or cationic complexes in the required ratio.

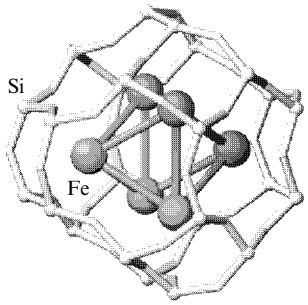

Figure 4. Schematic representation of a cluster in the β-cage of a Y-zeolite.[76]

works.[75, 91, 92]. Au_2Cl_6 was incorporated in dehydrated NaY through the gas phase in a high vacuum and then the gold was reduced to the 1+ oxidation state. As a result, AuCl clusters were formed in the zeolite pores.

It was also found to be rather promising to obtain functional optical materials based on nanoparticles of binary compounds in zeolite matrices. In such materials, it was possible to combine the properties of free nanoparticles with the solid-phase properties of the matrix. It should be noted that the open porosity of the zeolite matrix usually simplifies the reactions of compounds intercalated in it with gaseous reagents. For example, Garcia *et al.*[93] described a procedure for the preparation of a CdS/mordenite (MOR) composite. To do so, the starting zeolite $Na_8[Al_8Si_{40}O_{96}] \cdot 24\,H_2O$ (mordenite with a two-dimensional system of channels 0.65×0.70 nm and 0.26×0.57 nm) was treated with a cadmium nitrate solution, and sulfidised in a stream of hydrogen sulfide. The resulting nanocomposite contained cadmium sulfide particles with a diameter of ~60 nm that were much larger than the pore size. Although the zeolite lost crystallinity, the resulting nanocomposite partially retained the structural elements corresponding to the original mordenite structure. A NiS/Y nanocomposite was obtained in a similar way.[85] An NaY zeolite was placed in a $NiCl_2$ solution, dried (He, 400 °C, 2 h) and sulfidised (10% H_2S/H_2, 2 h) at different temperatures ($T = 25-400$ °C). In this case, the formation of large sulfide particles was observed as well.

A more successful example of using zeolites as nanoreactors is described in Ref. 84. Mixed sulfides of cobalt and molybdenum in a Y-zeolite were obtained by successive replacement of Na^+ ions by cobalt ions followed by incorporation of molybdenum hexacarbonyl into the zeolite in a stream of CO. According to chemical analysis, there are about two $Mo(CO)_6$ molecules per α-cage of the zeolite. The overall composition of the sample obtained at this stage is described by the formula Co(4 mass %)Mo(10 mass %)NaY. After that, the sample was sulfidised in a stream of H_2S at different temperatures (25–400 °C). The sizes of the resulting particles of mixed sulfides were 1–2 nm.

Zeolites are also widely employed as matrices for the synthesis of luminescent nanoparticles.[94]

At present, the complexity of studying the distribution of nanoparticles in a matrix by direct observation methods, such as transmission electron microscopy (TEM), is the main problem in the preparation of nanocomposites based on zeolites. Therefore, syntheses of nanocomposites isolated in matrices are most commonly based on matrices with ordered porous structures and with pore sizes of 2–50 nm. Such matrices include mesoporous molecular sieves and porous alumina.

2. Synthesis of nanoparticles in one-dimensional nanoreactors

The scope of materials that can be used as one-dimensional solid-state nanoreactors is not vast. It includes MFI-type zeolites, mesoporous molecular sieves and mesoporous structures based on alumina.

a. Zeolites of the MFI structural type

MFI type zeolites have an ordered system of channels with diameters ranging within 0.54–0.56 nm and with hexagonal packing (Fig. 5).[74, 95–100] Metal nanoparticles in channels of MFI-zeolites are usually obtained by ion exchange of protons (zeolite in the H^+-form) for metal cations or complexes followed by mild reduction in a stream of hydrogen.

It should be expected that the reduction of metal cations in the matrices of such zeolites would produce anisotropic nanoparticles (unfortunately, the size distribution of particles and their anisotropy were not studied due to the difficulties resulting from the small sizes of the channels).

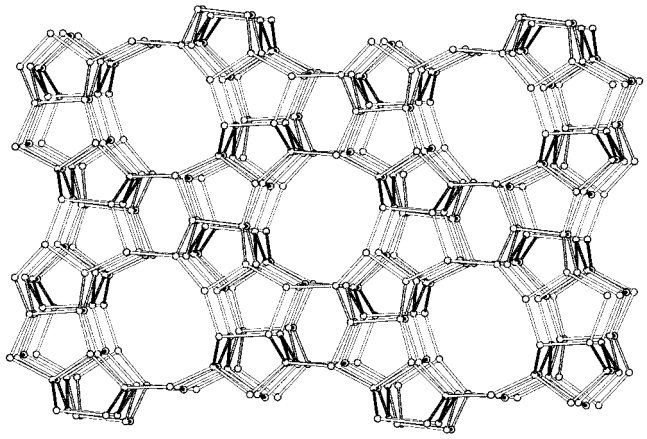

Figure 5. Structure of a zeolite with the MFI structural type.

b. Mesoporous molecular sieves

Mesoporous molecular sieves have been discovered by researchers of the Mobile Research and Development Corporation (USA) in 1992.[101] They synthesised a family of SiO_2-based molecular sieves (MCM-41) with a uniform and highly ordered distribution of pores, the size of which could be strictly controlled in the range from 2 to 10 nm, and with an extremely large specific surface area (~1000 $m^2\ g^{-1}$).

The template method is the most popular method for synthesising mesoporous SiO_2. A template is a centre around which the main structural units of a matrix are arranged and its framework is formed. Removal of a template produces a cavity with the same size and shape as those of the template. The accuracy of the 'printout' after the removal of the template depends on several factors: the nature of the template–matrix interaction, the ability of the matrix to assume the outlines of the template, the relative size of the template and the structural units of the matrix. The scheme of template synthesis is shown in Fig. 6.

Although the discovery of molecular sieves dates back to 1992, a 'template synthesis' was first described in 1949 in a study of gel formation by tetraethoxysilane (TEOS) in the presence of the methyl orange indicator (template). The silica gel formed upon condensation of TEOS selectively adsorbed methyl orange. Since that time, this rather simple and elegant method has become popular for the synthesis of numerous organic and inorganic materials.[30]

Let us consider the synthesis of molecular sieves for mesoporous SiO_2 (MCM) as an example. Samples of MCM are obtained by the polycondensation of silicon compounds [$Si(OMe)_4$ or $Si(OEt)_4$] in the presence of a template. Various molecules can serve as the template,[101–106] *e.g.*, noncovalently bound organic surfactants [as a rule, cetyltrimethylammonium bromide ($C_{16}H_{33}NMe_3Br$) is used].

Bifunctional molecules of cetyltrimethylammonium bromide are amphiphilic, *i.e.*, they contain a hydrophilic head group and a hydrophobic 'tail'. In aqueous solution, such molecules combine

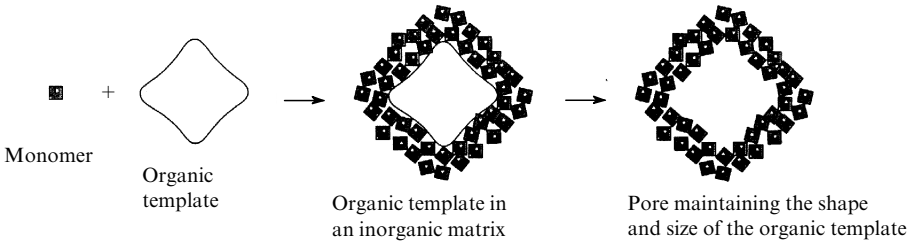

Figure 6. Scheme of template synthesis.

into micelles, in which the hydrophilic head groups form the external surface, whereas the hydrophobic 'tails' are oriented towards the centre. The extent of micellisation and the shape of micelles depend on the surfactant concentration. At high surfactant concentrations, micelles are aggregated into liquid-crystal phases the structure of which depends on the solution temperature and concentration. Figure 7 shows the phase diagram of the $H_2O-C_{16}H_{33}NMe_3Br$ system.[30]

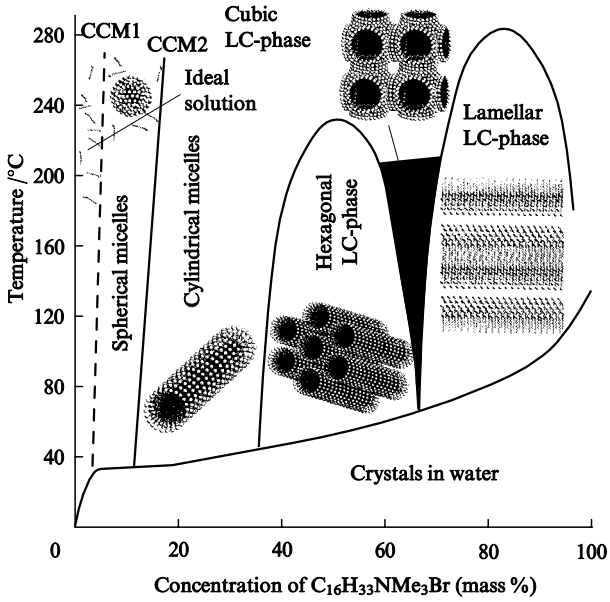

Figure 7. Schematic phase diagram of the $C_{16}H_{33}NMe_3Br-H_2O$ system (LC phase designates the liquid-crystal phase).[30]

A reaction mixture containing an aqueous solution of the surfactant, a tetraalkoxysilane and an acid (or alkali) is kept for a few hours at a constant temperature (80 °C). Hydrolysis of the tetraalkoxysilane produces mesoporous silica around the surfactant micelles.

Parameters affecting the gel formation include the pH of the solution, the nature and concentrations of the template and the organosilicon compound, the temperature, the type of the catalyst, *etc.*[103] Particular importance is attributed to the pH of the medium, more exactly, the ζ-potential that characterises the electrostatic interaction between the colloid particles and determines the structure of the polycondensation products. In the case of acid catalysis, the hydrolysis of a tetraalkoxysilane is probably the limiting step, whereas the condensation is relatively fast. As a result, weakly branched sol particles are formed.

Different types of template–matrix binding are possible. In our case, the template–matrix interaction occurs due to electrostatic forces, hydrogen bonds or van der Waals bonds.

Sodium silicate is sometimes used as the source of silicon.[105, 107] The types of mesoporous phases obtained by the method described are presented in Table 1 and in Fig. 8.

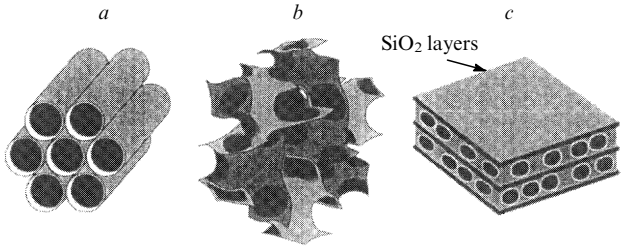

Figure 8. Possible structures of MCM-phases.[112] (*a*) hexagonal, (*b*) cubic, (*c*) lamellar.

Hydrothermal synthesis is an alternative method for the synthesis of mesoporous silica. A reaction mixture containing an aqueous solution of a surfactant and amorphous silica is subjected to prolonged hydrothermal treatment at about 150 °C. Such treatment results in the dissolution of silica accompanied by the rearrangement of its structure. Hydrolysed silicon oxide forms mesophases around the surfactant micelles.[113]

In the syntheses of MCM-41, the surfactant concentration in the starting solution is nearly always maintained below the critical micelle concentration (CMC1) (see Fig. 7), *i.e.*, the liquid-crystal phase is absent in the solution before the addition of a silicon source. This means that SiO_2 and a surfactant are mutually assembled into an organic–inorganic liquid-crystal phase during the reaction. It is assumed that ion exchange of the surfactant with multiply charged oligomeric silicate ions is the first step of the

Table 1. Types of mesoporous SiO_2 phases obtained by the template method.

Type of mesoporous SiO_2 phase	Template	Pore structure	Pore diameter /nm	Ref.
MCM-41	$C_nH_{2n+1}N^+Me_3X^-$ ($n = 6-22$, X = Hal, OH)	hexagonal (Fig. 8 *a*)	2–10	101
MCM-48	the same	cubic (Fig. 8 *b*)	2–5	108
MCM-50	"	lamellar (Fig. 8 *c*)	4	109
BSA-15	triblock-copolymers	hexagonal	5–30	104
MSU-V	$H_2N(CH_2)_nNH_2$ ($n = 12-22$)	hierarchic lamellar	1.3–2.7	110
MAS-5	$C_{16}H_{33}N^+Me_3Br^-$	hexagonal	3	111

formation of mesoporous materials if charged surfactants are used. Silicate ions are polydentate and can bind several surfactant molecules by shielding the repulsion forces between the head groups of the surfactant molecules, thus allowing micelles to increase in size. This effect is well known for simple surfactant–water systems. For example, the addition of electrolytes to $C_{16}H_{33}NMe_3Br$ solutions results in a transition from spherical to cylindrical micelles.[114] Hence, the interaction of surfactant micelles with silicate polyanions produces micellar rods encapsulated in silicate, which then spontaneously build a hexagonal structure.

It should be noted that this mechanism does not operate if neutral surfactants are used as templates. They have a much stronger tendency to form aggregates in water than charged surfactants (the CMC values for charged surfactants are about two orders higher than those of neutral surfactants with the same number of carbon atoms in the alkyl chain). The tendency of neutral surfactants towards aggregation combined with their tendency towards interaction with SiO_2 particles with the formation of hydrogen bonds is sufficient to create mesophases.[115]

The process for the preparation of porous amorphous silica usually includes three stages: synthesis of a gel, drying, and removal of the template. The diameter of pores in MCM-41 can be controlled during the synthesis by varying the type of the reagents used and the conditions of the synthesis. Drying of gels results in only a small shrinkage of pores and has only a small effect on their size, but considerably affects the gel structure. The method and conditions for template removal affect the final size of the pores but not their mutual arrangement. There is still no clear understanding about how the porosity can be controlled at each stage of the preparation of mesoporous SiO_2 (synthesis → drying → template removal) but certain factors determining the porosity have been studied quite thoroughly. For example, the pore size in the SiO_2–surfactant system can be roughly controlled by changing the surfactant 'tail' length. It was found that in the series of surfactants $C_nH_{2n+1}NMe_3Br$, n = 8, 10, 12, 14, 16, 18, the pore size in the resulting product increased by ~0.45 nm (Fig. 9 *a*,*b*) with each increase in n ($\Delta n = 2$). Yet another way to change the pore size is to introduce in the system a non-polar organic solvent [*e.g.*, mesitylene (Fig. 9 *c*,*d*)],[101,116] which is incorporated in the hydrophobic part of micelles during the synthesis, thus increasing their diameter.

The type of the template–matrix interaction affects the thickness of the SiO_2 walls. The silicate mesophases prepared using neutral surfactants have thicker pore walls ($\geqslant$1.7 nm) than the mesophases synthesised on the basis of ionic surfactants (0.8–1.3 nm).[115] There is no strong electrostatic interaction in the case of neutral surfactants; probably, this fact favours the further ordering and provides a product with thicker walls.

The capillary adsorption of gases at their liquid–gas transition temperatures is one of the main methods for the study of mesoporous phases. The results obtained by this method show that the specific surface areas of mesoporous phases are large (~1000 $m^2\ g^{-1}$) and the pore size distribution is narrow (Fig. 10). A detailed study of the gas adsorption in mesoporous matrices[117] showed that the pore size distribution can be calculated from data on the gas partial pressure above a sample (p/p_0) using a modified Kelvin equation:

$$r(p/p_0) = \frac{2V_L}{RT\ln(p/p_0)} + d(p/p_0) + 0.3,$$

where $r(p/p_0)$ is the pore size (nm); V_L is the molar volume of the gas used; γ is the surface tension factor of its liquid phase [$\gamma(N_2) = 8.88 \times 10^{-3}$ N m^{-1}],[117] $d(p/p_0)$ is the thickness of the liquid film adsorbed on the sample (calculated using the Harkins–Jura equation),[117] and 0.3 is the correction for the non-ideality of the system.

Studies of MCM-41 phases by electron microscopy and small-angle X-ray scattering (SAXS) showed that the samples have strictly ordered structures of pores uniformly distributed by size (Figs 9, 11).[118]

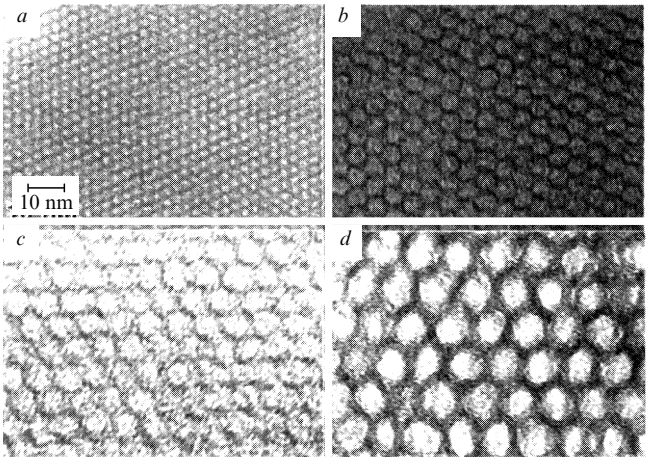

Figure 9. Photomicrographs of MCM-41 samples obtained by TEM.[101] (*a*) $C_8H_{17}NMe_3Br$ template, d = 2 nm; (*b*) $C_{16}H_{33}NMe_3Br$ template, d = 4 nm; (*c*) $C_{16}H_{33}NMe_3Br + Me_3C_6H_3$ template ($C_{16}H_{33}NMe_3Br$: $Me_3C_6H_3$ = 2), d = 6.5 nm; (*d*) same as above ($C_{16}H_{33}NMe_3Br$: $Me_3C_6H_3 > 3$), d = 10 nm.

Notation: α_s is standard adsorption, Q is amount of adsorbed gas, r is pore size, P_r is pore size distribution.

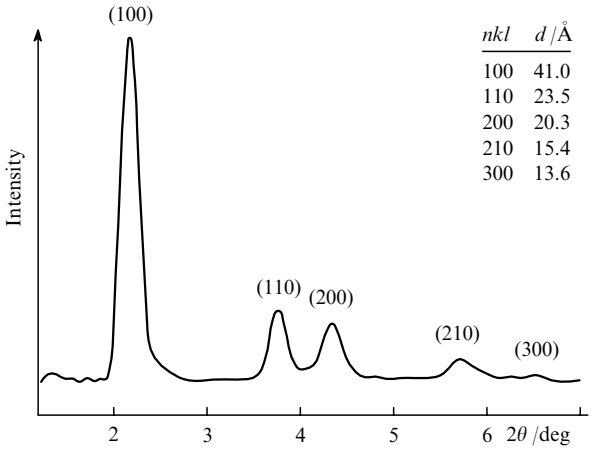

Figure 11. Small-angle X-ray scattering of an MCM-41 matrix.

All these facts make it possible to use materials based on mesoporous silica as catalyst supports, membranes, selective adsorbents, sensor materials and matrices for the preparation of various functional composite materials.

Films of mesoporous silica are of considerable interest since they can be used as media with low dielectric constants in the deposition of multiple-layer integrated circuits. Magnetic nanocomposites based on such films can be used for development of high-density information carriers.

There are various methods for the preparation of mesoporous SiO_2, many of which involve the chemical deposition of films from solutions. Obviously, the formation of mesophases in the synthesis of films occurs similarly to the synthesis of the corresponding bulk samples.

The orientation of films with respect to the plane of the substrate is one of the most important characteristics of films. In the case of mesoporous silica, special attention is paid to the mutual arrangement of the mesopores. As a rule, they are oriented parallel to a substrate, since the film – substrate interaction energy is a maximum for this orientation of micelles. For example, MCM-41 films have the (100)-orientation almost in all cases.‡ Syntheses of oriented films of mesoporous silica on glass, polymeric, graphite, mica and silicon substrates have been described.[119–121]

The ordering of pores in the substrate plane (*i.e.*, the formation of the rolling texture) is much more rare and is only possible if the substrate has a particular direction. The synthesis of epitaxial films of mesoporous SiO_2 on a Si (110) substrate can be

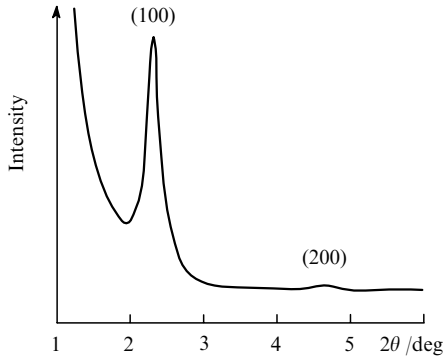

Figure 12. X-Ray diffraction pattern of a mesoporous silica film obtained on a Si (110) matrix.[119]

‡ It should be noted that the films formed at the liquid – gas interface also have the (100)-orientation.

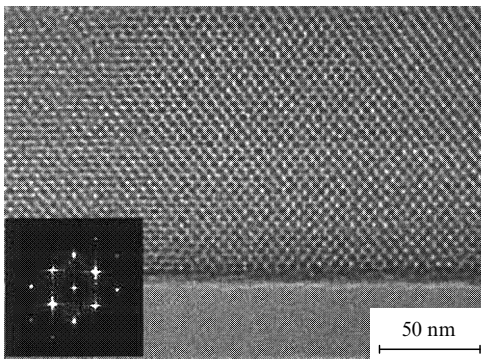

Figure 13. Photomicrograph of the cross section of a mesoporous silica film on a Si (110) matrix (the inset shows electron diffraction data).[119]

mentioned as an example.[119] Figure 12 shows the X-ray diffraction data for such films. The presence of the (100) and (200) diffraction maxima at 2θ values of 2.3° and 4.5° and the absence of the (110) peak suggest that the mesopores are oriented parallel to the substrate. Texture measurements showed that the pores in the substrate plane are oriented parallel to the [100] direction. These results are also confirmed by transmission electron microscopy data for a chip from a sample and by electron diffraction data (Fig. 13). At the same time, the SiO_2 films obtained on Si (100) and Si (111) substrates are not oriented in the substrate plane.

c. The use of mesoporous SiO_2 for the synthesis of nanocomposites

The application range of mesoporous phases and materials based on them is very broad due to their unique properties, such as the large specific surface area, the ordered system of mesopores, the uniform pore size distribution, the high diffusion rate of gases into the material bulk, *etc*. Mesoporous phases find use as catalysts [122] and catalyst supports;[123] matrices for conductive polyaniline [124] and carbon fibres;[125] tiny reactors for redox reactions;[126] selective membranes;[127] adsorbents with large surface area;[101] and porosity standards.[101]

In terms of structural parameters, the nanostructures synthesised inside cylindrical pores are subdivided into bulk nanoparticles, nanowires and nanotubes.[128] The methods for the synthesis of SiO_2-based nanocomposites can be classified into two groups. The first group includes the methods based on the impregnation of a porous material with metal salts followed by the chemical modification of the composite. For example, the synthesis of Ag and Cu nanoparticles in the mesoporous MCM-48 phase grade (mesoporous SiO_2 with cubic structure) was described.[39] MCM-48 samples were impregnated with solutions of $AgNO_3$ and $CuNO_3$ in ethanol and then dried to remove the solvent. During the evaporation of the solvent, the Ag^+, Cu^+ and NO_3^- ions were adsorbed on the silica surface. Reduction of the resulting composites resulted in Ag and Cu nanoparticles (Fig. 14) with sizes (~10 nm) exceeding the pore diameter of mesoporous silica (~3 nm). Presumably, in this case nanoparticles formed outside

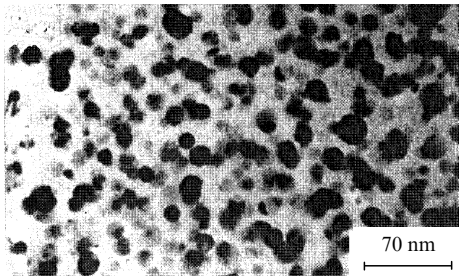

Figure 14. A TEM photomicrograph of mesoporous SiO_2 with incorporated Cu and Ag particles (Ag : Cu = 1 : 3).[39]

the pores. This probably resulted from low hydrophilicity of the inner surfaces of the mesopores [101] that complicated their impregnation with aqueous solutions.[129] As a result, the method for the synthesis of nanocomposites based on the impregnation of mesoporous silica with solutions of metal salts resulted in the formation of large particles.

The second group of methods is based on modifying mesoporous silica with metal complexes (in particular, complexes that form chemical bonds with silicon or oxygen atoms). The complexes can be incorporated in SiO_2 through the gas phase, by impregnation or by electrochemical treatment.

Jinwoo *et al.*[130] described the preparation of filiform Pd particles in the pores of mesoporous silica by incorporation of palladium hexafluoroacetylacetonate through the gas phase into the pores of an MCM-48 or MCM-41 matrix. Before the process, the matrices were annealed for 8 h at 400 °C. The precursor was incorporated into the pores *in vacuo* at 55 °C (as a result, the colour of the sample changed from white to yellow). The subsequent reduction of the palladium complex at 150 °C in a 10% H_2/N_2 mixture gave palladium nanowires (Fig. 15).

Incorporation of siloferrocenophane $[Fe(C_5H_4)_2SiMe_2]$ into the channels of mesoporous silica followed by polymerisation gave iron-containing particles.[128] It should be noted that the polymerisation of siloferrocenophane is accompanied by the formation of a chemical bond between the silicon atom of the complex and the oxygen atoms of mesoporous silica (Fig. 16 *a*), which allows one to decrease the mobility of the complex within the porous structure. Subsequent pyrolysis of the resulting composites in a stream of nitrogen at 900 °C results in the formation of iron monowires in a silica matrix (Fig. 16 *b*,*c*). Unfortunately, the nanoparticles obtained had nonuniform lengths (they filled the pores only partially) and thicknesses (the thickness nonuniformity can be explained by the partial melting of nanocrystalline iron during the annealing).

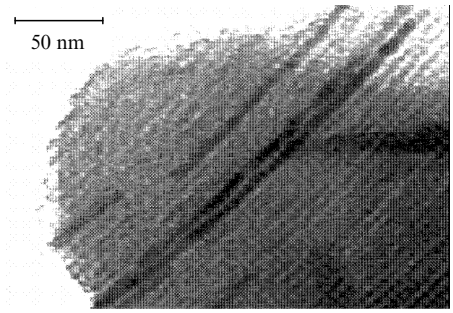

Figure 15. A TEM photomicrograph of Pd nanowires in an MCM-41 matrix.[130]

In the context of the synthesis of uniform particles, the study by Leon *et al.*[129] is of considerable interest. It reports the synthesis of germanium nanoparticles in a mesoporous silica matrix; these particles reproduce the shape and size of the pores. The nanoparticles were obtained by incorporation of Ge_2H_6 into the matrix through the gas phase at a high pressure (5–40 atm) at room temperature followed by thermal decomposition.

The synthesis of nanocomposites by incorporation of a metal complex into a mesoporous matrix in a liquid phase was described by Parala *et al.*[131] The nanoparticles of CdSe were obtained by impregnation of an MCM-41 mesoporous matrix with a solution of Me_2Cd and $(Bu_3P)_2Se$ in tributylphosphine followed by heating to 325 °C in trioctylphosphine oxide. As a result, CdSe nanoparticles with sizes of 3–5 nm formed inside the porous structure of MCM-41.

An alternative method for the synthesis of filiform iron nanoparticles was reported by Napolskii *et al.*[132] A nonpolar iron complex capable of decomposing at low temperatures with weak aggregation of nanoparticles was incorporated into the hydrophobic part of a liquid-crystalline micelle ($C_{16}H_{33}NMe_3Br$) in a mesoporous silica matrix (Fig. 17). $Fe(CO)_5$ was chosen as such a complex. The carbonyl complex was decomposed *in vacuo* under UV irradiation. The particles of metallic iron resulting from the decomposition (Fig. 18 *a*) were shown [133, 134] to contain a considerable fraction of amorphous iron; therefore, it was suggested to additionally crystallise iron particles in the channels of mesoporous silica by annealing in hydrogen flow at moderate temperatures.

The particles obtained after the annealing were characterised by a high anisotropy parameter, which was assessed using two independent methods: the temperature dependence of magnetic susceptibility and the small-angle polarised neutron scattering.[135–137] It was found that decomposition of $Fe(CO)_5$ at high temperatures resulted in a more complete crystallisation of iron, hence the nanocrystals grew lengthwise. Since the diameter of the nanoparticles does not change, this increases the geometrical anisotropy factor. For an iron-containing sample reduced at 375 °C, the anisotropy parameter equals 40, the coercive force is $\sim$450 Œ, and the saturation magnetisation is $\sim$3 emu g^{-1}. Thus, not only nanoparticles were obtained in the pores of mesoporous silica but also their distribution was made homogeneous.

A different approach to the synthesis of nanoparticles in the pores of mesoporous SiO_2 based on the hydrophilisation of the internal surfaces of a silica matrix by ethylenediamine was implemented by Zhang *et al.*[138] The nanoparticles of ZnO (a wide-gap semiconductor) § were obtained by adsorption of Zn^{2+}

§ The interest in ZnO nanoparticles is primarily due to the possibility of employing the latter in elements of short-wave electrooptical devices.

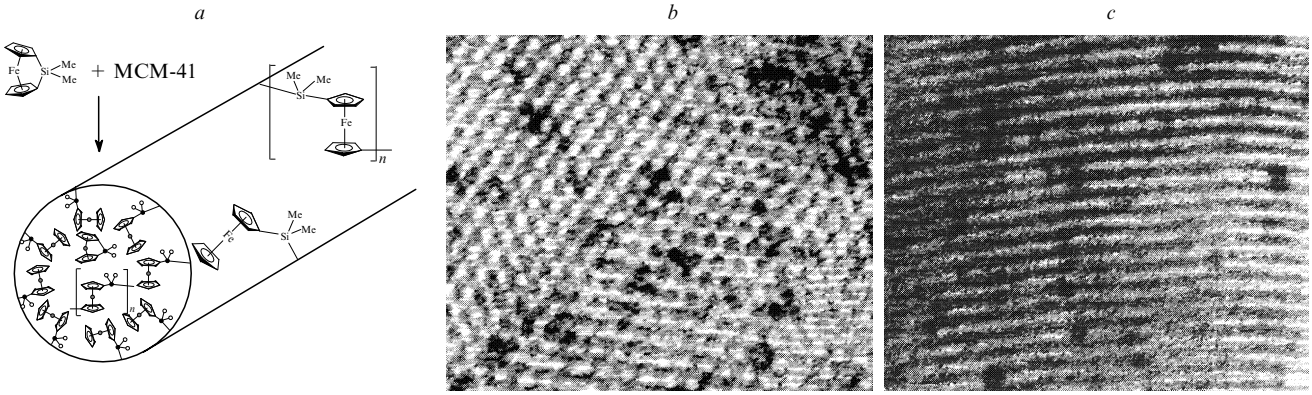

Figure 16. Scheme of the synthesis of iron nanowires in an MCM-41 matrix (*a*) and photomicrographs (*b*, *c*) of the resulting composites (*b* is cross section, *c* is longitudinal section).[128]

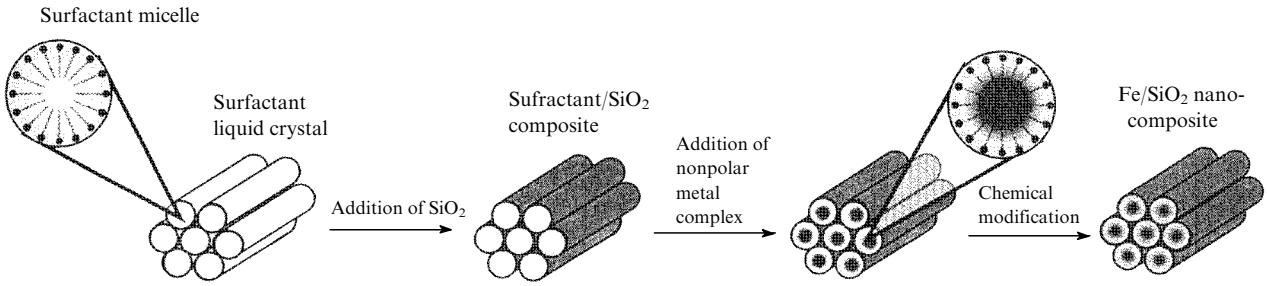

Figure 17. Scheme of synthesising iron nanowires in a mesoporous silica matrix.[132]

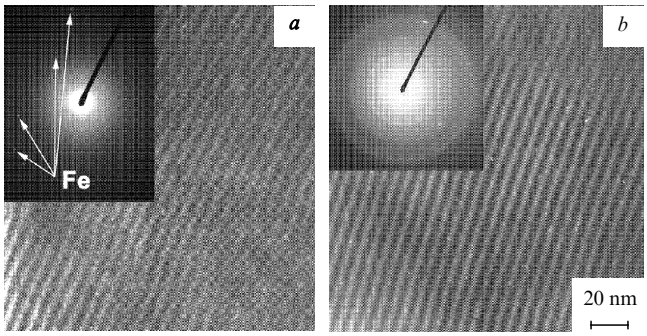

Figure 18. TEM image and electron diffraction (shown in the insets) of iron nanowires in a mesoporous silica matrix obtained by UV irradiation *in vacuo* (*a*) and additional crystallisation at 375 °C (*b*).[133]

cations on a porous silica surface modified with *N*-[3-(trimethoxysilyl)propyl]ethylenediamine followed by annealing in air at 600 °C. In principle, functional groups can be attached to both the internal and external surface of silica. In the latter case, this results in larger ZnO particles on the matrix surface. However, since the major part of the surface of mesoporous silica consists of the internal surfaces of the pores, the reaction of Zn^{2+} cations with ethylenediamine mostly occurs inside the porous structure. TEM data confirm the presence of zinc oxide nanoparticles in the pores of the mesoporous matrix and the absence of large particles on the external surface (Fig. 19). The content of zinc oxide in the samples reaches 9 mass %.

The absorption spectra suggest that the absorption edge of ZnO nanoparticles is shifted to the short-wave region (290 nm), whereas that of macrocrystalline ZnO is at 370 nm (3.1 eV). The considerable blue shift in the absorption spectra is caused by an

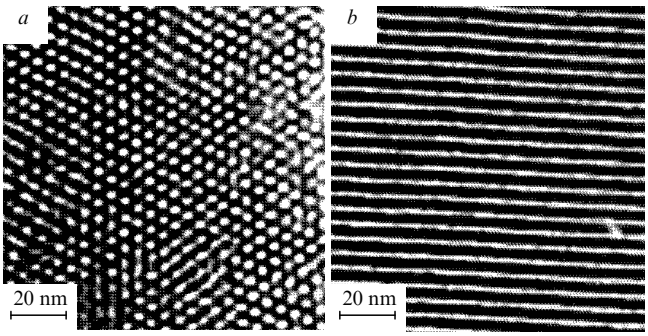

Figure 19. TEM image of ZnO particles in a mesoporous silica matrix;[139] (*a*) cross section, (*b*) longitudinal section.

increase in the band gap, which in turn is a manifestation of the quantum confinement effect. Studies of the photoluminescent properties of zinc oxide nanoparticles show the presence of a rather intense light emission in the blue part of the spectrum ($\sim$460 nm). The suggested method was tried for syntheses of other compounds, but it succeeded only in the case of cobalt oxide. Particles of precious metals such as silver, gold and palladium, as well as particles of nickel and copper oxides, could not be obtained using the method described above.

Particular interest is attracted by the synthesis of one-dimensional nanoparticles utilising films of mesoporous silica, including magnetic nanocomposites for data storage devices with ultra-high density of recording.

The rapid development of information technologies in the past years has necessitated the storage and processing of huge amounts of information, which has required that new devices with ultra-high areal density be created. Principally new magnetic materials with high-precision properties and nonlinear magnetic characteristics have been developed for these purposes.

According to literature data, ferromagnetic nanosized structures are the most promising magnetic materials for storage devices. However, materials based on spherical nanoparticles have low blocking temperatures and a near-zero coercive force at room temperature; therefore, it was suggested to use anisotropic nanoparticles.[139]

Yet another important requirement for magnetic materials based on nanoparticles is that magnetised nanoparticles must be firmly 'fixed' in a matrix to prevent their movement, aggregation and chemical interactions. This can be achieved by synthesising magnetic nanoparticles in nanoreactors. Utilisation of such particles instead of metallic alloys makes it possible to avoid the use of a protective layer on the magnetic data medium and thus to increase the resolution capability of the reading head.

Napolskii *et al.*[132] and Eliseev *et al.*[140] considered the prospects of magnetic nanocomposites obtained on the basis of epitaxial mesoporous SiO_2 films in storage devices with ultrahigh data density. It is known that mesoporous SiO_2 forms epitaxial films on certain supports [*e.g.*, on Si (110)]. It was found that the incorporation of a magnetic material (*e.g.*, iron) into the pores results in an ordered system of magnetic nanoparticles a few nanometres in diameter and several hundred nanometres long (Fig. 20).

Such particles are isolated from each other by silica walls; therefore, exchange interactions between them are sufficiently low.[141] Their geometrical anisotropy is yet another advantage that allows one to stabilise the magnetic moment of a separate particle and increase the coercive force. One more advantage should also be mentioned: the system of magnetic particles in a mesoporous silica reproduces the dimensions, shape and arrangement of pores, hence it is also ordered. This allows a reading head (for example, the tip of a magnetic force microscope) to be positioned with high precision when reading or writing data.[132]

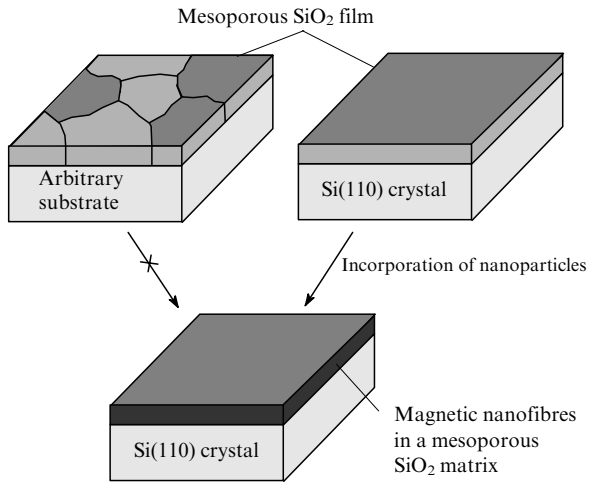

Figure 20. Scheme of growing of epitaxial films of Fe/SiO_2 nanocomposites for devices with ultra-high recording density.

d. Mesoporous aluminosilicates

Mesoporous materials based on silica with an ordered pore arrangement, in which a fraction of silicon atoms are replaced by aluminium atoms, are promising matrices for the synthesis of nanocomposites. Partial replacement of Si atoms by Al atoms in the silica structure creates a negative charge on the matrix, which is proportional to the amount of incorporated aluminium. Cations of transition metals can play the role of positively charged counterions located inside the pores; the number of such ions can be controlled by changing the content of aluminium in the matrix. Reduction of transition metal cations allows one to obtain nanocomposites with a predefined content of a metal phase in the aluminosilicate matrix.

Sasaki *et al.*[142, 143] synthesised platinum nano wires using mesoporous aluminosilicate FSM-16 with a hexagonal arrangement of pores ~ 3 nm in diameter. The matrix was annealed in an oxygen flow at 500 °C, impregnated with an H_2PtCl_6 solution and reduced under UV irradiation in the presence of a propan-2-ol vapour. This gave platinum nanowires 150 – 500 nm long (Fig. 21).

Subsequent utilisation of aluminosilicates for synthesising filiform nanoparticles of transition metals showed [141] that the morphology of nanoparticles in the samples depends on the Si : Al ratio in the aluminosilicate matrices. Nanocomposites containing filiform particles were obtained using aluminosilicate matrices with a small content of aluminium (< 10 mol.%). At higher aluminium concentrations in the matrix, not only nanofibres but also spherical particles with sizes of 3 – 10 nm formed; in this case, the total amount of the transition metal in the nanocomposite decreased. This is presumably explained by the formation of aluminium polyhydroxocomplexes that close the pores and prevent the incorporation of metal ions.

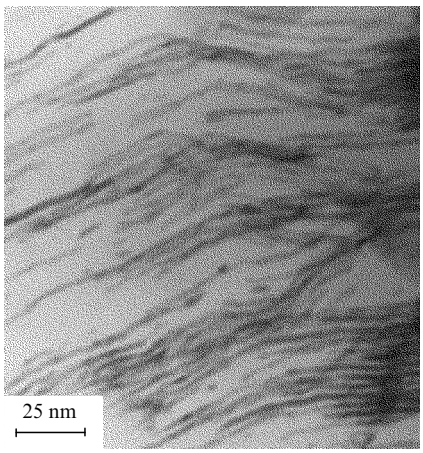

Figure 21. HRTEM photomicrograph of Pt nanowires in an FSM-16 matrix.[143]

Kolesnik *et al.*[144] and Eliseev *et al.*[145] compared the ion-exchanging properties of mesoporous aluminosilicates containing from 5 mol.% to 33 mol.% of aluminium obtained by cohydrolysis of silicon and aluminium compounds or by the hydrothermal method. It was shown that the parameters of ordering of the aluminosilicate structures depend on the hydrolysis rates of silicon and aluminium compounds.[146] It was found that $\sim 90\%$ of the overall number of aluminium atoms present in the reaction mixture are incorporated into the aluminosilicate structure, whereas the remaining 10% form polyhydroxocomplexes and block the pores.

e. Porous alumina

Films of porous alumina obtained by anodic oxidation are intensely studied in the context of their possible utilisation as templates in order to form nanostructured composites. The structures of such films contain an ordered pore system with the closest hexagonal packing, where the pores are arranged at right angles to the substrate surface. Their diameters and distance between the neighbouring pores can be varied in a broad range. The technology for the synthesis of porous alumina and its utilisation as a protective oxide coating has a long history. However, fundamental studies on the processes of self-organisation of nanostructures in a porous alumina matrix started only ten years ago. The latest achievements in the assembly of nanostructures using porous alumina were reviewed by Shingubara.[147] He also considered the utilisation of the resulting nanomaterials as high-density data storage media, functional nanosystems demonstrating quantum confinement effects, high-sensitivity chemical sensors, electronic devices with nanometre sizes and biochemical membranes. The main attention in our review will be given to synthetic approaches to the formation of nanocomposites with ordered structures of active sites in the porous alumina matrix.

The anodic oxidation of aluminium and its alloys in acidic electrolytes have been intensively studied for a long time due to their wide industrial utilisation. An early work [148] describes the structure of the porous alumina cell and the dependence of the lattice cell size on the voltage. A number of publications [149 – 151] report the assumed mechanism of the formation of mesopores during the electrolytic dissolution of aluminium. (Unfortunately, the nature of the nanopore self-organising process has not so far been established unambiguously.) Thompson *et al.*[151] studied the effect of several processes on the formation of nanoporous alumina, including the growth of alumina at the aluminium/alumina interface due to the transfer of Al^{3+}, OH^- and O^{2-} ions from the internal side of the oxide film to the external side, as well as the dissolution and deposition of alumina at the oxide film – solution interface. It is stated [152] that the morphology and conditions for the formation of a hexagonal ordered pore structure in alumina obtained by the anodic oxidation of aluminium in oxalic and sulfuric acids [153] are determined by the dependence of the coefficient of volume expansion of alumina on the anodising voltage and by the oxide formation rate. Nielsch *et al.*[154] assumed that the self-organisation of a structure requires a 10% porosity of the material, irrespective of other anodisation conditions. In other words, it is possible to obtain ordered porous alumina with any size of the lattice cell, provided that the applied voltage and the pH of the electrolyte satisfy the '10% porosity' rule. At present, the difference between the densities of alumina and metallic aluminium is also considered as an important factor for the formation of an ordered porous structure. Since the density of the oxide (~ 3900 kg m^{-3}) exceeds considerably the density of pure alumi-

nium (2698 kg m^{-3}) and electrochemical oxidation occurs only in a thin layer at the oxide film/metal interface, the increase in the density leads to the formation of an ordered porous structure.

The recent outburst of interest in the study of porous alumina was caused by the work by Masuda and Fukuda [155] who described the synthesis of a highly ordered porous alumina structure by two-stage oxidation. Initially, alumina with a highly ordered porous structure at the lower film boundary was obtained by the anodic oxidation of high-purity aluminium for 160 h at 0 °C in 0.3 M oxalic acid at a constant voltage of 40 V. The subsequent selective dissolution of the film in a mixture of 85% H_3PO_4 (35 ml $litre^{-1}$) and CrO_3 (20 g $litre^{-1}$) [156] at 80 °C gave aluminium with highly ordered relief of the surface. The second anodic oxidation of aluminium with such a roughened surface gave an oxide with a highly ordered nanopore structure. Such alumina can be used as a nanoreactor.

Figure 22 shows a typical structure of porous alumina obtained by two-stage anodic oxidation. Scanning electron microscopy data show the hexagonal packing of the nanopores. The mean pore diameter is 36 nm and the distance between the pore centres is ~90 nm. A cross-section of the porous structure (see the inset in Fig. 22) demonstrates the formation of the so-called 'barrier layer' ~30 nm thick with periodic roughness of the aluminium support. The neighbouring pores are separated by side walls ~50 nm thick.

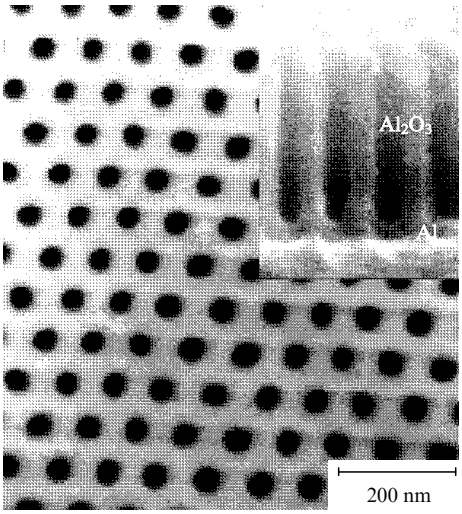

Figure 22. Typical structure of porous alumina obtained by two-stage anodic oxidation. The inset demonstrates the cross section of the film.

The choice of the acid in which the aluminium surface is subjected to anodic oxidation determines the size and geometric arrangement of the nanopores. The anodising voltage (V_a) which provides the formation of a porous alumina with highly ordered pore structure also depends on the acid.

Acid	V_a /V	D_{pore} /nm	D_{cell} /nm
H_2SO_4	25–27	>13	~55
$(COOH)_2$	40	>25	~90
H_3PO_4	195	>200	~500

The dependence of the mean cell size and the diameter of the pores on the voltage of anodic oxidation is shown in Fig. 23 for oxalic acid as the electrolyte.[157] The maximum ordering of the pores is achieved at a voltage of 40 V. The ordering increases with an increase in the duration of the first oxidation and the acid concentration. Masuda *et al.*[158, 159] also studied the conditions of the self-organisation of the porous structure of alumina obtained by the anodic oxidation of aluminium in sulfuric and phosphoric acids.

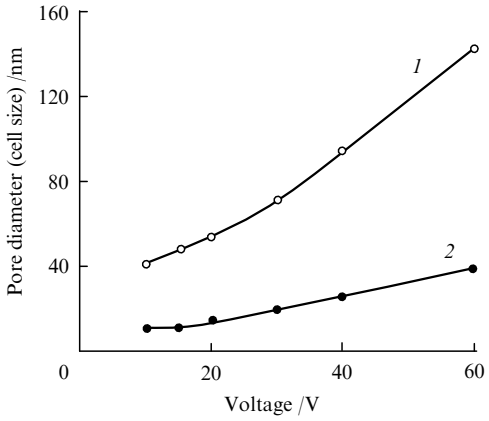

Figure 23. Dependence of the mean cell size (*1*) and pore diameter (*2*) on the anodic oxidation voltage in oxalic acid solution.[157]

Additional etching of the resulting porous material in appropriate acids makes it possible to widen the pores. The cell size of porous alumina differ slightly depending on the electrolyte used (at equal voltages). For example, the cell size in alumina obtained by anodic oxidation at 30–40 V in sulfuric acid is slightly smaller than in that obtained in oxalic acid.

Japanese researchers [160, 161] controlled the formation of mesopores by pretreatment of the starting aluminium surface. To do so, periodic mechanical defects were applied on an aluminium surface (by pressing aluminium with a silicon carbide having a preset surface periodicity at the mesolevel). The press-form was prepared using lithography and dry etching. This approach made it possible to obtain a well-ordered (by depth) pore structure (the ordering zone was 1 mm).

Yet another surface pretreatment method utilises the tip of an atomic force microscope (AFM) to apply defects on aluminium surface.[162] Using a diamond tip, it was found possible to create periodic depressions with a preset depth and geometric arrangement on aluminium surface. This method makes it possible to vary the structure of mesopores in a broad range. In particular, it was used to obtain a thin layer of alumina with a tetragonal pore packing. (As the thickness of the oxide coating increases, the porous structure tends to organise a hexagonal pore packing with a distance of ~90 nm between the pores.) The effect of the distance between the neighbouring defects on the organisation of the porous structure was studied. It was shown that the distance between the neighbouring pores could be varied from 65 to ~100 nm at a constant anodisation voltage of 40 V and that even a small mechanical strain ($\sim 5 \times 10^{-5}$ N) was sufficient for a controlled formation of mesopores by this method.

Alumina with an ordered mesopore structure was used for the synthesis of various nanomaterials. Porous alumina films are used as masks for etching certain materials, as templates for making polymer 'imprints' and as porous matrices for incorporating functional materials by electrochemical, sol–gel and CVD deposition.

Ion or plasma etching of semiconducting materials can serve as examples of the first process. In this case, the porous oxide structure of alumina is copied onto a substrate with a sufficiently high reproducibility.[163–165] Making an 'imprint' of a porous structure on a metal substrate by polymerisation of poly(methyl methacrylate) in the pores of alumina followed by dissolving alumina and sputter-deposition of a metal is a similar process (in this case, porous alumina plays the role of the template).[155] Incorporation of functional components into mesopores of an alumina matrix by electrochemical, sol–gel or CVD deposition is the most popular method for the synthesis of nanocomposites.

Studies of magnetic materials based on porous alumina were started a quarter of a century ago.[166–168] The main purpose of these studies was to create magnetic materials with ultrahigh data

density. The data density on modern data recording media reaches 100 Gb inch^{-2}, and the trend of the growth in the data carrier capacity has been maintained for over four decades. Currently, the possibility of creating materials with data density exceeding 1 Tb inch^{-2} is being studied.

Arrays of densely packed magnetic FePt nanoparticles (Fig. 24) is among the most promising magnetic materials;[169, 170] however, such particles with sizes of about 5–10 nm are in a superparamagnetic state and hence have a zero coercive force at room temperature. Ordered structures could not be obtained from these strongly anisotropic nanoparticles. Free FePt nanoparticles are generally unstable and tend to aggregation, which results in the necessity of creating a protective surface layer; the latter certainly decreases the prospects of using such structures as data media.

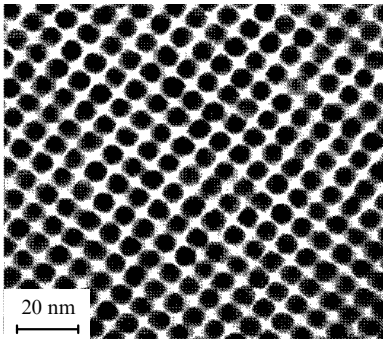

Figure 24. Array of densely packed magnetic FePt nanoparticles.[170]

It could be expected that magnetic nanofibres incorporated in a porous alumina matrix would satisfy the requirements for state-of-the-art data media. The simplicity of creating structures with high geometric anisotropy in the direction perpendicular to the substrate plane makes porous alumina very promising for the development of magnetic materials. Numerous publications are known that deal with the synthesis and study of nanoparticles of nickel,[171–176] iron,[172, 175, 177, 178] cobalt,[172, 175, 179–181] platinides,[173] lead [178] and alloys such as CoFe [182] and NiCo.[183]

Pulse deposition and electrodeposition with alternate current are the most efficient methods to synthesise metals in a porous alumina (deposition with direct current is accompanied by breakdown of the double electric layer, which results in the formation of large particles on the alumina surface). The use of electrodeposition of functional materials into alumina pores encounter a serious problem due to the existence of an Al_2O_3 barrier layer between the aluminium substrate and the lower boundary of a pore. Therefore, various methods have been developed for the removal of the barrier layer.[171, 184] The method for decreasing the barrier layer thickness by gradually decreasing the anodic potential [166] is recognised as the most successful. Yet another problem is that the formation of nanoparticles occurs at the porous structure–substrate interface and diffusion of solution ions to this interface is hindered; because of this, an important role in electrodeposition belongs to the time between successive deposition pulses.[171]

Magnetic Co nanowires with diameters of 10 to 60 nm and with distances of 60 to 120 nm between the adjacent wires (Fig. 25 *a*) were obtained using a porous alumina matrix synthesised by the anodic oxidation in oxalic or sulfuric acid. An HRTEM study of the cross-section of an array of nanofibres showed that the fibres consisted of partially aggregated cobalt nanoparticles (Fig. 25 *b*).[79]

An important advantage of the alumina matrix as a nanoreactor is that it is possible to obtain ferromagnetic fibres of different lengths by varying the duration of electrodeposition. Figure 26 shows the magnetic reversal curves for Co nanowires 5,

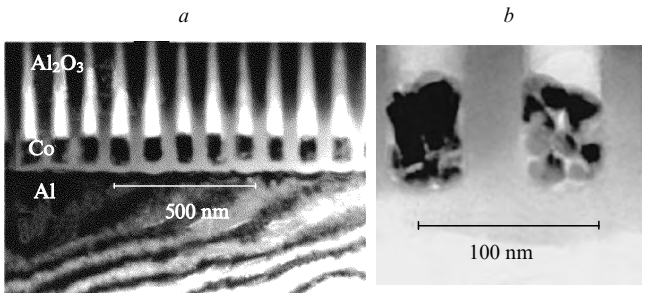

Figure 25. Cross section of an array of magnetic cobalt particles in a porous alumina matrix (*a* and *b* designate different magnifications).[79]

60 and 220 nm long. There are apparent differences in the magnetic anisotropy of such nanowires: cobalt nanowires ~5 nm long have a preferential anisotropy in the substrate plane, whereas longer wires (220 nm) are characterised by anisotropy in the direction perpendicular to the substrate. Thus, the magnetic anisotropy of ferromagnetic wires is mainly determined by the shape of the particles; this behaviour is typical of all ferromagnetic compounds. For iron fibres, there is a critical diameter corresponding to the maximum coercive force (2640 Œ) at room temperature [177] (at 5 K, no maximum on the 'coercive force–fibre diameter' plot was found).

In the $Fe_{1-x}Co_x$ system ($0 < x < 1$) obtained by controlled electrodeposition of the components,[182] a transition from the *bcc* crystal structure (Co content ~33%) to a mixed *hcp–fcc* structure (cobalt content ~67%) was observed. However, the coercive force was found to be almost the same for nanowires of both compositions and 9 nm in diameter: ~2900 Œ (for $Fe_{0.67}Co_{0.33}$) and ~2850 Œ (for $Fe_{0.33}Co_{0.67}$). Thus, the size and anisotropy of nanoparticles are the main factors determining the magnetic characteristics of ferromagnetic particles in the nanometre region.

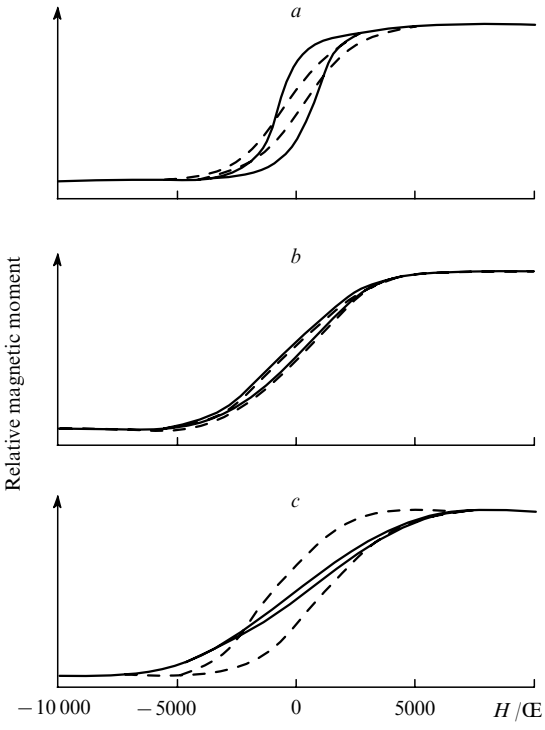

Figure 26. Magnetisation reversal curves for cobalt nanowires 5 nm (*a*), 60 nm (*b*) and 220 nm long (*c*) in a porous alumina matrix (solid line: the field is directed at right angle to the matrix plane; dashed line: the field is directed parallel to the matrix plane).

At the same time, decrease in the nanofibre diameter to 9 nm does not result in superparamagnetism. Calculations show that achieving a data density of about 1 Tb inch^{-2} requires that the distance between the adjacent nanofibres does not exceed 25 nm. This density has not been achieved to date.

In addition, optical nanostructured materials based on porous alumina arouse much interest because they possess a high luminescence intensity. Although the pore sizes in mesoporous alumina exceed the characteristic size required for the quantum confinement effect, it still has good luminescent properties that are not typical of bulk materials. First, porous alumina itself has luminescence in the blue region of the spectrum with a maximum intensity at 460 nm.[185] This emission band appears due to the formation of ionised oxygen vacancies (F^+-centres) in the strongly defective porous structure. The emission intensity can be further intensified by annealing the film at elevated temperatures.

High emission intensities were observed when the structure of mesoporous alumina was filled with zinc oxide. ZnO nanoparticles were synthesised in the matrix by hydrolysis of $Zn(OBu)_2$ in an aqueous medium.[186] The maximum luminescence intensity (485 nm) of zinc oxide nanoparticles approximately coincides with the maximum of irradiation from pure nanostructured ZnO, but the emission intensity of ZnO nanoparticles incorporated in a porous alumina matrix is almost 20 times higher, probably due to the increase in the number of ionised oxygen vacancies in ZnO nanoparticles located inside the alumina pores.

Several publications are available on the synthesis of optically active CdS nanowires prepared by electrodeposition;[187] and Bi_2Te_3;[188] titania doped with terbium or erbium (the sol–gel method);[189, 190] GaN nanoparticles (the sol–gel method),[164, 191] as well as dyes such as Rhodamine 6G and aluminium 8-hydroxyquinolinate[192] in a porous alumina matrix. It was suggested[184] to use anodised alumina for making electroluminescent materials; the aluminium substrate served as the cathode and a layer of conductive glass (ITO) served as the anode (the optically active component was incorporated into the pores). All these studies show the prospects of utilising nanostructures based on porous alumina films as electroluminescent materials.

Yet another use of porous alumina is related to the synthesis of two-dimensional photonic crystals. It is well known that photon band gap appears only if there is a highly ordered porous structure in sufficiently large areas. For this reason, the technology of aluminium pretexturing followed by anodic oxidation was developing in recent years.[157, 160, 161] This approach made it possible to obtain two-dimensional photonic crystals with a photon band gap in the visible spectral region.[193–197]

Porous alumina can be used to create field emitters based on carbon nanotubes. To do so, nanoparticles of metallic cobalt are electrochemically deposited in the pores of alumina (cobalt particles commonly used as catalysts for growth of carbon and carbon nitride nanotubes).[198–205] A photomicrograph of such an emitter is shown in Fig. 27.

Films of porous alumina are also promising as membrane materials. The transport of lithium ions[206] and other one-, two-[207] and trivalent cations[208] depends on the pore diameter, the pH of the medium and the ionic strength of the solution, as well as on the hydraulic permeability[209] of membranes. It is well known that the conductance of porous alumina considerably depends on the humidity. In view of this, an attempt was made to use a cell consisting of a layer of porous alumina compressed between metallic electrodes as a humidity sensor.[210] It was found that in the range from 50 to 100 ppm^{-1}, there is an almost linear dependence of the capacitance of this element on the air humidity, *i.e.*, such sensors are highly sensitive to humidity.

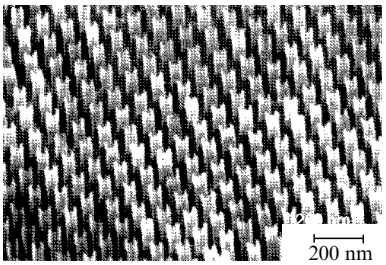

Figure 27. A scanning photomicrograph of a field emitter based on nanotubes synthesised in the pores of alumina.

It follows from the examples considered above that porous alumina is very a promising material for creating nanomaterials for magnetic data storage media, electronic devices, sensors and biomembranes. At present, methods for the synthesis of porous alumina with a pore diameter of $\leqslant 5$ nm are being developed in order to study quantum confinement effects, along with methods for the synthesis of porous membranes on solid semiconducting substrates characterised by high mechanical stability.

3. Synthesis of nanoparticles in two-dimensional nanoreactors. Layered double hydroxides

For two-dimensional nanoreactors, it is most efficient to use layered structures with variable dimensions of the structural cavities. The layers in such compounds are bound by weak van der Waals forces, hence the interlayer distance can be varied easily. Moreover, a layered structure allows one to accelerate considerably the diffusion of gases in the interlayer space and thus facilitate the chemical modification of layered compounds.[211, 212]

Several dozens of studies on the synthesis of nanocomposites using layered matrices have been published (see, *e.g.*, Refs 213–219). The compounds with negatively charged layers and cations in the interlayer space, *viz.*, aluminosilicates, are utilised the most widely. However, such compounds are generally nonstoichiometric, strongly hydrated and have cross-links between the layers; this complicates considerably the synthesis of nanomaterials on their basis and adversely affects the reproducibility of the results.[220, 221] This certainly prevents systematic studies on the mechanisms of nanostructure formation in layered matrices.

Layered double hydroxides (LDHs) with the composition $M^{2+}_{1-x}M^{3+}_x(OH)_2[X^{n-}_{x/n}\cdot m\,H_2O]$ (X is an anion) are the most widespread two-dimensional nanoreactors.[222] To date, compounds with $M^{2+} = Mg^{2+}$, Zn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Cd^{2+}, Sn^{2+}, Mn^{2+}, Pd^{2+}, Pt^{2+} and $M^{3+} = Al^{3+}$, Fe^{3+}, Cr^{3+}, Mn^{3+}, Ga^{3+}, In^{3+}, Bi^{3+}, Y^{3+}, La^{3+}, V^{3+}, Rh^{3+}, Ir^{3+} and Ru^{3+} have been obtained (see Refs 223–230). As a rule, the radii of the M^{2+} and M^{3+} cations participating in the formation of a layered structure should not differ more than 1.5-fold.[231] Virtually any anion or anionic complex can serve as the X^{n-} anion.[232] The structure of an LDH is a system of positively charged hydroxide layers $[M^{2+}_{1-x}M^{3+}_x(OH)_2]^{x+}$ and anions located in the interlayer space (Fig. 28).[233, 234] In addition to anions, the interlayer space commonly contains labile water molecules.[235] The LDH structure as a whole is stable due to the electrostatic interaction between the positively charged hydroxide layers and the interlayer anions bearing negative charges.

LDHs with the compositions $Li_{1-x}M^{3+}_x(OH)_2.[X^{n-}_{(2x-1)/n}\cdot m\,H_2O]$ $(x > 0.5)$[236] and $M^{2+}_{1-x}M^{4+}_x(OH)_2.[X^{n-}_{2x/n}\cdot m\,H_2O]$, where $M^{4+} = Zr^{4+}$, Ti^{4+}, Sn^{4+} or Se^{4+}, are also known (see Refs 237, 238). Moreover, cation-substituted layered hydroxides have been synthesised that contain several cations in oxidation states 2+ and/or 3+, *e.g.*, $M^{2+}_{1-x-y}(M')^{2+}_yM^{3+}_x(OH)_2[X^{n-}_{x/n}\cdot m\,H_2O]$ or $M^{2+}_{1-x-y}M^{3+}_x(M')^{3+}_y.(OH)_2[X^{n-}_{(x+y)/n}\cdot m\,H_2O]$.[239–241]

The vast majority of LDHs crystallise in the trigonal (rhombohedral) system. Hydrotalcite, a natural mineral with the composition $Mg_6Al_2(OH)_{16}[CO_3\cdot 4\,H_2O]$, has this structure. Compounds with the general formula $Mg_{1-x}Al_x(OH)_2[X^{n-}_{x/n}\cdot m\,H_2O]$ and with rhombohedral unit cells are called hydrotalcite-like compounds. Samples with the hydro-

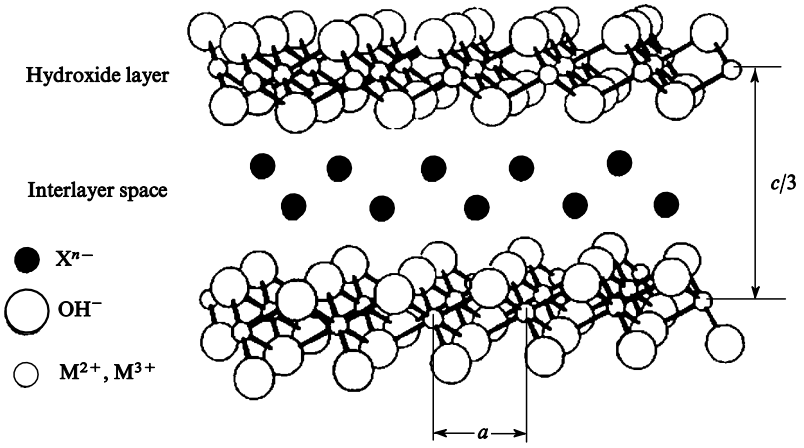

Figure 28. Structure of layered double hydroxides.

talcite structure and with x from 0.05 to 0.4 and m from 0 to 2 were obtained under laboratory conditions.

It should be noted that the arrangement of anions in the interlayer space can vary.[232, 242, 243] For example, the synthesis of LDHs with intercalated polyoxometallates, which have cylindrical symmetry, can result in two types of structures, *viz*., those with parallel and perpendicular arrangement of anions with respect to the hydroxide layers.[244] As a rule, anions are located in the interlayer space in such a way that its dimensions are minimised. However, as the $M^{3+}:M^{2+}$ ratio increases, the positive charge of the hydroxide layers also increases and more anions are required to compensate for it. If the charge of the anions is small, they can fail to fit in the interlayer space due to steric hindrance. Therefore, as the concentration of anions in the interlayer space increases, they need to be grouped into structures that are packed more densely. This is achieved either by arrangement of cylindrical anions at right angles to the hydroxide layers or by arrangement of anions in the interlayer space in two layers parallel to the hydroxide layers; in any case, this results in an increase in the interlayer distance. As a rule, if the unit cell parameter c and the anion size are known, it is possible to determine exactly which type of structure will be realised in a specific case.[245]

Layered double hydroxides have a number of unique properties that are important for the directed synthesis of nanomaterials. The stability of the layered structure of LDHs in a wide range of cation and anion sizes is among these properties. For example, samples of Mg-Al-LDHs containing various anions with sizes from 0.3 to 5 nm in the interlayer distance have been obtained. Furthermore, the number of anions present in the interlayer space of an LDH is determined by the $M^{z+}:M^{3+}$ ratio, which is easy to control during the synthesis. This makes it possible to obtain LDHs with preset stoichiometric compositions and hence to vary the concentration of reaction centres in a matrix.

The thermal stability of LDHs is yet another important property (thermal decomposition of LDHs occurs with retention of their layered structure). As a result, chemical reactions involving anions located in the interlayer space (*e.g*., reduction with hydrogen required for the preparation of magnetic nanocomposites) can be performed at elevated temperatures almost without destruction of the matrix that confines the reaction zone.

These properties open up rich possibilities for the chemical design of nanocomposite materials based on LDHs. First, the wide choice of cations makes it possible to choose a matrix that would satisfy the entire set of properties required from a material. For example, a diamagnetic matrix can be chosen for the synthesis of magnetic nanomaterials, or a matrix that is optically transparent in a specific spectral region can be selected for the preparation of optical nanocomposites. Second, by varying the $M^{2+}:M^{3+}$ cation ratio (*i.e*., the x value) and selecting a particular anionic complex and a chemical modification method, it is possible to vary widely the size and shape of nanoparticles.

Coprecipitation of hydroxides of M^{2+} and M^{3+} metals with an alkali from solutions of their salts at a controlled pH is the main method for synthesising LDHs.[246] To obtain an LDH with desired anions in the interlayer space, the coprecipitation is carried out in the presence of these anions in the initial solution:

$$(1-x)\,M^{2+} + x\,M^{3+} + 2\,OH^- + (x/n)\,X^{n-} \longrightarrow$$
$$\longrightarrow M^{2+}_{1-x}M^{3+}_{x}(OH)_2[X^{n-}_{x/n}].$$

It should be taken into account that if two or more types of anions are present in the solution, one of them will be incorporated preferentially.[247] The ability of anions to undergo preferential incorporation into the interlayer space is often called the selective intercalation constant of an anion. It depends both on the nature of the LDHs and on the conditions of the synthesis (pH, temperature).

A number of techniques are used to obtain LDHs with different anions in the interlayer space. LDHs in the carbonate or chloride form are usually utilised as the starting compounds.

Coprecipitation in the presence of an anion (the method described above). This method is very easy to implement but it does not allow one to obtain LDHs containing just one type of anions in the interlayer space. For this reason, it is only used where the required anion has a high selective intercalation constant.

Direct exchange of anions. This method is based on the anion-exchange properties of LDH.[248] If hydrotalcite (the carbonate form of LDH) is placed in a solution containing the required anion X^{n-}, partial exchange of carbonate ions for X^{n-} occurs, *i.e*., intercalation of the required anion into the interlayer space:

$$Mg_{1-x}Al_x\,(OH)_2[(CO^{2-}_3)_{x/2}] + (x/n)\,X^{n-} \rightleftharpoons$$
$$\rightleftharpoons Mg_{1-x}Al_x(OH)_2[X^{n-}_{x/n}] + (x/2)\,CO^{2-}_3.$$

Since the CO^{2-}_3 anions have a high selective intercalation constant, their complete displacement requires that hydrotalcite be repeatedly treated with a solution of X^{n-} (see Ref. 249). The main advantages of the ion-exchange method include its simplicity and the possibility of obtaining practically pure anion-substituted LDHs. However, the use of the ion exchange method does not allow one to obtain LDHs with large anions that generally have low selective intercalation constants. According to Drezdzon,[250] anion exchange is practically impossible if the size of X^{n-} exceeds 0.6–0.7 nm.

Syntheses of LDHs containing large anionic complexes by anion exchange usually involve sonication. For example, the synthesis of Mg-Al- and Zn-Al-LDHs containing anionic complexes of heteropolymetallates with sizes up to 1.5 nm by

exchange of NO_3^- anions for the corresponding anionic complexes on ultrasonic treatment of the system was described.[251,252]

Interaction of an X^{n-} solution with layered double oxides (LDOs). The method is based on the so-called 'memory effect' that is shown by LDOs obtained by thermal decomposition of LDHs. This effect was found by Chibwe and Jones[253] who showed that treatment of Mg-Al-LDOs with a dilute solution of a salt results in their rehydration to give LDHs with solution anions intercalated into the interlayer space:[254]

$$Mg_{1-x}Al_x(OH)_2[(CO_3)_{x/2}] \xrightarrow{150\ ^\circ C} \longrightarrow Mg_{1-x}Al_xO_{1+x/2} + H_2O + (x/2)\,CO_2,$$

$$Mg_{1-x}Al_xO_{1+x/2} + (x/n)\,X^{n-} + (1+x/2)\,H_2O \longrightarrow Mg_{1-x}Al_x(OH)_2[X^{n-}_{x/n}] + x\,OH^-.$$

Melt technique is based on the intercalation of carboxylate anions into LDHs. This method was implemented by heating a mixture of a solid carboxylic acid and hydrotalcite (or the corresponding LDO) at a rate of no more than 10 deg min^{-1} to a temperature $\sim$10 °C higher than the melting point of the acid.[255] The mixture was kept for 8 h at this temperature and then cooled to room temperature at a rate of $\sim$10 deg min^{-1}.

Many functional properties of materials based on LDHs are related to the special properties of anions intercalated into them. For example, the high reactivity of catalysts based on LDHs is usually due to the catalytic properties of the intercalated ions or products of their thermal decomposition. Depending on the nature of the anion, LDHs can show various magnetic, optical and electrophysical properties. For example, the presence of polymeric anions in the interlayer space induces unusual viscoelastic properties.[248,256]

Due to the sufficiently high interlayer distance in LDHs, diffusion of gases into the interlayer space occurs rather fast. This property is very important for the creation of catalysts and sensor materials with short response times. Moreover, the large interlayer distance makes it possible to perform the chemical modification of LDHs with various gaseous reagents without damaging the layered structure.

Layered double hydroxides are widely employed as catalysts for various organic reactions. Hydrotalcite-like LDHs with intercalated ions of polyoxometallates and Ni-containing LDHs obtained by thermal decomposition or reduction of various nickelates to metallic nickel by treatment with hydrogen are used most widely.[257–259]

Tichit *et al.*[260] describes a hydrogenation catalyst obtained by reduction of $Ni_{2.82}Al(OH)_{7.64}[(NO_3)_{0.17}(CO_3)_{0.41}\cdot 2.46\,H_2O]$ with hydrogen (T = 700 °C). It is a composite consisting of particles of metallic nickel and Al_2O_3; the sizes of these particles are several hundred nanometres. This catalyst is currently among the best nickel-based hydrogenation catalysts.[261]

There are several reasons that explain the popularity of LDH-based catalysts. First, owing to the high specific surface area and the presence of a rather wide interlayer space, they show a high catalytic activity. Second, a hydroxide matrix is an inert carrier for polyoxometallates that does not impair their catalytic properties over the entire lifetime of the catalysts. Third, both hydrotalcite-like LDH-catalysts in the polyoxometallate form and Ni-containing LDH-catalysts can operate at temperatures up to 800 °C without losing their catalytic properties and without a considerable decrease in the specific surface. Finally, the bulk distribution of the catalytic sites (polyoxometallates or metallic nickel) in such catalysts is very homogeneous, which increases the relative catalytic activity per unit mass. Moreover, the preparation of LDH-based catalysts is not too difficult. In fact, LDH-catalysts with polyoxometallate ions intercalated into them became strong competitors for classic oxide catalysts (SiO_2, Al_2O_3) impregnated with salts of various polyoxometallates.[262–264]

Some LDHs find use as solid electrolytes and electrodes due to the ionic conductance they possess.[265–268] The rather high ionic conductance of LDHs results from the high mobility of anions in the interlayer space. For example, the conductance of $Zn_2Cr(OH)_6[Cl\cdot m\,H_2O]$ at 17 °C is $10^{-3}\ \Omega^{-1}\ cm^{-1}$. Replacement of chloride ions by other anions decreases the conductance of this LDH to $10^{-4}\ \Omega^{-1}\ cm^{-1}$ (see Ref. 269). The authors called such compounds 'quasi-two-dimensional' electrolytes due to their high ionic conductance and layered structure. The ionic conductance of LDHs enables their practical application in sensors.[270,271]

The existence of rigid hydroxide layers that confine the interlayer space in the LDH structure creates conditions for the synthesis of nanosystems similar to conditions for their synthesis in nanoreactors.

The possibility of synthesising nanostructures with the use of LDHs was studied by a number of scientific groups. For example, the synthesis of a composite of cadmium sulfide nanoparticles and a solid solution of cadmium and zinc sulfides in the interlayer space of LDHs was reported.[272] An Mg-Al-LDH with intercalated $Cd(edta)^{2-}$ complex was used as the starting compound. The latter was obtained by treatment of an Mg-Al-LDO with an aqueous solution containing the above complex. Unfortunately, the EDTA-complex of cadmium used in this study was contaminated with nitrate ions that were also intercalated into the interlayer space. As a result, a compound with the composition $Mg_{0.654}Al_{0.346}(OH)_2[\{Cd(edta)\}_{0.075}(NO_3)_{0.196}\cdot 1.13\,H_2O]$ was obtained.

The size of the interlayer space in this compound was 0.285 nm (X-ray diffraction data). Since this distance matched the size of the Cd complex in the planar four-coordinate state (0.280 nm), it was assumed that the $Cd(edta)^{2-}$ complex was arranged in the interlayer space parallel to the hydroxide layers. The substituted LDH was sulfidised with sodium sulfide. The formation of cadmium sulfide follows from the change in the LDH colour from white to yellow and the appearance of cadmium sulfide reflections in the X-ray diffraction diagram. In fact, according to X-ray data, the interlayer distance in the LDH virtually did not change during the sulfidising, while the reflections of cadmium sulfide broadened considerably. Presumably, the sulfide was formed in the interlayer space of the LDH as plates no thicker than the interlayer distance (0.285 nm). However, this conclusion disagrees with spectrophotometric analysis data, according to which the absorption band edge for the samples obtained lies in the region of 460–480 nm; these values correspond to particles larger than 10 nm. This fact probably suggests that cadmium sulfide is most likely formed not only in the interlayer space but also on the surfaces of LDH particles. This conclusion is supported by the fact that sulfidising inevitably involves the anion exchange of interplanar ions for sulfide ions from the solution. In this case, sulfidising of the deintercalated cadmium complex should occur directly on the surfaces of the LDH particles.

Sato *et al.*[213,219,273–275] obtained nanosized cadmium and zinc sulfides using other layered compounds such as montmorillonite $\{(Na,K,Ca)(Al,Fe,Mg)[(Si,Al)_4O_{10}](OH)_2\cdot n\,H_2O\}$, $H_4Nb_6O_{17}$ and $H_2Ti_4O_9$.

Isupov *et al.*[276–281] studied the thermolysis of Li-Al-LDHs containing EDTA-complexes of certain transition metals. They showed that the thermal decomposition of $LiAl_2(OH)_6[\{M(edta)\}_{0.5}\cdot 2\,H_2O]$ (M = Cu, Co, Ni) *in vacuo* in an Li-Al oxide matrix resulted in nanoparticles of the transition metal M and that the size and morphology of the nanoparticles depended on the metal selected and on the decomposition conditions.

Thermolysis of Cu-containing LDHs at 400 °C gives spherical copper particles with sizes of 2–5 nm (in the interlayer space of the matrix) and 5–80 nm (on the surface), whereas thermolysis of Ni-containing LDHs gives spherical nickel particles with a $\sim$5 nm diameter and a very narrow size distribution. An increase

in the thermolysis temperature to 800 °C results in a growth in the particle size to 15 nm with a simultaneous broadening of the distribution. At the same time, thermolysis of Co-containing LDHs at 400–800 °C results in large (~100 nm) metal particles in the shape of disks, the size and morphology of which is virtually independent of the thermolysis temperature. It was shown that the reduction of the metal in the complex starts almost simultaneously with the end of the dehydration of the layered matrix. The formation of nanosized particles was explained by the influence of the matrix on the reduction process. Unfortunately, no conclusions were made concerning the reasons for the changes in the dependence of the size and morphology of the nanoparticles on the metal chosen and on the thermolysis conditions. It should be noted that decomposition of LDHs is accompanied by pyrolysis of the organic ligand to give amorphous carbon; as a result, final product is considerably contaminated with admixtures of metal carbides and the material loses its functional properties.

The formation of LDHs and the synthesis of nanocomposites on their basis were also studied by Tretyakov *et al.*[66, 282–292]

They performed[286, 291, 292] a detailed study of the anisotropy of iron and nickel nanoparticles obtained by reduction of anion-substituted Mg-Al-LDHs with different compositions in a stream of hydrogen at different temperatures (300–1000 °C). Based on electron microscopy data and magnetic measurements, the concentration dependences of the transverse and longitudinal anisotropy of metal nanophase reduced at different temperatures (see Ref. 66) were plotted. It was shown that, depending on the composition of the starting anion-substituted LDHs, metal nanoparticles with different dimensionality, *viz.*, from one- to three-dimensional, were formed in this system. An increase in the content of the metal complex in the LDH matrix resulted in a decrease in the dimensionality of the nanoparticles that formed and an increase in the anisotropy factor. It should be noted that the reduction temperature almost did not affect the morphology of the nanoparticles formed: an increase in the reduction temperature increased only the mean size of the nanoparticles, whereas their anisotropy changed insignificantly.

Yet another direction of studies by this group of researchers involved the synthesis of semiconducting nanostructures in the MS/Mg–Al–O system (M = Pb, Zn, Cd).[289, 290, 293, 294] They showed that direct sulfidising of Pb, Zn and Cd complexes intercalated in LDH in a stream of hydrogen sulfide at room temperature is unsuitable for the synthesis of MS/LDH nanocomposites. Therefore, they suggested using LDH systems where the formation of sulfides resulted from the decomposition of an intercalated sulfur-containing metal complex. Thiosulfate, thiocyanate and diethyldithiocarbamate compounds of Pb, Zn and Cd were used as such complexes. Decomposition of the latter ($T_{decomp} < 200$ °C)¶ in the interlayer space occurred without degradation of the LDH structure. For example, PbS/LDHs were obtained by thermal (100–200 °C) or photochemical (UV irradiation at 77 K) decomposition of $Mg_3Al(OH)_8 \cdot [\{Pb(S_2O_3)_2\}_{0.5} \cdot m\,H_2O]$.[290]

A considerable amount of attention was paid to the optical properties of the products obtained. High-resolution spectroscopy in the visible and UV spectral regions showed that the absorption edge for the PbS/LDH samples obtained by thermal treatment was within 500–750 nm. An increase in the annealing temperature shifts the absorption edge to the long-wave region, which indicates an increase in the particle size. Calculations show that the particle size changes insignificantly and lies within 3–5 nm for all the samples obtained. The spectrum of the sample obtained by UV irradiation shows additional maxima at ~580, ~400 and ~300 nm (Fig. 29) [for comparison, Fig. 29 also shows the spectra for the sample obtained by thermal decomposition (dashed line)]. These values are in good agreement with the $1S_e-1S_h$, $1S_e-1P_h$ and $1S_h-1P_e$ exciton transitions of lead sulfide.

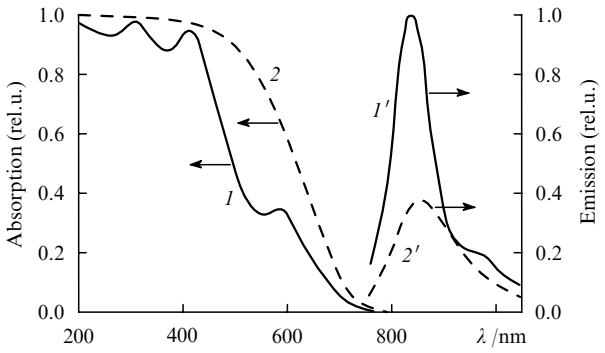

Figure 29. Absorption (*1*, *2*) and photoluminescence spectra (*1′*, *2′*) of PbS/LDH nanocomposites obtained by thermal decomposition at 200 °C (dashed line) and by decomposition under UV irradiation (solid line).[290]

These transitions are usually not observed in the spectra of PbS but they appear in the spectra of the PbS sol synthesised in the presence of polyvinyl alcohol.[295] Similar spectra were also obtained for nanoparticles of lead sulfide stabilised by protein molecules.[296] It is believed that the appearance of forbidden exciton transitions in PbS spectra is due to the modification of the nanoparticles' surfaces.

The photoluminescence spectra of the samples obtained by annealing at 200 °C and by UV photolysis are shown in the right part of Fig. 29. Each spectrum is characterised by the presence of two peaks at λ = 840 and 910–940 nm: the first one corresponds to the luminescent transition over the band gap, whereas the second one corresponds to the transition over the energy levels formed by surface defects. It should be noted that the integral intensity of the luminescence peak of the main state (transition over the band gap) for the sample obtained by UV irradiation is about four times higher than that for the sample obtained by annealing at T = 200 °C, which suggests that the quantum yield of luminescence increases.

The products of thermal and UV-induced decomposition of LDHs with intercalated $Pb(S_2O_3)_2^{2-}$ ions were studied by HRTEM.[290] A detailed study showed (Fig. 30)[290] that the PbS nanoparticles in the sample synthesised by UV photolysis have an amorphous shell, whereas those in the sample obtained by thermal

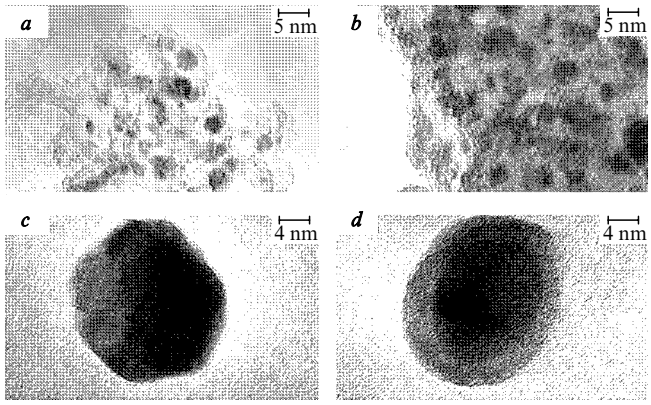

Figure 30. High-resolution electron photomicrographs of PbS particles in an LDH matrix obtained by thermal decomposition at 200 °C (*a*) and by decomposition under UV irradiation (*b*) (*c*, *d* are detailed photomicrographs of the largest particles).[290]

¶ It should be noted that in this case, the layered structure of the LDH affects the formation of semiconducting nanoparticles much more strongly than in the case where magnetic nanocomposites are synthesised by reduction at much higher temperatures than the destruction temperature of the LDH structure.

decomposition at 200 °C do not have such a shell. It is believed that the shell consists of amorphous sulfur that results from the UV-induced decomposition of the thiosulfate complex at low temperature; the absence of a similar shell in the sample obtained by thermal treatment is explained by the melting of elementary sulfur (m.p. = 119 °C). Most probably, the fact that nanoparticles of lead sulfide have an amorphous shell explains the appearance of exciton transitions in the absorption spectra and the increase in the photoluminescence intensity.

It should be noted that the optical properties of semiconducting nanoparticles depend not only on their composition, structure and size but also on the condition of the surface. It was shown that many defects on nanoparticle surfaces (*e.g.*, adsorbed atoms or structural point defects) can serve as potential holes or barriers for holes and electrons.[15] As a result, a change in the band structure and degradation of the optical properties of the nanosystem occur; the smaller the particles the more sensitive these changes to defects. In order to prevent such changes, passivation is used that makes it possible to bind the surface atoms with some other compound having a wider band gap.[297, 298] In other words, the particles are coated with a layer of an inert compound to give the so-called 'core–shell' nanoparticles. This improves considerably the optical properties of nanoparticles; as a result, these properties approach those of isolated nanoclusters.

The passivation effect is especially pronounced in luminescent properties of nanosystems.[299] In fact, the quantum yield of luminescence for coated nanoparticles of cadmium sulfide or selenide is considerably increased (almost by an order of magnitude) in comparison with free nanoparticles.[300, 301] According to literature data, the synthesis of nanoparticles in a shell is rather a complex multistage task. However, the authors succeeded in performing a one-stage synthesis of nanoparticles in a shell using anion-substituted LDHs. The interest in 'core–shell' systems is primarily related to the fact that the presence of a shell of a semiconductor with a large band gap or a dielectric results in the 'healing' of the majority of surface defects and an abrupt increase in the quantum yield of luminescence. Therefore, nanoparticles in shells show promise for creating lasers based on quantum points with adjustable wavelength and high generated power.

Yet another specific feature of LDHs is that destruction of the layered structure into separate hydroxide layers is possible. In fact, in the reaction of a dodecylsulfate-substituted Zn-Al-LDH $\{Zn_{0.67}Al_{0.33}(OH)_2[(C_{12}H_{25}SO_4)_{0.33}\cdot 2.1\,H_2O]\}$ with butanol at 120 °C, the layered structure is destructed in 24 h to give a colloid solution [302, 303] in which separate hydroxide layers are surrounded by surfactant molecules. Shaking this solution with aqueous solutions of salts results in sedimentation and recovery of the layered structure of the LDH (restructuring of the layered structure). In this case, solution anions are incorporated in the interlayer space. Hibino and Jones [304] described the destruction of the layered structure of an Mg-Al-LDH, which contained glycine anions in the interlayer space, on treatment with formamide. It was noted that the process occurred rather quickly even at room temperature.

A study of the reversible LDH for a pre-destructured sample of $Mg_2Al(OH)_6[(C_{12}H_{25}SO_4)\cdot m\,H_2O]$ showed that total recovery of the layered structure of the destructured LDH sample occurred in water and in aqueous solutions.

The reversible destruction of LDH into hydroxide layers may turn out to be rather promising for synthesising nanocomposite particles. It can be assumed that restructuring of a colloid solution of LDH layers in the presence of nanoparticles would result in the incorporation of the latter into the interlayer space of the LDH. In fact, the reaction of a colloid solution of a dodecylsulfate-substituted LDH in chloroform with a PbS sol gave a PbS/LDH nanocomposite.[289] The PbS particles formed in the matrix of the layered double hydroxide have sizes of 3–8 nm. The considerable broadening of the (00*l*) reflexes of the LDH and the low intensity of other reflexes suggest a violation of the mutual arrangement of the hydroxide layers due to intercalation of the PbS nanoparticles into the interlayer space. The accessibility of the starting reagents, the simplicity and cheapness of the synthesis, the facility of controlling the quantitative composition of the intermediates and final products and the possibility of incorporating various anions into the LDH structure make this method very promising for the synthesis of virtually any class of functional nanocomposites.

* * *

It should be noted in conclusion that utilisation of nanoreactors opens up rich possibilities for designing functional nanomaterials with predefined physicochemical characteristics that can find use in various fields of science and technology (*e.g.*, magnetic data storage devices, electronic devices, sensors, catalysts, membrane materials, *etc.*). A solid-state matrix makes it possible to avoid the aggregation of nanoparticles and protect them from external exposures, which facilitates considerably the application of such materials.

This review was financially supported in part by the Russian Foundation for Basic Research (Project No. 03-03-32182) and the programme for the State support of the leading scientific schools of the RF (Project NSh-2033.2003.3).

V.	Conclusion	935

Abstract. The review surveys different aspects of chemical studies of semiconducting clathrates belonging to a unique family of inclusion compounds. The classification, crystal and electronic structures, properties and methods for the synthesis of semiconducting clathrates are considered on the basis of analysis of recent publications. The prospects for fundamental research and the construction of new-generation materials based on semiconducting clathrates are discussed. The bibliography includes 161 references.

I. Introduction

The term 'clathrates' refers to compounds with a three-dimensional framework structure (host), whose cavities are occupied by isolated (in rare instances, one-dimensional infinite) associates of molecules, atoms or ions (guests), which do not form covalent bonds with the framework.[1] The crystal lattice of the host cannot exist in the absence of a guest. For the framework to be stabilised, cavities must be at least partially occupied. For this reason, clathrates are synthesised by co-crystallisation of a host and a guest. Generally, species included into a three-dimensional matrix cannot leave the latter without destruction of the overall architecture. The name 'clathrate' was first used by Powell in 1948 [2] (after the Latin word *clathratus*, which means 'enclosed or protected by cross bars of a grating'). Sometimes, the term 'clathrate' is used in a broader sense and applied not only to compounds in which the host has a three-dimensional structure (framework clathrates), but also to compounds with two-dimensional (layered clathrates or intercalates) and zero-dimensional (molecular clathrates) host structures. Examples are layered inclusion compounds of graphite and complexes of crown ethers with alkali metals. However, an extension of the term 'clathrate' to such systems is not commonly accepted.[2]

Over many years, only gas hydrates and compounds based on hydroquinone and urea have been assigned to clathrates, which have been considered as an exotic variety of inclusion compounds.[3] These compounds have attracted some interest from researchers because of their unusual structures. Certain silicates [4] and silicides [5] isostructural to gas hydrates and then germanides and stannides,[6] which were characterised in 1960 – 1980s, also aroused some interest. Only about two tens of papers have been published over the last 30 years.

The situation changed radically after the development of the Phonon Glass – Electron Crystal concept.[7] Taking into account this concept, particular inclusion compounds, which are poor conductors of heat (as amorphous compounds) and good conductors of electricity (as covalent semiconductors), can serve as a basis for the design of new-generation heat-saving materials.[8] In particular, this class of compounds includes clathrate germanides and stannides. The results of initial experiments published in 1998 [9] already confirmed that clathrates are promising new materials for thermoelectric cooling. This stimulated interest in semiconducting clathrates, as evidenced by a sharply increasing number of publications devoted to various aspects of the chemistry and physics of these compounds. In 2000, Bobev and Sevov published a brief review [10] concerned with the chemical aspects of clathrates. One year later, Nolas, Slack and Schjuman published a comprehensive review,[11] where the results of studies of the physical properties were discussed and related to the structural data.

Since that time, new types of clathrates have been synthesised. New data on the characteristic features of their crystal and electronic structures were obtained, which gave an insight into unusual transport properties of these compounds. Finally, clathrate silicides were found to exhibit superconducting properties. Therefore, the accumulated data on the crystal and electronic structures and the properties of semiconducting clathrates needed to be summarised. Our review is devoted to these problems. We consider the classification, crystal and electronic structures of semiconducting clathrates and some specific physical properties of these compounds determined by their structures. We also discuss prospects for gaining fundamental knowledge and constructing new materials.

Crystal hydrates of gases and liquids are the best known representatives of the clathrate family. Chlorine hydrate was discovered as early as 1811 by Davy, when he passed chlorine through water cooled to 2 – 3 °C.[12] In 1823, Faraday determined the composition of the new compound as $Cl_2 \cdot 10\,H_2O$,[1] which is close to the true composition $Cl_2 \cdot 7.25\,H_2O$. The crystal structure of chlorine hydrate was established by Allen as late as 1952.[13] In this compound, water molecules are linked by hydrogen bonds to form a three-dimensional framework (Fig. 1). Each water molecule is linked to four other water molecules. The framework contains polyhedral cavities. The oxygen atoms occupy the corners of these polyhedra, whereas the hydrogen atoms are

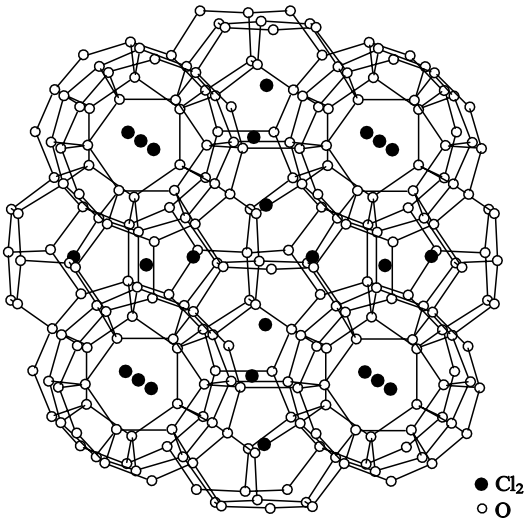

Figure 1. Crystal structure of chlorine hydrate $(Cl_2)_{6.34}[H_2O]_{46}$. Hydrogen atoms are omitted.

located at their edges. In the chlorine hydrate, there are 8 polyhedral cavities per 46 water molecules. If all cavities are occupied by chlorine molecules, the idealised formula is $(Cl_2)_8[H_2O]_{46}$. However, the true composition of the compound is close to $(Cl_2)_{6.34}[H_2O]_{46}$, and the chlorine molecules occupy cavities only partially. Strictly speaking, this compound cannot be assigned to hydrates based on its crystal structure. Nevertheless, this is the commonly accepted term, which is universally used in the literature.[1,3]

Numerous hydrates of other gases (for example, of noble gases Ar, Kr and Xe), gaseous and liquid inorganic compounds (N_2, O_2, CO_2, H_2S, PH_3, SO_2) and organic compounds [CH_4, CH_3Cl, C_2H_6, C_3H_8, $CHCl_3$, CH_3NO_2, cyclopentane, cyclobutanone, $(n\text{-}C_4H_9)_3SF$] were synthesised.[14] Clathrates in which compounds other than water (for example, phenol or hydroquinone) serve as the host are also known.[15] In all cases, the ratio of the cavity size in the host framework to the size of the guest molecules or atoms plays a decisive role in the formation of a clathrate structure, whereas the chemical nature of the guest molecules is of minor importance. Actually, small hydrogen, helium and neon molecules do not form such structures with water, whereas H_2S, PH_3, Cl_2 and Br_2, which have suitable sizes, are involved in such compounds even though they are chemically active and differ in acid-base and redox properties. It should be noted that the hydrogen hydrate can be prepared under high pressure, but the cavities in the framework formed by water molecules are occupied by clusters formed by two or four H_2 molecules, whose sizes match those of the cavities of different types.[16] All the above facts indicate that the size factor has a determining effect on the formation and stability of clathrates.

Prerequisites for the formation of clathrate structures are the presence of a host matrix built from tetrafunctional units (each unit forms four bonds within the matrix) and the ability of the corresponding guest species to occupy the cavities in the framework formed. In hydrates of gases and liquids, the host and guest atoms are formally uncharged, although it is these weak Coulombic interactions that play the major role in the stabilisation of the structure. All known hydrates crystallise in seven structural types, which differ in the type of polyhedra formed in the framework and the mode of their arrangement in the three-dimensional structure.[3]

Virtually all hydrates of gases and liquids decompose on heating, which strongly limits their application. Nevertheless, the possibility of using methane hydrate as a natural nanocrystalline container is discussed taking into account vast resources of methane, which exists as crystal hydrate on the World's Ocean Floor. There are plans to recover and transport these resources in the solid state.[17]

In addition to hydrates, there are about 120 inorganic compounds with clathrate structures, which are referred to as semiconducting clathrates. Our review is devoted to the latter compounds. In such clathrates, a three-dimensional framework is formed primarily by Group 14 elements (Si, Ge or Sn). These compounds are sometimes loosely (in our opinion) called 'intermetallic clathrates'.[18] It should be noted that the first compounds of this class, which were synthesised in the 1960s,[3] can be assigned to intermetallides because their frameworks consist of silicon atoms and the cavities are occupied by alkali metal cations. However, this is not correct for analogous compounds with pnicogens (P, As and Sb), tellurium and halogens (Cl, Br and I), which were also synthesised.[19–32] Therefore, the term 'intermetallic' can be applied only to some semiconducting clathrates. The term 'semiconducting' is also not perfect because the above compounds do not all have semiconducting properties (particular phases exhibit metallic conductivity). However, in our opinion, the term 'semiconducting' is more universal. Hereinafter, we shall use this term for all compounds of the class under consideration.

In contrast to hydrates, in which the host and guest atoms are formally uncharged, the framework and the guest atoms in semiconducting clathrates bear opposite charges. Besides, guests in semiconducting clathrates are always monoatomic. Compounds containing molecules or polyatomic ions as the guest are presently unknown.

1. Classification of semiconducting clathrates

Clathrate hydrates of gases and liquids crystallise in seven structural types, which are denoted by Roman numerals: type I clathrate, type II clathrate, ..., type VII clathrate.[3] Semiconducting clathrates crystallise only in three of these structural types, *viz.*, type I clathrate, type II clathrate and type III clathrate. Besides these, two structural types, which were not found for hydrates, are known as semiconducting clathrates. These types are referred to as the type VIII clathrate[33–35] and type IX clathrate.[36] Because of specific structural features, compounds of the latter type are sometimes called chiral clathrates.†

It should be noted that the distribution of semiconducting clathrates over the above structural types is essentially non-uniform. Almost 100 type-I clathrate compounds are known. About 10 compounds have the type-II clathrate structure, almost the same number of compounds have the type-IX clathrate structure, whereas only a few type-III clathrate and type-VIII clathrate compounds were synthesised.

Semiconducting clathrates can alternatively be classified according to the formal charge of the framework. The polyanionic and polycationic clathrates are distinguishable.[14,38] In polyanionic clathrates, the framework bears a negative charge and the guest atoms are positively charged (cations of alkali and alkaline-earth metals and europium). The reverse situation is observed for polycationic clathrates. In these compounds, the framework bears a positive charge and the guest atoms are negatively charged (halide anions).

2. Clathrate-forming polyhedra

The crystal structures of clathrates of any type contain a three-dimensional host framework, which is formed by tetrafunctional units and contains large cavities. The cavities in the framework are polyhedra with $n \geqslant 20$ vertices and regular pentagonal and hexagonal faces.[1,10,14] The polyhedra are denoted by the number of such faces.[39] For example, the notation [5^{12}] is used for a

† In a number of publications, type VIII clathrates are referred to as type III clathrates. This is incorrect because type III clathrates belong to the structural type of bromine hydrate $(Br_2)_{20}\square_{10}[(H_2O)_{172}]$,[1] for which semiconducting analogues are also known.[37] The structures of these compounds are radically different from chiral type VIII clathrates.

Table 1. Clathrate-forming polyhedra.

Name	Graphical representation	Notation	Number of penta/hexagons	Number of vertices	Observed in clathrates
Pentagonal dodecahedron		$[5^{12}]$	$\frac{12}{0}$	20	I, II, III VIII,[a] IX
Tetrakaidecahedron		$[5^{12}6^2]$	$\frac{12}{2}$	24	I, III
Pentakaidecahedron		$[5^{12}6^3]$	$\frac{12}{3}$	26	III
Hexakaidecahedron		$[5^{12}6^4]$	$\frac{12}{4}$	28	II

[a] The type VIII clathrate contains distorted pentagonal dodecahedra.

pentagonal dodecahedron, *viz*., a 20-vertex polyhedron containing 12 pentagonal faces. The 24-vertex polyhedron (hexakaidecahedron) containing 12 pentagonal and 2 hexagonal faces is denoted by $[5^{12}6^2]$. Table 1 lists all polyhedra found in the structures of semiconducting clathrates.

A guest atom is located inside each polyhedron. The guest atom and the polyhedron are sometimes denoted by $G@E_x$.[1] This notation signifies that the guest atom G is located inside an *x*-vertex polyhedron formed by E atoms. For example, the notation $Cs@Sn_{20}$ represents the pentagonal dodecahedron consisting of tin atoms with a cesium atom inside.

The pentagonal dodecahedron is a Platonic body, in which all corners are equivalent and all faces are identical (in real structures, of the same type).[1] This polyhedron was found in the structures of clathrates of all types, except for type-VIII clathrate compounds. In the latter, the polyhedra are slightly distorted. Since the pentagonal dodecahedron has several fivefold axes, it is impossible to fill space with only these polyhedra, and it is necessary to combine these polyhedra with polyhedra which contain, in addition, hexagonal faces. Evidently, the total size of the cavity increases with increasing number of hexagonal faces, and the volumes of the polyhedra containing hexagonal faces are larger than the volume of the pentagonal dodecahedron.

II. Crystal chemistry of semiconducting clathrates

1. Type I clathrate

The type-I clathrate structure contains two types of polyhedra, *viz*., pentagonal dodecahedra $[5^{12}]$ and larger 14-face tetrakaidecahedra $[5^{12}6^2]$. The tetrakaidecahedra are linked to each other by sharing hexagonal faces to form a three-dimensional system of mutually perpendicular non-intersecting channels (Fig. 2). The pentagonal dodecahedra are enclosed in this system of channels and are isolated from each other. The unit cell contains 46 atoms of the framework and has 2 small and 6 large cavities. Therefore, the formula of the corresponding ideal clathrate is $G_2^{I}G_6^{II}[E_{46}]$ (G is a guest). All semiconducting clathrates, which crystallise in this structural type are listed in Tables 2 and 3.

Most type-I clathrate compounds crystallise in the cubic system in the centrosymmetrical space group *Pm*3*n*; 46 atoms of the framework occupy three positions, *viz*., 6*c*, 16*i* and 24*k*. The atoms in the 16*i* and 24*k* positions are present in the polyhedra of both types, whereas the atoms in the 6*c* position are present only in the bulkier tetrakaidecahedra (see Fig. 2). The atom in the 6*c* position is tetrahedrally coordinated by four atoms occupying the 24*k* position. The atom in the 16*i* position is tetrahedrally coordinated by three atoms occupying the 24*k* position and one atom occupying the 16*i* position. The atom in the 24*k* position is tetrahedrally coordinated by one atom occupying the 6*c* position, two atoms occupying the 16*i* position and one atom occupying the 24*k* position (Fig. 3 *a*).

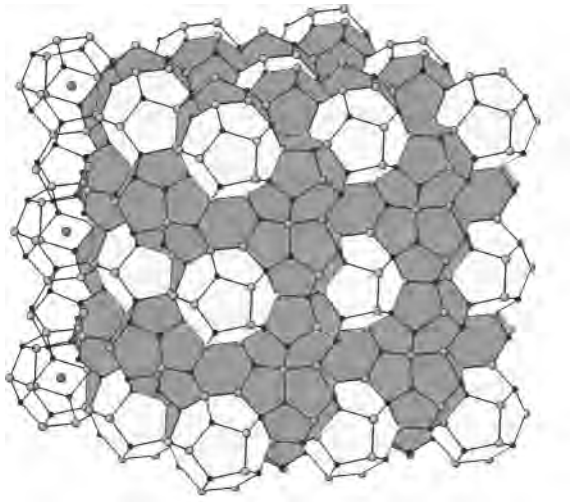

Figure 2. Polyhedral representation of the type-I clathrate structure.

In the structures of compounds of the general formula $X_8[Ge_{38}Z_8]$ (X = Cl, Br, I; Z = P, As, Sb), the centre of symmetry is absent. All these phases crystallise in the space group *P*43*n*, which is a non-centrosymmetrical analogue of the space group *Pm*3*n*.[19–21] Due to a loss of the centre of symmetry, the 16*i* position of the space group *Pm*3*n* is split into two eightfold 8*e* positions in the space group *P*43*n*. One of these positions is completely occupied by germanium atoms, whereas another one is occupied by pnicogen atoms. To our knowledge, the space

[a] A compound with a framework of Si atoms.

group *Pm*3*n*, in which the 16*i* position is occupied simultaneously by geranium and arsenic atoms, was described only for the $I_8[Ge_{38}As_8]$ phase in paper [23] published in 1982. However, the reliability of these data was not discussed in the cited study.

As can be seen from Table 2, there is a series of compounds of the general formula $A_8[E_{38}M_8]$ (A = Na, K, Rb, Cs, Ba; E = Si, Ge, Sn; M = Al, Ga, In, Zn, Cd), whose structures are also characterised by mixed occupancies of the positions of the framework by atoms of different types. However, the latter crystallise in the centrosymmetrical space group *Pm* 3*n*. It should be noted that the distribution of the heterometal atoms M over the positions of the framework in these compounds differs from that observed in pnicogen-containing clathrates in that the 'heteroatoms' either occupy predominantly the 6*c* position or are statistically distributed over all three positions, as exemplified by the $[Ge_{38}Ga_8]$ frameworks. In this case, the loss of an inversion centre cannot lead to additional ordering of the structure. Besides, the difference in the chemical nature of the atoms occupying the same position in the compounds under consideration is less significant than that in the case of the germanium/pnicogen pair.

The guest atoms in the type-I clathrate structure occupy the 2*a* and 6*d* positions, *viz*., the centres of the pentagonal dodecahedra and tetrakaidecahedra, respectively. According to the results of X-ray and neutron diffraction studies, the guest atoms show very large displacement parameters because of the absence of 'rigid' bonds between the framework and the guest. As expected, atoms execute larger-amplitude thermal motions in a larger space. For some compounds, it was proposed [9, 34, 76 – 79] that the guest atoms should be displaced from the 6*d* position to a position with a higher multiplicity and partial occupancy, *viz*., to 24*k* or 24*j* with 25% occupancy each or to 12*h* with 50% occupancy (Fig. 3 *b*). As can be seen from Fig. 3, the 6*d* position is tetrahedrally coordinated by the 24*k* positions, the 24*j* positions form a square about the *6d* position, and the 12*h* positions linearly coordinate the 6*d* position. However, this model of arrangement of the guest atoms in large polyhedra is possible only for a limited number of structures. In most cases, this model is incorrect because no displacements of the guest atoms from the 6*d* position were revealed in low-temperature X-ray diffraction experiments.[32, 80]

There are two modes of formation of a superstructure based on the crystal structures of type I clathrates (Fig. 4). One mode is observed in the $I_8[Sn_{14}In_{10}P_{21.2}\square_{0.8}]$ compound,[29] which crystallises in the tetragonal system in the space group $P4_2/m$. In this structure, the unit cell volume increases by a factor of five compared to the unit cell volume of the starting clathrate ($a_{super} \approx \sqrt{5}a_{clath}$, $b_{super} \approx \sqrt{5}b_{clath}$, $c_{super} \approx c_{clath}$), which is accompanied by partial ordering of vacancies in the clathrate framework. Ordering insures against mixed occupancy of the same position simultaneously by three- and four-coordinate metal atoms.

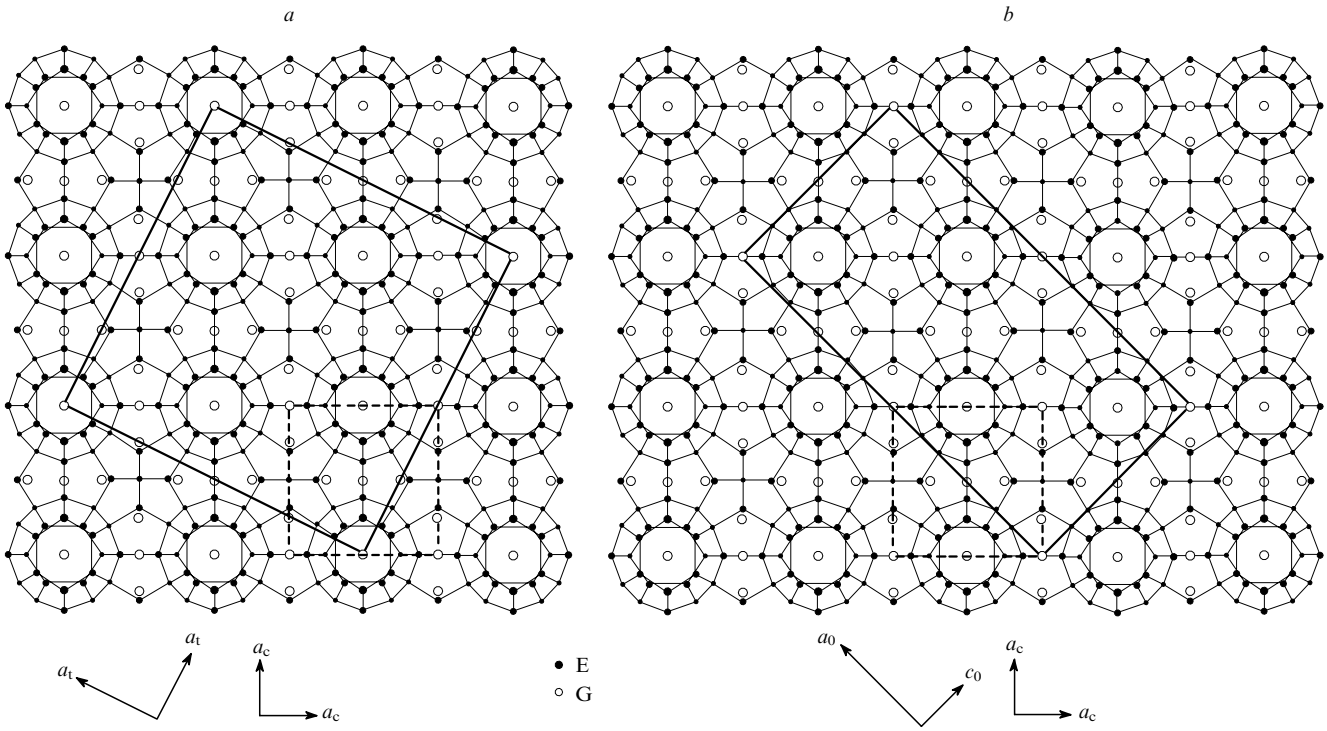

Figure 4. Superstructures of type I clathrates.
(*a*) The tetragonal superstruture $I_8[Sn_{14}In_{10}P_{21.2}\square_{0.8}]$, (*b*) the orthorhombic superstructure $Ba_8[Cu_{16}P_{30}]$; the initial cubic unit cell is indicated by dashed lines.

Another mode of formation of a superstructure is exemplified by the $Ba_8[Cu_{16}P_{30}]$ compound.[74] The latter is the only example of semiconducting clathrates, whose framework has no Group 14 elements. It crystallises in the orthorhombic system in the space group *Pbcn*, which is accompanied by an increase in the volume of the starting cubic unit cell by a factor of four ($a_{super} \approx \sqrt{2}a_{clath}$, $b_{super} \approx a_{clath}$, $c_{super} \approx 2\sqrt{2}a_{clath}$). In this compound, the copper atoms are always coordinated by four phosphorus atoms, whereas the phosphorus atoms have different coordination environments described as 3Cu + 1P, 2Cu + 2P and 1Cu + 3P. Evidently, this coordination of the copper atoms in the absence of a superstructure in the space group *Pm3n* can occur only if two positions are occupied by both the copper and phosphorus atoms.

Therefore, the formation of superstructures is, apparently, dictated by preferential coordination of atoms of different nature involved in the framework. Presumably, superstructures based on type I clathrates also occur in a number of other compounds (which prevents mixed occupancy of a position by atoms of different types). However, these types of ordering require a very large increase in the unit cell volume and, hence, may remain undetectable by conventional X-ray diffraction techniques.

2. Type II clathrate

The type-II clathrate structure also contains two types of polyhedra: pentagonal dodecahedra [5^{12}] and larger 16-face hexakaidecahedra [$5^{12}6^4$] (see Table 1). The type-I clathrate structure differs from the type-II clathrate structure (Fig. 5) in that the pentagonal dodecahedra in the former are not linked to each other, whereas these dodecahedra in the latter share faces and are packed in layers alternating in the order [ABC], which is typical of cubic close packing. The layers of pentagonal dodecahedra are linked to form a three-dimensional framework through hexakaidecahedra. The latter also share hexagonal faces and have a diamond-like arrangement in the cubic structure. The unit cell contains 136 atoms of the framework including 16 small and 8 large cavities. The formula of the corresponding ideal clathrate is $G^I_{16}G^{II}_8[E_{136}]$. As mentioned above, about 10 compounds have the type-II clathrate structure. This can be attributable to a large difference in the size of the polyhedra involved in the clathrate. As can be seen from Table 4, the type-II clathrate structure occurs either when compounds contain two cations, which differ substantially in size (for example, Na and Cs in $Na_{16}Cs_8[Ge_{136}]$) or when the guest atoms of one type occupy predominantly only one type of polyhedral cavity, whereas another type of cavity remains vacant. The type of the cavity being occupied depends on the size of the framework-forming element. In the case of tin, the large barium cations occupy only smaller cavities ($Ba_{16}\square_8[Ga_{32}Sn_{104}]$), whereas even rather small sodium cations occupy predominantly larger cavities in the framework formed by silicon atoms ($Na_x\square_{24-x}[Si_{136}]$, $x < 8$).

All compounds with the type-II clathrate structure crystallise in the cubic system in the centrosymmetrical space group *Fd3m*; 136 atoms of the framework occupy three positions, *viz.*, 8*a*, 32*e*

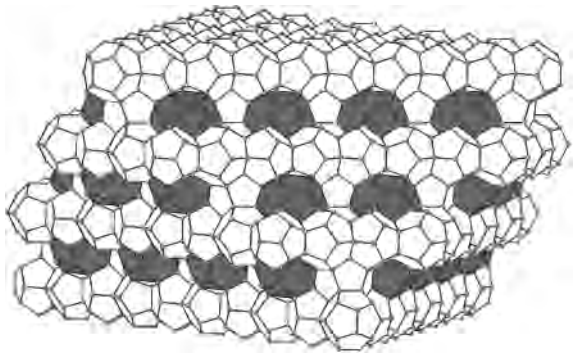

Figure 5. Overall view of the type-II clathrate structure.

Table 4. Compositions and structural features of polyanionic type-II clathrate phases.

Phase	Characteristics of the crystal structure	Ref.
$Na_x\square_{24-x}[Si_{136}]$	$1 < x < 23$; if $x < 8$, Na atoms occupy only larger cavities; at $x > 8$, smaller cavities begin to be filled	3, 40, 41, 81
$Na_x\square_{24-x}[Ge_{136}]$	$4 < x < 23$; if $x < 8$, Na atoms occupy only larger cavities; at $x > 8$, smaller cavities begin to be filled	82
$Cs_7\square_{17}[Si_{136}]$	Cs atoms occupy larger cavities	82
$Rb_8Na_{16}[Si_{136}]$	Rb atoms completely occupy larger cavities, Na atoms completely occupy smaller cavities	8
$Cs_8Na_{16}[Si_{136}]$	Cs atoms completely occupy larger cavities, Na atoms completely occupy smaller cavities	8, 83
$Rb_8Na_{16}[Ge_{136}]$	Rb atoms completely occupy larger cavities, Na atoms completely occupy smaller cavities	8
$Cs_8Na_{16}[Ge_{136}]$	Cs atoms completely occupy larger cavities, Na atoms completely occupy smaller cavities	8, 83
$Ba_{16}\square_8[Ga_{32}Sn_{104}]$	Ba atoms occupy only smaller cavities, and larger cavities are vacant	47, 84, 85

and 96*g*; 24 guest atoms occupy the 8*b* and 16*c* positions in the centres of the hexakaidecahedra and pentagonal dodecahedra, respectively. All positions of the framework in the type-II clathrate compounds (except for the $Ba_{16}\square_8[Ga_{32}Sn_{104}]$ compound) are occupied by atoms of one element. In the $Ba_{16}\square_8[Ga_{32}Sn_{104}]$ structure, the gallium and tin atoms are statistically distributed over all positions of the framework. Type II clathrates are characterised by full occupancies of the positions of the framework, whereas vacancies (if they are present) occur only in the guest positions (see Table 4).

3. Type III clathrate

Only two semiconducting clathrates with the type-III clathrate structure, *viz*., $Cs_{30}[Na_{2.5}Sn_{162.6}]$ and $Cs_{13.8}Rb_{16.2}[Na_{2.8}Sn_{162.3}]$, are known.[37] The structures of bromine hydrate $(Br_2)_{20}\square_{10}[(H_2O)_{172}]$ and dimethyl ether hydrate $(CH_3OCH_3)_{20}\square_{10}[(H_2O)_{172}]$ can be considered as prototypes of the type-III clathrate structure,[3] which consist of three types of polyhedra, *viz*., pentagonal dodecahedra $[5^{12}]$, larger tetrakaidecahedra $[5^{12}6^2]$ and even larger 15-face pentakaidecahedra $[5^{12}6^3]$ (see Table 1). Their ratio in the structure is 10 : 16 : 4, *i.e*., there are 30 polyhedra per unit cell. These polyhedra share faces to form a three-dimensional framework (Fig. 6) containing 172 atoms. The formula of the ideal type III clathrate is $G^{I}_{10}G^{II}_{16}G^{III}_{4}[E_{172}]$. Both compounds with the semiconducting type-III clathrate structure crystallise in the tetragonal system in the centrosymmetrical space group $P4_2/mnm$. All three types of cavities are completely occupied. In the $Cs_{30}[Na_{2.5}Sn_{162.6}]$ structure, all cavities are filled with cesium atoms. In the case of $Cs_{13.8}Rb_{16.2}[Na_{2.8}Sn_{162.3}]$, a situation, though more complicated, is also reasonable. In this structure, the largest pentakaidecahedra are occupied predominantly by cesium atoms, the smallest pentagonal dodecahedra are occupied predominantly by rubidium atoms, and the medium-sized tetrakaidecahedra are filled with cesium and rubidium atoms with equal probability.

The compositions of semiconducting type III clathrates differ slightly from the ideal composition, which is associated with the presence of vacancies in the framework. The reasons for the appearance of such vacancies and their amounts are discussed in detail below. The defect formation in the type-III clathrate structure differs from that in the type-I clathrate structure. In the type-III clathrate structure, vacancies are partially clusterised, *i.e*., a pair of tin atoms (Sn_2) is replaced by one sodium cation, which is located at the midpoint of the tin–tin bond (see Fig. 6). Hence, the formulas of the compounds under consideration can be written as $Cs_{30}[Na_{1.33x-10}Sn_{172-x}]$ and $Cs_{13.8}Rb_{16.2}.[Na_{1.33x-10}Sn_{172-x}]$ ($x \approx 9.6$).

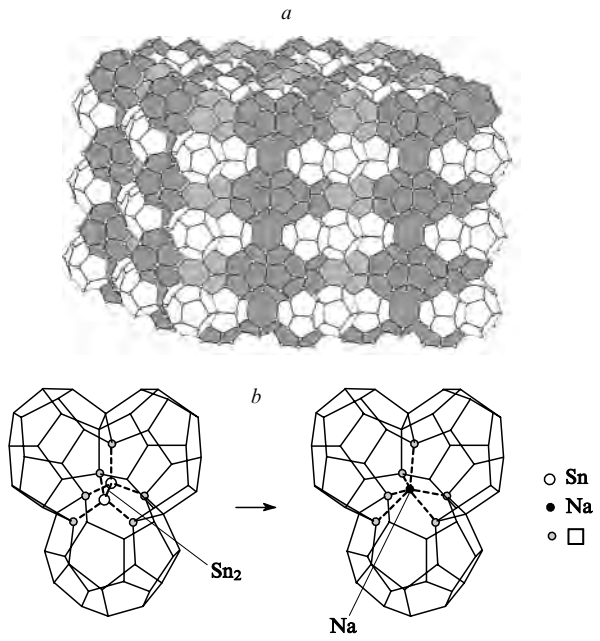

Figure 6. Type-III clathrate structure.
(*a*) Overall view, (*b*) formation of vacancies in the positions of tin atoms and replacement of these atoms with sodium atoms.

4. Type VIII clathrate

There are only two compounds, *viz*., α-$Eu_8[Ga_{16}Ge_{30}]$ (see Ref. 34) and α-$Ba_8[Ga_{16}\ Sn_{30}]$, with the type-VIII clathrate structure.[33,35] Both these compounds have a high-temperature β modification with the same composition and the type-I clathrate structure.[63] The type-VIII clathrate structure, unlike the type-I clathrate structure, has only one type of filled cavity (Fig. 7). These cavities can be described as distorted E_{20+3} polyhedra, which are derived from pentagonal dodecahedra as a result of the cleavage of three E–E bonds and the formation of nine new such bonds upon the addition of three additional E atoms. Since it is impossible to fill the complete space with this type of polyhedra, the structure also contains small eight-vertex cavities, which remain vacant. The formula of the ideal compound with the type-VIII clathrate structure is $G_8[E_{46}]$. Both known compounds crystallise in the cubic system in the non-centrosymmetrical space group $I43m$. The framework has 4 positions occupied by the E atoms of the framework (12*d*, 2*a*, 24*g* and 8*c*) and one guest position (8*c*). In both compounds, the gallium atoms are statistically mixed with Group 14 elements in all four positions of the framework. In studies,[34,35] the Ga : E ratio in the phases under consideration was demonstrated to be other than 16 : 30, *i.e*., these phases possess a certain homogeneity region and can contain a small excess of gallium. For the compound with E = Sn, this fact was established by X-ray diffraction.[35] In the case of E = Ge, non-stoichiometry was determined only on the basis of indirect evidence taking into account the physical properties of samples containing Ga and Ge in different ratios.[34]

5. Type IX clathrate

Type-IX clathrate compounds (or 'chiral' clathrates) crystallise in the cubic system in the non-centrosymmetrical space group $P4_132$. Eleven known compounds of this type are listed in Table 5. The main framework-forming polyhedron in the type-IX clathrate structure, like that in other clathrate structures, is a pentagonal dodecahedron. These polyhedra share faces to form a helix about each 4_1 axis (which accounts for the name 'chiral clathrate') (Fig. 8). The helical chains fill the space only partially, the channels between these chains being occupied by additional guest atoms of two types. The coordination of these atoms can be described as follows: one of these atoms is located in the 20-vertex open cavity and another atom is located in a distorted cube formed by the E atoms (see Fig. 8). The guest atoms located inside the pentagonal dodecahedra occupy the 8*c* position. Two other types of guest atoms can be described in different ways:

(1) both atoms completely occupy the 12*d* and 4*b* positions in the centres of the open twenty-vertex polyhedra and the cubes, respectively;[86–91, 94]

Table 5. Type-IX clathrate phases.

Framework-forming element	Phase	Ref.
Si	$Ba_6[Si_{25}]$	86
Ge	$Ba_6[Ge_{24}\square_1]$	87
	$Ba_{24}[Ge_{100}] \equiv Ba_6[Ge_{25}]$	88, 89
	$Na_2Ba_4[Ge_{25}]$	90
	$Ba_6[Ge_{23}Sn_2]$	87
	$Ba_6[Ge_{22}In_3]$	87
	$Ba_6[Ge_{21}In_4]$	36, 91
Sn	$K_6[Sn_{25}]$	92, 93
	$K_{7.4}[Sn_{25}]$	69
	$Rb_3Na_5[Sn_{25}]$	94
	$K_6[Sn_{23}Bi_2]$	92, 93

(2) the atoms in the centres of the open twenty-vertex polyhedra partially occupy the 24*e* position, and the atoms in the centres of distorted cubes completely occupy the 4*b* position;[69, 87, 92, 94, 95]

(3) both atoms partially occupy the 24*e* positions in the vicinity of the corresponding 12*d* and 4*b* positions.[93, 96]

It should be noted that the guest atoms in all models show large displacement parameters. In a number of studies (see, for example, Ref. 97), it was noted that a decrease in the temperature causes a phase transition accompanied by a change in the structure such that the atom is shifted from the 12*d* position to the 24*e* position with 50% occupancy.

The atoms of the framework occupy six positions, *viz*., three 24*e*, one 12*d* and two 8*c*. The type-IX clathrate structure differs essentially from all other types in that only 68 atoms of the framework (in two 24*e* positions and in the 12*d* and 8*c* positions) are four-coordinate, whereas 32 atoms (in the 24*e* and 8*c* positions) are three-coordinate. It should be noted that the type-IX clathrate structure has four formula units. The compositions of the clathrate phases given in Table 5 correspond to the compositions reported in the original studies. It can be seen that such compounds contain different amounts of guest atoms. This fact correlates with the electronic structures of semiconducting clathrates and is discussed in detail below.

6. Compounds structurally related to clathrates

Several compounds related to clathrates were described in the literature. The crystal structures of these compounds also contain the major polyhedron of clathrate structures, *viz*., the pentagonal dodecahedron. Examples are $Cs_3Na_{10}Sn_{23}$,[94] $Cs_2BaCu_8Te_{10}$,[98, 99] $Ba_{16}Na_{204}Sn_{310}$ (see Ref. 100) and $Te_{7+x}Si_{20-x}$ ($x \approx 2.5$).[101] The structure of the $Cs_3Na_{10}Sn_{23}$ compound contains layers of the face-sharing pentagonal dodecahedra $Cs@Sn_{20}$. These layers are analogous to the layers present in the type-II clathrate structure (see Fig. 5). In the $Cs_3Na_{10}Sn_{23}$ structure, these layers alternate with layers consisting of the $(Sn_4)^{4-}$ isolated tetrahedra, and the

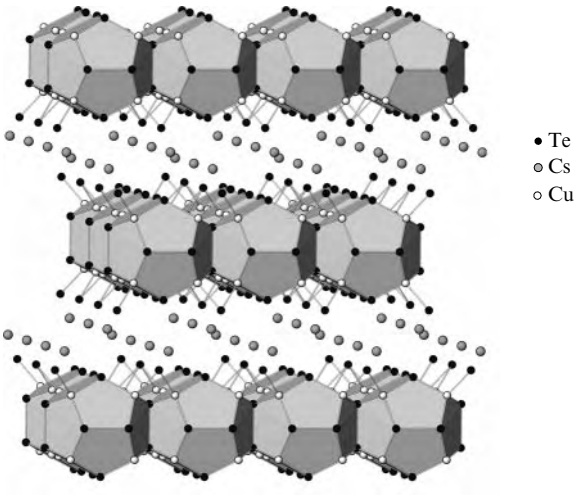

Figure 9. Crystal structure of $Cs_2BaCu_8Te_{10}$.

cavities between the polyhedra are occupied by sodium atoms. Another type of layer formed by the pentagonal dodecahedra is observed in the $Cs_2BaCu_8Te_{10}$ structure, in which the $Ba@Cu_8Te_{12}$ polyhedra share edges to form a layer. The layers are separated by cesium atoms (Fig. 9). The above-described compounds contain two-dimensional infinite fragments of clathrate structures.

The structures of the following two compounds have finite fragments. The structure of the $Ba_{16}Na_{204}Sn_{310}$ phase contains fragments of four vertex-sharing pentagonal dodecahedra $Ba@Sn_{20}$. Two other polyhedra of the host in this phase are the disordered $Na@Sn_{12}$ icosahedron and the 'empty' eight-vertex polyhedron Sn_8. The latter can be described as either a distorted cube or a distorted Archimedean antiprism. The space between the polyhedra is filled with sodium atoms. The structure of the $Te_{7+x}Si_{20-x}$ phase has the isolated pentagonal dodecahedra $Te@Te_{2.5}Si_{17.5}$, and the cavities between the latter are occupied by tellurium atoms. Interestingly, this compound is characterised by charge inversion, *viz*., the tellurium atoms, which are not involved in the polyhedron, bear a negative charge, *i.e*., they can formally be considered as Te^{2-} dianions.

A series of gallides and germanides of alkali, alkaline-earth and rare-earth metals, in which the positively charged guest metal atoms have rather high coordination numbers (from 14 to 19), were described in the literature.[102–115] Some researchers assigned these compounds to clathrate-like substances. However, in our opinion, it is unjustified to consider these compounds as related to clathrates because their crystal structures have no closed cavities and fragments of clathrate structures.

III. Electronic structures and properties of semiconducting clathrates

The electronic structures of semiconducting clathrates can qualitatively be described using the Zintl concept, *viz*.,the electron transfer from electropositive guest metal atoms to the framework formed by main-group atoms with localised covalent bonds.[38] Zintl phases are characterised by the strict correspondence between the crystal structure and electronic structures.

Classical Zintl phases are binary and ternary compounds, which contain alkali and alkaline-earth metals as cations and main-group elements from Groups 13–15 as anions and have structures of any complexity.[38] In such compounds, the cation donates electrons to the anion to form a closed-shell electronic configuration. The anion acquires an electron octet through the formation of two-centre two-electron homonuclear bonds and localised lone electron pairs. As a result, these compounds exhibit properties characteristic of Zintl phases. Evidently, if all atoms have closed-shell electronic configurations, all bonding and non-bonding (corresponding to lone electron pairs) states in the covalent anionic sublattice are filled, whereas all antibonding states are vacant. Correspondingly, Zintl phases exhibit semiconducting properties, even though they are polar intermetallides.

In addition to classical phases, there are the so-called metallic Zintl phases. These are compounds of Group 13 and 14 elements with alkali metals,[116] which can formally be described in terms of the Zintl concept. However, their properties differ from those predicted according to this concept. If the octet rule is obeyed, a change in the energy of interaction in going from a local level to an extended system can lead to the disappearance of a band gap and the appearance of metallic conductivity.[117,118] There are also 'non-traditional' Zintl phases. Among the latter are, for example, compounds containing transition metals, which cannot obey the octet rule but which can adopt the so-called closed-shell d-electron configurations (d^0, d^{10} and, sometimes, d^6 in an octahedral environment and d^8 in a square environment).[119,120] Inverted Zintl phases are generally assigned to 'non-traditional' phases. In such compounds, main-group elements form a cationic sublattice and acquire an electron octet, excess electrons being donated to eletronegative elements (halogens). This is accompanied by charge inversion: negatively charged halogen atoms are 'equivalent' to positively charged alkali and alkaline-earth metal cations in traditional Zintl phases.[38,121]

The detailed consideration of the Zintl concept and the properties of Zintl phases is beyond the scope of our review.‡ Here we demonstrate that most semiconducting clathrates are Zintl phases from the viewpoint of their formal electronic structures. However, some properties of these compounds cannot be explained in terms of the Zintl concept.

1. Type I clathrate

According to the Zintl concept, if the framework of the type I clathrate $A_8[E_{46}]$ is formed only by Group 14 atoms, which have four valence electrons and form four two-centre two-electron bonds, and has no vacancies, the $[E_{46}]$ framework should be electroneutral in the absence of guest atoms. The metal atoms A (alkali or alkaline-earth) placed in the polyhedral cavities in this framework acquire an electron octet due to donation of their valence electrons to the framework. A total of $8n$ electrons per formula unit (n is the valence of the A atom) are donated. Since these electrons occupy the antibonding conduction σ*-band of the host framework, the clathrate with the ideal composition $A_8[E_{46}]$ should exhibit metallic rather than semiconducting properties. Excess electrons in the σ*-band can be compensated in two different ways: by removal of some atoms of the framework or the partial replacement of the atoms of the framework by metal atoms having a smaller number of valence electrons.

In the former case, the removal of one E atom compensates four excess electrons. It is necessary to create $d = 8n/4$ vacancies in the framework. This situation is observed in alkali metal stannides ($d = 2$) of the general formula $A_8[Sn_{44}\square_2]$ (A = K, Rb, Cs) (see Table 2).[8,47,69,70]

In the case of heterovalent substitution, one heterometal atom M compensates $(14-z)$ excess electrons (z is the group number for the metal under consideration in the long-period form of the Periodic system of elements). The total number of metal atoms (y) required for the formation of the vacancy-free compound $A_8[M_yE_{46-y}]$ is calculated by the equation

$$y = \frac{8n}{14-z}.$$

The formulas of the ideal clathrates upon heterovalent substitution are given in Table 6.

Excess electron can also be compensated simultaneously through the formation of vacancies in the framework and hetero-

‡ These problems were discussed in detail in original studies.[38,121]

Table 6. Compositions with the type-I clathrate structure $A_8[M_yE_{46-y}]$, which were prepared by heterovalent substitution and obey the Zintl rule.

z	y	Composition ($n = 1$)	y	Composition ($n = 2$)
13	8	$A_8[M_8E_{38}]$	16	$A_8[M_{16}E_{30}]$
12	4	$A_8[M_4E_{42}]$	8	$A_8[M_8E_{38}]$
11	2.7	$A_8[M_{2.7}E_{43.3}]$	5.3	$A_8[M_{5.3}E_{40.7}]$
10	2	$A_8[M_2E_{44}]$	4	$A_8[M_4E_{42}]$

valent substitution. According to the Zintl concept, the coefficients y and d for the polyanionic clathrate $A_8[M_yE_{46-y-d}\square_d]$ are related by the equation

$$y(14-z) + 4d = 8n.$$

Such a 'twofold' compensation can be exemplified by the $Ba_8[Cd_4Ge_{40}\square_2]$ compound ($n = 2$, $z = 12$, $d = 2$, $y = 4$).[68]

In the case of heterovalent substitution of a p metal (Al, Ga, In, Zn or Gd) for a Group 14 element in polyanionic clathrates, the compositions determined by X-ray diffraction analysis are always identical to those predicted according to the Zintl concept (see Table 2). In some early studies, the synthesis of polyanionic clathrates, whose compositions do not satisfy the Zintl concept (for example, $K_8[Ga_{23}Sn_{23}]$ [122]), was mentioned. However, these data were not confirmed in later studies.[8, 46, 47, 55, 59] All clathrate compounds belonging to Zintl phases exhibit semiconducting and diamagnetic properties.[7, 9, 46, 47, 55–60, 68, 71, 72, 123]

Frameworks formed simultaneously by gallium and germanium atoms do not obey the Zintl principle. X-ray and neutron diffraction studies demonstrated that gallium atoms, unlike all other heteroatoms, are mixed with germanium atoms in all three positions of the clathrate frameworks.[8, 34, 57, 58, 62, 64, 65] Taking into account this fact, it can be hypothesised that the formation of phases, which exhibit metallic conductivity and whose compositions differ from those predicted in terms of the Zintl concept, is more favourable in mixed gallium-germanium systems.

Almost without exception, compounds prepared by heterovalent substitution of d metals for Group 14 elements do not satisfy the Zintl concept.[53] However, the compositions given in Table 2 were calculated on the assumption that all d-metal atoms are in the d^{10} state, although they can occur in other stable oxidation states. Besides, poor reliability factors ($R_1 \approx 6\%$–10%) may indicate that the structural features of the clathrate framework (for example, occupancies of atom positions) were not all established reliably.

The only europium-containing type I clathrate, *viz*., the β-$Eu_8[Ga_{16}Ge_{30}]$ phase,[34, 62, 124] is of particular interest. For this phase, the magnetic moment per europium atom is 7.9 μ_B, which corresponds to Eu^{2+}. Below 36 K, this phase behaves as a soft ferromagnetic material. At 36 K, ferromagnetic ordering (Fig. 10) occurs, which is accompanied by a stepwise change in the heat capacity.[34]

The compositions of binary clathrate silicides and the $Ba_8[Ge_{43}\square_3]$ compound deviate substantially from those predicted in terms of the Zintl principle. Recall that the Zintl concept is a simplified approach, according to which filling of electronic states can be considered on the basis of only formal oxidation states. Evidently, effects associated with the formation of energy bands in extended structures are ignored within the framework of this approach. The specificity of the electronic structures of clathrate silicides, which do not obey the Zintl rule, is apparently associated with the energy features of the atomic orbitals of silicon.[42, 82] The strength of the Si–Si bond (226 kJ mol^{-1}) [125] is substantially higher than that of the homoatomic bond between the germanium and tin atoms. Since the band gap in clathrates is small, the filling of the conduction band with excess electrons appears to be more favourable than the cleavage of the bonds between the silicon atoms and formation of vacancies in the clathrate framework. Consequently, there is no need for a strict

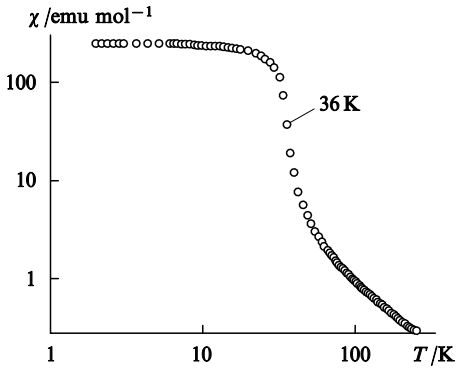

Figure 10. Temperature dependence of the magnetic susceptibility for β-$Eu_8[Ga_{16}Ge_{30}]$ according to the results of the study.[34]

correspondence between the composition of the compound and the number of electrons donated by the guest cation. Hence, many silicon-based clathrates have a wide non-stoichiometric region with respect to the cation. As an example we refer to $Rb_{8-x}Si_{46}$ ($x < 2$).[45] Such type I clathrates exhibit metallic conductivity and Pauli paramagnetism typical of metals.[126, 127]

In a series of studies, it was demonstrated that phases having no vacancies in the guest sublattice can be synthesised only under high pressure ($\sim$3 GPa).[48–51, 128] This method of synthesis allows one to prepare phases with unusual physical properties. Barium-containing silicides are low-temperature superconductors (T_c for $Ba_{7.76}\square_{0.24}[Si_{46}]$ is 9.0 K).[50, 51] This is the only example of superconductors with a framework formed by sp^3-hybridised silicon atoms. In studies,[50, 51] this fact was accounted for by partial overlapping of the s orbitals of the barium atoms with the orbitals of the atoms of the framework. An increase in the pressure leads to an increase in the amount of intercalated barium and an increase in the a parameter of the cubic unit cell. The partial replacement of barium with sodium or of silicon with germanium leads to a decrease in the superconducting transition temperature.[43, 44, 49]

The deviation of the composition of the germanium phase $Ba_8[Ge_{43}\square_3]$ (see Refs 49 and 61) from that predicted according to the Zintl concept ($Ba_8[Ge_{42}\square_4]$) is attributable to the fact that the formation of a large number of vacancies (four) in the framework is energetically less favourable than the formation of a smaller number of vacancies and doping of four excess electrons into the conduction band. Measurements of the resistive properties demonstrated that the $Ba_8[Ge_{43}\square_3]$ phase actually exhibits metallic conductivity.[61]

According to the Zintl concept, the framework of the inverse polycationic clathrates $X_8[E_{46}]$ (X is halogen) should donate eight excess electrons per formula unit to the X atoms. This is most easily achieved in the case of germanium compounds.[19–23] Each pnicogen atom in $X_8[Ge_{38}Z_8]$ (Z = P, As, Sb; X = Cl, Br, I) has 5 valence electrons, *i.e*., one electron more than the number of electrons required for the formation of four two-centre two-electron bonds. Correspondingly, 8 excess electrons are donated from eight pnicogen atoms to halogen atoms.

A different situation is observed in polycationic tin clathrates. The formula of ideal tin phosphide halide is $X_8[Sn_{24}P_{22}]$ (X = Br, I). Since each phosphorus atom donates one excess electron, while halogen atoms require only eight electrons to acquire an electron octet, the $X_8[Sn_{24}P_{22}]$ structure has $22-8 = 14$ excess electrons. These electrons can be compensated (as in the case of polyanionic clathrates) in two different ways: by the partial removal of the atoms of the framework or the partial replacement of the tin atoms with metal atoms having a smaller number of valence electrons.

In the former case, the removal of one phosphorus atom leads to compensation of five excess electrons. It is necessary to create $14/5 = 2.8$ vacancies. This corresponds to the $X_8[Sn_{24}P_{19.2}]$ com-

position, which is identical to that determined experimentally to within experimental error.[25, 31, 32]

In the case of heterovalent substitution, one heterometal atom M compensates $(14-z)$ excess electrons. To prepare the vacancy-free $X_8[M_ySn_{24-y}P_{22}]$ compound, the total number of metal atoms y can be calculated by the equation

$$y = \frac{14}{14-z}.$$

As can be seen from Table 3, the compositions of some vacancy-free tin phosphide halides, which were prepared by heterovalent substitution using p-metals (Ga, In, Zn, Gd) and even d-metals (Cu), are consistent with those predicted according to the Zintl concept.[26, 28, 29, 31, 75]

Excess electrons can be compensated simultaneously through the formation of vacancies in the framework and heterovalent substitution. In this case, according to the Zintl concept, the coefficients y and d for the polycationic clathrate $X_8[M_ySn_{24-y}P_{22-d}\square_d]$ are related by the equation

$$y(14-z) + 5d = 14.$$

The $I_8[Sn_{14}In_{10}P_{21.2}\square_{0.8}]$ ($z = 13$, $d = 0.8$, $y = 10$)[29] and $I_8[Sn_{20}Zn_4P_{20.8}\square_{1.2}]$ compounds ($z = 12$, $d = 1.2$, $y = 4$)[75] can serve as examples of the above-mentioned 'twofold' compensation.

The replacement of tin atoms with copper atoms in arsenide iodide can afford both a phase, which satisfies the Zintl principle ($I_8[Sn_{19.3}Cu_{4.7}As_{22}]$), and a phase containing an excess of copper ($I_8[Sn_{17.6}Cu_{6.4}As_{22}]$).[31] Since there are only a few tin arsenide iodides (see Table 3), the reasons for deviations from the Zintl principle remain unclear. There are two possible explanations: (1) the presence of transition metal atoms, which can adopt several stable electronic configurations; (2) as in the case of silicides, the cleavage of the As–As bonds and formation of vacancies are energetically less favourable than doping of excess electrons into the conduction band. A lack of data on the conductivity and magnetic susceptibility for these phases does not allow one to unambiguously decide between the above two schemes.

In the structures of all type I clathrates, vacancies are always located in the 6*c* position.[8, 25, 31, 32, 47, 49, 61, 64, 68–70] In this case, some atoms in the 24*k* position become three-coordinate. The presence of two types of tin atoms in the structures of alkali metal stannides was confirmed by ^{119}Sn NMR spectroscopy.[129] The distribution of the heterometal atoms over the positions of the framework in polyanionic clathrates differs from that observed in polycationic clathrates. In the former case, electropositive heterometals always fill first the 6*c* position and then the 16*i* position. The electronegative element (Sb) always fills the 24*k* position.[66, 67] Gallium, which is intermediate between the above-mentioned elements, can be mixed with Group 14 elements in all three positions of the framework.[8, 34, 57, 58, 62, 64, 65] In the case of polycationic clathrates, any heterometal occupies the 24*k* position together with tin,[26, 28, 29, 31, 75] which is accompanied by splitting of this position into two or three positions with partial occupancies, and some tin atoms are also three-coordinate. The coordination of tin atoms in polycationic clathrates can be confirmed not only by NMR spectroscopy but also by ^{119}Sn Mössbauer spectroscopy.[25, 26, 29, 75] In addition, the stereoactivity of the lone electron pairs on three-coordinate tin atoms can be judged from data on the quadrupole splitting of lines in the Mössbauer spectra.

The diamagnetic character of the temperature dependence of the magnetic susceptibility for certain polycationic type I clathrates, whose electronic structures obey the Zintl rule, is violated in the 200–250 K region, which is manifested in the appearance of a sharp jump in the curve $\chi(T)$.[32] As the field strength increases, this jump decreases up to its complete disappearance at $H \approx 5$ T. Low-temperature studies of the crystal structures of the $I_8[Sn_{24}P_{19.3}]$ and $Br_8[Sn_{24}P_{19.6}]$ compounds by X-ray diffraction analysis and Mössbauer, NMR, and X-ray photoelectron spectroscopy showed that a decrease in the temperature causes no structural changes.[32] Taking into account this fact, it can be concluded that a jump in the magnetic susceptibility curve is associated with either relaxation processes or a change in the mechanism of the electron–phonon interaction. Actually, the estimated value of the Debye temperature (below which, quantisation of thermal vibrations occurs) is 200–240 K. This conclusion is indirectly confirmed by the data on the temperature behaviour of the heat capacity of the $I_8[Sn_{24}P_{19.3}]$ phase. Thus, the maximum positive deviation from the Dulong–Petit law is observed at 250 K.[32]

An interesting and important transport property of semiconducting type I clathrates is their abnormally low heat conductivity.[7, 9, 34, 62, 72, 76, 78, 80, 123, 124, 130–132] At room temperature, the heat conductivity of many type I clathrates is 0.5–1.5 W m^{-1} K^{-1}, which is comparable to that of amorphous compounds. Moreover, a low-temperature region of the temperature dependence of the heat conductivity for most clathrates is typical of amorphous compounds (Fig. 11 *a*). This fact was initially explained by scattering of heat-carrying phonons by low-frequency vibrations of guest atoms inside the clathrate frameworks. Actually, calculations based on the Wiedemann–Franz law demonstrated that the electronic component of the heat conductivity is no higher than 6%–8%.[7, 9, 72, 78, 130] Consequently, the heat conductivity is determined primarily by its lattice component, and the guest atoms have high thermal parameters and can serve as efficient rattlers§ (Fig. 11 *b*). This mechanism is evidenced also by a slight decrease in the heat conductivity of most clathrates with decreasing temperature, which corresponds to a decrease in vibration amplitudes of the guest atoms.[80, 131] Such compounds are called phonon glasses, because glasses (in the general case, amorphous compounds) are characterised by a great number of structural irregularities, which effectively scatter pho-

§ Weakly bound atoms or molecules, which can freely rotate or vibrate within a closed cavity and scatter heat-carrying phonons.

nons (the vibrational modes).[6] However, a detailed consideration of the temperature dependence of the heat conductivity showed that the region of this dependence below 50 K cannot be described as photon scattering by vibrations of guest atoms.[133] Two other possible mechanisms, *viz*., lattice relaxation and tunnelling of the guest atoms in a larger cavity to several nearby positions (see Fig. 3 *b*), were proposed.[34, 130, 133, 134] The characteristic features of a particular clathrate compound determine which process dominates.

The structures of the energy bands of type-I clathrate compounds were studied using various approximations, from the extended Hückel method to *ab initio* calculations.[9, 29, 38, 79, 135–144] Calculations showed that clathrates, which obey the Zintl rule, are narrow gap semiconductors. It appeared that the presence of vacancies predicted in terms of the Zintl concept is a necessary condition for the formation of semiconductors. If this condition is not met, one would expect the appearance of metallic properties.[29, 38, 141] For the polycationic clathrates, it was established that either orbitals of three-coordinate tin atoms having a lone electron pair or orbitals of heterometal atoms make the major contribution to the states in the vicinity of the Fermi level (Fig. 12).[29] The results of calculations for the $I_8[Sn_{24}P_{19.3}]$ phase agree well with the data from Mössbauer spectroscopy. The latter demonstrated that the lone electron pairs are not localised on tin atoms; instead, they form an extended band in the vicinity of the Fermi level.[29] Therefore, the properties of type I clathrates can be varied by changing the concentration of vacancies and performing various substitutions in the clathrate framework. Calculations also showed that the guest atoms in all type-I clathrate compounds are ionised.[29, 145] In particular, the charge on the halogen atoms in polycationic clathrates can be as high as -0.95, which is close to the corresponding oxidation state of the element. Arguments in favour of the atomic (non-ionised) state of the strontium atoms in $Sr_8[Ga_{16}\ Ge_{30}]$, which were adduced in several studies (see, for example, Ref. 77), were demolished in more recent studies.[144]

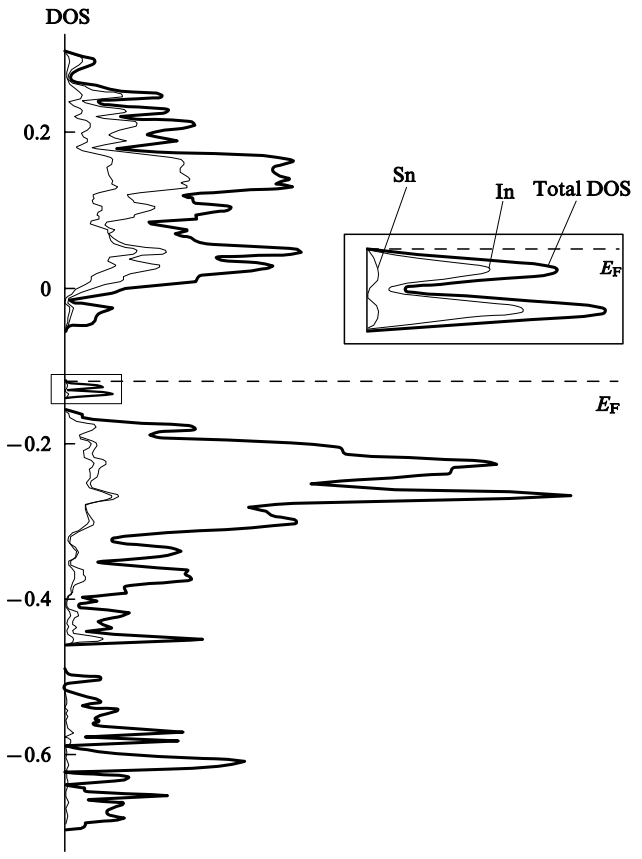

Figure 12. Plot of the density of states (DOS) for $I_8[Sn_{10}In_{14}P_{22}]$.[29]

2. Type II clathrate

In the framework of type-I clathrate compounds, as in the ideal type I clathrate, all atoms form four bonds. Correspondingly, all electrons donated by the guest atoms are excessive. Compensation of excess electron by replacing 32 tin atoms with gallium atoms occurs only in the $Ba_{16}\square_8[Ga_{32}Sn_{104}]$ compound (see Table 4).[47, 84, 85] This is sufficient for compensation of 32 electrons of 16 barium atoms. In all other cases, the compositions of the phases do not obey the Zintl rule. Such phases exhibit metallic conductivity and Pauli paramagnetism.[8, 83, 145, 146]

Studies of the band structures [126, 135, 146, 147] gave an insight into the electronic structures of type-II clathrate phases. Calculations for the hypothetical unfilled framework $[Si_{136}]$ showed that there is a strongly localised vacant nonbonding band with a capacity of 24 electrons in the vicinity of the Fermi level. The insertions of alkali metal (sodium) atoms into the polyhedral cavities in the framework of $Na_x[Si_{136}]$ is accompanied by ionisation of these atoms and filling of the nonbonding band with their valence electrons. If $x \geqslant 8$, the nonbonding band of the framework overlaps with the valence band. Hence, this compound must exhibit metallic properties. Correspondingly, at $x < 8$ silicide must possess semiconducting properties. However, the band gap between the valence and nonbonding bands is so narrow that it becomes smaller than kT at temperatures higher than 40 K, and $Na_x[Si_{136}]$ with $x < 8$ exhibits semiconducting properties only at low temperatures. Calculations of the band structures for silicides were confirmed by ^{29}Si and ^{23}Na NMR spectroscopy.[146, 147] The results of these calculations provide an explanation as to why the structure of the only barium-containing type II clathrate obeys the Zintl rule: the number of electrons donated by the barium atoms to the framework (32 electrons) is larger than the capacity of the nonbonding band (24 electrons), and doping of electrons into the conduction band is energetically unfavourable. That is why the type II clathrate, containing barium atoms as the guest, was synthesised only by partial heterovalent substitution of the atoms of the framework to compensate excess electrons.

It should be noted that silicon-based type II clathrates are characterised by very small compressibility comparable to that of silicon with a diamond-like structure.[148] Actually, the $Na_x[Si_{136}]$ compounds are not transformed into diamond-like silicon under high pressure; instead, they, like diamond-like silicon, are transformed into silicon with the structure of β-tin under a pressure of $\sim$11 GPa. The bulk modulum of $Na_x[Si_{136}]$ is only 8% smaller than that of diamond-like silicon. Hence, such clathrates hold considerable promise as superhard materials. Moreover, calculations demonstrated that carbon-based clathrates (if they will be synthesised) would be expected to have compressibility comparable to that of diamond and smaller than that of cubic boron nitride.[148, 149]

3. Type III clathrate

The general formula of type-III clathrate phases is $A_{30}[Na_{1.33x-10}Sn_{172-x}]$ ($x \approx 9.6$). The framework contains both isolated and 'clusterised' vacancies that formed upon the removal of a pair of bound tin atoms.[37] According to the Zintl concept, the presence of one isolated vacancy in the framework compensates four electrons. However, the removal of a pair of bound tin atoms compensates only six electrons. Actually, the removal of one tin atom gives rise to four three-coordinate tin atoms, each being involved in three bonds and having a lone electron pair. Five electrons are required for this coordination of the tin atom (three electrons for bonds with three other atoms and two electrons for the lone pair). Since the tin atom has only four electrons, one additional electron is necessary for each three-coordinate atom. Therefore, the removal of one tin atom compensates four electrons. The removal of a pair of tin atoms gives rise to only six three-coordinate atoms and, correspondingly, only six electrons are compensated (Fig. 13). It was demonstrated [37] that the ratio between the isolated and clusterised vacancies in the framework of type-III clathrate compounds, on the one hand, and the alkali

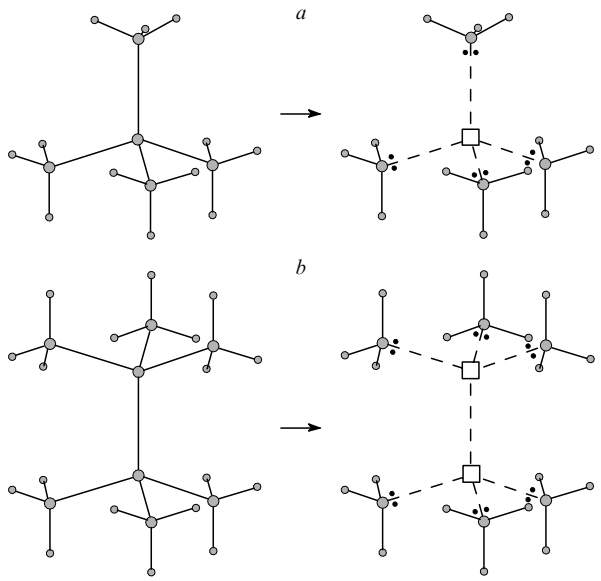

Figure 13. Clusterisation of the lone electron pairs of Group 14 elements in the case of formation of one (*a*) and two adjacent vacancies in the clathrate lattice (*b*).

metal atoms, on the other hand, is in complete agreement with the Zintl concept. Actually, magnetic measurements showed that both type-III clathrate compounds are diamagnetic.[37]

4. Type VIII clathrate

Type-VIII clathrate compounds are low-temperature polymorphs of type-I clathrate compounds.[63] The α phase (type VIII clathrate) of $Eu_8[Ga_{16}Ge_{30}]$[34] is stable up to 969 K, whereas the β phase (type I clathrate) is stable only over a narrow temperature range (969 – 972 K). At 972 K, the latter phase melts congruently. It should be noted that single-phase samples of the α and β phases were synthesised only using quenching to the corresponding temperatures (960 and 970 K for the α and β phases, respectively).

According to the Zintl concept, these compounds should have the same ideal composition: $A_8[Ga_{16}E_{30}]$ (A = Eu, Ba; E = Ge, Sn). However, the real compositions of these phases do not satisfy the Zintl rule. In early studies, the type-VIII clathrate compound in the Ba – Ga – Sn system was characterised as $Ba_8[Ga_{17.4}Sn_{28.8}]$.[33] More detailed investigation of the structure of this compound confirmed that its composition does not satisfy that predicted in terms of the Zintl concept. The refined composition of the phase is $Ba_8[Ga_{17.20(5)}Sn_{28.80(5)}]$.[35]

In the $Eu_8[Ga_{16}Ge_{30}]$ phase, as in other frameworks formed by gallium and germanium, the Ga : Ge ratio differs from 16 : 30.[133] The europium-containing α and β phases exhibit, on the whole, similar properties.[34] The magnetic moment per europium atom in the α modification also corresponds to Eu^{2+}. This phase is a soft ferromagnet and undergoes ferromagnetic ordering at 10.5 K. At this temperature, there is a jump in the temperature dependence of the heat capacity. A decrease in the temperature of ferromagnetic ordering compared to the analogous temperature for the type I clathrate is associated with the fact that the shortest Eu – Eu distances in the β phase are 5.23 Å, whereas the corresponding distances in the α phases are larger (5.56 Å).

5. Type IX clathrate

The type IX clathrate $A_6[E_{25}]$ is the only representative of clathrate compounds whose ideal framework contains three-coordinate atoms. Of the 25 atoms of the framework, 8 atoms are three-coordinate and 17 atoms are four-coordinate. Since each three-coordinate Group 14 atom requires one additional electron, the guest atoms should dope 8 electrons per formula unit into the framework to form an electroneutral compound. Among phases whose frameworks are formed exclusively by Group 14 atoms, the compositions of only two phases, *viz*., $Rb_3Na_5[Sn_{25}]$ (see Ref. 94) and $Ba_6[Ge_{24}\square_1]$,[87] obey the Zintl rule (see Table 5). In the latter phase, 4 excess electrons are compensated by the formation of one vacancy,[87] which is distributed over all positions of the framework in a complex fashion. It should be noted that the formation of this vacancy was not confirmed in other studies.[88, 89] By contrast, this phase was demonstrated to have no vacancies and its composition is inconsistent with the Zintl concept. Moreover, it was established[89] that it is impossible to synthesise a single-phase sample with composition $Ba_6[Ge_{24}\square]$.

Three phases, whose compositions obey the Zintl rule, *viz*., $Ba_6[Ge_{22}In_3]$,[87] $Ba_6[Ge_{21}In_4]$ (see Refs 36 and 91) and $K_6[Sn_{23}Bi_2]$,[92, 93] were synthesised by heterovalent substitution. In the first two phases, 4 excess electrons from the barium atoms are compensated by indium atoms (according to the Zintl concept, the four-coordinate indium atom compensates one electron, and the three-coordinated indium atom compensates two electrons). In the $Ba_6[Ge_{22}In_3]$ and $Ba_6[Ge_{21}In_4]$ phases, the indium atoms are distributed over all positions of the framework in a complex fashion. Hence, this distribution may also be considered as consistent with the Zintl concept. In the $K_6[Sn_{23}Bi_2]$ structure, the bismuth atoms occupy the three-coordinate positions of the framework. Each bismuth atom has 5 valence electrons, which are required for this coordination. Correspondingly, only 6 three-coordinate tin atoms remain in the framework, and six electrons from potassium atoms are sufficient for the formation of an electron-balanced compound. Phases whose electronic structures satisfy the Zintl rule, are diamagnetic narrow gap semiconductors.[36, 87, 91]

Compounds which do not obey the Zintl rule can be divided into two groups, *viz*., electron-excessive $Ba_6[Si_{25}]$ (+4*e*), $Ba_6[Ge_{25}]$ (+4e), $Ba_6[Ge_{23}Sn_2]$ (+4e) and $Na_2Ba_4[Ge_{25}]$ (+2e) and electron-deficient $K_6[Sn_{25}]$ (−2e).

The composition of potassium stannide with the type-IX clathrate structure has been initially characterised as $K_{7.4}[Sn_{25}]$.[69] However, the description of the positions and occupancies of the potassium atoms in this structure was doubtful, because the potassium atoms in this model were located at physically unreasonable short distances (2.92 Å). Later on, this phase was demonstrated to have a $K_6[Sn_{25}]$ composition.[92] To explain the fact that this composition does not satisfy the Zintl principle, the band structure of $K_6[Sn_{25}]^{2-}$ of the $K_6[Sn_{23}Bi_2]$ compound, which is isoelectronic to the Zintl phase, was calculated.[92, 93] This hypothetical structure is in complete agreement with the Zintl concept, and the calculations showed the typical semiconducting band structure with a band gap of ~1 eV. However, this band structure features an isolated filled band with a capacity of two electrons at the top of the valence band. Filling of this band influences primarily the interaction (repulsion) between 8 lone electron pairs of the tin atoms directed toward the centre of a distorted cube (see Fig. 8 *d*) and the potassium atom located in the centre of this cube. The repulsion is so high that a decrease in the number of electrons belonging to three-coordinate tin atoms is more favourable. Hence, the upper two-electron band in $K_6[Sn_{25}]$ is vacant. The replacement of two out of eight tin atoms with bismuth atoms (suppression of stereoactivity of the lone electron pair is more typical of the latter atoms) decreases repulsion between electrons giving rise to the classical Zintl phase $K_6[Sn_{23}Bi_2]$.[92, 93]

The band structures of electron-excessive phases were investigated.[95] In particular, the Fermi level was demonstrated to be located in the conduction band. According to the results of resistive measurements, such phases actually exhibit metallic conductivity.[86, 97, 150] The reason for the disorder in the guest sublattice (see the crystal structure of the type IX clathrate) was revealed. In the ordered structure, the Fermi level falls in a peak of the density of states. In the authors' opinion,[95] this fact may be indicative of the instability of the structure. Displacements of the

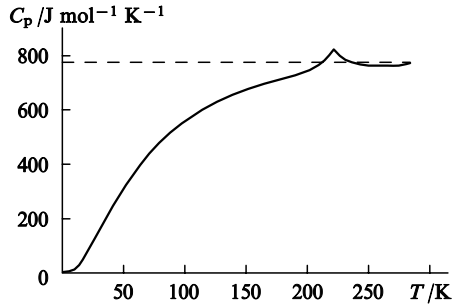

Figure 14. Temperature dependence of the heat capacity for $Ba_6[Ge_{25}]$.[97]

guest atoms from the ideal position to a partially occupied adjacent position leads to splitting of this peak into two peaks with larger and smaller energies. Therefore, a 'band' analogue of the Jahn–Teller effect is manifested in the crystal, and the density of states at the Fermi level substantially decreases.[95]

As expected, electron-excessive phases have metallic conductivity. A study of the heat capacity of the $Ba_6[Ge_{25}]$ phase revealed[97] a positive deviation from the Dulong–Petit law analogous to that observed for polycationic type I clathrates (Fig. 14). However, the authors of the cited study[97] explained this fact by a structural phase transition. At temperatures higher than the phase transition temperature, the barium atoms have high vibrations and can migrate from one partially occupied 24*e* position to another. A decrease in the temperature leads to 'freezing' of the barium atoms in the partially occupied 24*e* positions, which is indirectly confirmed by measurements of the temperature dependences of the electrical resistance, magnetic susceptibility and charge carrier mobility. In the $Na_2Ba_4[Ge_{25}]$ phase, 2/3 of barium atoms in the centres of the open 20-vertex polyhedra are replaced with sodium atoms. This phase is more ordered, and no structural transitions are observed in this phase down to 2 K.[97] Interestingly, both barium-containing germanides with the type-IX clathrate structure exhibit superconducting properties at low temperatures.[150] The superconducting transition temperatures T_c for the 'disordered' $Ba_6[Ge_{25}]$ phase and the 'ordered' $Na_2Ba_4[Ge_{25}]$ phase are 0.24 and 0.84 K, respectively. However, the temperature T_c of the disordered phase increases by a factor of more than 16 in response to external pressure (at 3.4 GPa, $T_c \approx 4.0$ K).[151] This fact was attributable to ordering of the barium atoms in the open cavities. Under high pressure, the barium atoms move from the partially occupied 24*e* positions to the 12*d* and 4*b* positions with 100% occupancy. The superconducting transition temperature for the ordered phase remains virtually unchanged under external pressure.[151] The above-mentioned compounds serve as examples of superconductors containing sp^3-hybridised atoms of p-elements.

IV. Methods for the synthesis of semiconducting clathrates

Since guest metal atoms (alkali metals, alkaline earth metals and europium) are highly reactive, polyanionic clathrates are generally synthesised under an inert gas (argon or helium) in sealed niobium or tantalum tubes, which are further placed in evacuated quartz tubes before annealing. Polycationic clathrates are more commonly synthesised simply in evacuated quartz tubes. It is more convenient to consider procedures for the synthesis of semiconducting clathrates for each particular main framework-forming element, *viz*., silicon, germanium or tin.

Silicon with a diamond-like structure has a very high melting point (1685 K) and, correspondingly, very low reactivity. Hence, the stoichiometric synthesis of binary clathrate silicides can be performed only at a high temperature under external pressure. For example, this procedure was used for the synthesis of $Ba_8[Si_{46}]$,[48–51] $Na_{8-x}Ba_x[Si_{46}]$,[43,44] $Ba_8[Si_{46-x-y}Ge_x\square_y]$ (see Ref. 49) and $Ba_{24}[Si_{100}]$.[86] The synthesis temperature was 1073–1573 K, and the pressure was 1.5–3 GPa. Another procedure for the synthesis involves thermal decomposition of binary silicides MSi (M = Na, K, Rb) to give $M_8[Si_{46}]$ or $M_x[Si_{136}]$ depending on the reaction conditions.[5,40,42,81,82] Heating to 500–700 K in the absence of dynamic vacuum can afford either type-I or type-II clathrate compounds with an x of ~ 10.[5,40–42] Under conditions of dynamic vacuum, syntheses produce primarily type II clathrate compounds. Depending on the reaction time, temperature and gas pressure, x can substantially be decreased (down to $x = 0.1$ at $\sim 10^{-3}$ Pa and 700 K).[152] Ternary clathrate silicides can be synthesised by the stoichiometric method. It should be noted that samples are usually pre-treated to enhance the reactivity of the starting compounds by performing either arc melting of the sample (for example, in the case of $Sr_8[Ga_xSi_{46-x}]$)[52] or heating of the sample to very high temperatures of 1300–1700 K (for example, in the case of $Ba_8[M_xSi_{46-x}]$, where M = Ni, Pd, Pt, Cu, Ag, Au),[53] generally, in an high-frequency furnace.

Germanium (T_m = 1210 K) is more reactive than silicon in spite of the fact that elemental germanium also has a diamond-like structure. Clathrate germanides can be synthesised by annealing stoichiometric amounts of the corresponding elements at 850–1250 K. As in the case of clathrate silicides, pre-treatment of samples is almost always required. For example, the $Ba_6[Ge_{25}]$ compound was prepared using arc melting[88] or induction heating.[89] The use of arc melting often leads to depletion of the reaction mixture due to evaporation of the most volatile metal and, correspondingly, to deviation from the starting stoichiometry. Because of this, this method is more often used for the synthesis of single crystals of clathrate compounds.[76,88] Single-phase samples are commonly synthesised using induction heating.[34,36,55–61,64,90,91] Since certain clathrate phases are stable only in a narrow temperature range (for example, β-$Eu_8[Ga_{16}Ge_{30}]$), the synthesis of such compounds involves quenching.[34]

Taking into account that the melting point of tin is low (505 K), stannides are generally prepared by annealing of a stoichiometric mixture of the elements without pre-treatment. In some instances, reaction mixtures containing an excess of tin are used. In such cases, tin serves also as a flux (for example, in the synthesis of the type IX clathrate $Rb_3Na_5[Sn_{25}]$).[91] The usual synthesis temperature is 600–700 K. Some tin-containing clathrates also cannot be prepared without quenching (for example, $Ba_8[Ga_{17.2}Sn_{28.8}]$).[33,35]

Polycationic clathrates are commonly synthesised by the simple stoichiometric method.[19–23,25,26,28,29,31,32] Elemental halogens are difficult to use because of their high volatility and also because chlorine and bromine are not solids under normal conditions. Therefore, halides of either metals or non-metals (MX_4, MX_2, TeI_4, ZX_3, where M = Ge, Sn; Z = P, As, Sb; X = Cl, Br, I) are usually used as the starting compounds. The synthesis temperatures vary from 670–830 K for tin-containing phases[25,26,28,29,31,32] to 1070 K for the $I_8[I_{1.5}Si_{44.5}]$ compound.[27,30] Polycationic clathrates can also be synthesised by the chemical transport reaction method. Since halogens and halides used as precursors are molecular compounds, they can serve as efficient transport agents. The chemical transport reaction method can be used for the preparation of single crystals and single-phase samples of polycationic clathrates. For example, single crystals of $Br_{2.4}I_{5.6}[Sn_{24}P_{19.2}\square_{2.8}]$ were grown in a temperature gradient of 825 – 725 K with the use of SnI_4 as the transport agent.[31,32]

V. Conclusion

Further studies of semiconducting clathrates will be aimed primarily at acquiring new fundamental knowledge and constructing new materials.

The fundamental scientific interest is associated primarily with the fact that particular type-I clathrate silicides [48, 50, 51] and type-IX clathrate germanides [150, 151] exhibit superconducting properties. Notwithstanding the fact that T_c for these compounds is no higher than 9.0 K, the occurrence of superconductivity in sp^3-hybridised systems is of obvious importance for a better understanding of this phenomenon. First data on the electron–phonon mechanism of superconductivity in clathrates were published as late as 2003.[153, 154]

An interesting field of investigation of semiconducting clathrates is concerned with elucidation of the reasons for the occurrence of such complicated structures, which are characterised by unusual filling of space with atoms and the unusual electron density distribution, and by the fact that the majority of these structures are thermodynamically stable and have diverse crystal structures. In particular, stability of the type-I clathrate compounds characterised by a distribution of the oppositely charged guest and host atoms was explained [155] in terms of periodic nodal surfaces (PNS),[155, 156] which allow one to relate the topology of the electron density distribution to the crystal structure. This method was also used for the description of the pathway of the phase transition between the α and β forms of $Eu_8[Ga_{16}Ge_{30}]$.[63]

Applied aspects of research on semiconducting clathrates are associated with the prospects of construction of new materials based on type-I clathrate compounds for thermoelectric cooling. The best currently available figure of merit (0.35) [157] is smaller than the maximum value (1.4) achieved for other types of inclusion compounds, *viz*., filled scutterudites.[132, 158] Nevertheless, there is no doubt that semiconducting clathrates hold promise,[11] and relative failures at the present stage of the investigation of these compounds are due to the fact that fundamental problems remain unsolved.[159, 160] Among such problems are the elucidation of the mechanisms of the abnormally low heat conductivity of clathrates and the prediction of fine changes in the electronic structure upon heterovalent substitution, including the prediction of the effective masses and concentrations of charge carriers.

Evidently, a combination of fundamental and applied studies [161] of semiconducting clathrates will contribute substantially to the development of inorganic and supramolecular chemistry, solid state chemistry and condensed matter physics.

Inorganic structures as materials for gas sensors †

R B Vasiliev, L I Ryabova, M N Rumyantseva, A M Gaskov

Contents

I.	Introduction	939
II.	Mechanism of gas sensitivity of semiconductor materials	940
III.	Mechanism of gas sensitivity of systems with heterojunctions	943
IV.	Conclusion	954

Abstract. Studies concerned with the design of new inorganic materials for gas sensors based on semiconductor structures are analysed. The influence of adsorbed molecules on the electronic state and electrical conductivity of the surface and inner interfaces in semiconductor materials is discussed. The mechanism of gas sensitivity is considered taking metal/insulator/semiconductor, semiconductor/insulator/semiconductor, metal/semiconductor, and semiconductor/semiconductor structures as examples. Specific features of the behaviour of heterostructures based on nanocrystalline metal oxides on single-crystalline silicon substrates with a SiO_2 dielectric layer are pointed out. The sensor properties of semiconductor structures in the detection of various molecules are described. The bibliography includes 114 references.

I. Introduction

Chemical sensors are among the most efficient environmental control, human physiology control and food quality control tools. Recently, design of new materials possessing a high and selective sensitivity to specific types of molecules has been a subject of intensive research. The authors of numerous publications on the subject (see, *e.g.*, reviews and monographs [1–7]) have paid considerable attention to fundamental concepts of adsorption mechanisms and to the character of electronic properties of the surface of oxide materials. This review mainly concerns problems related to processes occurring at interfaces of various semiconductor structures that are used as sensor elements. Usually, gas sensing elements of such structures are semiconductor metal oxides SnO_2, ZnO, WO_3 and In_2O_3.[7–17] The ability of these materials to detect gas molecules is due to their fundamental physical and chemical properties. The conductivity of wide-gap semiconductors in the temperature range 300 – 800 K is strongly dependent on the state of the surface. At these temperatures, redox reactions proceed on the oxide surfaces. The chemical properties of the surface also play an important role in the gas sensitivity mechanism. The oxide surfaces are characterised by good adsorption properties and high reactivities that are due to the presence of (i) free electrons in the conduction band, (ii) surface and bulk oxygen vacancies and (iii) reactive chemisorbed oxygen.[18,19]

In (traditional) resistive gas sensors the mechanism of gas sensitivity involves chemisorption on the surface accompanied by a change in the concentration of charge carriers (hereafter, carrier concentration) in the bulk of a semiconductor. The sensor response is a result of a change in the bulk conductance of a polycrystalline semiconductor material. The state of contacts between grains in the polycrystalline system contributes largely to the conductance. Such systems are extremely sensitive to trace amounts of oxidising or reducing agents present in the atmosphere. At the same time, information on the composition of the gas phase is insufficient due to the low selectivity of adsorption processes. The main goal of numerous studies aimed at improving the sensor parameters of materials is to optimise the electronic properties or the adsorption capacity of the materials. However, this approach is of limited use because resistive semiconductor gas sensors combine the functions of the sensing element (receptor) and signal transducer in the same material. Enhancement of sensitivity by changing the state of the surface leads to a change in the carrier concentration in the bulk of the semiconductor grain, *i.e.*, to a change in the parameters of the transducer. The receptor and transducer functions can be separated in those systems which include an interface between materials with different electronic properties. The conductance of such systems (the so-called heterostructures) is governed by the height of an energy barrier to charge carriers at the heterointerface. Chemisorption affects the electronic state of the interface, thus being responsible for the onset of gas sensitivity. Yet another advantage of the heterostructure gas sensors over resistive sensors is that they permit control of both the resistance and capacitance by varying the voltage and frequency of the reference signal.

The inorganic structures used for fabrication of various types of gas sensors are listed in Table 1.

Most often, gas sensors employ the so-called Schottky diodes (metal/semiconductor systems) as heterocontacts. The sensor properties of the Schottky diodes based on noble metals possessing catalytic properties (Pt, Pd; hereafter, catalytic metals) and single-crystalline silicon or silicon carbide have been studied in detail.[57] The Schottky diodes are extremely sensitive to trace amounts of hydrogen. The action mechanism of these systems

† This is the last review in a series of publications concerning the main avenues of research carried out at the Inorganic Chemistry Chair, Department of Chemistry and Department of Materials Science, M V Lomonosov Moscow State University [see *Russian Chemical Reviews* **73** (9) (2004)].

Table 1. Inorganic structures used in gas sensors.

Structure	Method of synthesis [a]	Molecules detected	Ref.
Metal/insulator/semiconductor			
$Pd/SiO_2/Si$	EBE	H_2, C_2H_5OH, $(CH_3)_2CO$, NO	20–22
$Pd/SiO_2/Si$	LIE	NH_3	23
$Pt/SiO_2/Si$	EBE	H_2	24
$Ru/SiO_2/Si$	EBE	H_2	25
$Ir/SiO_2/Si$	EBE	H_2	25
$Pd/SiO_2/SiC$	EBE	H_2	26
Semiconductor/insulator/semiconductor			
$SnO_2/SiO_2/Si$	SP	NH_3, C_2H_5OH	27
Metal/semiconductor			
Pd/Si	EBE	H_2	28–31
Pd/SnO_2	CVD	H_2, CO, O_2	32–34
Pd/TiO_2	EBE	H_2	35
Pd/TiO_2	TVE	H_2	36
Pt/SnO_2	CVD	NO_2	37
Pt/TiO_2	EBE	CO, O_2	38
Semiconductor/semiconductor			
PbS/Si	TVE	H_2	39
WO_3/Si	MS	NO	40
SnO_2(M)/Si	SP	NO_2, C_2H_5OH	41, 42
CuO/ZnO	SPS	CO, H_2, C_3H_8, H_2O	43–50
CuO/ZnO	MS	H_2, CO, H_2O	51
La_2CuO_4/ZnO	SPS	H_2, CO, H_2O	52, 53
CuO/SnO_2	MS	H_2S	54–56

involves formation of a dipole layer at the metal/silicon interface. Yet another example is provided by a PbS/Si semiconductor/semiconductor heterojunction.[39] Its sensitivity to hydrogen is also due to the change in the carrier concentration in the PbS layer upon dissociative dissolution of hydrogen. The sensitivity of these systems to hydrogen is first of all associated with the impossibility of more complex molecules reaching the heterojunction region owing to limitations imposed on diffusion in crystalline systems. The use of porous nanocrystalline systems based on semiconductor oxides removes limitations on the diffusion of gas molecules.

In this review we will consider the electronic state of interfaces (surface and heterocontacts) in semiconductors under adsorption and the mechanisms of gas sensitivity of various types of heterostructures including those based on nanocrystalline metal oxides.

II. Mechanism of gas sensitivity of semiconductor materials

The mechanism of gas sensitivity in semiconductors has been studied in detail.[58–62] Materials used in resistive gas sensors are characterised by a reversible change in the conductivity depending on the gas phase composition. Accompanying processes can be divided into two main groups, *viz*., processes proceeding on the surface and in the bulk of the semiconductor material. The first group includes adsorption of gas molecules and chemical reactions on the surface and causes a change in the electronic state of the surface. The second group is associated with the change in the free carrier concentration in the near-surface layer as a result of electron exchange with the surface and also includes diffusion of atoms and variation of the concentration of bulk defects. All these changes caused by the interaction between the semiconductor material and the gas phase affect the carrier concentration and mobility (μ). In turn, changes in these parameters change the conductivity.

The electrophysical properties of a finite semiconductor are to a great extent determined by the presence of a specific class of energy levels (the so-called surface states) in the band structure. A comprehensive treatment of the surface states and interfaces has been given in a monograph [63] and a particular case of the surfaces of oxide materials was considered in Refs 64 and 65.

The interaction with the gas phase modifies the surface states. It should be noted that physisorption has little effect on the free carrier concentration and can influence only the electron work function needed to leave the semiconductor. Chemisorption is accompanied by charge exchange between the adsorbed molecule and the semiconductor. Consider an n-type semiconductor (SnO_2, ZnO, In_2O_3) in the framework of a simplest model.[66] Assume that there are no surface eigenstates on the surface of the semiconductor before adsorption (in the initial state) so that the energy bands are flat (Fig. 1). Depending on the electronegativity of the adsorbate molecule, the following types of chemisorption are possible:

(1) the electron affinity, A, of the adsorbate molecule is greater than the semiconductor work function, ϕ_{sc}; as a consequence, a surface acceptor level, E_{sa}, is formed, the near-surface layer of the semiconductor becomes depleted of electrons and the work function increases;

(2) the ionisation energy, I, of the adsorbate molecule is lower than the semiconductor work function, ϕ_{sc}; in this case, a surface donor level, E_{sd}, is formed, the near-surface layer of the semiconductor becomes enriched with electrons and the work function decreases.

The interfacial potential barrier, V_s, and the thickness, L, of the depletion layer, are given by:[67]

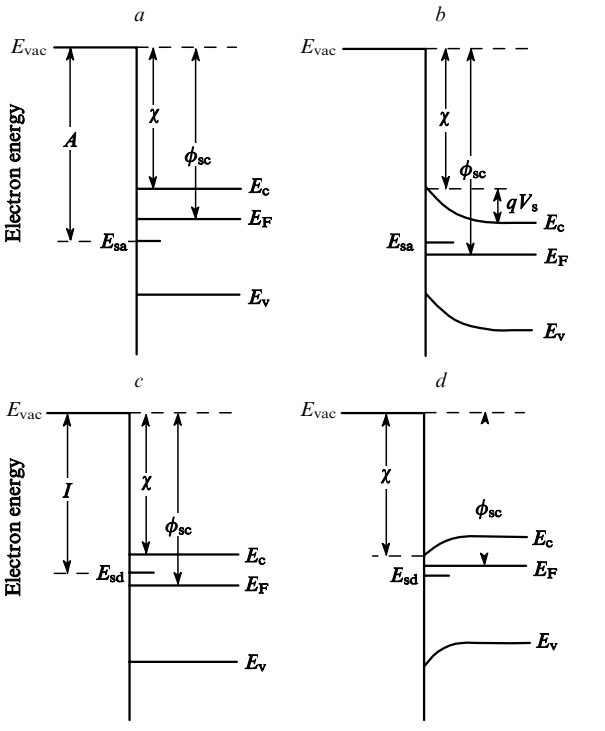

Figure 1. Band diagram of n-type semiconductor under adsorption of acceptor (*a*, *b*) and donor (*c*, *d*) molecules.[63]
Initial states (*a*, *c*) and final states (*b*, *d*); E_{vac} is the vacuum energy; E_c is the conduction band edge energy, E_v is the valence band edge energy, E_{sa} is the acceptor level, E_{sd} is the donor level, A is the electron affinity of the adsorbate, I is the ionisation energy of the adsorbate, χ is the electron affinity of the semiconductor and ϕ_{sc} is the semiconductor work function.

$$V_s = \frac{2\pi Q_s^2}{\varepsilon N_d} = \frac{2\pi (qN_s)^2}{\varepsilon N_d}, \quad (1)$$

$$L = L_D \left(\frac{eV_s}{kT}\right)^{1/2}, \quad (2)$$

where Q_s is the surface charge density, ε is the dielectric constant, N_d is the concentration of the donor impurity, q is the charge of the surface states, N_s is the density of the charged surface states, k is the Boltzmann constant, T is the absolute temperature and L_D is the Debye screening length

$$L_D = \left(\frac{\varepsilon kT}{2\pi e^2 N_d}\right)^{1/2}.$$

Typically, a doped semiconductor with $N_d \approx 10^{18}-10^{20}$ cm^{-3} and $N_s \approx 10^{13}$ cm^{-2} is characterised by $V_s \approx 1$ eV and $L \approx 1-100$ nm.[7]

Usually, semiconductor oxides used as gas sensors are polycrystalline materials with grain sizes ranging from 10 to 100 nm.[7] As the grain size decreases, the proportion of the surface atoms in the sensor material increases; correspondingly, the effective adsorption surface area and the contribution of the surface to the electrophysical properties also increase. The structure of a polycrystalline material is schematically shown in Fig. 2. Each grain is covered with a chemisorbed oxygen layer, which results in the formation of a near-surface layer depleted of charge carriers and intergranular potential energy barriers to charge carriers (the so-called double Schottky barriers). The conductivity of this system is determined by the electronic properties of the grain bulk and by transport of carriers through the barriers between grain contacts. Two mechanisms of conductivity of polycrystalline materials have been considered.[7]

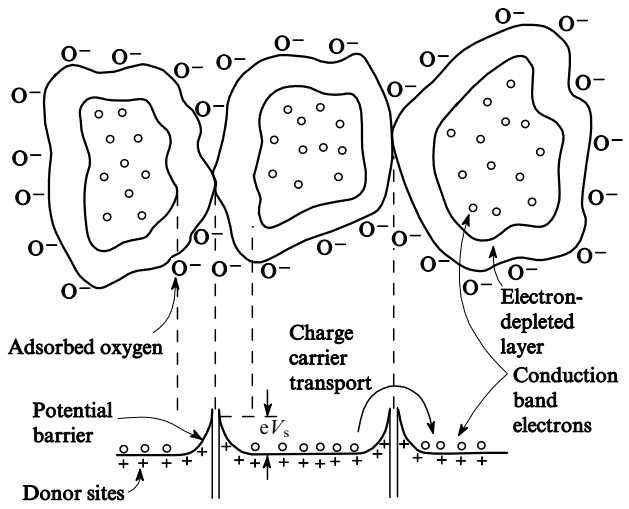

Figure 2. Polycrystalline oxide structure (above) and the corresponding band diagram (below).[59]

1. Surface trap limited conductivity mechanism. The conductivity is governed by the changes in the carrier concentration in the depletion layer and the potential energy barriers between grain contacts do not contribute to the conductivity. This mechanism is possible either in the case of surface conductivity (adsorption on a single-crystalline material) or when the intergranular barriers are low. The key parameter determining the conductivity is the thickness of the depletion layer.

2. Barrier-limited conductivity mechanism assumes a constant total carrier concentration and variable carrier mobilities. This mechanism is typical of all polycrystalline materials for which the energy of the intergranular barriers is higher than kT. The key parameter responsible for conductivity is the barrier height at grain boundaries.

It should be noted that depletion of charge carriers in the near-surface layer and formation of a surface potential barrier are characteristic of both mechanisms. However, in the former case charge carriers move along the interface or over the surface, whereas in the latter case they move through a potential barrier.

A method was proposed[7] for calculating the changes in the carrier concentration under adsorption proceeding by the first mechanism. The surface reactions considered were as follows:

$$\frac{m}{2}\,O_2 + e \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} O_m^-, \quad (3)$$

$$O_m^- + m\,R \xrightarrow{k_2} m\,RO + e, \quad (4)$$

where R is the molecule of the reducing gas and m is the coefficient related to a particular form of chemisorbed oxygen (O_2^- or O^-). It should be noted that the existence of O^{2-} oxygen ions was also reported (see, *e.g.*, Ref. 68).

If a solid is in equilibrium with the gas phase, the equation for a surface coverage, $\theta = N_s/N_0$ (N_s is the number of occupied adsorption sites and N_0 is the total number of adsorption sites), with chemisorbed oxygen can be written as follows:

$$\theta = \frac{k_1 n (p_{O_2})^{m/2}}{k_{-1} + k_1 (p_{O_2})^{m/2} + k_2 (p_R)^m}, \quad (5)$$

where n is the equilibrium electron concentration.

In the case of adsorption on a thin film (film thickness, h, is less than the Debye screening length, L_D; *i.e.*, a totally depleted film) the conductivity (σ) is given by[7]

$$\sigma = \text{const} \exp\left[\frac{-(E_s - E_d)}{kT}\right] k_1^0 (p_{O_2})^{-m/2} \left[k_{-1}^0 + k_2^0 (p_R)^m\right], \quad (6)$$

where the first term (const) depends on the doping level, the conductivity of the bulk semiconductor and the number of adsorption sites on the surface; E_s is the ionisation energy of the surface state; E_d is the ionisation energy of the donor impurity and k_i^0 is the pre-exponent in the Arrhenius equation.

The conductivity is characterised by an activation energy ($E_s - E_d$), being also a power function of the partial pressures of oxygen and the reducing gas. The exponent is determined by the equilibrium forms of oxygen chemisorbed on the surface.

Similar schemes for calculating the electron concentration under equilibrium conditions were considered in other studies.[59, 60] Zemel[60] related the surface charge to the decrease in the surface concentration of oxygen vacancies ($V_O^\times$). In the course of chemisorption an oxygen ion occupies a position of the surface oxygen vacancy. The change in the surface concentration of ionised oxygen sites and the negative charge surface are given by

$$-\left[\Delta O_s^{2-}\right] = \left[V_{O_s}^\times\right] - \left[V_O^\times\right], \quad (7)$$

$$Q_s = -2e\left[\Delta O_s^{2-}\right]. \quad (8)$$

Assuming that the near-surface layer of each grain is electron-depleted, the expression for the effective electron concentration (n_{ef}) is as follows

$$n_{ef} = n_0 - \frac{\alpha Q_s}{eW}, \quad (9)$$

where n_0 is the bulk carrier concentration and α/W is the ratio of the grain surface area to the grain volume.

With the known average electron concentration[60] it is possible to estimate the surface charge density from relation (9). Polycrystalline SnO_2 with a carrier concentration of 10^{19} cm^{-3} and typical grain sizes of 10–100 nm becomes totally depleted of charge carriers at a surface charge density of 10^{13} cm^{-2}, which approx-

imately corresponds to one chemisorbed species per 100 surface atoms.

Generally, one should take into account a decrease in the electron concentration with shortening the distance from the surface. In this case, the effective carrier concentration is given by [69]

$$n_{\mathrm{ef}} = \frac{1}{d}\int n_0 \exp\left[\frac{-V(z)}{kT}\right] \mathrm{d}z, \tag{10}$$

where d is the grain diameter and $V(z)$ is the potential ($z = 0$ corresponds to surface and $z > 0$ corresponds to the grain bulk).

Consider the barrier-limited conductivity mechanism. As mentioned above, a double Schottky barrier is formed at each grain contact. For a unit contact the carrier current, j, is related to the barrier height, V_s, and the voltage applied, U, as follows [70]

$$j \propto \exp\left(\frac{-eV_s}{kT}\right)\sinh\left(\frac{eU}{2kT}\right). \tag{11}$$

In this case (assuming equal potential energy barriers between grain contacts) the conductivity of the polycrystalline system is exponentially related to the barrier height [71]

$$\sigma \propto \sigma_0 \exp\left(\frac{-eV_s}{kT}\right), \tag{12}$$

where σ_0 is a constant depending on the specific bulk conductivity of the grain.

The barrier height is proportional to the surface charge [see Eqn (1)]. Relation (12) predicts that a minor variation of the surface charge must cause significant changes in the conductivity of the polycrystalline material. At the same time a material with no potential energy barriers between grain contacts must be characterised by linear dependences of the carrier concentration and, correspondingly, conductivity on the surface charge. Therefore, systems with the barrier-limited conductivity mechanism seem to be attractive for design of materials for gas sensors. The gas sensing properties of polycrystalline ceramics with this conductivity mechanism have been studied.[72]

A number of studies on the Hall effect in polycrystalline oxides (SnO_2, ZnO) under adsorption of gaseous ethanol and nitrogen dioxide have been reported (see, *e.g.*, Refs 60, 73–75). This allowed the contribution of the carrier mobility to the conductivity of the material to be separated. It was found that the change in the carrier mobility is small compared to the change in the carrier concentration and makes an insignificant contribution to the electrical response of the material. Numerical calculations of the heights of the potential energy barriers between grain contacts as functions of the grain size and shape [58, 76] carried out for mobile donor atoms (high-temperature case) showed that the barrier height decreases substantially as the grain size decreases (Fig. 3). The shape of the grain has almost no effect on the barrier height; however, the formation of intergranular 'necks' affects this parameter. The profile of the potential inside two contacting grains connected by a neck of diameter D is shown in Fig. 4. A neck is a homogeneous contact region, which is not a charged interface between two grains. An increase in D causes a substantial decrease in the barrier height at the interface. Different types of intergranular necks are shown in Fig. 5. At $D > 2L$ (L is the thickness of the depletion layer) (Fig. 5 *a*), a conducting channel is formed (in this case adsorption affects only the diameter of this channel); at $D < 2L$ (Fig. 5 *b*) the barrier is too low but adsorption influences this parameter; and at $D = 0$ (double Schottky barrier) (Fig. 5 *c*), adsorption affects the barrier height (note that a zero neck radius does not mean the absence of contact between two grains).

Thus, the barrier-limited conductivity mechanism is possible only in rather large ($d \gg 2L_D$), *i.e.*, mostly ceramic crystalline samples. Sintering of samples leads to intergrowth of crystallites and redistribution of the bulk concentration of donor ions as a result of diffusion and can cause a decrease in the contribution of the barrier-limited conductivity mechanism.

The conductivity of a polycrystalline material with the barrier-limited conductivity mechanism was studied as a function of the partial pressure of gas.[7] The surface coverage with chemisorbed

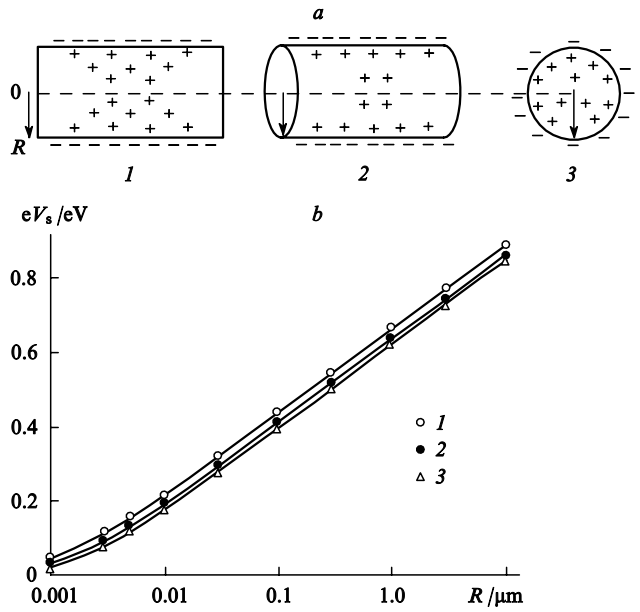

Figure 3. Grain geometries used in the solution of the Poisson equation (*a*) and intergranular barrier heights, eV_s, plotted *vs.* grain size, R, for totally depleted grains (*b*).[76]
Surface concentration of donor sites $N_{ds} = 10^{26}$ m^{-3}, $T = 573$ K. Grain shape: (*1*) slab (1D), (*2*) cylinder (2D) and (*3*) sphere (3D).

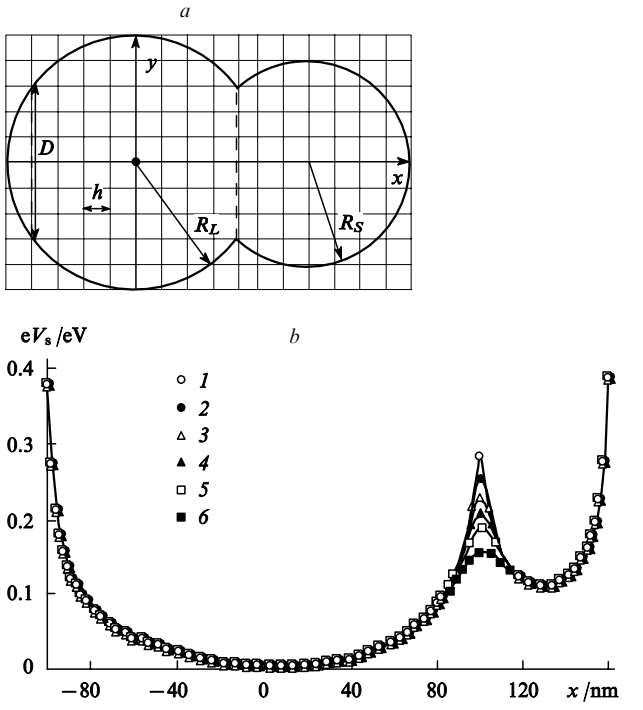

Figure 4. Schematic illustration of a contact between two grains (*a*) and calculated potential profile (*b*).
(*a*) D is the diameter of the contact circle in a neck; h is the mesh size used in the numerical solution; and R_L and R_S are the grain radii ($R_L = 100$ nm, $R_S = 30$ nm);[76]
(*b*) D /nm: 4 (*1*), 6 (*2*), 9 (*3*), 13 (*4*), 20 (*5*) and 28 (*6*).

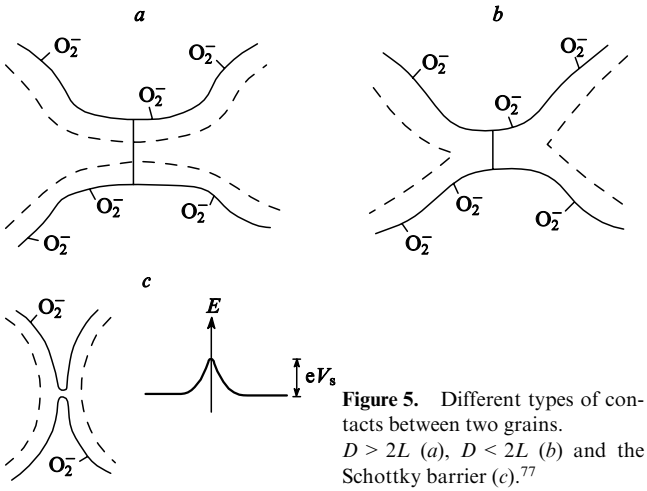

Figure 5. Different types of contacts between two grains. $D > 2L$ (*a*), $D < 2L$ (*b*) and the Schottky barrier (*c*).[77]

oxygen and the barrier height, V_s, at the interface between two grains are given by

$$\theta = k_1^0 N_d \exp\left[\frac{-(E_s - E_d)}{kT}\right] \exp\left(\frac{-eV_s}{kT}\right) \frac{(p_{O_2})^{m/2}}{k_{-1}^0 + k_2^0 (p_R)^m}, \quad (13)$$

$$V_s = \frac{kT}{e}\left\{\text{const} + \frac{m}{2} \ln p_{O_2} - \ln\left[k_{-1}^0 + k_2^0 (p_R)^m\right]\right\}, \quad (14)$$

where const depends on the Debye screening length. From this the relation for the conductivity is

$$\sigma \propto \frac{k_{-1}^0 + k_2^0 (p_R)^m}{(p_{O_2})^{m/2}}, \quad (15)$$

i.e., the barrier height is proportional to the logarithm of the partial pressure of gas, which corresponds to a power dependence of the conductivity. Thus, the conductivity depends on the partial pressure of gas in the same manner for both the barrier-limited conductivity mechanism and in the absence of potential energy barriers at interfaces between grains.[7] The reason is that electrons must overcome a potential barrier to be trapped on the surface. The interface coverage with chemisorbed oxygen varies only slightly with an increase in the partial pressure of oxygen. For instance, in a typical case $N_d \approx 10^{18}$ cm^{-3} and $N_s \sim 10^{15}$ cm^{-2} the maximum coverage is $\theta \approx 10^{-3}$.

In a vast majority of experimental studies the heights of the barriers between grains were determined from the temperature dependences of conductivity [see relation (12)]. The dependence of the average barrier height on the oxygen content in SnO_2 ceramics is shown in Fig. 6. As should be expected, in accord with relation (14) the average barrier height increases as the oxygen pressure increases. The experimental data on the barrier heights for polycrystalline SnO_2 are listed in Table 2.

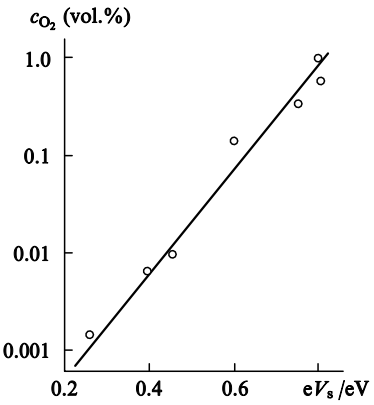

Figure 6. Average barrier height, V_s, in SnO_2 ceramic plotted *vs.* oxygen content in gas phase.[77]

Table 2. Intergranular barrier height in polycrystalline SnO_2.

eV_s /eV	T /K	p_{O_2} /atm	Ref.
Sintered ceramics			
0.64	770	1	78
0.62	770	1	79
Thin film			
0.73	700	10^{-2}	80
0.65	773	2.1×10^{-2}	81

Note that the barrier height calculated from the temperature dependence of conductivity corresponds to the activation energy for conductivity and is not directly related to the actual barriers between grains in the material. A proof of the barrier-limited conductivity mechanism is provided by the nonlinear current–voltage curve. However, there is a limitation associated with the fact that the potential applied is distributed along a chain of barriers connected in series. For small grains, nonlinear current–voltage curves are observed only at large potentials (this potential range is usually left out of consideration). A nonlinear current–voltage curve was obtained in experiments with tin dioxide ceramics.[77] The bulk and interface contributions to the conductivity of a polycrystalline material can also be separated using the complex impedance technique.[82,83] The complex impedance measurements of palladium-doped tin dioxide were reported.[84] Figure 7 presents the sensor response (calculated as the ratio of the resistance in gas to the resistance in air) plotted *vs.* the frequency of the reference signal. At low frequencies, a rather high sensitivity and near absence of high-frequency components were observed.

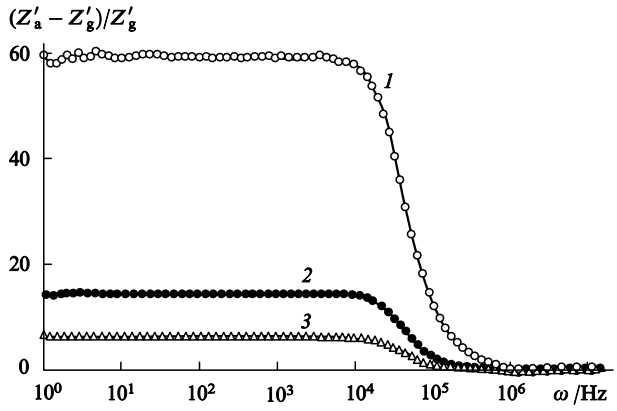

Figure 7. Sensor response, $[(Z'_a - Z'_g)/Z'_g]$, plotted *vs.* reference signal frequency, ω, for SnO_2(Pd) samples on an insulating support at 400 °C;[84] Z'_a is the resistance in air and Z'_g is the resistance in gas; gas concentration in air /ppm: (*1*) 80 (C_2H_5OH), (*2*) 1000 (CH_4) (*3*) and 300 (CO).

III. Mechanism of gas sensitivity of systems with heterojunctions

Systems with heterojunctions (heterostructures) are comprised of two or more layers with different chemical compositions and electronic properties. The main types of systems with heterojunctions are as follows:

— metal/insulator/semiconductor (MIS) structures,
— metal/semiconductor structures (Schottky diodes),
— semiconductor/insulator/semiconductor structures and
— semiconductor/semiconductor structures.

Interaction of heterostructures with the gas phase can lead to modification of the electronic states at the interface and in the bulk of the layers. In most cases the electrical response in heterostructures is associated with a change in the state of the interface and involves processes at the interface between three phases, *viz*., solid 1/solid 2/gas.[38] In this connection it is of importance whether the gas molecules can reach the heterointerface. This imposes some limitations on the composition and microstructure of materials for heterostructures and on the compositions of gases detected.

Two main mechanisms of gas sensitivity of heterostructures are as follows.

1. Change in the electron work function as a result of formation of a dipole layer by adsorbed molecules.

2. Change in position of the Fermi level in the bulk of the semiconductor.

These two mechanisms will be considered in detail taking the structures mentioned above as examples.

1. Methods of fabrication of heterostructures

Semiconductor heterostructures are often fabricated using various thin-film and ceramics growth techniques. Interrelations between the growth conditions and the compositions, crystal structures, morphologies and electrophysical properties of the materials that form a heterostructure have been reported in studies on CVD,[35,85–88] magnetron sputtering,[51,54,55,89] spray pyrolysis of organometallic and inorganic compounds,[27,90–94] thermal vacuum evaporation,[95] screen printing[96] and solid-phase synthesis.[43–47,52]

2. Metal/insulator/semiconductor structures

The gas sensitivity of the MIS structures is based on the change in the electron work function needed to leave the metal under adsorption of molecules at the metal/insulator interface. The metallic layer of the MIS structures is made of the catalytically active metals (Pt, Pd). In most cases silicon is used as the semiconductor because this allows dielectric oxide layers to be grown with ease on the Si surface upon thermal oxidation. In addition, the silicon support permits a ready incorporation of the MIS structures into electronic microchips. Except for some specific cases considered below the MIS structures are hydrogen sensitive. Figure 8 illustrates the interaction between $Pd/SiO_2/Si$ structures and hydrogen, which involves[20] adsorption of hydrogen molecules on the metal surface and subsequent palladium-catalysed dissociation of H_2 into atoms followed by diffusion of hydrogen atoms through the metal layer towards the metal/oxide interface. These processes can be represented as follows:

$$H_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} 2H_a, \qquad (16)$$

$$H_a \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} H_b \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} H_{ai}, \qquad (17)$$

where H_a is hydrogen adsorbed at the surface, H_b is hydrogen dissolved in the metal, H_{ai} is hydrogen adsorbed at the metal/oxide interface and k_i are the rate constants for these processes.

It should be emphasised that permeability of the palladium layer to hydrogen atoms is a necessary condition, which should be met to provide the possibility for these atoms to reach the M/SiO_2 interface and thus make corresponding structures gas sensitive. Hydrogen adsorption on the metal surface and at the M/SiO_2 interface leads to formation of the dipole layer.

In the band diagram of an MIS structure the formation of the dipole layer corresponds to the change in the metal work function by a value of $e\Delta V_s$. The change in the work function at the metal/gas interface was confirmed by photoemission spectroscopy[20] and by using a Kelvin probe.[21] Simultaneous registration of the change in the metal work function using the Kelvin probe technique and the ΔU value determined from the capacitance–voltage curves showed that these processes occur in parallel. This in turn confirms that the shift of the electrical characteristics is associated with the dipole layer and that this layer is formed at the metal/insulator rather than the insulator/semiconductor interface. The mechanism of formation of the dipole layer as a result of polarisation of hydrogen atoms is still to be clarified. It is assumed that ionisation of a hydrogen atom adsorbed at the M/SiO_2 interface accompanied by transition of an electron to the conduction band of the metal is the basis for this process.[20] In this case a dipole can be formed by a proton and a charge induced in the metal. According to calculations, the charges in the dipole are separated by about 1.4×10^{-3} nm and the adsorbed hydrogen atom has an unusually high dipole moment (2 D, which is atypical of hydrogen adsorption on metal surfaces).[24] It was assumed that hydrogen is adsorbed on the 'oxide side' of the interface. This is confirmed by the difference between the heats of adsorption on the metal surface (0.43 eV per atom) and at the metal/oxide interface (0.86 eV per atom). The bridging oxygen atom of the oxide can act as an adsorption site.

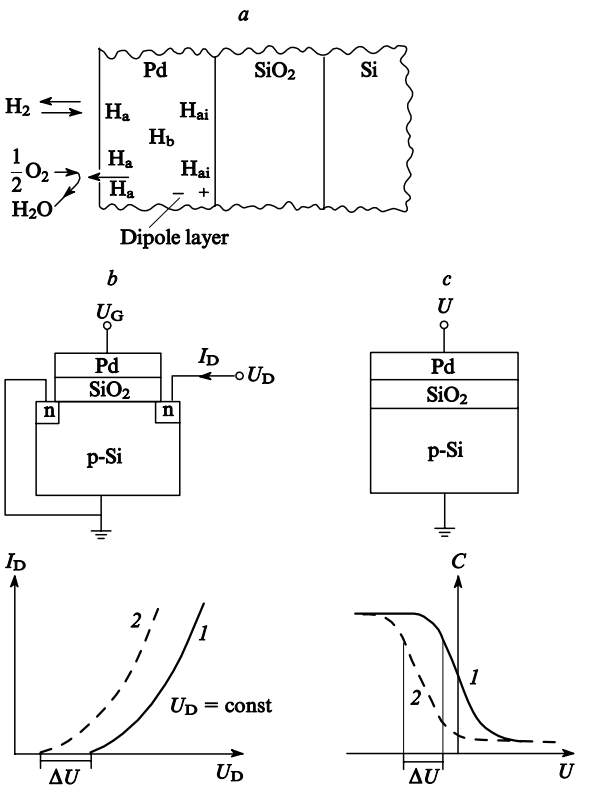

Figure 8. Brief description of the hydrogen sensitive MIS structure (taking a $Pd/SiO_2/Si$ structure as an example).[20]
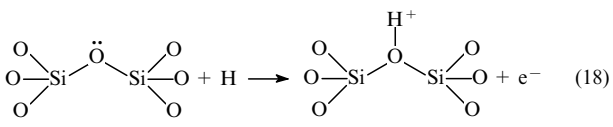
Processes characterising the interaction with the gas phase (*a*), an MIS transistor and its current–voltage curve (*b*) and an MIS capacitor and its capacitance–voltage curve (*c*); in air (*1*) and under hydrogen (H_{ai}) adsorption at the Pd/SiO_2 interface (*2*).



(18)

Lundstrom[25] analysed the temporal dependences of the sensor response and suggested co-existence of two types of hydrogen adsorption sites on the 'metal' side and on the 'oxide' side.

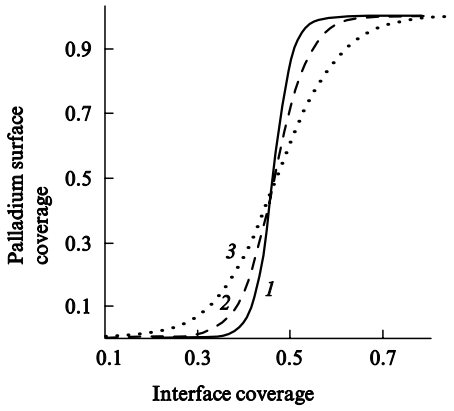


Figure 9. Relation between palladium surface coverage and Pd/SiO_2 interface coverage with hydrogen atoms.[24]
T/K: 223 (*1*), 423 (*2*) and 873 (*3*).

Since the heat of hydrogen adsorption at the metal/oxide interface is higher, hydrogen is mainly adsorbed at this interface. The results of calculations of the ratio between the specific concentrations of hydrogen at the surface and at the metal/oxide interface are shown in Fig. 9.[24] Thus, the structure can produce an electrical response even at very low specific surface concentration of hydrogen. In an inert atmosphere, this permits detection of extremely low hydrogen concentrations (at 10^{-3} ppb level).

The electrical response of the system is related to the partial pressure of hydrogen in an inert atmosphere as follows:[20]

$$\frac{1}{\Delta U} - \frac{1}{\Delta U_{\max}} = \frac{1}{\Delta U_{\max}} \left(\frac{\text{const}}{p_{H_2}} \right)^{1/2}, \qquad (19)$$

where

$$\text{const} = \frac{k_{-1}}{k_1} \left(\frac{k_{-2}k_{-3}}{k_2 k_3} \right)^2.$$

The results of calculations using Eqn (19) are in good agreement with the experimental dependences (Fig. 10). The maximum response, $\Delta U_{\max}$, corresponding to fully occupied adsorption sites is 0.5 V. The $\Delta U_{\max}$ value is determined by the concentration of active adsorption sites and depends on the state of the heterointerface.

As mentioned above, the MIS structures based on continuous metal films are sensitive to hydrogen or to molecules that can decompose at the surface and produce hydrogen. At the same time the sensitivity to hydrogen strongly depends on the presence of other gases that can be formed in the surface reactions, thus reducing the surface concentration of hydrogen. For instance, oxygen can react with adsorbed hydrogen as follows [20]

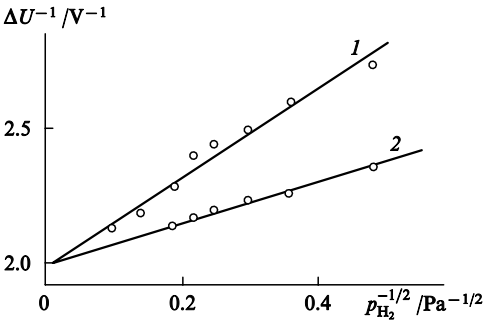

Figure 10. The response ΔU plotted *vs.* the partial pressure of hydrogen at 240 (*1*) and 280 °C (*2*).[20]

$$O_2 + 2H_a \longrightarrow 2(OH)_a, \qquad (20)$$

$$OH_a + H_a \longrightarrow H_2O, \qquad (21)$$

where H_a is the adsorbed hydrogen atom and $(OH)_a$ is the adsorbed hydroxy group.

Carbon and nitrogen monoxides also reduce the sensitivity to hydrogen [22,97] by blocking the adsorption sites.

MIS structures based on porous metal films can be sensitive to molecules having a permanent dipole moment, *e.g.*, NH_3,[23] ethanol, acetone and water.[98] The mechanism of formation of the dipole layer in this case is still poorly studied.

In addition to silicon-based structures, MIS structures based on silicon carbide (a material with a wider energy gap) have also been studied.[26] This permits operation at higher temperatures and reduces the poisoning effect of the working substance. Not only platinum- and palladium-based but also Ru- and Ir-based MIS structures are known.[25] Changes in the gas sensitivity are due to different catalytic activities of the metals; palladium-based systems were found to be the most efficient. The sensitivity to hydrogen was enhanced using a double metal layer (platinum on palladium);[98] however, the mechanism of this phenomenon has not been studied as yet.

3. Semiconductor/insulator/semiconductor structures

An example of the semiconductor/insulator/semiconductor structure is provided by a $SnO_2/SiO_2/Si$ structure fabricated using two methods, *viz.*, spray pyrolysis (SnO_2 layer)[27] and aerosol–gel (SiO_2 layer) techniques.[99,100] The capacitance–voltage curves of the $SnO_2/SiO_2/Si$ structures obtained under gas adsorption conditions are presented in Fig. 11. Curve *1* corresponds to the ground (low-capacitance; $C_{U=0}$ = 0.1 nF) state of the structure in N_2 atmosphere. In the presence of polar gas molecules, *e.g.*, H_2O, C_2H_5OH or NH_3, the capacitance in the forward branch of the capacitance–voltage curve substantially increases. Curves *2–4* were obtained after a 10 min exposure of the structure to different mixtures of the gases mentioned above with N_2. Prolonged exposure (> 10 h) leads to saturation of the signal of the gas sensor. Curve *5* corresponds to a saturation level of C = 5.8 nF obtained at zero bias after 24 h exposure to a mixture of N_2 with H_2O (1%) at room temperature. It should be noted that enhancement of the gas sensitivity corresponds to an increase in the capacitance in the forward branch of the capacitance–voltage curve rather than its shift along the voltage axis.

Changes in the capacitance on periodic change in the composition of the gas phase at zero potential are shown in Fig. 12. Each cycle involved a 1 h exposure of the structure to N_2 followed by a

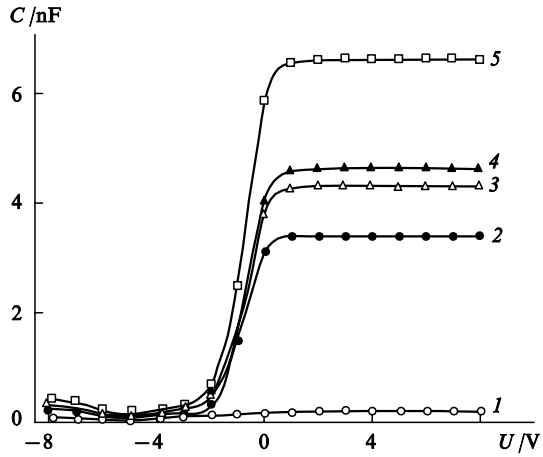

Figure 11. Typical capacitance–voltage curves of a $SnO_2/SiO_2/Si$ heterostructure in N_2 atmosphere (*1*), after 10 min exposures to mixtures of N_2 and C_2H_5OH (1%) (*2*), H_2O (1%) (*3*), NH_3 (1%) (*4*) and after 24 h exposure to a mixture of N_2 and H_2O (1%) (5) at 20 °C.[27]

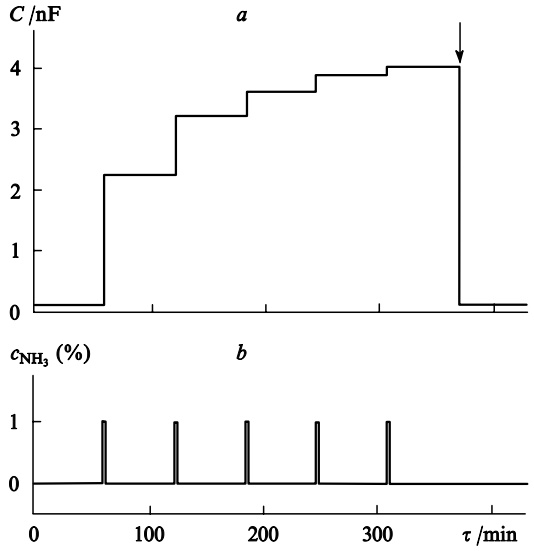

Figure 12. Time dependences of the capacitance of a $SnO_2/SiO_2/Si$ heterostructure on periodic change in the gas phase composition (*a*) and NH_3 concentration in nitrogen (*b*).[27]
Switching-on a 10 V electric pulse is arrowed.

2 min exposure to a mixture of N_2 with NH_3 (1%). As can be seen, the capacitance increases in proportion to the time of exposure to the gas mixture containing NH_3. An important feature of the structures studied is their ability to retain the capacitance $C(\tau)$ for a long time after removal of the active component from the gas mixture. This property is responsible for the 'memory' effect towards the external action and allows the structures in question to be used as dosimeters. The capacitance achieved in the atmosphere containing molecules analysed is retained on nearly 50 h exposure to N_2 or in air. Similar $C(\tau)$ dependences were observed for gas mixtures containing ethanol and water. The sensor response of the structure, S, calculated as $C(\tau)/C(\tau = 0)$ was 44, 33 and 58 rel. u. after 24-h exposure to gas mixtures of N_2 with 1% of NH_3, C_2H_5OH or H_2O, respectively. The system returned to the low-capacitance ground state (see curve *1* in Fig. 11) after application of a 10–15 V electric field pulse of direct polarity; the relaxation process was nearly 30 s long (Fig. 13).

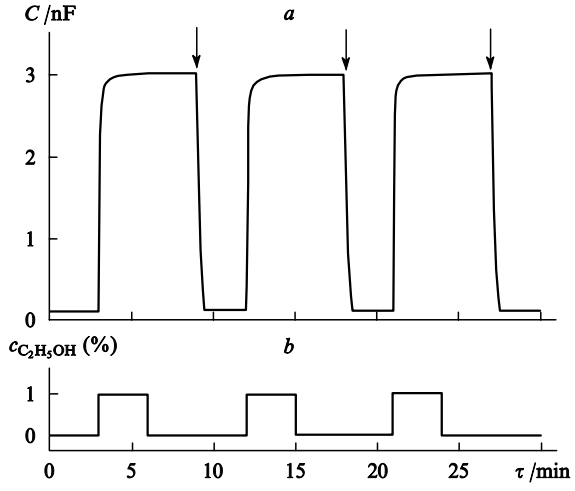

Figure 13. Time dependences of the capacitance of a $SnO_2/SiO_2/Si$ heterostructure on cyclic variation of the gas phase composition (*a*) and C_2H_5OH concentration in nitrogen (*b*).[27]
Switching-on a 10 V electric pulse is arrowed.

The properties of the $SnO_2/SiO_2/Si$ heterostructures significantly differ from those of other heterostructures. Of particular interest are the gas sensitivity mechanism and the relaxation process. Analysis of the capacitance–voltage curve of the $SnO_2/SiO_2/Si$ heterostructures (see Fig. 11) revealed their similarity to the curves obtained for the MIS structures. The direct branch corresponding to the gas sensitive state is of prime interest. A plateau in the direct branch corresponds to the capacitance of the SiO_2 dielectric layer, which is determined by its thickness (d), dielectric constant (ε) and the surface area (S)

$$C = \frac{\varepsilon\varepsilon_0 S}{d}. \tag{22}$$

An increase in the capacitance in the direct branch under adsorption of gas molecules is equivalent to the increase in the effective ε constant. The aerosol–gel grown SiO_2 layer plays a specific role. Silica thus produced differs from the thermally grown SiO_2, which is traditionally used as insulator in the MIS structures. The IR spectra of the aerosol–gel deposited SiO_2 layers indicate the presence of trace amounts of charged radicals (alkoxy groups and protons H^+) capable of forming mobile space charge regions.[100]

Similar heterostructures containing thermally grown SiO_2 produce no sensor signal. Hence, the gas sensitivity mechanism can involve changes in the proton concentration in the SiO_2 layer, which lead to an increase in the effective dielectric constant. All molecules studied can be involved in protonation of SiO_2. Water or ethanol can dissociate to give protons; the interaction of an ammonia molecule with a proton results in an ammonium ion.

Significant acceleration of the capacitance relaxation on application of electric field pulses can be due to migration and redistribution of protons in the SiO_2 layer. In this case the capacitance of the structure returns to the initial value. Proton migration in the SiO_2 layer in an electric field has been reported (see, *e.g.*, Refs 101 and 102).

Sensors based on $SnO_2/SiO_2/Si$ heterostructures can be of considerable interest as dosimeters. The possibility of controlling relaxation processes ('reset' of accumulated signal) by changing the electric field seems to be an advantage offered by these structures, because the performance of conventional gas sensors can be improved only by heating the structure, which usually limits the range of the operating temperatures to 200–400 °C.

4. Metal/semiconductor structures

Metal/semiconductor structures represent heterocontacts between a metal and a semiconductor with different electron work function. The condition for formation of a Schottky barrier at the heterointerface can be written as follows:[63]

$$\text{n-type semiconductor, } \phi_m > \phi_{sc}; \tag{23}$$

$$\text{p-type semiconductor, } \phi_m < \phi_{sc}, \tag{24}$$

where ϕ_m is the electron work function of the metal and ϕ_{sc} is the electron work function to the semiconductor.

Similarly to MIS structures, gas sensitive Schottky diodes usually employ catalytic metals. The semiconductor layer can be made of various materials including conventional (Si, GaAs) and oxide semiconductors (SnO_2, ZnO, TiO_2). Note that silicon-based Schottky diodes have a thin (20–30 Å) SiO_2 layer transparent to tunnelling. This precludes formation of silicides (*e.g.*, Pd_2Si) that are responsible for loss of sensitivity and reduces the density of proper surface states at the heterointerface.[28]

Usually, Schottky diodes are hydrogen sensitive (similarly to the MIS structures); however, sensitivity to other gases (O_2, CO, NO) has also been reported.

The current flowing through a Schottky diode is a nonlinear function of the voltage applied:[39]

$$j = \text{const}\ \exp\left(-\frac{e\phi_{ms}}{kT}\right)\left[\exp\left(\frac{e}{\beta kT}\right)-1\right] = \quad (25)$$

$$= j_s\left[\exp\left(\frac{eU}{\beta kT}\right)-1\right],$$

where j is the current density, ϕ_{ms} is the height of the Schottky barrier at the interface, U is the voltage applied, β is the non-ideality coefficient of the current–voltage curve and j_s is the saturation current density; the numerical value of the constant is related to the carrier transport mechanism (emission or diffusion).

The sensitivity of the Schottky diode to adsorption of gas molecules is associated with the change in the electron work function of the metal in the course of formation of the dipole layer. The mechanism of formation of the dipole layer in the Schottky diodes is similar to that considered for the MIS structures. The barrier height changes by $e\Delta V_s$ (Fig. 14) under adsorption conditions,[20] which leads to a change in the saturation current (typically, by two to three orders of magnitude at a hydrogen concentration of 100 ppm). For instance, a sensor response, $j_s(H_2)/j_s(\text{air})$, of 10^3 at a hydrogen concentration of 280 ppm in inert atmosphere was reported for a Pd/SiO_2/a-Si : H diode based on hydrogenated amorphous silicon.[29] The change in the barrier height under H_2 adsorption was directly measured for the Pd/SiO_2/a-Si : H diode using the temperature dependence of the reverse current and the capacitance–voltage ($C-U$) curve.[30] These two methods gave consistent results for the decrease in the barrier height (0.48 eV at a hydrogen concentration of 0.5 vol.%). At the same time the carrier concentration in the silicon layer obtained from the data of $C-U$ measurements remained unchanged.

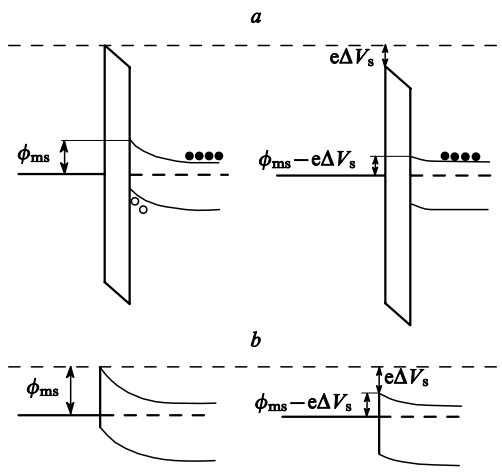

Figure 14. Band diagrams of Schottky diodes.
Metal/insulator/semiconductor structure (*a*) and metal/semiconductor structure (*b*). Shown is the change, $e\Delta V_s$, in the barrier height due to the formation of the dipole layer.[20]

Studies of the $Pd/SiO_2/Si$ diode revealed[28] clearly seen maxima in the reverse branch of the capacitance–voltage curve in the presence of trace amounts of hydrogen (*cf.* a monotonic change in air, Fig. 15). The appearance of peaks was associated with the interface states. The maximum capacitance corresponds to the case where position of the Fermi level matches that of the interface state (trap) and carriers become entrapped. According to calculations, the corresponding levels are 0.65 and 0.4 eV below the conduction band of Si.[31] The appearance of interface states was also reported in another study.[103] In the case of DC measurements the interface states are responsible for the tunnelling component of the electric current; *i.e.*, gas sensitivity is associated with electron tunnelling between the metal and the interface states of the semiconductor.

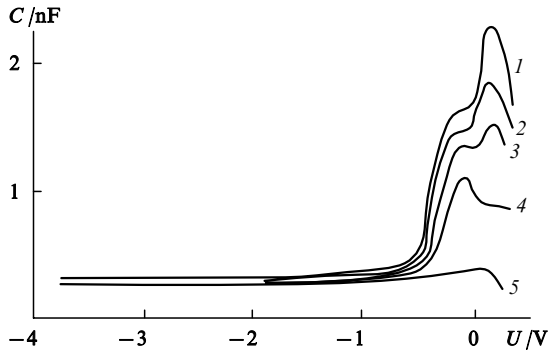

Figure 15. Capacitance–voltage curves of a $Pd/SiO_2/Si$ heterostructure in hydrogen (*1–4*) and oxygen (*5*) atmospheres at different frequencies at 70 °C.[28]
Frequency /Hz: 0.5 (*1*), 2 (*2*), 5 (*3*), 10 (*4*) and 0.5–10 (*5*).

The gas sensitivity mechanism of the Schottky diodes based on oxide layers (*e.g.*, a Pd/SnO_x heterocontact[32–34]) is different from that described above. Adsorption of gaseous O_2, CO and H_2 causes a change in the capacitance of the heterocontact and, hence, a shift of the $C-U$ curve by a value of ΔU. Similar results were obtained for platinum-based heterocontacts. At the same time the Ag/SnO_x heterocontact exhibited no gas sensitivity. The gas sensitivity mechanism was associated with chemisorption of oxygen molecules at the Pd/SnO_x interface and the formation of an electrical double layer by the negatively charged oxygen ions and positively charged ions in the near-surface region. The interaction with the gas causes changes in the concentration of chemisorbed oxygen and, correspondingly, in the ΔU value. This mechanism is supported by the linear dependence of ΔU on the partial pressure of oxygen plotted in the $\Delta U^{-1}-(p_{O_2})^{-1/2}$ coordinates. Similar dependences were obtained for CO adsorption. This sensitivity mechanism was also proposed for a Pt/TiO_2 Schottky diode.[38] Adsorption of oxygen changes the forward current flowing through the diode; the higher the partial pressure of O_2, the lower the current. The reverse is observed under CO adsorption. Processes occurring at the interface are illustrated by the band diagram shown in Fig. 16. Adsorption at the interface

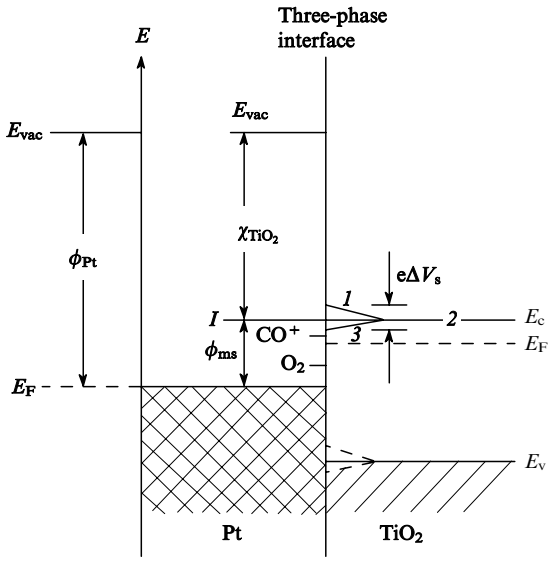

Figure 16. Band diagram of a Pt/TiO_2 heterojunction under adsorption of electron-donor (CO) and electron-acceptor (O_2) molecules.[38]
Depending on the occupation of the CO^+ and O_2^- surface states, the near-surface TiO_2 layer can be depleted of (*1*) or enriched with (*3*) electrons. Flat-band case (*2*).

leads to the formation of the O_2^- and CO^+ surface states lying 700 meV above and 133 meV below the Fermi level of the bulk TiO_2, respectively. As a consequence, the near-interface depletion layer of TiO_2 becomes even more depleted of or, correspondingly, enriched with charge carriers. The Schottky barrier becomes higher in the former and lower in the latter case. The role of the platinum/titanium dioxide interface should be emphasised. Annealing at 1070 K leads to disappearance of gas sensitivity and to linearisation of the nonlinear current – voltage curve. This can be due to platinum diffusion into the TiO_2 layer and formation of a transient layer.

An interesting example is provided by a Pd/TiO_2/n-Si diode structure [35] with extremely high sensitivity to hydrogen at room temperature, *viz*., 50 for 4 ppm and 10^5 for 10 000 ppm of H_2. The major contribution to the sensor response is assumed to come from the TiO_2 layer. Replacement of n-type silicon by p-type silicon caused a dramatic decrease in sensitivity (by two orders of magnitude). The change in the barrier height at the interface under hydrogen adsorption was estimated at 0.31 eV, which is comparable with the change in this parameter in the metal – SiO_2 – silicon systems. The Pd/TiO_2/n-Si structure can be treated as a semiconductor/semiconductor heterocontact rather than a Schottky diode.

A somewhat different mechanism of gas sensitivity was reported for a Pt/SnO_2 structure fabricated as a planar contact of specific shape.[37] The structure is highly sensitive to NO_2 traces (10^{-1} ppb) and has a rectified current – voltage curve. The current mainly changes at positive potentials. The mechanism of sensitivity was associated with extension of the depletion layer in tin dioxide under NO_2 adsorption. This leads to closure of the conducting channel and the forward current flowing through the structure dramatically decreases.

5. Semiconductor/semiconductor structures

Semiconductor/semiconductor heterostructures are of considerable interest for the design of gas sensing materials. Most of them are based on oxide semiconductors and usually comprise layers with different types of conductivity. The mechanisms of gas sensitivity of these structures are more intricate compared to the structures considered above and have no unambiguous interpretation. Two main mechanisms of gas sensitivity involve the formation of the dipole layer at the heterointerface and changes in the carrier concentration in a particular layer.

The basic relations for gas sensitivity of these heterostructures were reported by Zemel *et al*.[39] Consider a heterocontact between two semiconductors, S_1 and S_2. Let the electronic properties of S_1 be sensitive to the composition of the gas phase and let S_1 be also a kind of membrane providing diffusion of the gas molecules. Adsorption and subsequent molecular diffusion cause changes in the carrier concentration and, correspondingly, in position of the Fermi level of S_1 or lead to formation of the dipole layer at the heterointerface, which in turn is responsible for the change in the barrier height at the heterointerface.

The gas sensitivity of this system is affected by the carrier concentration in the S_1 layer and the thickness of this layer. Suppose that the current flowing through the heterojunction is given by Eqn (25), *i.e*., there is a well-defined saturation current governed by the height of the potential energy barrier. The relations listed below describe the change in the saturation current $\Delta j = j/j_0$ [j is the current under gas adsorption and j_0 is the current in the absence of adsorption (initial state)]:

degenerate semiconductor S_1, bulk effect

$$\Delta j = \exp\left(\frac{2}{3}\frac{e}{kT}\frac{\Delta c \phi_0}{n_0}\right); \tag{26}$$

non-degenerate semiconductor S_1, bulk effect

$$\Delta j = 1 + \frac{\Delta c}{n_0}; \tag{27}$$

degenerate and non-degenerate semiconductor S_1, a dipole layer at the interface

$$\Delta j = \exp\left(\frac{e}{kT}\Delta c Z_d^2\right). \tag{28}$$

Here Δc is the change in the concentration of electrically active states (bulk defects or dipolar molecules at heterointerface) due to adsorption of gas molecules, ϕ_0 is the initial barrier height at the heterointerface, n_0 is the initial carrier concentration in the S_1 layer and Z_d is the dipole moment of the adsorbed molecules.

The lower the carrier concentration in the sensitive layer, the higher the sensitivity of the heterojunction to adsorption of gas molecules in the case of bulk effect. Heterojunctions based on degenerate semiconductors (here, the carrier concentration is at least three orders of magnitude greater than the carrier concentration in non-degenerate semiconductors) are insensitive to gas molecules. However, if the dipole layer is formed, the sensitivity no longer depends on the carrier concentration, being determined only by the dipole moment of the adsorbed molecules. The effect of the charged surface states contributing to the capacitance is similar to the effect of the dipole layer.

A heterojunction operating by the mechanism of change in the space charge occurs in, *e.g*., the PbS/Si structure sensitive to hydrogen atoms.[39] Diffusion of hydrogen atoms towards the PbS causes an increase in the carrier (electron) concentration due to the fact that hydrogen atoms occupy positions of the lead vacancies. This leads to an increase in the height of the potential energy barrier at the heterointerface. The change in the reverse current as a function of the thickness, L, of the PbS layer is given by the following expressions

$$\Delta j = \frac{e[H_{Pb}]L}{Q_1} \text{ at } L < L_D, \tag{29}$$

$$\Delta j = \frac{[H_{Pb}]}{n_0} \text{ at } L > L_D, \tag{30}$$

where $[H_{Pb}]$ is the concentration of hydrogen atoms occupying positions of the lead vacancies, Q_1 is the uncompensated charge in the PbS layer, L_D is the Debye screening length for PbS and n_0 is the initial carrier concentration in the PbS layer.

Thickening of the PbS layer makes the material more sensitive and at $L > L_D$ the change in the reverse current is governed by the change in the carrier concentration. On the other hand, thickening of this layer makes the response time of heterostructures much longer.

Yet another example is provided by a Pt/n-SnO_2/p-diamond structure.[104] As the partial pressure of oxygen changes, the forward current also changes. The mechanism of gas sensitivity was associated with the change in the concentration of oxygen vacancies in the tin dioxide layer:

$$1/2\,O_2(gas) + V_O^{\bullet\bullet} + 2e = O_O^{\times}. \tag{31}$$

The role of platinum is to promote chemisorption of oxygen. It should be noted that the sensor response cannot be unambiguously related to the n-SnO_2/diamond heterointerface because platinum forms a Schottky barrier with tin dioxide and the height of this barrier also depends on the carrier concentration in SnO_2.

All systems considered above are sensitive at elevated temperatures. An example of a heterojunction, which is sensitive to NO at room temperature, is provided by the (Pt,Pd)/WO_3/Si system.[40] Adsorption of nitrogen monoxide causes an increase in the forward current. The authors [40] failed to determine which of the two heterointerfaces, (Pt, Pd)/WO_3 or WO_3/Si, is responsible for the onset of gas sensitivity. However, it was found that the WO_3 layer on insulator has a constant resistivity under NO adsorption. This can indicate that the mechanism of gas sensitivity is associated with the formation of charged states at the heterointerface or

with the formation of the dipole layer rather than the change in the carrier concentration in the WO_3 layer.

a. SnO_2(M)/Si structures

Heterostructures n-SnO_2(M)/p-Si (M = Cu, Pd, Ni) with a tin dioxide layer 1 μm thick were grown by aerosol pyrolysis ($SnO_{2(pyr)}$/Si) (see Ref. 41) and by magnetron sputtering ($SnO_{2(mag)}$/Si) (see Ref. 42) on a p-type single-crystalline silicon substrate (resistivity 10 Ω cm). A schematic view of the heterostructures studied is presented in Fig. 17. The dopant concentrations in the films synthesised were determined by local X-ray spectroscopic analysis. They are listed in Table 3.

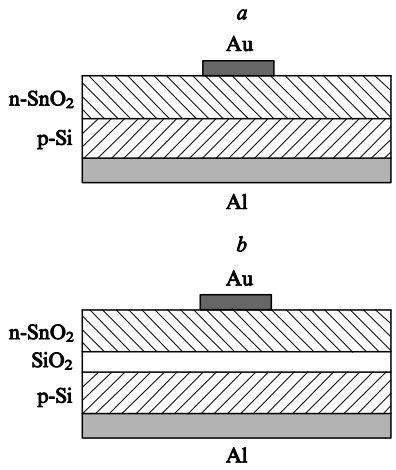

Figure 17. Schematic view of two heterostructures, n-SnO_2/p-Si (*a*) and n-SnO_2/SiO_2/p-Si (*b*).

The current – voltage curves of the $SnO_2(M)_{(pyr)}$/Si heterostructures measured in dry N_2 atmosphere at room temperature exhibit clearly seen portions of saturation current at reverse biases (Fig. 18). This points to the formation of a Schottky barrier at the heterojunction. The saturation current strongly depends on the type of dopant. The current – voltage curves of $SnO_{2(mag)}$/Si heterostructures are also rectifying in character; however, saturation of the reverse current is less pronounced.

Table 3. Main parameters of the current – voltage curves of heterostructures $SnO_2(M)_{(pyr)}$/Si.

Heterostructure	[M] (at.%)	j_s /μA cm^{-2}	β	R_s /Ω	E_a /eV
$SnO_{2(pyr)}$/Si		7.3	8.5	2×10^4	0.39 ± 0.02
$SnO_2(Ni)_{(pyr)}$/Si	0.8	9.0	10.7	5×10^3	0.51 ± 0.01
$SnO_2(Pd)_{(pyr)}$/Si	1.4	75.0	18.0	1×10^4	0.24 ± 0.03
$SnO_2(Cu)_{(pyr)}$/Si	0.6	88.0	13.5	3×10^3	0.27 ± 0.03

When analysing the current – voltage curves of the heterostructures under study, one should take into account that the surface area of the gold contact is much less than the surface area of the SnO_2 layer. Because of the 'current spreading' over the SnO_2 layer with a finite resistance the spreading resistance can contribute to the conductivity. Therefore, the current – voltage curves of the heterostructures cannot be exactly described by the relation (25). To allow for the current spreading, Eqn (25) was argumented with an additional parameter R_s (resistance connected in series with the Schottky barrier). Then, relation (25) takes the form

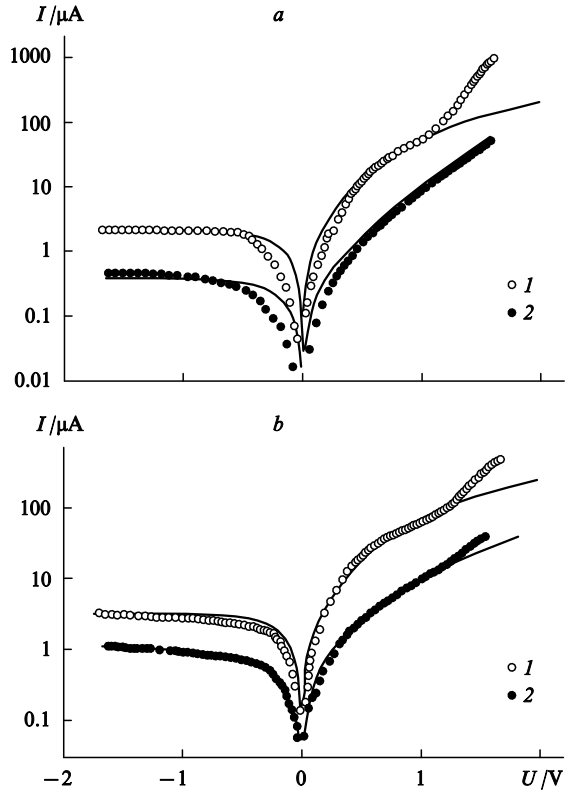

Figure 18. Capacitance – voltage curves of different heterostructures: $SnO_{2(pyr)}$/Si (*1*), $SnO_2(Ni)_{(pyr)}$/Si (*2*) (*a*) and $SnO_2(Cu)_{(pyr)}$/Si (*1*), $SnO_2(Pd)_{(pyr)}$/Si (*2*) (*b*) measured in dry nitrogen atmosphere.[91]
Full and open circles denote the experimental data and solid curves denote the results of calculations.

$$I = I_s\left\{\exp\left[\frac{e(U - IR_s)}{\beta kT}\right] - 1\right\}, \qquad (32)$$

where I is the current flowing through the heterostructure and I_s is the saturation current.

Thus, the current flowing through the heterostructure at a certain temperature depends on three parameters, *viz*., the saturation current, non-ideality coefficient, β, and the effective spreading resistance, R_s.

An attempt to describe the current – voltage curves of the magnetron sputtering fabricated heterostructures using relations (25) and (32) failed. The experimental U/j dependence obtained for the $SnO_{2(mag)}$/Si structure and the results of numerical simulation using the Schottky model with the parameters $j_s = 4.2$ μA cm^{-2} and $\beta = 15$ are shown in Fig. 19. As can be seen, the experimental and calculated data are inconsistent. For comparison we also present the experimental and calculated (with the parameters $j_s = 7.3$ μA cm^{-2} and $\beta = 8.5$) U/j dependences for the $SnO_{2(pyr)}$/Si heterostructure. Probably, in the magnetron sputtering fabricated heterostructures the contribution of the transient layers at the heterointerface to the formation of the Schottky barrier is greater than in the structures with the tin dioxide layer deposited by spray pyrolysis. This assumption is also consistent with the increase in the non-ideality coefficient ($\beta = 15$) of the structure in question. The formation of transient layers in the synthesis of films by magnetron sputtering was also reported by Golan *et al.*[105]

At reverse biases and at fixed U value, all the heterostructures studied exhibit an exponential dependence of the current on the reciprocal temperature. The activation energies, E_a, calculated from the equation

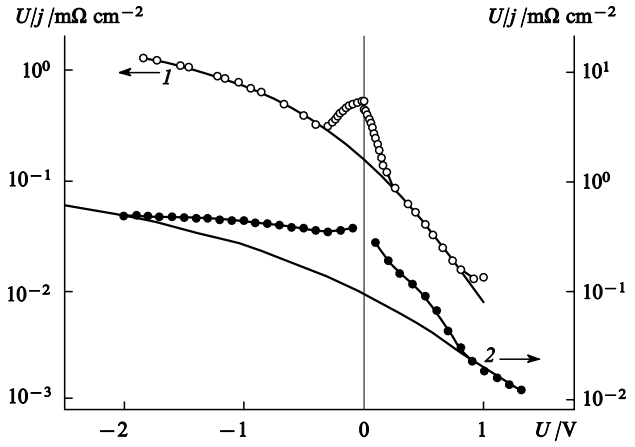

Figure 19. Impedance – voltage curves obtained for two heterostructures, $SnO_{2(pyr)}$/Si (*1*) and $SnO_{2(mag)}$/Si (*2*).[91]
Full and open circles denote the experimental data and solid curves denote the results of calculations.

$$I \propto \exp\left(\frac{E_a}{kT}\right),$$

are listed in Table 3. In the case of clearly seen saturation current the activation energy at reverse biases can be related to the barrier height. Among the spray pyrolysis fabricated structures, the maximum barrier height was found for $SnO_2(Ni)_{(pyr)}$/Si. The $SnO_{2(mag)}$/Si heterostructures are characterised by $E_a = (0.27 \pm 0.03)$ eV.

Changes in the barrier height at the heterointerface upon doping of the oxide layer can be due to the following reasons. Being an electron acceptor, copper can cause a dramatic increase in the film resistance, R, owing to compensation of donor oxygen vacancies.[106] Doping with nickel also leads to a substantial increase in the resistance and the appearance of activation-type portions in the temperature dependences of R. An increase in the nickel content causes a smooth increase in E_a up to 500 meV, which is most likely due to the increase in the intergranular barriers.[107] The activation energy of the copper-doped films reaches a value of 130 meV, which is comparable with the ionisation energy of oxygen,[108] and then remains unchanged with an increase in the dopant concentration. Doping of tin dioxide films with palladium was accompanied by the formation of metallic palladium clusters.[109] Since the palladium work function is greater than that of tin dioxide [63] doping can lead to depletion of charge carriers in the SnO_2 regions contacting Pd clusters and, correspondingly, to a decrease in the effective electron concentration in the tin dioxide layer. The decrease in the carrier concentration is supported by the high (compared to pure tin dioxide samples) resistance of the palladium doped structures. Thus, a decrease in the barrier height in the $SnO_2(M)_{(pyr)}$/Si heterostructures doped with copper and palladium correlates with the decrease in position of the Fermi level in the SnO_2 layer, which corresponds to the decrease in the carrier concentration. The increase in the barrier height in the nickel doped samples has no unambiguous explanation as yet.

Figure 20 presents the capacitance – voltage curves of the $SnO_2(Ni)_{(pyr)}$/Si heterostructures. A feature of these structures is a maximum of capacitance at positive biases, which can be associated with the contribution of an additional component corresponding to charge exchange between the interface states.[110–112] The character of changes in the capacitance – voltage curves at different frequencies of the reference signal confirms this assumption. Heterostructures fabricated by magnetron sputtering exhibit similar capacitance – voltage curves.

Adsorption of NO_2 and C_2H_5OH molecules strongly affects the electrophysical properties of the $SnO_2(M)_{(pyr)}$/Si heterostructures. Reproducible changes in the capacitance of the $SnO_2(Ni)_{(pyr)}$/Si heterostructure at zero potential on cyclic change in the gas phase composition from N_2 to $N_2 + C_2H_5OH$ (1%) mixture are shown in Fig. 21. The presence of ethanol molecules in the gas phase causes a substantial increase in the capacitance.

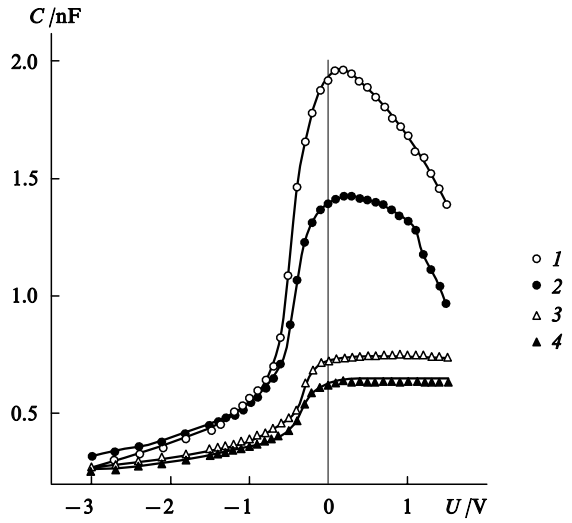

Figure 20. Capacitance – voltage curves of a $SnO_2(Ni)_{(pyr)}$/Si heterostructure at different frequencies.[92]
Signal frequency /kHz: 0.5 (*1*), 1 (*2*), 10 (*3*) and 20 (*4*).

The current – voltage curves of the $SnO_2(M)_{(pyr)}$/Si heterostructures change at both the forward and reverse biases. As an example, Fig. 22 presents the current – voltage curves of the $SnO_{2(pyr)}$/Si heterostructure in dry N_2 atmosphere (ground state) and in two mixtures, $N_2 + NO_2$ (0.1%) and $N_2 + C_2H_5OH$ (1%). Ethanol molecules were found to have an identical effect on all kinds of heterostructures, namely, the current considerably increases at forward biases and decreases at reverse biases. Adsorption of NO_2 molecules induces an opposite process for all heterostructures, *viz*., the current decreases at forward biases and increases at reverse biases. Changes in the saturation current at negative biases suggest a change in the barrier height at the heterointerface. Ethanol molecules adsorbed on the SnO_2 surface possess electron-donor properties.[64] Nitrogen dioxide molecules are electron acceptors and form a surface level in the band gap. The energy of this level is lower than that of the acceptor level of

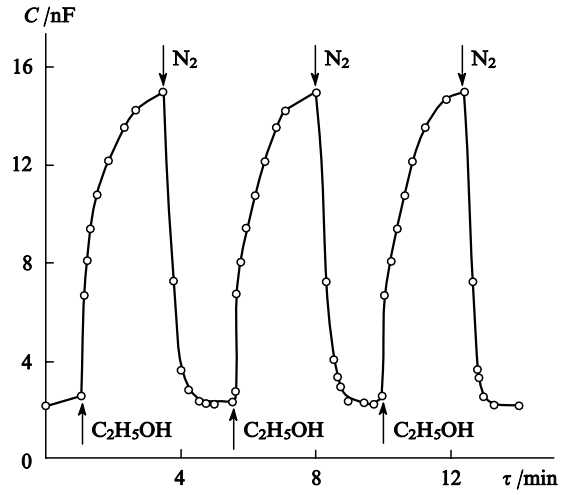

Figure 21. Periodic changes in the capacitance of a $SnO_2(Ni)_{(pyr)}$/Si heterostructure at 1 kHz on cyclic change in the gas phase composition from N_2 to $N_2 + C_2H_5OH$ (1%) mixture.[93]

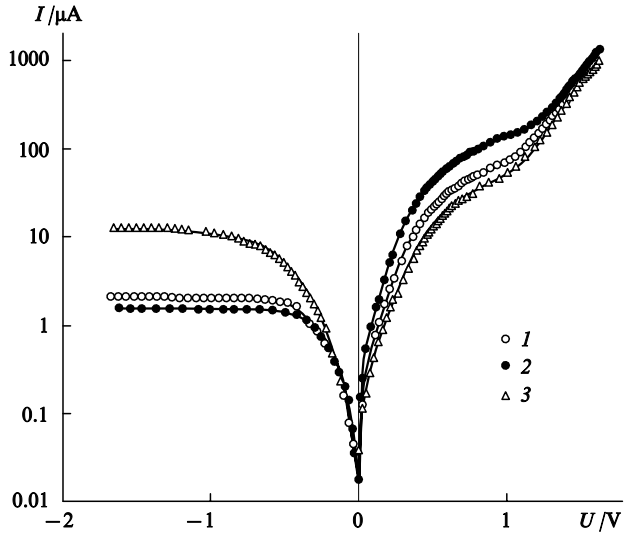

Figure 22. Current – voltage curves of a $SnO_{2(pyr)}$/Si heterostructure in different atmospheres: (*1*) N_2, (*2*) $N_2 + C_2H_5OH$ (1%) and (*3*) $N_2 + NO_2$ (0.1%).[93]

chemisorbed oxygen.[113] Thus, adsorption of NO_2 molecules causes a decrease in the effective carrier concentration and, correspondingly, a decrease in the barrier height. Adsorption of ethanol causes an opposite effect.

At forward biases, the change in the current flowing through the structure is to a great extent determined by spreading over the SnO_2 layer. A decrease in the tin dioxide resistance on adsorption of ethanol molecules leads to an increase in the effective spreading area, which governs the surface area of the working heterocontact. An increase in the SnO_2 resistance on adsorption of nitrogen dioxide leads to the opposite effect.

Adsorption of ethanol molecules causes an increase in the capacitance, the most pronounced effect being observed at positive biases. Modifications of the capacitance – voltage curves of the $SnO_2(Ni)_{(pyr)}$/Si structure in different atmospheres are shown in Fig. 23. The curve obtained in the presence of ethanol molecules has a clearly seen maximum whose position is shifted relative to the capacitance maximum for the curve obtained in the N_2 atmosphere. In the case of NO_2 adsorption the capacitance at forward biases decreases.

Thus, not only the change in the barrier height at the heterointerface but also the formation of the surface (interface) states influences the gas sensitivity. As mentioned above, the capacitance depends on charge exchange between the interface states responsible for the appearance of a maximum in the capacitance – voltage curve at forward biases. Changes in the capacitance peak amplitude under adsorption conditions (see Fig. 23) are characterised by the same features as the change in C upon variation of the frequency of the reference signal (see Fig. 20), which governs the contribution of charge exchange between the interface states. Therefore, the increase in the capacitance under ethanol adsorption can be associated with an increase in the density of electrically active surface states while the decrease in the capacitance under nitrogen dioxide adsorption can be due to a decrease in the density of the surface states.

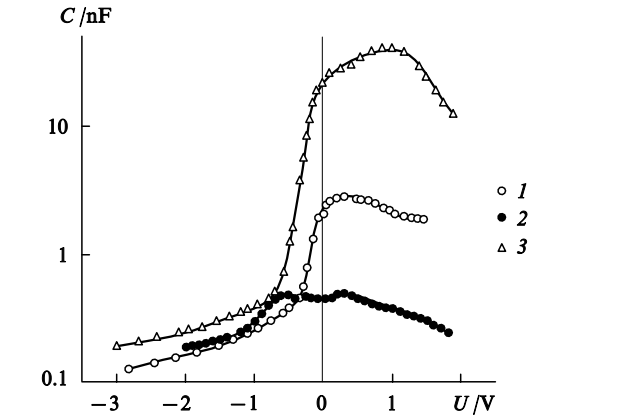

Figure 23. Capacitance – voltage curves of a $SnO_2(Ni)_{(pyr)}$/Si heterostructure in different atmospheres: (*1*) N_2, (*2*) $N_2 + C_2H_5OH$ (1%) and (*3*) $N_2 + NO_2$ (0.1%).[92]

The magnetron sputtering fabricated heterostructures behave in a significantly different manner under gas adsorption conditions. In NO_2-containing atmosphere, the current decreases at all forward and reverse biases. These changes in the shape of the current – voltage curves can be explained assuming that the major contribution to the conductivity of the structure comes from the resistance of the oxide layer rather than the heterojunction.

Additional information on changes in the current – voltage and capacitance – voltage curves can be obtained by analysing the voltage dependence of the sensor signal. The expression for the sensor signal has the form

$$S = \frac{r_1 - r_2}{r_2}, \; r_1 > r_2, \tag{33}$$

where r_1 and r_2 are the electrophysical characteristics of the sensor (current or capacitance) in N_2 atmosphere and in the gas mixture, respectively.

The sensitivities of the $SnO_2(Ni)_{(pyr)}$/Si heterostructure to NO_2 and C_2H_5OH calculated from the current – voltage and capacitance – voltage curves are presented in Fig. 24. The sensitivity – voltage plots exhibit non-monotonic changes. Clearly seen maxima are observed in both the $S(U)$ curves calculated using the capacitance – voltage curves under ethanol adsorption and in the $S(U)$ plots constructed using the current – voltage curves under NO_2 adsorption. The dependence of the sensitivity on the potential applied allows the best operating mode of a gas sensor to be chosen.

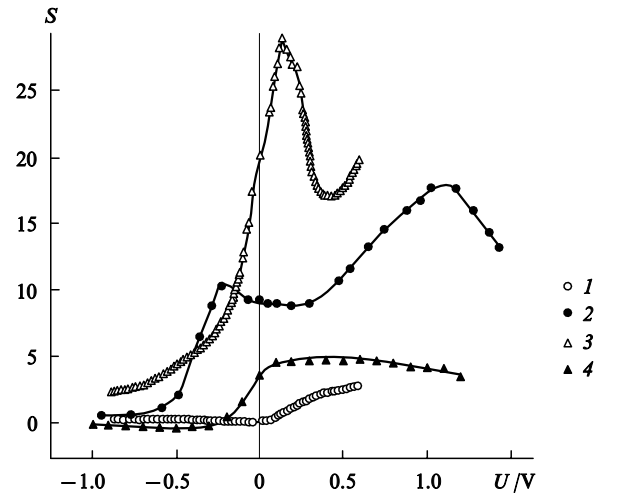

Figure 24. Sensitivity of a $SnO_2(Ni)_{(pyr)}$/Si heterostructure to C_2H_5OH (*1*, *2*) and NO_2 (*3*, *4*) plotted *vs.* voltage applied. Calculated using the current – voltage (*1*, *3*) and capacitance – voltage (*2*, *4*) curves.[93]
Gas concentration: C_2H_5OH (1%) and NO_2 (0.01%).

b. p-M_1O/n-M_2O structures

Considerable attention has been paid to studies of thin-film and ceramic n – p-heterojunctions based on semiconductor oxides

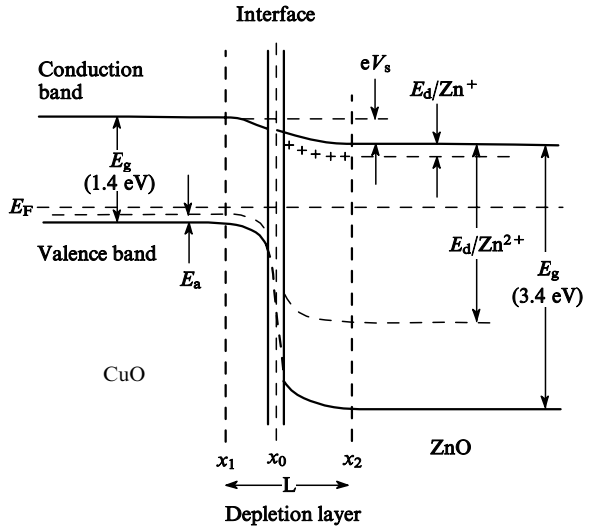

Figure 25. Band diagram of a CuO/ZnO heterojunction.[48]
E_d is the energy of the donor level and E_g is the energy gap width.

with different types of conductivity. These systems are H_2 and CO sensitive. The band diagram of a p-CuO/n-ZnO heterojunction is shown in Fig. 25. The energy barrier to carriers appears between the narrow-gap CuO with hole-type conductivity and the wide-gap ZnO with electronic conductivity. The heterojunction retains its rectifying characteristics over a wide temperature range (25–400 °C). Analysis of the current–voltage and capacitance–voltage curves showed that the energy barrier at the heterointerface cannot be correctly described by the Schottky model.[48] This is most likely due to the high concentration of surface states. If the gas phase contains CO and H_2 molecules, at elevated temperatures the current flowing through the heterojunction changes in both the forward and reverse branches and the sensitivity to CO is much higher than the sensitivity to H_2 at equal gas concentrations. The mechanism of selective sensitivity to CO was associated[68] with the following processes:

$$CO(gas) + h^+ \longrightarrow CO^+_{ads}(CuO\ surface), \quad (34)$$

$$1/2\,O_2(gas) + e^- \longrightarrow O^-_{ads}(ZnO\ surface), \quad (35)$$

$$CO^+_{ads} + O^-_{ads} \longrightarrow CO_2(CuO-ZnO\ heterointerface). \quad (36)$$

Analysis of complex impedance spectroscopy data showed that the interaction with CO molecules manifests itself in the form of additional capacitance and resistance components corresponding to the heterointerface.[48] It was assumed[49] that adsorption of CO molecules leads to the formation of additional interface states at the CuO/ZnO interface and that these states can be involved in tunnelling of charge carriers, which is responsible for the appearance of the additional component of electric current.

The sensitivity to CO can be enhanced by doping the CuO layer with alkali metals.[67] Metal cations increase the concentration of chemisorbed CO molecules, thus acting as additional adsorption sites. Another way of sensitivity enhancement is to anneal the CuO layer in inert atmosphere at 850 °C.[49] This is accompanied by partial reduction of CuO and an increase in the concentration of Cu^+ defects that also act as adsorption sites for CO molecules.

CuO/ZnO heterojunctions are sensitive to moisture content at room temperature. A change in the relative humidity from 0% to 90% causes the forward current to be changed by two orders of magnitude. Individual CuO and ZnO layers are insensitive to moisture content. A feature of these heterojunctions is a maximum in the dependence of sensitivity I_{H_2O}/I_{dry} (I_{H_2O} is the current in moist air and I_{dry} is the current in dry air) on the potential, which was associated[50] with electrolysis of water molecules. The

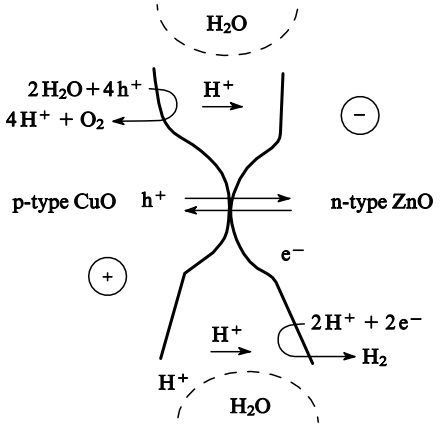

Figure 26. Schematic illustration of the mechanism of carrier transport through the CuO/ZnO heterointerface in the presence of water vapours.[53]

mechanism of gas sensitivity is schematically illustrated by Fig. 26. Two major processes are as follows:[53]

$$2\,H_2O + 4h^+ \longrightarrow 4\,H^+ + O_2\ (CuO\ surface), \quad (37)$$

$$2\,H^+ + 2e^- \longrightarrow H_2\ (ZnO\ surface). \quad (38)$$

In accord with this mechanism the adsorbed water molecules continuously leave the oxide surfaces. This permits shortening of the relaxation time of this heterojunction.

A La_2CuO_4/ZnO heterojunction exhibits a similar sensitivity to moisture content.[53] This structure is characterised by an increase in the forward current by four orders of magnitude upon changes in the relative humidity from 0% to 95%.

CuO/SnO_2 heterostructures (Fig. 27) were fabricated by magnetron sputtering of metals with subsequent thermal oxidation.[54, 55] The conditions for the oxidising annealing and the electrical properties of CuO films and the CuO/SnO_2 heterostructures, determined in each successive stage of annealing are listed in Table 4. The resistance of the CuO films changes non-monotonically in different stages of annealing. In the first stage (300 °C, 4 h) the resistance increases due to partial oxidation of the metal films.

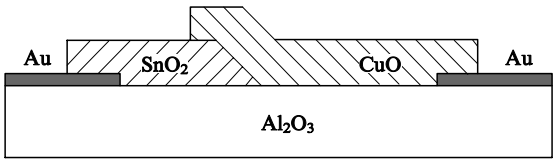

Figure 27. Schematic representation of a CuO/SnO_2 heterostructure.

Table 4. Electrical properties of CuO/SnO_2 heterostructures and CuO films in different stages of oxidising annealing.[55]

Stage	T/°C (see [a])	t/h (see [b])	Resistance at 25 °C/Ω		E_a/eV	
			CuO	CuO/SnO_2	CuO	CuO/SnO_2
0	–	–	1.0	1.5	–	–
1	300	4	5.1×10^6	2.3×10^6	0.22	–
2	300	2	1.5×10^6	1.8×10^6	–	–
3	400	10	1.9×10^5	3.1×10^5	0.16	0.14
4	450	10	1.5×10^5	7.3×10^5	–	–
5	500	10	1.3×10^5	2.2×10^7	0.14	0.19

[a] Annealing temperature. [b] Annealing duration.

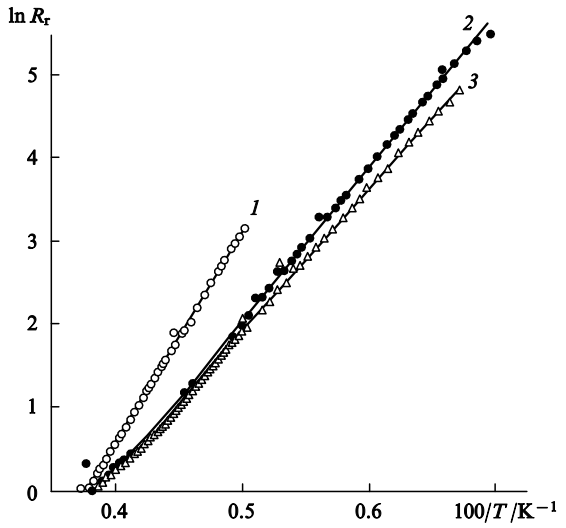

Figure 28. Relative resistance of CuO films in the first (*1*), third (*2*) and fifth (*3*) stages of annealing plotted *vs.* temperature.[55]

Subsequent thermal oxidation at 400 °C (10 h) and 500 °C (10 h) is accompanied by a decrease in the resistance. The temperature dependences of the relative resistance, $R_r = R(T)/R_{260\ K}$, of the CuO films are shown in Fig. 28. Linear plots obtained in the $\ln(R_r) - 1/T$ coordinates indicate the activation mechanism of conductivity. The activation energies, E_a, calculated using the relation

$$R \propto \frac{E_a}{RT},$$

decrease after each stage of annealing (see Table 4).

In the early stages of annealing (stages 1–3) the resistance of the heterostructures correlates with the data obtained for CuO films (Fig. 29). Further oxidation causes a substantial increase in the resistance of the heterostructures. The temperature dependences of the relative resistance of the heterostructures after the third stage and after complete oxidation at 500 °C are shown in Fig. 30. An increase in the resistance is accompanied by an increase in the activation energy. The temperature dependence of the resistance of the CuO/SnO_2 heterostructures after annealing at 400 °C exactly matches that of the CuO film after complete oxidation at 500 °C (see Fig. 30).

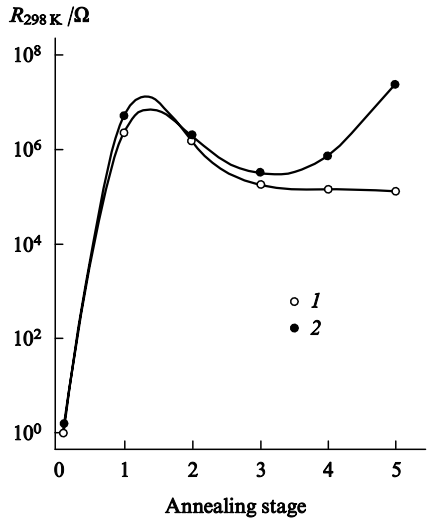

Figure 29. Changes in the resistance (T = 298 K) of CuO films (*1*) and CuO/SnO_2 heterostructures (*2*) in different stages of annealing.[55]

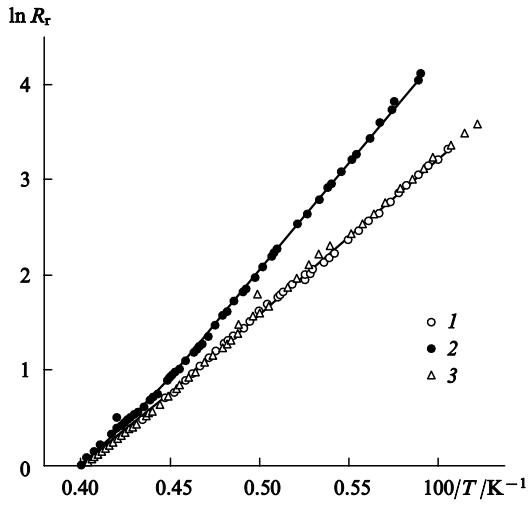

Figure 30. Relative resistance of CuO/SnO_2 (*1*), CuO/SnO_2 (*2*) and CuO film (*3*) samples in the third (*1*) and fifth (*2*, *3*) stages of annealing plotted *vs.* temperature.[55]

A secondary neutral mass spectrometry study [55] of the thickness distribution of the constituent elements of the CuO/SnO_2 heterostructures revealed three regions corresponding to CuO, SnO_2 and a transient layer at the CuO/SnO_2 interface. Therefore, the conductivity of these heterostructures can be described using an equivalent circuit including resistors connected in series and corresponding to CuO ($R1$), SnO_2(CuO) transient layer ($R2$) and SnO_2 ($R3$). Non-monotonic change in the resistance of the entire heterostructure during the oxidising annealing is governed by the contributions of different structural regions to the total resistance. In the initial stages of oxidation (stages 1–3) the CuO film is the most resistive element of the heterostructure. Further heating and an increase in the annealing duration lead to the formation of the SnO_2(CuO) transient layer whose resistance governs the conductivity of the entire heterostructure. The high resistance of the SnO_2(CuO) transient layer can be due to both the effect of compensation of intrinsic donor defects (oxygen vacancies) in SnO_2 by impurity acceptor sites, Cu_{Sn}, and the appearance of barriers at the n-SnO_2/p-CuO grain boundaries.

It should be noted that the CuO/SnO_2 heterostructures are characterised by linear current–voltage curves in all stages of annealing, though individual CuO and SnO_2 layers have p-type and n-type conductivities, respectively. This effect can be due to both the formation of the transient layer and the nanometre grain size of the contacting CuO and SnO_2 layers. The nanostructure has a very strong effect on electrical transport in semiconductors. For instance, gold contacts deposited on nanocrystalline SnO_2 are ohmic in character, whereas gold contacts deposited on single-crystalline SnO_2 form a Schottky barrier of 0.5 eV.[114] Thus, the interface between nanocrystalline materials can be transparent for tunnelling of charge carriers.

The sensor signals of the CuO/SnO_2 heterostructures in different stages of oxidising annealing were measured in a gas mixture containing 16.6 ppm of H_2S in N_2. The CuO/SnO_2 heterostructures annealed at 400 °C exhibit no sensitivity to H_2S (see curves *1* in Fig. 31 *a*,*b*). Raising the annealing temperature causes the appearance and amplification of the sensor signal (curves *2* and *3* in Fig. 31 *a*) with a maximum value of $S = 10^2$ observed after complete oxidation of the heterostructures at 500 °C over a period of 10 h. This maximum value is comparable with the magnitude of the sensor signal obtained for bulk doped SnO_2(CuO) films (curve *4* in Fig. 31 *b*). It should be noted that the CuO films exhibit no sensor sensitivity even when completely oxidised (curve *3* in Fig. 31 *b*). This indicates that the heterostructures become sensitive to H_2S only after formation of the SnO_2(CuO) transient layer

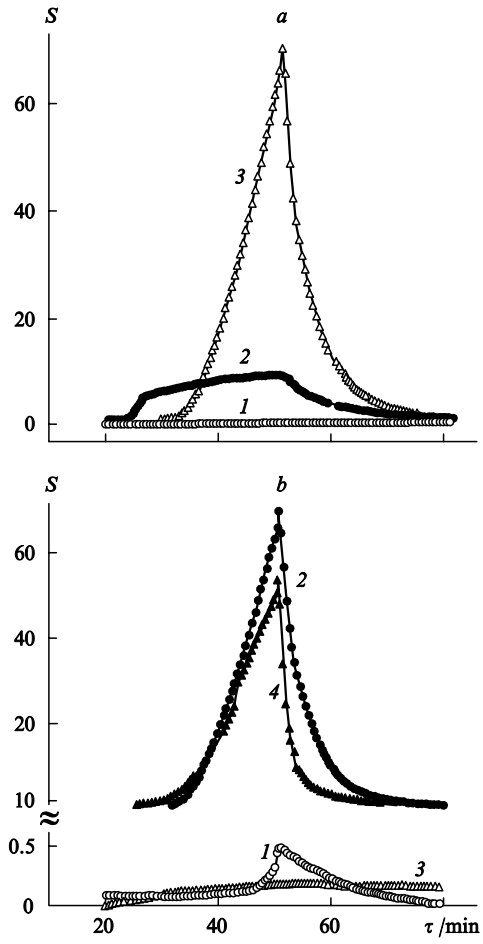

Figure 31. Sensitivities of materials to 16.6 ppm of H_2S in N_2 at 150 °C;[55] CuO/SnO_2 heterostructures in the third (*1*), fourth (*2*) and fifth (*3*) stages of annealing (*a*);
CuO/SnO_2 heterostructures in the third (*1*) and fifth (*2*) stages of annealing, CuO films (*3*) in the fifth stage of annealing and SnO_2(CuO) films (*4*) (*b*).

responsible for the appearance of the sensor signal. As the transient layer becomes the most resistive element of the equivalent circuit, the sensor sensitivity appears, the response signal reaching its maximum at the highest resistance of the heterostructure.

IV. Conclusion

Analysis of the available information on the properties of materials based on inorganic structures shows that interfaces in these objects are extremely sensitive to the state of the environment. Modern technologies offer great prospects for design of interfaces, especially in thin-film structures based on materials with different electronic properties. The vast majority of recent studies are concerned with MIS structures based on catalytic metals with well-studied mechanism of sensor sensitivity. Nevertheless, yet another type of structures, *viz*. those based on semiconductor oxides are also of interest. Porous nanocrystalline semiconductor oxides with large specific surface areas (150–200 $m^2\ g^{-1}$) are expected to extend the range of materials for gas sensors.

It should be noted that the possibility of detection and interpretation of the useful signal of the sensing elements can be significantly enhanced using gas sensors based on structures with heterojunctions. These structures are more complex systems compared to simple resistive transducers and offer a number of advantages. The main advantage is a much greater amount of information that can be read and, in some cases, stored. The amount of information is determined by the possibility of detecting the field and frequency dependent resistive and capacitance responses. Thus, one structure can be used instead of a chain or even an array of resistive transducers.

In spite of recent advances in using structures with heterojunctions as sensing elements of gas sensors, much is yet to be done. Considerable efforts should be made to solve the problem of degradation-induced instability of parameters of these structures. Development of methods of fast signal reset at room temperature is also of great importance. In this connection information on signal quenching by electric field pulses is of particular interest.

Pointing out the importance of applied aspects, we must also pay attention to interdisciplinary problems of basic research on interfaces under gas adsorption conditions. Studies on the chemical and physical mechanisms of processes occurring in various structures in static and high-frequency fields and in gas atmospheres of different compositions will find new fields of practical application of these processes.

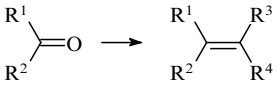
Abstract. The published data on the methods for alkene synthesis by olefination of carbonyl compounds are generalised and systematised. The main attention is given to the use of transition metals and organoelement compounds. The review covers the data on both classical and newly developed methods that are little known to chemists at large. The bibliography includes 276 references.

I. Introduction

Olefination of carbonyl compounds, *i.e.*, conversion of the carbonyl group into a double carbon – carbon bond, is one of the paramount strategies in the regioselective synthesis of substituted alkenes.[1 – 3]



Thus many total syntheses of complex molecules, including natural compounds, involve the formation of a C = C bond by this particular route.[4] Olefination is the construction of an alkene from two different components, *viz.*, a carbonyl compound and an olefinating agent, which allows broad variation of the nature of substituents at the double bond.

Numerous reviews and monographs deal with separate classical olefination procedures; however, their collective description is virtually absent. A systematic consideration of the existing olefination methods is given only in *Comprehensive Organic Synthesis,* which covers the literature up to the year of 1999.[2] The handbook *Comprehensive Organic Transformations* contains a large set of olefination reactions with no comments.[5] The book *Preparation of Alkenes*[1] published in 1996 provides a brief description of the main olefination procedures, such as the Wittig, Peterson, Julia, Johnson and McMurry reactions, aldol condensation and reductive coupling of polyhaloalkanes with carbonyl compounds in the presence of chromium derivatives. In addition, this book describes some standard procedures for the synthesis of alkenes. Other reviews are devoted to the methods for the synthesis of individual types of unsaturated compounds. Thus the review[6] published in 1983 considers the use of various olefination procedures for the synthesis of stilbenes. The review[7] describes the McMurry and Barton – Kellog reactions and their application in the synthesis of sterically hindered alkenes. The review[8] deals with the addition reactions of CH-acids to aldehydes under conditions of phase transfer catalysis which sometimes yield alkenes. One of the chapters in the review[9] published in 2001 and devoted to the synthesis of conjugated dienes considers the use of olefination in the synthesis of dienes.

The striking progress in this field of organic synthesis is associated first of all with the use of various transition metals, reagents based on them and organoelement compounds; however, many novel olefination procedures are not mentioned in the reviews and monographs published so far. Besides, new modifications, reagents and catalysts of the classical reactions are being constantly developed, which has made it possible to extend the range of their practical applications and ensures higher yields, greater selectivity and milder reaction conditions.

The present review provides a comparative analysis of methods used for the olefination of carbonyl compounds and covers the literature published up to the end of 2003.

The carbonyl carbon atom bears a partial positive charge; therefore, general olefination procedures include, as a rule, the addition of various C-nucleophiles (both preformed and prepared *in situ*) to the carbonyl group. In this review, the methods used for converting the carbonyl group into the C = C bond are classified according to the type of nucleophilic species that attack the carbonyl carbon atom. Correspondingly, all olefination methods are divided into four groups, *viz.*, addition of ylides or carbanions stabilised by heteroatoms in the α-position to the carbonyl group (Section II); condensation of carbonyl compounds with various CH-acids (Section III); olefination with reagents based on metals (Section IV). Reactions not involving direct synthesis of alkenes, *e.g.*, the Grignard reaction, are excluded from consideration where possible. The methods not included in the first three groups are considered in Section V.

In describing the olefination reactions, we placed the main emphasis on both the preparative aspects and reaction mechanisms. The review displays the most recent modifications of the olefination reactions, since the traditional methods are considered

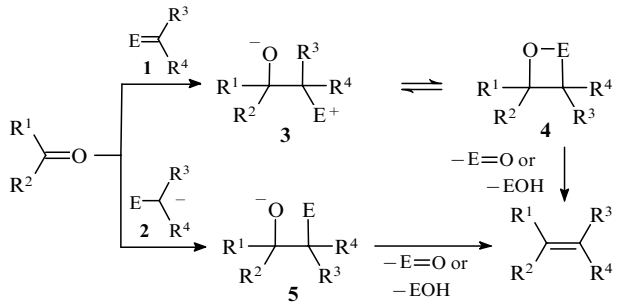
in sufficiently great detail in the reviews.[10–35] The generally known data are cited only if they are of critical importance.

II. Addition of ylides or carbanions stabilised by heteroatoms in the α-position

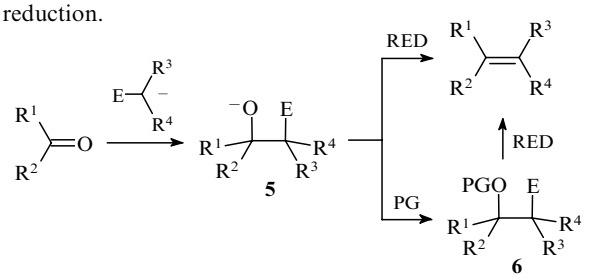
This Section is devoted to the olefination methods based on the addition, to the carbonyl group, of ylides of the type **1** or of carbanions of the type **2** stabilised either by elements from Groups IIIA–VIIA of the Periodic System or by functional groups containing heteroatoms. Reactions of ylides **1** with carbonyl compounds yield the intermediates **3** with a betaine structure or the cyclic intermediates **4**. The addition of the carbanions **2** to the carbonyl group results in alkoxides of the corresponding β-hydroxy organoelement compounds **5**.



E is heteroatom or functional group.

Depending on the nature of the heteroatom, further transformations of the intermediates into the target alkenes occur in two routes. It is of note that the loss of the organoelement fragment usually occurs in the above-described reactions, which points to its subsidiary role. Elements with electronegativities lower than that of carbon (Table 1) and with high affinities for oxygen are eliminated from the intermediate compounds as the corresponding oxygen-containing products, *viz*., organoelement oxides and hydroxides. Thus, the olefinating agents can simultaneously act as the reducing agents.

If the electronegativity of an element is close to that of carbon or exceeds it (Cl, Br), the conversion of intermediate alkoxides of the type **5** into alkenes requires the use of additional reducing agents. In this case, the formation and reduction of the intermediate compounds **5** are carried out in succession. Very often, this is preceded by protection of the hydroxy group by silylation or acylation; in this case, it is protected compounds **6** that are subject to reduction.



RED is a reducing agent, PG is protecting group.

The reaction of carbonyl compounds with isocyanides (Section II.3.a) is a special case. Here, the role of a reducing agent is played by the carbon atom of isocyanide, although the corresponding carbanion is stabilised by the nitrogen-containing functional group.

Table 1. The electronegativity and energy of the single bond E–O of Group IIIA–VIIA elements of the Periodic System.

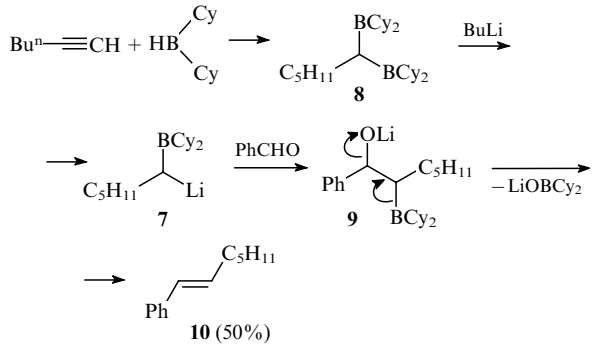
1. Reagents based on Group IIIA elements

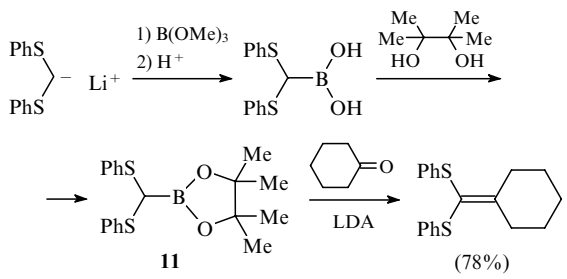
A series of olefinating agents for the synthesis of alkenes based on organoboron compounds have been prepared.[1, 2, 10, 39] Thus the *gem*-lithioorganoboron reagent **7** synthesised *in situ* by metallation of *gem*-diborane **8** adds to benzaldehyde, aliphatic ketones and diaryl ketones to give an intermediate of type **9**.[40]



Cy is cyclo-C_6H_{11}.

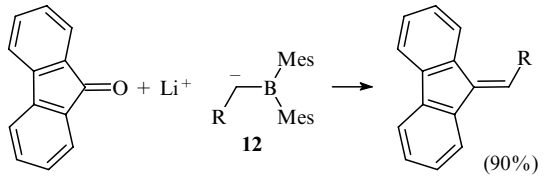
Subsequent β-elimination of dialkyl borinate gives alkenes in 20%–50% yields; the *trans*-isomer of alkene **10** is formed predominantly from benzaldehyde. The high affinity of boron for oxygen is the driving force of this elimination (see Table 1). Thus, the organoboron reagent **7** acts simultaneously as the reducing agent. The necessity for the preliminary synthesis of *gem*-diborylalkane **8** is a significant disadvantage of this method.

The use of cyclic boronate **11** as an olefinating agent allows conversion of aldehydes and ketones into dithioacetals of homologous ketenes.[41]



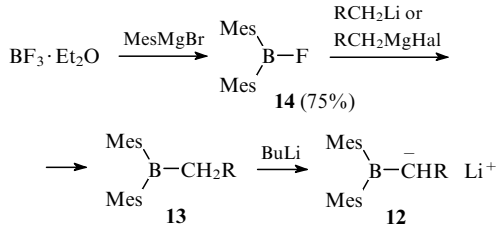
LDA is lithium diisopropylamide.

The addition of carbanions of type **12** stabilised by an α-boron atom to aromatic carbonyl compounds gives alkenes in good yields.[42,43]



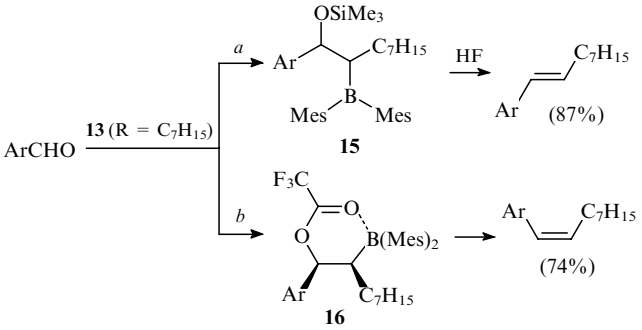
R = Me.

The carbanions **12** are prepared from dimesitylalkylboranes **13**, which in turn are synthesised from boron trifluoride etherate by successive addition of two equivalents of mesitylmagnesium bromide and subsequent treatment of compound **14** with Grignard reagents or organolithium compounds.[44]



R = H, Alk.

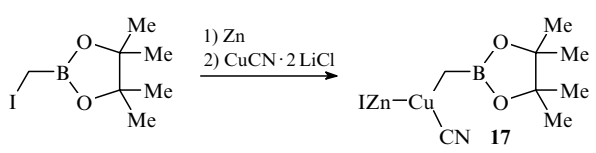
In the case of aromatic aldehydes, the stereochemistry of alkene formation can be controlled by modifying the reaction conditions. Silylation of an intermediate alcohol and subsequent treatment of the silyl derivative **15** with hydrofluoric acid afford *E*-isomers of alkenes in high yields and with good stereoselectivity.

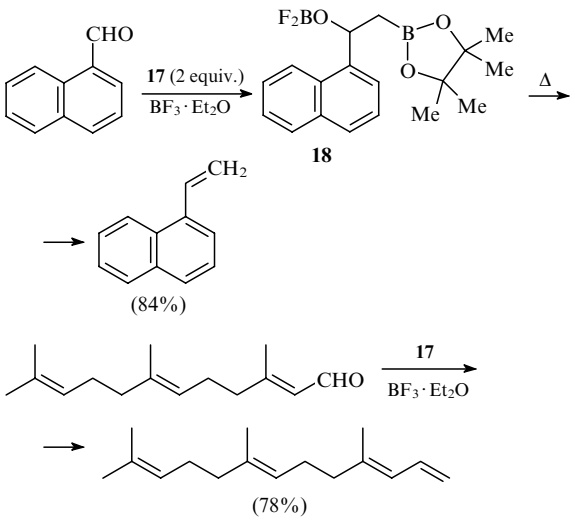


Ar = 4-MeOC$_6$H$_4$; (*a*) BuLi, Me$_3$SiCl; (*b*) BuLi, (CF$_3$CO)$_2$O.

Treatment of the intermediate alcohol with trifluoroacetic anhydride results in *Z*-isomers of alkenes; aromatic aldehydes containing electron-withdrawing groups in the *para*-position are an exception.[42] Presumably, the stereochemistry of this reaction is determined by coordination of the acyl oxygen atom to the boron atom in the intermediate **16**.

It was found that α-boron-substituted zinc organocyanocuprate **17**,[45] which reacts with a vast variety of electrophiles including carbonyl compounds, can be used as a convenient methylenating reagent. Its reactions with aldehydes in the presence of Lewis acids and subsequent thermolysis of the intermediate **18** yield terminal alkenes. The area of application of the reagent **17** includes aliphatic, aromatic and α,β-unsaturated aldehydes.

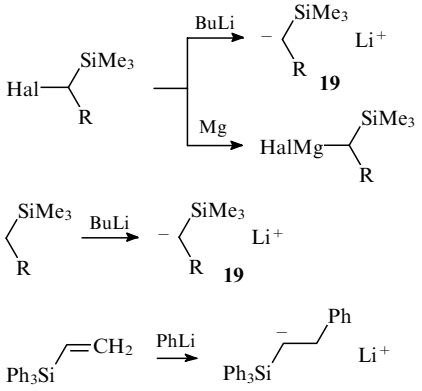




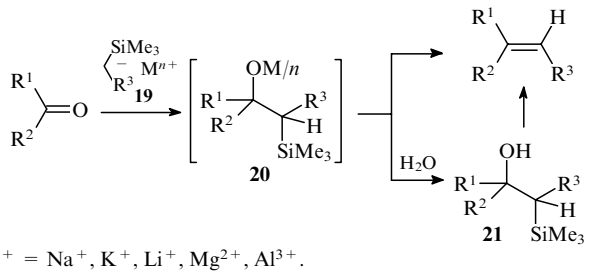
2. Reagents based on Group IVA elements

a. Silicon-based reagents: the Peterson olefination and related methods

The reaction of carbonyl compounds with carbanions stabilised by α-triorganylsilyl groups and subsequent elimination of the intermediate silanol is a general olefination method (the Peterson olefination).[1,2,11–15] Since the moment of its discovery in 1968,[46] this reaction has been used, along with the Wittig and the Julia reactions, in the synthesis of diverse alkenes. Silyl carbanions R$\overline{\text{C}}$HSiMe$_3$ **19** are employed as the olefinating agents. These are prepared by the Grignard reaction or by metallation of α-halogenosilanes, by deprotonation of silanes with strong bases as well as by addition of organometallic compounds to vinylsilanes. The deprotonation of silanes is favoured by the presence of other electron-withdrawing groups in the molecule. Aromatic, aliphatic and unsaturated aldehydes and ketones can be used as the carbonyl components.

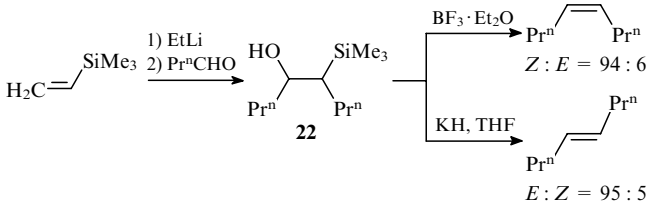


The addition of the α-silyl carbanion **19** to the carbonyl group yields the alkoxide intermediate **20**, which eliminates silanol and is converted into an alkene. The formation of a stable Si—O bond is a driving force of this reaction (see Table 1). If the intermediate **20** has an ionic nature (*e.g.*, if the role of a counterion is played by Na$^+$ or K$^+$, or the substituent R^3 represents an anion-stabilising group), silanol is spontaneously eliminated and an alkene is formed.[46,47] If the intermediate **20** has a covalent nature, *i.e.,* the role of a counterion is played by Li$^+$, Mg^{2+} or Al^{3+}, the corresponding β-hydroxy silanes **21** can be isolated.

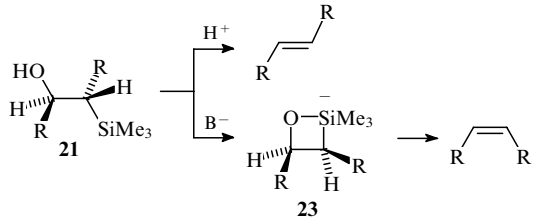


M^{n+} = Na^+, K^+, Li^+, Mg^{2+}, Al^{3+}.

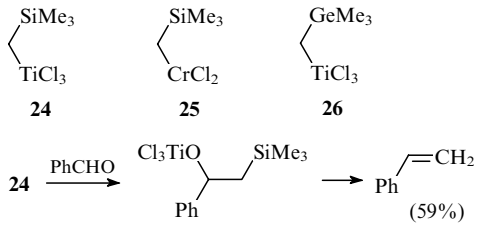
The elimination of silanol from β-hydroxy silanes in the presence of acids or bases occurs according to different mechanisms and yields opposite alkene isomers.[13, 14, 48] Thus treatment of the β-hydroxy silane **22** with boron trifluoride etherate yields an *E*-isomer of oct-4-ene, whereas a *Z*-isomer is formed predominantly in the presence of KH.[48]



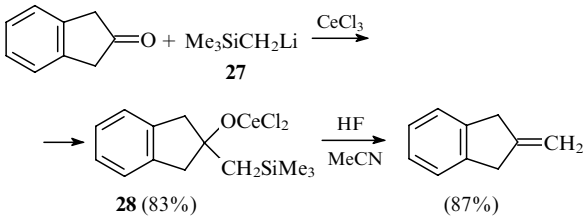
Such a stereoselectivity of the Peterson reaction is due to the fact that elimination of hydroxy- and trialkylsilyl groups in acidic media occurs from the thermodynamically most favourable *anti*-periplanar conformation of the *O*-protonated form of β-hydroxy silane **21**. In the presence of bases, alkenes having opposite geometries are formed from the intermediate siloxetane **23** by *syn*-elimination of silanol. The possibility of control over the geometry of reaction products is a main advantage of the Peterson olefination; however, the formation of β-hydroxy silanes **21** should be put under control in order to achieve stereoselectivity. Otherwise, the diastereomers formed have to be separated.



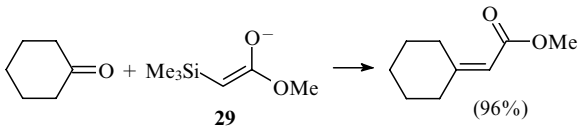
Lithium or magnesium salts of silicon-containing compounds are commonly used as the olefinating agents; however, several modern modifications of the Peterson reaction have been developed on the basis of transition-metal derivatives. In one of them, organometallic compounds **24**, **25** and **26** obtained *in situ* from transition-metal halides ($TiCl_4$, $CrCl_3$) and metallated silane (Me_3SiCH_2MgCl) or germane (Me_3GeCH_2MgCl) are used as the methylenating reagents.[49] Thus, the modified reagent actually represents an α-trimethylsilyl(germyl)-carbanion with a transition metal as a counterion. This family of reagents was used for the conversion of some aliphatic and aromatic aldehydes into terminal alkenes in high yields. Ketones do not enter into this reaction.



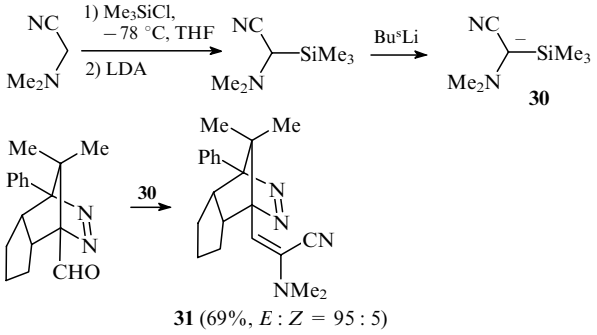
Apparently, the Peterson reaction with the system (trimethylsilyl)methyllithium (**27**) – cerium(III) chloride proceeds in a similar way.[50, 51] This system allows methylenation of a broad range of aldehydes and ketones including easily enolisable ones, since the basicities of organocerium reagents are much lower than that of the lithium derivative. Silanol is eliminated from the intermediate **28** under the action of HF or KF; the yields of the terminal alkenes are usually high (80% – 90%).



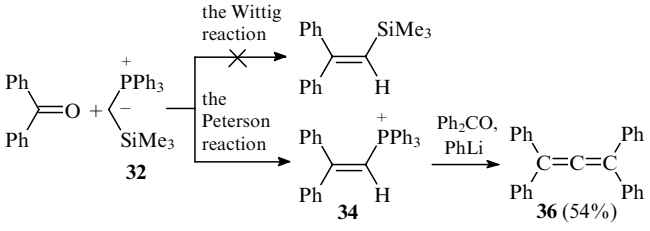
Some methods for the synthesis of various functionalised alkenes are based on the Peterson reaction. Thus a stabilised Peterson reagent, *viz*., ester α-silylenolate **29**, was used for the synthesis of α,β-unsaturated esters.[52] Compound **29** is easily prepared by deprotonation of the corresponding α-silylcarboxylates with strong bases like lithium diisopropylamide.

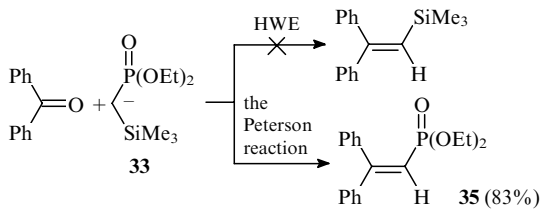


The polyfunctional anion **30** stabilised by trimethylsilyl and cyano groups is used in the synthesis of captodative alkenes of the type **31,** which contain both the donor (dimethylamino group) and acceptor (cyano group) substituents.[53] In the case of aliphatic aldehydes, this reaction occurs with high stereoselectivity and yields predominantly *E*-isomers of alkenes, whereas in the case of aromatic aldehydes and ketones the stereoselectivity of the reaction is lower.

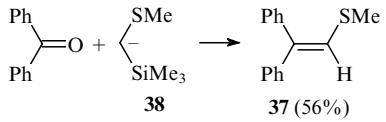


A comparison of the Peterson and the Wittig reactions, on the one hand, and the Peterson and the Horner – Wadsworth – Emmons (HWE) reactions, on the other hand, was carried out using the olefinating agents **32** and **33** stabilised by both silicon and phosphorus atoms. It was found that the reaction with benzophenone yields exclusively phosphorus-containing alkenes **34** and **35**.[12, 54, 55] Thus, the silyl groups are more prone to elimination than the phosphate groups. The vinyltriphenylphosphonium salt **34** can be used in particular in the synthesis of allenes of type **36**.

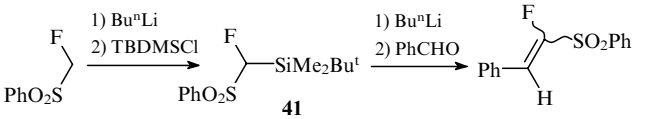


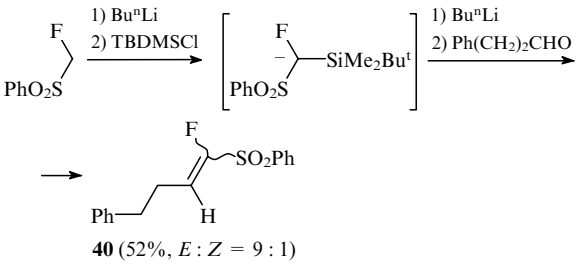


The mixed reagent **38**, which represents a carbanion stabilised simultaneously by sulfur and silicon atoms, was used in the synthesis of vinyl sulfides **37**.[55]



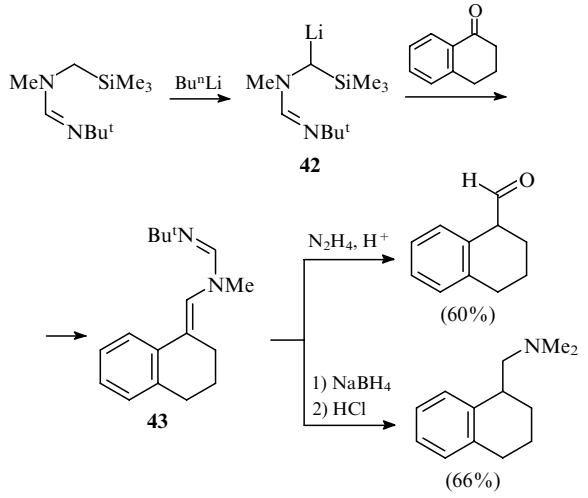
Stereoselective synthesis of unsaturated fluorine-containing sulfones **39** and **40** has been carried out using the organosilicon reagent **41**.[56] The olefination procedures make use of the previously synthesised reagent **41** or that prepared *in situ*.



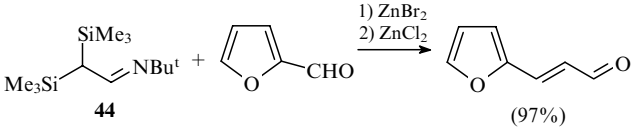


TBDMS is Bu^tMe_2Si.

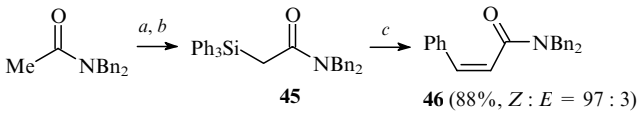
The lithium salt of formamidine **42** containing a trimethylsilyl group was used in homologisation of carbonyl compounds.[57, 58] The reaction of the salt **42** with carbonyl compounds yields enamines **43** which can be further reduced to saturated amines or converted into the corresponding aldehydes.



The use of the disilyl derivative **44** for olefination allows the preparation of α,β-unsaturated aldehydes.[59] The reactions with aldehydes yield *E*-isomers.

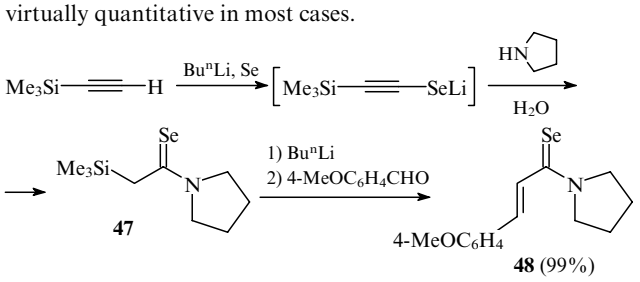


Triphenylsilylacetamides **45** can also be used as the olefinating agents. The reactions with aldehydes afford predominantly *Z*-isomers of the corresponding α,β-unsaturated amides **46**.[60]

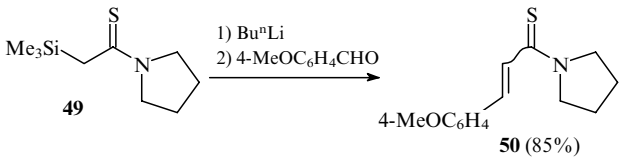


(*a*) LDA; (*b*) Ph_3SiCl; (*c*) PhCHO, KHMDS, THF, −78 °C;
KHMDS is potassium hexamethyldisilazanide.

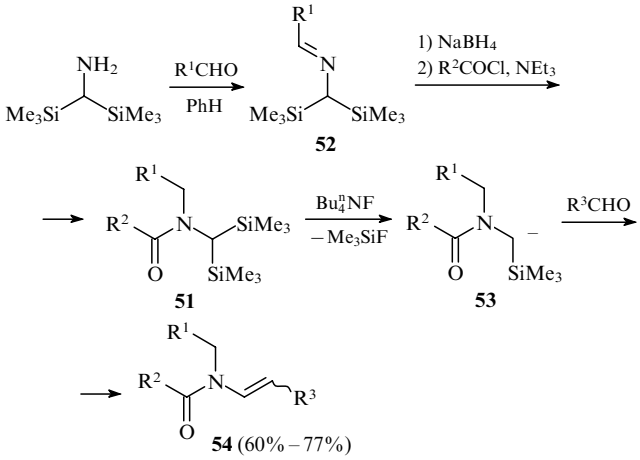
The reagent **47** synthesised from trimethylsilylacetylene was used for the preparation of selenoamides of substituted cinnamic acids **48**.[61] The reactions of the selenoamide **47** with aromatic aldehydes in the presence of Bu^nLi result in *E*-isomers of unsaturated selenoamides **48**; the yields of the reaction products are virtually quantitative in most cases.



The reactions of aldehydes with α-silylthioacetamide **49** yield unsaturated thioamides **50** (*e.g.*, as 1 : 1 mixtures of isomers).[61]

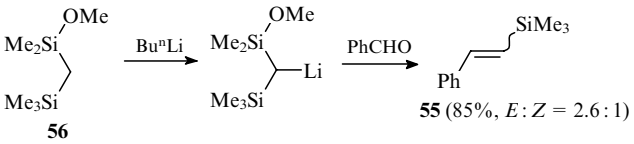


The olefination by *gem*-disilyl reagents **51** derived from imines **52** has been described.[62] This reaction occurs in the presence of tetrabutylammonium fluoride. Substituted benzaldehydes, pivalic and 2-methylcinnamic aldehydes were assayed as candidates for the carbonyl components. The carbanion **53** formed upon cleavage of a trimethylsilyl group under the action of the fluoride ion seems to play the role of an olefinating agent. The corresponding enamides **54** are obtained in good yields; however, the selectivity of the reaction is low.



R^1 = Ar; R^2, R^3 = Alk, Ar.

Carbonyl compounds can be transformed into vinylsilanes **55** using *gem*-disilylmethane **56** containing a methoxy group at one of the silicon atoms.[63] Deprotonation of compound **56** and addition of the carbanion to the carbonyl group result in silicon-substituted alkenes. It is only the methoxysilyl group that is eliminated due to coordination of lithium to the oxygen atom in the intermediate.

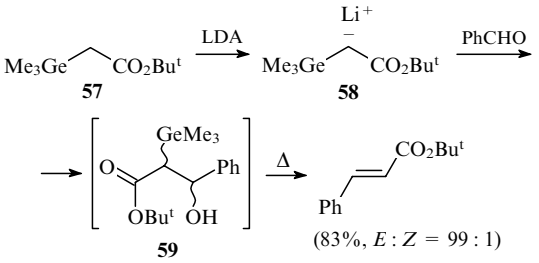


56

55 (85%, $E:Z = 2.6:1$)

b. Germanium-based reagents

An analogue of the Peterson reaction, which makes use of (trimethylgermyl)acetates **57**, has been described.[64] Their deprotonation affords carbanions **58** stabilised by the germanium atom, which add to aldehydes and ketones. Elimination of germanol (thermal or acid-induced) from intermediate diastereomeric β-hydroxy germanes **59** yields *E*-isomers of α,β-unsaturated esters. The reaction occurs with high stereoselectivity; both *threo*- and *erythro*-isomers **59** are converted into *E*-isomers of unsaturated compounds.

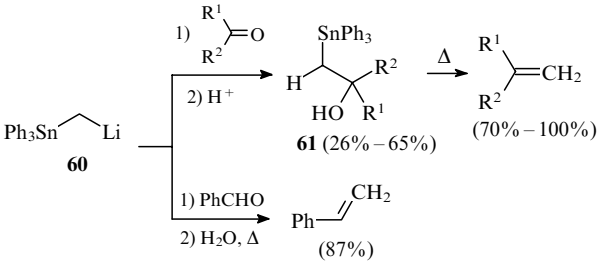


57 **58** **59**

(83%, $E:Z = 99:1$)

c. Tin- and lead-based reagents

A series of olefinating agents have been prepared based on organotin and -lead compounds.[65–76] Metallation of triphenylstannylmethyl iodide leads to triphenylstannylmethyllithium **60**, which adds to aldehydes and ketones to yield 2-triphenylstannylethanols **61**.[65] Subsequent thermal elimination of Ph_3SnOH gives terminal alkenes. This reaction may involve isolation of intermediate compounds **61** or be carried out as a one-pot synthesis. The total yield of alkenes is usually low (18%–62%), but can significantly be increased if the isolation step of intermediate stannyl ethanols **61** is excluded.



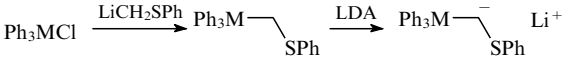
60

61 (26%–65%) (70%–100%)

(87%)

R^1 = Alk, Ar; R^2 = H, Alk.

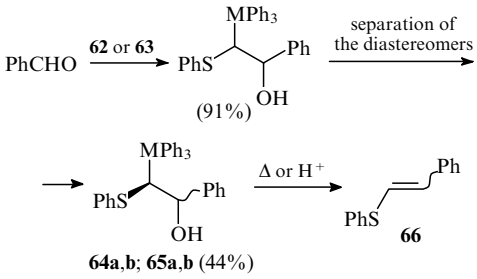
The anions **62** and **63** stabilised simultaneously by the trimethylstannyl (**62**) or trimethylplumbyl (**63**) and phenylthio groups were used as olefinating agents.[66, 67]



62, **63**

M = Sn (**62**), Pb (**63**).

The reagents **62** and **63** react with benzaldehyde to give diastereomeric pairs of phenylthio(triphenylstannyl)ethanols **64a**,**b** and phenylthio(triphenylplumbyl)ethanols **65a**,**b**. Separation of the diastereomers and subsequent thermal elimination or acid treatment yields *E*- or *Z*-isomers of β-(phenylthio)styrene **66**.



(91%)

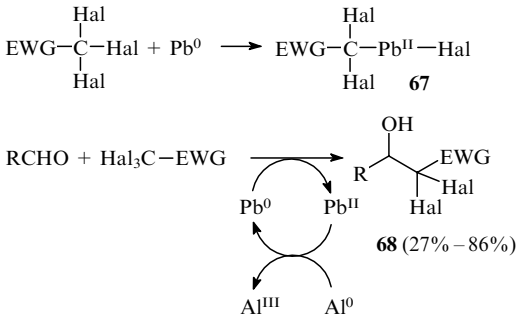
Pb	*threo*-**65a**	*E* (87)	*E* + *Z* (67)
	erythro-**65b**	*E* + *Z* (98)	*E* (83)

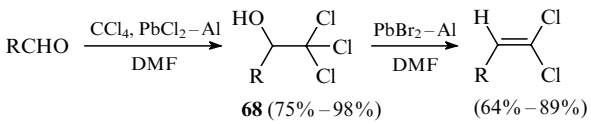
A method for the conversion of aromatic and aliphatic aldehydes into substituted alkenes by reductive addition of polyhalogeno compounds, such as tetrachloro- or tetrabromomethane, bromotrichloromethane, trichloroacetamide and trichloroacetonitrile, to aldehydes in the presence of a bimetallic system Pb–Al, has been developed.[68] This utilises aluminum foil as a reducing agent and lead halide as a catalyst. It was suggested[68] that the reaction proceeds *via* the organolead compound **67** formed upon oxidative addition of Pb^0 to the polyhalogenoalkane; subsequent reaction of the intermediate **67** with the carbonyl group yields the hydroxy derivatives **68**.



68 (27%–86%)

Hal = Cl, Br; EWG = Cl, Br, CN, $CONH_2$.

Reductive 1,2-elimination of the vicinal chlorine atom and the hydroxy group, which yields alkenes, was studied in the example of alcohols **68** based on CCl_4. The system $PbBr_2$–Al has proved to be an efficient reducing agent.[68]

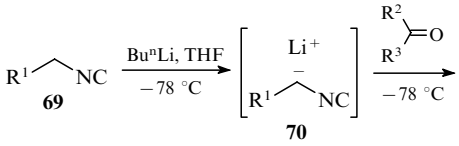


68 (75%–98%) (64%–89%)

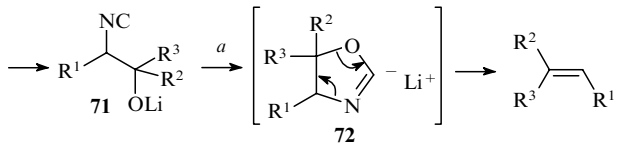
3. Reagents based on Group VA elements

a. Carbanions stabilised by the isocyanide group

The isocyanide group can stabilise carbanions in the α-position.[69] The isocyanides **69** generate the carbanions **70** that add to the carbonyl groups of aldehydes and ketones to give the adducts **71**. Subsequent elimination of lithium cyanate, which proceeds *via* the oxazoline carbanion **72**, yields alkenes.

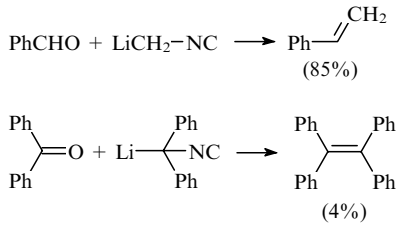


69 **70**



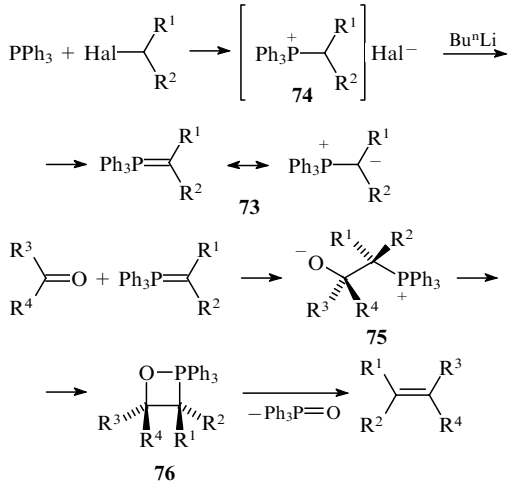
(*a*) from −78 to −20 °C.

This reaction usually proceeds with low yields and is highly sensitive to steric hindrance in both metallated isocyanide and the carbonyl compound. Thus the yield of tetraphenylethylene is much lower than that of styrene.



b. The Wittig reaction

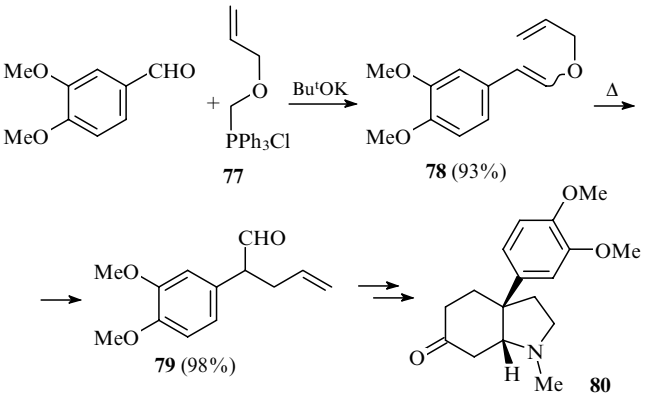
A related group of methods is based on the Wittig reaction with phosphorus ylides and its modifications involving phosphonate anions (the Horner–Wadsworth–Emmons modification) or phosphine oxides (the Horner method).[2] The formation of P–O bonds, which proceeds with a considerable gain of energy, is the driving force of these reactions (see Table 1). At present, this methodology is the most general and efficient approach to the synthesis of alkenes. From the moment of its discovery in 1953, the Wittig reaction has been the subject of intense studies; its synthetic applications, the olefination mechanism and effects of various factors on its direction and stereochemistry have been rather extensively studied and are documented in many reviews and monographs.[2,16–21] In addition, the description of the Wittig reaction and its applications have been included in manuals of organic chemistry, therefore, there is no need to dwell upon them. This reaction has been used in the syntheses of numerous compounds including natural products.[70] A great number of publications are devoted to the theoretical studies of the reaction mechanism.[71,72] The Wittig reaction is general and applicable to aldehydes and ketones containing various functional substituents, such as nitro, hydroxy, alkoxy, amino and alkoxycarbonyl groups as well as halogen. The presence of double and triple bonds conjugated with the carbonyl group does not prevent the reaction. Phosphorus ylides (phosphoranes) **73** prepared by the treatment of phosphonium salts **74** with strong bases are used as the olefinating agents in the Wittig reaction; the phosphonium salts **74** are usually synthesised from phosphines and alkyl halides.



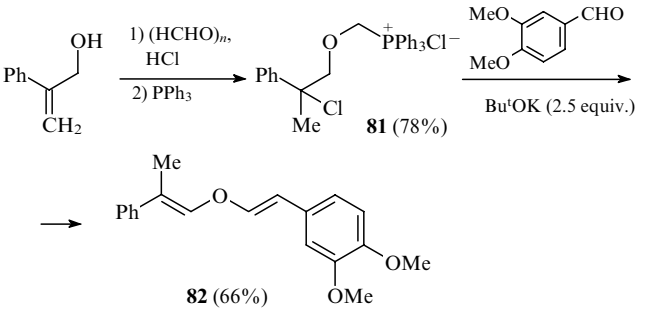
An alternative method for the synthesis of ylides includes reactions of phosphines with carbenes generated *in situ* upon catalytic decomposition of diazoalkanes [the so-called salt-free phosphorus ylides (Section V.3)]. Simple ylides (R^1, R^2 = H or Alk) are highly reactive and react with low active carbonyl substrates, such as ketones and esters, whereas the presence of electron-withdrawing groups (COR, CN, CO_2R, CHO) in the α-position of ylides makes these compounds more stable, but less reactive. It was found that the Wittig reaction proceeds through the formation of betaine **75**, its cyclisation into oxaphosphetane **76** and subsequent elimination of triphenylphosphine oxide.

Special mention should be made of the stereochemical result of the Wittig reaction. The so-called 'non-stabilised' phosphoranes react with aldehydes to yield predominantly (*Z*)-1,2-disubstituted alkenes. This method underlies a basic strategy in the synthesis of such compounds. In contrast, stabilised phosphoranes of the type Ph_3P = CH(EWG) yield *E*-isomers in reactions with aldehydes. These regularities have been reviewed in detail elsewhere.

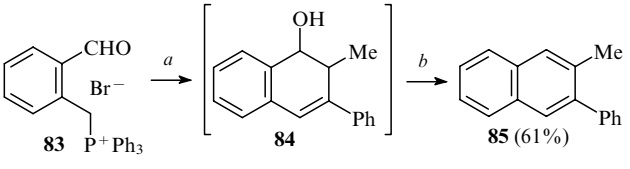
In this Section, we consider the most recent applications of the Wittig reaction. The allyl vinyl ether **78** is the olefination product of veratric aldehyde with the olefinating agent **77** containing the allyloxy group.[73] Subsequent Claisen rearrangement gives the aldehyde **79**, which is further converted into the alkaloid mesembrine (**80**).



The phosphonium salt **81** was used in the synthesis of non-symmetrical divinyl ethers **82**.[74] The use of an excess base in the Wittig reaction ensures high yields of the target products.

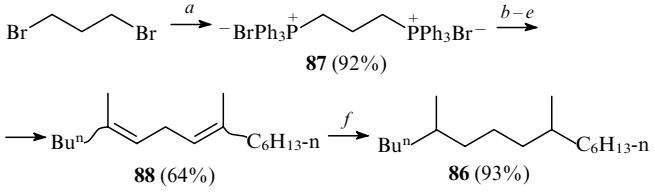


The use of the Wittig reaction in the synthesis of various cyclic systems is a promising methodology. Thus the reaction of the ylide **83** containing an aldehyde group with propiophenone enolate results in annelation and formation of the alcohol **84**, which is further dehydrated to give the substituted naphthalene **85**.[75] Various aromatic and aliphatic aldehydes and ketones were used as the carbonyl components in this reaction.



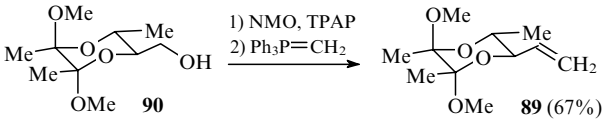
(*a*) PhCOEt, LDA; (*b*) TsOH.

The double Wittig reaction was used in the synthesis of the pheromone **86** (5,9-dimethylpentadecane).[76] The bisphosphonium salt **87** was sequentially introduced into a one-pot reaction with octan-2-one and hexan-2-one. Subsequent hydrogenation of the diene **88** yielded the pheromone **86** in the form of a racemic mixture of diastereomers.



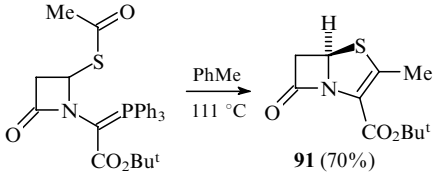
(*a*) PPh_3 (2.1 equiv.), DMF; (*b*) Bu^nLi (1.1 equiv.); (*c*)  ;
(*d*) Bu^nLi (1.1 equiv.); (*e*)  ; (*f*) H_2, Pd/C.

Preparation of aldehydes *in situ* by the oxidation of primary alcohols with *N*-methylmorpholine *N*-oxide in the presence of a catalytic amount of tetrapropylammonium perruthenate is a recent modification of the Wittig reaction.[77] This approach was used in the synthesis of the terminal alkene **89** from the alcohol **90**.

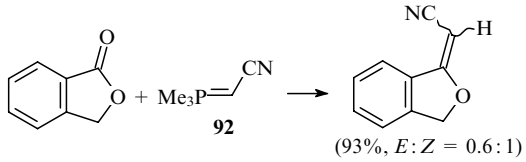


NMO is *N*-methylmorpholine *N*-oxide;
TPAP is tetrapropylammonium perruthenate.

It is not only aldehydes and ketones, but also esters, thiol esters, carboxylic anhydrides, amides and imides that can sometimes be used as substrates in the Wittig reaction.[16] Thus the intramolecular Wittig reaction was used by Woodward for the synthesis of the penicilline derivative **91**.[16,78]



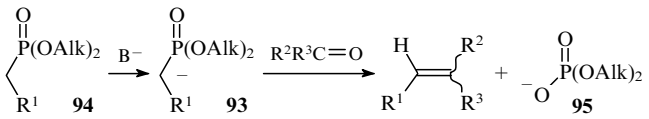
Cyanomethylenetrimethylphosphorane **92** was used in the synthesis of unsaturated nitriles from esters, lactones and imides.[79]



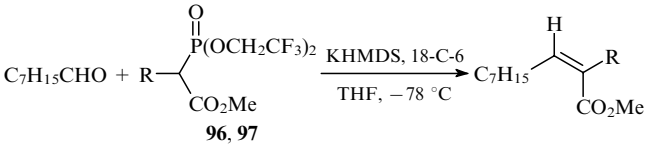
Despite its obvious versatility, the Wittig reaction has one disadvantage, *viz*., the necessity to use stoichiometric amounts of phosphines. Separation of reaction products from phosphine oxides complicates the experimental procedure. Other disadvantages include low stereoselectivity (in the case of allylic and benzylic ylides) and low reactivity of α,β-unsaturated and sterically hindered ketones.[80]

c. The Horner – Wadsworth – Emmons reaction

The Horner – Wadsworth – Emmons reaction (HWE) also known as a phosphonate modification of the Wittig reaction is widely employed in the synthesis of substituted alkenes.[1,2,16,18,22] In this case, the role of the nucleophile is played by the phosphonate anions **93** formed upon deprotonation of phosphonates **94** by strong bases, *e.g*., sodium hydride or potassium *tert*-butoxide. Anions of the type **93** are stronger nucleophiles than phosphorus ylides; therefore, the Horner – Wadsworth – Emmons method is efficient in the synthesis of alkenes from sterically hindered ketones which are not olefinated under the conditions of the classical Wittig reaction.[18] The second reaction product is dialkyl phosphate **95**, which is readily soluble in water; this, in turn, significantly facilitates the isolation of the target alkenes. However, the necessary presence of an anion-stabilising group in the α-position of the phosphonate reagent is a limitation of the method, which significantly narrows the area of its application in comparison with the classical Wittig reaction. Most commonly, the role of the stabilising group is played by the carboxy group; however, aryl or alkenyl groups and even halogens sufficiently stabilise the phosphonate anion.

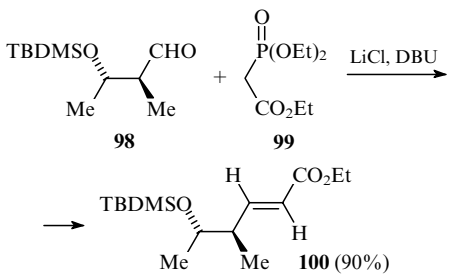


The mechanism of the Horner – Wadsworth – Emmons reaction is similar to that of the Wittig reaction and includes the formation of cyclic oxaphosphetanes. Variation of the olefination conditions and reagents allows one to synthesise *E*- and *Z*-alkenes with a high degree of stereoselectivity. *Z*-Isomers of alkenes are predominantly formed under conditions of kinetic control, *e.g*., at low temperatures, in weakly polar solvents (THF, CH_2Cl_2), under the action of strong bases containing a potassium atom (KHMDS, $KOBu^t$) for deprotonation and in the presence of crown ethers.[81] The use of bis(trifluoroethyl)phosphonates **96** and **97** also favours the formation of alkenes having a *Z*-configuration.



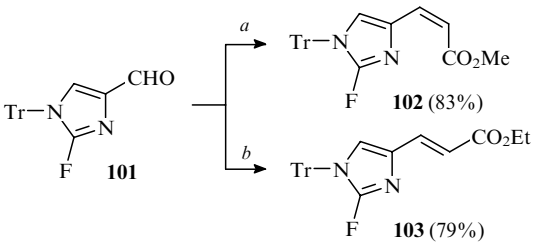
R = H (90%, *Z*:*E* = 12:1); R = Me (88%, *Z*:*E* = 46:1).

The optimum conditions for the synthesis of thermodynamically more stable *E*-isomers of alkenes are as follows: the reaction is to be carried out at 20 °C in polar solvents in the presence of lithium halides, amines are used as bases and phosphonates should contain bulky substituents.[82] Thus the olefination of aldehyde **98** with diethyl phosphonate **99** yields the *E*-isomer of the α,β-unsaturated ester **100**. Treatment of ketones with phosphonate anions under the conditions of the Horner – Wadsworth – Emmons reaction also yields both *E*- and *Z*-alkenes, although with lower stereoselectivity than in the case of aldehydes.



DBU is 1,8-diazabicyclo[5.4.0]undec-7-ene.

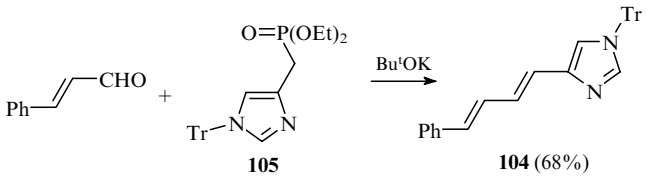
Thus by varying the reaction conditions and the structure of the phosphonate fragment, one can effectively control the stereochemistry of the olefination reaction.[83] The olefination of imidazolecarbaldehyde **101** with bis(trifluoroethyl) phosphonate **96** gives the unsaturated ester **102** with *Z*-configuration, whereas diethyl phosphonate **99** yields the *E*-isomer of the ester **103**.



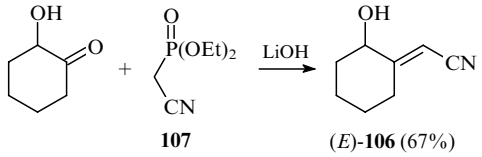
(*a*) $(CF_3CH_2O)_2P(O)CH_2CO_2Me$ (**96**), KHMDS, 18-C-6 (1.5 equiv.);

(*b*) $(Et_2O)_2P(O)CH_2CO_2Et$ (**99**), KHMDS, 18-C-6 (5 equiv.); Tr = Ph_3C.

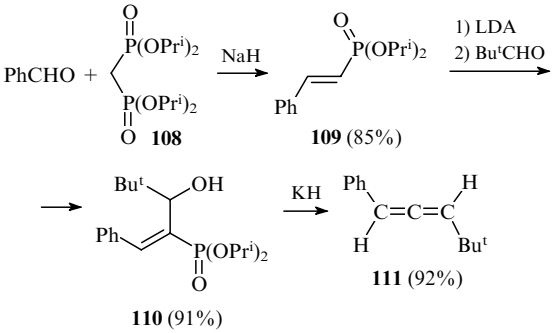
Synthesis of dienylimidazoles **104** was effected using the reagent **105** containing an imidazole nucleus.[84] Alkenes are formed stereospecifically and the configuration of the newly formed double bond of diene **104** was *E*.



The use of potassium carbonate[85] or lithium hydroxide as promoters is a convenient modification of the Horner–Wadsworth–Emmons reaction.[86] Thus the addition of LiOH increases the stereoselectivity and prevents side reactions in the synthesis of unsaturated esters and nitriles.[86] This approach was used in the stereospecific synthesis of unsaturated nitriles **106**, where diethylphosphonoacetonitrile (**107**) was used as the olefinating agent. High stereoselectivity of this reaction is due to coordination of lithium in the transition state to the hydroxy group in the α-position of the substrate.

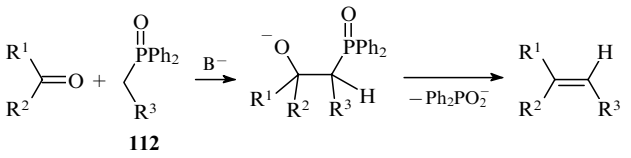


The reaction of benzaldehyde with methylenedi(phosphonate) **108** was used in the synthesis of allenes from carbonyl compounds.[87] The reaction of compound **108** with aldehydes gave the corresponding alkenylphosphonates **109**. Their subsequent treatment with LDA and the addition of the second carbonyl compound afford hydroxyalkenylphosphonates **110**, which can be converted into allenes **111** by treatment with potassium hydride.

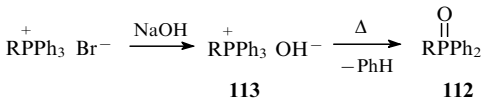


d. The Horner–Wittig reaction

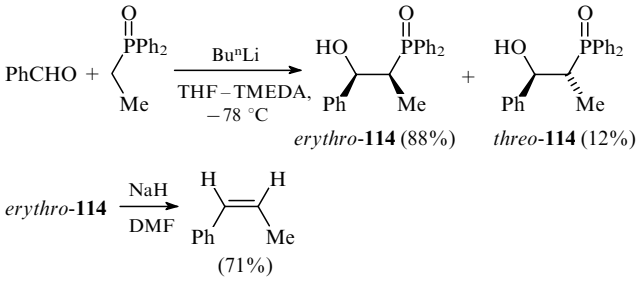
The use of the reaction of phosphine oxides **112** with aldehydes in the presence of potassium *tert*-butoxide or sodium amide for the synthesis of alkenes was recommended by Horner.[2, 18, 88] In this case, the role of the olefinating agent is played by the phosphine oxide anion generated upon deprotonation of compound **112**. Its addition to the carbonyl group yields β-hydroxy phosphineoxide, which undergoes further *syn*-elimination of the anion $Ph_2PO_2^-$.



The corresponding phosphine oxides **112** can be prepared by thermal decomposition of alkyltriphenylphosphonium hydroxides **113**.[18]

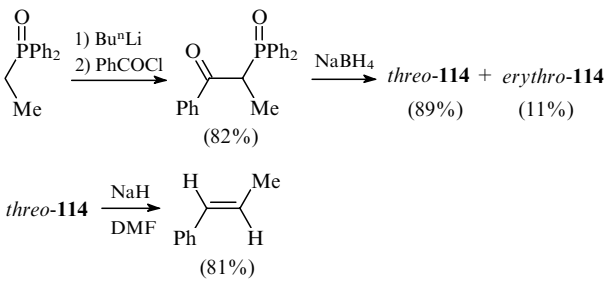


If sodium or potassium bases are used in the Horner–Wittig reactions, the elimination of $Ph_2PO_2^-$ from hydroxy phosphine oxide occurs *in situ*, whereas in the case of lithium bases β-hydroxy phosphine oxides can be isolated.[89] Upon subsequent treatment with other bases (NaH, KOH, $KOBu^t$), β-hydroxy phosphine oxides undergo *syn*-elimination resulting in alkenes, *Z*-isomers from the *erythro*-adducts and the corresponding *E*-isomers from the *threo*-adducts. Similar transformations were described for the adducts **114**.[89]



TMEDA is *N,N,N′,N′*-tetramethylethylenediamine.

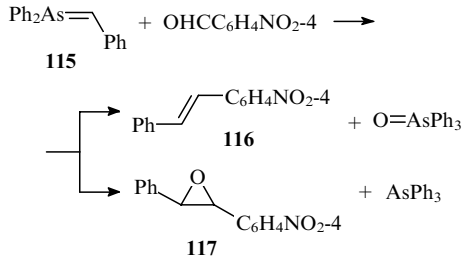
The ratio of diastereomers of β-hydroxy phosphine oxides **114** can be changed by varying the nature of the solvent, the base and the reaction temperature.[89] In weakly polar solvents (THF, ether), *erythro*-diastereomers are formed predominantly at low temperatures (−78 °C) and in the presence of the system Bu^nLi–TMEDA, while mixtures of isomeric β-hydroxy phosphine oxides are usually formed at elevated temperatures and in more polar solvents. β-Hydroxy phosphine oxides enriched in the *threo*-stereomer are formed upon reduction of the corresponding β-oxophosphine oxides with sodium borohydride.[90]



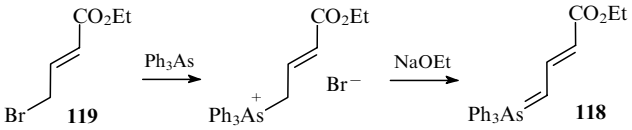
e. Arsenic-based reagents

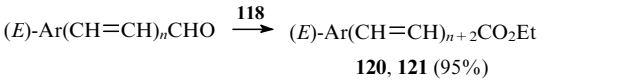
Carbanions stabilised by arsenic and antimony are less commonly used in olefination reactions in comparison with their phosphorus analogues. Arsenic and antimony ylides containing electron-withdrawing groups are more reactive than the corresponding phosphoranes. Their reactions with aldehydes were used for the development of effective methods for the synthesis of some substituted alkenes the preparation of which by the Wittig reaction is either difficult or impossible. The properties and

applications of arsenic ylides (arsoranes) are described in a review.[91] The corresponding ylides are formed upon alkylation of triphenylarsine and subsequent deprotonation of the resulting arsonium salts. As a rule, olefination with arsenic ylides occurs stereospecifically. Arsenic ylides react with carbonyl compounds to give both alkenes and epoxides (this reaction route is more typical of sulfur ylides). Presumably, this is due to a lower affinity of arsenic for oxygen in comparison with phosphorus (see Table 1). Thus the reaction of arsorane **115** with 4-nitrobenzaldehyde yields a mixture of stilbene **116** and epoxide **117**.



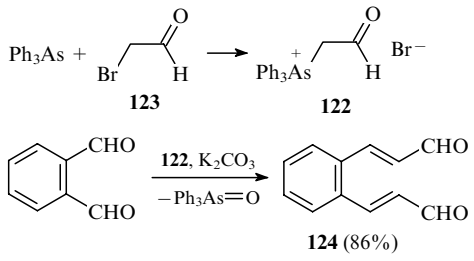
Ylides stabilised by electron-withdrawing groups manifest higher proneness for olefination, whereas more reactive ylides react with the predominant formation of epoxides.[91] Thus the ylide **118** derived from the ethyl 4-bromocrotonate **119** is used in the stereoselective synthesis of alka-2,4-dienoates **120** and 2,4,6-trienoates **121**.[92]



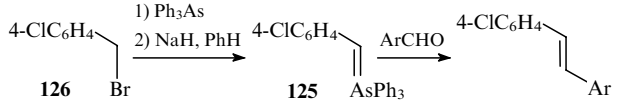


Ar = 4-ClC$_6$H$_4$, n = 0 (**120**); Ar = Ph, n = 1 (**121**).

Arsenic ylide **122**, the reaction product of triphenylarsine and bromoacetaldehyde **123**, reacts with phthalic aldehyde in the presence of potassium carbonate, to give the α,β-unsaturated aldehydes **124** in high yields; the nature of the carbonyl components can be varied over a broad range. This reaction is stereoselective; the ratio of the *E*- and *Z*-isomers of the target alkenes is no less than 97 : 3.[93]

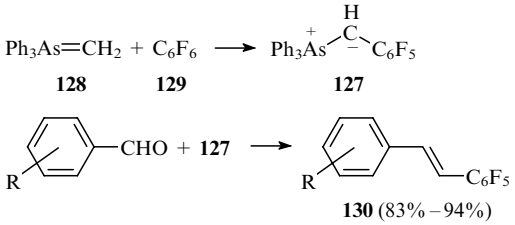


Arsenic ylide **125** generated from 4-chlorobenzyl bromide **126** was used in the stereoselective synthesis of *trans*-isomers of nonsymmetrical stilbenes [94] from diverse aromatic aldehydes containing both donor and acceptor substituents in the aromatic nucleus. The yields vary from 40% to 80%; it is the corresponding *trans*-stilbenes that were obtained in all cases.



Ar = Ph, 3-NO$_2$C$_6$H$_4$, 4-NO$_2$C$_6$H$_4$, 4-MeC$_6$H$_4$, 4-MeOC$_6$H$_4$, 4-ClC$_6$H$_4$, 4-Me$_2$NC$_6$H$_4$, 3,4-(MeO)$_2$C$_6$H$_3$, 3,4-(MeO)$_2$-6-BrC$_6$H$_2$, 2-furyl.

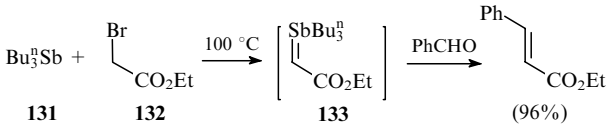
(Pentafluorophenylmethylene)triphenylarsorane **127** obtained *in situ* by a reaction of methylenetriphenylarsorane **128** with hexafluorobenzene **129** gives stereospecifically non-symmetrical *E*-stilbenes **130** containing a perfluorophenyl substituent.[95]



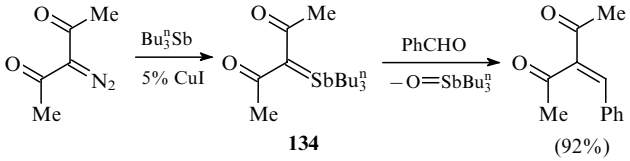
130 (83% – 94%)

f. Antimony-based reagents

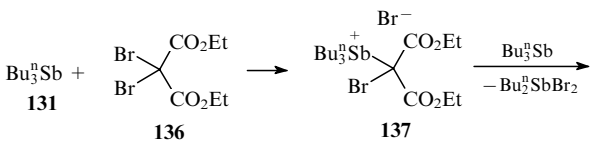
The use of the system tributylstibine – ethyl bromoacetate as an olefinating agent allows transformation of some aromatic and aliphatic aldehydes and ketones into α,β-unsaturated esters.[96] A significant advantage of this method is the possibility to conduct the reaction in the absence of strong bases. A mixture of stibine **131** and ethyl bromoacetate (**132**) plays the role of an olefinating agent. Unfortunately, the mechanism of this reaction has not been reported, [96] but it is assumed that it resembles that of the Wittig reaction and involves the formation of antimony ylide **133**.

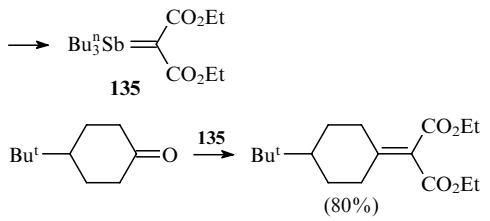


The reaction of antimony ylides **134** prepared by the copper(I) iodide-catalysed decomposition of α-diazo-β-dicarbonyl compounds with aromatic and aliphatic aldehydes and ketones yields α,β-unsaturated esters and ketones. As regards its outcome, this reaction is similar to the Knoevenagel reaction. In most cases, the yields are nearly quantitative. Studies of a relationship between the oxidation state of copper and the nature of the catalyst counterion and the yields of the target products revealed that copper(I) halides are the catalysts of choice.[97] Triphenylstibine should be used in equimolar amounts, and triphenylstibine oxide is formed as a second reaction product. A salient advantage of this method is that the ylide does not require strong bases for its generation. The use of derivatives of other Group VA elements (Ph_3As, Ph_3Bi) in this reaction is less efficient, whereas in the case of triphenylphosphine the target product is not formed at all. These results are different from the literature data on the olefination of carbonyl compounds by diazoalkanes in the presence of triphenylphosphine catalysed by such metals as rhodium and ruthenium (see Section V.3).



An alternative approach to the synthesis of antimony ylides **135** includes a reaction of tributylstibine **131** with *gem*-dibromomalonates **136**.[98] The quarternary antimonium salts **137** formed react with the second equivalent of stibine to yield stiboranes **135**. The latter play the role of olefinating agents which can be introduced into reactions with aliphatic ketones.



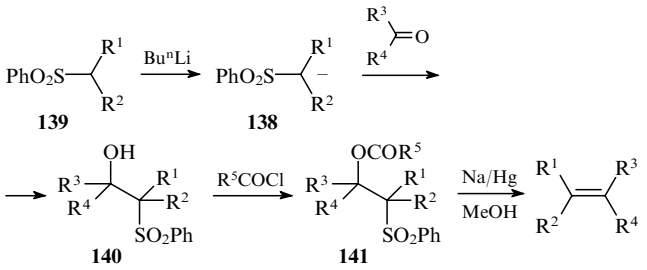


4. Reagents based on Group VIA elements

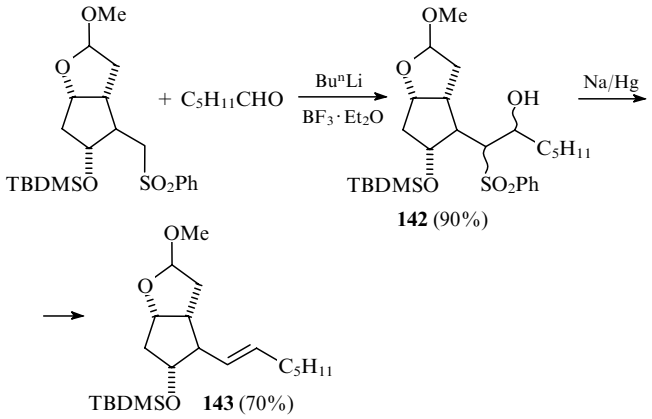
The olefination reactions considered in this Section include the addition, to the carbonyl group, of carbanions stabilised by a sulfo- or a sulfoximino group in the α-position as well as by selenium and tellurium.

a. The Julia reaction

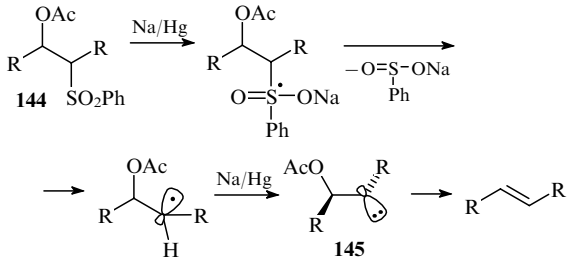
The Julia reaction (also referred to as the Julia – Lythgoe reaction in the English-language literature) consists of the generation of carbanions **138** upon deprotonation of sulfones **139** by strong bases.[1, 2, 99–101] Subsequent addition of the anion **138** to the carbonyl group yields a mixture of diastereomeric β-hydroxy sulfones **140**. The reaction is accelerated in the presence of Lewis acids, such as boron trifluoride etherate[102] and magnesium bromide.[103] Then, the hydroxy group of β-hydroxy sulfones **140** is converted into a good leaving group (acetate, benzoate, *p*-toluenesulfonate); subsequent reduction of α-acyloxy sulfones **141** with sodium amalgam in methanol gives alkenes.[23]



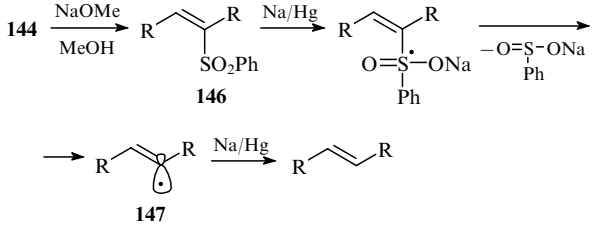
Sometimes, the modification step of the hydroxy group is omitted and β-hydroxy sulfones **140** are subjected to reductive elimination.[102] Thus the reduction of the adduct **142** with sodium amalgam gives the alkene **143** in high yield.



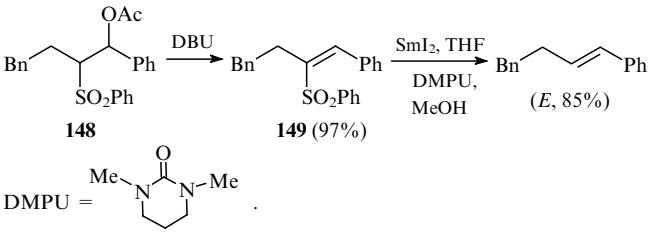
Reductive elimination occurs with high stereoselectivity: 1,2-disubstituted alkenes are formed exclusively as *E*-isomers.[2] It was shown that the geometry of the resulting alkene does not depend on the stereochemistry of the intermediate β-hydroxy sulfone; diastereomeric *erythro*- and *threo*-acetoxysulfones **144** are converted into the same *trans*-alkene,[104] which is one of the main advantages of the Julia reaction. High *E*-selectivity is explained by the fact that the intermediate anion **145** formed in the reductive elimination step has time to acquire a thermodynamically more favourable *trans*-configuration prior to the elimination of the acetate ion.



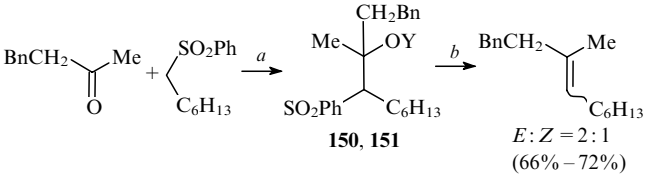
An alternative mechanism of reductive elimination includes preliminary formation of vinyl sulfones **146** and their subsequent reduction first to the vinyl radicals **147** and then to alkenes.[105]



Toxic sodium amalgam can be replaced by other reducing reagents, such as magnesium or samarium iodide (the latter is generated *in situ* from samarium and iodine).[2, 105] In the latter case, β-acetoxy sulfone **148** is converted into vinyl sulfone **149** and then reduced with samarium iodide. Such a reduction usually occurs with high yields (69% – 95%) and high stereoselectivity and affords 1,2-disubstituted alkenes; however, the necessity to use nine equivalents of samarium iodide makes this method extremely expensive.

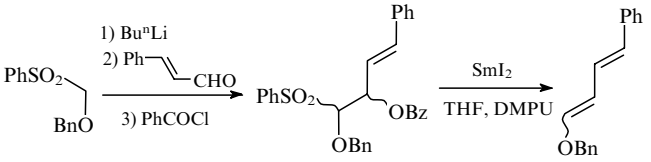


The Julia method is a convenient tool for the synthesis of alkenes; however, its main disadvantage is its multistep character. In addition, the synthesis of tri- and tetra-substituted alkenes proceeds in low yields. The use of disubstituted sulfones and aldehydes (rather than monosubstituted sulfones and ketones) is more preferable for the preparation of trisubstituted alkenes[1] due to reversibility of the reaction of a sulfone-derived anion with a ketone.[106, 107] A modified one-pot procedure, which includes acylation or silylation of β-hydroxy sulfones and reduction of the intermediates **150** and **151** with samarium iodide, allows the involvement of ketones into the reaction.[106, 107] However, the stereoselectivity of formation of trisubstituted alkenes is usually low; the *E* : *Z* ratio is ~2 : 1.



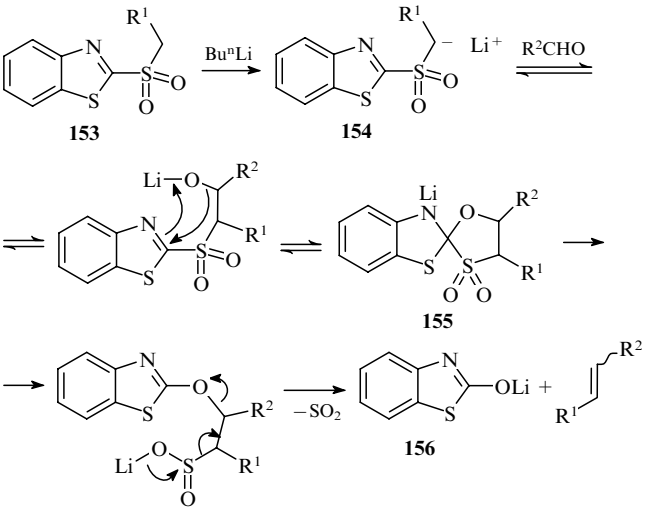
150: Y = Me_3Si (69%); **151**: Y = Bz (85%);
(*a*) 1) Bu^nLi, 2) Me_3SiCl or PhCOCl; (*b*) SmI_2, THF, HMPA;
HMPA is hexamethylphosphoramide.

This approach was used in the synthesis of the diene **152**, which contains a benzyloxy group at the terminal atom of the diene system.[107] Dienes like compound **152** are promising substrates for the Diels–Alder reaction.

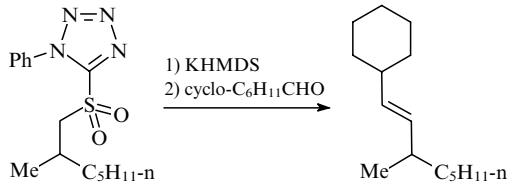


152 (82%, $E,E:E,Z = 1.7:1$)

The modification of the Julia reaction based on the use of benzothiazol-2-yl sulfones **153** as olefinating agents, has been named the Julia–Kocienski reaction. Upon addition of anions **154** to aldehydes, the adducts **155** are formed which undergo elimination of SO_2 resulting in the *trans*-isomers of 1,2-disubstituted alkenes and a lithium salt of 1,3-benzothiazol-2-one **156** as a side product.[108] The use of heteroaryl sulfones allows one to exclude the reductive elimination step.

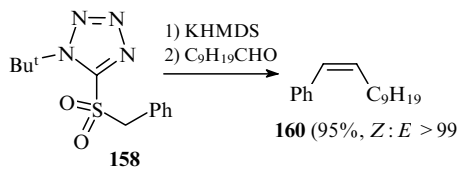


In a more recent study,[109] Kocienski suggested the use of sulfones **157** containing a phenyltetrazole system. These sulfones are more stable; the stereoselectivity of the reaction and the yields of the alkenes are higher than in the case of reagents containing a benzothiazole substituent.[109]



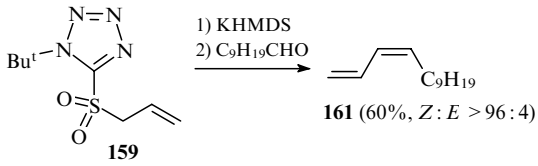
157 (59%, $E:Z = 99:1$)

Analogous reagents **158** and **159** contain a 1-*tert*-butyl-1*H*-tetrazol-5-yl system; the carbanion formed is additionally stabilised by a phenyl or vinyl group.[110] With these reagents, the yields of 1,2-disubstituted alkenes are higher than in the case of the reagent **157**; the formation of alkenes **160** and **161** proceeds with high *Z*-stereoselectivity.



158

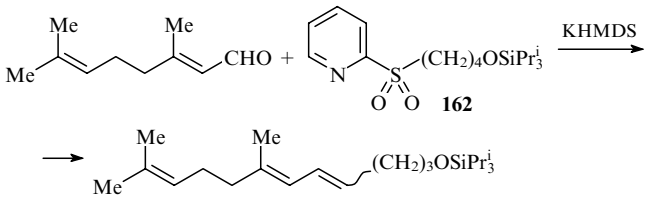
160 (95%, $Z:E > 99:1$)



159

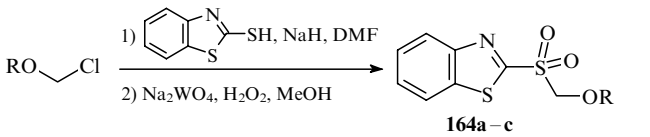
161 (60%, $Z:E > 96:4$)

The condensation of 2-pyridylsulfone **162** with α,β-unsaturated aldehydes occurs with predominant formation of *E,Z*-isomers of dienes. Compound **163** was obtained in 64% yield.[111]



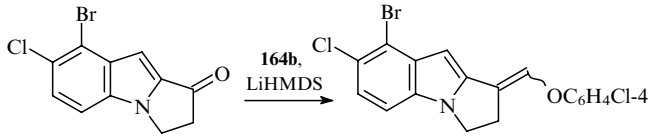
163 (64%; $E,Z:E,E = 88:12$)

β-Alkoxy sulfones **164a–c** can be used in the synthesis of enol ethers from aldehydes and ketones by the Julia–Kocienski reaction.[112] The formation of the ethers **165** occurs with low stereoselectivity, albeit in good yields.



164a–c

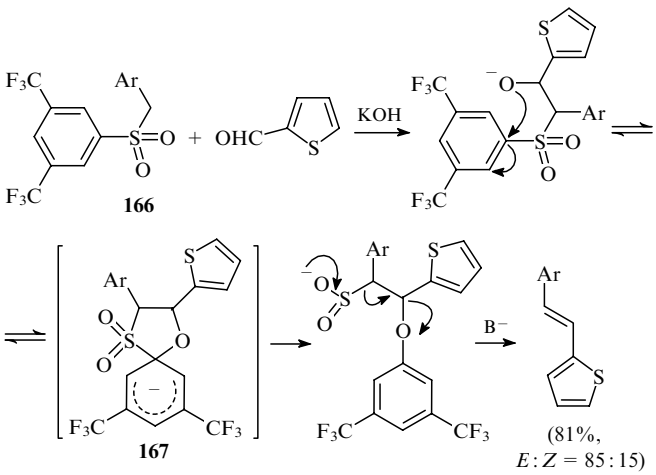
R = Bn (**a**, 68%); 4-ClC_6H_4 (**b**, 80%); $MeOCH_2CH_2$ (**c**, 75%).



165 (85%, $E:Z = 74:26$)

LiHMDS is lithium hexamethyldisilazanide.

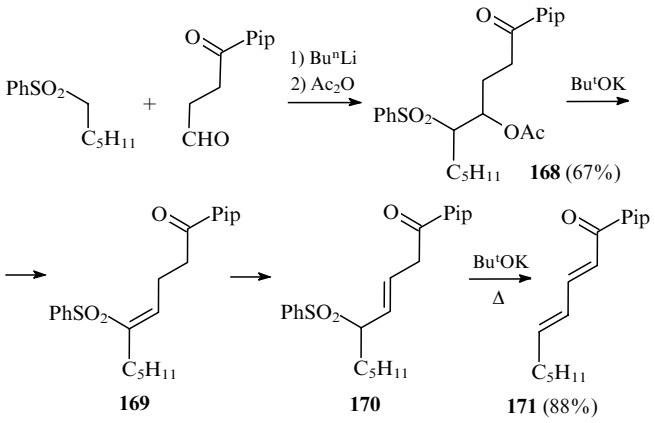
The sulfone **166** containing an electron-deficient arene fragment was used in yet another modification of the Julia–Kocienski reaction.[113] The addition of a carbanion generated from compound **166** to aldehydes and subsequent β-elimination of 3,5-bis(trifluoromethyl)phenoxide from the adduct **167** upon treatment with a base with concomitant liberation of SO_2 afford alkenes in high yields and with high *E*-stereoselectivities.



Ar = 3,5-$(MeO)_2C_6H_3$.

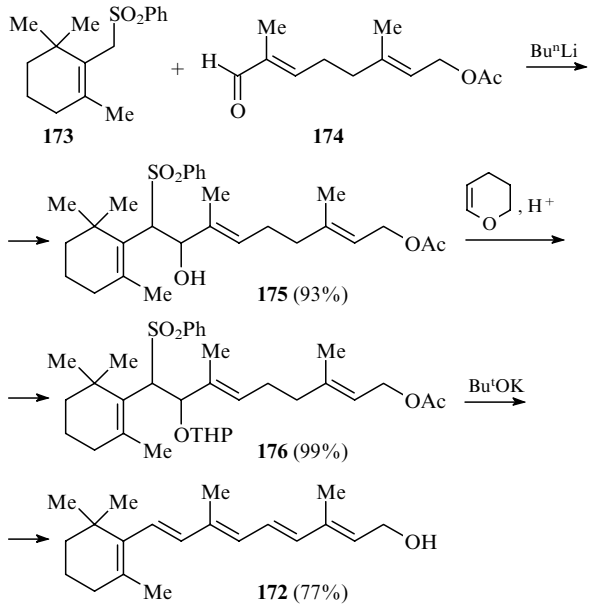
The Julia reaction can be used in the synthesis of conjugated polyenes from carbonyl compounds. Thus compound **168** prepared from hexylphenyl sulfone and the corresponding aldehyde was treated with a strong base, such as potassium *tert*-butoxide.[114]

The first step includes elimination of acetic acid and formation of the vinylic sulfone **169** which is rearranged into the allylic sulfone **170**. The latter undergoes 1,4-elimination to give a diene **171** (usually, with *E*,*E*-configuration).[115, 116] The intermediate vinylic sulfone **169** can be isolated upon treatment of **168** with an equimolar amount of a base. Subsequent cleavage of the sulfone requires a fourfold excess of potassium *tert*-butoxide and heating.



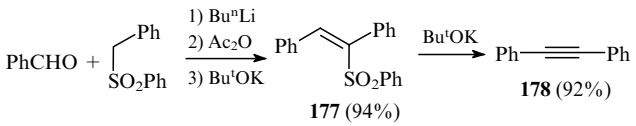
PiP is piperidin-1-yl.

The Julia method was used in the synthesis of many natural compounds including muscone and some retinoids.[2, 101, 117] Thus synthesis of retinol **172** involved the addition of β-cyclogeranyl sulfone **173** to the aldehyde **174**. The resulting β-hydroxy sulfone **175** was protected with a tetrahydropyranyl group; the product **176** was treated with potassium *tert*-butoxide. Subsequent elimination of the protected hydroxy group and the sulfone with concomitant rearrangement of multiple bonds yields the target compound **172** in which all the double bonds have a *trans*-configuration.

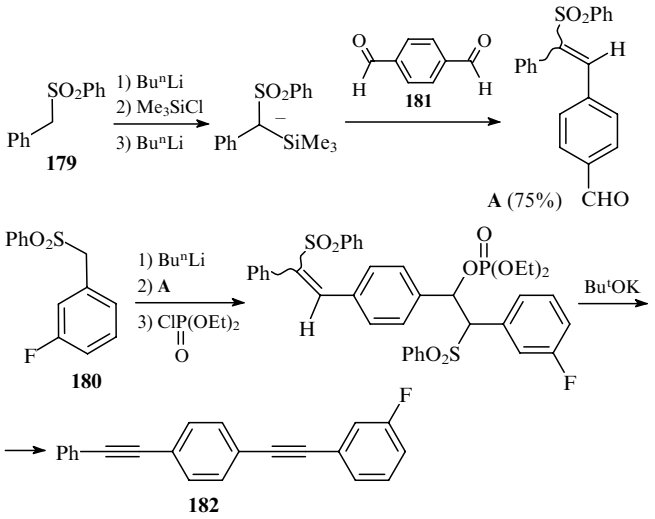


THP is tetrahydropyran-2-yl.

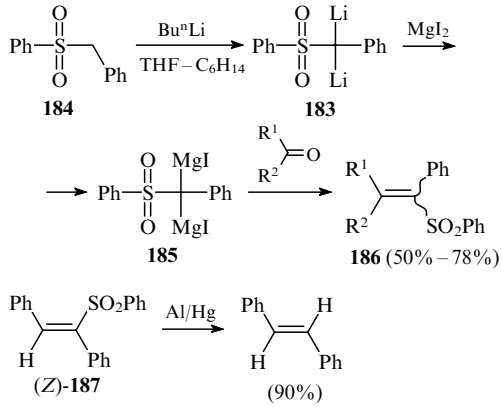
If the shift of double bonds in vinylic sulfones, *e.g.*, in compound **177**, is impossible, subsequent elimination yields acetylene **178**.[115]



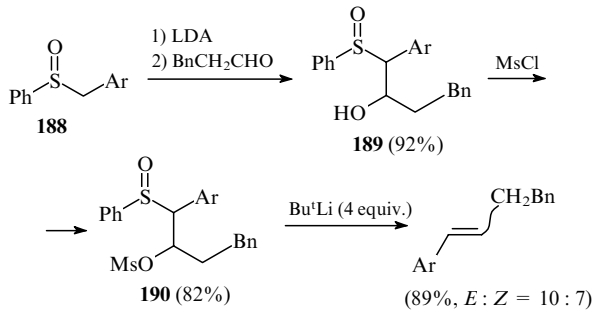
The addition of sulfones to dialdehydes allows one to synthesise non-symmetrical polyacetylenes.[118] Thus consecutive addition of two different sulfones (**179** and **180**) to the carbonyl groups of the dialdehyde **181** and elimination of the sulfonyl groups yield diacetylene **182** with different substituents.



Benzyl phenyl sulfone α,α-dilithium derivative **183**, which is easily prepared by the double metallation of benzyl phenyl sulfone **184**, can be converted into an organodimagnesium compound **185** *in situ* using lithium – magnesium exchange upon treatment with magnesium iodide. The dimetallated sulfone **185** is a convenient olefinating agent, which reacts with aliphatic, aromatic and unsaturated aldehydes or ketones to give α,β-unsaturated sulfones **186** in good yields.[119] The sulfonyl group is removed using aluminium amalgam or the system $LiAlH_4 - CuCl_2$.[120] Unfortunately, in the majority of cases this reaction occurs non-stereoselectively and yields first a mixture of *E*- and *Z*-isomers of sulfones and then a mixture of the corresponding alkenes. The desulfonylation occurs in good yields (40% – 90%). Thus *trans*-stilbene is formed in 90% yield from the *Z*-sulfone **187**.[120]

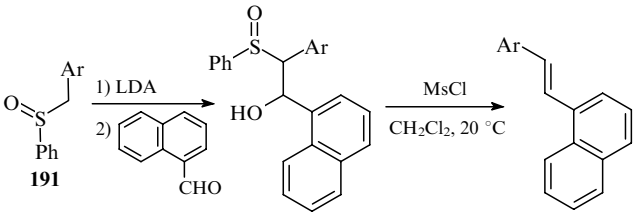


A sulfoxide modification of the Julia-type olefination reaction has been developed.[121, 122] In the case of sulfoxides **188,** the acidity of α-hydrogen atoms is lower than that of sulfones; this makes the corresponding carbanions more reactive as a result of which even ketones can be used as the carbonyl components in this reaction. Mesylation of the intermediate β-hydroxy sulfoxides **189** and reduction of the intermediates **190** by Grignard reagents or *tert*-butyllithium result in alkenes. In the case of an aliphatic substrate (*e.g.*, 3-phenylpropanal), the stereoselectivity of the reaction with all arylmethyl phenyl sulfoxides studied was low.



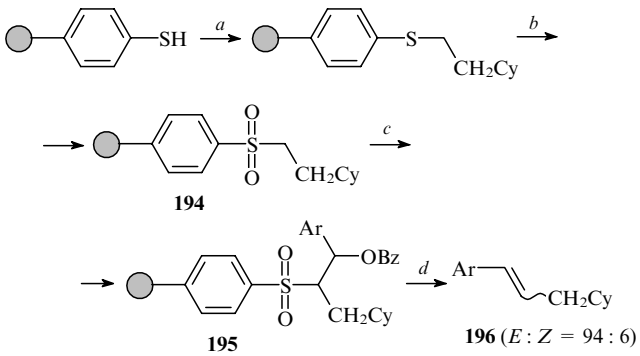
Ms = $MeSO_2$.

On going to aromatic aldehydes, non-symmetrical stilbenes are formed in this reaction exclusively as *trans*-isomers.[122] For example, the addition of sulfoxide **191** to 1-naphthaldehyde and mesylation of β-hydroxy sulfoxide **192** result in spontaneous elimination and formation of the *trans*-alkene **193**.



Ar = 4-$MeOC_6H_4$.

A recent modification of the Julia reaction consists of solid-phase synthesis.[123] A polymer containing pendent benzenethiol units is converted into the olefinating agent **194** by sequential *S*-alkylation and oxidation of the sulfide. Subsequent deprotonation and addition of anisaldehyde followed by benzoylation of the resulting β-hydroxy sulfone and reduction of compound **195** with samarium iodide yield the alkene **196** in 27% yield (starting from benzenethiol). The stereoselectivity of this reaction depends on the type of the acylating reagent (Ac_2O or PhCOCl) and the solvent used for reductive elimination.

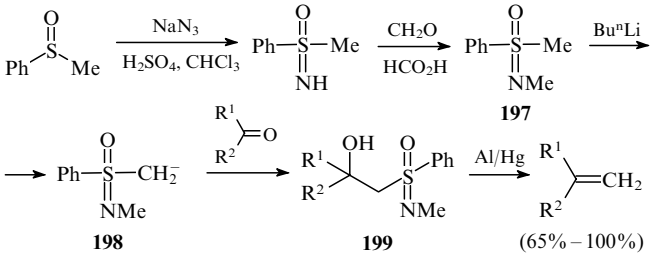


(*a*) 1) Bu^{t}OK (12 equiv.), 2) $CyCH_2CH_2OTs$ (2 equiv.), THF – DMSO (2 : 1), 20 °C; (*b*) *m*-CPBA (4 equiv.), CH_2Cl_2, 20 °C; (*c*) 1) Bu^{n}Li, 2) ArCHO, 3) PhCOCl; (*d*) SmI_2 (7 equiv.), THF, DMPU, 20 °C; Ar = 4-$MeOC_6H_4$; *m*-CPBA is *m*-chloroperbenzoic acid;

— polymeric support.

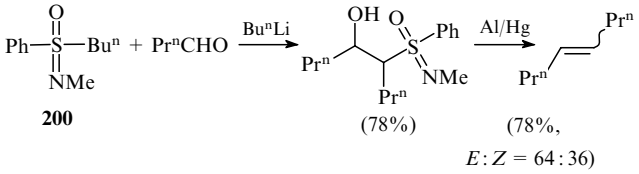
b. The Johnson reaction

In 1973, Johnson proposed to use sulfoximine **197** for methylenation of carbonyl compounds.[124, 125] The carbanion **198** prepared by deprotonation of the imine **197** with n-butyllithium appeared to be a strong C-nucleophile. Its addition to the carbonyl group of ketones yields β-hydroxy sulfoximine **199** which is further reduced with aluminium amalgam to the corresponding terminal alkene. The starting sulfoximine **197** can easily be prepared from methyl-phenyl sulfoxide.[124] The reaction can be carried out in a one-pot manner, without isolation of the intermediate **199**.[124] The Johnson reaction proved to be effective in the synthesis of terminal alkenes from both ketones and aldehydes. The carbanion **198** was found to be more nucleophilic than methylene triphenylphosphorane, this can be used in the synthesis of alkenes that cannot be prepared by the Wittig reaction.[2, 126]

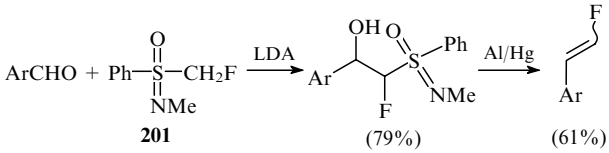


R^1 = Alk, Ar; R^2 = H, Alk.

The use of higher homologues of sulfoximines, *e.g.*, compound **200**, in reactions with aldehydes and ketones allows one to synthesise non-terminal alkenes; however, in this case the reaction occurs with low stereoselectivity.[125]

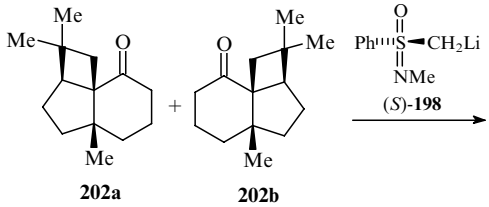


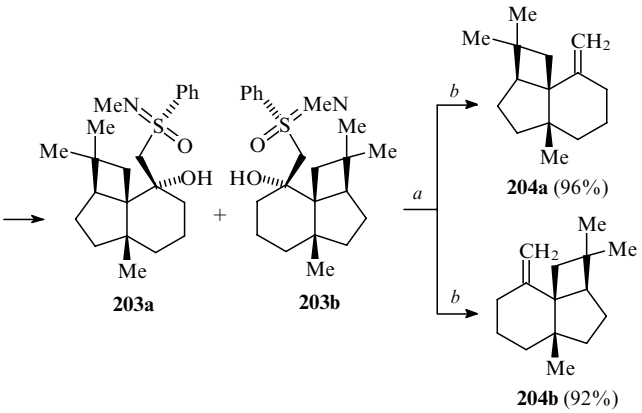
α-Fluoromethyl sulfoximine **201** was recommended as a convenient fluoromethyenating agent.[127] It was employed in the synthesis of a series of vinyl fluorides from aromatic and aliphatic aldehydes and ketones. This reaction is non-stereoselective and yields a mixture of alkene isomers in a 1 : 1 ratio.



Ar = 4-$MeOC_6H_4$.

It should be noted that the Johnson reagent (sulfoximine **197**) contains an asymmetrical sulfur atom. The reaction of an individual *S*-enantiomer of the carbanion **198** with a racemic mixture of the ketone **202** (**202a**, **202b**), chromatographic separation of the intermediate diastereomeric β-hydroxy sulfoximines **203a**,**b** and subsequent reductive elimination of sulfoximine resulted in the alkene enantiomers **204a**,**b** in the optically pure state.[128]

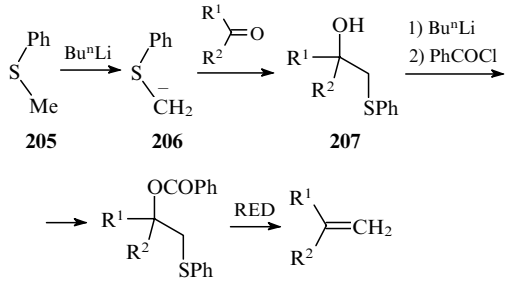




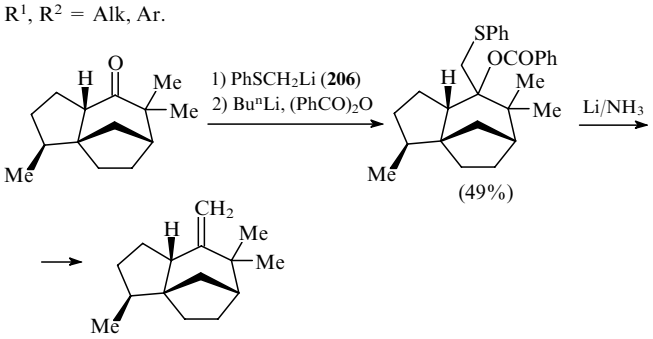
(*a*) separation of diastereomers; (*b*) Al/Hg.

c. Other sulfur-containing reagents

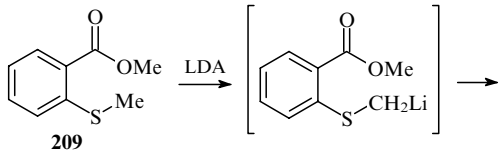
The carbanion **206** generated from thioanisole (**205**) adds to the carbonyl group of aliphatic and aromatic ketones to give β-phenylthioethanol **207**.[129] Benzoylation of the hydroxy group and subsequent reductive elimination of the ester and phenylthio groups yield terminal alkenes. Lithium in liquid ammonia,[129] the system $TiCl_4-Zn$ [2] or metallic titanium are used as the reducing agents.[130] Cage ketones can also be employed as the carbonyl components.[129]

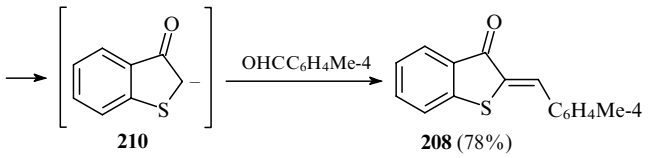


R^1, R^2 = Alk, Ar.



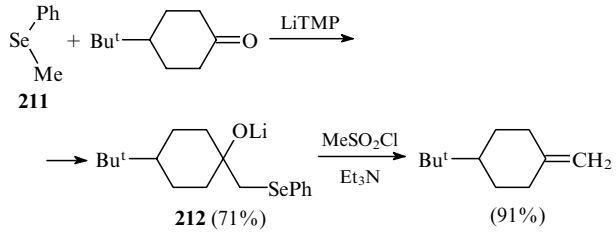
In the synthesis of thioaurones, *e.g.*, 2-(arylmethylidene)benzothiophen-3-ones **208**, 2-methylthiobenzoic acid or its methyl ester **209** were used as the olefinating agents.[131] This reaction is accompanied by anionic intramolecular cyclisation of the ester **209**, which yields the intermediate **210**; subsequent addition of the latter to the carbonyl group gives the alkene **208**. It should be noted that this reaction occurs stereospecifically and yields exclusively the *Z*-isomer of the alkene **208**. Other aliphatic and aromatic aldehydes can also enter into this reaction.[131]



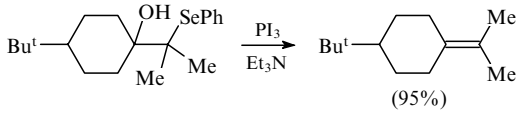


d. The Krief–Reich reaction

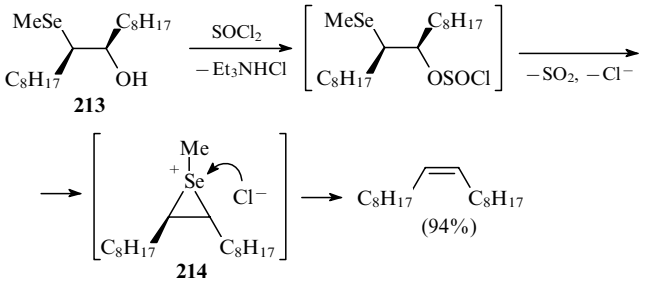
The olefination of carbonyl compounds by carbanions stabilised by selenium atoms is referred to as the Krief–Reich reaction.[2, 24, 132–134] The addition of carbanions prepared by deprotonation of alkyl aryl selenides **211** (see Ref. 3) or treatment of diselenoacetals with butyllithium,[135] to the carbonyl group results in β-hydroxy selenides **212**, which can further be converted into various products. In particular, alkenes are prepared by elimination of the hydroxy and selenyl fragments using methanesulfonyl chloride, $SOCl_2$ [134] or PI_3 in the presence of triethylamine.[135]



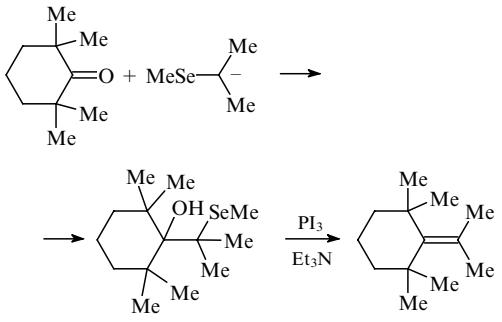
TMP is 2,2,6,6-tetramethylpiperidin-1-yl.



The modification of the OH-group of β-hydroxy selenide **213** by treatment with thionyl chloride results in its conversion into a good leaving group; elimination of the latter yields the selenonium cation **214**. An attack by an external nucleophile at the selenium atom of the cation **214** yields alkenes.[2, 136]

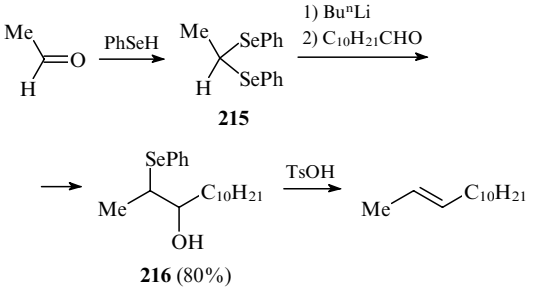


The Krief–Reich reaction was used in the synthesis of various types of alkenes including sterically hindered ones.[137]



The Krief–Reich methodology can be used for cross-coupling of two different aldehydes.[132] Conversion of one of them into selenoacetal **215,** treatment of the latter with n-butyllithium and addition of the resulting carbanion to the second aldehyde result

in β-hydroxy selenide **216**. Subsequent elimination of the hydroxy and selenyl fragments yields alkenes.

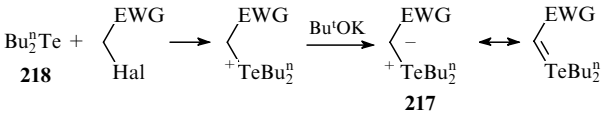


215

216 (80%)

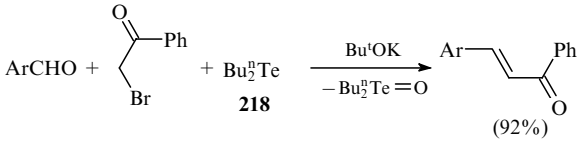
d. Tellurium-based reagents

Tellurium ylides **217** containing an electron-withdrawing group (ester, cyano, keto, *etc.*) in the α-position are used in the synthesis of α,β-unsaturated esters, nitriles and ketones.[138, 139] To this end, aromatic aldehydes are treated with α-halo-substituted esters or nitriles in the presence of equimolar amounts of dibutyl telluride **218**. The corresponding tellurium ylides **217** are generated *in situ* by deprotonation of telluronium salts. This reaction results in good yields, it is highly stereoselective and gives predominantly *E*-isomers of alkenes. It is of note that reactions of tellurium ylides with carbonyl compounds yield olefination products, whereas reactions of sulfur ylides with the carbonyl group give epoxides.



218 **217**

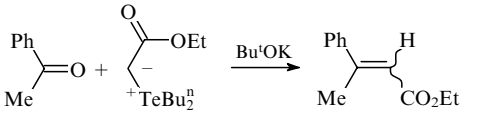
EWG = CO_2R, COR, CN; Hal = Cl, Br.



(92%)

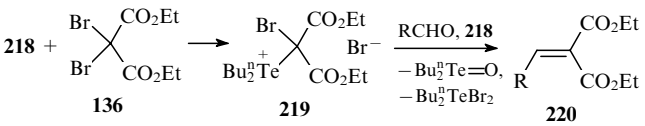
Ar = 4-$NO_2C_6H_4$.

Both aldehydes and ketones can be used as the carbonyl components; however, in the case of non-symmetrical ketones the stereoselectivity of alkene formation is low.[139]



(68%, *E* : *Z* = 11 : 1)

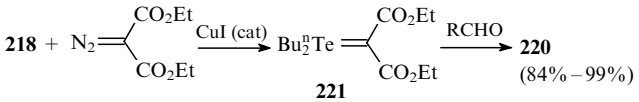
In the presence of dibutyl telluride **218**, dibromomalonate **136** can be used as the olefinating agent in reactions with aromatic aldehydes.[140] The reaction mechanism is similar to that considered above for the olefination with tributylstibine (Section II.3.e) and includes the formation of the telluronium salt **219** as a result of the alkylation of dibutyl telluride. In the presence of a second equivalent of dibutyl telluride, the salt **219** reacts with aldehydes to give α,β-unsaturated malonates **220**.



136 **219** **220** (84%–99%)

R = Alk, Ar, Het.

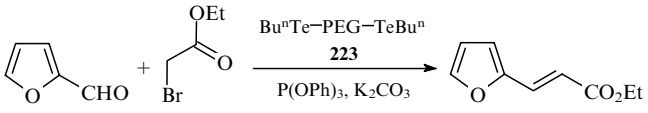
The copper-catalysed decomposition of diazo compounds in the presence of dialkyl or diaryl tellurides yields tellurium ylides **221**, which react with aldehydes to give alkenes.[141]



221 **220** (84%–99%)

R = Alk, Ar, Het.

A method for the synthesis of α,β-unsaturated esters, *e.g.*, the furan derivative **222**, has been developed where the telluride is coupled to polyethylene glycol (**223**).[142, 143] The tellurium derivative was used in catalytic amounts (2 mol.%), and equimolar amounts of triphenyl phosphite are required for the reduction of tellurium oxide formed. The yields of the target alkenes are usually close to quantitative; the stereoselectivity of the reaction is extremely high.



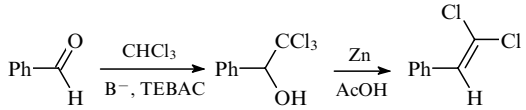
222 (96%, *E* : *Z* = 99 : 1)

PEG is polyethylene glycol.

5. Reagents based on Group VIIA elements

Addition of anions generated from tri-, di- and monohalomethanes to aldehydes and ketones $R^1R^2C{=}O$ and subsequent reduction of β-halogeno alcohols yields *gem*-dihaloalkenes $R^1R^2C{=}CHal_2$, vinyl halides $R^1R^2C{=}CHHal$ or terminal alkenes $R^1R^2C{=}CH_2$. This group of olefination methods was developed relatively recently, but nevertheless has rather a broad range of synthetic applications.

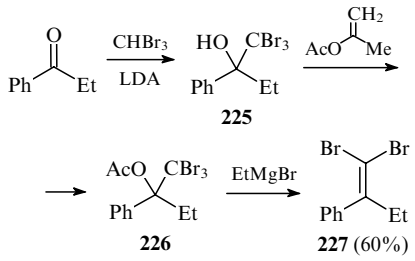
Reduction of aryltrichloromethylmethanols of the type **224** or their acetates,[144] with zinc in acetic acid (2–4 equiv.) or electrochemically is a convenient route to the synthesis of dichloroalkenes.[145] The corresponding alcohols are prepared by condensation of aldehydes with chloroform in the presence of phase-transfer catalysts [8, 145] or by a reaction of aldehydes with the trichloromethyl anion generated from trichloroacetic acid.[146]



224 (87%)

TEBAC is triethylbenzylammonium chloride.

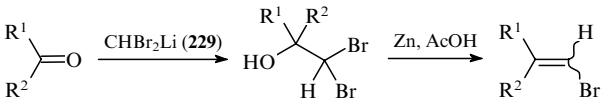
gem-Bromochloroalkenes and *gem*-dibromoalkenes can be prepared by a similar procedure using dibromochloromethane and bromoform, respectively.[147] Thus the addition of the tribromomethyl anion to ethyl phenyl ketone results in tribromomethylpropanol **225**. Subsequent acylation of the hydroxy group and reduction of the resulting ester **226** with Grignard reagent yield the dibromoalkene **227**. Other alkyl aryl and dialkyl ketones are also used as the carbonyl substrates.[147]



225 **226** **227** (60%)

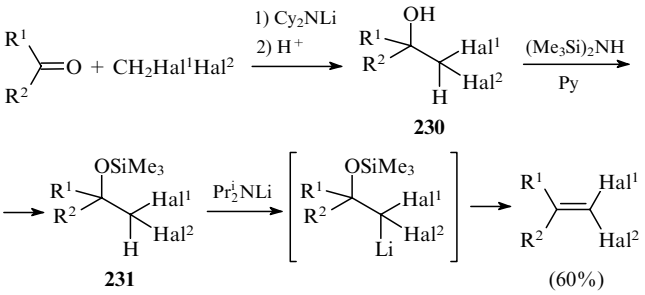
Bromoalkenes **228** can be obtained from carbonyl compounds by treatment with dibromomethyllithium **229** generated *in situ* from dibromomethane and lithium dicyclohexylamide.[148] This reaction is applicable to a vast variety of aromatic and aliphatic aldehydes and ketones including α,β-unsaturated aldehydes and

ketones, which afford the corresponding bromo-substituted dienes. However, the stereoselectivity of the formation of bromoalkenes is usually low.



R^1, R^2 = Alk, Ar.

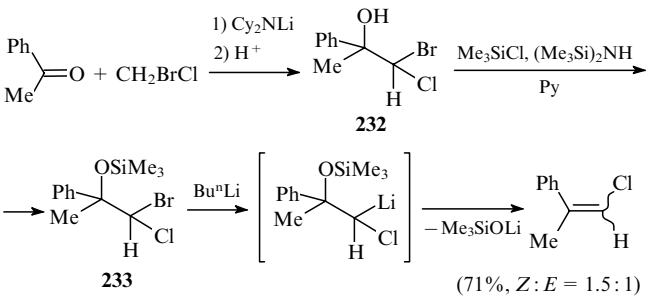
The reactions of carbonyl compounds with dihalomethanes (CH_2Cl_2, CH_2Br_2, CH_2BrCl) in the presence of lithium dicyclohexylamide and subsequent acidification of the reaction mixture yield the corresponding β,β-dihalo-substituted alcohols **230**; treatment of the latter with chlorotrimethylsilane in the presence of hexamethyldisilazane and pyridine gives the silylated derivatives **231**.[149] This reaction occurs with good yields and can be applied to both aliphatic and aromatic carbonyl substrates.



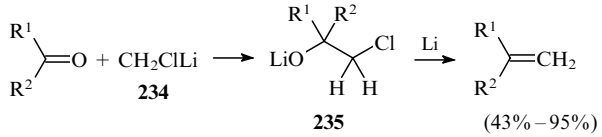
R^1 = H, Me, Et; R^2 = Et, C_7H_{15}, Ph; R^1–R^2 = $(CH_2)_3$, $(CH_2)_5$; Hal^1, Hal^2 = Cl, Br.

Subsequent treatment of compounds **231** with lithium diisopropylamide yields dihaloalkenes through C-deprotonation and β-elimination of silanol.

Silylation of an intermediate **232** derived from bromochloromethane and subsequent treatment of the silyl derivative **233** with n-butyllithium results in the chemoselective exchange bromine–lithium; elimination of silanol yields monohaloalkenes. However, the stereoselectivity of the synthesis of vinylic halides is very low: the isomer ratio is close to equimolar.



The use of chloromethyllithium **234** generated from chloroiodomethane as the olefinating agent in reactions with ketones results in terminal alkenes.[150] This reaction occurs *via* the intermediate **235**; subsequent reduction of the latter with lithium yields the target products.

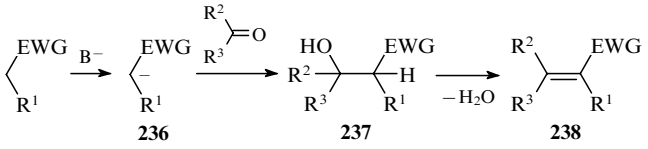


R^1, R^2 = Alk, Ar.

Thus condensation of polyhalomethyl anions with carbonyl compounds followed by acylation or silylation of intermediate alcohols and their subsequent reduction or elimination yield terminal alkenes or vinylic halides. However, the multistep character of this method is its disadvantage.

III. Condensation of carbonyl compounds with CH-acids

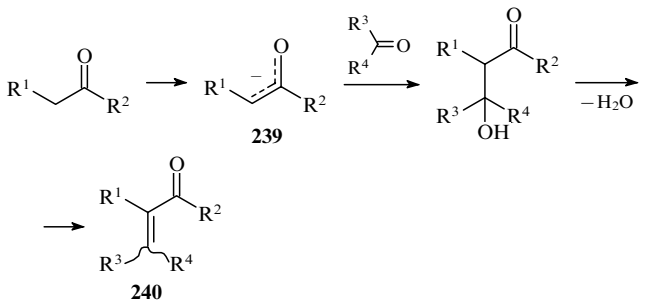
Compounds containing one or several electron-withdrawing groups at one carbon atom (CH-acids) are deprotonated in the presence of bases; the carbanions **236** formed add to the electrophilic carbon atom of the carbonyl group to give the alcohols **237**. If a CH-acid contains more than one hydrogen atom in the α-position relative to the electron-withdrawing group, the condensation products undergo dehydration resulting in the formation of alkenes **238** containing electron-withdrawing substituents. The presence of electron-withdrawing groups favours elimination according to the E1cb mechanism.



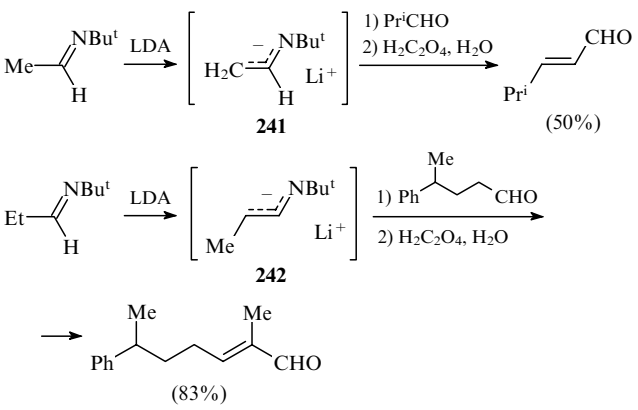
Many of the reactions described in this chapter were discovered as early as the 19th century; however, this branch of organic chemistry is still developing and novel modifications of the known reactions, reagents and catalysts continue to appear. A method for the synthesis of alkenes using carbanions stabilised by an electron-deficient aromatic system has been developed recently. Reactions of carbanions, which differ in the nature of substituents at the CH-acidic centre, are used in organic synthesis; these will be described in the chapters that follow.

1. Aldol condensation and its modifications

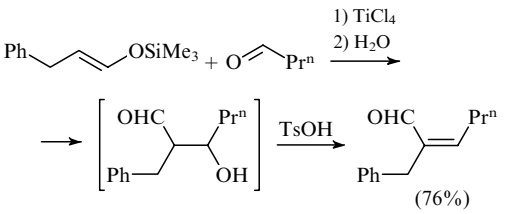
Reactions of enolate anions **239** generated from aldehydes and ketones with carbonyl compounds yield enals or enones **240**.[1,2] In these reactions, aldehydes and ketones play the role of both nucleophiles (the methylene component) and electrophiles (the carbonyl component). This allows both self-condensation and cross-coupling. Both bases and acids can be used as catalysts.



At present, direct chemo- and regioselective aldol condensation is based on the use of specially prepared metal enolates as well as of enol silyl ethers [151] and azaenolates.[152–154] Methods for the synthesis of enols and enolates as well as asymmetric syntheses based on them are documented in numerous reviews and monographs.[2,155–166] Thus conversion of one of the carbonyl compounds into an imine or a dimethylhydrazone by treatment with a primary amine or 1,1-dimethylhydrazine is a convenient procedure for modification of the aldol condensation.[2,152–154] Subsequent deprotonation of imines by non-nucleophilic bases yields azaenolates **241** and **242**, which act as the olefinating agents in the reaction with aldehydes and ketones.[3] The β-hydroxyimines formed are converted into α,β-unsaturated carbonyl compounds upon acid treatment. The condensation occurs stereospecifically and gives usually *trans*-isomers of alkenes.

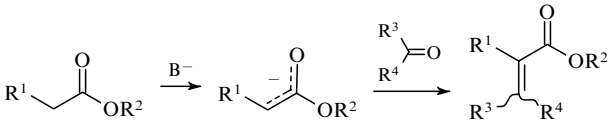


Preliminary conversion of a carbonyl compound, which plays the role of a nucleophilic component, into an enol silyl ether is yet another method for selective aldol cross-coupling.[151] In the case of non-symmetrical carbonyl compounds, enol ethers can be prepared regioselectively. Under conditions of kinetic control, a less substituted enol is formed predominantly, whereas under conditions of thermodynamic control a more stable substituted enol is the main product. Further reactions of enol silyl ethers with carbonyl compounds in the presence of Lewis acids yield β-hydroxy ketones or α,β-unsaturated ketones.[151]



2. Condensation of aldehydes and ketones with esters

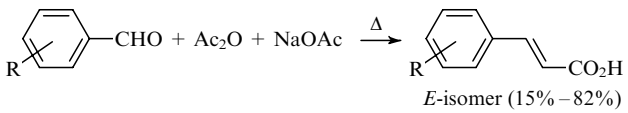
Esters $R^1CH_2COOR^2$ are used as nucleophilic components in condensations with carbonyl compounds, which yield α,β-unsaturated acids or esters.



Esters usually require stronger bases for the generation of enolates than in the aldol condensation due to lower CH-acidity of hydrogen atoms in the α-position. This method is of a rather historical significance; the range of its application is fairly narrow due to drastic reaction conditions.[3] Modern approaches are based on the use of stronger bases of the LDA type, which allows complete deprotonation of the ester.

3. The Perkin reaction

Condensation of aromatic aldehydes and ketones with carboxylic anhydrides or their analogues is referred to as the Perkin reaction.[3,25] This reaction requires heating, sometimes rather significantly (up to 200–250 °C), of the reaction mixture. If an anhydride contains more than one α-hydrogen atom, dehydration takes place; the intermediate salt of β-hydroxy acid is never isolated. The role of a base in the Perkin reaction is always played by a sodium or potassium salt of the acid corresponding to the anhydride introduced into the reaction; however, in some versions, ammonia, triethylamine and some other amines are used. Aromatic aldehydes and their vinylogues ArCH=CHCHO are used as the carbonyl components. The Perkin reaction is a convenient procedure for the synthesis of substituted cinnamic acids from accessible aromatic aldehydes, the predominant formation of *E*-isomers is observed. However, at present this reaction has a rather historical significance, since it requires drastic conditions and often the yields of target products are low.

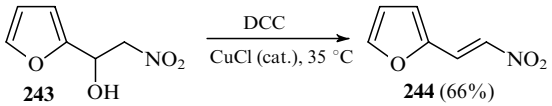


R = OH, OAlk, Hal, NO_2.

4. The Henry reaction

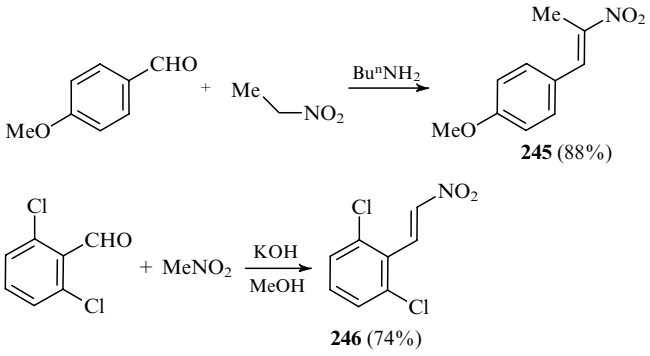
Condensation of carbonyl compounds with nitro derivatives is called the Henry reaction or the nitroaldol reaction.[2] It represents the most convenient method for the synthesis of nitro alcohols and nitro alkenes.[26–29,167] The nitroaldol reaction employs weak bases, since aliphatic nitro compounds are characterised by high CH-acidity. Amines, alkalis, carbonates and alkali metal alkoxides are usually employed as catalysts.

The reaction is often stopped at the step of a nitro alcohol; subsequent dehydration is carried out with dehydrating agents, such as dicyclohexylcarbodiimide, pivaloyl chloride, phthalic anhydride or methanesulfonyl chloride.[27] Thus the dehydration of the β-nitro alcohol **243** with dicyclohexylcarbodiimide in the presence of catalytic amounts of CuCl yields the nitro alkene **244**.[168]

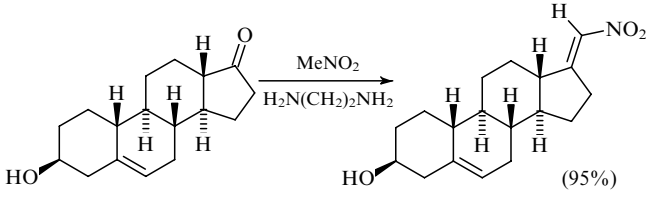


DCC is dicyclohexylcarbodiimide.

Aromatic aldehydes are directly converted into nitro alkenes **245** and **246** due to a considerable energy gain upon formation of the double bond conjugated to an aromatic system. The synthesis of alkenes **245** and **246** occurs in a stereoselective manner.[3]



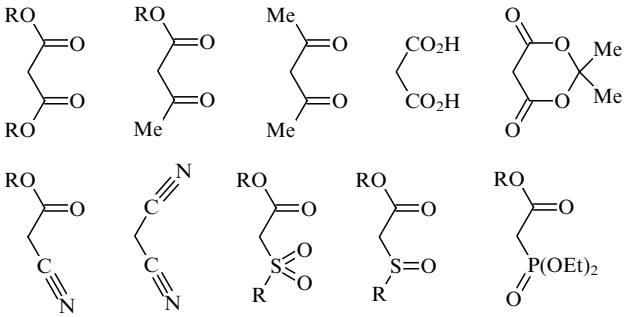
The olefination of ketones with nitromethane in the presence of ethylenediamine also results in unsaturated compounds.[27]



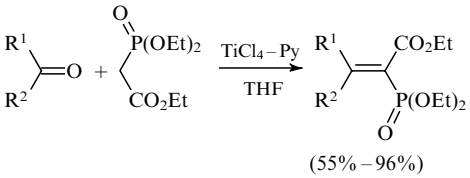
5. The Knoevenagel reaction

Reactions of aldehydes and ketones with compounds of the type $(EWG)_2CH_2$, which contain a reactive methylene group (1,3-diketones, 1,3-keto esters, malonates, ethyl cyanoacetate, malononitrile, *etc.*), are usually referred to as the Knoevenagel reaction,[3] although this definition is not quite correct.

In addition to 1,3-dicarbonyl compounds,[169,170] the Knoevenagel reaction widely employs alkyl cyanoacetates,[171] sulfonyl[172] and sulfinyl acetates,[173] as well as phosphonoacetates.[174]



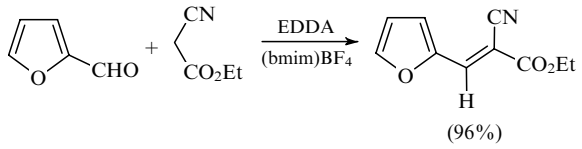
The generation of enolates from compounds containing two electron-withdrawing groups allows the use of weaker bases than the traditional aldol condensation, *viz*., amines, acetates as well as a mixture of $TiCl_4$ and pyridine.[174]



(55%–96%)

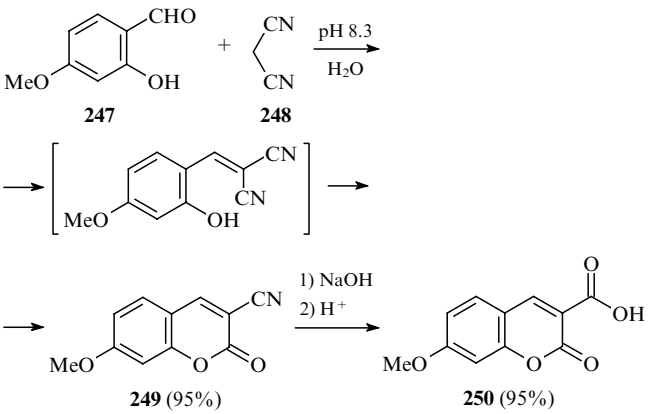
R^1, R^2 = Alk, Ar.

In one of the most recent modifications of the Knoevenagel reaction, ionic liquids are used as solvents. Thus condensation of diverse aromatic and aliphatic carbonyl compounds with ethyl cyanoacetate, acetylacetone and ethyl acetoacetate in 1-butyl-3-methylimidazolium tetrafluoroborate [(bmim)BF_4] was studied in the presence of ethylene diammonium diacetate (EDDA) as the catalyst.[173] This reaction is stereospecific and gives *E*-isomers of alkenes; in most cases, the yields of reaction products are virtually quantitative.



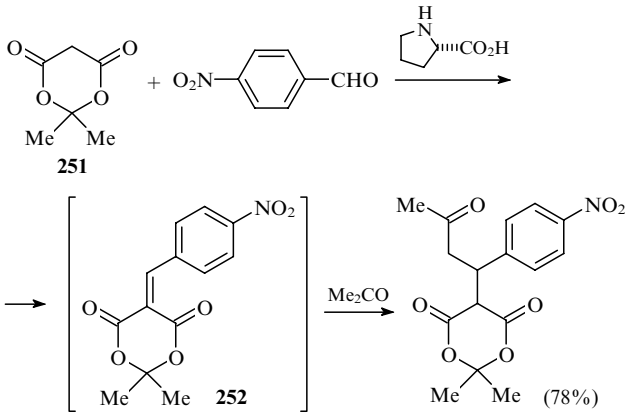
(96%)

The condensation of salicylic aldehydes with Meldrum's acid or malonic acid is widely used in the synthesis of substituted coumarin-3-carboxylic acids.[3] Its most recent version consists of a reaction of salicylic aldehydes of the type **247** with malononitrile **248** under heterogeneous conditions in the presence of an aqueous alkali or sodium hydrogen carbonate.[175] This results in substituted 3-cyanocoumarin **249**; its subsequent alkaline hydrolysis gives the coumarin-3-carboxylic acid derivative **250**. Both reaction steps occur in high yields.

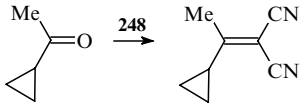


249 (95%) **250** (95%)

A three-component reaction representing the proline-catalysed condensation of aldehydes with Meldrum's acid **251** and subsequent Michael addition of ketone enolates to the adduct **252** formed, has been developed.[176] In this reaction, two C–C bonds are formed.

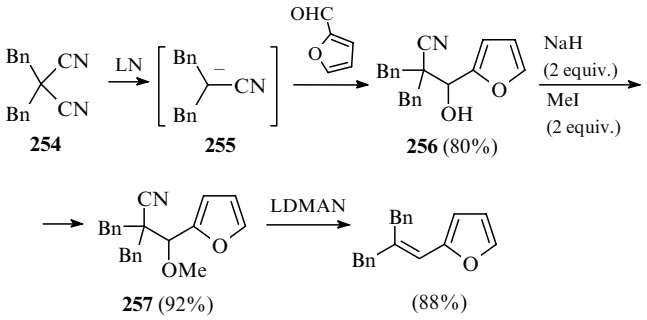


The use of malononitrile **248** in organic synthesis has been surveyed;[177–179] its condensation with carbonyl compounds is widely used in the synthesis of alkylidene- and arylidenemalononitriles. In particular, cyclopropyl-substituted dinitrile **253** was prepared in this manner.



253 (81%)

And finally, special mention should be made of an original olefination procedure based on reductive addition, to the carbonyl group, of *gem*-dinitrile **254**, which is prepared by bisalkylation of malononitrile.[180] Reduction of *gem*-dinitrile **254** with lithium naphthalenide leads to the loss of one cyano group.The carbanion formed **255**, which is stabilised by the residual cyano group, is an effective nucleophile which reacts with a broad range of electrophiles including carbonyl compounds. The intermediate β-hydroxy nitrile **256** is further *O*-alkylated. Reductive elimination of the vicinal alkoxy- and cyano fragments by treatment of compound **257** with lithium 1-(dimethylamino)naphthalenide yields the corresponding alkene. This reaction results in the loss of both cyano groups. It is noteworthy that the possibility of synthesising tetrasubstituted alkenes from ketones is a significant advantage of this method.



254 **255** **256** (80%)

257 (92%) (88%)

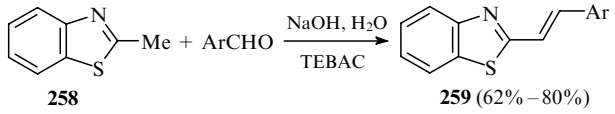
LN is lithium naphthalenide;
LDMAN is lithium 1-(dimethylamino)naphthalenide.

6. Condensation of carbonyl compounds with other CH-acids

Carbanions stabilised by an electron-deficient aromatic system can be used as olefinating agents.[2, 6, 181] Condensation of the corresponding CH-acids with aromatic aldehydes in the presence of bases is used for the preparation of non-symmetrical stilbenes or their heterocyclic analogues.[6] Pyridine, piperidine, alkali metal alkoxides and, less frequently, alkalis are commonly used as the bases.

Thus the reaction of aromatic aldehydes with 2-methylbenzothiazole **258** in the presence of aqueous alkali and a phase-transfer

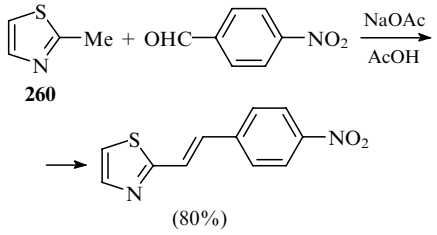
catalyst yields olefination products, *viz*., 2-styrylbenzothiazoles **259**.[181]



258 **259** (62% – 80%)

Ar = Ph, 2-ClC_6H_4, 4-ClC_6H_4, 4-MeC_6H_4, 4-$MeOC_6H_4$.

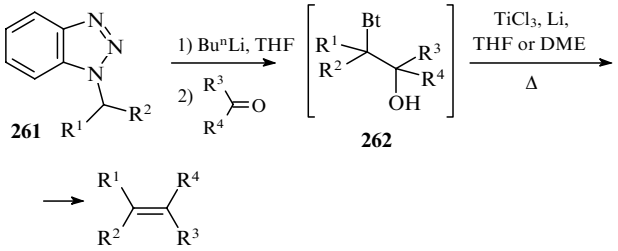
Synthesis of styrylthiazole is carried out in acetic acid in the presence of sodium acetate.[182] Protonation of the nitrogen atom of the heterocyclic base **260** increases the CH-acidity of the methyl group and favours its reaction with benzaldehydes. Lewis acids ($ZnCl_2$) and protic acids (HCl, H_3BO_3) can be used as catalysts.



260

(80%)

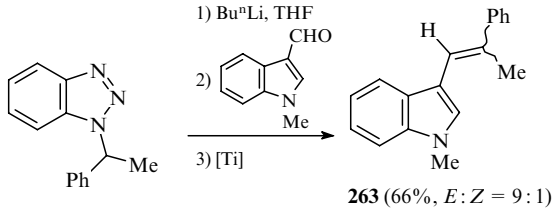
Katritzky *et al*.[80, 183, 184] have proposed the use of *N*-alkylbenzotriazole anions **261** in the condensation of carbonyl compounds for the synthesis of allyl- and benzyl-substituted alkenes. The alcohols **262** formed containing a benzotriazole system are reduced to alkenes upon treatment with low-valence titanium derivatives; the heterocyclic system is thereby eliminated.



261 **262**

Bt is benzotriazol-1-yl.

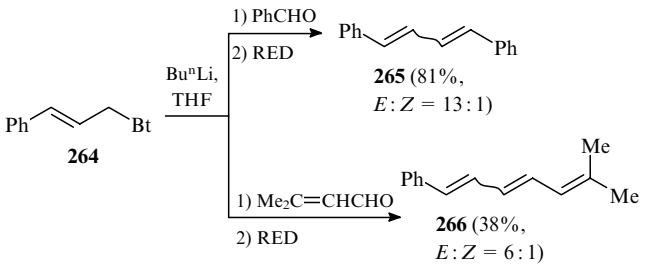
The olefination proceeds in good yields (53% – 81%) and high *E*-stereoselectivity not only in the case of 1,2-disubstituted, but also tri- and tetrasubstituted alkenes. Thus stereoselectivity of the formation of the trisubstituted alkene **263**, which represents a heterocyclic analogue of stilbene, was fairly good.



263 (66%, $E:Z = 9:1$)

Aliphatic and aromatic aldehydes and ketones as well as α,β-unsaturated carbonyl compounds were used as the carbonyl substrates. Unfortunately, the range of olefinating agents is limited to *N*-allyl- and *N*-benzylbenzotriazole derivatives.

This approach is used in the stereoselective synthesis of some conjugated dienes and trienes.[183, 184] Thus the reagent **264** was used to yield conjugated diene **265** and triene **266**:



264

IV. Reagents based on transition and non-transition metals

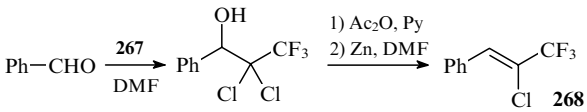
A great diversity of methods for the olefination of carbonyl compounds is known which make use of reagents based on metals, in the first place, transition metals.[1, 3] In these reactions, metal compounds usually play the role of reducing agents. Reagents based on titanium, zinc and chromium are especially popular.

1. Reagents based on Group IIB metals

a. Zinc-based reagents

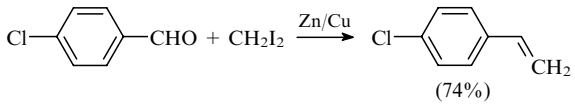
Reductive coupling of polyhaloalkanes with carbonyl compounds in the presence of zinc was used in the synthesis of various halogen-substituted alkenes.[185 – 187] It was shown that treatment of zinc with 1,1,1-trichloro-2,2,2-trifluoroethane gives a stable organozinc reagent **267**, its addition to aromatic and aliphatic aldehydes yields the corresponding alcohols. The latter can be reduced to trifluoromethyl-substituted alkenes by excess zinc. In the case of benzaldehyde, the yield of the reaction product **268** (over three steps) was 84%.[186, 187]

267



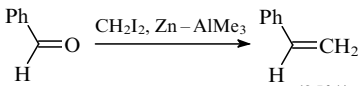
268

Diiodomethane was used as a methylenating agent in the synthesis of terminal alkenes from aromatic aldehydes in the presence of a zinc – copper couple.[188]

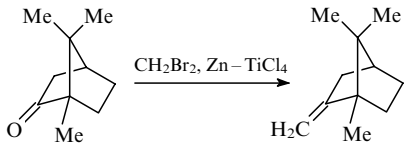


(74%)

The Oshima – Lombardo reaction includes methylenation of carbonyl compounds by dihalomethanes (CH_2I_2, CH_2Br_2) catalysed by $Zn-TiCl_4$ or $Zn-AlMe_3$ systems.[1, 189] A *gem*-organodizinc compound of the type $HalZnCH_2ZnHal$ (**269**, Hal = I, Br) is used as the olefinating agent.

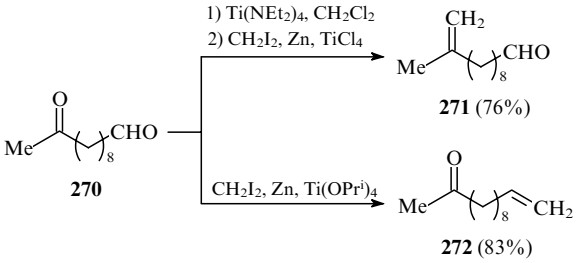


(85%)



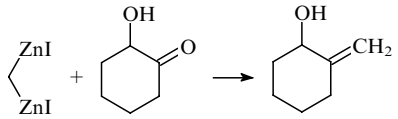
(92%)

It should be noted that the presence of ester or lactone fragments does not prevent methylenation of carbonyl groups.[190] Selective methylenation of the aldehyde group in the presence of the keto group and *vice versa* is a salient advantage of the Oshima – Lombardo reaction.[191] Thus the methylenation of a keto group, which does not affect an aldehyde group, can be performed following treatment of the substrate with tetrakis(diethylamino)titanium (this results in selective protection of the aldehyde group due to complex formation). The chemoselective methylenation of an aldehyde in the presence of a ketone is carried out using titanium isopropoxide or trimethylaluminium. This approach was demonstrated in a spectacular way in the selective methylenation of either keto or aldehyde groups of the keto aldehyde **270** to give isomeric oxo alkenes **271** and **272**, respectively.



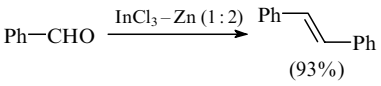
270 **271** (76%) **272** (83%)

The *gem*-organodizinc reagent **269** (Hal = I) was used in the synthesis of substituted allylic alcohols and amines from α-hydroxy and α-amino ketones.[192] Presumably, in this case coordination of the heteroatom to zinc takes place, which favours the methylenation reaction. The methylenation of substrates containing no such substituents in the α-position requires the presence of titanium salts.



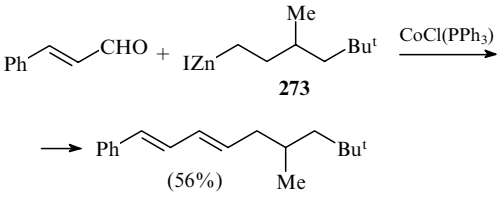
269 (90%)

Reductive coupling of carbonyl compounds in the presence of the system $InCl_3$ – Zn yields symmetrical alkenes; this reaction occurs stereospecifically and yields *E*-isomers.[193] Aromatic and aliphatic aldehydes and ketones are used as substrates. This process is similar to the McMurry reaction (see Section IV.3.a).



(93%)

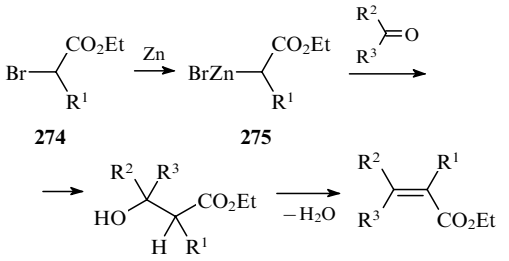
The organozinc compound **73** was used in the stereoselective olefination of aromatic and unsaturated aldehydes. In the presence of a cobalt(I) complex, the reaction occurs under mild conditions and yields *E*-isomers of alkenes.[194]



273

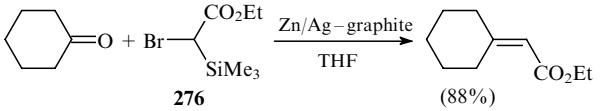
(56%)

The Reformatsky reaction represents the reaction of carbonyl compounds with α-halo-substituted esters **274** or their vinilogues $RCHHalCH=CHCO_2Et$ in the presence of zinc.[195] Its first step includes insertion of zinc into the C—Hal bond and formation of the organozinc intermediate **275** (the Reformatsky reagent), which represents zinc enolate. The intermediate organozinc compound is not isolated. β-Hydroxy esters are usually formed from aliphatic carbonyl compounds, which can easily be dehydrated into α,β-unsaturated esters. In the case of aromatic aldehydes and ketones, dehydration usually takes place directly in the reaction mixture.



274 **275**

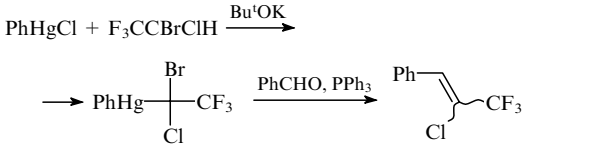
A mixed-type version of the Reformatsky and Peterson reactions based on the use of (halogeno)trimethylsilylacetate **276** is known.[196] The use of this reagent allows direct preparation of alkenes avoiding β-hydroxy derivatives.



276 (88%)

b. Mercury-based reagents

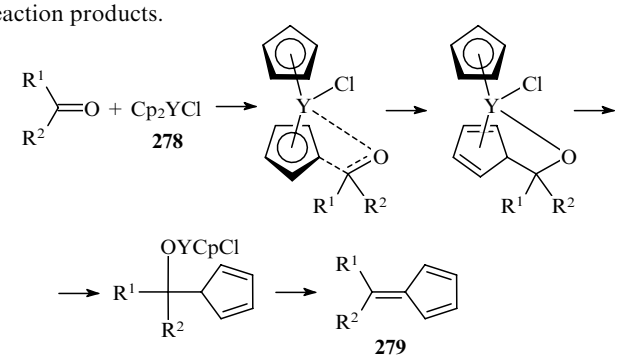
A multistep synthesis of trifluoromethyl-substituted alkenes **268** using organomercurials as CF_3-group sources has been developed.[197] The organomercuric compound **277** prepared by treatment of phenylmercury chloride with halothane $CF_3CBrClH$ in the presence of potassium *tert*-butoxide served as the olefinating agent. Treatment of benzaldehyde with the reagent **277** in the presence of triphenylphosphine yields a mixture of *E*- and *Z*-isomers of the trifluoromethyl-substituted alkene **268** in an equimolar ratio. Low yields and high toxicities of the mercury compounds make this method inconvenient for application in synthetic practice.



277 **268** (38%, $E:Z = 1:1$)

2. Reagents based on Group IIIB metals

The use of dicyclopentadienylyttrium chloride **278** as the olefinating agent yields fulvenes **279**.[198] Thus the reagent **278** acts as a synthetic equivalent of the cyclopentadienyl anion. The first step includes coordination of yttrium to the oxygen atom of the carbonyl group. Subsequent addition of cyclopentadienyl to the carbon atom and elimination of yttrium oxide give fulvenes **279**. Both aldehydes and ketones give high yields (57% – 96%) of reaction products.



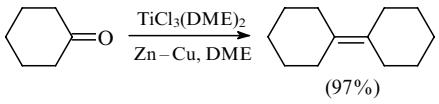
278 **279**

Cp is cyclopentadienyl.

3. Reagents based on Group IVB metals

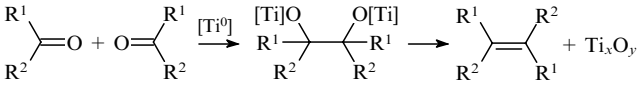
a. The McMurry reaction

The McMurry reaction is the olefination of carbonyl compounds in the presence of low-valence titanium derivatives yielding various alkenes.[1] The formation of very strong Ti—O bonds is the driving force of this reaction. This reaction consists of reductive dimerisation of carbonyl compounds and gives symmetrical alkenes. The mechanism of the McMurry reaction and its synthetic applications have become the subject of intense studies which have been reviewed.[30–35] Both aldehydes and ketones are employed. Dimerisation of aromatic aldehydes is used for the synthesis of substituted stilbenes.[6]



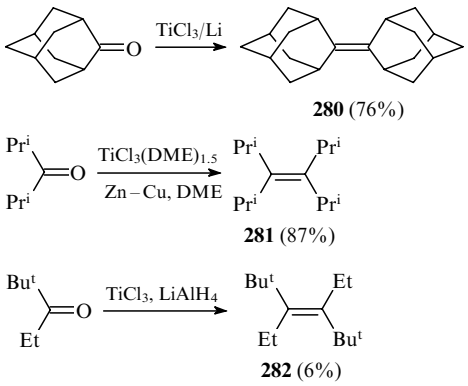
DME is 1,2-dimethoxyethane.

Various titanium derivatives playing the role of reducing agents can be prepared by *in situ* reduction of $TiCl_4$ or $TiCl_3$ with zinc, a zinc–copper alloy, lithium aluminium hydride and alkali metals. It is believed that zero-valent titanium is formed under these conditions. The first step of the McMurry reaction actually represents pinacol condensation; however, the *vic*-diols formed undergo further reduction to alkenes.

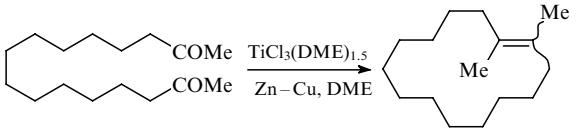


Functional groups, such as nitrile, amide, ester, *p*-toluenesulfonyl, *etc*., are not affected under the conditions of the McMurry reaction.[30] An epoxide or a *vic*-diol fragment present in the substrate is reduced to the alkene. Nitro groups, oximes and sulfoxides do not withstand the reaction conditions and are reduced.[30]

Reductive dimerisation according to McMurry was used for the preparation of a series of crowded alkenes containing bulky substituents, *e.g.,* adamantylideneadamantane (**280**),[30] tetraisopropylethylene (**281**)[199] and even di-*tert*-butyldiethylethylene (**282**).[200] Unfortunately, tetra-*tert*-butylethylene could not be prepared by this method.[30]

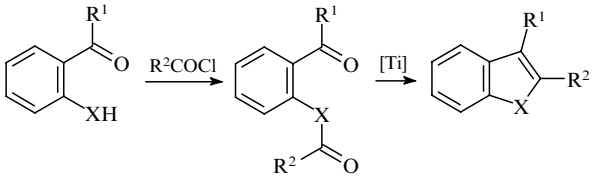


Reductive dimerisation of dicarbonyl compounds is a convenient method for the synthesis of cyclic alkenes with ring size varying from 3 to 36.[201] The synthesis of medium and large rings from dicarbonyl derivatives is carried out under high dilution; the ring closure proceeds in high yields and is highly stereoselective. Medium and large rings are usually formed with *E* configuration of the double bond.[199] Thus the endocyclic alkene **283** was prepared by the McMurry reaction.



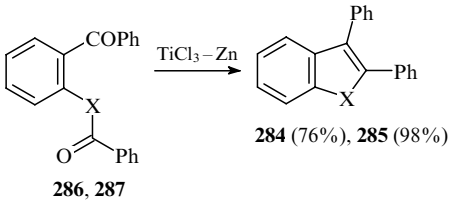
283 (82%, $E:Z = 92:8$)

It is unreasonable to prepare non-symmetrical alkenes by the McMurry reaction, since dimerisation of two carbonyl compounds gives all three possible alkenes. However, intramolecular coupling of substrates containing non-equivalent carbonyl groups represents a smooth access to non-symmetrical cycloalkenes. Thus the cyclisation of *o*-acylamino- or acyloxy-substituted benzophenones yields various indole and benzofuran derivatives.[202]



X = O, NH, NAlk; R^1 = Alk, Ar; R^2 = H, Alk, Ar, OAlk, $NAlk_2$.

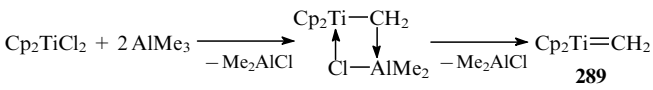
The use of the McMurry reaction in the synthesis of substituted furans **284** and indoles **285** from compounds **286** and **287** has been described by Furstner *et al*.[203, 204]

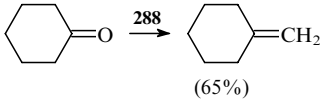


X = O (**284**, **286**); NH (**285**, **287**).

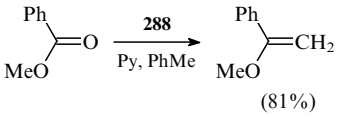
b. The Tebbe reaction

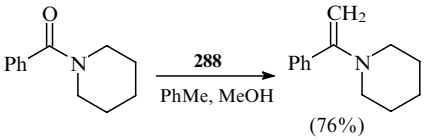
In 1978, Tebbe *et al*.[205] proposed to use metallacyclobutane **288** as a C_1-synthon, which became a popular reagent for olefination of carbonyl compounds. The Tebbe reagent is prepared *in situ* by the addition of commercially available titanocene dichloride to trimethylaluminium in toluene.[206] Under olefination conditions, the reagent **288** is converted into a highly reactive methylene-titanocene complex **289**. Donor ligands (*e.g*., THF or pyridine) are beneficial for the reaction, they favour elimination of the Lewis acid (Me_2AlCl) from the ring.[207]





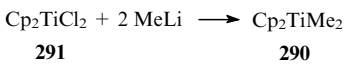
Carboxylic acid derivatives, *viz*., esters[208] and amides,[209] can be used as carbonyl components along with aldehydes and ketones. Thus, vinyl ethers and enamines can be obtained by the Tebbe reaction.

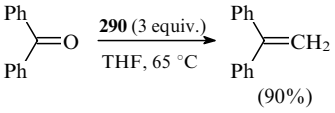


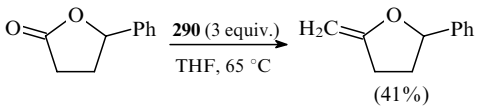


c. Dialkyltitanocenes

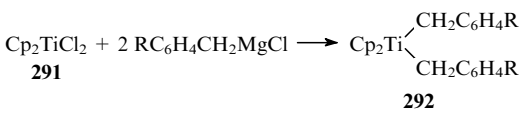
In 1990, Petasis and Bzowej[210] developed a new methylenating agent, *viz*., dimethyltitanocene Cp_2TiMe_2 (**290**), as an alternative to the Tebbe reagent. The advantages of this reagent include its stability and availability; besides, it does not contain aluminium. The Petasis reagent is prepared by mixing titanocene dichloride **291** with methyllithium. The area of its synthetic applications practically coincides with that of the Tebbe reagent.[211]





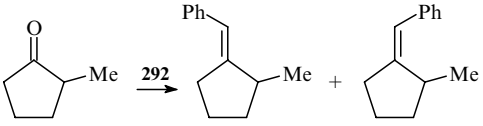


Several more olefinating agents have been developed based on titanocene dichloride **291**.[212,213] Thus the reactions of complex **291** with substituted benzylmagnesium chlorides yield dibenzyltitanocenes **292**.



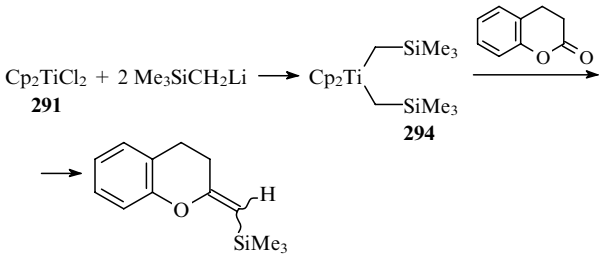
R = H, F, Cl, OMe.

The reactions of carbonyl compounds with the reagent **292** (R = H) yield aryl-substituted alkenes **293**.[212] Low stereoselectivity of this reaction is its main disadvantage.



293 (75%, $E:Z$ = 1 : 1)

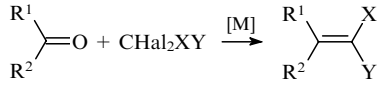
The reactions of a silicon-containing reagent **294** prepared from titanocene dichloride **291** with carbonyl compounds and carboxylic acid derivatives yield vinylsilanes **295**.[213,214]



295 (83%, $Z:E$ = 2.5 : 1)

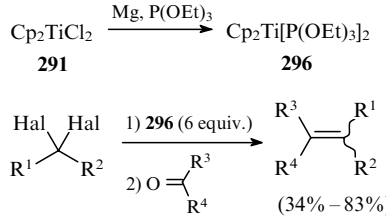
d. Miscellaneous titanium-based reagents

Reductive coupling of polyhalogeno compounds $CHal_2XY$ (Hal, X, Y = Cl, Br) with aldehydes and ketones is widely used in the synthesis of various substituted alkenes.



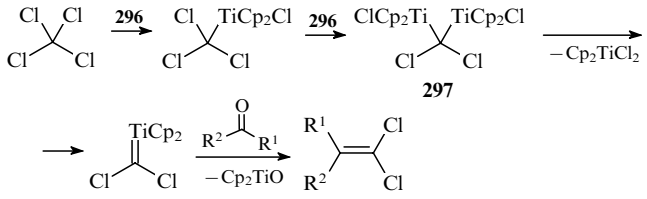
[M] is a reducing metal derivative in lower oxidation states.

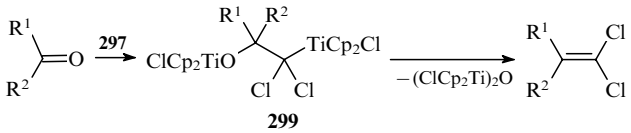
Thus the olefination of aromatic and aliphatic aldehydes and ketones by *gem*-dihalo compounds has been described.[215–217] The titanium derivative **296** prepared *in situ* by reduction of titanocene dichloride **291** with magnesium in the presence of triethyl phosphite was used as the reducing agent.



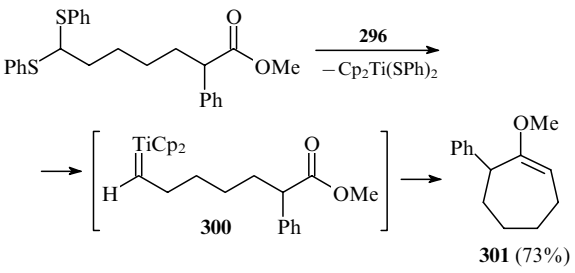
R^1, R^2 = H, Alk, Hal; Hal = Cl, Br; R^3 = Alk; R^4 = H, Alk, OAlk.

Aliphatic and aromatic aldehydes and ketones as well as esters and lactones can be used as carbonyl components. This is an undisputable advantage of the reaction, since it allows one to synthesise acyclic and cyclic vinyl ethers with different types of substitution at the double bond. Dichloro- and dibromoalkanes as well as chloroform and carbon tetrachloride are used as polyhaloalkane components. As a rule, the reaction proceeds stereoselectively and results in the predominant formation of a less sterically hindered alkene isomer. The reaction mechanism includes consecutive insertion of two molecules of the titanium derivative **296** into the C–Hal bond of the polyhaloalkane resulting in the intermediate **297**. Elimination of the Cp_2TiCl_2 molecule affords the titanium-carbene complex **298** which reacts with the carbonyl compound to give a dichloroalkene. The synthesis of dichloroalkenes can proceed in a different route, namely, *via* intermediate complexes of the type **299** prepared by addition of the organotitanium compound **297** to the carbonyl group. The necessity of using six equivalents of the reducing agent (compound **296**) is a serious disadvantage of this method.



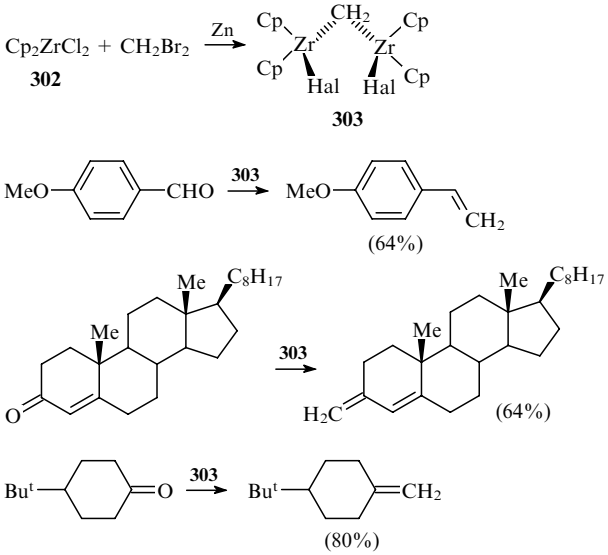


The use of the system dithioacetal – $Cp_2Ti[P(OEt)_3]_2$ (**296**) for olefination allows the transformation of carbonyl compounds into alkenes.[218,219] As in the case of polyhaloalkanes, the titanium-carbene complex is the key intermediate in this reaction. Intramolecular cyclisation of the titanium-carbene complex **300**, which contains simultaneously a dithioacetal fragment and an ester group, resulting in the cyclic vinyl ether **301**, is an example of such a reaction.[218]

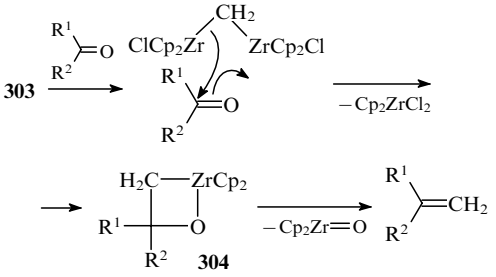


d. Zirconium-based reagents

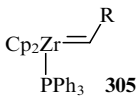
The reaction of zirconocene dichloride **302** with dibromomethane in the presence of zinc yields a methylene-zirconium complex **303**, which was used as a methylenating agent in the synthesis of terminal alkenes.[220] Aliphatic, aromatic and α,β-unsaturated aldehydes and ketones were used as the carbonyl components.



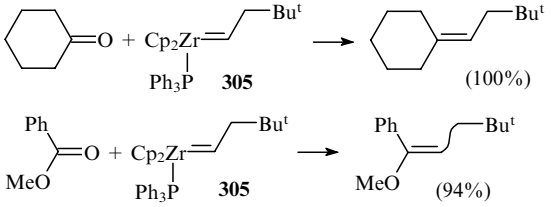
The hypothetical mechanism of this reaction includes coordination of the zirconium atom to the carbonyl oxygen atom and an attack of the nucleophilic carbon atom on the carbon atom of the carbonyl group. This reaction yields metallaoxacyclobutane **304**; subsequent rapid elimination of zirconocene oxide gives the target alkenes.[220]



Alkylidenezirconium complexes **305** were used as olefinating agents for the introduction of longer-chain carbon fragments.[221,222] In contrast to the methylene complex **303**, these can be used in the synthesis of alkenes not only from ketones, but also from esters, lactones [222] and imidates.[223]

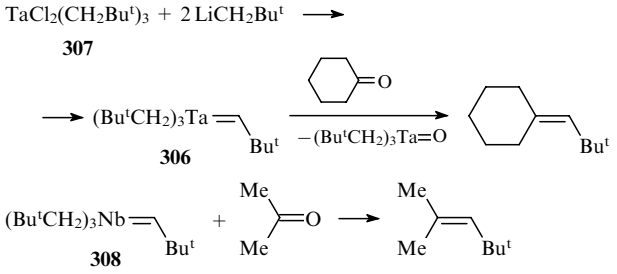


R = Bu^n, Bu^s, CH_2Bu^t, cyclo-C_5H_{11}.



4. Reagents based on Group VB metals

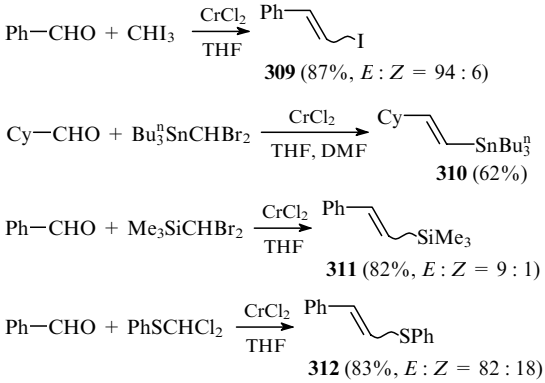
Alkylidene complexes of nyobium and tantalum (the Schrock carbenes) manifest nucleophilic properties.[223,224] It was shown that the neopentylidenetantalum complex **306** formed upon reduction of compound **307** with neopentyllithium can be used for the introduction of the neopentylidene group into a broad range of carbonyl compounds.[225] Aldehydes, ketones, amides and esters were used as the carbonyl components of this reaction. The yields of alkenes varied from 35% to 90%. The neopentylideneniobium complex **308** manifests similar reactivity.



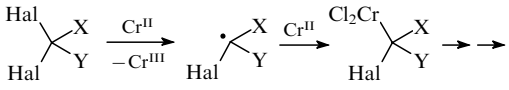
5. Reagents based on Group VIB metals

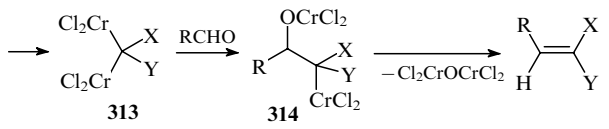
a. Chromium-based reagents

Reductive coupling of *gem*-dihalo compounds $CHal_2XY$ with aldehydes in the presence of chromium(II) chloride as the reducing agent is widely used in the synthesis of various alkenes.[1] It was found that reactions of such dihaloalkanes with aldehydes are stereoselective and give predominantly *E*-isomers of alkenes. Various substituted dihaloalkanes including those containing heteroatoms can be used as the olefinating components. This yields vinyl halides **309**,[226] vinylstannanes **310**,[227] vinylsilanes **311** and vinyl sulfides **312**.[228]



The mechanism of this reaction consists of substitution of chromium for two halogen atoms resulting in *gem*-organodichromium compounds **313**, which further add to the aldehyde. Subsequent elimination of a chromium(III) salt from the intermediate **314** yields alkenes.[1,226,229]





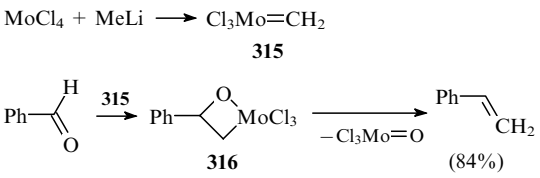
313 314

Hal = Cl, Br, I; X, Y = H, Alk, Hal, SR, $SnAlk_3$, $SiAlk_3$; R = Alk, Ar.

High yields and high stereoselectivity are indisputable advantages of this method. The disadvantages include the necessity of using six equivalents of the reducing agent and conducting the reaction in an inert atmosphere in dry solvents. The use of this method for the olefination of ketones has not been reported so far.

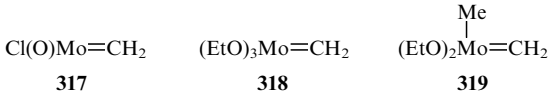
b. Molybdenum-based reagents

The methylene-molybdenum complex $Cl_3Mo{=}CH_2$ (**315**) prepared by treatment of molybdenum(V) chloride with methyllithium is a very mild methylenating agent. This reacts with aldehydes and ketones to give terminal alkenes in good yields.[230]



315 316 (84%)

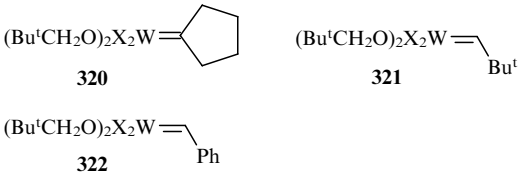
Presumably,[230] this methylenation occurs *via* metallacyclobutane **316**. A family of methylenating agents **317**–**319** based on molybdenum have been synthesised. Reagents **315** and **317** have proved to be the most reactive.



317 **318** **319**

c.Tungsten-based reagents

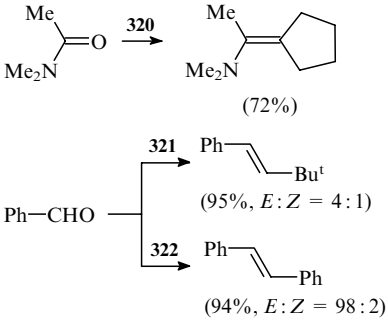
The tungsten-carbene complexes **320**–**322** are convenient reagents for the synthesis of sterically hindered (including exocyclic) alkenes.[231]



320 **321** **322**

X = OCH_2Bu^t, Cl, Br, I.

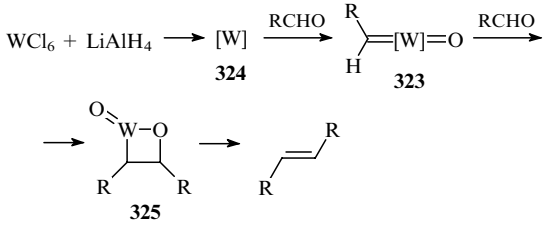
The role of a carbonyl component can be played by aromatic and aliphatic aldehydes, ketones, lactones and amides. The reaction is carried out using stoichiometric amounts of tungsten-carbene complexes. The yields are good in all cases.



(72%) (95%, *E*:*Z* = 4:1) (94%, *E*:*Z* = 98:2)

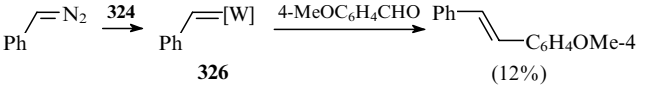
Reductive dimerisation of aromatic aldehydes and ketones, which gives good yields of symmetrical alkenes, is carried out in the presence of low-valence tungsten derivatives (the so-called 'tungsten' version of the McMurry reaction)[232] prepared *in situ* by treatment of WCl_6 with butyllithium.

It was recommended[233] to perform the coupling of aldehydes and ketones with a reagent formed upon reduction of WCl_6 with lithium aluminium hydride (its structure is not reported by the authors) as a reducing agent. Coupling was shown to occur in moderate yields with both aliphatic and aromatic substrates. Studies of the reaction mechanism suggest that the tungsten-carbene complex **323** formed as a result of insertion of the reagent **324** (marked as [W] in the scheme) into the carbonyl group is involved in the formation of alkenes. Subsequent addition of the second aldehyde molecule to the complex **323** and fragmentation of the metallacyclobutane intermediate **325** results in alkenes.



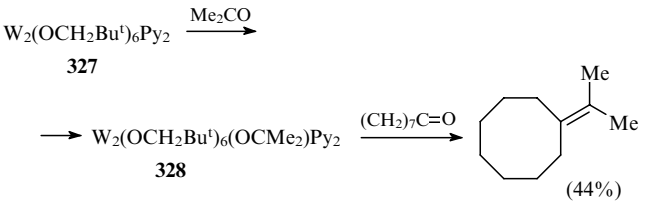
324 **323** **325**

The reaction of anisaldehyde with phenyldiazomethane in the presence of the reagent **324** gives *p*-methoxystilbene in low yield. In this case, the role of the olefinating agent is played by the diazo compound, while the tungsten-carbene complex **326** is a putative intermediate.[233]



326 (12%)

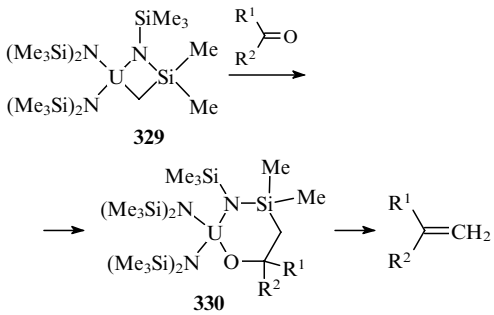
The binuclear tungsten complex $W_2(OCH_2Bu^t)_6Py_2$ (**327**) was proposed for cross-coupling of two different carbonyl compounds.[234] Its reaction with acetone yields the complex $W_2(OCH_2Bu^t)_6(OCMe_2)Py_2$ (**328**). Subsequent treatment of aldehydes and ketones with the reagent **328** converts the carbonyl group into the isopropylidene group, *i.e.*, affords reductive cross-dimerisation products.



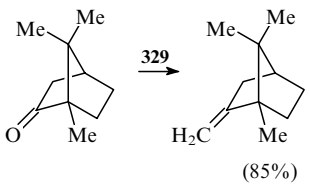
327 **328** (44%)

6. Uranium-based reagents

The metallacycle **329** based on uranium was proposed as a mild methylenating agent for cyclic and sterically hindered ketones as the carbonyl components.[235] It was shown that the olefination proceeds *via* intermediate six-membered metallacycles of the type **330**. High sensitivity of these complexes to moisture and air is a disadvantage.



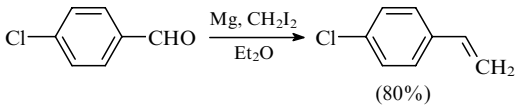
329 **330**



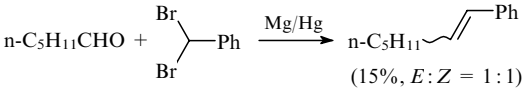
7. Reagents based on non-transition metals

Reductive coupling of carbonyl compounds with dihaloalkanes in the presence of non-transition reducing metals is also used in the synthesis. Presumably, the reactions of reducing metals with *gem*-dihaloalkanes afford *gem*-organodimetallic derivatives CH_2M_2, which yield the corresponding terminal alkenes in reactions with aldehydes and ketones.[39]

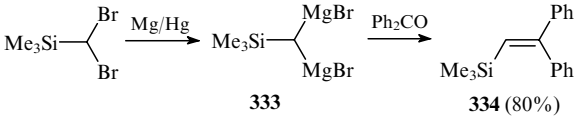
Dibromomethane and diiodomethane react with magnesium or magnesium amalgam to give *gem*-organodimagnesium compounds $CH_2(MgBr)_2$ (**331**) and $CH_2(MgI)_2$ (**332**). The latter proved to be convenient methylenating agents in the transformations of diverse carbonyl compounds into alkenes. These reactions usually give the products in high yields.[236]



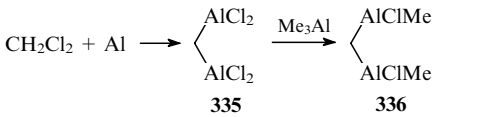
If benzylidene bromide $PhCHBr_2$ is used as the olefinating agent, the yield of the alkene is low. Therefore, this method can be used only for the incorporation of a methylene fragment.[236]

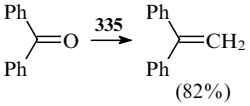


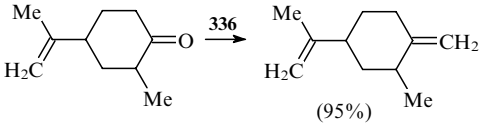
gem-Organodimagnesium compound **333** containing a trimethylsilyl group was successfully used in the synthesis of 1,1-diphenyl-2-trimethylsilylethylene **334** from benzophenone.[237] However, the yield of the expected reaction product with cyclohexanone was only 13%.



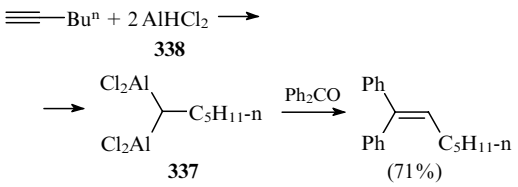
A method for the synthesis of terminal alkenes from ketones (including easily enolisable ones) using a family of *gem*-organodialuminium reagents of the type **335** and **336** has been developed.[238] The reagent **335** was prepared by boiling aluminum powder in dichloromethane in the presence of catalytic amounts of CH_2Br_2 as a primer.







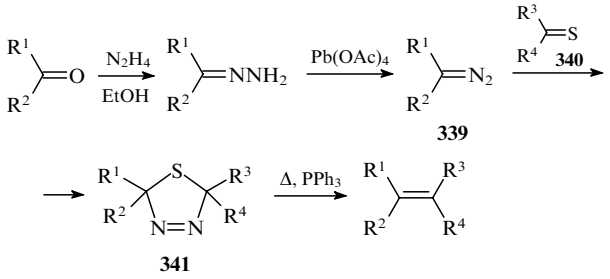
1,1-Bis(dichloroaluminio)hexane (**337**) prepared by the addition of two molecules of dichloroalane **338** to hex-1-yne was used in the synthesis of non-terminal alkenes from aromatic ketones.[39, 238]



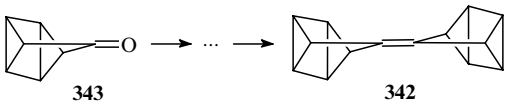
V. Miscellaneous olefination methods

1. The Barton – Kellogg reaction

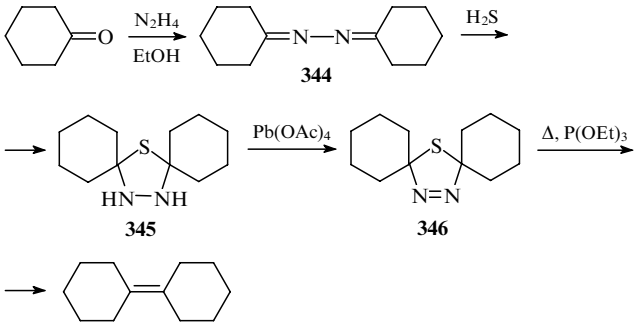
The Barton – Kellogg olefination represents the condensation of diazo compounds **339** with carbonyl derivatives **340** resulting in thiadiazolines **341**. Subsequent heating of the latter in the presence of triphenylphosphine yields alkenes.[239] The Barton – Kellogg reaction can be regarded as a reductive coupling of two different carbonyl compounds, since diazo compounds **339** are usually prepared by oxidation of hydrazones.



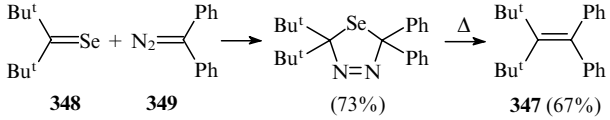
The Barton – Kellogg reaction was employed in the synthesis of sterically hindered alkenes. Thus bi(quadricyclylidene) **342** was prepared from the ketone **343** using this reaction sequence.[7]



A version of the Barton – Kellogg reaction is known where the carbonyl compound is converted into a symmetrical azine **344**.[240, 241] Subsequent cyclisation upon treatment with hydrogen sulfide yields thiadiazolidine **345**; the latter is further oxidised to thiadiazoline **346** with lead tetraacetate. Thermolysis of compound **346** with simultaneous desulfurisation with triethyl phosphite yields a symmetrical alkene.

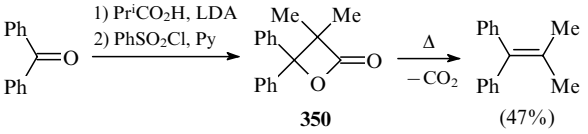


A procedure based on the use of selenocarbonyl compounds was effective in the synthesis of sterically hindered alkenes.[7, 24] Thus 2,2-di-*tert*-butyl-1,1-diphenylethylene (**347**) was prepared from di-*tert*-butylselone **348** and diphenyldiazomethane **349**.[24]



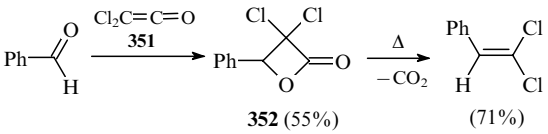
2. Thermal splitting of β-lactones

Thermal splitting of β-lactones **350** is a convenient method for the preparation of alkenes containing alkyl and aryl substituents at the double bond.[242] The corresponding lactones are formed by cyclisation of β-hydroxy acids under the action of benzenesulfonyl chloride in the presence of pyridine, while β-hydroxy acids are, in turn, prepared either by the condensation of dilithium derivatives of carboxylic acids with aldehydes and ketones or by the Reformatsky reaction. Thermolysis of β-lactones at 140–160 °C gives the corresponding alkenes in yields varying from moderate to quantitative.



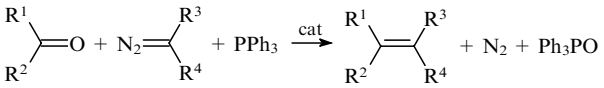
Sometimes, the formation of alkenes from β-hydroxy acids may take place *in situ* even in the step of lactone formation. It was found that the cyclisation of β-hydroxy acids in the presence of pyridine on gentle heating (45–55 °C) is accompanied by simultaneous decarboxylation of lactones, which yields almost exclusively *E*-stereoisomers of alkenes. Since the cyclisation of β-hydroxy acids results in the formation of the least sterically hindered lactones, *cis*-elimination of carbon dioxide yields the least hindered alkenes.

A two-step procedure for the synthesis of dichlorostyrenes from the corresponding aldehydes has been proposed.[243] The first step includes the [2 + 2]-cycloaddition of dichloroketene **351** to an aldehyde. The lactone **352** undergoes thermal decarboxylation to give the corresponding dichlorostyrene. The yields in the first step are 29%–83%, those in the second step are 23%–86%. In the case of aldehydes containing electron-withdrawing substituents, the yields are higher than from aldehydes containing donor groups.



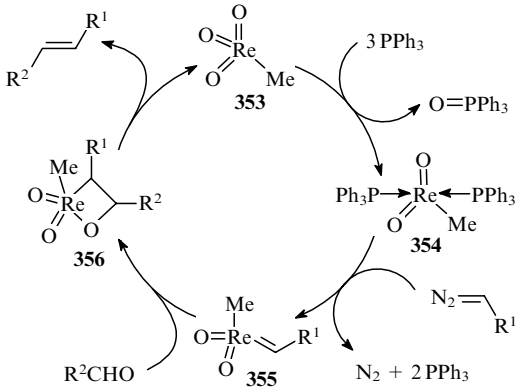
3. Olefination of carbonyl compounds by diazoalkanes in the presence of metal-complex catalysts

A method for the olefination of carbonyl compounds by stable diazoalkanes in the presence of stoichiometric amounts of triphenylphosphine catalysed by metal complexes based on rhenium,[244–251] ruthenium,[252,253] rhodium,[253] iron,[254–258] cobalt [259] and molybdenum,[260] has been developed.

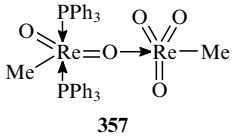


This reaction, which is analogous to the Wittig reaction, does not require strong bases for the synthesis of phosphorus ylides.[253] In the majority of cases, ylides are synthesised from stable diazoalkanes containing an electron-withdrawing group, although trimethylsilyldiazomethane was also employed.[253] The necessity to use stable diazocompounds and stoichiometric amounts of triphenylphosphine in this reaction poses certain restrictions on its synthetic application.

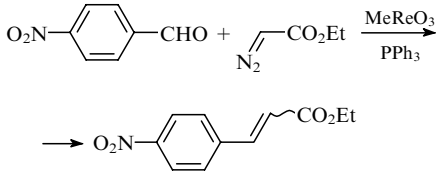
This version of olefination widely employs rhenium catalysts, *e.g.*, methyltrioxorhenium (**353**).[244,245] The olefination of carbonyl compounds upon treatment with ethyl diazoacetate or ethyl diazomalonate in the presence of equimolar amounts of triphenylphosphine and catalytic amounts of $MeReO_3$ has been described.[245] In the absence of the catalyst, no olefination occurs; the diazo compound reacts with the aldehyde to give a nonsymmetrical azine. It has been shown [246] that the rhenium(V) derivative **354** formed upon reduction of methyltrioxorhenium with triphenylphosphine plays the role of a true catalyst. Presumably, this reaction proceeds *via* the rhenium-carbene complex **355** as a key intermediate.[245,246] Subsequent [2 + 2]-cycloaddition of the carbonyl group to the carbene complex **355** results in metallacyclobutane **356**, the fragmentation of the latter yields an alkene.



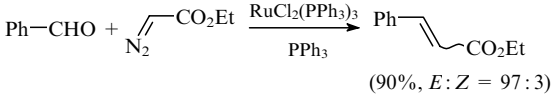
A binuclear rhenium(VII)–rhenium(V) complex **357** formed in the reaction of methyltrioxorhenium with triphenylphosphine [246] and an η^2-alkyne methyldioxorhenium complex [248] can be used as catalysts.



This method was used in the synthesis of α,β-unsaturated acid esters starting from aliphatic, aromatic and α,β-unsaturated aldehydes and cyclic ketones as the carbonyl components. *E*-Isomers of alkenes are formed in this reaction in high yields (80%–97%). In the case of aromatic aldehydes, the presence of electron-withdrawing substituents in the *para*-position relative to the carbonyl group favours the reaction.

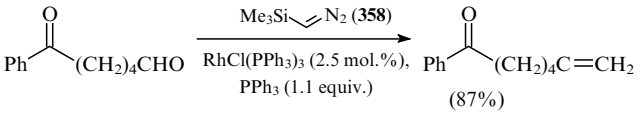


The ruthenium complex $RuCl_2(PPh_3)_3$ is yet another convenient catalyst for the olefination of aldehydes with ethyl diazoacetate in the presence of triphenylphosphine.[252] The mechanism of this reaction is not specified, but the formation of a ruthenium–carbene complex is conjectured. The stereoselectivity of this reaction is high both in the case of aliphatic and aromatic substrates; the ratio of *E*- and *Z*-isomers of α,β-unsaturated esters is no less than 9 : 1.

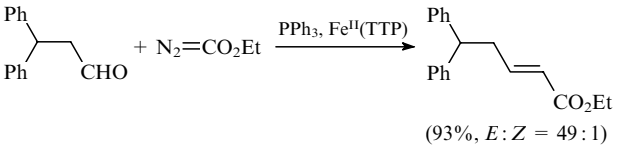


Trimethylsilyldiazomethane (**358**), in the presence of equimolar amounts of triphenylphosphine, was proposed for the methylation of aldehydes.[253] The choice of an optimum catalyst for this reaction, *viz.*, the Wilkinson catalyst $RhCl(PPh_3)_3$, was made based on the results of studies of catalytic activities of several rhodium and ruthenium complexes. This method proved to be suitable for the synthesis of terminal alkenes from various aldehydes. Functional or protective groups do not interfere with

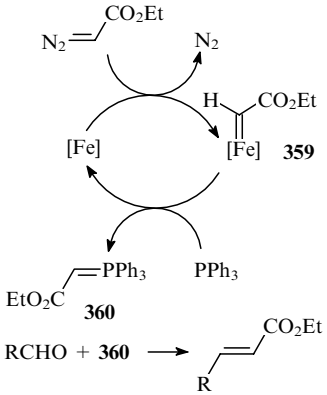
this reaction. It is of note that the keto group of the substrate is not involved in the reaction. The yields of the alkenes are 60% – 98%.



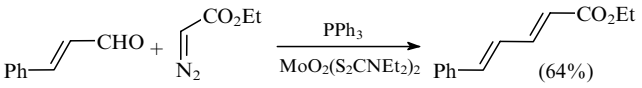
The olefination of aldehydes with ethyl diazoacetate in the presence of an iron(II) complex with tetra(*p*-tolyl)porphyrin [Fe^{II}(TTP)] proceeds with very high *trans*-stereoselectivity and in nearly quantitative yields.[254]



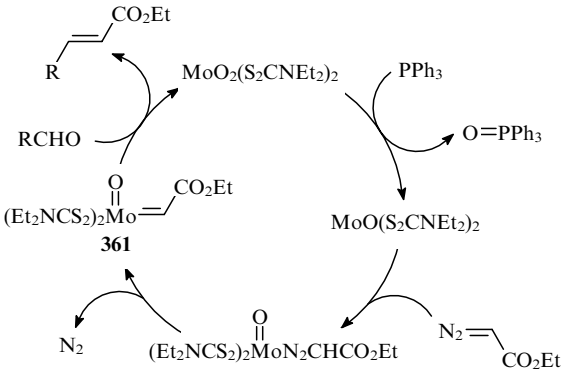
Presumably,[254] the mechanism of this reaction includes the formation of the iron carbene complex **359**, which is further involved in the transfer of carbene to triphenyl phosphine resulting in the ylide **360**. The olefination step itself is not included in the catalytic cycle.



A similar olefination reaction is catalysed by the molybdenum complex $MoO_2(S_2CNEt_2)_2$.[260] This reaction proceeds with high stereoselectivity, but the yields of the corresponding alkenes are lower than in the catalysis by other metals. Aromatic, aliphatic and α,β-unsaturated aldehydes were used as the carbonyl components.

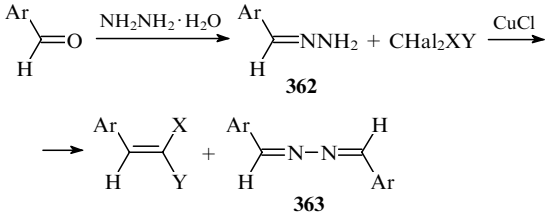


The reaction mechanism involves the formation of the molybdenum-carbene complex **361** which plays the role of the olefinating agent.



4. Catalytic olefination of hydrazones

A new, in principle, reaction of the catalytic olefination of hydrazones of carbonyl compounds was discovered in 1999.[261] It was found that the reaction of *N*-unsubstituted hydrazones of aromatic aldehydes **362** with *gem*-dihalo compounds $CHal_2XY$ in the presence of catalytic amounts of copper(I) chloride yields substituted alkenes. Symmetrical azines of the carbonyl derivatives **363** are formed as side products of transformations of hydrazones; this reaction is accompanied by evolution of nitrogen. Thus, a new double carbon – carbon bond is formed in this reaction.

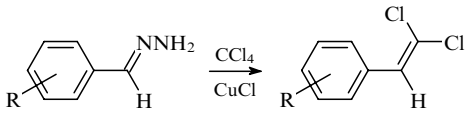


Ar = 4-$NO_2C_6H_4$, 4-ClC_6H_4, 4-$MeOC_6H_4$; Hal, X, Y = F, Cl, Br, I.

Since hydrazones are readily available, this reaction can be used as a simple two-step procedure for the synthesis of alkenes from carbonyl compounds.

In addition to copper salts, the oxidation of hydrazones with tetrachloromethane is catalysed by salts of other transition metals, such as silver, lanthanum, titanium, manganese, cobalt, rhodium, palladium and platinum. However, the highest yields of alkenes are obtained in the presence of CuCl.

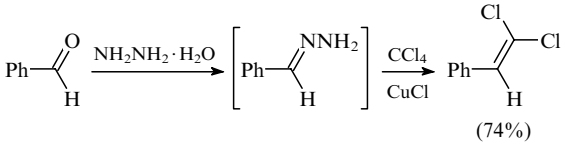
This reaction served as the basis for the development of novel methods for the synthesis of various substituted alkenes. Thus the use of CCl_4 as the olefinating agent allows one to synthesise the corresponding dichloroalkenes.[262]



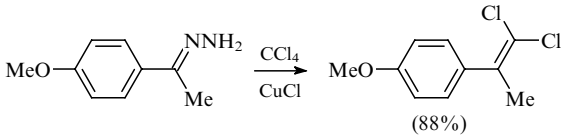
R = H (27%); 4-Cl (82%)

Substrates containing electron-withdrawing substituents in the aromatic nucleus (*e.g.*, chlorine, bromine, nitro and cyano groups) are converted into β,β-dichlorostyrenes in high yields. If hydrazones containing donor substituents or benzaldehyde hydrazone are used, the yields of dichloroalkenes are low. Low stabilities of the corresponding hydrazones are the main reason for the low yields of dichlorostyrenes in these cases.

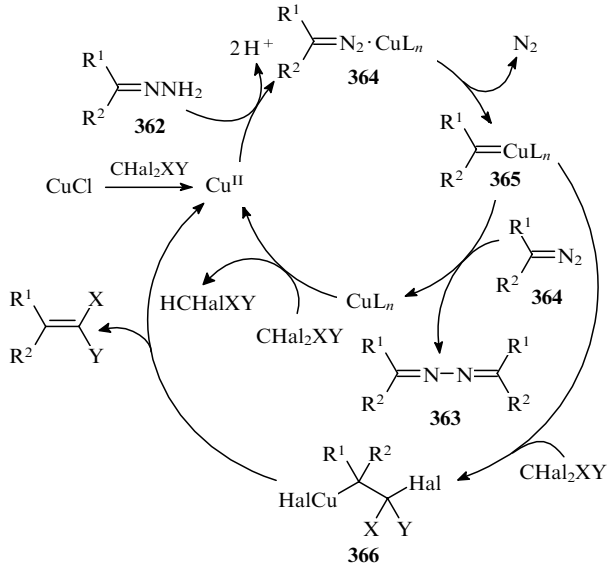
A simplified procedure for the one-pot synthesis of dichloroalkenes directly from aldehydes, which obviates the preparation and isolation of hydrazones, has been developed.[263] Besides, in the case of donor substrates the yields of dichloroalkenes are significantly higher.



The area of synthetic applications of the catalytic olefination reaction is not confined to hydrazones of aromatic aldehydes; alkyl aryl ketone hydrazones can be converted into tetrasubstituted alkenes in good yields.[264]

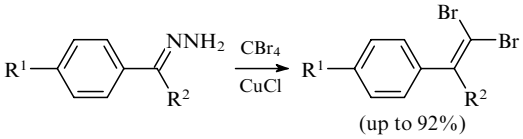


A mechanism of this reaction, which describes its catalytic cycle, has been proposed.[265–267] The first step includes oxidation of hydrazones **362** to the corresponding diazoalkanes **364** with copper(II) formed upon oxidation of CuCl with polyhaloalkanes. The diazo compounds **364** undergo further copper-catalysed fragmentation to give the copper-carbene complex **365**, the key intermediate of the olefination reaction. Further transformations of the complex **365** can proceed in two different routes. The reaction with polyhaloalkanes gives alkenes and is accompanied by regeneration of the catalyst (Cu^{II}) (the outer cycle). This reaction proceeds through oxidative addition of copper across the C—Hal bond and formation of the organocopper intermedate **366**. The side reaction, *i.e.*, the formation of azines **363**, occurs upon reaction of the complex **365** with the second molecule of diazoalkane **364** (the inner cycle).

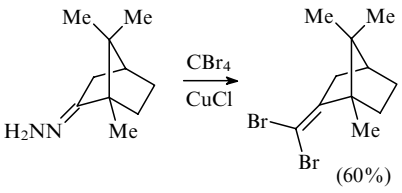


A salient advantage of this reaction is that the preparation of alkenes from carbonyl compounds does not require the use of external reducing agents, since this function is in fact fulfilled by hydrazine.

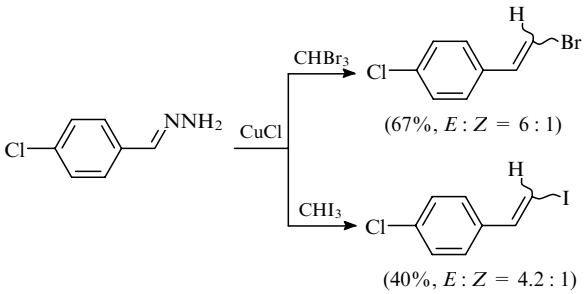
In addition to CCl_4, other polyhaloalkanes can be used as the olefinating agents; by varying the latter, one can obtain various types of alkenes. In particular, with CBr_4 as the olefinating agent, hydrazones of carbonyl compounds are converted into the corresponding dibromoalkenes.[264, 268, 269]



R^1 = H, MeO, Br; R^2 = H, Et.

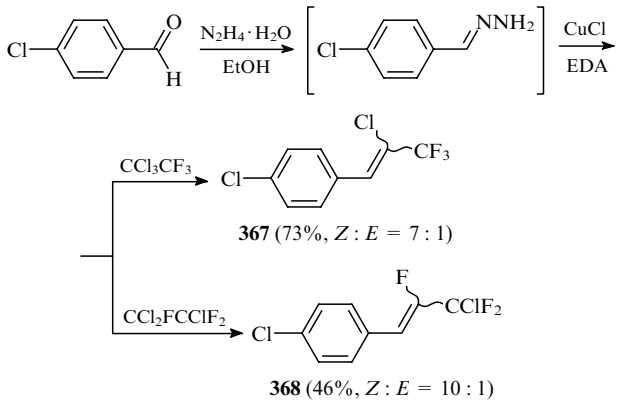


In the case of trihalomethanes (haloforms), the reaction with hydrazones yields monohalogenoalkenes. The reaction of the hydrazones of aromatic aldehydes with $CHBr_3$ leads to β-bromostyrenes stereoselectively (predominantly, *E*-isomers).[270]



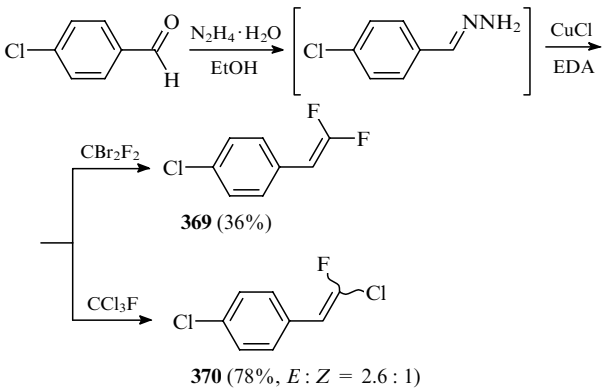
Reactions of hydrazones with iodoform proceed in a similar way. In this case, the corresponding vinyl iodides are formed as the reaction products.[271]

Fluorine-containing alkenes are formed if fluorochloroalkanes (Freons) are used as the olefinating agents. Thus reactions of hydrazones of aromatic aldehydes prepared *in situ* synthesised with Freons CCl_2FCClF_2 and CCl_3CF_3 yield fluoro alkenes **367** and **368**[272] (predominantly, less sterically hindered *Z*-isomers). The stereoselectivity of this reaction is rather high; the ratio of the isomers depends on the nature of the aromatic system and the position of the substituents in the benzene ring. Thus the stereoselectivity of the reaction increases in the case of donor substrates and decreases in the case of substrates containing electron-withdrawing groups.

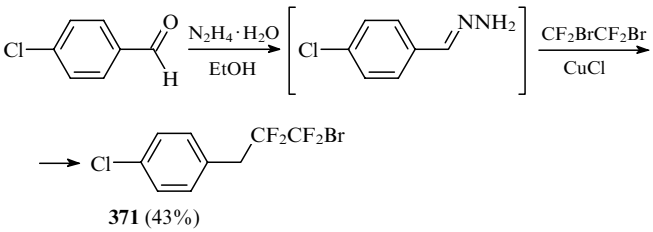


EDA is 1,2-ethylenediamine.

Dibromodifluoromethane and trichlorofluoromethane were used as fluorine-containing C_1-synthons in the catalytic olefination reaction, which afforded the corresponding *gem*-difluorostyrenes **369** (see Ref. 273) and chlorofluorostyrenes **370**.[274]

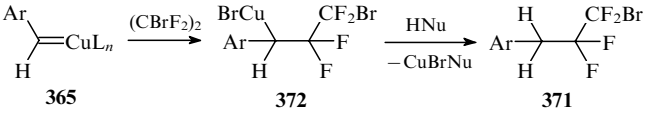


In the case of dibromotetrafluoroethane $CBrF_2CBrF_2$, the corresponding arylbromotetrafluoropropanes **371** (rather than unsaturated compounds) are formed as reaction products.



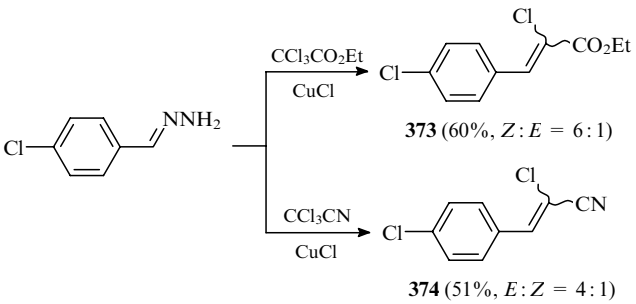
371 (43%)

It was found that in this case the abnormal course of this reaction is due to the high stability of the C–F bond. The reaction of the copper-carbene complex **365** with $CBrF_2CBrF_2$ yields the corresponding organocopper intermediate **372**; elimination of CuBrF from this intermediate is hardly likely and only the saturated compound **371** is formed.



365 **372** **371**

Polyhalogenated reagents, such as CCl_3CO_2Et and CCl_3CN, are used in the synthesis of functionalised unsaturated compounds. Thus the reactions of hydrazones with ethyl trichloroacetate and trichloroacetonitrile give α-chlorocinnamates **373**[275] and α-chlorocinnamonitriles **374**.[276]



373 (60%, $Z:E = 6:1$)

374 (51%, $E:Z = 4:1$)

VI. Conclusion

A survey of the current literature demonstrates that the methods for olefination of carbonyl compounds are quite numerous and differ in the nature of the olefinating agents, reaction conditions, types of carbonyl substrates and, correspondingly, types of unsaturated compounds formed.

It is of note that the correct comparison of efficiencies of various olefination procedures is difficult, since many exotic chemical methods are more captivating than practical and have not received wide application because of their high cost, low availability of the corresponding reagents and certain inertiality of thought inherent in some synthetic chemists. Nevertheless, the present review gives an idea about both the wide arsenal and explosive development of this branch of synthetic organic chemistry.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 03-03-32052a).

Abstract. The published data on oxide materials as positive electrodes for lithium-ion batteries are described systematically. The mechanisms of structural changes in cathode materials occurring during the operation of lithium-ion batteries and the problems concerned with their selection are discussed. Modern trends in optimising cathode materials and lithium-ion batteries on the whole are considered. The bibliography includes 167 references.

I. Introduction

Whittingham[1] seems to be the first to demonstrate, by the example of Li_xTiS_2, that the process of electrochemical intercalation of lithium into the positive electrode structure can be utilised in rechargeable cells with lithium anodes. He described the reversible topotactic reaction of lithium insertion into titanium disulfide matrices in the $0 \leqslant x \leqslant 1$ composition range with a plateau at 2 V (with respect to metallic lithium) and a current density in the range 1 – 10 mA cm^{-2}. In the following several years, he and other authors studied a variety of materials with the aim of using them as positive electrodes in secondary lithium cells, *viz*., sulfides MoS_2 and $NiPS_3$, oxides V_2O_5 and MoO_3,[2] oxyhalide FeOCl,[2,3] oxide V_6O_{13},[4] sulfides $Ti_{1+x}S_2$ and TiS_3,[5] layered oxides MO_2 (M = Ti, V, Mn, Mo, W, Nb, Ru, Ir, Os)[6] and lithium cobaltate Li_xCoO_2.[7] Further development of lithium cells was impeded by the difficulties concerned with practical implementation of the reversible operation of negative electrodes made of metallic lithium and the choice of electrolytes. In the early 1980s, several authors[7–9] suggested to apply the principle of lithium electrochemical intercalation for negative electrodes as well. The substitution of reversible lithium intercalation host compounds for metallic lithium gave rise to a new generation of lithium batteries.

The development of a new kind of lithium battery was announced in 1990 by Sony Energetic Incorporated[10] and in 1991 and by Moli Energy Limited[11] and Bell Communications Research.[12] The basis for this was laid by Japanese scientists[13,14] who had discovered that certain carbon forms are capable of reversible lithium intercalation and can be used as materials for negative electrodes.

In these cells, the positive electrodes represented lithiated cobalt oxide (lithium cobaltate) $LiCoO_2$ (Sony), lithiated nickel oxide (lithium nickelate) (Moli) and lithium – manganese spinel $Li_xMn_2O_4$ (Bellcore). At first, these kinds of batteries were named 'rocking-chair' cells, which reflected their ability to transfer lithium from positive to negative electrode (charge) and back (discharge). At present, the conventional name is lithium-ion battery (LIB).

Commercial production of lithium-ion batteries with $LiCoO_2$ cathodes (voltage range 2.5 – 4.2 V, average voltage 3.6 V) was pioneered by Sony in 1991. The batteries had a high voltage level and the highest energy density (with respect to both mass and volume) among secondary cells of that time. Commercialisation of LIB has given powerful impetus to studies in this field, which included the search for new cathode materials. In the past decade, the number of publications on this subject has run into several thousands.[15] The reason for this lies in the fact that, despite all the merits of lithium cobaltate [high average voltage and high energy density, low self-discharge (the capacity fade in the discharged state at open circuit), simplicity of its industrial synthesis, good cyclability], its drawbacks came to light almost immediately. The latter are, first of all, the high cost and toxicity. Taking into account the volume of sales ($40 bln. per year) and the LIB market structure (cellular phones, video cameras, portable computers), these problems are certainly very serious. Moreover, the capacity of lithium cobaltate, even if having a high theoretical value (274 mA h g^{-1}), in practice does not exceed 150 mA h g^{-1}, because the discharge of Li_xCoO_2 involves a phase transition from its tetragonal form to a monoclinic one at $x \approx 0.5$; hence, stable cycling is possible only in the composition range $0.5 < x < 1$. Although lithium cobaltate is still used as the cathode material in the majority of commercial LIB, attempts to improve this material or find another one, cheaper and less toxic, have never stopped. According to the prognoses made by LIBES (Lithium Battery Energy Storage Technology Research Associa-

tion)[16] and such companies as SAFT,[17] the LIB production will continue to increase; however, the market structure is to change (for instance, according to certain estimates, the cellular phone market, the greatest LIB consumer, is close to saturation) as well as the requirements to LIB. The use of LIB in medicine and space technology (*e.g.*, for satellites) requires much longer service life (at least 15 years in place of the usual 3–5 years of present cells). Their use in military equipment will require not only the increased service life but also the wider rage of operation temperatures (now, it is from −20 to 60 °C) and the possibility of operating at high currents. The use of LIB as reserve power sources of autonomous power-consuming devices (including submarines and planes) and in electrical vehicles and cars with the so-called hybrid power sources (a combination of internal combustion engines with powerful rechargeable batteries) requires both the higher power level and lower costs. The high cost and the capacity fade during operation (the latter should not exceed 20% in 10 years) are the critical parameters in all application fields. All these problems are discussed in numerous publications devoted to materials for positive electrodes of LIB.

In addition to lithium cobaltate, the possible candidates for the cathode materials in LIB with average voltage of 4 V should also involve lithium nickelate $LiNiO_2$ and lithium-manganese spinel $LiMn_2O_4$. An analysis[18] has shown that it is these oxides that have the lithium intercalation potential in the required voltage range. That is why the mentioned compounds and their derivatives were studied most thoroughly. Thus, when analysing the literature data, it is reasonable to consider these three compounds separately while cathode materials based on different compounds united in a special group.

In should be stressed that, in fact, a cathode material represents a composite involving a certain carbon form (as a rule, carbon black) added with the aim of increasing the conductivity together with a binder represented most often by polyvinylidene fluoride. The content of these components in the material, the morphology of the latter, the particle size of the ingredients, and also the methods of cathode manufacturing (chemical method, cold pressing or film formation for polymeric LIB) have a great effect on the electrochemical behaviour of the resulting cathodes; however, these questions deserve special consideration and are beyond the scope of this review.

II. Lithium cobaltate and related materials

Depending on the synthetic method, two forms of $LiCoO_2$ can be obtained. A compound synthesised at high temperatures has a layered structure; that synthesised at low temperatures has the spinel structure. The majority of commercial LIB utilise the high-temperature form of stoichiometric lithium cobaltate, which can be cycled in the voltage range from 2.5 to 4.3 V and the composition range $0.5 < x < 1$ with the reversible capacity of 135–150 mA h g^{-1}. The upper voltage limit ($\sim$ 4.3 V) is chosen for a number of reasons, including safety requirements and the possibility of forming gaseous products. However, first of all, one has to take into account that a phase transition of $LiCoO_2$ from a layered hexagonal structure with rhombohedral symmetry (space group *R*3*m*) to monoclinic structure occurs at $x \approx 0.5$.

The structure of hexagonal $LiCoO_2$ (α-$NaFeO_2$ type, Fig. 1) consists of CoO_2 layers built of interlinked CoO_6 octahedra and separated by lithium-ion layers with octahedral coordination. The cation layers are located in voids of the almost perfect face-centred cubic sublattice of oxygen ions (alternating ABC layers, O3 structure). Other synthetic forms of lithium cobaltate differ in the arrangement of cations (also coordinated in octahedra) in the supercompact oxygen-ion packing. For instance, the low-temperature synthesis results in lithium cobaltate with the spinel structure.

The charging consists of the removal of lithium from the lithium cobaltate lattice by the reaction

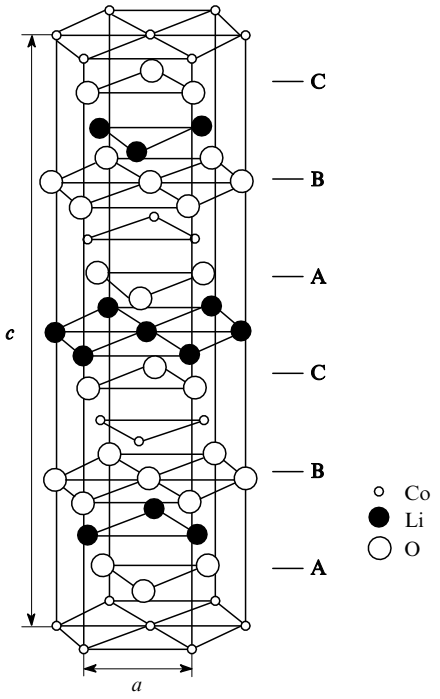

Figure 1. Crystal structure of lithium cobaltate with alternating ABC layers.

$$LiCoO_2 - (1-x)Li^+ - (1-x)e^- \longrightarrow Li_xCoO_2 .$$

As a result, the electrostatic repulsion of CoO_2 layers should become greater and the distance between the layers (the lattice parameter *c*) should increase. The discharge represents a reverse reaction. For a sufficiently long time, it was assumed that reversible cycling to voltages higher than 4.3 V, *i.e.*, up to the complete delithiation leading to CoO_2 is impossible, because removal of lithium should increase the repulsion between the CoO_2 layers and result in the structure failure (the hexagonal form O3 of cobalt oxide is unstable). Later, Amatucci *et al.*[19] have shown that the complete electrochemical delithiation can be achieved upon charging up to 5.2 V. Using a special cell designed for *in situ* XRD experiments, it was shown that upon complete delithiation a transition to a more organised truly hexagonal O1 structure isostructural to CdI_2 occurs rather than the expected decomposition of the original rhombohedral structure. Intercalation of lithium results immediately in the reverse phase transition.

As a whole, changes occurring in a single charge–discharge cycle of stoichiometric lithium cobaltate are sufficiently well studied (see Refs 19–21). In the *x* range from 1 (0.9, according to Ref. 19†) to $\sim$ 0.75–0.78, two hexagonal phases coexist (a wide plateau at 3.9 V in the charge–discharge curve). For *x* from 0.8 to 0.22–0.25, again a single hexagonal phase is present. In a very narrow interval, $x = 0.44–0.49$ (see Refs 20 and 21) (0.46–0.51, according to Ref. 19), the lattice symmetry changes to the monoclinic one; the appearance of this phase is associated with the ordering of ions in lithium layers. Phase transitions to the monoclinic structure and back to the hexagonal phase give rise to two small plateaux at approximately 4.08 and 4.15 V. Substantial changes occur upon reaching 4.2 V. At this voltage, the parameter *c* abruptly decreases indicating the gradual transition to the monoclinic symmetry at 4.5 V and $x = 0.22–0.25$.[19,20] The formation of this second monoclinic phase is explained by the Jahn–Teller effect due to the appearance of low-spin cobalt ions (d^5). Further deintercalation of lithium ions manifests itself, at

† According to data by Amatucci *et al.*,[19] in the *x* range from 1 to $\sim$0.9 the initial hexagonal phase is conserved.

first, by the co-existence of hexagonal and monoclinic phases. After a number of phase transitions,[19] the process is finished at 5.2 V with the formation of the well-crystallised hexagonal phase mentioned above. It should be noted that 95% of initial lithium can be intercalated back into the structure of electrochemically synthesised cobalt oxide.[19]

A relatively small number of studies deal with the changes in the $LiCoO_2$ crystal structure caused by long-term electrochemical cycling. X-ray diffraction, electron diffraction and transmission electron spectroscopy studies[22,23] have shown that after many charge–discharge cycles (~ 300) in the 3.0–4.3 V interval the layered structure of lithium cobaltate gradually gives way to the spinel structure (space group *Fd*3*m*). The lower electrochemical activity of the latter is partially responsible for the capacity fade upon prolonged cycling. Yet another reason for the cycling-induced capacity fade of lithium cobaltate is the change in the surface area of particles, which can reduce the cathode volume and break the electric contact with the active-substance particles. The above-mentioned phase transition at $x = 0.5$ makes the greatest contribution to the capacity fade during cycling in the 2.5–4.3 V range. Lithium cobaltate is very sensitive to overcharge. There are no theoretical limitations to the further polarisation of negative electrodes upon reaching the lithium electrode potential. As a result, a layer of metallic lithium which is highly reactive with respect to the electrolyte can deposit on the carbon surface.[24] This is also favoured by the low thermal stability of lithium cobaltate.[25] Hence, LIB based on lithiated cobalt oxide are equipped with electronic guarding devices, which impairs their specific characteristics and increases the cost of the finished articles.

The self-discharge of LIB with cathodes of lithiated cobalt oxide can be due to different processes, the main one being apparently the interaction of the electrode material with the solvent. However, despite the relatively high (~ 4.2 V) open circuit voltage (OCV) of LIB, their self-discharge is very low. The film formation on the negative electrode was shown to play an important role in the self-discharge process.[26] As was demonstrated[27] by using a method which allows separate determination of cathode and anode contributions,[28] the capacity fade may also be due to the phase transition from the hexagonal structure to spinel, which occurs on the surface of grains under the effect of increasing internal stresses.

In most publications, attempts were made to relate structural and electrochemical characteristics of the cathode material to the method of its preparation.[20,21,29–35] As was noted above, commercial LIB largely utilise the high-temperature (HT) form of $LiCoO_2$. As a rule, the latter is obtained by solid-state synthesis, *i.e.*, high-temperature annealing (700–850 °C) of cobalt carbonate or oxide with lithium oxide or hydroxide in air or in oxygen. This method has a number of drawbacks including the long time of synthesis, high energy consumption and the loss of lithium (it is evaporated in the course of long-term synthesis). As an alternative, sol–gel technologies were developed for the synthesis of lithium cobaltate.[29,30,33]. This method provides better homogeneity of the starting compounds and hence better uniformity of the resulting oxide, minimises the heat treatment time and requires much lower temperatures to produce the same HT form of $LiCoO_2$. As a rule, salts of lower carboxylic acids are used, and the synthesis is carried out in the presence of a chelating agent (citric, oxalic, malonic and other acids) and alcohol (*e.g.*, ethylene glycol). Annealing of the resulting gel at ~ 550 °C affords the high-quality final product.[29,33] According to the literature data, the HT form of $LiCoO_2$ obtained at lower temperatures by the sol–gel method exhibits somewhat better electrochemical characteristics: at the discharge to 2.8 V, its capacity reaches 150 mA h g^{-1}; moreover, the charge–discharge voltage is slightly lower, which is important in view of preventing the electrolyte decomposition.[30]

Among other methods for synthesising lithium cobaltate, mention should be made of a method with mechanochemical treatment, which allows the lower temperatures of final annealing,[31,32] a method employing cryochemical crystallisation,[34] a method of spraying[33] and synthesis in a microwave oven.[36] The mechanochemical synthesis of crystalline $LiCoO_2$ is complicated by its instability with respect to mechanochemical treatment and by redox processes which involve the gas phase.[31] It was shown that the formation of the HT-modification of $LiCoO_2$ can occur at 400 °C.[31] The important features of the resulting cathodic material are the uniform composition, morphology, particle size, texture, all of which strongly affect the electrochemical characteristics of fabricated positive electrodes. All the listed methods provide greater (as compared with the solid-state synthesis) homogeneity upon blending the initial substances and better uniformity of the final product with respect to both composition and particle size (including submicron particles), which defines the enhanced capacity, improves the cycling process and increases the possibilities of cycling at higher charge–discharge rates.[29–31,32–34] The advantages of the microwave synthesis include considerably reduced time of synthesis and, as a consequence, a decrease in lithium losses during this process.[36]

Several authors[37,38] reported on the impossibility of synthesising nonstoichiometric compositions of lithium cobaltate. However, according to other authors,[39–41] such compounds can be obtained. Later, the former authors[37,38] also described nonstoichiometric $LiCoO_2$.[42,43] The limit of the existence of solid solutions with excess lithium corresponds to $x = 1.15$. By iodometric titration, it was found that the valence of cobalt in Li_xCoO_2 remains equal to 3.0 up to $x = 1.15$ and decreases to 2.9 only for higher x. The electroneutrality of compounds with $1 < x < 1.15$ is maintained as a result of the decrease in the cobalt content.[42] It was shown that extra lithium gives rise to both cobalt and oxygen vacancies and affects the electrochemical characteristics of the material.[42,43] A small excess in lithium (up to $x = 1.1$) enhanced the capacity, improved the material cyclability and diminished irreversible losses in the first charge–discharge cycle; for higher x, the capacity was found to fade due to the decrease in the cobalt content.[42] In contrast to stoichiometric $LiCoO_2$, nonstoichiometric samples remained structurally homogenous and demonstrated no transition to the monoclinic phase,[41] so that the steps in the charge–discharge curve at 4.08 and 4.15 V ($x = 0.5$) were observed to disappear.[42,43] The results of these studies[41–43] confirmed the rather unexpected results of calculations[44–48] which derived that oxygen ions play the key role in the redox processes during electrochemical intercalation–deintercalation of lithium, notwithstanding the concepts of classical inorganic chemistry according to which delithiation should involve oxidation of cobalt to the tetravalent state. According to calculations, lithium extraction involves the transfer of electronic density to oxygen ions and changes in the hybridisation of oxygen and cobalt orbitals, while the charge of cobalt remains surprisingly constant. Thus, the so-called 'self-regulated' response is observed, *i.e.*, minimisation of the external impact by rehybridisation. The excess of lithium in Li_xCoO_2 gives rise to new states of oxygen ions and statistically distributed vacancies in cobalt and oxygen layers rather than to oxidation of cobalt.[41]

Using nonempirical calculation methods, the authors of theoretical studies cited above determined the average voltage of lithium intercalation into layered matrices of the same structure MO_2 to give $LiMO_2$ for different metal atoms (M = Co, Ni, Ti, V, Cu) and also for a constant chemical composition with different ordering in cations, which included different structures (lithium cobaltate: rhombohedral layered structure and spinel[47]). A detailed theoretical study was carried out for $LiCoO_2$.[49] The results of this study agree well with the experimental observations discussed above.[19–21]

A large number of studies dealt with properties of lithium cobaltate doped with different metals ($LiCo_{1-y}M_yO_2$) aimed at improving its electrochemical characteristics and simultaneously reducing the cost (see, *e.g.*, Refs 50–52). The use of such dopants as nickel, iron and manganese somewhat improved the cyclability of $LiCoO_2$ by stabilising its structure and lowering the probability

of phase transitions. Such metals as aluminium and magnesium were also tested as the dopants. Based on aforementioned ideas on the significant role of oxygen ions in the redox process, it was predicted and later confirmed experimentally that introduction of aluminium increases the charge–discharge voltage.[53,54] By studying the electrochemical characteristics of $LiCo_{1-y}Al_yO_2$ (y = 0.05–0.25), it was shown that aluminium, even if slightly affecting the theoretical and experimental specific capacity (*ca.* 120 mA h g^{-1} for the optimal composition $LiCo_{0.8}Al_{0.2}O_2$), substantially improves the cycling reversibility due to the formation of single-phase samples (the steps in the charge–discharge curve disappear).[30] The results mentioned above [53,54] on the increase in the average charge—discharge voltage were confirmed. Although high voltage is desirable for providing the high energy density of LIB, voltage above 4.2–4.5 V poses serious complications associated with the choice of electrolytes and the extensive practical application of such batteries. Of the materials considered, only $LiCo_{1-y}Ni_yO_2$ has a small niche in the LIB production.[35]

At present, the efforts of scientists engaged in industrial production of cathode materials based of lithium cobaltate are mainly concentrated on studies of their morphological properties and texture, elucidation of the dependence of their electrochemical characteristics on the particle size and size distribution and optimisation of the compositions and methods for fabrication of the cathode mass.[25] It was shown that smaller sizes of powder particles, more uniform size distributions [29–34,32–34,55] and the formation of small agglomerates of fine spherical particles [55] impart better electrochemical characteristics to cathode materials. As was mentioned above, physical characteristics of crystalline materials strongly depend on the synthetic method, the temperature interval chosen, the time of thermal treatment, starting compounds and sample prehistory.

We deliberately leave the questions associated with polymeric LIB beyond the scope of our survey, because the major relationships and trends found for cathode materials are also valid for compounds used in polymeric batteries. However, it is evident that characteristics of the latter should depend much more strongly on the material morphology, particle size and size distribution. For films, of great importance are the texture, the preferential orientation when films are applied on supports, the application method, *etc*. It should be taken into account that common polymeric electrolytes used in such LIB decompose at 3.8 V, which imposes certain limitations on the cathode materials used. All these problems require special consideration.

III. Lithium nickelate and related materials

Lithium nickelate was suggested as the cathode material almost simultaneously with lithium cobaltate,[11] its cost and toxicity are substantially lower as compared with cobaltate, whereas the experimental specific capacity is apparently among the highest known for this class of lithiated oxides $LiMO_2$ (185 and 210 mA h g^{-1} when charged to 4.1 and 4.2 V, respectively).[25] However, $LiNiO_2$ has not yet found use in commercial LIB. This is due first of all to the difficulties associated with the synthesis of such a compound with a stoichiometric or merely reproducible composition. In practice, the obtained compounds have a composition $Li_{1-x}Ni_{1+z}O_2$ where z depends on the conditions of synthesis and on average varies from 0.05 to 0.20.[56] Optimisation of the process can decrease z but has not yet provided values below 0.01–0.02.[25,56] The decrease in the lithium content in a compound lowers the specific capacity of the sample. Nonstoichiometry appears due to instability of trivalent nickel at high temperatures. 'Extra' nickel ions in the bivalent state occupy lithium positions. XRD data point to the ordered arrangement of lithium and nickel cations in the lithium layers;[56] hence, the more correct formula of lithium nickelate should indicate the occupied positions like $[Li_{1-z}Ni^{2+}_z]_{3a}[Ni^{3+}_{1-z}Ni^{2+}_z]_{3b}[O_2]_{6c}$ (rhombohedral structure $R3m$).[57] The presence of nickel ions in the lithium positions prevents free transport of lithium ions. Moreover, in the course of deintercalation, additional nickel ions were observed to occupy the lithium positions.[58] Electrostatic repulsion between lithium ions and extra nickel ions and reduction of the distance between the layers due to the presence of bi- and trivalent nickel substantially impair the reversibility of the charge–discharge process.[56,59,60] Furthermore, lithium nickelate is less stable with respect to overcharging (due to the greater cycling depth and structural changes).[61]

Lithium nickelate has the same structure of the α-$NaFeO_2$ type as lithium cobaltate, namely, the ordered rocksalt structure with alternating Li^+ and Ni^{3+} layers which occupy octahedral voids in the supercompact cubic packing of oxygen ions. However, for trivalent nickel (electronic configuration $t^6_{2g}e^1_g$), the Jahn–Teller effect is observed; hence, despite the identical structures, lithium nickelate and cobaltate behave differently. The distortion of NiO_6 octahedra due to the Jahn–Teller effect (different lengths of N—O bonds) was first discovered when analysing the fine structure of X-ray absorption spectra.[62] This distortion is of the local nature and cannot be observed in ordinary XRD spectra. Thus the lowering of the local symmetry from rhombohedral to monoclinic was observed. According to calculations,[63,64] the monoclinic distortion observed in the course of lithium deintercalation is due to the combined action of the Jahn–Teller cooperative effect and the ordering of the Li-ion vacancies. Ultimately, the lattice distortion has the decisive effect on the propensity of lithium nickelate to reversibly intercalate–deintercalate lithium. The phase diagram of Li_xNiO_2 calculated in the aforementioned studies [63,64] is in sufficient agreement with experimental results;[65–68] however, it should be stressed that the sequence of phase transitions in Li_xNiO_2 as a function of intercalation depth is not yet determined as reliably as for lithium cobaltate and certain discrepancies are still observed.[65–69] The number of individual phases detected in the system during the charge–discharge varies from three [67] to eight (according to *ab initio* calculations).[64] According to both experimental results [65–68] and calculations,[63,64] the rhombohedral phase exists in the $0.75 < x < 1$ range, whereas the monoclinic phase occurs at $0.4 < x < 0.75$. Within this range, lithium nickelate exhibits good electrochemical characteristics (the corresponding potential range is from approximately 3.6–3.65 to 3.9–4.0 V). Charging to 4.2 V substantially changes the Li_xNiO_2 structure, which is associated with great changes in its volume and the loss of charge–discharge reversibility.[66,68] The nickel dioxide phase $\square NiO_2$ (see ‡) (space symmetry $R3m$) is unstable in nonaqueous solvents at room temperature.[66] As in the case of cathodes based on lithium cobaltate, the surface of particles also changes, which results in the formation of microcracks and finally in the cathode failure.[70,71] The thermal behaviour of completely or partially charged Li_xNiO_2 was studied by differential scanning calorimetry (DSC).[72] It was shown that exothermal peaks of decomposition of delithiated phases for the samples with $x \leqslant 0.25$ are observed at temperatures above 180 °C, whereas the reaction begins at room temperature.

It was found [50] that doping with cobalt stabilises the lithium nickelate structure and minimises deviation from stoichiometry. The introduction of a 3d metal prevents lithium from ordering over the vacancies and weakens the monoclinic distortion, which results in a more stable structure. The charge–discharge curves for such samples are smoothed out, which points to the smaller number of phase transitions during intercalation–deintercalation. That is why the majority of scientists used this way for improving the electrochemical characteristics of lithiated nickel oxide and for studying the properties of doped lithium nickelates. Manganese,[73–80] cobalt,[50,81–86] iron,[87,88] aluminium,[72,89] titanium,[74,89] copper [89] and magnesium [90] were chosen as the dopants. Multicomponent systems with two dopants, *e.g.*, cobalt and gallium,[58] cobalt and aluminium,[61,91] cobalt and titanium,[92] cobalt and magnesium,[91] manganese and aluminium, manganese

‡ Symbol □ means vacancy.

and cobalt, manganese and magnesium, manganese and titanium,[80] gallium and magnesium,[93] and even systems with three dopants [92] were also studied.

According to the results of *in situ* X-ray spectroscopy with synchrotron emission, $LiNi_{1-y}Co_yO_2$ samples first undergo fast and almost complete oxidation of nickel, whereas cobalt is slowly oxidised at the end of charging.[83] Samples doped with cobalt exhibit higher thermal stability in the completely charged state and, hence, are more resistant towards overcharging.[80] For such systems, heat-induced (in the 50–150 °C range) structural changes were studied as a function of the cobalt content. For equal discharge depths (the same x) in $Li_xNi_{1-y}Co_yO_2$ ($y \leqslant 0.30$) in CD2032 coin cells, the temperature-induced changes in the $c:a$ ratio of the hexagonal lattice parameters (which reflects the degree of trigonal distortion) decrease with the increase in the cobalt content.[86] For cobalt-doped samples $LiNi_{1-y}Co_yO_2$, the smallest cycling-induced changes in the unit cell volume and reversible lithium intercalation–deintercalation at higher cycling rates in the range $0.2 \leqslant y \leqslant 0.4$ were observed.[50,94] At the same time, very good characteristics were reported for $LiNi_{0.5}Co_{0.5}O_2$,[85] $LiNi_{0.8}Co_{0.2}O_2$,[95] $LiNi_{0.85}Co_{0.15}O_2$ (see Ref. 83) and similar compositions. Solid solutions $LiNi_{1-y}Co_yO_2$ demonstrated good electrochemical characteristics for virtually all y values in the range $0.2 \leqslant y \leqslant 0.85$.

XRD and Mössbauer spectroscopy studies have shown that the introduction of Fe prevents the phase transition in solid solutions $Li(Ni_{1-y}Fe_y)O_2$ ($y \leqslant 0.30$) with rhombohedral structure.[87] Deintercalation up to $x = 0.12$ results only in oxidation of Ni^{2+}. As indicated by Mössbauer spectra, further deintercalation increases the oxidation state of iron and simultaneously trivalent nickel is oxidised to the tetravalent state. However, as the amount of introduced iron increases, the capacity is observed to substantially decrease, which can only be attributed to the decrease in the concentration of electrochemically active nickel. Moreover, the charge–discharge voltage of such samples is somewhat higher, which suggests that nickel oxidation in this compound is complicated as compared with pure lithium nickelate.

Kim and Amine [89] studied how the oxidation state of a dopant (bi-, tri- and tetravalent ions, namely, Cu^{2+}, Al^{3+}, Ti^{4+}) added to lithium nickelate affects the characteristics of the resulting material. Introduction of copper not only substantially decreased the specific capacity of samples (because copper is electrochemically inactive in this range), but also noticeably impaired their ability to reversibly intercalate–deintercalate lithium. Moreover, samples containing copper tend to form cubic lattices rather than layered structures. Introduction of aluminium resulted in the formation of stable solid solutions; however, the specific capacity of aluminium-containing substances also decreased with Al concentration, even if to the lesser extent than for copper; and the cycling reversibility was impaired. Finally, a 10%–20% titanium admixture, even if insignificantly (2.5%–5%) lowering the capacity (down to capacities of 187 and 161 mA h g^{-1} for 2.8 and 4.3 V, respectively), substantially improved the reversibility of the charge–discharge process (100 cycles). This can be explained by the fact that both nickel and bivalent copper can reside in the lithium layer, which impairs the electrochemical characteristics of the original nickelate. XRD analysis with Rietveld refinements have shown that in $Li_{1-x}(Ni_{1-y-z}Co_yMg_x)O_2$ bivalent magnesium ions occupy the positions of bivalent nickel in lithium layers.[91] Introduced trivalent aluminium was shown to substitute trivalent nickel ions in nickel layers and, at best, had no effect on the migration of Ni^{2+} ions to the lithium layers. Finally, Ti^{4+} ions compensate both the charge deficiency and the structural instability caused by the presence of Ni^{2+} ions in the lithium layers.

The information on the influence of aluminium added to lithium nickelate on the structural and electrochemical characteristics of the latter is ambiguous. It was shown that, in contrast to lithium nickelate, $Li(Ni_{1-x-y}Co_xAl_y)O_2$ demonstrates no phase transitions during cycling and can be deeply discharged (to voltages below 2.5 V), which increases the specific capacity and ensures its long shelf-life in the discharged state (its characteristics remained virtually unchanged after two years storage at 40 °C).[61] It was also noted that addition of aluminium has a positive effect on the thermal stability during lithium deintercalation.[61,92] However, the results of DSC studies [91] suggest that the thermal stability of multidoped samples $Li(Ni_{0.80}Co_{0.15}Al_{0.05})O_2$ reveals no dependence of the decomposition temperature on the nature and concentration of the second (after cobalt) dopant for equal degrees of lithium extraction. At the same time, the increase in the grain size enhanced the thermal stability regardless of the lithium extraction degree. It was also stated [72] that substitution of a fourth part of Ni atoms [$Li(Ni_{0.75}Al_{0.25})O_2$] suppresses the exothermal reaction of decomposition, making the resulting compound more resistant to overcharge. A cathode made of this material demonstrated a specific capacity up to 150 mA h g^{-1}; however, its characteristics can be improved by optimising the conditions of its synthesis and fabrication of the positive electrode.

In recent years, mixed lithiated oxides based on nickel and manganese were actively studied.[73–80] These compounds can be classified among both nickel-based materials ($LiNiO_2$) and manganese-based materials ($LiMnO_2$). At the same time, in contrast to lithium cobaltates and nickelates, lithiated manganese oxide ($LiMnO_2$) has a layered rhombohedral structure (space group *Pmnm*).[95] For a long time, due to different structures of lithium nickelate and lithium manganate, all attempts to obtain solid solutions in the Li–Ni–Mn–O systems with layered rhombohedral structures failed. A large body of data appeared only after Makimura and Ohzuku [73] proposed to synthesise these substances from a binary nickel–manganese hydroxide [$Ni(OH)_2$ and $Mn(OH)_2$ in the 1 : 1 ratio]. Later, the compound $LiNi_{0.5}Mn_{0.5}O_2$ was actively studied both experimentally and theoretically (*ab initio* calculations).[95] In the voltage range from 4.0 to 2.0 V, its specific capacity was 200 mA h g^{-1} with sufficiently good cyclability;[78] moreover, as compared with lithium nickelate, the material proved to be more resistant to heating. Samples of manganese–nickel oxides of other compositions were synthesised and studied.[75–77,79] Different synthetic methods were used, including those based on the sol–gel technology with organic acids as the chelating agents (*e.g.*, see Refs 75, 79). According to the results obtained (including those of nonempirical calculations [95]), $LiNi_{0.5}Mn_{0.5}O_2$ contains bivalent nickel and tetravalent manganese. Intercalation–deintercalation of lithium in the course of charge–discharge in the range between 4.0 and 2.0 V involves a two-electron process of nickel oxidation–reduction. The oxidation state of manganese remains unchanged. The absence of Mn^{3+} and Ni^{3+} ions which cause lattice distortion due to the Jahn–Teller effect and subsequent structural rearrangement makes this compound stable during cycling. It was found [77] that in the voltage range from 2.0 to 1.25 V one more lithium atom per formula unit can be inserted to give $Li_2Ni_{0.5}Mn_{0.5}O_2$ with hexagonal symmetry (space group *P3m*1). This compound has excellent cyclability but is unstable in air. However, the latter problem can be partially solved by synthesising composites based on it [*e.g.*, with Li_2TiO_3 (see Ref. 77)]. Presumably,[77] the form with the higher lithium content can be used for the development of a new kind of LIB in which the Li_2MO_2 phase is introduced to compensate the first-cycle irreversible losses.

Quite recently, an interesting compound, namely, $LiCo_{1/3}Ni_{1/3}Mn_{1/3}O_2$ was synthesised and studied.[96] This mixed oxide was obtained from a ternary hydroxide. It possesses very good characteristics: the specific capacity of *ca.* 200 mA h g^{-1} (2.5–4.5 V), insignificant capacity losses during 30 charge–discharge cycles and enhanced thermal stability.

Mention should be made of studies on partial substitution of fluoride or sulfide anions for oxygen anions in the oxygen sublattice of lithium nickelate. This substantially improved the reversibility of the charge–discharge process for layered $LiNiS_yO_{2-y}$ (see Ref. 97), although the sulfide anions added

lowered the specific capacity of the sample (the higher S^{2-} concentration, the lower the capacity). Ohzuku, Ueda and Kouguchi[98] suggested another way of improving cyclability which consists of introducing fluoride anion by adding HF to the original material. Similar results were obtained by other authors.[90] The synthesised samples of $Li_{1-z}Ni_{1+z}F_yO_{2-y}$ ($y = 0.015$, $z = 0.06$) demonstrated better cycling reversibility as compared with those nonsubstituted. The effect of dual doping with cations and anions was studied.[99] The compound $Li_{1.075}Ni_{0.755}Co_{0.17}$ $O_{1.9}F_{0.1}$ obtained by solid-phase synthesis demonstrated the best characteristics: initial capacity 182 mA h g^{-1} with only 2.8% lost during cycling (100 cycles). These results make it possible to assume that both cationic and anionic substitutions can contribute to the improvement of cyclability.

From the foregoing it is evident that for lithium nickelate the synthetic method still plays a greater role than for lithium cobaltate. Studies on the nature of starting materials, the synthesis temperature and the time of thermal treatment have shown that smaller deviations from stoichiometry are observed for more reactive starting materials and relatively low (600–700 °C) temperatures.[56] Under certain conditions,[56, 69] samples withstanding a large number of charge–discharge cycles (more than 50 cycles; capacity loss less than 0.12% per cycle) can be obtained.[69] The electrochemical behaviour of $LiNi_{1-y}Co_yO_2$ samples prepared by solid-phase synthesis was shown to be closely related to their particle size and size distribution.[82] The Coulomb efficiency in the first cycle is higher the smaller the particles, while the specific capacity remains virtually unchanged. As for lithium cobaltate, a comparison of samples obtained by solid-state synthesis and sol–gel methods confirmed that the latter method provides better homogeneity of starting reagents and the smaller particle size. As a rule, the starting compounds in the sol–gel method include aqueous solutions of nickel and metal-dopant salts, nickel hydroxide and a solution of ammonium hydroxide as the complex-forming agent. The ammonia concentration and pH of the solution were shown to be the most important synthetic parameters in view of preparing samples with desired properties.[84] Organic acids can also be used as the complex-forming agents in the sol–gel technology.[75, 79]

To increase the energy density of LIB, one should use materials possessing both high specific capacity and high density. The higher degrees of crystallinity and the greater particle size, the smaller bulk densities of materials, but simultaneously the lower specific capacities of samples. The bulk density is closely related to the morphology of particles, their sizes and size distribution. However, among materials with the same degrees of crystallinity, spherical particles have the highest bulk density. Thus, the characteristics of cathodes for nickel hydride batteries could be substantially improved when using $Ni(OH)_2$ with spherical particles was used.[84] Samples of cobalt-doped lithium nickelate $LiNi_{0.8}Co_{0.2}O_2$ with quasi-spherical particles and a narrow size distribution were synthesised.[84] This allowed the authors to increase the bulk density of $LiNi_{0.8}Co_{0.2}O_2$ up to 3.24 g cm^{-3} as compared with 2.3 g cm^{-3} for common commercial samples of this material. As compared with commercial samples produced by Merck (irregular crystals with a wide size distribution), $LiNi_{0.8}Co_{0.2}O_2$ samples with spherical particles demonstrated not only high bulk weight but also improved electrochemical characteristics when cycled in the range from 3.0 to 4.3 V (217 mA h g^{-1} in the first cycle and a discharge capacity of 172 mA h g^{-1} in further cycles, as compared with 210 and 165 mA h g^{-1}, respectively, for commercial samples).

IV. Lithium–manganese spinel and spinel-based materials

Among cathode materials under consideration, lithiated manganese oxides and their derivatives are the cheapest and most readily available. Their advantages also include a sufficiently high discharge voltage, high thermal stability especially in the discharged state and nontoxicity. That is why, the compounds of this class were the subject of active studies and wide speculations.

It should be noted that the Li–Mn–O system is much more complex as compared with Li–Co–O and Li–Ni–O systems, because it includes more than ten stable compounds with different structures that contain manganese in various oxidation states and have different degrees of defectiveness.[100] Figure 2 shows an isothermal section of the phase diagram for the Li–Mn–O ternary system (see Ref. 100) and also demonstrates the 'routes' of electrochemical insertion and extraction of lithium (designated by dashed lines with the corresponding average charge–discharge voltages written on the top) and the compounds involved (*T* and *C* designate tetragonal and cubic structures). Lithium intercalation–deintercalation is possible for samples located between λ-MnO_2 ($\square Mn_2O_4$, a stable compound) and $LiMn_2O_4$ (at 4 V), $LiMn_2O_4$ and $LiMnO_2$ ($Li_2Mn_2O_4$) (at 3 V), $Li_4Mn_5O_{12}$ and $Li_7Mn_5O_{12}$ (the latter two compositions can be represented as $LiMn_{1.67}Li_{0.33}O_4$ and $Li_2Mn_{1.67}$ $Li_{0.33}O_4$).

Among the compounds mentioned above, lithium–manganese spinel $LiMn_2O_4$ attracts the keen attention of scientists. Spinel is crystallised in the cubic system (space group *Fd*3*m*). The crystal structure of normal spinel $A[B_2]O_4$ is shown in Fig. 3. Oxygen anions form a supercompact cubic lattice where cations are localised in tetrahedral and octahedral voids. Two limiting positions are possible for cations. In normal spinels, atoms A occupy tetrahedral positions (8*a*), while cations B occupy octahedral positions (16*d*). In inverted spinels, atoms A and a half of atoms B are located in octahedral positions, the remaining atoms B occupy tetrahedral positions. Between these two versions, a continuous series of intermediate structures can be realised. It is a

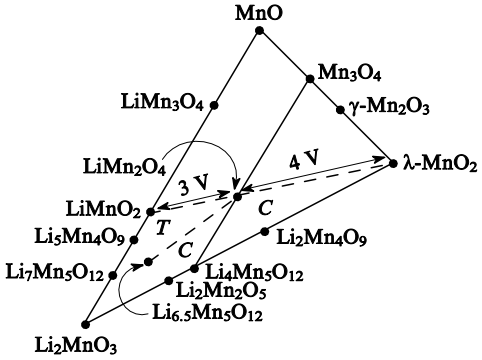

Figure 2. Isothermal section of a phase diagram for a ternary system Li–Mn–O.[100]

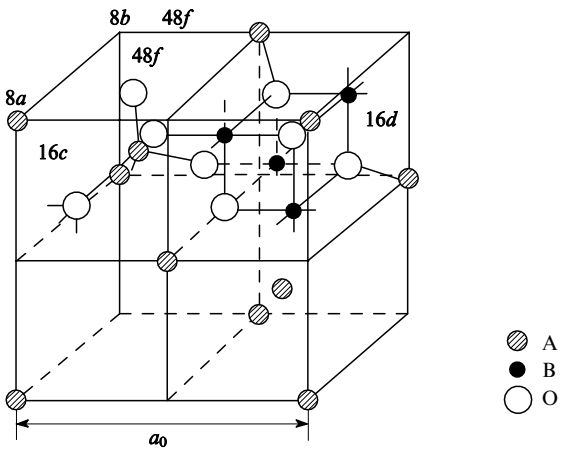

Figure 3. A scheme of $A[B_2]O_4$ spinel structure.

possibility to form different kinds of cationic positions and vacancies (defective structures) that determines the stability of spinel structures with different cations in variable valences. For the same reason, the spinel structure of $LiMn_2O_4$ can host lithium ions in both octahedral and tetrahedral positions.[101] Moreover, there is a 'hierarchy' of voids in the spinel structure, which suggests that discharge characteristics of cathodes based on these structures vary nonmonotonically in the absence of kinetic limitations.[102]

Indeed, electrodes with the working voltage of 4 V are formed when lithium is electrochemically intercalated–deintercalated into tetrahedral positions 8*a* of $Li_x\ Mn_2O_4$ spinel (for normal spinel).[103] For $x > 1$ (according to certain results,[100] at $x > 1.08$), lithium begins to migrate to octahedral positions. The process occurs at 3 V and results in the formation of a layered rhombohedral phase of $LiMnO_2$. In principle, if we consider the overall transition from λ-MnO_2 to $LiMnO_2$ from the theoretical viewpoint, the latter compound could be characterised as an excellent cathodic material with the theoretical capacity of 285 mA h g^{-1}. However, two different electrochemical mechanisms are responsible for the two plateaux at 3 and 4 V, *i.e.*, with a great voltage difference. From the viewpoint of practice, materials with such properties are of no interest.[25] The mentioned phase transition of the first kind was attributed to the increase in Mn^{3+} concentration, which strengthens the co-operative Jahn–Teller effect and gives rise to tetragonal distortions followed by structural changes.

As a whole, the following changes occur during the charge–discharge of a material with the stoichiometric composition $LiMn_2O_4$ in the range from 3.5 to 4.5 V.[104] At $\sim$ 4 V, lithium is electrochemically extracted and inserted in two stages divided by a small step of 0.1 V at $x = 0.45–0.6$ (4.05 and 4.15 V, respectively). The presence of this step is explained by the ordering of the remaining half of lithium ions over tetrahedral positions,[105] which contributes to the gradual specific capacity loss of the spinel. In the x range from 1 to 0.5, two phases coexist. For x below $\sim$ 0.5, also two $Li_xMn_2O_4$ cubic phases coexist, namely, with x equal to 0.15 and 0.4.[104]

Structural and phase transitions that occur during cycling, especially in the high voltage range, are accompanied by great changes in the cathode material bulk and, ultimately, cause irreversible changes in the cathode properties. Among the drawbacks of $Li_xMn_2O_4$ spinel, mention should be made of its relatively low theoretical specific capacity (148 mA h g^{-1}), the capacity loss during storage, especially at high temperatures, and the danger of its dissolution in inorganic solvents in the presence of moisture.

A spinel with nonstoichiometric composition $Li_{1+x}Mn_2O_4$ demonstrates much better cycling reversibility.[106] The disappearance of the step in the cycling curve suggests the homogeneous structure of nonstoichometric spinel. This is explained by the increase in manganese vacancies, which is responsible for certain strengthening of the Mn—O bond, and changes in the surrounding of lithium in tetrahedral positions.

It should be noted that the properties of lithium–manganese spinel strongly depend on the synthetic method.[18, 103, 106–111] Single-phase samples are obtained in the range $0.9 < x < 1.15$.[18] The parameter a of the spinel cubic lattice and the oxygen ion deficiency are shown to increase with an increase in the temperature of synthesis, or (when samples are prepared by quenching) with an increase in the quenching temperature and a decrease in quenching time. The loss of oxygen is responsible for tetragonal distortion of the spinel lattice. As the quenching temperature increases, the phase structure of $LiMnO_2$ spinel undergoes the following changes: first, a two-phase domain appears (840–890 °C), then, a domain of the existence of a single tetragonal phase is observed (895–910 °C) and, finally, above 910 °C, a domain of mixed phases (the main phase is rhombohedral $LiMnO_2$) occurs. The transition from the spinel phase to the tetragonal one is reversible. Spinels synthesised at low temperatures contain higher concentrations of oxygen and lower concentrations of trivalent manganese, which reduces the specific capacity of a sample to a certain extent but enhances its cyclability due to the weaker distortions associated with the Jahn–Teller effect.[107, 108] Moreover, both anionic and cationic kinds of nonstoichiometry were shown to depend not only on the temperature of synthesis but also on the nature of the starting compounds.[109, 110] The anionic nonstoichiometry has the greater effect on the properties of $LiMn_2O_4$, as compared with cationic nonstoichiometry (the Li/Mn ratio).[111] Certain publications[108, 112] reported good cyclability of samples made of disordered defective spinels with the nonstoichiometry Li/Mn < 1 (average cycling capacity of 120 mA h g^{-1}).

Different methods were used for the synthesis of lithium–manganese spinels, *viz.*, various versions of solid-phase synthesis,[103, 106, 109, 111] including those using the mechanical processing,[113–115] microwave synthesis,[116] sol–gel syntheses with different starting substances and chelating agents (*e.g.*, citric, polyacrylic and stearic acids),[107, 110, 117, 118] a method using the starting reagent in the form of an oil emulsion.[119] The development of synthetic methods is largely focused on the preparation of spinel phases nonstoichiometric in lithium and oxygen and more uniform with respect to composition and particle size.

The drawbacks of lithium–manganese spinels mentioned above can be eliminated by modifying their compositions (doping with cations and anions as in the case of lithium cobaltate and lithium nickelate) and surface as well as by using nonstoichiometric compositions.

Surface is modified in order to form a protective film preventing dissolution of the cathodic material in the electrolyte, *e.g.*, by encapsulating surface particles of $LiMn_2O_4$ in lithium borate. Another goal is to directly affect the active centres on the surface of lithium–manganese spinels, *e.g.*, by treating the surface with acetylacetone.[120] Moreover, the $LiMn_2O_4$ surface is often modified to compensate the losses in the first charge–discharged cycle. Thus by coating the $LiMn_2O_4$ surface with lithium cobaltate in the form of microemulsion, it is possible to reduce the specific capacity losses from 12% to 5% in 100 cycles.[121] To compensate the first-cycle losses, it was proposed[122] to add (to the bulk) Li_2CuO_2 which has an irreversible yet high specific capacity (320—340 mA h g^{-1}).

Numerous studies were devoted to modification of lithium–manganese spinels by doping. The following dopants were studied: Co,[108, 123–127] Ni,[81, 123, 124, 127–130] Cr,[124, 127, 129, 131–136] Fe,[123, 137] Al,[137, 138] Mg,[137, 139], Cu (see Ref. 137), *etc*. Simultaneous doping with two elements was also suggested.[137, 139, 140] These studies were carried out by various techniques: X-ray diffraction, X-ray photoelectron spectroscopy (XPS), ESR, Fourier-transform IR spectroscopy (FTIRS), EXAF spectroscopy, electron microscopy, neutron diffractometry, DSC and cyclic voltammetry. Electrochemical tests were also carried out.

In these publications, the effect of a metal M in $Li[Mn_{2-y}M_y]O_4$ was studied in the domains of existence of single-phase products with the spinel structure over the entire concentration range. In the majority it was shown that partial substitution for manganese in 16*d* positions weakens the distortion due to the Jahn–Teller effect, thus stabilising the spinel structure, and also reduces the specific capacity losses at high voltage (> 4 V). Moreover, as a rule, a step in the charge–discharge curve at $x \approx 0.5$ is 'smoothed', which apparently can be explained in the same way as for the case of nonstoichiometric spinel samples (the latter can be considered as lithium-doped), *i.e.*, by changes in the Mn—O bond strength and in the surrounding of lithium ions in tetrahedral positions. At high concentrations of an introduced substituent, the dopant ions can partly occupy the 8*a* positions of lithium [123, 137] (partially inversed spinel). The increase in the degree of substitution into 8*a* positions with an increase in the dopant concentration was shown to impede the migration of lithium ions and reduce the specific capacity of the cathode material.[137]

Doping (*e.g.*, with chromium) also increases the diffusion coefficient of lithium,[136] which allows one to increase the current density of the charge–discharge process. It should be noted that, in the voltage range from 2.5 to 4.5 V, oxidation–reduction of manganese occurs. In this case, doping is ineffective; hence, when improving the reversibility of electrochemical intercalation–deintercalation of lithium, it should be borne in mind that the lower capacities of materials the higher dopant concentrations (see, *e.g.*, Refs 125, 126, 134, 136).

Simultaneous introduction of anionic (S^{2-}) and cationic (Mg^{2+}) substituents is beneficial as regards reversibility but substantially reduces (up to 85 mA h g^{-1}) specific capacities of samples.[139]

Yet another feature of lithium–manganese spinel which has not been touched upon above, namely, the low-temperature transition to the other rhombic phase at 280–285 K deserves mention.[140, 141] Multidoping (with cobalt and nickel) makes it possible to suppress this phase transition,[141] because the latter is also caused by distortions due to the Jahn–Teller effect; this will allow using LIB at low temperatures.

Since the advent of electrolytes stable at high voltages, it has been found that cycling of doped samples up to 5.1–5.2 V gives rise to the second wide plateau (at $\sim$4.7–4.8 V) in the cycling curve.[81, 123, 127, 137] Its appearance is associated with redox transformations of the dopant metal,[123, 127] as was demonstrated by several techniques including the analysis of the fine structure of X-ray absorption spectra.[127] The reversibility of this process at $\sim$4.7–4.8 V strongly depends on the degree of crystallinity and the morphology of particles and takes the maximum value for quasispherical particles.

The role of the morphology of cathode-material particles, their sizes and size-distribution has been discussed in the previous Sections devoted to lithium cobaltate and lithium nickelate. Yet another study in which these problems are discussed in detail deserves mention.[142] It was shown that at high cycling rates of lithium–manganese spinel, it is the morphology of particles that plays the key role rather than their sizes. Hence, larger but porous particles with big surface areas exhibit better electrochemical characteristics, do not crack when cycled and do not affect greatly the cathode volume.

V. Miscellaneous materials with average voltage of 4 V

Although the main objective of this survey is to discuss cathode materials based on lithium cobaltate, lithium nickelate and lithium–manganese spinel, *i.e.*, compounds which are recognised to date as the main candidates for lithium-ion batteries,[143] a small group of different LIB materials with the voltage of 4 V also deserve discussion.

It should be noted that the efforts to apply materials based on layered manganese compounds never stop. These materials are often synthesised (for example, by ion exchange) in such a way as to make their structure as close to the structures of lithium cobaltate and lithium nickelate with good cyclability as possible.[73–80, 144–148] All of them, as a rule, are stabilised by introducing different dopants, *e.g.*, aluminium,[145] iron, manganese, cobalt,[146] chromium [147, 148] and, most often, nickel.[73–80] Properties of such materials are discussed in detail in section III using the example of nickel compounds.

Attempts were undertaken to develop cathodes based on the orthorhombic phase of $LiFeO_2$. However, the charge–discharge process in these compounds is irreversible due to the instability of Fe^{4+} in Li_xFeO_2 with respect to electrolyte.[25]

Recently, there was reported [149] a new cathode material in the Li–Co–Ti–O system. The resulting layered material has a structure resembling those of Li_2MnO_3 and Li_2TiO_3 and represents a solid solution of Li_2TiO_3 and Li_2CrO_2 with the general composition of Li_3CrTiO_5 ($Li[Li_{0.2}Cr_{0.4}Ti_{0.4}]O_2$). The samples were identified in the monoclinic system (space group $C2/m$). It was shown that this compound undergoes a redox process involving chromium (Cr^{3+}/Cr^{6+}) with a very good cycling reversibility in the voltage range from 2.0 to 4.8 V. Similar results (with electrochemically active chromium) were obtained for $LiMn_xCr_{1-x}O_2$.[148]

Recent publications discussed the prospects of using $LiFePO_4$.[150–153] This material is cheap, safe, has a high energy density and is sufficiently attractive as regards the working voltage (3.5 V); however, it has an extremely low electronic conductivity. Nevertheless, the introduction of a small amount (no more than 1%) of a dopant metal (Zn, Nb or Mg) was shown to increase the electronic conductivity by eight orders of magnitude.[151]

VI. The prospects of using metastable superstructures

The analysis of published data shows that most scientists tend to develop positive-electrode materials based on single-phase structures or solid solutions. However, as has already been noted in the previous section (see, *e.g.*, Ref. 77), the prospects of using complex multicomponent systems based on oxides of cobalt, nickel and manganese including multidoped systems are also considered. Thus in studies on the electrochemical behaviour of composites $LiMO_2 \cdot Li_2M'O_3$ (M = Co, Ni, Mn; M′ = Ti, Zr, Mn) [77, 154, 155] it was found that the addition of $Li_2M'O_3$ enhances the stability of the positive-electrode material. It was also shown [156] that the addition of $LiNi_{0.8}Co_{0.2}O_2$ to lithium–manganese spinel $Li_{1+x}Mn_{2-x}O_4$ inhibits spinel dissolution in the electrolyte and reduces capacity losses during storage at elevated temperatures. Mention should be made of several patents in which the materials for positive electrodes of lithium-ion batteries were developed on the basis of lithiated oxides. For instance, a mixture of $Li_xNi_yCo_zM_nO_2$ (M = Al, Ti, W, Cr, Mo, Mg, Ta, Si or their combinations) with lithium–manganese spinel $Li_xMn_{2-r}M'_rO_4$ (M′ = Cr, Ti, V, Ni, Co, Fe, Sn, Zn, Zr, Si or their combinations) was proposed to enhance the cycling stability of capacity characteristics and the stability with respect to overcharging.[157] A Japanese Patent of the Fuji Photo Film Company [158] also suggested using a mixture of two lithiated oxides, *viz.*, lithium cobaltate $Li_{1-y}CoO_2$ ($0.1 \leqslant y \leqslant 1$) and a spinel $Li_{2-x}Mn_2O_4$ ($0 \leqslant x \leqslant 1$). The materials were applied simultaneously on aluminium foil; one layer is expanded during the discharge, while the other is contracted. This material provided high initial capacity and stable cycling characteristics and eliminated the electrolyte leakage. Multiphase systems based on lithium–manganese spinel and lithiated oxides $LiNiO_2$, Li_2NiO_2, $LiNi_2O_4$, $Li_2Ni_2O_4$ and $LiNi_{1-x}M_xO_2$ (M = Co, Mn, Al) were suggested by scientists from the Japanese 'NEC Corporation'[159] with the aim of improving the cyclability, shelf life and safety of lithium-ion batteries. The authors of a patent [160] aimed at the development of LIB with enhanced high-temperature stability during discharge and overcharge and, at the same time, preservation of high energy characteristics suggested the use of a composite of the two following compounds as the positive-electrode material: $Li_xM_yO_4$ ($0 < x < 2$); $0.8 < y < 1.2$; M = Fe or Fe_zMn_{1-z}) and one of the lithiated oxides $LiCoO_2$, $LiNiO_2$ or $LiMn_2O_4$ with the potential of lithium intercalation–deintercalation higher than that of $Li_xM_yPO_4$.

From our viewpoint, along with analysing possible practical approaches to the development of such multiphase systems (and solid solutions), attempts should be made to understand the mechanisms of formation of these compositions and to study the processes that occur during the formation of eutectic compositions and solid solutions. It should be noted that, according to published data, eutectic compositions were never studied as candidates for cathode materials, although, undoubtedly, they are of interest. In recent years, a group that includes the authors of this review accomplished a number of studies aimed at elucidating self-organisation mechanisms for structures like supramolecular ensembles in the series of two-phase systems of oxides and

selenides. In a survey devoted to this problem,[161] we proposed to consider the structure of resulting eutectics and solid solutions as supramolecular structures formed due to self-organisation of incommensurable (which is also true for multiphase compositions of positive-electrode materials under discussion) interacting structures of components. Experimental studies of some eutectic oxide ($PbO-ZnO$, $PbO-Mo_2O_3$, $PbO-Y_2O_3$, $PbO-V_2O_5$)[162] and selenide ($GaSe-Ga_2Se_3$) (see Ref. 163) systems demonstrated that such self-organisation can occur and anomalous phases can form due to interaction of their components. The survey involved a theoretical part, in which the process of formation of supramolecular ensembles was considered within the framework of a static version of the Frenkel–Kontorova model for finite systems.[164–166] In this model, abstract thermodynamic criteria such as surface energy or surface tension are replaced by real parameters of interacting structures, *viz*., incommensurability, rigidity and interaction potential. The results of analytical and numerical simulations in terms of this approach allowed us to make certain very significant conclusions on how the mechanochemical processing affects the interacting substructures, to follow the variation of model parameters with temperature and characterise the excited states of the system, thus linking them with the synthetic conditions. It was shown that under certain conditions such systems demonstrate quite a number of very steady metastable states. Only the case of one-dimensional incommensurability was considered; however, the results obtained can be used for explaining certain phenomena observed for eutectic phases and solid solutions.

From our viewpoint, the presented approach to the problem of the formation of self-organised incommensurable interacting structures of eutectic compositions can be extended to multiphase materials for positive electrodes of lithium-ion batteries. The problem is how to choose a multiphase composition which when cycled would reversibly pass from one metastable structure to another without any substantial kinetic barriers and any significant changes in the crystal lattice volumes of these metastable structures. The understanding of self-organisation mechanisms in such multiphase compositions (including considerations in terms of the Frenkel–Kontorova model) opens up possibilities for optimising the methods of synthesising such structures and selecting their components.

VII. Conclusion

The researches directed at improving the performance of lithium-ion batteries constantly become more active. As mentioned above, the number of publications approaches several thousand.[15] Numerous patents devoted to this subject also deserve mention. Despite the incompleteness of selected information, the analysis carried out allowed us to follow the modern approaches to optimising lithium ion batteries. Optimisation of LIB concerns their reactor part as such and involves the materials for fabricating anodes and cathodes. It is noteworthy that in the past 3–4 years the number of publications devoted to negative-electrode materials became relatively smaller, while the number of studies dealing with cathode materials stayed at approximately the same level during the past 5–7 years.

In the field of cathode materials, the major research direction concerns the development of compounds or compositions that will allow us to change expensive, scarce and carcinogenic lithium cobaltate for cheaper, more available and safer materials. Moreover, the problems of improving the charge–discharge characteristics of the cathode material (capacity and energy), enhancing the reversibility and stability (structural and at elevated temperatures), increasing its charge and discharge rates, advancing the technology of electrode production and making the cell operation safer are posed.

For this purpose, the majority of leading research laboratories and companies tend to make positive-electrode materials more complex. Particularly, many studies were devoted to multidoping, *i.e*., simultaneous introduction of two and more dopants, including their combinations with anionic substituents. First of all, this concerns lithium–manganese spinel, when certain samples of substituted spinels are considered in terms of using them as the cathodes in the voltage region of 5 V. Much attention is paid to nickel–manganese oxides, including those doped with other elements $LiNi_{1-x-y}Mn_xM_yO_2$ (M = Al, Ti, W, Cr, Mo, Mg, Ta, *etc*.), and mixed ternary oxides $LiNi_{1-x-y}Mn_xCo_yO_2$ which are often multidoped as well.

In addition to compositions representing solid solutions, *e.g*., systems $xLi_2M'O_3(1-x)LiMO_2$ (M′ = Mn, Ti, Zr, Ru and M = Mn, Ni, Co), the group of M Thackeray[154, 155, 167] works on multiphase compositions which represent mixtures of different oxides. Finally, many laboratories all over the world actively study $LiFePO_4$,[167] *e.g*., as a component of multiphase systems.

The review is financially supported by the Russian Foundation of Basic Research (Project Nos 03-03-32467 and 02-03-32135).

VI.	Conclusion	1029

Abstract. The review surveys geometric and algebraic models of chemical conversion (exchange) processes occurring in multicomponent salt systems in the molten state. Thermochemical and matrix methods for the construction of conversion figures are described in detail. The practical applications of matrices and graphs in studies of complex systems are illustrated. There are good prospects for using multicomponent salt systems in thermal power sources and high-temperature processes, such as electrolytic aluminising of niobium and silver plating. The bibliography includes 62 references.

I. Introduction

Multicomponent reciprocal salt systems are involved as major components in many natural (rocks, minerals, glasses, salt lakes) and artificial (fertilisers, materials of construction) materials. Technologies for the production of salts, heat technology, manufacturing engineering (salt melts are used for chemical thermal treatment of metal and alloy products), metallurgy and foundry practice are the most important areas of applications of multicomponent systems. In the last quarter of the 20th century, salt systems found increasing application due to considerable growth in the production of semiconducting materials and progress in the nuclear industry, rocket technology with the use of autonomous power supply sources and other branches.

Investigation of reciprocal systems containing four or more components (unlike binary and ternary systems) requires a special approach. Prior to the experiment, it is necessary to carry out a theoretical examination of the composition diagram,[1–5] *viz*., to partition the diagram of an *n*-dimensional polytope, derive non-equilibrium and singular stars and reveal conversion elements.†

Geometric, matrix and algebraic models are widely used in analysis of reciprocal systems. Below we describe models of conversion (exchange) processes occurring in reciprocal systems. These models are based on interchange reactions in systems consisting of inorganic salts. Composition figures (polytopes) are generally partitioned without considering the formation of binary and triple salts. However, as will be demonstrated in the present review, phase diagrams of compositions corresponding to conversion elements, which were determined experimentally by differential thermal analysis (DTA), provide sufficient information also on complexation processes in multicomponent systems.

Non-equilibrium and singular stars, which are graphical models of reciprocal systems, reflect the compositions of simplex cells resulting from the partition of polytopes. Radishchev [2] considered a singular star as a stable complex of a system and defined it as a combination of geometric models of the system derived by partitioning the composition figures into simplexes. Therefore, a singular star consists of stable simplexes and is represented as a graph. Alekseeva and Dombrovskaya [5] characterised a singular star as an equilibrium chemical diagram. The latter is a geometric figure that represents a combination of components, which do not react with each other on mixing.

The partition of composition diagrams and location of the compositions of simplex cells in reciprocal systems are determined by exchange reactions occurring in these systems. According to the criterion proposed by Voskresenskaya,[2,3] the exchange reactions are shifted toward the formation of a salt pair, which is derived from another salt pair with heat evolution ($\Delta_f H_{298} < 0$). The validity of this criterion was confirmed by numerous experiments.[2,3]

The partition can be carried out in various ways, *e.g*., using geometric, matrix and combined (matrices + graphs) approaches. Methods were developed for partitioning polytopes into multidimensional figures consisting of any number of components with the use of tables of vertex indices in the absence of connections between salts [3] and taking into account the complex formation in terms of the graph theory.[4]

An intersection of non-equilibrium and equilibrium complexes of a system gives geometric elements, which model interchange reactions (the so-called conversion elements).

† In physicochemical analysis of multicomponent salt systems, the term 'conversion' is used to describe transformations of two salts into two other salts, both pairs having the same ion composition and different molecular compositions. The conversions of basic and secant elements are distinguished.

In systems containing no less than 9 salts, the basic elements are salt compositions corresponding to geometric figures, which serve as the basis of simplexes of a cyclic fragment of a star (triangles for quinary reciprocal systems consisting of nine salts, tetrahedra for senary reciprocal systems consisting of 12 salts, *etc.*).

The secant elements are geometric figures corresponding to metastable pairs of the starting salts, which react to form reaction products (a non-equilibrium partition), or stable salt pairs formed by exchange reactions (an equilibrium partition). The diagonals of a composition square of a system serve as secant elements for ternary reciprocal systems, two triangles serve as secant elements for quaternary reciprocal systems consisting of six salts, *etc.*

Non-equilibrium and equilibrium partitions can be represented in a matrix form as tables of vertex indices and matrices of reciprocal salt pairs. In matrices used in physicochemical analysis, both composition figures and exchange reactions occurring in the system as well as the reaction products and particular thermochemical relations are encoded. For example, a matrix referred to as a table of vertex indices [2,3] contains information on how many times each salt is formed in the system under consideration by exchange reactions. The composition of a system is expressed by ions rather by the formulas of salts, and the compositions of the salts are seen at the intersection of a row and a column of the matrix. For example, the table of vertex indices for the A,B//X,Y,Z,T system (A and B are cations; X, Y, Z and T are anions) is as follows:

	X	Y	Z	T
A	0	1	2	3
B	3	2	1	0

In this matrix, the AY salt is a product of one exchange reaction (1), and the BT salt is metastable (0), *i.e.*, the latter is the starting compound rather than a product of any reaction.

In a matrix of reciprocal salt pairs,[3] the numbers 1 and 0 signify stability and instability, respectively, of a salt pair. Compounds produced in an exchange reaction are denoted by unity. The number of unities is equal to the number of exchange reactions in the system. For example, the matrix for a quaternary reciprocal system A,B//X,Y,Z consisting of four salts is as follows:

	BX	BY	BZ
AX	0	1	1
AY	0	0	1
AZ	0	0	0

Radishchev [2] introduced the concepts of a point of complete conversion and a point of incomplete conversion for ternary reciprocal systems and the concept of a conversion line for quaternary reciprocal systems. These concepts are used in physicochemical analysis. Radishchev derived components of conversion figures of secant elements for reciprocal systems consisting of eight salts and considered the conversion of axial (basic) triangles and secant elements of quinary reciprocal systems consisting of nine salts. The further development of these concepts involved three lines.

1. The construction of conversion figures of basic elements.[3] Presently, this line of investigation has no practical application.

2. The construction and investigation of conversion figures of secant elements.[6] These figures reflect the main thermochemical relations and the energetics of exchange reactions.

3. The construction of conversion figures taking into account the formation of binary and ternary compounds involving salts. These figures are very complicated, and calculations for these systems can be carried out only on a computer. The energy characteristics of particular compositions can be estimated by calculation methods (these characteristics can also be estimated using conversion figures of secant elements, the procedure being more simple). This line of investigation has not been developed in detail.

The second line served as the basis for devising a conversion method for studying reciprocal multicomponent systems.[6] This method was used for solving a number of theoretical problems and practical tasks.[7,8] For example, this method made it possible to choose salt compositions characterised by the optimal heat-accumulation properties [8–10] and determine the final target products in complex mixtures.[11]

The first review on the conversion method was given in the monograph,[3] where the essence of this method was presented, procedures for deriving conversion elements were considered, examples of conversion figures and the prediction of phases, which crystallise from melts modelled by these figures, were offered, and a proximate method for studying multicomponent reciprocal systems was briefly described.

Phase complexes of systems were extensively studied by the conversion method in the late 1970s/early 1980s. Selected results were given in the monograph;[11] however, a systematic review was lacking. The practical application of the conversion method to the solution of applied problems (in particular, for heat accumulation) was described in the monograph.[8] More recent reviews on the modelling of conversion processes are lacking. This method was only briefly mentioned (a few references were given) in the monograph,[4] because the latter was devoted to an alternative methodology for studying complex salt systems.

Up to the mid-1990s, experimental data on conversion elements and their practical applications were accumulated.[11–18] Theoretical studies were devoted primarily to a combination of the conversion and matrix methods and examination of energy transfer processes in exchange reactions.[19–31] In this period, a method was devised for the construction of singular stars of tetrahedra from conversion elements; matrices of conversion figures and conversion graphs were derived; the structures of conversion figures of quinary reciprocal systems of the 3//3 series were refined; the fine energy structure of axial triangles of quinary reciprocal systems consisting of nine salts was revealed; the mechanism of transformation of a system from a non-equilibrium state to an equilibrium state was studied and intermediate stars of pentatopes and tetrahedra of reciprocal systems of the 3//3 series were derived; energy diagrams for the transformation from a non-equilibrium combination of three salts (a non-equilibrium triangle) to an equilibrium state (a stable axial triangle) were constructed; relationships between various models of conversion processes were revealed. Based on the conversion method, heat-accumulation compositions were developed, and studies of the behaviour of ionic liquids in multicomponent melts at various temperatures were started.

The concept of rational investigation of multicomponent reciprocal salt systems in melts was elaborated. This concept is based on thermochemical (energy) criteria and Kurnakov's correspondence principle.

The aim of the present review is to summarise data on the modelling of conversion processes in salt melts. Theoretical and experimental studies, which were performed in the last 20 years, were surveyed. The relationship between models used in studies of exchange equilibria was demonstrated. The conversion method of investigation of reciprocal systems was shown to be of importance in solving technological problems and developing fundamental sciences.

II. Conversion figures, conversion graphs and matrices

1. Ternary reciprocal systems

A stable secant complex of ternary reciprocal systems consisting of four salts is represented by one stable diagonal, which divides the composition square of a system into two ternary systems (Fig. 1). The stable AX – BY diagonal intersects the metastable AY – BX diagonal (a metastable secant complex) in the centre of

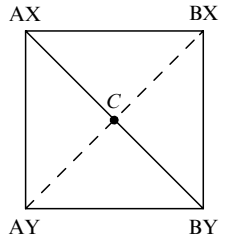

Figure 1. Composition square of the ternary reciprocal system A,B//X,Y with the full conversion point *C*.

the square, *viz*., at the point *C* (a point of complete conversion). At this point, salts of a metastable pair are completely transformed into a stable pair (complete conversion):

$$AY + BX = AX + BY.$$

An incomplete transformation of salts, *i.e*., incomplete conversion, corresponds to an arbitrary point of the composition figure, for example, on the metastable diagonal, but off the conversion point.

2. Quaternary reciprocal systems consisting of six salts

The conversion figure of a quaternary reciprocal system A,B,C//X,Y consisting of six salts of the 2//*n* (*n*//2) series contains two conversion lines denoted in the Fig. 2 as *EF* and *FT*. The points of complete conversion are *E*, *T* and *F*. The following exchange reactions correspond to these points:

for the point *E*: $CX + AY = AX + CY$, the first-stage reaction,

for the point *T*: $AX + BY = AY + BX$, the first-stage reaction,

for the point *F*: $CX + BY = BX + CY$, the second-stage reaction.

By summing these equations, we obtain

$$2\,CX + AY + 2\,BY + AX = AX + 2\,CY + 2\,BX + AY$$

or

$$CX + BY = CY + BX.$$

Hence, two first-stage reactions in the A,B,C//X,Y system are independent, whereas the reaction corresponding to the point of complete conversion *F* depends on the first-stage reactions.

The full conversion figure includes three points of complete conversion denoted as *E*, *F* and *T* (in accordance with the number of interchange reactions occurring in the system) and two conversion lines (see Fig. 2) converging to a common point corresponding to the second-stage reaction.

Since the conversion figure is a part of a composition figure, one can construct the phase diagram of the system under study using the lines of the conversion figures as the composition axis. The conversion figure is a polythermal section, which reflects the dependence of the melting point on the combination of salt pairs. This diagram displays salts, which initially crystallise from melts, secondary, tertiary, *etc*. crystallisation products and temperatures corresponding to invariant points.

If only vertices and edges of a conversion figure are displayed, one obtains a conversion graph. The vertices of this graph correspond to salt pairs or thermal effects of exchange reactions giving rise to these salts. In the latter case, the graph is referred to as an energy graph. This graph can be used for thermochemical calculations.

Each vertex of a conversion figure or a conversion graph corresponds to a reaction of a particular stage, and the degree of this vertex (*i.e*., the number of edges incident to this vertex) depends on the stage of the corresponding reaction. As a rule, the higher the stage, the larger the number of edges incident to the vertex of the graph corresponding to this reaction. Therefore, the number of reactions of a particular stage can directly be determined from the graph. The number of edges incident from vertices of conversion graphs for systems containing different numbers of salts are given in Table 1.

Rapid progress in computer technology made it possible to use matrix methods for displaying composition figures and physicochemical interactions in systems,[3] and, consequently, the use of the conversion method [6] for solving various applied problems on a computer caused a need to go from geometric objects, *viz*., graphs of conversion figures, to matrices of these figures.[32, 33]

It is known that each graph has its own adjacency matrix $A = (a_{ij})$ with dimensions $n \times n$, in which the element a_{ij} is equal to the number of edges of the graph connecting the vertices V_i and V_j. The distinguishing feature of the graphs of conversion figures is that they have no multiple edges. Hence, elements of rows and columns of the matrix can be only 1 or 0. The number of rows and columns in the matrix is determined by the number of vertices of the graph, *i.e*., the number of points of complete conversion of ternary reciprocal systems involved in the figure. For example, the graph of a conversion figure of any quaternary reciprocal system consisting of 6 salts can be expressed by a matrix, in which the points *A* and *C* correspond to first-stage reactions, and the point *B* corresponds to a second-stage reaction.

	A	*B*	*C*
A	0	1	0
B	1	0	1
C	0	1	0

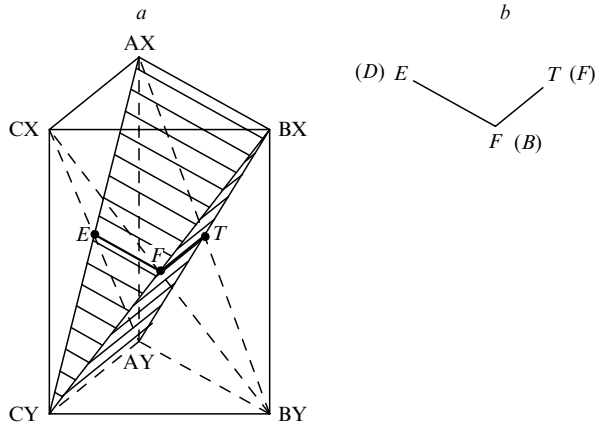

Figure 2. Arrangement of the conversion lines in the composition prism (*a*) and the conversion figure (*b*) of the quaternary reciprocal system A,B,C//X,Y (letters in parentheses correspond to a special case, *viz*., the Na,K,Ba//F,WO_4 system).

Table 1. Number of edges of conversion graphs incident to the points corresponding to reactions of particular stages for systems consisting of 4 – 12 salts.

Number of salts	Number of edges for the reaction of stage				
	I	II	III	IV	V
4	1	0	0	0	0
6	1	2	0	0	0
8	2	3	4	0	0
9 of the type					
A ⇄ B	2	5	5	8	0
C	3	3	0	8	0
D ⇄ E	2	6	0	0	0
10 (2//*n* series)	3	4	5	6	0
12 (2//*n* series)	4	5	6	7	8

The matrix of a conversion graph has the following properties.

1. The sum of the numbers in each row and each column is equal to the degree of the corresponding vertex of the graph (in the above matrix, the point *B* has two connections, and the points *A* and *C* each have one connection).

2. The matrix is symmetric with respect to the diagonal, whose elements are zero.

3. The matrix unambiguously defines the graph with an accuracy of up to isomorphous; hence, the corresponding graph can be constructed based on any matrix.

For practical use of a conversion figure, it is not necessary to construct the corresponding graph from the adjacency matrix. Geometric objects can completely be excluded, because the matrix of a conversion figure contains all necessary information. For example, the degree of a vertex of a graph defines not only the number of edges connecting this vertex to other vertices (*i.e.*, the number of conversion lines) but also the number of chemical reactions giving rise to the corresponding salt pair, as well as the reaction stage (the diagonal), on which the conversion point is located, and the compositions of simplexes of a singular star.

3. Quinary reciprocal systems consisting of eight salts of the 2//*n* (*n*//2) series

A conversion figure of a quinary reciprocal system consisting of eight salts (Fig. 3) contains six vertices (in accordance with the number of exchange reactions), eight conversion lines, two conversion triangles (*4–1–6* and *2–6–5*) and one conversion square (*3–5–6–4*). The third-stage reaction corresponds to the vertex 6, which has the largest number of connections to other vertices. The second-stage reactions correspond to the points *4* and *5*. The vertices *1*, *2* and *3* are the points of complete conversion of ternary reciprocal systems, in which first-stage reactions proceed.

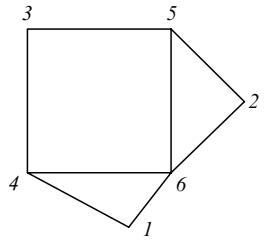

Figure 3. Conversion figure of a quaternary reciprocal system consisting of eight salts.

A conversion figure is a geometric model of chemical processes occurring in a system. This figure forms as the intersection of stable and metastable complexes or singular or non-equilibrium stars. Each element of the conversion figure (a point, a line, a plane, *etc.*) models exchange reactions taking place in the system. The point reflects a reaction of one salt pair (*i.e.*, one reaction), the line reflects an interaction between two salt pairs (two reactions), the plane reflects an interaction between three salt pairs (three reactions), *etc*. For systems including no less than 5 components, a fragment of the conversion figure enclosed by four conversion lines, which is commonly referred to as a conversion square, can be divided by the diagonal into two triangles.

Conversion triangles and squares have central points, which are points of complete conversion for a particular number of reactions. For each point of the conversion figure, a chemical reaction can be constructed. The number of salts involved in this reaction is equal to the number of these salts located at the vertices, which enclose this fragment of the conversion figure. The reaction equations include salts in stoichiometric amounts.

As an example we refer to the quinary reciprocal system Li,Na//Br,Cl,NO_3,SO_4 consisting of 8 salts. The thermochemical characteristics of this system are given in Table 2.

The matrix of the conversion graph for this system takes the form

	1	*2*	*3*	*4*	*5*	*6*
1	0	0	0	1	0	1
2	0	0	0	0	1	1
3	0	0	0	1	1	0
4	1	0	1	0	0	1
5	0	1	1	0	0	1
6	1	1	0	1	1	0

Table 2. Points of complete conversion and thermochemical relations for the quinary reciprocal system Li,Na//Br,Cl,NO_3,SO_4 .

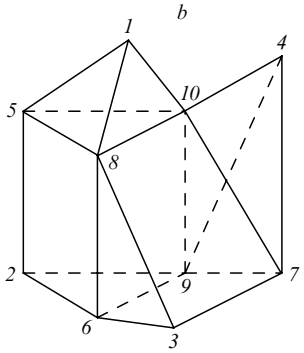
Point	Ternary reciprocal system	Stable salt pair	Reaction	
			stage	*Q*
1	Li,Na//Cl,Br	LiCl + NaBr	I	Q_1
2	Li,Na//NO_3,SO_4	Li_2SO_4 + $NaNO_3$	I	Q_2
3	Li,Na//Cl,NO_3	$LiNO_3$ + NaCl	I	Q_3
4	Li,Na//Br,NO_3	$LiNO_3$ + NaBr	II	$Q_4 = Q_1 + Q_3$
5	Li,Na//Cl,SO_4	Li_2SO_4 + NaCl	II	$Q_5 = Q_2 + Q_3$
6	Li,Na//Br,SO_4	Li_2SO_4 + NaBr	III	$Q_6 = Q_1 + Q_2 + Q_3$

4. Senary reciprocal systems consisting of ten salts of the 2//*n* (*n*//2) series

The conversion figure of a senary reciprocal system shown in Fig. 4 *a*,*b* contains conversion points, lines, triangles and squares along with bulk elements, such as conversion tetrahedra

a

	Na_2SO_4	$NaNO_3$	NaCl	NaBr	NaI
Li_2SO_4	0	1	1	1	1
$LiNO_3$	0	0	1	1	1
LiCl	0	0	0	1	1
LiBr	0	0	0	0	1
LiI	0	0	0	0	0



c

	I^-	Br^-	Cl^-	NO_3^-	SO_4^{2-}
Li^+	0	1	2	3	4
Na^+	4	3	2	1	0

Figure 4. Conversion graph inscribed in the matrix of mutual salt pairs (*a*), the conversion figure of secant tetrahedra (*b*) and the table of vertex indices (*c*) of the senary reciprocal system Li,Na//Cl,Br,I,NO_3,SO_4 consisting of ten salts.

(*1–5–10–8* and *4–7–9–10*) and triangular prisms (*4–7–10–8–6–3* and *5–8–10–9–6–2*). The point *10*, from which six conversion lines emerge, corresponds to a fourth-stage reaction. The points *8* and *9* (five lines) correspond to third-stage reactions. The points of complete conversion, from which four conversion lines emerge (the points *7*, *6* and *5* in Fig. 4 *b*), correspond to second-stage reactions.

Other vertices are points of complete conversion modelling first-stage reactions. The matrix table of vertex indices of the senary reciprocal system Li,Na//Br,Cl,I,NO_3,SO_4 is presented in Fig. 4 *c*.

5. Quinary reciprocal salt systems consisting of nine salts of the 3//3 series

Three thermochemical (five topological A, B, C, D, E) types of reciprocal quinary systems, *viz*., 9A ⇄ 9B, 9C ⇄ 9C′ and 9D ⇄ 9E, are known.[2] These pairs are characterised by the same set of reactions of particular stages (Table 3). However, their singular stars have different geometry (different topology) and, correspondingly, different notations.

Table 3. Number of reactions of particular stages for reciprocal systems of the 3//3 series.

Type of system	Number of reactions of a given stage			
	I	II	III	IV
9A ⇄ 9B	4	2	2	1
9C ⇄ 9C′	4	4	0	1
9D ⇄ 9E	6	3	0	0

The conversion figure of a reciprocal system of any thermochemical type of the 3//3 series is a graph, whose vertices correspond to points of complete conversion of ternary reciprocal systems involved in a more complex system (Figs 5–7). The lines of complete conversion of quaternary reciprocal systems serve as edges of the graph. For systems of the 2//*n* (*n*//2) series, the conversion figures contain no other conversion elements. Hence, the thermochemical type of the conversion figure coincides with the topological type. The structures of the conversion figures of quinary reciprocal systems of the 3//3 series are complicated,

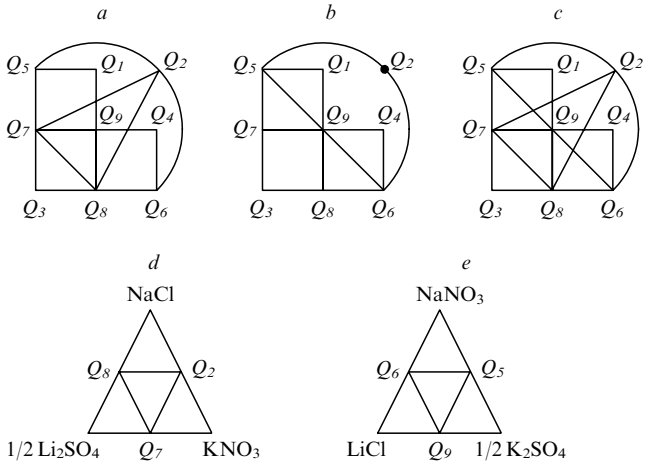


Figure 5. Conversion figures of quinary reciprocal systems consisting of nine salts of different topological types.
(*a*) 9A type; (*b*) 9B type; (*c*) 9A ⇄ 9B type; (*d*) the conversion lines $Q_9–Q_2–Q_7$ intersecting the axial stable triangle of the 9A ⇄ 9B-type Li,Na,K//Cl,NO_3,SO_4 system; (*e*) the conversion lines $Q_9–Q_5–Q_6$ intersecting the axial metastable triangle of the 9A ⇄ 9B-type Li,Na,K// Cl,NO_3,SO_4 system.

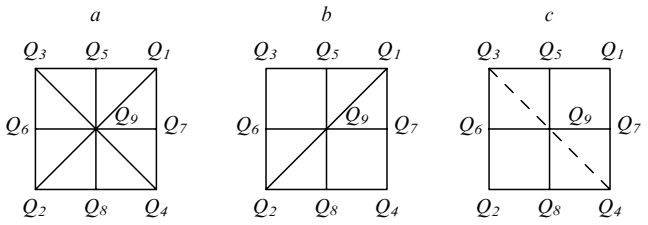

Figure 6. Conversion figures of the 9C-type quinary reciprocal system.
(*a*) The common conversion figure for the 9C ⇄ 9C′ equilibrium; (*b*) the conversion figure with the conversion lines $Q_1–Q_9–Q_2$ intersecting the axial stable triangle; (*c*) the conversion figure with the conversion lines $Q_3–Q_9–Q_4$ intersecting the axial metastable triangle.

because each topological type of these systems is characterised by its own conversion figure. It should be noted that the conversion figures of the same thermochemical type (9A ⇄ 9B, 9C ⇄ 9C′, 9D ⇄ 9E)[6,8] differ in the position of additional lines resulting from the intersection of axial (basic) triangles with conversion planes. Therefore, there are various topological types of conversion figures, which have a common thermochemical framework.

The number of edges incident to a vertex of a graph depends on the stage of the reaction, which is modelled by a particular conversion point. Systems of the 3//3 series differ in the characteristic features from 2//*n* (*n*//2) systems. For example, the points corresponding to second-stage reactions in 9B-type systems (see Fig. 5 *b*, the points Q_5 and Q_6) can have a larger number of connections than the points corresponding to third-stage reactions (the points Q_7 and Q_8 in Fig. 5 *b*).

The points of intersection of the first-stage diagonals in 9C-type systems also have different numbers of connections (Fig. 6, the points Q_1, Q_2, Q_3 and Q_4), which indicates that systems of the 3//3 series are more complicated than systems of the 2//*n* series.

From the thermochemical point of view, the conversion squares of 9C-, 9D- and 9E-type quinary reciprocal systems consisting of nine salts are equivalent, because they have diagonals corresponding to reactions of the same stages: I, II, II, IV (9C type); I, I, II, II (9D and 9E types). In 9A- and 9B-type systems, the conversion squares are thermochemically non-equivalent. For example, the conversion squares for 9A-type systems ($Q_1–Q_5–Q_7–Q_9$ and $Q_4–Q_6–Q_8–Q_9$) have the same sets of stages of the diagonals (I, II, III, IV), whereas the $Q_3–Q_7–Q_8–Q_9$ square differs from these squares (a set of stages of the I, III, III and IV diagonals). The same is true for 9B-type systems: the $Q_1–Q_5–Q_7–Q_9$ and $Q_4–Q_6–Q_8–Q_9$ squares are equivalent,

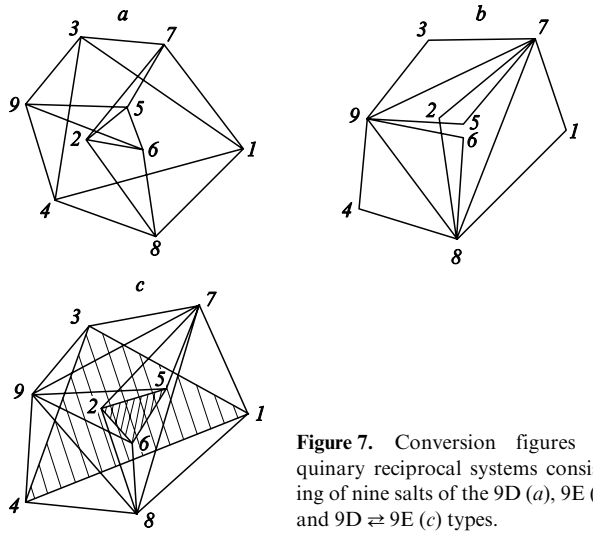

Figure 7. Conversion figures of quinary reciprocal systems consisting of nine salts of the 9D (*a*), 9E (*b*) and 9D ⇄ 9E (*c*) types.

whereas the $Q_3-Q_7-Q_9-Q_8$ square differs from the above two squares. This fact indicates that salts (or salt pairs) in the $Q_3-Q_7-Q_9-Q_8$ (9A type) and $Q_8-Q_9-Q_7-Q_3$ (9B type) squares are less reactive, and this region of the model (a conversion square) is characterised by a smaller number of reactions between salts, which are involved in pairs located at the vertices of this conversion square. The latter can be considered as the most stable square. The nature of the thermochemical non-equivalence of the conversion squares in 9A- and 9B-type systems (see Fig. 5 *a*,*b*) calls for a more detailed study.

Comparative investigation of conversion figures of systems belonging to different topological and thermochemical types may be useful in constructing mixtures of reciprocal salt systems possessing desired properties. Changes in the reactivity of a salt mixture upon the addition of a new component or the replacement of one component with another one can be predicted on the basis of conversion figures.

For example, the replacement of a component in a 9A-type system giving rise to a 9C-type system can lead to an increase in the reactivity of the salt system, because the conversion squares for 9A-type systems contain sets of higher-stage diagonals compared to the set of diagonals of the conversion squares for 9C-type systems. The reactivity of the mixtures can be further increased on going to 9D- or 9E-type systems (see Fig. 7).

Let us consider this relationship using real systems as examples.

a. Type 9A ⇄ 9B

Systems of the 9A ⇄ 9B thermochemical type are characterised by the occurrence of nine reactions (four first-stage reactions, two second-stage reactions, two third-stage reactions and one fourth-stage reaction). Topological conversion graphs for 9A- and 9B-type systems contain nine points corresponding to the number of exchange reactions (see Fig. 5 *a*,*b*), squares and triangles located on different planes of the three-dimensional space resulting from the intersection of secant tetrahedra of singular and non-equilibrium stars.[8]

The main framework of these figures is composed of lines corresponding to conversion figures of quaternary systems consisting of six salts. These lines connect nine vertices of the conversion figure. For example, these are the $Q_5-Q_7-Q_3$, $Q_6-Q_8-Q_3$, $Q_1-Q_9-Q_8$, $Q_4-Q_9-Q_7$, $Q_1-Q_5-Q_2$ and $Q_2-Q_6-Q_4$ lines in 9A-type systems (see Fig. 5 *a*). The inner lines, *viz*., Q_7-Q_8, Q_2-Q_8 and Q_2-Q_7 in 9A-type systems and Q_5-Q_6, Q_5-Q_9 and Q_6-Q_9 in 9B-type systems (see Fig. 5 *b*), are a special case. These lines intersect the planes of axial (stable and metastable) triangles (see Fig. 5 *d*,*e*). In Fig. 5 *c*, three conversion squares ($Q_1-Q_5-Q_7-Q_9$, $Q_3-Q_7-Q_9-Q_8$ and $Q_4-Q_6-Q_8-Q_9$) reflect chemical interactions in the quinary reciprocal system consisting of nine salts.

b. Type 9C ⇄ 9C′

The conversion figure of quinary systems of the 9C ⇄ 9C′ thermochemical type (see Fig. 6) contains nine vertices (in accordance with the number of points of complete conversion of ternary reciprocal systems involved in a quinary reciprocal system consisting of nine salts) and 16 lines, twelve of which are fragments of the conversion figures of all six reciprocal systems consisting of six salts involved in the quinary system.[8] Four lines emerging from the central point of the square (the point of intersection of the stable highest-stage diagonal with the corresponding metastable diagonal) are special lines. Both the stable and metastable axial triangles are divided into four triangles by these lines together with the conversion line of basic elements of a 9C ⇄ 9C′-type quinary reciprocal system consisting of nine salts.

c. Type 9D ⇄ 9E

The conversion figure of reciprocal systems of the 9D ⇄ 9E thermochemical type is a graph (see Fig. 7), whose vertices correspond to nine points of complete conversion of nine ternary reciprocal systems and edges correspond to 12 conversion lines of quaternary reciprocal systems consisting of six salts. The inner lines corresponding to interactions between all salts of the system are the *7–8*, *8–9*, *7–9* (E type); *5–6*, *5–2*, *2–6* (D type); *1–4*, *4–3*, *1–3* (common) lines, which intersect the planes of two stable axial triangles and one metastable triangle.

Nine diagonals (six first-stage diagonals and three second-stage diagonals) serve as thermochemical characteristics of 9D ⇄ 9E-type systems.

The thermal effects of the second-stage reactions can be expressed in a dual fashion as the sums of the thermal effects of first-stage reactions.

$$Q_2 + Q_3 = Q_1 + Q_5 = Q_7,$$

$$Q_1 + Q_6 = Q_2 + Q_4 = Q_8,$$

$$Q_4 + Q_5 = Q_3 + Q_6 = Q_9.$$

From these equations it follows that

$$Q_2-Q_1 = Q_5-Q_3 = Q_6-Q_4.$$

These relations can be used for solving problems associated with the construction of systems possessing the desired thermochemical characteristics of salt compositions.

III. Methods of construction of conversion figures

Several methods were developed for the construction of conversion figures, the so-called, geometric, thermochemical and matrix methods.

As mentioned above, the geometric method[2] is very complicated, because it requires the use of multidimensional geometry. According to this method, the conversion figures are constructed by intersecting stable and metastable complexes.

The thermochemical method[8] is based on thermochemical relations, which are used for the construction of an energy graph. Generally, the centre of this graph is occupied by a conversion point corresponding to the highest thermal effect, which is the sum of several thermal effects. This point has the largest number of thermochemical connections. For example, the point Q_9 for 9C ⇄ 9C′-type systems consisting of nine salts (see Fig. 6 *c*) has six connections and is connected to all points corresponding to reactions with independent thermal effects (first-stage reactions). The latter points have a minimum number of connections (three) and are connected to points corresponding to reactions with dependent thermal effects (as summands) and the point corresponding to the reaction with the highest thermal effect. The points corresponding to the thermal effects of second-stage reactions are connected to the points corresponding to first-stage reactions and the point corresponding to the reaction with the highest thermal effect. Three lines emerge from each of these points.

The conversion figure for systems of the 2//*n* type can be constructed from conversion figures of lower dimensionality. For example, the conversion figure of secant tetrahedra for systems of the 2//4 series can be constructed from the conversion figures of systems of the 2//3 series.

The matrix metod[8,33] will be discussed below.

1. The thermochemical method for the construction of conversion figures of systems of the 2//*n* (*n*//2) series

Conversion figures of systems of the 2//*n* (*n*//2) series are shown in Figs 1; 2 *a*,*b*; 3; 4 *a*,*b*.

Let us consider the method for the construction of conversion figures of a quaternary reciprocal system consisting of six salts using the Li,Na//Cl,NO_3,SO_4 system as an example. The conversion figure of reciprocal systems of the 2//3 (3//2) series is constructed based on thermochemical relations. The point of complete conversion corresponding to a second-stage reaction is connected by conversion lines to the points corresponding to first-stage reactions. The thermochemical relations for the Li,Na//

Table 4. Thermochemical relations for the Li,Na//Cl,NO_3,SO_4 system.

Ternary reciprocal system	Stable salt pair	Reaction [a]	
		stage	Q /kJ (mol equiv)$^{-1}$
Li,Na//Cl,SO_4	Li_2SO_4 + NaCl	II	$Q_3 = Q_1 + Q_2 = 26.78$
Li,Na//NO_3,SO_4	Li_2SO_4 + $NaNO_3$	I	$Q_1 = 7.95$
Li,Na//Cl,NO_3	$LiNO_3$ + NaCl	I	$Q_2 = 18.83$

[a] Hereinafter, the thermal effects of the reactions are given in kJ per mole of equivalents.

Cl,NO_3,SO_4 system are given in Table 4. The elements of the conversion figure of this system are listed in Table 5.

Three points of complete conversion correspond to the following chemical reactions:

point *B*: $2\,LiCl + Na_2SO_4 = Li_2SO_4 + 2\,NaCl - Q_3$,

point *C*: $2\,LiNO_3 + Na_2SO_4 = Li_2SO_4 + 2\,NaNO_3 - Q_1$,

point *A*: $2\,LiCl + 2\,NaNO_3 = 2\,LiNO_3 + 2\,NaCl - Q_2$.

The composition figures of systems of the 2//4 (4//2) series have three first-stage diagonals, two second-stage diagonals and one third-stage diagonal. The conversion figure of these systems consists of two triangles and one quadrangle connected in a particular manner.

Table 5. Conversion elements for the Li, Na//Cl,NO_3,SO_4 system.

Conversion element	Salt composition
Point *A*	$LiNO_3$, NaCl
Point *B*	Li_2SO_4, NaCl
Point *C*	Li_2SO_4, $NaNO_3$
Line *A* – *B*	Li_2SO_4, $LiNO_3$, NaCl
Line *B* – *C*	Li_2SO_4, NaCl, $NaNO_3$

The thermochemical relations in the quinary system Li,Na// Br,Cl,NO_3,SO_4 consisting of eight salts are given in Table 6. The elements of the conversion figure are shown in Fig. 8.

Table 6. Thermochemical relations for the Li,Na//Br,Cl,NO_3,SO_4 system.

Ternary reciprocal system	Metastable pair	Stable pair	Reaction	
			stage	Q
Li,Na//Cl,Br	LiBr + NaCl	LiCl + NaBr	I	Q_1
Li,Na// NO_3,SO_4	$LiNO_3$ + + Na_2SO_4	Li_2SO_4 + + $NaNO_3$	I	Q_2
Li,Na//Cl,NO_3	LiCl + $NaNO_3$	$LiNO_3$ + NaCl	I	Q_3
Li,Na//Br,NO_3	LiBr + $NaNO_3$	$LiNO_3$ + NaBr	II	$Q_4 = Q_1 + Q_3$
Li,Na//Cl,SO_4	LiCl + Na_2SO_4	Li_2SO_4 + NaCl	II	$Q_5 = Q_2 + Q_3$
Li,Na//Br,SO_4	LiBr + Na_2SO_4	Li_2SO_4 + NaBr	III	$Q_6 = Q_1 + Q_2 + Q_3$

The conversion figure for the Li,Na//Br,Cl,NO_3,SO_4 system is constructed based on the thermochemical relations taking into account the following facts. The centre of the conversion figure should be occupied by a point corresponding to the maximum thermal effect. This is the point *B* in Fig. 8 corresponding to intersection of the stable Li_2SO_4 – NaBr diagonal (a third-stage diagonal) and the metastable LiBr – Na_2SO_4 diagonal. The point *B* has the maximum number of connections to points of intersection of the lowest-stage diagonals (four connections).

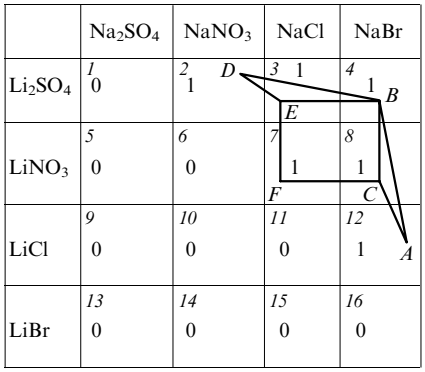

Figure 8. Conversion graph of the quaternary reciprocal system Li,Na// Cl,Br,NO_3,SO_4 inscribed in the matrix of mutual salt pairs.

These are the points *A* (a point of intersection of the first-stage diagonals LiCl – NaBr and LiBr – NaCl), *D* (a point of intersection of the first-stage diagonals Li_2SO_4 – $NaNO_3$ and $LiNO_3$ – Na_2SO_4), *E* (a point of intersection of the second-stage diagonals Li_2SO_4 – NaCl and LiCl – Na_2SO_4) and *C* (a point of intersection of the second-stage diagonals $LiNO_3$ – NaBr and LiBr – $NaNO_3$).

The points of intersection of second-stage diagonals (*E* and *C*) each have three connections to the points of intersection of first-stage diagonals (*A*, *D* and *F*) and the point of intersection of fourth-stage diagonals (*B*). Finally, the points of intersection of first-stage diagonals *A*, *D* and *F* each have two connections (see Fig. 8).

The conversion elements for the Li,Na//Br,Cl,NO_3,SO_4 system are given in Table 7.

The following reactions occur in the system:

point *A*: $2\,LiBr + 2\,NaCl =$ (1)

$= 2\,LiCl + 2\,NaBr - 6.69$ kJ (mol equiv)$^{-1}$,

point *B*: $2\,LiBr + Na_2SO_4 =$ (2)

$= Li_2SO_4 + 2\,NaBr - 33.47$ kJ (mol equiv)$^{-1}$,

point *C*: $2\,LiBr + 2\,NaNO_3 =$ (3)

$= 2\,LiNO_3 + 2\,NaBr - 25.52$ kJ (mol equiv)$^{-1}$,

point *D*: $2\,LiNO_3 + Na_2SO_4 =$ (4)

$= Li_2SO_4 + 2\,NaNO_3 - 7.95$ kJ (mol equiv)$^{-1}$,

Table 7. Conversion elements for the Li,Na//Br,Cl,NO_3,SO_4 system.

Conversion element	Salt composition
Point *A*	LiCl, NaBr
Point *B*	Li_2SO_4, NaBr
Point *C*	$LiNO_3$, NaBr
Point *D*	Li_2SO_4, $NaNO_3$
Point *E*	Li_2SO_4, NaCl
Point *F*	$LiNO_3$, NaCl
Line *A* – *B*	Li_2SO_4, NaBr, LiCl
Line *A* – *C*	$LiNO_3$, NaBr, LiCl
Line *B* – *C*	Li_2SO_4, $LiNO_3$, NaBr
Line *B* – *E*	Li_2SO_4, NaBr, NaCl
Line *B* – *D*	Li_2SO_4, $NaNO_3$, NaBr
Line *C* – *F*	$LiNO_3$, NaBr, NaCl
Line *D* – *E*	Li_2SO_4, $NaNO_3$, NaCl
Line *E* – *F*	Li_2SO_4, $LiNO_3$, NaCl
Triangle *A* – *B* – *C*	Li_2SO_4, $LiNO_3$, LiCl, NaBr
Triangle *B* – *E* – *D*	Li_2SO_4, $NaNO_3$, NaCl, NaBr
Plane *B* – *C* – *F* – *E*	Li_2SO_4, $LiNO_3$, NaCl, NaBr

point E: $2\,LiCl + Na_2SO_4 =$ (5)

$= Li_2SO_4 + 2\,NaCl - 26.78$ kJ (mol equiv)$^{-1}$,

point F: $2\,LiCl + 2\,NaNO_3 =$ (6)

$= 2\,LiNO_3 + 2\,NaCl - 18.83$ kJ (mol equiv)$^{-1}$.

By summing the reactions (1)–(6), we obtain the overall equation for the chemical reactions proceeding in a reciprocal system consisting of eight salts

$$6\,LiBr + 2\,LiCl + 3\,Na_2SO_4 + 2\,NaNO_3 = 3\,Li_2SO_4 + 2\,LiNO_3 + 2\,NaCl + 6\,NaBr.$$

The right-hand side of the equation represents the most stable salt composition. In the diagram of this system, this composition is modelled by a four-vertex sphenoid, which can include stable eutectic mixtures characterised by the highest thermal capacity.[8]

2. The thermochemical method for the construction of conversion figures of the 3//3 series

The principle for the construction of conversion figures of secant tetrahedra for reciprocal systems consisting of nine salts of various thermochemical types is analogous to that used for systems of the 2//n (n//2) series. Let us consider selected systems.

a. System Li,Cd,Na//Cl,NO$_3$,SO$_4$ (9A type)

The centre of the conversion graph (see Fig. 5 *a*) is occupied by the point Q_9 corresponding to intersection of fourth-stage diagonals (the $LiNO_3 + CdCl_2$ salt pair). This point has four thermochemical connections to the points Q_1, Q_4 (points of intersection of first-stage diagonals) and Q_7, Q_8 (points of intersection of third-stage diagonals). Data on the salt compositions corresponding to these points, the reaction stages and constituent thermal effects are given in Table 8. The points of intersection of third-stage diagonals Q_7 and Q_8 each have 5 connections: one connection between these points (Q_7-Q_8 lines), one connection to the point Q_9, one connection to the point Q_2, one connection to the point Q_3 (the latter three points correspond to first-stage reactions; the Q_3-Q_8, Q_3-Q_7 and Q_2-Q_7, Q_2-Q_8 lines) and connections to the points of intersections of second-stage diagonals (the Q_6-Q_8 and Q_5-Q_7 lines).

The following three connections correspond to the points of intersection of second-stage diagonals Q_5 and Q_6: two connections to the points of intersection of first-stage diagonals (the Q_1-Q_5, Q_2-Q_5, Q_2-Q_6 and Q_4-Q_6 lines) and connections to the points of intersection of third-stage diagonals (the Q_5-Q_7 and Q_6-Q_8 lines). The points of intersection of first-stage diagonals have the minimum number of connections (2) (except for the point Q_2). These points form the Q_1-Q_5, Q_2-Q_5, Q_1-Q_9, Q_2-Q_6, Q_2-Q_7, Q_2-Q_8, Q_3-Q_7, Q_3-Q_8 and Q_4-Q_6, Q_4-Q_9 lines.

Each of three conversion squares and the conversion triangle (see Fig. 5 *a*) are characterised by a particular set of stages of stable diagonals. These three conversion squares are thermochemically non-equivalent. The conversion square $Q_9-Q_8-Q_3-Q_7$ includes a point of intersection of fourth-stage diagonals, two points of intersection of third-stage diagonals and one point of intersection of first-stage diagonals. Consequently, these points correspond to the most stable salts of the system.

The relationships between the geometric elements of conversion and the chemical composition of the quinary reciprocal system Li,Cd,Na//Cl,NO$_3$,SO$_4$ are given in Table 9. The conversion figure of this system is characterised by the following features: the point of complete conversion of ternary reciprocal systems corresponds to crystallisation of two salts with different cations and anions; the conversion line of quaternary reciprocal systems corresponds to crystallisation of four salts with either three different cations and two different anions or with two different cations and three different anions; the planes, which characterise interactions in the quinary reciprocal system, correspond to crystallisation of four or five salts. (The conversion figure of the thermochemical type 9A ⇄ 9B is shown in Fig. 5 *c*.)

Table 8. Points of complete conversion and thermochemical relations for the Li,Cd,Na//Cl,NO$_3$,SO$_4$ system.

Point	Ternary reciprocal system	Stable salt pair	Reaction	
			stage	Q /kJ (mol equiv)$^{-1}$
1	Li,Cd//SO$_4$,NO$_3$	$LiNO_3 + CdSO_4$	I	$Q_1 = 2.51$
2	Li,Na//SO$_4$,NO$_3$	$NaNO_3 + Li_2SO_4$	I	$Q_2 = 7.95$
3	Na,Cd//Cl,SO$_4$	$Na_2SO_4 + CdCl_2$	I	$Q_3 = 12.55$
4	Li,Na//Cl,NO$_3$	$LiNO_3 + NaCl$	I	$Q_4 = 18.41$
5	Na,Cd//SO$_4$,NO$_3$	$NaNO_3 + CdSO_4$	II	$Q_5 = Q_1 + Q_2 = 10.46$
6	Li,Na//Cl,SO$_4$	$Li_2SO_4 + NaCl$	II	$Q_6 = Q_2 + Q_4 = 26.36$
7	Na,Cd//Cl,NO$_3$	$NaNO_3 + CdCl_2$	III	$Q_7 = Q_1 + Q_2 + Q_3 = 23.01$
8	Li,Cd//Cl,SO$_4$	$Li_2SO_4 + CdCl_2$	III	$Q_8 = Q_2 + Q_3 + Q_4 = 38.91$
9	Li,Cd//Cl,NO$_3$	$LiNO_3 + CdCl_2$	IV	$Q_9 = Q_1 + Q_2 + Q_3 + Q_4 = 41.42$

Table 9. Conversion elements for the Li,Cd,Na//Cl,NO$_3$,SO$_4$ system.

Reciprocal system	Conversion element	Salt composition
Li,Cd//NO$_3$,SO$_4$	point Q_1	$LiNO_3$, $CdSO_4$
Li,Na//NO$_3$,SO$_4$	point Q_2	Li_2SO_4, $NaNO_3$
Na,Cd//Cl,SO$_4$	point Q_3	Na_2SO_4, $CdCl_2$
Li,Na//Cl,NO$_3$	point Q_4	$LiNO_3$, NaCl
Cd,Na//NO$_3$,SO$_4$	point Q_5	$NaNO_3$, $CdSO_4$
Li,Na//Cl,SO$_4$	point Q_6	Li_2SO_4, NaCl
Na,Cd//Cl,NO$_3$	point Q_7	$NaNO_3$, $CdCl_2$
Li,Cd//Cl,SO$_4$	point Q_8	Li_2SO_4, $CdCl_2$
Li,Cd//Cl,NO$_3$	point Q_9	$LiNO_3$, $CdCl_2$
Li,Cd,Na//NO$_3$,SO$_4$	pair of lines $Q_1-Q_5-Q_2$	$LiNO_3$, Li_2SO_4, $NaNO_3$, $CdSO_4$
Na,Cd//Cl,NO$_3$,SO$_4$	pair of lines $Q_5-Q_7-Q_3$	$NaNO_3$, Na_2SO_4, $CdCl_2$, $CdSO_4$
Li,Na//Cl,NO$_3$,SO$_4$	pair of lines $Q_2-Q_6-Q_4$	$LiNO_3$, Li_2SO_4, NaCl, $NaNO_3$
Li,Na,Cd//Cl,SO$_4$	pair of lines $Q_6-Q_8-Q_3$	Li_2SO_4, NaCl, Na_2SO_4, $CdCl_2$
Li,Cd//Cl,NO$_3$,SO$_4$	pair of lines $Q_1-Q_9-Q_8$	$LiNO_3$, Li_2SO_4, $CdCl_2$, $CdSO_4$
Li,Na,Cd//Cl,NO$_3$	pair of lines $Q_4-Q_9-Q_7$	$LiNO_3$, NaCl, $NaNO_3$, $CdCl_2$
Li,Na,Cd//Cl,NO$_3$,SO$_4$	triangle $Q_8-Q_9-Q_7$	$LiNO_3$, Li_2SO_4, $NaNO_3$, $CdCl_2$
	triangle $Q_7-Q_3-Q_8$	Li_2SO_4, $NaNO_3$, Na_2SO_4, $CdCl_2$
	square $Q_4-Q_9-Q_8-Q_6$	$LiNO_3$, Li_2SO_4, NaCl, $CdCl_2$
	square $Q_1-Q_9-Q_7-Q_5$	$LiNO_3$, $NaNO_3$, $CdCl_2$, $CdSO_4$
	square $Q_7-Q_9-Q_8-Q_3$	Li_2SO_4, $NaNO_3$, $LiNO_3$, Na_2SO_4, $CdCl_2$

b. System K,Ba,Na//F,MoO$_4$,WO$_4$ (9B type)

For 9B-type systems (unlike 9A-type systems), the conversion figure of secant tetrahedra contains one conversion square

Table 10. Points of complete conversion and thermochemical relations for the K,Ba,Na//F,MoO_4,WO_4 system.

Point	Ternary reciprocal system	Stable salt pair	Reaction	
			stage	Q /kJ (mol equiv)$^{-1}$
1	Ba,Na// MoO_4,WO_4	Na_2WO_4 + + $BaMoO_4$	I	$Q_1 = 1.67$
2	K,Ba//F,MoO_4	$BaF_2 + K_2MoO_4$	I	$Q_2 = 2.51$
3	Na,K// MoO_4,WO_4	K_2WO_4 + + Na_2MoO_4	I	$Q_3 = 12.34$
4	Ba,Na//F,WO_4	$BaWO_4 + (NaF)_2$	I	$Q_4 = 19.04$
5	K,Ba// MoO_4,WO_4	K_2WO_4 + + $BaMoO_4$	II	$Q_5 = Q_1 + Q_3 = 14.01$
6	Ba,Na//F,MoO_4	$(NaF)_2 + BaMoO_4$	II	$Q_6 = Q_1 + Q_4 = 20.71$
7	K,Na//F,MoO_4	$(NaF)_2 + K_2MoO_4$	III	$Q_7 = Q_1 + Q_2 + + Q_4 = 23.22$
8	K,Ba//F,WO_4	$BaF_2 + K_2WO_4$	III	$Q_8 = Q_1 + Q_2 + + Q_3 = 16.52$
9	K,Na//F,WO_4	$(NaF)_2 + K_2WO_4$	IV	$Q_9 = Q_1 + Q_2 + + Q_3 + Q_4 = 35.56$

$Q_3-Q_7-Q_9-Q_8$ and five conversion triangles, $Q_1-Q_9-Q_5$, $Q_5-Q_7-Q_9$, $Q_4-Q_9-Q_6$, $Q_6-Q_8-Q_9$ and $Q_5-Q_6-Q_9$ (a degenerate triangle, see Fig. 5 *b*,*c*). The thermochemical relations for the K,Ba,Na//F,MoO_4,WO_4 system are given in Table 10.

The framework of the conversion graph for this system is constructed analogously to the conversion graph for 9A-type systems. The difference is that the former contains the additional Q_5-Q_6, Q_5-Q_9 and Q_6-Q_9 lines resulting from the intersection of the conversion figure with the axial triangle of the $(NaF)_2-K_2WO_4-BaMoO_4$ system. The point of intersection of fourth-stage diagonals Q_9 has the largest number of thermochemical connections (six connections) (see Fig. 5 *b*). The points Q_5 and Q_6, which correspond to second-stage reactions, each have four thermochemical connections. The points Q_7 and Q_8 corresponding to third-stage reactions each have three connections, and the points Q_1, Q_2, Q_3 and Q_4 corresponding to first-stage reactions each have two connections.

A chemical conversion reaction of the salts, which are located at the vertices of metastable figures, into salts located at the vertices of stable figures can be written for each point of the conversion figure. To follow the conversion in quinary reciprocal systems consisting of nine salts, one can use special diagrams put forward by Radishchev.[2] These diagrams can be constructed as follows: three-dimensional figures, which intersect each other (a pyramid and a sphenoid), are projected onto the plane of intersection of both spaces ‡ (giving rise to a conversion square, Fig. 9). The metastable and stable diagonals in this planar figure are indicated by dashed and solid lines, respectively.

For the K,Ba,Na//F,MoO_4,WO_4 system, this method gave one of conversion squares $B-Z-T-F$ of secant tetrahedra (see Fig. 9) resulting from the intersection of the metastable sphenoid $(KF)_2-Na_2WO_4-K_2MoO_4-BaWO_4$ and the stable pyramid $(NaF)_2-Na_2MoO_4-BaMoO_4-BaF_2-K_2WO_4$.

The equation for the central point of the conversion square $B-Z-T-F$ has the form

$$2\,(KF)_2 + 2\,Na_2WO_4 + 2\,K_2MoO_4 + 2\,BaWO_4 = \quad (7)$$
$$= (NaF)_2 + BaF_2 + BaMoO_4 + Na_2MoO_4 + 4\,K_2WO_4.$$

‡ The figures are located in different three-dimensional spaces involved in this four-dimensional space.

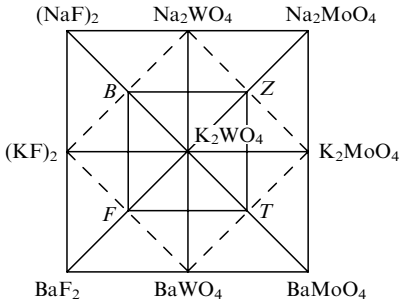

Figure 9. Conversion square $B-Z-T-F$ (a fragment of the conversion figure) of the 9B-type quinary reciprocal system Na,K,Ba//F,MoO_4,WO_4.

The right-hand side of the equation includes a metastable pair of salts, which react according to the equation

$$BaF_2 + Na_2MoO_4 = (NaF)_2 + BaMoO_4. \quad (8)$$

By summing the equations (7) and (8), we obtain

$$2\,(KF)_2 + 2\,Na_2WO_4 + 2\,K_2MoO_4 + 2\,BaWO_4 = \quad (9)$$
$$= 2\,(NaF)_2 + 4\,K_2WO_4 + BaMoO_4.$$

The exchange reactions afford salts, which form a stable axial triangle.

c. System Li,Na,K//Cl,Br,SO_4 (9C type)

Let us consider a procedure for the construction of a conversion figure based on stages of stable diagonals using the Li,Na,K// Cl,Br,SO_4 system as an example (see Fig. 6).

The thermal effects of the second-stage reactions giving rise to the stable $Na_2SO_4 + (KBr)_2$ (Q_5), $(LiCl)_2 + (KBr)_2$ (Q_6), $Li_2SO_4 + (KCl)_2$ (Q_7) and $Li_2SO_4 + (NaBr)_2$ (Q_8) pairs are the sums of two effects, and the thermal effect of the fourth-stage reaction [the stable $Li_2SO_4 + (KBr)_2$ pair (Q_9)] is the sum of four effects (Table 11). Hence, the conversion point corresponding to the second-stage reaction should have the following three connections: two connections to conversion points corresponding to first-stage reactions and one connection to the Q_9 point. Below are given the thermochemical connections for four points of complete conversion.

Table 11. Points of complete conversion and thermochemical relations for the Li,Na,K//Cl,Br,SO_4 system.

Point	Ternary reciprocal system	Stable salt pair	Reaction	
			stage	Q /kJ (mol equiv)$^{-1}$
1	K,Na//Cl,SO_4	$Na_2SO_4 + (KCl)_2$	I	$Q_1 = 3.56$
2	Li,Na//Cl,Br	$(LiCl)_2 + (NaBr)_2$	I	$Q_2 = 6.69$
3	Na,K//Cl,Br	$(KBr)_2 + (NaCl)_2$	I	$Q_3 = 7.53$
4	Li,Na//Cl,SO_4	$Li_2SO_4 + (NaCl)_2$	I	$Q_4 = 26.78$
5	K,Na//Br,SO_4	$Na_2SO_4 + (KBr)_2$	II	$Q_5 = Q_1 + Q_3 = 11.09$
6	Li,K//Cl,Br	$(LiCl)_2 + (KBr)_2$	II	$Q_6 = Q_2 + Q_3 = 14.22$
7	Li,K//Cl,SO_4	$Li_2SO_4 + (KCl)_2$	II	$Q_7 = Q_1 + Q_4 = 30.34$
8	Li,Na//Br,SO_4	$Li_2SO_4 + (NaBr)_2$	II	$Q_8 = Q_2 + Q_4 = 33.47$
9	Li,K//Br,SO_4	$Li_2SO_4 + (KBr)_2$	IV	$Q_9 = Q_1 + Q_2 + + Q_3 + Q_4 = 44.56$

Point of complete conversion	Thermochemical connections
Q_5	Q_1-Q_5, Q_3-Q_5, Q_5-Q_9
Q_6	Q_2-Q_6, Q_3-Q_6, Q_6-Q_9
Q_7	Q_1-Q_7, Q_4-Q_7, Q_7-Q_9
Q_8	Q_2-Q_8, Q_4-Q_8, Q_8-Q_9

The conversion graph presented in Fig. 6 *b*,*c* is constructed based on thermochemical relations in such a way that the central conversion point Q_9 is connected to the points of intersection of second-stage diagonals (the points Q_5, Q_6, Q_7 and Q_8) and the conversion points corresponding to first-stage reactions (Q_1, Q_2, Q_3 and Q_4) along the diagonal of the conversion square.

The main thermochemical framework of the conversion figure of secant tetrahedra for systems consisting of nine salts of any type can also be constructed from the conversion figures of quaternary reciprocal systems consisting of six salts, which are involved in this quinary system of the 3//3 series. The conversion lines of the quaternary reciprocal systems involved in the Li,Na,K//Cl,Br,SO_4 system are as follows:

System	Conversion line
Na,K//Cl,Br,SO_4	$Q_1-Q_5-Q_3$
Li,K//Cl,Br,SO_4	$Q_6-Q_9-Q_7$
Li,Na//Cl,Br,SO_4	$Q_2-Q_8-Q_4$
Li,Na,K//Cl,Br	$Q_3-Q_6-Q_2$
Li,Na,K//Cl,SO_4	$Q_4-Q_7-Q_1$
Li,Na,K//Br,SO_4	$Q_8-Q_9-Q_5$

The above-listed lines serve as the outer edges of the graphs and the inner lines dividing the figure into four smaller squares.

The conversion figure of a 9C-type quinary system (see Fig. 6 *b*,*c*) contains nine vertices (in accordance with the number of ternary reciprocal systems involved in the quinary system) and 14 lines, twelve of which are elements of the conversion figures of all six reciprocal systems consisting of six salts, which are involved in this quinary system. Two lines emerging from the central point of the square (the point of intersection of the most stable fourth-stage diagonal with the corresponding metastable diagonal) are special lines (Q_9-Q_1 and Q_9-Q_2, Fig. 6 *b*; Q_3-Q_9 and Q_4-Q_9, Fig. 6 *c*). These lines together with the conversion line of the basic elements of the 9C-type quinary reciprocal system consisting of nine salts divide the stable and metastable axial triangles into four triangles.

d. System Na,K,Ca//F,Cl,WO_4 (9D type)

Let us consider the construction of a conversion figure of the topological type D using the Na,K,Ca//F,Cl,WO_4 system as an example. The thermochemical characteristics of this system and the salt compositions for the conversion elements are given in Tables 12 and 13, respectively. The conversion figure of secant tetrahedra is shown in Fig. 7 *a*. The conversion graph of this system consists of three conversion planes and two conversion triangles: *9–6–8–4*, *2–7–1–8*, *9–3–7–5*, *3–4–1*, *2–6–5*. Each conversion square necessarily includes two points of intersection of second-stage diagonals and two points of intersection of first-stage diagonals [9D-type systems are characterised by the presence of six first-stage diagonals and three second-stage diagonals (see Table 12)]. The vertices of the conversion triangles *3–4–1* and *2–6–5* are the points of intersection of first-stage diagonals. The conversion squares (the main framework of the conversion figure) of this system are identical to the conversion squares of 9E-type systems. There are the following special six inner lines in the conversion figure of the Na,K,Ca//F,Cl,WO_4 system: *3–4*, *3–1*, *4–1*, *2–5*, *2–6* and *5–6*. These lines correspond to exchange reactions proceeding in the quinary reciprocal system consisting of nine salts and intersect the planes of the stable basic triangles $CaWO_4-(NaF)_2-(KCl)_2$ and $CaF_2-K_2WO_4-(NaCl)_2$.

Table 12. Thermochemical relations for the 9D-type quinary reciprocal system Na,K, Ca//F,Cl,WO_4 consisting of nine salts.

Metastable salt pair	Stable salt pair	Reaction	
		stage	Q /kJ (mol equiv)$^{-1}$
$CaF_2+Na_2WO_4$	$CaWO_4+(NaF)_2$	I	$Q_1=12.636$
$Na_2WO_4+(KCl)_2$	$K_2WO_4+(NaCl)_2$	I	$Q_2=22.720$
$(KF)_2+(NaCl)_2$	$(NaF)_2+(KCl)_2$	I	$Q_3=32.342$
$K_2WO_4+CaCl_2$	$CaWO_4+(KCl)_2$	I	$Q_4=40.710$
$CaWO_4+(KF)_2$	$K_2WO_4+CaF_2$	I	$Q_5=42.426$
$(NaF)_2+CaCl_2$	$CaF_2+(NaCl)_2$	I	$Q_6=50.794$
$Na_2WO_4+(KF)_2$	$K_2WO_4+(NaF)_2$	II	$Q_7=Q_2+Q_3=$ $=Q_1+Q_5=55.062$
$Na_2WO_4+CaCl_2$	$CaWO_4+(NaCl)_2$	II	$Q_8=Q_2+Q_4=$ $=Q_1+Q_6=63.430$
$(KF)_2+CaCl_2$	$CaF_2+(KCl)_2$	II	$Q_9=Q_4+Q_5=$ $=Q_3+Q_6=83.136$

Table 13. Salt compositions for conversion elements of the 9D-type Na,K,Ca//F,Cl,WO_4 system.

System	Conversion element	Salt composition
Na,Ca,K//F,WO_4	*1–7*	NaF, K_2WO_4, $CaWO_4$
Na,Ca//F,Cl,WO_4	*1–8*	NaF, NaCl, $CaWO_4$
Na,K//F,Cl,WO_4	*2–7*	NaF, NaCl, K_2WO_4
Na,Ca,K//Cl,WO_4	*2–8*	NaCl, K_2WO_4, $CaWO_4$
Na,Ca,K//F,Cl	*3–9*	NaF, KCl, CaF_2
Ca,K//F,Cl,WO_4	*4–9*	CaF_2, KCl, $CaWO_4$
Ca,K//F,Cl,WO_4	*5–9*	KCl, K_2WO_4, CaF_2
Na,Ca,K//F,Cl	*6–9*	NaCl, KCl, CaF_2
Na,K//F,Cl,WO_4	*3–7*	NaF, KCl, K_2WO_4
Na,Ca,K//F,WO_4	*5–7*	NaF, K_2WO_4, CaF_2
Na,Ca,K//Cl,WO_4	*4–8*	NaCl, KCl, $CaWO_4$
Na,Ca//F,Cl,WO_4	*6–8*	CaF_2, NaCl, $CaWO_4$

The points of intersection of second-stage diagonals each have four thermochemical connections. The points of intersection of first-stage diagonals *1–7*, *2–7*, *3–7*, *5–7*, *1–8*, *2–8*, *4–8*, *6–8*, *3–9*, *4–9*, *5–9*, *6–9* have the same number of connections (see Fig. 7 *a*). These 12 lines form the 9D ⇄ 9E-type framework of the conversion figure common to the two types. The salt compositions involved in the thermochemical 9D ⇄ 9E-type framework of the conversion figure belong to quaternary reciprocal systems.

The special conversion lines *2–5–6* and *1–3–4* correspond to the NaCl, K_2WO_4, CaF_2 and NaCl, KCl, $CaWO_4$ salt compositions, respectively in the Na,Ca,K//F,Cl,WO_4 system.

Hence, the conversion figure of secant tetrahedra for 9D-type quinary reciprocal systems consisting of nine salts is a graph containing nine points of complete conversion of ternary reciprocal systems, 12 lines (edges) corresponding to salt compositions of six salts and six special inner lines, which model an interaction in a system composed of nine salts.

e. System Na,Ba,Fe//Cl,S,SO_4 (9E type)

The conversion figure of reciprocal systems of the 3//3 series of the 9E topological type is a nine-point graph (see Fig. 7 *b*).

Nine points of complete conversion of ternary reciprocal systems serve as vertices of the graph, and 12 conversion lines of quaternary reciprocal systems consisting of six salts, which are constituents of the main thermochemical framework of the figure, serve as edges. Six triangular planes are sections of the composition prism for a quinary reciprocal system consisting of nine salts. The *8–7*, *9–8* and *7–9* diagonals intersecting the plane of the axial stable triangle are special inner lines of three conversion squares.

Nine diagonals (six first-stage diagonals and three second-stage diagonals) serve as the thermochemical characteristics of 9E-type systems. The thermal effects of a second-stage reaction can be expressed as the sums of the thermal effects of first-stage reactions:

$$Q_1 + Q_3 = Q_2 + Q_4,$$

$$Q_1 + Q_6 = Q_5 + Q_4,$$

$$Q_2 + Q_6 = Q_3 + Q_5.$$

From these equations it follows that

$$Q_6 - Q_5 = Q_4 - Q_1 = Q_3 - Q_2,$$

i.e., the thermal effects for six diagonals are related by the following condition: the differences for three pairs of thermal effects should be equal to each other. For example, these differences for the Na,Ba,Fe//Cl, S,SO_4 system are as follows:

$$Q_6 - Q_5 = 89.12 - 85.56 = 3.56 \text{ kJ (mol equiv)}^{-1},$$

$$Q_4 - Q_1 = 10.04 - 6.48 = 3.56 \text{ kJ (mol equiv)}^{-1},$$

$$Q_3 - Q_2 = 11.72 - 8.16 = 3.56 \text{ kJ (mol equiv)}^{-1}.$$

The main thermochemical characteristics of the Na,Ba,Fe//Cl,S,SO_4 system (9E type) are given in Table 14. The conversion graph of the 9E-type system consists of three conversion squares, which are divided by diagonals into six triangles. The diagonals of the conversion squares are the *7–8*, *8–9* and *7–9* lines, which correspond to the FeS + $(NaCl)_2$, FeS + $BaSO_4$ and $(NaCl)_2$ + $BaSO_4$ salt pairs, respectively. These lines intersect the stable axial triangle $(NaCl)_2$–FeS–$BaSO_4$ and characterise the chemical interaction in the quinary reciprocal system Na,Ba,Fe//Cl,S,SO_4. The conversion points *1*, *2*, *3*, *4*, *5* and *6* corresponding to first-stage reactions are involved in conversion squares (two points per square) and each have two thermochemical connections to conversion points corresponding to second-stage reactions. For example, the conversion square *4–9–6–8* includes the conversion points *4* and *6* (first-stage reactions) connected to the points *8* and *9* (second-stage reactions).

The points *7*, *8* and *9* each have six thermochemical connections (four connections to the points corresponding to first-stage reactions and two connections to each other). The points corresponding to second-stage reactions should be connected to other points, *viz*., the conversion points of first-stage reactions. For example, the point *9* is connected to the points *3* and *5* [the points of intersection of the first-stage diagonals $BaCl_2$ + FeS (Q_5) and $BaSO_4$ + $FeCl_2$ (Q_3)], and the point *8* is connected to the points *1* and *4* [the points of intersection of the first-stage diagonals $FeSO_4$ + $(NaCl)_2$ (Q_1) and $(NaCl)_2$ + BaS (Q_4)]. Finally, the point *7* corresponding to the second-stage reaction giving rise to the $(NaCl)_2$ + $BaSO_4$ pair (Q_7) is connected to the points *1* and *2* of the conversion square *2–7–1–8* and the points *3* and *5* of the conversion square *9–3–7–5*. All these constructions are determined by the thermochemical dependences of the second-stage reactions on the first-stage reactions. For example, the thermal effect of the second-stage reaction giving rise to the $BaSO_4$ + FeS pair is equal to the sum of the thermal effects of the first-stage reactions (see Table 14) Q_5 (the stable $BaCl_2$ + FeS pair) and Q_3 (the stable $BaSO_4$ + $FeCl_2$ pair)

$$Q_9 = Q_5 + Q_3 = 85.56 + 11.72 = 97.28 \text{ kJ (mol equiv)}^{-1}.$$

At the same time, this thermal effect is related to the thermal effects of the first-stage reactions yielding the $BaSO_4$ + Na_2S (Q_2) and Na_2SO_4 + FeS (Q_6) pairs

$$Q_9 = Q_2 + Q_6 = 8.16 + 89.12 = 97.28 \text{ kJ (mol equiv)}^{-1}.$$

Analogously, the thermal effect of the second-stage reaction giving rise to the $(NaCl)_2$ + FeS pair (Q_8) is equal to the sum of the thermal effects of the following first-stage reactions: $(NaCl)_2$ + BaS (Q_4) and $BaCl_2$ + FeS (Q_5) as well as $(NaCl)_2$ + $FeSO_4$ (Q_1) and Na_2SO_4 + FeS (Q_6)

$$Q_8 = Q_4 + Q_5 = Q_1 + Q_6 = 10.04 + 85.56 = \\ = 6.48 + 89.12 = 95.60 \text{ kJ (mol equiv)}^{-1}.$$

Analogously, the following equation can be written for Q_7:

$$Q_7 = Q_2 + Q_4 = Q_1 + Q_3 = 8.16 + 10.04 = \\ = 6.48 + 11.72 = 18.20 \text{ kJ (mol equiv)}^{-1}.$$

The above-considered methods for the construction of conversion figures of secant elements for quinary reciprocal systems consisting of nine salts of various thermochemical types are simple, convenient and do not require complicated tools of multidimensional geometry.

The general algorithm for the construction of conversion figures of secant tetrahedra for quinary reciprocal systems consisting of nine salts of various thermochemical types can be stated as follows:[8]

(1) the determination of stable diagonals in ternary reciprocal systems based on the thermal effects of exchange reactions;

(2) the determination of reaction stages and the constituent thermal effects;

(3) the determination of the thermochemical type of the system;

(4) the determination of the number of thermochemical connections for each point of complete conversion corresponding to the diagonal of the corresponding stage from the thermochemical relations in the system;

(5) the connection of nine points of complete conversion of ternary reciprocal systems, which correspond to intersections of diagonals of the stable and metastable complexes of the system, in accordance with the number of thermochemical functional connections revealed for each conversion point.

Table 14. Points of complete conversion and thermochemical relations for the Na,Ba,Fe//Cl,S,SO_4 system.

Point	Ternary reciprocal system	Stable salt pair	Reaction	
			stage	Q /kJ (mol equiv)$^{-1}$
1	Na,Fe//Cl,SO_4	$(NaCl)_2$ + $FeSO_4$	I	$Q_1 = 6.48$
2	Ba,Na//S,SO_4	Na_2S + $BaSO_4$	I	$Q_2 = 8.16$
3	Ba,Fe//Cl,SO_4	$BaSO_4$ + $FeCl_2$	I	$Q_3 = 11.72$
4	Na,Ba//Cl,S	$(NaCl)_2$ + BaS	I	$Q_4 = 10.04$
5	Ba,Fe//Cl,S	$BaCl_2$ + FeS	I	$Q_5 = 85.56$
6	Na,Fe//S,SO_4	Na_2SO_4 + FeS	I	$Q_6 = 89.12$
7	Na,Ba//Cl,SO_4	$(NaCl)_2$ + $BaSO_4$	II	$Q_7 = Q_2 + Q_4 = Q_1 + Q_3 = 18.20$
8	Na,Fe//Cl,S	$(NaCl)_2$ + FeS	II	$Q_8 = Q_5 + Q_4 = Q_1 + Q_6 = 95.60$
9	Ba,Fe//S,SO_4	$BaSO_4$ + FeS	II	$Q_9 = Q_2 + Q_6 = Q_3 + Q_5 = 97.28$

3. The matrix method for the construction of conversion figures

The thermochemical method is simple and convenient but requires the determination of the stages of stable diagonals, which is not always possible because of the lack of reliable data on the enthalpies of formation of salts. This gave impetus to the development of a procedure without this drawback. The matrix method is the most descriptive way of constructing conversion figures of secant elements.[8,32,33] This method does not require numerical values of the thermal effects of exchange reactions. To construct a conversion figure for reciprocal systems of the 2//n (n//2) series using matrices of reciprocal salt pairs, it is only necessary to know which salt pair is more stable. The presence (or the absence) of unities in cells of matrices of reciprocal salt pairs determines the sought-for thermochemical relations.

In the ternary reciprocal system A,B//X,Y, a stable diagonal in a four-cell matrix is denoted by unity. The conversion point of this system results from the intersection of the AX – BY and AY – BX diagonals, which occupy the cells 2 and 3, respectively. Since the conversion point belongs both to stable and metastable diagonals, it can be placed either in the cell 2 or in the cell 3. For convenience, let us display the point of complete conversion of the ternary reciprocal system in the cell occupied by the stable diagonal, *i.e.*, in the cell with unity.

	BX	BY
AX	1) 0	2) 0
AY	3) 1	4) 0

In the matrix of reciprocal salt pairs of a quaternary reciprocal system consisting of six salts, three cells are occupied by unities. A stable salt pair, *i.e.*, the unity located at the intersection of a row and column with two unities, forms a stable second-stage diagonal. The other two salt pairs denoted by unities correspond to first-stage diagonals.

	BX	BY	BZ
AX	0	0	1
AY	1	0	1
AZ	0	0	0

A conversion figure is constructed as follows: points corresponding to points of complete conversion of ternary reciprocal systems are placed in cells with unities. Then the points are connected by straight lines emerging from the point corresponding to the second-stage diagonal.

Let us consider the construction of a conversion figure of secant elements for more complex systems of the 2//*n* series, for example, for a quinary reciprocal system consisting of eight salts. This system is represented by a matrix consisting of 16 cells, six of which have unities and correspond to stable diagonals of ternary reciprocal systems. The matrix of reciprocal salt pairs for the Li,Na//Cl,Br,NO_3,SO_4 system is presented in Fig. 8.

For convenience, the conversion figure of the salt is placed in the matrix in such a way that the first row contains three unities, the second row has two unities, and the third row contains one unity, *i.e.*, in accordance with an increase in the stability of salts of the upper row and a decrease in the stability of salts of the left column. The unity in the fourth cell corresponds to a third-stage diagonal, unities in the third and eighth cells correspond to second-stage diagonals, and all other unities correspond to first-stage diagonals (see Fig. 8).

Conversion figures are constructed by connecting successively the points placed in cells with unities. The conversion point corresponding to the intersection of a stable third-stage diagonal and its metastable pair is connected by straight lines to the points in cells occupied by second-stage diagonals. The latter points, in turn, are connected to the point in the cell occupied by a first-stage diagonal. Therefore, the connection of four points located in the cells of the upper right part of the matrix by lines gives rise to a fragment of the conversion figure forming a quadrangle. Triangles result from the connection of points located in the first row and the last column of the matrix, respectively. The order in which the points are connected can be represented by the following scheme. The quadrilateral fragment of the conversion figure is $3 \to 4 \to 8 \to 7 \to 3$; the first triangle is $2 \to 3$ and $2 \to 4$; the second triangle is $8 \to 12$ and $4 \to 12$. In the case of this arrangement of unities and zeros in the matrix, the conversion figure always has the form shown in Fig. 8.

A conversion figure can be constructed in an alternative way. Let us consider this procedure with the use of the same Li,Na//Cl,Br,NO_3,SO_4 system consisting of eight salts as an example.

1. First, we write matrices of reciprocal salt pairs, which are constituents of quaternary reciprocal systems consisting of six salts.

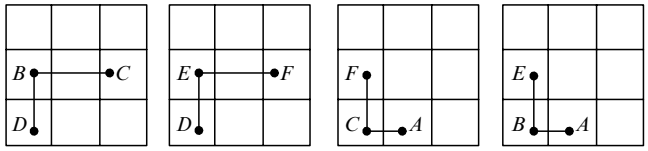
	NaBr	Na_2SO_4	NaCl
LiBr	0	0	0
Li_2SO_4	1	0	1
LiCl	1	1	0

	NaBr	$NaNO_3$	NaCl
LiBr	0	0	0
$LiNO_3$	1	0	1
LiCl	1	1	0

	NaCl	$NaNO_3$	Na_2SO_4
LiCl	0	0	0
$LiNO_3$	1	0	1
Li_2SO_4	1	1	0

	NaBr	$NaNO_3$	Na_2SO_4
LiBr	0	0	0
$LiNO_3$	1	0	1
Li_2SO_4	1	1	0

2. Then we inscribe conversion figures for all quaternary reciprocal systems into the matrices by connecting the points corresponding to unities in rows and columns.



3. Finally, the conversion figures are transferred to a matrix of a quinary reciprocal system consisting of eight salts. The conversion figure for the Li,Na//Cl,Br,NO_3,SO_4 system is obtained automatically.

This procedure is particularly convenient for the construction of conversion figures for senary and more complex systems of the 2//*n* (*n*//2) series, because it substantially simplifies the determination of thermochemical relations.

The proposed algorithm is applicable only to systems of one thermochemical type, *viz.*, to systems of the 2//*n* (*n*//2) series. For systems consisting of nine salts of the 3//3 series, three matrices of the 2//3 (3//2) series involved in this quinary system should be considered.[32]

Conversion figures for various thermochemical types of quinary reciprocal systems are different. Hence, the algorithms for the construction of these figures are also different.

Let us consider the procedure for the construction using the Ba,K,Na//F,MoO_4,WO_4 system (the $B \rightleftarrows A$ thermochemical type) as an example. The thermochemical relations for this system are given in Table 15.

Table 15. Points of complete conversion and thermochemical relations for the Na,K,Ba//F,MoO_4,WO_4 system.

Point	Ternary reciprocal system	Stable salt pair	Reaction	
			stage	Q /kJ (mol equiv)$^{-1}$
1	Na,Ba//F,WO_4	$(NaF)_2 + BaWO_4$	I	$Q_4 = 19.04$
2	K,Ba//F,MoO_4	$K_2MoO_4 + BaF_2$	I	$Q_2 = 2.51$
3	Na,Ba// MoO_4,WO_4	$Na_2WO_4 +$ $+ BaMoO_4$	I	$Q_1 = 1.67$
4	Na,K// MoO_4,WO_4	$Na_2MoO_4 +$ $+ K_2WO_4$	I	$Q_3 = 12.34$
5	Na,Ba//F,MoO_4	$(NaF)_2 + BaMoO_4$	II	$Q_5 = Q_1 + Q_4 =$ $= 20.71$
6	K,Ba// MoO_4,WO_4	$K_2WO_4 +$ $+ BaMoO_4$	II	$Q_6 = Q_1 + Q_3 =$ $= 14.01$
7	K,Ba//F,WO_4	$BaF_2 + K_2WO_4$	III	$Q_7 = Q_1 + Q_2 + Q_3 =$ $= 16.52$
8	K,Na//F,MoO_4	$(NaF)_2 + K_2MoO_4$	III	$Q_8 = Q_1 + Q_2 + Q_4 =$ $= 23.22$
9	K,Na//F,WO_4	$(NaF)_2 + K_2WO_4$	IV	$Q_9 = Q_1 + Q_2 +$ $+ Q_3 + Q_4 = 35.56$

This system includes three quaternary reciprocal systems of the 3//2 series (Na,K,Ba//F,WO_4; Na,K,Ba//F,MoO_4; Na,K,Ba//MoO_4,WO_4) and three systems of the 2//3 series (Na,Ba//F,MoO_4,WO_4; K,Ba//F,MoO_4,WO_4; Na,K//F,MoO_4,WO_4). The matrices of reciprocal salt pairs and the matrices of conversion figures for these systems are given below (in the matrices of reciprocal salt pairs, the point numbers from the matrices of the conversion figures are given in parentheses).[11]

Let us write the matrix table consisting of 9 columns and 9 rows and then place unities from the matrices of the conversion figures in rows and columns. The conversion graph corresponding to this matrix belongs to the 9B topological type (Fig. 10).

	Z	*K*	*E*	*D*	*T*	*C*	*F*	*A*	*B*
Z(*1*)	0	0	0	0	1	0	0	0	1

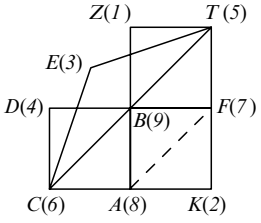

Figure 10. Conversion figure of the 9B-type quinary reciprocal system Na,K,Ba//F,MoO_4,WO_4.

A conversion graph can be constructed by the matrix method using an alternative procedure. In this case, stable salt pairs, which are determined from the melting diagram (if data on the enthalpies of formation of the salts are lacking) of ternary reciprocal systems, serve as the starting data. Let us consider the construction of a conversion graph using the quinary reciprocal system Ag,Li,Na//Cl,NO_3,SO_4 of the $9C \rightleftarrows 9C'$ type as an example. The thermochemical data for this system are given in Table 16. This system includes nine ternary reciprocal systems. Stable salt pairs for these systems are determined from experimental data.

Table 16. Thermochemical characteristics of the 9C-type quinary reciprocal system Ag,Li,Na//Cl,NO_3,SO_4.

Ternary reciprocal system	Stable salt pair	Reaction	
		stage	*Q*
Ag,Li//Cl,SO_4	AgCl + Li_2SO_4	IV	$Q_9 = Q_1 + Q_2 + Q_3 + Q_4 = Q_8 + Q_7 = Q_5 + Q_6$
Ag,Na//Cl,SO_4	AgCl + Na_2SO_4	II	$Q_8 = Q_3 + Q_4$
Li,Na//Cl,SO_4	NaCl + Li_2SO_4	II	$Q_7 = Q_1 + Q_2$
Ag,Li//Cl,NO_3	AgCl + $LiNO_3$	II	$Q_6 = Q_2 + Q_4$
Ag,Na//Cl,NO_3	AgCl + $NaNO_3$	I	Q_4
Li,Na//Cl,NO_3	NaCl + $LiNO_3$	I	Q_2
Ag,Li//NO_3,SO_4	$AgNO_3$ + Li_2SO_4	II	$Q_5 = Q_1 + Q_3$
Ag,Na//NO_3,SO_4	$AgNO_3$ + Na_2SO_4	I	Q_3
Li,Na//NO_3,SO_4	$NaNO_3$ + Li_2SO_4	I	Q_1

Two adjacency matrices (Fig. 11) are constructed from the matrices of reciprocal salt pairs of six reciprocal quaternary systems involved in the Ag,Li,Na//Cl,NO_3,SO_4 system.[33] In one matrix, the salts are arranged according to common cations (the cation matrix I), whereas the salts in another matrix are arranged according to common anions (the anion matrix II). As a result, the thermochemical characteristics of all six quaternary reciprocal systems, which are involved in the quinary reciprocal system of nine salts, are determined.

From the matrices I and II, it is evident that the AgCl and Li_2SO_4 salts each have four unities; the $AgNO_3$, $LiNO_3$, NaCl, $NaNO_3$ and Na_2SO_4 salts each have two unities; and the Ag_2SO_4 and LiCl salts have no unities.

Then the table of vertex indices is compiled (Table 17).

Table 17. Table of vertex indices for the 9C-type quinary reciprocal system Ag,Li,Na//Cl,NO_3,SO_4.

Metal	Cl	NO_3	SO_4	$\sum$
Ag	4	2	0	6
Li	0	2	4	6
Na	2[a]	2[b]	2[c]	6
$\sum$	6	6	6	18

Note. Here and in the figures presented below, the indices of different salts of the same metals are labelled a, b, c.

It is known that this type of system is characterised by one fourth-stage reaction, four first-stage reactions, and four second-stage reactions. The pair of salts, both of which are characterised by the presence of four unities in the corresponding adjacency matrices, AgCl – Li_2SO_4 (the thermal effect of the reaction is Q_9), corresponds to a fourth-stage reaction. The salt pairs produced in second-stage reactions are located at the intersection of rows and columns with two unities in the adjacency matrices I and II: AgCl – Na_2SO_4 (Q_8), NaCl – Li_2SO_4 (Q_7), AgCl – $NaNO_3$ (Q_6) and $AgNO_3$ – Li_2SO_4 (Q_5).

Other salt pairs are formed by first-stage reactions (Q_1, Q_2, Q_3 and Q_4). To determine the constituents of the thermal effects of the

Na_2SO_4	1	0	0	1	0	0	0	0	0

Figure 11. Cation (I) and anion (II) adjacency matrices of the quinary reciprocal system Ag,Li,Na//Cl,NO_3,SO_4.

reactions, submatrices of quaternary reciprocal systems extracted from the adjacency matrices I and II should be considered. For the Ag,Li//Cl,NO_3,SO_4 system (in the upper right part of the cation matrix), the following reactions can be written:

$$AgNO_3 + LiCl = AgCl + LiNO_3 - Q_6$$

$$1/2\,Ag_2SO_4 + LiNO_3 = 1/2\,Li_2SO_4 + AgNO_3 - Q_5$$

$$1/2\,Ag_2SO_4 + LiCl = 1/2\,Li_2SO_4 + AgCl - Q_9$$

Hence, $Q_9 = Q_6 + Q_5$.

A consideration of the Ag,Li,Na//Cl,SO_4 system (the upper right semimatrix in the anion matrix) shows that $Q_9 = Q_7 + Q_8$. Other relations given in Table 16 are obtained in the same way.

Then the matrix of the conversion figure of the Ag,Li,Na//Cl,NO_3,SO_4 system is compiled (Fig. 12 *a*). This matrix includes unities from the matrices I and II along with two connections, *viz*., *1*–9 and *9*–*4*, resulting from the intersection of the stable (AgCl–Li_2SO_4–$NaNO_3$) and metastable (Ag_2SO_4–LiCl–$NaNO_3$) axial triangles of singular and non-equilibrium stars.

Once all necessary connections have been determined from the matrix of the conversion figure, one can construct the conversion graph of the quinary reciprocal system Ag,Li,Na//Cl,NO_3,SO_4 of the 9C type (Fig. 12 *b*).

Using the matrix of the conversion figure, one can find the salt compositions of secant tetrahedra and determine the total thermal effect for each tetrahedron.[8] For this purpose, it is necessary to perform a summation over the corresponding rows of the matrix. For example, the rows *5*, *3*, *8* and *9* should be summed for the

Triangle $Q_4 - Q_6 - Q_9$	$LiNO_3 - Li_2SO_4 - NaNO_3 - AgCl$	$Q_9 + Q_6 + Q_4$
Triangle $Q_4 - Q_8 - Q_9$	$NaNO_3 - Li_2SO_4 - Na_2SO_4 - AgCl$	$Q_9 + Q_8 + Q_4$

For the practical application of conversion figures, the corresponding graphs need not be constructed from the adjacency matrices. Geometric images can completely be omitted, because the matrix of the conversion figure contains all necessary information. For example, the degree of a vertex of a graph not only defines the number of connections of this vertex to other vertices (*i.e.*, the number of conversion lines) but also indicates the number of chemical reactions giving rise to a salt pair, the stage of diagonals, the intersection of which is occupied by a particular conversion point; the compositions of simplexes of a singular star, and the heat capacities of mixtures corresponding to secant elements of the singular star.

IV. Practical applications of matrices and graphs in studies of complex systems

Matrices of reciprocal salt pairs with inscribed conversion figures can be used for searching for salt mixtures, which are characterised by the highest energy capacity and are constituents of simplexes for systems of the 2//*n* (*n*//2) series.[8]

The thermochemical relations in a system can be judged from a matrix of reciprocal salt pairs with an inscribed conversion figure of secant elements, *i.e.*, such matrices allow one to determine the reaction stages yielding the corresponding salt pairs. It can easily be found out which simplex has a higher energy capacity. The larger the number of unities in the matrix that contains elements of a conversion figure (from which a simplex is obtained), the higher the total heat content of the salt mixture and, consequently, the higher all other energy characteristics.

All simplexes of a singular star of a system can be determined from the conversion figure inscribed into a matrix of reciprocal salt pairs, *i.e.*, triangulation can be performed without the use of tools of multidimensional geometry.

1. Construction of singular stars of secant tetrahedra of systems of the 2//*n* (*n*//2) series

Let us consider the determination of simplexes from a conversion figure inscribed into a canonical matrix b_0 of reciprocal salt pairs [11] for a system consisting of sodium, potassium and barium fluorides and tungstates (Fig. 13). In the Na,K,Ba//F,WO_4 system, $BaF_2 + K_2WO_4$, $(NaF)_2 + BaWO_4$ and $K_2WO_4 + (NaF)_2$ are stable pairs. The former two pairs are generated by first-stage

a

b_0	$(NaF)_2$	$(KF)_2$	BaF_2
Na_2WO_4	0	0	0
K_2WO_4	1	0	1
$BaWO_4$	1	0	0

b

$$\begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{pmatrix}$$

Figure 13. Conversion graph inscribed in the matrix of mutual salt pairs of the quaternary reciprocal system Na,K,Ba//F,WO_4 (*a*), and the general form of the matrix (*b*).

reactions, whereas the third pair is formed by a second-stage reaction. These pairs correspond to unities in cells of the matrix. Points are placed in cells with unities, and then the points are connected by solid lines to form the conversion figure of this system inscribed in the matrix (Fig. 13 *a*). The analysis of the conversion figure of the system starts with the determination of secant simplexes (triangles).

The vertices of the first triangle are determined from the row, which includes one of the lines a_{21} or a_{23}. This line corresponds to potassium tungstate, which forms stable pairs with sodium and barium fluorides.

Therefore, $K_2WO_4 - (NaF)_2 - BaF_2$ is one of the stable triangles. The vertices of the corresponding metastable triangle represent salts located in cells with zeros, which are symmetric to cells with unities relative to the zero diagonal. The cell a_{21} with unity is symmetric to the cell a_{12} with zero, and the cell a_{23} is symmetric to the cell a_{32}. Hence it follows that the $K_2WO_4 + (NaF)_2$ pair corresponds to the metastable $Na_2WO_4 + (KF)_2$ pair, and the stable $K_2WO_4 + BaF_2$ pair corresponds to the $BaWO_4 + (KF)_2$ pair. This gives rise to the metastable $Na_2WO_4 - (KF)_2 - BaWO_4$ triangle. The compositions of the stable $K_2WO_4 - (NaF)_2 - BaWO_4$ triangle and the metastable $(KF)_2 - Na_2WO_4 - BaF_2$ triangle are determined analogously from the conversion line in the column of the matrix.

The next stage involves the determination of tetrahedra of singular and non-equilibrium stars of the system. A stable sphenoid (irregular tetrahedron) is determined by salts corresponding simultaneously to all unities of the matrix (the overall conversion figure). In the case under consideration, this is the $K_2WO_4 - (NaF)_2 - BaWO_4 - BaF_2$ tetrahedron. The metastable sphenoid is formed by salts, which determine the row and column with three or two zeros [$BaWO_4 - BaF_2 - Na_2WO_4 - (KF)_2$]. Salts corresponding to the shared edge of the stable and metastable sphenoids are determined by the row and column with two zeros ($BaWO_4 - BaF_2$).

Stable tetrahedra correspond to salts, which occupy the cells of an entire row or column, through which conversion lines pass. For the system under consideration, these are the stable $K_2WO_4 - (KF)_2 - (NaF)_2 - BaF_2$ (row) and $(NaF)_2 - K_2WO_4 - Na_2WO_4 - BaWO_4$ (column) tetrahedra. Metastable tetrahedra are formed from columns and rows containing salts, which are located in cells with zeros, the cells being symmetric to cells with unities relative to the zero diagonal. The a_{21}, a_{22}, a_{23} row is symmetric to the a_{12}, a_{22}, a_{32} column, and the a_{11}, a_{21}, a_{31} column is symmetric to the a_{11}, a_{12}, a_{13} row. Hence, $K_2WO_4 - (KF)_2 - Na_2WO_4 - BaWO_4$ and $Na_2WO_4 - (NaF)_2 - (KF)_2 - BaF_2$ are metastable tetrahedra.

All elements of the stable and metastable complexes of the system are given in Table 19. The results obtained for the Na,K,Ba//F,WO_4 system according to the above-described procedure correlate well with the experimental data.[11]

Therefore, this method provides a simple and convenient way to determine secant elements of singular and non-equilibrium stars for reciprocal systems of the 2//*n* (*n*//2) series without the use

Table 19. Compositions of simplexes of the singular and non-equilibrium stars for the Na,K,Ba//F,WO_4 system.

Secant elements		Stable cells of singular star	Metastable cells of non-equilibrium star
stable	metastable		
$(NaF)_2-K_2WO_4-BaWO_4$	$(KF)_2-BaF_2-Na_2WO_4$	$(NaF)_2-K_2WO_4-BaWO_4-BaF_2$ $(NaF)_2-Na_2WO_4-BaWO_4-K_2WO_4$	$(KF)_2-Na_2WO_4-BaWO_4-BaF_2$ $(KF)_2-Na_2WO_4-BaF_2-(NaF)_2$
$(NaF)_2-K_2WO_4-BaF_2$	$Na_2WO_4-(KF_2)-BaWO_4$	$(KF)_2-NaF-BaF_2-K_2WO_4$	$(KF)_2-K_2WO_4-Na_2WO_4-BaWO_4$

of complicated geometric constructions. This method is rapid and allows one to study multicomponent systems (for example, systems containing 8, 10 or 12 salts).

The simultaneous determination of the energy characteristics of simplexes makes it possible (after the transformation of a conversion figure to an energy graph) to obtain a rapid semi-quantitative estimate of the energy capacities of salt compositions within one system. The estimation is performed as follows: the heats of melting of the salts involved in tetrahedra are added to the heats of exchange reactions occurring between the salts (taking into account whether the reaction is endothermic or exothermic, which is established by calculations or determined experimentally from DTA data). If the heats of melting of salts have similar values, the main difference in the energy capacity of salt mixtures is associated with the heats of reactions. Therefore, the energy capacity of a mixture depends on the number of exchange reactions that can occur between the salts. This value can easily be determined from the energy models (graphs).

For reciprocal systems containing six salts, the singular star consists of three tetrahedra divided by two secant triangles. Salt mixtures with the highest energy capacity are generally modelled by sphenoids, because they are intersected by two conversion lines, and, consequently, the salts belonging to the sphenoids are involved in three exchange reactions [in the case under consideration, the $(NaF)_2-BaWO_4-BaF_2-K_2WO_4$ sphenoid]. Other tetrahedra correspond to two exchange reactions. Hence, the overall thermal effect of the reaction of salts involved in a sphenoid is equal to twice the sum of the thermal effects of first-stage reactions.

It was experimentally established that a eutectic present in a sphenoid has the highest energy capacity.[8] Eutectics in systems consisting of six salts were found according to this procedure. The energy capacities of such eutectics are twice as high as those of foreign standards.[9,10] These eutectics were used as heat-accumulation mixtures in thermal chemical power sources.

2. Construction of systems with the desired direction of interchange reactions

Analysis of matrices of reciprocal salt pairs represents the basis for the rational choice of salts for the preparation of systems with the desired direction of exchange reactions. To prepare a quaternary reciprocal system consisting of six salts with the desired direction of interchange reactions, salts can be chosen using summary matrix tables of reciprocal salt pairs composed for particular groups of cations and anions.[3]

If the aim is to prepare a system characterised by the highest stability of a particular salt, the ions should be chosen using a matrix, in which this salt has two unities. In this case, the desired salt (for example, AX) is formed in the system according to the following reactions:

$$AY + BX = AX + BY,$$

$$AZ + BX = AX + BZ.$$

To construct a quinary reciprocal system consisting of nine salts, in which the desired salt is the most stable, one should be guided by the following principle. The chosen composition should be such that the desired salt has two unities in two of the three matrices compiled for the starting quaternary reciprocal systems or at least has two unities in one matrix and one unity in another matrix. For instance, the aim is to choose a salt composition of nine salts involving alkali metal halides and sulfates such that the exchange reactions are shifted toward the formation of lithium sulfate.

To solve this problem, cations, whose halides form stable pairs with lithium sulfate, are found from the matrix tables. All cations of Group I elements satisfy this requirement. If the choice is limited to lithium, sodium and potassium salts, a salt composition with the desired direction of exchange reactions can be constructed using a mixture of lithium, sodium and potassium chlorides, bromides and sulfates or a mixture of chlorides, iodides and sulfates of these alkali metals. In these cases, the following quinary reciprocal systems of nine salts are formed: Li,Na,K//Cl,Br,SO_4; Li,Na,K//Cl,I,SO_4; Li,Na,K//Br,I,SO_4.

In addition to lithium sulfate, the basic triangle for such systems involves a pair of sodium and potassium halides, which has unity in the third starting matrix. For the Li,Na,K//Cl,Br,SO_4 system, this is the KBr – NaCl pair, *i.e.*, the basic triangle has the composition $Li_2SO_4-KBr-NaCl$. This fact was confirmed by experimental data.[8] Lithium sulfate is formed according to the following equation:

$$2\,LiBr + K_2SO_4 + NaCl = Li_2SO_4 + 2\,KBr + NaCl.$$

The NaCl salt has crystallisation fields both in the non-equilibrium and basic triangles (Fig. 14).

For particular pairs of cations, reciprocal quaternary and quinary systems are conveniently constructed by setting up series of chemical reactivity (stability) of salts with these cations. For example, there are the following series of stability for systems involving lithium and sodium (stability increases from left to right):

LiI, LiBr, LiCl, $LiNO_3$, Li_2SO_4;

Na_2SO_4, $NaNO_3$, NaCl, NaBr, NaI.

To construct a quaternary reciprocal system of six salts characterised by the highest stability of a particular salt (for

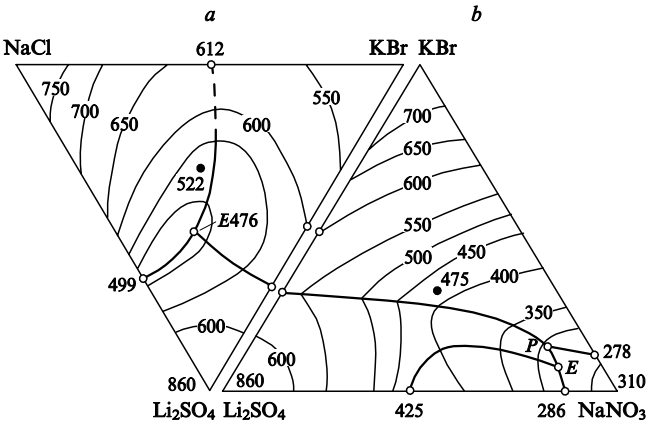

Figure 14. Axial stable triangles of the quinary reciprocal systems Li,Na,K//Cl,Br,SO_4 (*a*) and Li,Na,K//Br,NO_3,SO_4 (*b*).
E and *P* are quasiternary eutectic and peritectic points, respectively; the temperatures are given in degrees Centigrade.

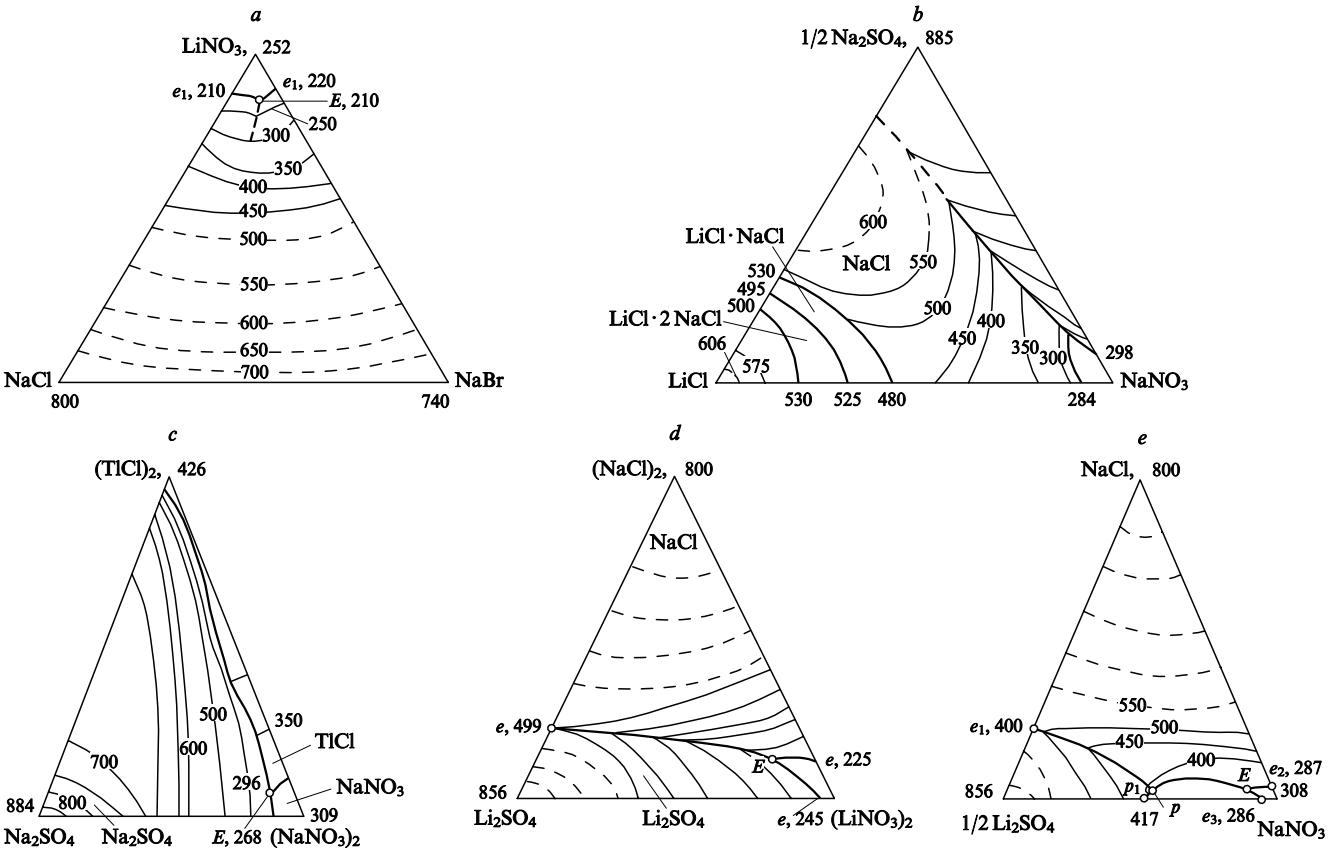

Figure 15. Sections of the quaternary reciprocal systems Li,Na//Cl,Br,NO_3 (*a*), Li,Na//Cl,NO_3,SO_4 (*b*), Na,Tl//Cl,NO_3,SO_4 (*c*) and Li,Na//Cl,NO_3,SO_4 (*d*, *e*); *e* and *p* are the saddle eutectic and peritectic points, respectively; the temperatures are given in degrees Centigrade.

example, lithium nitrate), a composition of salts, which are located in the left side of the series of stability (*i.e.*, lithium chlorides and bromides, chlorides and iodides, bromides and iodides), should be chosen. Actually, investigation of the quaternary reciprocal system Li,Na//Cl,Br,NO_3 demonstrated that $LiNO_3$ is the most stable salt in this system even in the presence of stable sodium salts (Fig. 15 *a*).

Let us consider another situation, where the aim is to change the direction of the exchange reaction in the reciprocal system Li,Na//Cl,NO_3,SO_4 consisting of six salts toward the formation of sodium sulfate.

The matrix of reciprocal salt pairs for this system has the form

		I		
		Na^+		
	c_0	Cl^-	NO_3^-	SO_4^{2-}
	Cl^-	0	0	0
Li^+	NO_3^-	1	0	0
	SO_4^{2-}	1	1	0

The main reaction

$$2\,LiCl + Na_2SO_4 = Li_2SO_4 + 2\,NaCl,$$

proceeding in this system can be shifted in the required direction by replacing one of the ions. In deciding on a cation to be replaced, one should choose an ion characterised by a reciprocal matrix. In the case under consideration, this is the type *c*, because the starting system has the matrix c_0. The thallium ion satisfies this requirement.

		II		
		Na^+		
	c	Cl^-	NO_3^-	SO_4^{2-}
	Cl^-	0	1	1
Tl^+	NO_3^-	0	0	1
	SO_4^{2-}	0	0	0

The main reaction in the Na,Tl//Cl,NO_3,SO_4 system is

$$2\,NaCl + Tl_2SO_4 = Na_2SO_4 + 2\,TlCl.$$

This fact can be confirmed by comparing the corresponding sections of the Li,Na//Cl,NO_3,SO_4 (Fig. 15 *b*) and Na,Tl//Cl,NO_3,SO_4 systems (Fig. 15 *c*).

In the former system, sodium sulfate is involved in the metastable $LiCl-Na_2SO_4-NaNO_3$ section. The liquidus surface of the section is shown in Fig. 15 *b*. It can be seen that the section is metastable, because it involves NaCl as the exchange product. After the replacement of the lithium ion with thallium, the section becomes stable.

The direction of the exchange reactions in quinary reciprocal systems consisting of 8 or 9 salts can be changed in the same manner as for reactions in quaternary reciprocal systems, except for the fact that one or two reciprocal matrices should be used.

Analysis of matrices of reciprocal salt pairs gives an idea of how one can influence the complexation processes. Let us consider the situation where complex compounds are formed by a stable salt produced by an exchange reaction. The complexation leads to a decrease in stability of the salt, and the yield of the salt in the reaction also decreases. To prevent complexation, it is necessary

to replace one component. For example, stability of lithium sulfate in the quaternary reciprocal system Li,Na//Cl,NO_3,SO_4 is low due to formation of $Li_2SO_4 \cdot Na_2SO_4$.

It is necessary to choose a salt composition, in which the $Li_2SO_4 \cdot Na_2SO_4$ compound has no effect on stability of the salt under consideration. It appeared that the stability of the desired salt can be increased within the same system by introducing an excess of lithium ions. For example, Li_2SO_4 is more stable in the presence of lithium nitrate (Fig. 15*d*). If it is required to replace a particular ion in a system with another ion, one should use an ion, the replacement of which leaves the main exchange reaction unaffected. In the Li,Na//Cl,NO_3,SO_4 system, the nitrate ion satisfies this requirement. This ion can be replaced with an anion or cation provided that the type of the matrix of reciprocal salt pairs remains unchanged. As can be seen from the series of chemical interactions of the cations, any cation to the left of lithium can be used for the replacement. Let us use potassium. In this case, the quaternary reciprocal system Li,K,Na//Cl,SO_4 is formed. The elementary matrix of this system is as follows:

	c_0	SO_4^{2-} Li^+	Na^+	K^+
	Li^+	0	0	0
Cl^-	Na^+	1	0	0
	K^+	1	1	0

In this matrix, lithium sulfate has two unities. This compound is formed by the reaction

$$K_2SO_4 + 2\,LiCl = Li_2SO_4 + 2\,KCl.$$

The $Li_2SO_4 \cdot Na_2SO_4$ compound in the Li,K,Na//Cl,SO_4 system occupies a small volume and is not manifested in the phase diagrams of stable sections.

The choice of salts, which promote immiscibility with retention of the direction of the exchange reaction toward the formation of the desired salt, is of practical interest. For instance, immiscibility in reciprocal systems can be used for extraction of salts from melts.

Suppose that there is a need to choose a salt composition, which consists of nine salts involving the Li^+ and Na^+ cations and is suitable for extraction of lithium sulfate from melts. Initially, information on which salts (in combination with lithium sulfate) lead to immiscibility can be extracted from the analysis of the data on ternary reciprocal systems. These salts are silver, cadmium and thallium chlorides. Then we choose cations, which have no effect on the stability of Li_2SO_4, based on series of chemical interactions for the halide – sulfate exchange.

For these cations, other anions can be included in the consideration (for example, nitrate ions, which do not decrease the stability of the salt of interest, in whatever combination desired). The procedure gives the following systems: Ag,Li,Na//Cl,NO_3,SO_4; Ag,Li,Na//Cl,Br,SO_4; Cd,Li,Na//Cl,NO_3,SO_4; Cd,Li,Na//Cl,Br,SO_4; Li,Na,Tl//Cl,NO_3,SO_4; Li,Na,Tl//Cl,Br,SO_4. Some of these systems were studied experimentally. For the Li,Na,Cd//Cl,NO_3,SO_4 system, the immiscibility region in the phase diagram of the axial stable triangle comprises 54.5% of the diagram.

3. Construction of singular stars of secant tetrahedra for systems consisting of nine salts

To construct singular stars, it is necessary to determine the salt compositions of secant tetrahedra. This can be done by interpreting elements of the graph (the conversion figure of this system).[8, 34, 35]

Let us consider the procedure for the determination of salt compositions of secant tetrahedra using the quinary reciprocal system Li,Na,K//Cl,Br,NO_3 consisting of nine salts as an example. This system belongs to the 9B topological type.[8, 23, 36] The conversion graph of this system is shown in Fig. 16. The stable salt pairs and elements of singular and non-equilibrium stars are given in Table 20.

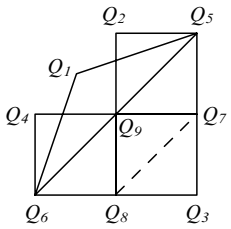

Figure 16. Conversion figure of the 9B-type quinary reciprocal system Li,Na,K//Cl,Br,NO_3.

Table 20. Elements of the conversion graph and salt compositions of secant tetrahedra for the quinary reciprocal system Li,Na,K//Cl,Br,NO_3.

Element of conversion graph	Stable salt pair	Element of singular star
Square	$LiNO_3 + KCl$ (Q_4)	pyramid
$Q_4 - Q_6 - Q_8 - Q_9$	$LiNO_3 + NaCl$ (Q_6)	$LiNO_3 - KCl - NaCl - NaBr - KBr$
	$LiNO_3 + NaBr$ (Q_8)	tetrahedra
	$LiNO_3 + KBr$ (Q_9)	$LiNO_3 - KCl - NaCl - KBr$
		$LiNO_3 - NaCl - NaBr - KBr$
Square	$KBr + NaNO_3$ (Q_2)	pyramid
$Q_2 - Q_5 - Q_7 - Q_9$	$KBr + NaCl$ (Q_5)	$KBr - LiNO_3 - LiCl - NaCl - NaNO_3$
	$KBr + LiCl$ (Q_7)	tetrahedra
	$KBr + LiNO_3$ (Q_9)	$KBr - LiNO_3 - LiCl - NaCl$
		$KBr - LiNO_3 - NaNO_3 - NaCl$
Square	$LiCl + NaBr$ (Q_3)	sphenoid
$Q_3 - Q_8 - Q_9 - Q_7$	$LiNO_3 + NaBr$ (Q_8)	$NaBr - KBr - LiNO_3 - LiCl$
	$LiNO_3 + KBr$ (Q_9)	
	$LiCl + KBr$ (Q_7)	
Triangle	$NaCl + KNO_3$ (Q_1)	tetrahedron-hemipyramid
$Q_1 - Q_5 - Q_6$	$KBr + NaCl$ (Q_5)	$LiNO_3 - KBr - NaCl - KNO_3$
	$NaCl + LiNO_3$ (Q_6)	

The salt compositions of the tetrahedra can be determined according to three procedures.

1. The procedure based on the thermochemical relations in a system. Individual squares and triangles of the conversion figure are considered. For each point of complete conversion, stable pairs and the corresponding stages of stable diagonals are written. For example, the point Q_4 for the conversion square $Q_4 - Q_6 - Q_8 - Q_9$ corresponds to the first-stage diagonal $LiNO_3 - KCl$, the point Q_6 corresponds to the second-stage diagonal $LiNO_3 - NaCl$, the point Q_8 corresponds to the third-stage diagonal $LiNO_3 - NaBr$, and the point Q_9 corresponds to the fourth-stage diagonal $LiNO_3 - KBr$. The $LiNO_3$ salt is repeated four times and, consequently, serves as the vertex of the pyramid, whose base is formed by the ternary reciprocal system Na,K//Cl,Br. The pyramid is composed of two tetrahedra, *viz.*, $LiNO_3 - KCl - NaCl - KBr$ and $LiNO_3 - NaCl - NaBr - KBr$, sharing the axial triangle $LiNO_3 - NaCl - KBr$. Analogously, the $LiNO_3 - NaNO_3 - NaCl - KBr$ and $LiNO_3 - LiCl - NaCl - KBr$ tetrahedra are determined from the conversion square $Q_2 - Q_5 - Q_7 - Q_9$.

2. The procedure based on chemical reactions described by conversion figures. By summing the reactions for points of complete conversion of ternary reciprocal systems, we obtain the reaction equation for the central point of the conversion square. For example, for the $Q_2 - Q_5 - Q_7 - Q_9$ square (see Fig. 16),

$$LiBr + KCl + NaBr + KCl + NaBr + KNO_3 + LiBr + KNO_3 =$$
$$= LiNO_3 + LiCl + 4\,KBr + NaCl + NaNO_3.$$

The salts formed in the reactions are placed at the vertices of the $KBr - LiNO_3 - LiCl - NaCl - NaNO_3$ pyramid, with the ternary reciprocal system Li,Na//Cl,NO_3 lying on its base. The salt

compositions of the tetrahedra involved in the pyramid can be derived from the reaction equations for the conversion triangles:

for the $Q_2-Q_5-Q_9$ triangle,

$$2\ KNO_3 + NaBr + NaBr + KCl + LiBr = \\ = 3\ KBr + LiNO_3 + NaCl + NaNO_3;$$

for the $Q_5-Q_7-Q_9$ triangle,

$$NaBr + LiBr + 2\ KCl + KNO_3 = \\ = 3\ KBr + LiNO_3 + NaCl + LiCl.$$

3. The geometric procedure.[8, 34] A fragment of the conversion figure, *viz*., a square or triangle, is displayed on the plane, and points of complete conversion are indicated. The conversion square is inscribed in a quadrangle (Fig. 17). The notations of salts common to each pair of points are placed at the vertices of the tetrahedron. For example, the NaBr salt is common to the points Q_3 and Q_8, $LiNO_3$ is common to the points Q_8 and Q_9, *etc*. The conversion triangle is inscribed in a tetrahedron parallel to one of its faces. A salt common to three points of complete conversion serves as a vertex of the resulting tetrahedron.

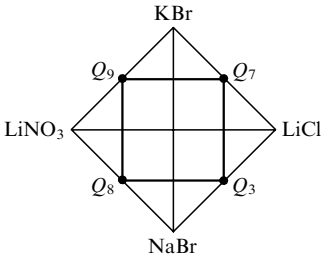

Figure 17. Geometric procedure for the determination of the salt compositions of the tetrahedra for the reciprocal system Li,Na,K// Cl,Br,NO_3 consisting of nine salts.

Once the salt compositions of the tetrahedra have been determined, the scheme of a singular star is constructed taking into account the reaction stages and constituents of the thermal effects.

The tetrahedra in the singular star are connected to each other in a particular manner. Schemes of singular stars of tetrahedra can be derived by analogy with singular stars of pentatopes.[8] Systems belonging to different topological types are characterised by different schemes (Fig. 18). In Fig. 18, the points correspond to the tetrahedron, and the line characterises the presence of three common salts involved in the tetrahedron. Hence, the triangle formed by stable diagonals serves as a connection unit between the tetrahedra.

Each topological type of a singular star of tetrahedra is characterised by a particular set of reaction stages.

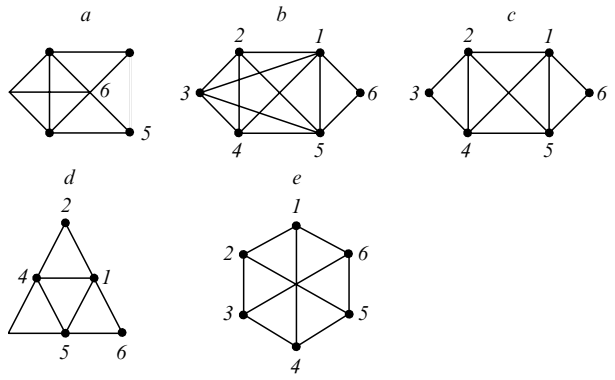

Figure 18. Schemes of singular stars of secant tetrahedra for quinary reciprocal systems of the topological types 9A (*a*), 9B (*b*), 9C (*c*), 9D (*d*) and 9E (*e*).

Schemes of connections between tetrahedra represent graphs with different arrangements of vertices corresponding to the topological type of the system. Analysis of such graphs allows one to reveal the reactivity of salts, which compose any tetrahedron of a singular star. The advantage of this procedure for the construction of graphs of singular stars of tetrahedra for systems of various topological types is that it clearly shows the relationships between the thermochemical relations, chemical reactions in the system as a whole and its constituents and the geometric elements of singular stars.

4. Proximate method for studying phase complexes of reciprocal salt systems in melts

According to Kurnakov's theory, the composition – property diagram of a system is formed at the intersection of the coordinate frame (the phase diagram of the system) with the phase complex. Triangulation methods allow one to construct a phase complex of a system after the construction and partitioning of the composition diagram.

The conversion method[6] enables one to study and construct phase diagrams of multicomponent reciprocal systems without preliminary investigation of the composition diagram, because conversion figures of secant elements can be constructed and analysed with the use of matrices of reciprocal salt pairs, sometimes without deducing singular and non-equilibrium stars.[8, 32, 33]

This method of studying phase complexes of reciprocal condensed systems reduces substantially the time of experimentation and, hence, is a proximate method, which allows one to solve a number of problems in serial technological investigations.[7] The essence of the method is that the minimum number of points in phase diagrams are studied experimentally. Differential thermal analysis (DTA) is used as the main method, which should be supplemented with methods for the determination of compositions of invariant points (zone melting, chemical analysis) and methods for the identification of phase compositions (powder X-ray diffraction analysis, microstructural analysis).

Investigation of a phase diagram is simplified due to a decrease in the amount of required data. With information only on binary systems and polymorphism of salts in hand, it is sufficient to study one point of complete conversion for a ternary reciprocal system. For quaternary reciprocal systems, two lines of complete conversion should be studied if experimental data on points of complete conversion of ternary reciprocal systems are available, and so forth.[11, 36]

The procedure for studying systems is as follows. Investigation of a ternary reciprocal system starts with the measurement of a thermogram of the point of complete conversion, *i.e*., the point corresponding to the equivalent ratio of a pair of salts, which have no ions in common. The thermogram is interpreted using data on the phase complex of binary systems.[36, 37] The first thermal effect corresponds to the onset of crystallisation of the phase, which crystallises at the point of complete conversion. The phase can be identified by microstructural analysis or otherwise. The second peak in the thermogram is assigned to co-crystallisation of the phases that form by the exchange reaction or complex formation. Data on binary systems give an indication of the irreversibly reciprocal character of a ternary reciprocal system, and the presence of two thermal effects in the thermogram confirms this suggestion. In this case, the temperatures of invariant points can be determined by thermographic analysis.[37]

In addition to the temperatures of invariant points, it is necessary to determine their compositions by zone melting followed by chemical analysis. Therefore, to reveal the phase complex of irreversibly reciprocal ternary systems, one needs to study several concentration points. Methods were developed for the calculation of crystallisation surfaces of ternary reciprocal systems and their sections.[38–42] Combinations of calculation and experimental methods were also used.[43–45]

The question about complexation in a ternary reciprocal system can also be solved using a thermogram for the point of

complete conversion, in which the thermal effects are observed. These effects accompany the following processes: the onset of crystallisation; co-crystallisation of a salt pair formed by an exchange reaction; co-crystallisation of a stable salt pair with a compound resulting from complexation.[37]

Thermograms of the points of complete conversion[11] are shown in Fig. 19. The Na,Ba//F,WO_4 system is irreversibly reciprocal, which was confirmed experimentally (Fig. 19 *a*). The Na,K//F,WO_4 system is complicated by the complexation process. The thermogram of the point of complete conversion of this system (Fig. 19 *b*) shows that the following competitive reactions proceed in the system

$$2\,KF + Na_2WO_4 = 2\,NaF + K_2WO_4,$$

$$3\,KF + Na_2WO_4 = 2\,NaF + KF\cdot K_2WO_4.$$

The compound is formed in the secondary reaction, which does not take place at the point of complete conversion. The overall phase complex of this system can be revealed by also studying points of incomplete conversion.[8, 11]

The conversion figure becomes more complicated as the number of components increases. Investigation of two lines of complete conversion, which include points of complete conversion of ternary reciprocal systems, is sufficient to obtain phase complexes of systems consisting of six salts.[46] The phase diagram of the Na,K,Ba//F,WO_4 system is shown in Fig. 20. The conversion lines *B*, *D* and *F* serve as the composition axis of this diagram. Based on analysis of the diagram, one can draw conclusions regarding the crystallisation volumes in the system under consideration, exchange and complexation reactions and invariant points.

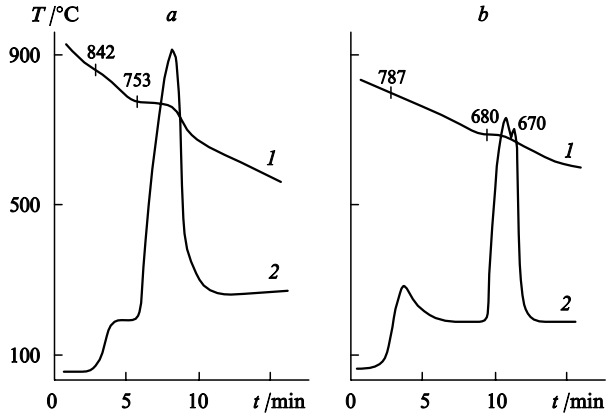

Figure 19. Thermograms of the points of complete conversions of the Na,Ba//F,WO_4 (*a*) and K,Ba//F,WO_4 (*b*) systems.
(*1*) Thermal analysis, (*2*) DTA.

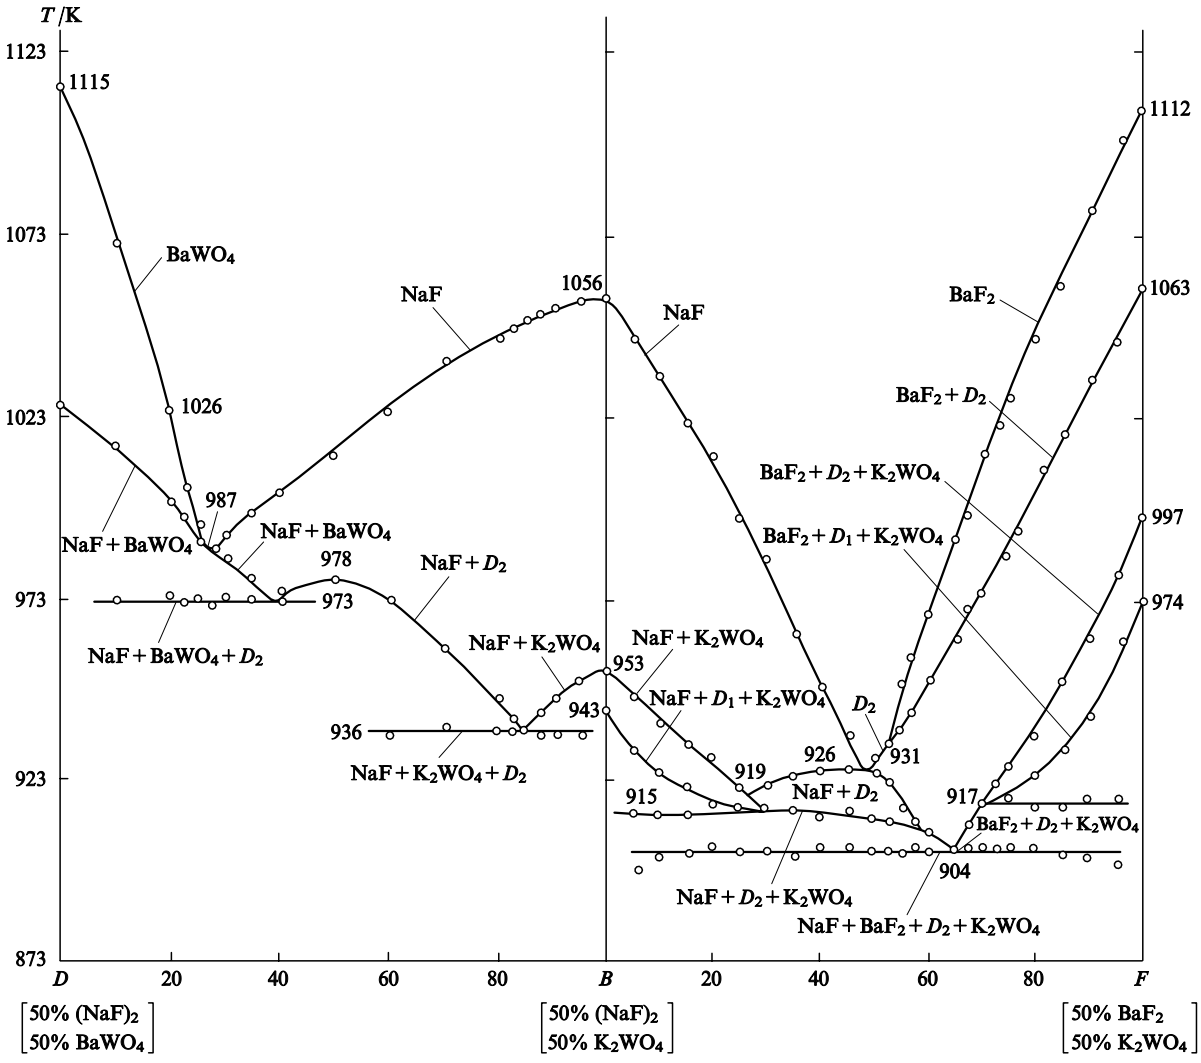

Figure 20. Temperature–composition diagram for the quaternary reciprocal system Na,K,Ba//F,WO_4.[11]
The composition axis represents the conversion lines *B*–*D* and *B*–*F* (see Fig. 2 *b*), $D_1 = KF\cdot K_2WO_4$, $D_2 = K_2WO_4\cdot BaWO_4$.

For example, the BaF_2, $BaWO_4$ and NaF salts are characterised by the largest volumes in the Na,K,Ba//F,WO_4 system. Experimental study of the conversion lines demonstrated that the following reactions occur in the system containing metastable salts in a stoichiometric ratio:

$$2\,KF + BaWO_4 = BaF_2 + K_2WO_4,$$

$$2\,KF + Na_2WO_4 = 2\,NaF + K_2WO_4,$$

$$BaF_2 + Na_2WO_4 = 2\,NaF + BaWO_4,$$

$$2\,KF + 2\,BaWO_4 = BaF_2 + K_2WO_4 \cdot BaWO_4,$$

$$3\,KF + Na_2WO_4 = 2\,NaF + KF \cdot K_2WO_4.$$

The $B-D$ line in Fig. 20 intersects the crystallisation fields of sodium fluoride, as evidenced by two branches of primary crystallisation intersecting at the point with coordinates 987 K and 27.5% of B. This point lies on the curve, which separates the crystallisation fields of NaF and $BaWO_4$ (Fig. 21). The curves of secondary crystallisation ($NaF + BaWO_4$), ($NaF + K_2WO_4 \cdot BaWO_4$) and ($NaF + K_2WO_4$) intersect at two points with the following coordinates: 973 K, 38.5% of B; and 936 K, 84% of B. These points correspond to quasiternary eutectics in the plane of the $(NaF)_2 - BaWO_4 - K_2WO_4$ triangle.

At 50% of B, a minimum is observed at 978 K in the curve of secondary crystallisation, and only two phases, *viz*., sodium fluoride and $K_2WO_4 \cdot BaWO_4$, are observable (see Fig. 20).

The results of powder X-ray diffraction analysis of the points of co-crystallisation of three phases on the $B-D$ line with $B > 50\%$ demonstrated that the following phases occur on this line: NaF, $K_2WO_4 \cdot BaWO_4$ and K_2WO_4. For melts with $B < 50\%$, the NaF, $K_2WO_4 \cdot BaWO_4$ and $BaWO_4$ phases were detected. The central point of the conversion line is characterised by crystallisation of two phases, *viz*., NaF and $K_2WO_4 \cdot BaWO_4$.

On the whole, the conversion lines and, consequently, the $(NaF)_2 - K_2WO_4 - BaWO_4$ triangle correspond to four phases, *viz*., NaF, K_2WO_4, $K_2WO_4 \cdot BaWO_4$ and $BaWO_4$ (see Figs 20, 21).

The $B-D$ line of complete conversion lies in the plane of the diagonal triangle $(NaF)_2 - K_2WO_4 - BaWO_4$, whose vertices correspond to salts formed by exchange reactions in the Na,K,Ba//F,WO_4 system. By summing the equations of the exchange reactions for the points B and D, we obtain the equation for the conversion line $B-D$.

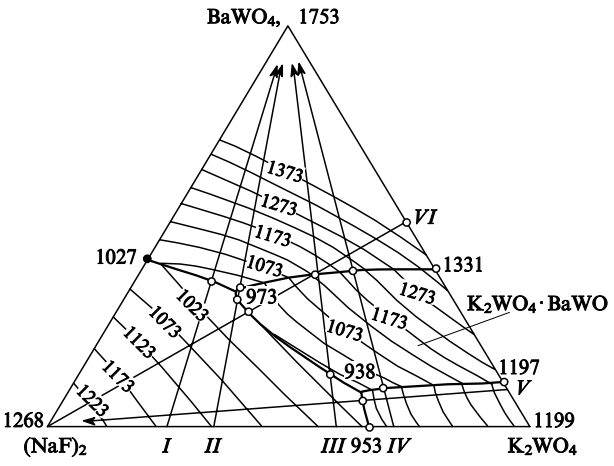

Figure 21. Phase diagram of the secant triangle $(NaF)_2 - BaWO_4 - K_2WO_4$ of the Na,K,Ba//F,WO_4 system.
Here and in Fig. 22, the temperatures are given in Kelvin (K); $I-VI$ denote the sections studied.

For the point B:

$$2\,KF + Na_2WO_4 = 2\,NaF + K_2WO_4,$$

for the point D:

$$BaF_2 + Na_2WO_4 = 2NaF + BaWO_4.$$

The following reaction corresponds to the central point of the $B-D$ line:

$$2\,KF + BaF_2 + 2\,Na_2WO_4 = 4\,NaF + K_2WO_4 + BaWO_4. \quad (10)$$

The data on the boundary elements show that K_2WO_4 and $BaWO_4$ taken in a ratio of 1:1 form the highly stable $K_2WO_4 \cdot BaWO_4$ compound

$$K_2WO_4 + BaWO_4 = K_2WO_4 \cdot BaWO_4. \quad (11)$$

By summing the latter two equations, we obtain

$$2\,KF + BaF_2 + 2\,Na_2WO_4 = 4\,NaF + K_2WO_4 \cdot BaWO_4. \quad (12)$$
